Conclusion

Bone quality is no longer a cloudy concept but an ensemble of well-defined biomechanical parameters. Currently, FEA is the only in vivo imaging method to assess some of these parameters. Bone geometry can be measured by QCT, which is also the basis for FEA. DXA aBMD is a good surrogate of bone quality and currently remains the most important measurement in clinical routine. Hip fracture prediction remains challenging and more efforts should be directed to the integration of fall risk and muscle properties. QCT and FEA may eventually replace DXA for prediction of vertebral fractures but further validation is required. QCT and FEA will also play a dominant role in opportunistic screening.

Contrary to earlier expectations, differences in trabecular structure cannot be exploited to improve fracture prediction to a level necessary for an individual diagnosis. Homogenized FE models are surprisingly accurate. The correlation with strength is only slightly improved by μFEA (Pahr and Zysset, 2009; Zysset *et al.*, 2013), which requires the segmentation of the trabecular network. However, difference in the trabecular architecture may be important to identify phenotypes of osteoporosis for targeted treatment.

3D-DXA is an interesting development because advanced analysis methods such as assessment of cortical parameters or even FEA can be applied to DXA directly. This could revolutionize fracture prediction and monitoring of osteoporosis because DXA equippment is widely available. On the other hand, the achievable quality of 3D-DXA images may not be adequate to determine parameters of bone quality with sufficient accuracy.

Introduction

Osteoporosis is the most prevalent metabolic bone disease and its impact is expected to rise throughout the world with the aging of the population (Harvey *et al.*, 2010). It is defined as a disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and consequent increase in fracture risk (Anon, 1993). Low bone mass, measured as bone mineral density (BMD), is asymptomatic and its important outcome is fracture, a cause of morbidity and mortality. This is especially true for hip fracture (Kanis and Johnell, 2005). Therefore, the clinical management focus in osteoporosis is to prevent or reduce the risk of fracture and follow the response to therapy. The identification of the patients to be treated relies on bone mineral density (BMD) measurement, most commonly using dual-energy X-ray absorptiometry (DXA) (Kanis *et al.*, 2008). Also, algorithms to estimate fracture risk based on BMD and other clinical features (age, gender, prior fractures, parental hip fracture history, body mass index, ethnicity, smoking, alcohol use, glucocorticoid use, rheumatoid arthritis, and secondary osteoporosis) such as FRAX are commonly used in clinical practice to guide the treatment of individual patients (Kanis *et al.*, 2011).

However, important gaps remain with interpretation of results particularly with regard to identification of individuals who would best benefit from intervention and, for those patients on treatment, the optimal manner in which response to treatment should be monitored. In this regard, there has been interest in the clinical potential of bone turnover markers (BTM) as tools to assess fracture risk, to monitor treatment, to predict response to treatments and to take the best intervention strategies (Vasikaran *et al.*, 2011). One of the great advantages of BTM is that they are measured in samples (blood or urine) that are easily collected. Also, their determination can be performed quite easily and levels provide information that is complementary to BMD. However, there are some weaknesses in the use of BTM in clinical practice. Among these, one can cite the biological, the preanalytical and the analytical variabilities. Indeed, BTM need to be measured in the morning(their concentrations are highest in the second half of the night and at time of waking whereas they are lowest in afternoon and evening), and in a fasting state (feeding leads to a significant decrease particularly for bone resorption markers) (Vasikaran *et al.*, 2011). Furthermore, no standardization of BTM assays exist, there are very few external quality control programs which include BTM, there are important method-to-method variations (Jørgensen *et al.*, 2017; Chubb *et al.*, 2015a) and many different BTM exist in the market, that have been used in various studies in the past, which makes it difficult to compare results. Therefore, in 2010, the International Osteoporosis Foundation (IOF)—International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) Joint Working Group on Bone Marker Standards (WG-BMS) published an extensive review supporting the role of BTM in the management of patients with osteoporosis (Vasikaran *et al.*, 2011). The Working Group acknowledged that there was no perfect (or gold standard) BTM but recommended one bone formation marker (serum procollagen type I N-propeptide (PINP)) and one bone resorption marker (serum C-terminal telopeptide of type I collagen, (CTX)) be used as reference markers, to be measured by standardized assays in observational and intervention studies in order to assess their clinical performance as well as to provide data by which alternatives could be assessed thus enlarging the international experience of the application of these markers to clinical medicine. In 2012 the National Bone Health Alliance extended the literature review on this subject arriving at similar recommendations (Bauer *et al.*, 2012). The IFCC-IOF Working Group for the Standardization of Bone Marker Assays was established in 2012 to standardize or harmonize serum/plasma CTX and PINP assays depending on feasibility.

Bone Turnover Markers: Definition

BTM are biochemical products preferably measured in blood, but also in urine that reflect the metabolic activity of bone but without any function in controlling skeletal metabolism. Traditionally, they are categorized as markers of bone formation or bone resorption (**Table 1**).

☆*Change History*: January 2018. E Cavalier, R Eastell, NR Jørgensen, K Makris, S Vasikaran and HA Morrish, on behalf of the IFCC-IOF Working Group for Standardization of Bone Marker Assays updated the text and references.

Table 1 Bone turnover markers: nomenclature, abbreviations and description

Marker	*Full name*	*Origin*	*Assay*	*Comments*
Resorption				
u-NTX	Urinary amino-terminal cross-linking telopeptide of type I collagen	Osteoclastic hydrolysis of type I collagen, generated by cathepsin K	Automated manual	Must be adjusted to levels of urinary creatinine Specificity: collagen type I, with highest contribution probably from bone Sources of variability: influenced by circadian rhythm
s-NTX	Serum amino-terminal cross-linking telopeptide of type I collagen			Specificity: collagen type I, with highest contribution probably from bone; smaller response to therapy may indicate some lack of bone specificity Sources of variability: influenced by renal function and circadian rhythm
u-CTX	Urinary carboxy-terminal cross-linking telopeptide of type I collagen			Must be adjusted to levels of urinary creatinine Specificity: collagen type I, with highest contribution probably from bone u-CTX is isomerized (β) or nonisomerized (α). Isomerized if not otherwise specified Sources of variability: influenced by circadian rhythm
s-CTX	Serum carboxy-terminal cross-linking telopeptide of type I collagen			s-CTX is always isomerized (β) Specificity: collagen type I, with highest contribution probably from bone Sources of variability: very dependent on time of day and food (must be collected after an overnight fast); influenced by renal function, liver function and circadian rhythm
s-ICTP or CTX-MMP	Carboxy-terminal cross-linking telopeptide of type I collagen	Osteoclastic hydrolysis of collagen generated by matrix metalloproteinases	Manual	Specificity: collagen type I, with highest contribution probably from bone. Results from MMP digestion of collagen and not responsive to usual treatments for osteoporosis Sources of variability: influenced by renal and liver function and circadian rhythm
u-DPD	Urinary deoxypyridinoline	Proteolytic hydrolysis of collagen, found in bone	Automated manual	Must be adjusted to levels of urinary creatinine Total or free (nonpeptide-bound) Specificity: highest contribution from bone, present in mature collagen only Sources of variability: independent of dietary sources, influenced by UV radiation and circadian rhythm
u-PYD	Urinary pyridinoline	Found in bone, cartilage, tendon, blood vessels	Automated manual	Must be adjusted to levels of urinary creatinine Total or free (nonpeptide-bound) Specificity: highest contribution from bone and cartilage, present in mature collagen only Sources of variability: independent of dietary sources; influenced by liver function, active arthritis and UV radiation, and circadian rhythm

Table 1 Continued

Marker	*Full name*	*Origin*	*Assay*	*Comments*
Formation				
s-OC	Serum osteocalcin	Hydroxyapatite-binding protein exclusively synthesized by osteoblasts and odontoblasts	Automated manual	Specificity: specific marker of osteoblast function but also liberated from bone matrix during resorption process Subject to rapid degradation in serum leads to heterogeneity of OC fragments: usually measured as intact [1–49] or N-mid [1–43] fragment, or can be undercarboxylated (ucOC) Sources of variability: influenced by renal function and circadian rhythms; large inter-laboratory variation
u-OC	Urinary osteocalcin		Manual	Adjusted to levels of urinary creatinine Specificity: specific marker of osteoblast function but also liberated from bone matrix during resorption process Mid (predominant fragments) or long (only longest fragment) in urine Sources of variability: influenced by renal function and circadian rhythm
s-ALP	Serum alkaline phosphatase (total)	Ubiquitous, membrane bound tetrameric enzyme located on the outer cell surface of various tissues: liver, bone, intestine, spleen, kidney and placenta	Automated manual	Specificity: nonspecific for bone (about 50% is liver isoform in healthy individuals Multiple assay methodologies Source of variability: very small circadian rhythm
s-BALP	Serum bone-specific alkaline phosphatase	Ubiquitous, membrane bound tetrameric enzyme located on the outer cell surface of osteoblasts	Automated manual	Specificity: specific for bone, but with a certain cross-reactivity with liver isoform (up to 20%) Source of variability: very small circadian rhythm Semantic confusion and may be expressed as “mass” (Ostase) or enzymatic units (ratio about 50% between both)
s-PICP	Procollagen type I C propeptide	Precursor molecules of collagen type I synthesized by osteoblasts	Manual	Specificity: mostly derived from bone collagen type I (around 90%). Short serum half-life. Regulated by hormones (thyroid, IGF-1) Source of variability: small circadian rhythm
s-PINP	Procollagen type I N propeptide		Automated manual	Specificity: mostly derived from bone collagen type I Assay: may recognise trimer alone (intact) or trimer and monomer (total PINP). Monomers accumulate in renal failure Source of variability: small circadian rhythm
Osteoclastic enzymes				
s-TRACP	Serum tartrate-resistant acid phosphatase	Includes two isoforms: type 5a (platelets, erythrocytes and other sources) and type 5b (osteoclasts)	Automated manual	Reflects the number of osteoclasts Only resorption marker that does not accumulate in renal failure
Cat K	Cathepsin K	Catalytic enzyme expressed by osteoclasts	Manual	

(*Continued*)

Table 1 Continued

Marker	*Full name*	*Origin*	*Assay*	*Comments*
				Could be a specific marker of osteoclast activity. Potential therapeutic target
Regulators of bone turnover				
OPG	Osteoprotegerin	Osteoblasts. OPG is a glycoprotein that circulates as a monomer or homodimer and may be bound to RANKL	Manual	Difficult to measure. We don't know which of the three molecular forms is more clinically relevant to measure. Circulating levels may be not reflecting local bone marrow production. Serum levels may not reflect accurately the risk of fracture or bone loss and serial changes may not reflect response to treatment
RANKL	Receptor activator of nuclear factor-kappaB ligand	Osteoblasts	Manual	Difficult to measure since serum levels are very low and because of analyte instability. Circulating levels may be not reflecting local bone marrow production. Serum levels may not reflect accurately the risk of fracture or bone loss and serial changes may not reflect response to treatment
SCL	sclerostin	Osteocytes	Manual	There is a very bad concordance between the assays that measure sclerostin. This has lead to confusion in clinical studies Also, according to the assays sclersotin seems to accumulate or not in CKD. The structure of active sclerostin is a triple loop, but many inactive fragments that corss-react at various extents with the antibodies used in the assays also seem to circulate. Sclerostin is a major pharmaceutical target.
DKK-1	Dickkopf-1 related protein	Osteocytes	Manual	Regulates bone metabolism through the Wnt signalling pathway by inhibiting osteoblast differentiation and FGF-23. Some data on the utility of assessment of DKK-1 and FGF-23 in osteoporosis have been published, but the importance of these mediators in the regulation of bone metabolism has not been established.
FGF-23	Fibroblast growth factor 23	Biologically active intact FGF23 has an estimated half-life of 20 to 60 minutes and is cleaved enzymatically into inactive C-terminal and N-terminal fragments	Automated manual	There are 2 types of assays: one that only recognizes intact-FGF23, and one that detects both intact-FGF23 and C-terminal fragments. In most CKD studies there appears to be a good correlation between intact and C-terminal FGF23 but in some diseases (iron deficiency, GALNT3 mutation) iFGF23 is lower whereas inactive C-terminal fragments are high. Correlate with left ventricular volume

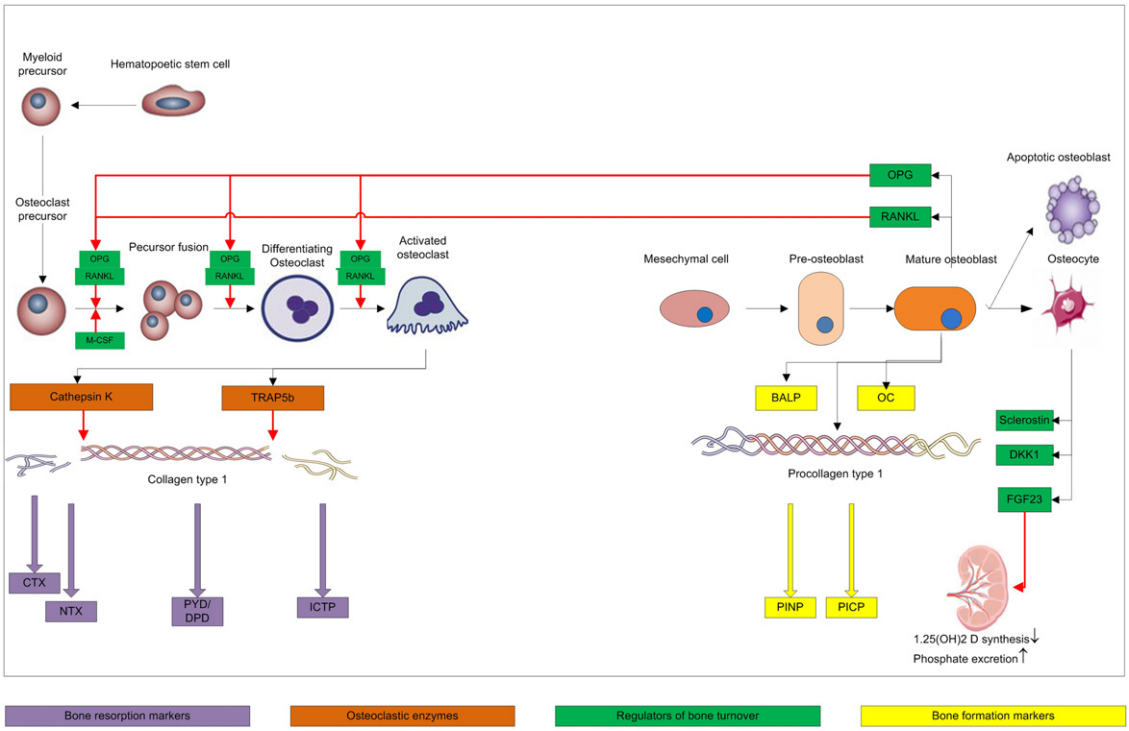

Fig. 1 Biochemical markers of bone turnover. Currently available markers include both enzymes and nonenzymatic peptides derived from cellular and noncellular compartments of bone. They are usually classified according to the metabolic process they are considered to reflect. Most biochemical markers of bone resorption are related to collagen breakdown products. Other markers of bone resorption include noncollagenous matrix proteins or osteoclast-specific enzymes. In contrast, markers of bone formation are either by-products of collagen neosynthesis, or osteoblast-related proteins. This distinction, however, is not absolute, since some markers reflect, at least in part, both bone formation and bone resorption (e.g., certain OC fragments). Furthermore, most of these molecules are also present in tissues other than bone, and nonskeletal processes may therefore influence their circulating or urinary levels. Finally, changes in markers of bone turnover are not disease specific but reflect, as an integral measure, alterations in the metabolism of the entire skeletal envelope independently of the underlying cause. Results of bone marker measurements should always be interpreted taking into account patient's clinical picture. The bone remodeling cycle lasts 150–200 days and is primarily mediated by osteoblastic signals which promote the differentiation and maturation of osteoclast precursors. RANKL (a product of osteoblast precursors and/or mature osteoblasts) is the key osteoblastogenic cytokine which in the presence of a permissive concentration of M-CSF is capable of inducing osteoclast formation and promoting osteoclast resorptive activity in the absence of any other cytokine. OPG (also a product of mature osteoblast and their precusrors but also a product of B cells) functions as a decoy receptor, preventing the association of RANKL with RANK receptor and thus moderating the osteoclastogenesis and bone resorption. The binding of RANKL to RANK initiates the differentiation of early osteoclast precursor into preosteoclasts. Preosteoclasts fuse with each other to produce multinucleated bone resorbing osteoclasts recognized by the expression of key osteoclast markers including TRAP5b, cathepsin K, and MMP9. Activated osteoclasts create resorption pits with low pH to dissolve the inorganic matrix and lysomal enzymes, such as TRAP and cathepsin K, effectively digest the exposed type-1 collagen releasing specific degradation products Osteoblasts are attracted to eroded bone surface and begin to form new osteoid. Type-1 collagen, abundant in osteoblasts, is secreted as a procollagen precursor molecule into the extracellular space where it is cleaved, by specific propeptidases, at the amino-and carboxy-terminals releasing pro-peptides into the blood. Initially hydroxyapatite crystals are deposited in the osteoid then a slower mineralization process continues over several months, followed by a period of quiescence. *Red arrow* indicate action, *black arrow* production. Modified (and enriched) from Krane, S. M. (2005). K. and van Laar, J. M. (2013). The clinical utility of bone marker measurements in osteoporosis. *Journal of Translational Medicine* **11**, 201.

Biomarkers of Bone Formation

Markers of bone formation are direct or indirect products of active osteoblasts expressed during various phases of their development and reflect different aspects of osteoblast function (**Fig. 1**). The bone matrix is a complex structure composed of mineralized type I collagen. This protein is synthesized by the osteoblasts as a precursor molecule (procollagen) whose extension peptides at each end (procollagen type I N propeptide (PINP) and procollagen type I C propeptide (PICP)), are cleaved by enzymes during bone matrix formation and released into the circulation. The most abundant noncollagenous bone protein is osteocalcin (OC). It is also produced by osteoblasts during bone formation, and some proportion finds its way into the extracellular compartment where it can be measured. Of note, OC is also liberated from the bone matrix during bone resorption, which makes that OC cannot be considered as a "true" bone formation marker. Interestingly, OC has been shown to be involved in the energy metabolism by its interplay with insulin (Karsenty and Ferron, 2012), but this is out of the scope of this article. OC is

excreted by the kidneys and its fragments may also be measured in urine. Newly formed osteoid undergoes maturation followed by mineralization, and during this phase, alkaline phosphatase (ALP) is secreted by osteoblasts into the extracellular fluid and can be measured in serum. However, only about half of the total ALP activity in blood in healthy adults derives from bone, the other half being predominately of hepatic origin. Hence, total ALP measurement has a poor specificity and assays that detect more specifically the bone derived isoform (BAP) are available. Unfortunately, a certain intermethod variability also exists for this biomarker (Cavalier *et al.*, 2014).

Regulation of bone formation

The canonical Wnt-β-catenin signaling pathway controls the fate of mesenchymal stem cells (MSCs) and their differentiation into various cell lineages. This pathway enhances osteoblastic differentiation from MSCs, promotes osteoblast maturation and osteoblast and osteocyte survival and inhibits osteoclastogenesis (Baron and Kneissel, 2013; Plotkin and Bellido, 2016). This is achieved indirectly via the increase of the expression of osteoprotegerin (OPG) in osteoblasts and osteocytes. Dikkopf related protein (DKK-1) is a Wnt antagonist expressed in osteoblasts and in osteocytes at much higher levels (Paic *et al.*, 2009). Experimental studies in mice have shown that overexpression of DKK-1 in osteoblastic cells has as result decreased bone formation and low bone mass (Li *et al.*, 2006). Another antagonist of Wnt signaling is sclerostin, which is primarily expressed by mature osteocytes but not by early osteocytes or osteoblasts. Sclerostin binds to Wnt coreceptors and antagonizes downstream signaling (Poole *et al.*, 2005; Moester *et al.*, 2010; Sapir-Koren and Livshits, 2014). Absence of SOST (the gene that encodes for sclerostin) expression or secretion of sclerostin in humans has as result sclerosteosis (van Buchem disease) or craniodiaphyseal dysplasia, which are inherited diseases of high bone mass characterized by excessive bone mass formation. On the other hand overexpression of the SOST gene results in overproduction of sclerostin which in turn results in decreases in bone mass (Baron and Kneissel, 2013; Moester *et al.*, 2010; Sapir-Koren and Livshits, 2014).

Biomarkers of Bone Resorption

The commonly used bone resorption markers are degradation products of type I collagen, but noncollagenous proteins such as the enzyme of osteoclast origin tartrate resistant acid phosphatase 5B (TRAP-5B) have also been investigated as resorption markers. The pyridinium cross-links, pyridinoline (PYD), and deoxypyridinoline (DPD) are formed during the maturation of bone collagen, present in significant amounts in bone and dentine, released during resorption of bone and excreted in urine in the free and peptide-bound forms without being metabolized. The peptide-bound forms of PYD and DPD include the C-terminal and N-terminal cross-linking telopeptides (CTX, NTX) of the type I collagen molecule, and these are also released into the circulation and subsequently excreted in urine.

Osteoclastic Enzymes

Tartarate resistant acid phospatase (TRAP-5b)

TRAP-5b is produced by osteoclasts and is considered a good marker of bone resorption (Halleen *et al.*, 2000). During bone resorption osteoclasts secrete TRAP-5b which produces reactive oxygen species to digest bone degradation products in the microenvironment of bone matrix. If the action of TRAP-5b in the bone is still not fully understood it reflects both the osteoclast activity and number and has been shown to be inversely correlated with bone mineral density (BMD) in postmenopausal women and to predict an increased risk of hip or vertebral fracture (Nenonen *et al.*, 2005).

Cathepsin K

The enyme cathepsin K is a member of the cysteine protease family, and unlike other cathepsins has the unique ability to cleave both the helical and the telopeptide regions of collagen type I. It is a lysosomal enzyme and this active form is produced in vivo in the lysosomes is believed to occur in the low acid pH environment of the lysosomes and subsequently is released into bone resorption lacunae. Some of this cathepsin K is released into circulation and could be a specific biological marker of osteoclast activity. Increased levels of cathepsin K have been reported in individuals with postmenopausal osteoporosis, Paget disease, and rheumatic diseases (Chapurlat and Confavreux, 2016; Harvey *et al.*, 2010).

Regulation of bone resorption

Osteocytes produce cytokines that regulate osteoblast formation and survival (Plotkin and Bellido, 2016). Osteoclastogenesis involves the activation of the receptor activator of nuclear factor κB (RANK) in osteoclast precursors induced by RANK ligand (RANKL), which is produced mainly by osteoblastic cells (and in a lesser extent by osteocytes) (Kearns *et al.*, 2008). The antiosteoclastogenic cytokine OPG is expressed in both osteoblasts and osteocytes and it acts as a decoy receptor for RANKL, binds RANKL and competes RANK and therefore inhibits osteoclast differentiation (Harvey *et al.*, 2010; Anon, 1993; Kanis and Johnell, 2005). Moreover OPG is a target of the canonical Wnt signaling and experimental studies have shown that mice that lack β-canetin in osteoblasts exhibit low levels of OPG, increased numbers of osteoclasts and as a results low bone mass. These finding show that regulation of OPG by the Wnt-β-canting signaling has an important role in the control of bone resorption (Plotkin and Bellido, 2016; Weitzmann, 2013).

Regulators of osteoclastic–osteoblastic activity: Osteocytic signaling pathways

Osteocytes are the most abundant cells in bone and are essential the functioning of the human skeleton. They constitute >90% of bone cells. Osteocytes are differentiated osteoblasts, that live within the bone matrix and are highly connected not only among themselves but also with cells on the bone surface and the bone marrow. These "quiescent" cells are literally buried in the mineralized bone tissue and are very active. They coordinate bone acquisition during growth and the maintenance of healthy skeletal frame for movement support and the protection of essential organs. Osteocytes orchestrate the function of osteoblasts and osteoclasts by the production and secretion of factors that enable the skeleton to adapt to mechanical and hormonal changes. Moreover they secrete hormones that affect other tissues and regulate mineral homeostasis and hematopoiesis. Osteocytes produce and secrete factors that affect other bone cells by paracrine and/or autocrine mechanisms (RANKL, OPG and sclerostin) and secrete hormones (FGF23) that affect other tissues by endocrine actions. These pathways are now considered as potential therapeutic targets in an attempt to improve human skeletal health (Plotkin and Bellido, 2016; Dallas *et al.*, 2013; Bellido, 2014).

Phosphate metabolism and matrix mineralization

Fibroblast growth factor 23 (FGF23) is produced by osteocytes (and possibly by osteoblasts) and has a key role in the "bone-parathyroid-kidney" axis and the regulation of phosphate/calcium metabolism. FGF23 binds to one or several FGF receptors and the Klotho coreceptor in the renal proximal tubules and inhibits the expression of the types IIa and IIc sodium-phosphate cotransporters on the apical membrane of the renal proximal tubular cells. This leads to an increase in renal phosphate excretion. In contrast to PTH, which also induces phosphaturia and increases renal 1α-hydroxylase, FGF23 suppresses 1α-hydroxylase and stimulates renal 24-hydroxylase activity. This action leads to a decrease of 1,25-dihydroxy vitamin D ($1,25(OH)_2D$) production.

While FGF23 regulates phosphate and $1,25(OH)_2D$ levels, FGF23 is itself regulated by both phosphorus and $1,25(OH)_2D$ and probably by PTH. Indeed enhanced FGF23 production was observed after dietary phosphate loading and administration of $1,25(OH)_2D$ and PTH, while dietary phosphorus restriction reverses this trend. However the most significant increases of FGF23 levels have been observed in patients with chronic kidney disease (CKD). In patients with CKD, circulating levels of FGF23 rise progressively as renal function declines well before the onset of a critical reduction in the nephron number. These, early increased, FGF23 levels during CKD, are observed well before phosphate/PTH levels increase or $1,25(OH_2)D$ levels decrease, and the exact mechanisms and the triggers of this increase remain unknown. Several studies have shown that elevated levels of FGF23 are independently associated with greater risks of death, cardiovascular events progression to end-stage renal disease and premature allograft loss after kidney transplantation (Plotkin and Bellido, 2016; Shimada *et al.*, 2004; Hu *et al.*, 2013; Kuro-o, 2013; Urakawa *et al.*, 2006).

BTM Concentrations for Predicting Fracture Risk

Estrogen deficiency links to an osteoblastic overexpression of the Receptor Activator of Nuclear Factor Kappa B Ligand (RANKL) which cannot be adequately controlled by osteoprotegerin, its decoy receptor. This excess of RANKL activates RANK receptors, located on preosteoclasts and mature osteoclasts, leading to accelerated bone resorption (Boyle *et al.*, 2003). The overall imbalance between formation and resorption at the level of bone tissue is maintained for several decades after menopause, leading to increased risk of fracture. It may thus be logical to associate the high levels of BTM, and especially bone resorption markers to increased fracture risk.

The IOF-IFCC WG-BMS review by Vasikaran *et al.* described 22 studies, in which the relationship between bone turnover markers and incident fractures was examined (Vasikaran *et al.*, 2011). Eighteen of them showed that one or more markers were associated with risk of subsequent fracture with the concentration of bone resorption markers more consistently associated with fracture risk than bone formation markers. This was the case for studies in both men and women and seven of these studies even reported that in women with a low BMD, the presence of increased BTM had an additive effect on fracture risk. Since that time three more studies (reviewed in Morris *et al.*, 2016) have been published, including a metaanalysis. The metaanalysis examined the performance characteristics of PINP and CTX for fracture risk prediction in untreated individuals and found a modest, but significant association between both PINP and CTX concentrations at baseline and fracture risk (Johansson *et al.*, 2014). The results of this metaanalysis have to be examined with caution as it combined results for CTX generated by the two clinical laboratory automated assay methods currently available (IDS iSYS and Roche Cobas) and these assays do not appear to provide comparable values for CTX (Chubb *et al.*, 2015a). Similarly the PINP data were generated by different assays. In the Australian Health In Men Study the association of bone turnover markers with hip fracture incidence in older men was examined. Total osteocalcin (tOC), undercarboxylated osteocalcin (ucOC) and CTX were associated with hip fractures in univariate analyses, but only tOC remained significantly associated with incident hip fractures in multivariate analyses adjusting for age and glucocorticoid use (Chubb *et al.*, 2015b). In contrast to the above, a Japanese study of the Taiji cohort of both men and women failed to demonstrate a significant association between a broad range of BTM and incident fracture risk. However, the study was insufficiently powered for a fracture endpoint as this cohort included relatively young subjects (mean age approximately 60 years) resulting in a low number of osteoporotic fractures (32) during the 10-year follow-up period (Yoshimura *et al.*, 2011).

These more recent findings support the previous interpretation in the Vasikaran review (Vasikaran *et al.*, 2011).There are significant associations between bone turnover markers and incident fracture risk, though the association is modest. Most studies demonstrate a relation between bone turnover markers and fracture, yet there are limitations to the studies. These include the variable use of markers of bone formation (BAP, PINP, PICP, total osteocalcin, intact osteocalcin) and of bone resorption (ICTP, CTX, NTX-I, PYR, DPD, beta-CTX), differences in analytical assays and platforms, inconsistencies in expression of risk, as well as inconsistent predictive value for a specific marker in the individual studies reported (see **Table 1** for abbreviations of BTM).

BTM Concentrations for Monitoring Treatment

One of the great advantages of BTM over BMD is that they may rapidly show responses to the treatments used for osteoporosis. Hence, this rapid response (or the absence of response) may help the clinician decide on the dosage of the drug and the frequency of the administration -or even to change the treatment. Also, the percentage of variation of the BTM after treatment is quite large (e.g., bisphosphonates lead to a decrease of 50% of bone resorption marker, or even more) whereas the increment in BMD is quite modest (e.g., 5%–10%).

The use of BTMs for the monitoring of treatment requires a baseline assessment with a repeat measurement at some defined point during treatment. To interpret the variation observed between two results, one has to take into consideration two variations, namely the analytical variation (CV_a), expressed as the coefficient of variation (in percent) of the analytical method used to measure the BTM, and the intraindividual variation of the BTM (CV_i), also expressed in percent, which is the natural biological variation of the biomarker around its homeostatic set-point. In order to be confident ($P < 0.05$) that a change in a BTM value has occurred, then (assuming a normal distribution) the change in measured value must exceed $\sqrt{2} \times 1.96 \times \sqrt{(CV_i^2 + CV_a^2)}$ which is termed the "Least Significant Change (LSC) or "Reference Change Value" (RCV). Taking into consideration the fact that CV_a should at least be 1/4 of CV_i, we can come to the conclusion that LSC $\approx 3 \times CV_i$. For example, the LSC for CTX might be $3 \times 9.6 \approx 29\%$. In a woman with a baseline value of 500 ng/L for CTX, the LSC would be ± 145 ng/L, and so a significant decrease would be a value of 355 ng/L or below and a significant increase would be a value of 645 ng/L or above. Watch out that this is only true when the same preanalytical (time of sampling, sample type, fasting statutes, …) and analytical (same method) conditions are utilized. When monitoring treatment in clinical practice, it is also possible to note whether patients are below the geometric mean for a healthy young woman (35 μg/L for PINP, 280 ng/L for CTX). Indeed, before treatment, women with osteoporosis are above these thresholds in 90% of cases whereas on oral bisphosphonate therapy, 90% are below the threshold (Naylor *et al.*, 2016; Diez-Perez *et al.*, 2017).

The IOF-IFCC WG-BMS review (Vasikaran *et al.*, 2011) also reported seven studies concerning the relationship between change in BTM and fracture risk reduction with different drugs given for postmenopausal osteoporosis. These studies showed in general that the larger the decrease in BTM, the larger the reduction in fracture risk. One of the outcomes from such studies is to assess the extent to which a biological marker is a surrogate end-point for a clinical event, which is known as the "treatment effect explained." In the case of clinical trials for osteoporosis treatment, the clinical endpoint is fracture and the surrogate biological markers are BTM. The treatment effect explained was calculated for two of these seven studies, namely the VERT (Eastell *et al.*, 2003) and the MORE (Eastell *et al.*, 2003) trials). In the VERT trial, the change in u-CTX and u-NTX at 3–6 months explained between 54% and 77% of the fracture risk reduction with risedronate and in the MORE study, the change in PINP and OC explained 28% and 34%, respectively, of the vertebral fracture risk reduction with raloxifene. So, about half of the fracture risk reduction with these drugs, which work through the inhibition of bone turnover, could be associated with the measured change in BTM during the first year of treatment. However the review highlights many limitations to these studies: only a subset of patients generally had the BTM measured, so that the number of fractures considered was small, the size of the study was also generally quite small and BTM were not always collected in the correct way. Also, the IOF-IFCC WG-BMS also highlight some pitfalls in the statistical approach. There have now been two further studies that examine this question, one a follow-up analysis of zoledronic acid (HORIZON trial (Jacques *et al.*, 2012)) and the other a new analysis with bazedoxifene (Bruyère *et al.*, 2012), a selective estrogen receptor modulator, similar to raloxifene. In the HORIZON trial, the change in PINP at 1 year explained 58% of the treatment effect on new vertebral fracture (statistically significant), and there was a significant association with nonvertebral fracture. This figure was similar to the 54% treatment effect explained change in total hip BMD over 3 years and vertebral fracture. The effect explained by PINP was independent of that explained by total hip BMD, so the results of these two tests are complementary. Regarding the trial with bazedoxifene, the change in CTX at 1 year explained 16% and change in OC 6% of the treatment effect on new vertebral fracture (statistically significant). There was no overall reduction of nonvertebral fractures in this study so any relationship with marker change could not be tested. Once again the conclusions made in the original report (Vasikaran *et al.*, 2011) are at least partially supported by these new analyses. The treatment effect explained by BTM is at least as great as BMD. The finding of significant positive associations between the reduction in BTM and the reduction in fracture risk support the use of BTM in monitoring treatment. The limitation noted in the IOF-IFCC WG-BMS report that studies were often small subsets of the main trial was true for the zoledronic acid study but not for the bazedoxifene study, which is the largest study to date. The studies were also criticized for not obtaining samples under optimal conditions. This again was not true of these two studies as the patients from the bazedoxifene study were in the fasting state for the blood draw, a critical requirement for serum CTX.

Paget's Disease of Bone

Paget's disease of bone (osteitis deformans) is a chronic benign disorder of bone that generally affects one or several bones. It is characterized by a marked increase in bone turnover, leading to overproduction of bone of poor quality, responsible for hypertrophy, osteosclerosis, and bone fragility. BTM are routinely used for assessing the disease activity and for monitoring the efficacy of bisphosphonate therapy. Because of a marked increase in bone turnover, serum total ALP activity is the most commonly used bone marker for Paget's disease for both applications. Although serum total ALP is adequate to monitor most patients with active disease, this marker may lack sensitivity in patients with monostotic disease affecting a small bone and in patients with purely osteolytic lesions. Among more specific BTM, BALP, and PINP appear to be the most sensitive markers for assessing disease activity. These markers may be particularly interesting for patients with monostotic disease (Garnero and Delmas, 2004). On the contrary, osteocalcin lacks sensitivity probably because the fraction of newly synthesized osteocalcin that is incorporated into bone matrix may be increased because of the high mineral content of the woven bone. For bone resorption, urinary NTX and urinary nonisomerized α-CTX (and not β-CTX because pagetic bone matrix is characterized by an impaired degree of β -isomerization of type I collagen molecules) appear to be the most sensitive bone resorption markers both for assessing disease activity and for monitoring efficacy of bisphosphonate therapy. In 2014, the Endocrine Society published a clinical practice Guideline on Paget's disease of bone (Singer *et al.*, 2014). Regarding the diagnosis of the disease, the authors recommend with high quality evidence that after radiological diagnosis of Paget's disease, the initial biochemical evaluation of a patient should be done using serum total ALP or with the use of a more specific marker of bone formation when appropriate. They consider that the low cost and the universal availability of the total ALP is a great advantage over more specific formation biomarkers, but recommend that in patients with abnormal liver or biliary tract function, a more specific biomarker of bone formation should be used to assess response to treatment or follow evolution of the disease in untreated patients. In this situation, PINP is the best option and has great advantages over osteocalcin and BALP because of the lack of sensitivity of the first, and cross-reactivity with liver isoenzyme for the second marker. If PINP cannot be used because of cost or unavailability, plasma β-CTX and urinary α-CTX or NTx can be used. In untreated Paget's disease, α-CTX (measured by ELISA only) which contains an aspartyl-glycine motif derived from newly formed collagen, is raised proportionately more than β-CTX, which is formed from spontaneous isoaspartyl formation as the bone ages in response to treatment (albeit β-CTX slightly underestimates the response to treatment of very active disease due to the isomerization phenomenon). The advantage of telopeptide assays over bone formation assays is faster demonstration of a maximal decrease in bone resorption than in bone formation after treatment. Regarding the monostotic Paget's disease, the Working Group suggests (with a low quality evidence) that PINP or BALP and β-CTX or NTx should be used for assessing the activity of the disease, although these may be normal when evidence of disease activity is still clearly demonstrated on scintigraphy.

Effect of Renal Impairment on BTM Concentrations

Chronic Kidney Disease-Mineral and Bone Disorder (CKD-MBD)

Bone health is very frequently altered in Chronic Kidney Disease (CKD) and these patients are at increased risk of fractures whether they are dialyzed (Jadoul *et al.*, 2006) or not (Nickolas *et al.*, 2008). Indeed, these patients are often characterized by either increased or decreased bone turnover, linked to over- or under-secretion of parathyroid hormone (PTH). The gold standard to evaluate bone turnover is bone biopsy. Unfortunately, use of bone biopsies to determine bone turnover is hampered by the invasive nature of the procedure and the difficulty for correct interpretation of the results, limiting its use to a few specialized centers (Torres *et al.*, 2014). In clinical practice repeated bone biopsies are problematic for the follow-up of the patients or to assess effect of a treatment. Hence, BTM are essential in clinical practice to evaluate bone turnover. In 2009 the international recommendations in nephrology, Kidney Disease: Improving Global Outcomes (KDIGO) guidelines (Moe *et al.*, 2009) recommended the measurement of PTH and BALP in the assessment of metabolic bone disease of CKD (CKD-MBD). BALP was selected because serum concentrations are unaffected by renal function since it is cleared by the liver and with a molecular weight above 50,000 D it is unlikely to be filtered at the kidney but as already mentioned, it does suffer from some analytical and clinical issues (Cavalier *et al.*, 2014).

Is There any Place for Other BTM in CKD-MBD?

PINP

PINP consists of three subunit chains of type 1 procollagen (2 pro-α1 chains and 1pro-α2 chain) that are noncovalently linked and is produced in equimolar amounts with collagen deposited in bone tissue (Koivula *et al.*, 2012). Once in the circulation, PINP is rapidly bound and internalized by liver endothelial cells through their scavenger receptors (Melkko *et al.*, 1994). In human serum, PINP is present in two major forms, an intact trimeric form and a monomeric form. This latter form tends to be elevated in CKD patients. PINP determination can be performed either with automated (Roche Elecsys/Cobas and IDS iSYS) or manual (Orion Diagnostica) methods but the "Total" PINP assay (Roche Elecsys/Cobas) recognizes both the trimeric form and the monomers whereas the "Intact" PINP assays (IDS iSYS and Orion Diagnostica) recognize the trimeric form only. In CKD patients, it has been shown that patients with a glomerular filtration rate (GFR) below 30 mL/min/1.73 m2 have PINP concentrations that are overestimated by the "Total" assay due to the cross-reactivity with the monomeric form (Cavalier *et al.*, 2013). Assays specific for "Intact" PINP are recommended for use with CKD patients. While IOF and IFCC recommend serum CTX as the bone resorption biomarker for clinical research studies in osteoporosis it is not

recommended in CKD-MBD by the KDIGO guidelines since serum PTH or BALP are more effective at predicting clinical outcomes or bone histology (KDIGO Working Group, 2013; Delanaye *et al.*, 2014).

CTX

Serum CTX concentrations in patients undergoing hemodialysis are some five times higher than those of the normal population due to its accumulation with decreased renal function and frequent secondary hyperparathyroidism (Delanaye *et al.*, 2014).

TRAP-5B

Tartrate resistant acid phosphatase 5B (TRAP-5B) may be a suitable alternative for the monitoring of the bone resorption in CKD patients as it presents very interesting features: its serum concentrations are not influenced by kidney function and it is a noncollagen bone resorption marker with serum concentrations significantly correlating with histological indices of osteoclast number, bone formation rate, and mineral apposition rate in uremic patients (Hu *et al.*, 2013). TRAP-5B has recently become available on the automated IDS iSYS platform which may increase its potential as a routine marker for clinical laboratories increasing the data on this marker since such information is scarce (Shimada *et al.*, 2004).

Interpretation and Reference Intervals of Bone Turnover Markers Concentrations

BTM reference intervals are useful for interpreting the results from osteoporosis patients but by themselves they are of limited value for fracture prediction in untreated, individual patients. The need to establish reference intervals from healthy premenopausal women aged 30–45 years when concentrations are at a nadir has been emphasized (Vasikaran *et al.*, 2011; Szulc *et al.*, 2017). Ideally the subjects used for these studies should have normal BMD at the spine (Vasikaran *et al.*, 2011), but also should not suffer from secondary hyperparathyroidism linked, for instance, to a vitamin D deficiency. Expert opinion also suggests that the mean of the premenopausal reference interval can be used as a treatment target for antiresorptive therapy (Vasikaran *et al.*, 2011; Delmas *et al.*, 2000). It is considered necessary to establish reference intervals for different geographic areas and ethnicities (Vasikaran *et al.*, 2011). Furthermore due to differences that currently exist between results from the different commercial clinical assays, current reference intervals need to be method specific and reference intervals from different methods cannot be used interchangeably. The different reference ranges of CTX and PINP obtained up to now in the literature have been exhaustively reviewed in (Morris *et al.*, 2016). The results of this review show that the largest variation between the reference intervals appear to be between the Roche and IDS-iSYS assays for CTX although data for the IDS-iSYS assay are limited. Most of the studies have been performed in Caucasian individuals and data are clearly lacking for other ethnicities, and especially for subjects from Asian origin, which are increasingly concerned by osteoporosis. The variation across geographic regions appears to be minor except for those from Saudi Arabia.

BTM and Bone Metastases

Various neoplastic diseases and their treatments have significant effect on bone health. Metastatic bone disease is mostly seen with specific cancer types (most commonly from breast, prostate, lung, kidney and multiple myeloma). Bone metastases (BM) are a major complication in the clinical management of neoplastic diseases because of its prevalence and because of the proven relationship between cancer cells and stromal cells in the bone. Moreover biomarkers can reflect multiple interactions of cancer cells with osteoclasts and osteoblasts and they can have a role in the pathways involved in cancer progression in the bone (Ferreira *et al.*, 2015). These interactions between the tumor and the bone results in increased rates of osteolysis and osteogenesis and release of high levels of several biochemical markers that their measurement can be performed in blood or urine. The measurement of CTX, NTX, PINP, PICP or bone specific ALP can provide information not only on the rates of bone resorption or formation but also on the effect of tumor growth on bone turnover (Ferreira *et al.*, 2015; Coleman *et al.*, 2011). Although several studies showed a value in the measurement of bone turnover markers in order to evaluate BM status and to evaluate the response to therapy (Brown *et al.*, 2005; Ulrich *et al.*, 2001; Fizazi *et al.*, 2009; Stopeck *et al.*, 2010), the most recent practice guidelines have not recognized a definitive role of bone turnover biomarkers in the interpretation of clinical outcomes and treatment response in patients with BM (Coleman *et al.*, 2014; Van Poznak *et al.*, 2011).

Bone markers have been used in clinical studies for the evaluation risk of bone metastases development after cancer treatment, for the diagnosis of bone metastases and for the prediction of patient's outcome. Detailed discussion can be found elsewhere (Ferreira *et al.*, 2015; Jung and Lein, 2014; Joerger and Huober, 2012).

We must note here that bone markers reflect the ongoing bone resorption and formation of the body as whole and do not provide information to a specific site of the skeleton (where the metastases are, and they are not disease specific. They reflect alterations in skeletal metabolism independent of the underlying cause (Seibel, 2005).

Primary Hyperparathyroidism

Claudio Marcocci and Filomena Cetani, University of Pisa, Pisa, Italy and University Hospital of Pisa, Pisa, Italy

Introduction

Primary hyperparathyroidism (PHPT) is due to an increased secretion of parathyroid hormone (PTH) by one or more parathyroid glands. It represents the third most common endocrine disease and the most frequent cause of hypercalcemia in the general population. The classical presentation of PTHT was characterized by skeletal, renal, and neuromuscular manifestations. Nowadays the disease is generally diagnosed when asymptomatic, even though some patients may present bone loss and kidney stones. A normocalcemic variant of PHPT has recently been identified.

Epidemiology

Until the early 1970s PHPT was considered rare. In the 1970s the estimated prevalence varied from 1:1000 persons in the United States to 4.3:1000 persons in Sweden, where an even higher prevalence (21:1000 persons) was reported in 1990 in women aged 55–75 years. Recent data indicate that the estimated prevalence of PHPT in the general population in United States is 0.86%.

The incidence of PHPT has markedly increased following the introduction of serum calcium in the multichannel autoanalyzer. The incidence varies according to geographic areas and assessment measures. Data derived from the Rochester Epidemiological project firstly identified the asymptomatic variant and reported an incidence of about 30 per 100,000 person-years, with a decline in the late 1990s to 22 per 100,000 person-year. Recent data in the United States derived from the Kaiser Permanente Health Care database in California indicate an incidence of 79.6 per 100,000 person-years in women and 35.6 per 100,000 person-years in men of all races, with the highest rate among blacks. In Europe, a survey performed in Denmark has shown an increasing incidence over the period 1977–2010, up to an annual rate of 16 per 100,000. The increase was particularly evident in women after the age of 50 years. Epidemiological data are not available in other countries. Data from Latin America and Asia indicate that the symptomatic form still is the most common, even though a trend to an increased rate of asymptomatic cases has been reported over the last 10 years.

The incidence peaks in the sixth decade of life. Women are more affected than men, with female to male ratio of 3:1, whereas there is no sex difference before the age of 45 years. PHPT is rare in children and adolescent. In the latter cases it is important to consider a genetic cause.

Etiology

PHPT mostly presents as a sporadic disease (90%), but may be part of hereditary syndromes [e.g., multiple endocrine neoplasia (MEN) type 1, 2A, and 4, hyperparathyroidism-jaw tumor syndrome (HPT-JT), and familial isolated primary hyperparathyroidism (FIPH)]. A solitary, benign adenoma is found in 80%–85% of cases. The histology is characterized by an encapsulated collection of chief cells (less frequently oxyphil cells), surrounded by a rim of normal parathyroid cells. The remaining parathyroid glands are normal.

Multigland involvement (either multiple adenoma or hyperplasia of all parathyroid gland) is found in 15%–20% of cases and is more common in hereditary cases, particularly MEN1. It may present in an asynchronous manner and can be confused with a sporadic single gland disease when only one affected gland if detected at initial surgery. Rarely (less than 1%), PHPT is caused by a parathyroid carcinoma, in which mitoses, fibrous trabeculae, vascular or capsular invasion, and infiltration of surrounding tissue are present. In the absence of local infiltration or metastases, the diagnosis of parathyroid carcinoma may be difficult at histology. Genetic studies (*CDC73* gene mutations) and immunohistochemical studies [loss of parafibromin (the protein encoded by the *CDC73* gene) expression] may help in equivocal cases. Very rarely hyperparathyroidism may be caused by ectopic PTH production by a nonparathyroid neoplasia. Predisposing factors are external neck irradiation in childhood and long-term lithium therapy.

Pathophysiology

Control of PTH Secretion

Extracellular ionized calcium (Ca_o^{2+}), by interacting with the Ca^{2+} sensing receptor (CaSR) present on the surface of parathyroid cells, is the main regulator of PTH synthesis and secretion. There is an inverse sigmoidal relationship between Ca_o^{2+} concentration and PTH release: in adenoma, parathyroid cells are less sensitive to Ca_o^{2+}, the "set point" (i.e., the concentration of Ca_o^{2+} causing a

 doi:10.1016/B978-0-12-801238-3.65217-0

50% inhibition of the maximal PTH secretion) is shifted to the right and each cell secretes more PTH. On the other hand, in hyperplasia the set-point for Ca_o^{2+} is unchanged and each cells secretes a normal amount of PTH.

1,25-Dihydroxyvitamin D ($1,25(OH)_2D$) suppresses the transcription of PTH gene and parathyroid cell proliferation. This effect is due to either circulating $1,25(OH)_2D$ or its local production by 1α-hydroxylation of circulating 25-dihydroxyvitamin D (25(OH)D).

Serum phosphate, by binding to Ca^{2+}, lowers serum calcium concentration and indirectly stimulates PTH secretion. In addition, a direct stimulatory effect seems to be mediated through an increased stability of PTH mRNA.

Finally, experiments performed in rats and parathyroid cell in culture indicates that fibroblast-growth factor 23 (FGF23) inhibits PTH synthesis and secretion and, perhaps, parathyroid cell proliferation. The role of FGF23 in the pathogenesis of PHPT in humans remains unclear. As a matter of fact, serum levels of FGF23 are increased in patients with PHPT likely reflecting an adaptive response to offset the increased levels of $1,25(OH)_2D$ secondary to the high serum concentration of PTH.

The pathophysiology of PHPT is characterized by the loss of the homeostatic control of PTH synthesis and secretion from one or more parathyroid glands, leading to excessive secretion of PTH by individual cells (adenoma) or increased parathyroid cell proliferation (hyperplasia), where each cell synthesizes and secrete a normal amount of PTH.

Target Organs of PTH

Bone and kidney are the major targets organ of PTH. In bone, PTH acts an osteoblast, osteoclasts, and osteocytes. The net effect depends on the dose and timing of PTH signaling. In healthy individuals PTH is secreted in a pulsatile manner, with a circadian rhythm, and the two opposite effects, namely stimulation of bone resorption and bone formation, are well balanced. In patients with PHPT the sustained increased concentration of PTH causes bone loss particularly at cortical sites, osteoporosis, and an increased risk of fragility fractures.

Molecular Pathogenesis

The molecular basis of PHPT remains unclear in the majority of cases, despite major progresses on the mechanisms responsible for parathyroid tumorigenesis has been performed in the last decades. Most parathyroid tumors are monoclonal, that is, the tumor is caused by an acquired genetic defect in key genes conferring to a single parathyroid cell a selective growth advantage. Conversely, hyperplastic parathyroid cells have a polyclonal origin, even though monoclonality has been shown in some cases. Two categories of genes controlling the growth of parathyroid cells and PTH synthesis/secretion may be involved: oncogenes and tumor-suppressor genes. Proto-oncogenes have a role in the control of cell proliferation, cell differentiation, and cell death. Several mechanisms are responsible for the conversion of a proto-oncogene to an oncogene, resulting in either an increased expression of its encoded protein or the synthesis of a new functioning protein. Most oncogenes bare dominant mutations and therefore abnormality of a single copy of the gene is sufficient for expression of the growth trait. Conversely, tumor suppressor genes encode for proteins that normally inhibit cell proliferation and one normal copy of the gene suffices to control cell proliferation. Therefore, inactivation of both copies of the genes is required for uncontrolled cell growth.

Germline mutations are commonly detected in hereditary forms, whereas somatic mutations may be found in sporadic cases, even though germline mutations have also been described. The studies of clonal DNA defects and inherited tumor predisposition syndromes have given a great contribution in the identification of genes involved in parathyroid tumorigenesis. The genetic abnormalities and the clinical manifestations are reported in **Table 1**.

Cyclin D1 gene

The cyclin D1 gene (*CCND1*) (initially named *PRAD1*) encoding cyclin D1 is an oncogene that is activated by a pericentromeric inversions of chromosome 11 that place the *CCND1* gene near the regulatory sequences upstream of the PTH gene. Thus, since PTH is highly expressed in parathyroid cells, the rearrangement leads to overexpression of cyclin D1 mRNA and protein, which cause parathyroid cell proliferation. This rearrangement has been found in up to 8% of sporadic parathyroid adenomas whereas cyclin D1 overexpression in 20%–40% of these tumors.

Multiple endocrine neoplasia type 1 (MEN1) gene

The multiple endocrine neoplasia type 1 (*MEN1*) tumor suppressor gene, at 11q13 encoding menin, is a "classic" tumor suppressor gene contributing to a cell's advantage through its biallelic inactivation. *MEN1* mutations (including large deletions) are found in up to 90% of familial MEN1 syndrome and are scattered in the coding regions of the gene. Up to 10% of patients may have de novo germline mutations. MEN1 mutations are also detected in up to 27% of familial isolated primary hyperparathyroidism (FIHP). In sporadic parathyroid adenomas, the loss of one *MEN1* allele has been detected in 20%–40% of cases together with a somatic inactivating mutation of the other allele in about 50% of these tumors.

Cyclin-dependent kinase inhibitor 1B (CDKN1B)/cyclin dependent kinase inhibitor (CDKI) gene

Germline mutations of the *CDKN1B* gene at 12p13.1, encoding the $p27^{kip1}$ cyclin dependent kinase inhibitor (CDKI), are responsible for the multiple endocrine neoplasia type 4 (MEN4). The most common phenotype of the 19 MEN4 syndrome described to date is represented by PHPT and pituitary adenomas. Somatic *CDKN1B* mutations have been identified in seven

Table 1 Hereditary forms of PHPT

Disorder (OMIM)	*Chromosomal locus*	*Gene (protein)*	*Pattern of inheritance*	*Clinical manifestations*
MEN 1 (131100)	11q13.1	*MEN 1* (menin)	Autosomal dominant	PHPT (95%), pancreatic neuroendocrine tumors (40%), anterior pituitary tumors (30%); less frequently adrenal adenoma, angiofibromas, carcinoid, collagenomas, lipomas
MEN 2A (171400)	10q11.21	*RET*	Autosomal dominant	Medullary thyroid carcinoma (90%), pheochromocytoma (50%), PHPT (20%)
MEN 4 (610755)	12p12.1	*CDKN1B* (p27)	Autosomal dominant	MEN-1 associated tumors in association with MEN 1-associated or nonassociated tumors (adrenal, thyroid, gonadal, renal)
HPT-JT (145001)	1q31.2	*CDC73* (parafibromin)	Autosomal dominant	PHPT (80%) due to parathyroid carcinoma (15%), ossifying fibromas of mandible and maxilla (30%), renal lesions and uterine, testicular, and thyroid tumors
FIHP (145000)	11q13.1, 1q31.2, 3q13.3–q21.1 and 6p24.2	*MEN1, CDC73, CaSR, GCM2*	Autosomal dominant	PHPT alone, without other manifestations typical of a syndromic form

Abbreviations: *OMIM*, online Mendelian inheritance in man; *MEN*, multiple endocrine neoplasia; *HPT-JT*, hereditary hyperparathyroidism-jaw tumor; *RET*, rearranged during transfection; *CDKN1B*, cyclin dependent kinase inhibitor 1B; *CaSR*, calcium sensing receptor; *GCM2*, glial cells missing homolog 2.

apparently sporadic parathyroid adenomas; one of them also harbored loss of heterozygosity (LOH) at 12p13.1. In five of seven cases, the mutation was germline. Biallelic loss of the *CDKN1B* is very rare in parathyroid tumors suggesting that this gene is a haploinsufficient tumor suppressor, but loss of p27 protein expression is a frequent finding.

No mutations of *CDK1C*, *CDKN2A*, or *CDKN2D* have been detected in sporadic parathyroid adenomas. Point mutations in *CDKN1A*, *CDKN2B*, or *CDKN2C* were detected in five parathyroid adenomas; all but one was germline or of undetermined germline/somatic status. Hypermethylation of *CDKN2A* and *CDKN2C* has also been found in parathyroid adenomas.

Cell division cycle 73 (CDC73) gene

Inactivating germline mutations of the tumor suppressor *CDC73* gene, located at 1q31 encoding parafibromin, are responsible for the hyperparathyroidism-jaw tumor (HPT-JT) syndrome. The mutations are scattered along the entire coding region of the gene although most are located in exons 1, 2, and 7. The majority of the mutations are nonsense leading to a truncate parafibromin protein. Germline *CDC73* mutations are also found in up to 15% of FIHP. Somatic mutations of this gene have also been reported in up to 70% of patients with sporadic parathyroid carcinoma, and in about one-third of them the mutation is germline. *CDC73* mutations are very rare in sporadic parathyroid adenoma.

PRUNE2 *gene*

Germline and somatic mutations of the prune homolog 2 (Drosophila) (*PRUNE2*) gene have been detected in 18% of patients with parathyroid carcinoma.

*Calcium-sensing receptor (*CaSR*) gene*

Loss-of-function mutations of the *CaSR* gene are responsible for familial hypocalciuric hypercalcemia (FHH) and neonatal severe hyperparathyroidism (NSHPT) while activating mutations are detected in patients with autosomal dominant hypocalcemia. Loss-of-function mutations lead to a reduction of the sensitivity to extracellular calcium with alterations of the calcium-set-point in parathyroid cells. Patients with FHH and NSHPT develop little or severe parathyroid hyperplasia, respectively suggesting that *CaSR* may functions as a tumor suppressor gene. Mutations of *CaSR* gene have been detected in up to 7% of FIHP. However, no somatic mutations of *CaSR* gene have been found in sporadic parathyroid adenomas. Of note, a reduced expression of CaSR mRNA and protein has been detected in these tumors.

*Catenin B-1 (*CTNNB1*) gene*

Contradictory results have been reported on the role of mutations in the *CTNNB1*, the gene encoding for β-catenin. Almost 600 parathyroid adenomas have been studied for the presence of *CTNNB1* mutations with negative results. Two studies have identified a somatic homozygous stabilizing mutation in exon 3 of *CTNNB1* gene leading to a change of a serine to alanine at amino acid 37 (S37A) in up to 7% parathyroid adenomas. Discrepant results have also been reported on the Beta-catenin staining.

Clinical Presentation

In Western countries the "classical" symptomatic form of PHPT, characterized by hypercalcemia, renal (nephrolithiasis and nephrocalcinosis) and skeletal (osteitis fibrosa cystica, fragility fractures) manifestations, is rarely seen (Fig. 1). Nowadays, most patients diagnosed with PHPT lack these manifestations and present with subtle and nonspecific clinical features, like weakness, easy fatigability, anxiety, and mood alteration (asymptomatic PHPT). Nephrolithiasis is still the most common of the classic clinical manifestations (15%–20%), and silent stones are frequently detected at ultrasound. *Osteite fibrosa cistica* is very rarely observed and when present is associate with severe disease. Skeletal involvement can be documented by measurement of bone mineral density (BMD), which is typically reduced at sites rich in cortical bone (one third distal radius). Studies using peripheral high resolution quantitative CT has recently shown that both cortical and trabecular sites are targets of excess PTH. Trabecular bone involvement has recently been confirmed by the trabecular bone score (TBS), which shows reduced values at the lumbar spine. Fracture rate at vertebral and nonvertebral is increased in patients with PHPT. A recent prospective study has shown an increased rate of morphometric vertebral fractures in postmenopausal women with asymptomatic PHPT (Fig. 2), supporting the recommendation to perform vertebral imaging in patient's workout.

The clinical manifestation of the hereditary forms of PHPT are summarized in Table 1.

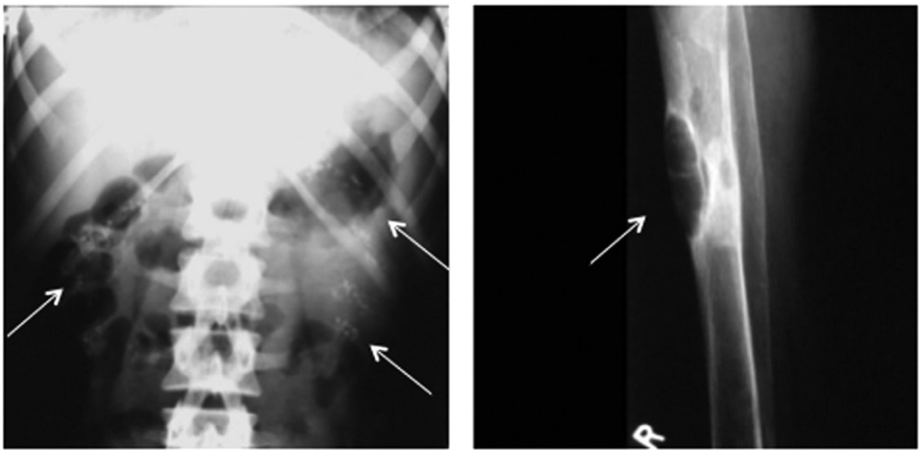

Fig. 1 *Left panel*: Bilateral nephrocalcinosis (*arrows*); *right panel*: *Osteite fibrosa cystica*.

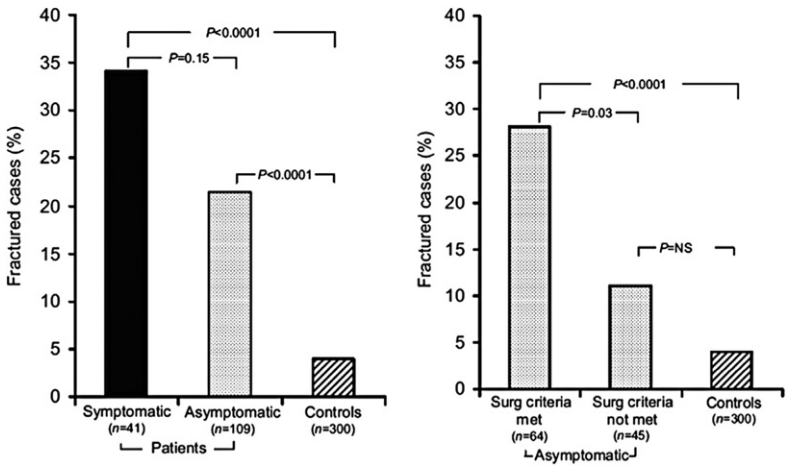

Fig. 2 Rate of morphometric vertebral fractures in postmenopausal women with PHPT. *Left panel*: Patients with symptomatic and asymptomatic PHPT and controls. *Right panel*: patients with asymptomatic PHPT, grouped according to whether they met or did not meet the criteria for parathyroidectomy and controls. *P* values refer to Odds ratios between different groups. Morphometric vertebral fractures in postmenopausal women with primary hyperparathyroidism. *The Journal of Clinical Endocrinology and Metabolism* 94, 2306–2312, with permission.

Nonclassical Manifestations

Cardiovascular abnormalities observed in "classical" PHPT, namely valvular and vascular calcification and left ventricular hypertrophy, are rarely seen. Hypertension is still rather common and subtle cardiovascular involvement (i.e., arrhythmias, increased vascular stiffness, and endothelial dysfunction) may be present in the patients with the modern form of PHPT. Increased cardiovascular mortality is present in patients with moderate to severe PHPT and persists after successful parathyroidectomy (PTx). Conversely, most, but not all studies indicate that patients with asymptomatic PHPT do not share this risk.

Psychological and cognitive complaints, like weakness, easy fatigability, depression, anxiety, and related symptomatology are common but not specific and can be present in many chronic diseases. Observational studies on cognitive function have been inconsistent and data on quality of life have recorded in three randomized trials shown either no difference or some degree of deterioration in psychological domain and mental component summary of the SF-36 between patients with asymptomatic PHPT and controls. PTx was associated with improvement in some SF-36 domains but the results varied among the three studies. Other studies have also shown that successful parathyroid surgery is associated with improvement in neurocognitive function, depressive and anxiety symptoms, and quality of life.

Normocalcemic PHPT

A new variant of PHPT has recently been identified, namely subject with persistently elevated serum PTH associated with repeatedly normal albumin-adjusted and ionized serum calcium (normocalcemic PHPT). This entity can only be detected if PTH is measured in individuals with normal serum calcium and can only be diagnosed when all other causes of secondary hyperparathyroidism (Table 2), particularly low vitamin D deficiency/insufficiency, have been excluded in in the diagnostic workout of patients with initial biochemical features of normocalcemic PHPT. In this regard a cut-off value of serum 25(OH)D >30 ng/mL should be taken. In borderline cases retesting after vitamin D and calcium supplementation may be advisable and may lead in some cases to the classical hypercalcemic PHPT. Other causes of secondary hyperparathyroidism, such renal failure, gastrointestinal diseases associated with malabsorption, hypercalciuria, and other metabolic bone diseases that could affect PTH levels (e.g., Paget's disease) should be considered and ruled out. Finally, the use of medications, which might affect PTH levels or calcium metabolism (estrogens, thiazide diuretics, lithium, bisphosphonates, denosumab, and anticonvulsants) should also be excluded. The epidemiology of normocalcemic PHPT has been investigated in various populations, often in selected gender and age groups. Data collected in nonselected populations indicate a prevalence of 0.4%–16.7%, using different biochemical cut off values for its diagnosis. This new phenotype may represent an early phase of mild hypercalcemic PHPT, but in some cases it may progress to a more severe form with nephrolithiasis, rapid loss of bone mass and factures. Finally, in other cases the biochemical and clinical profile of normocalcemic PHPT has remained stable over a few years of follow up. Successful PTx followed by decrease of serum calcium and normalization of PTH has been reported.

Evaluation and Diagnosis

The finding of hypercalcemia on routine blood testing or in postmenopausal women investigated for osteoporosis is typically the first clue to the diagnosis of PHPT. Hypercalcemia, preferably albumin-corrected total calcium (measured total calcium in

mg/dL + [0.8 × (4.0 − serum albumin in g/dL)] should be confirmed in repeated testing. It is important to remind that in mild cases of PHPT serum calcium levels may be in the (upper) normal range in repeated testing. Measurement of ionized calcium may be useful in selected patients either to discover those who have PHPT but normal serum calcium as well as to recognize those with artifactual hypercalcemia (hyperalbuminemia, thrombocytosis, Waldstrom's macroglobulinemia, and myeloma) in whom ionized calcium is normal. Serum PTH should then be measured and the finding of an elevated (or unexpectedly normal) concentration associated with hypercalcemia are virtually diagnostic of PHPT. It should be kept in mind that a similar biochemical profile could be observed in patients treated with lithium or thiazide diuretics, or affected by tertiary hyperparathyroidism and FHH. A careful medical history could help to rule out these possibilities. A low/undetectable serum PTH in a hypercalcemic patient excluded the diagnosis of PHPT and suggests a form of PTH-independent hypercalcemia (**Table 3**). The most common cause is hypercalcemia of malignancy, in which hypercalcemia is due to lytic bone metastases or by the secretion by the tumor of PTH-related peptide. This peptide shares with PTH the amino-terminal active part, but does not cross react with the PTH assay. The finding of increased PTH levels and consistently normal albumin-adjusted ionized serum calcium and no other causes of secondary hyperparathyroidism raise the possible diagnosis of normocalcemic PHPT (see before). The extremely rare possibility of parathyroid cancer should be suspected in patients, especially males, with markedly increased levels of serum calcium (>14 mg/dL) and PTH (3–10 times the upper normal limit).

Renal function should be evaluated and either creatinine clearance or eGFR calculated. Serum phosphate is normal or in the low-normal range in mild PHPT and low in severe cases. Twenty-four hours urinary calcium should also be measured and if calcium excretion is greater than 400 mg a more extended evaluation of the stone risk profile should be performed. Measurement of 24-h urinary calcium and creatinine levels is also of help in the differential diagnosis between PHPT and FHH, where the calcium to creatinine clearance ratio is usually <0.01, a finding never observed in PHPT. Bone turnover markers may be increased, particularly in patients with severe bone involvement. Vitamin D status should be assessed by measurement of serum 25(OD)D, which is frequently below the normal limit. Low 25(OH)D may further stimulate PTH secretion and account for further elevation of serum PTH.

Once the diagnosis of PHPT has been established, a hereditary form should be considered, particularly in patients aged less than 30 years and/or, a family history of hypercalcemia and neuroendocrine tumors (**Table 1**). In this setting serum calcium should be measured in first-degree relatives and genetic tests eventually performed.

Renal imaging by ultrasound or CT should be carried out in all patients, even in those with no history of nephrolithiasis, since silent kidney stones are common in patients with asymptomatic PHPT and occasionally detected also in patients with more severe form of PHPT. More rare is nephrocalcinosis (**Fig. 2**). Bone mineral density (BMD) by dual-energy X-ray absorptiometry (DXA) at

the lumbar spine, hip, and one-third distal radius should also be measured. Most patients show low values at the latter site, which is rich in cortical bone, with a relative preservation of bone mass the lumbar spine and to less extent at the hip, where the trabecular bone is more represented. However, high-resolution peripheral QCT and the trabecular bone score (TBS), which can be derived from the DXA data obtained at the lumbar spine, have clearly shown ultrastructure abnormalities at the cortical level. Vertebral imaging by X-ray or DXA [vertebral fracture assessment, VFA)] should also be routinely performed to detect silent vertebral deformities since vertebral fracture risk is increased also in asymptomatic patients. A more extensive X-ray study of the skeleton might be considered in patients with severe PHPT to detect *osteite fibrosa cystica*.

Parathyroid imaging studies (ultrasound and sestamibi scanning) has no values in the diagnosis of PHPT (**Fig. 3**, upper and central panels). Both are useful tools in patients selected for PTx to localize the abnormal parathyroid gland and particularly when the minimally invasive approach is used. Sestamibi scanning has the advantage to localize ectopic parathyroid gland outside the neck. In selected cases, particularly in remedial PTx, second-line imaging studies (CT and RM) should be considered (**Fig. 3**, lower panel).

Natural History

The natural history of PHPT varies according to its severity. Patients with symptomatic PHPT who either do not undergo surgery or are not cured by PTx usually have a progression of the disease, particularly recurrent kidney stones.

Three prospective clinical studies in which patients with asymptomatic PHPT were randomized to surgery of surveillance have shown improvement in the former, even if they did not meet the criteria for surgery, and stability in the latter over up to 2 years follow-up. Conversely, an increase, but not statistically significant, an increased rate of vertebral fractures was observed over 5 years in patients followed without surgery than in those cured by PTx. Long-term observational studies indicate that the disease remains stable in the majority for up to 8–9 years, but progression of the disease occurred in about one third of them, particularly in those with the longest follow up and younger age at the study entry.

Calcium intake should not be restricted and be similar to that recommended in the general population (preferably with food). Patients with a low vitamin D status should be supplemented with daily doses of 800–1000 IU of vitamin D or, alternatively, with weekly or monthly doses calculated on this daily doses. A serum level of 25(OH)D $>$ 20 ng/mL should be reached, but a higher target ($>$30 ng/mL) is suggested by some experts.

General principles for monitoring are reported in **Table 4**. Serum calcium and creatinine (eGFR) should be measured annually and BMD at lumbar spine, total hip and distal forearm measured every 1–2 years. Vertebral morphometry (by X-ray or VFA) should be performed in patients with back pain or height loss. If nephrolithiasis is suspected, 24-h urinary collection for biochemical stone risk profile and renal imaging (X-ray, ultrasound or CT) should be performed.

Parathyroid surgery should be recommended in the following instances: (i) increase of serum ($>$1 mg/dL above the upper normal limit); (ii) decrease of creatinine clearance $<$60 cm^3/min; (iii) discovery of nephrocalcinosis or kidney stones; (iv) decrease of BMD *T* score at any site $<$2.5 or greater than the least significant change (as defined by the International Society for Clinical Densitometry, even if the *T* score is not in the osteoporotic range); (v) occurrence of clinical fractures or morphometric vertebral fractures, even if asymptomatic.

Stability of serum calcium, creatinine, PTH, urinary calcium up to 10 years and BMD up to 8 years has been shown in patients with asymptomatic PHPT. Progression of the disease (worsening of hypercalcemia and decrease of BMD at the one-third distal radius and hip) has been reported in about one third of cases and is more likely to occur in patients with the longest follow up and younger age at the study entry.

Treatment

The aim of treatment is to normalize biochemical abnormalities and improve, and eventually completely revert the clinical manifestations of the disease.

Surgical Treatment

PTx represents the only definitive cure of PHPT. It is appropriate to consider for any patient with a confirmed diagnosis of PHPT and should be recommended in those with symptomatic disease. When successful PTx is followed by normalization of serum calcium and PTH, improvement of BMD and reduction of the risk of nephrolithiasis and fragility fractures. In experienced hands the rate of cure reaches 95%–98% with a negligible rate of surgical complications. It is therefore important that patients selected for surgery should be referred to an experienced parathyroid surgeon. A focused minimally invasive approach, guided by imaging studies associated with intraoperative monitoring of serum PTH, is the most commonly used surgical procedure in sporadic PHPT. In hereditary cases bilateral neck exploration by classical cervicotomy is still the recommended procedure since multigland involvement is common in these cases. In the rare cases where there is the suspicion of parathyroid carcinoma the "en-block" resection of the parathyroid lesion together with the ipsilateral thyroid lobe and the adjacent structures is recommended. During surgery, particular attention should be paid to avoid seeding of neoplastic parathyroid cells.

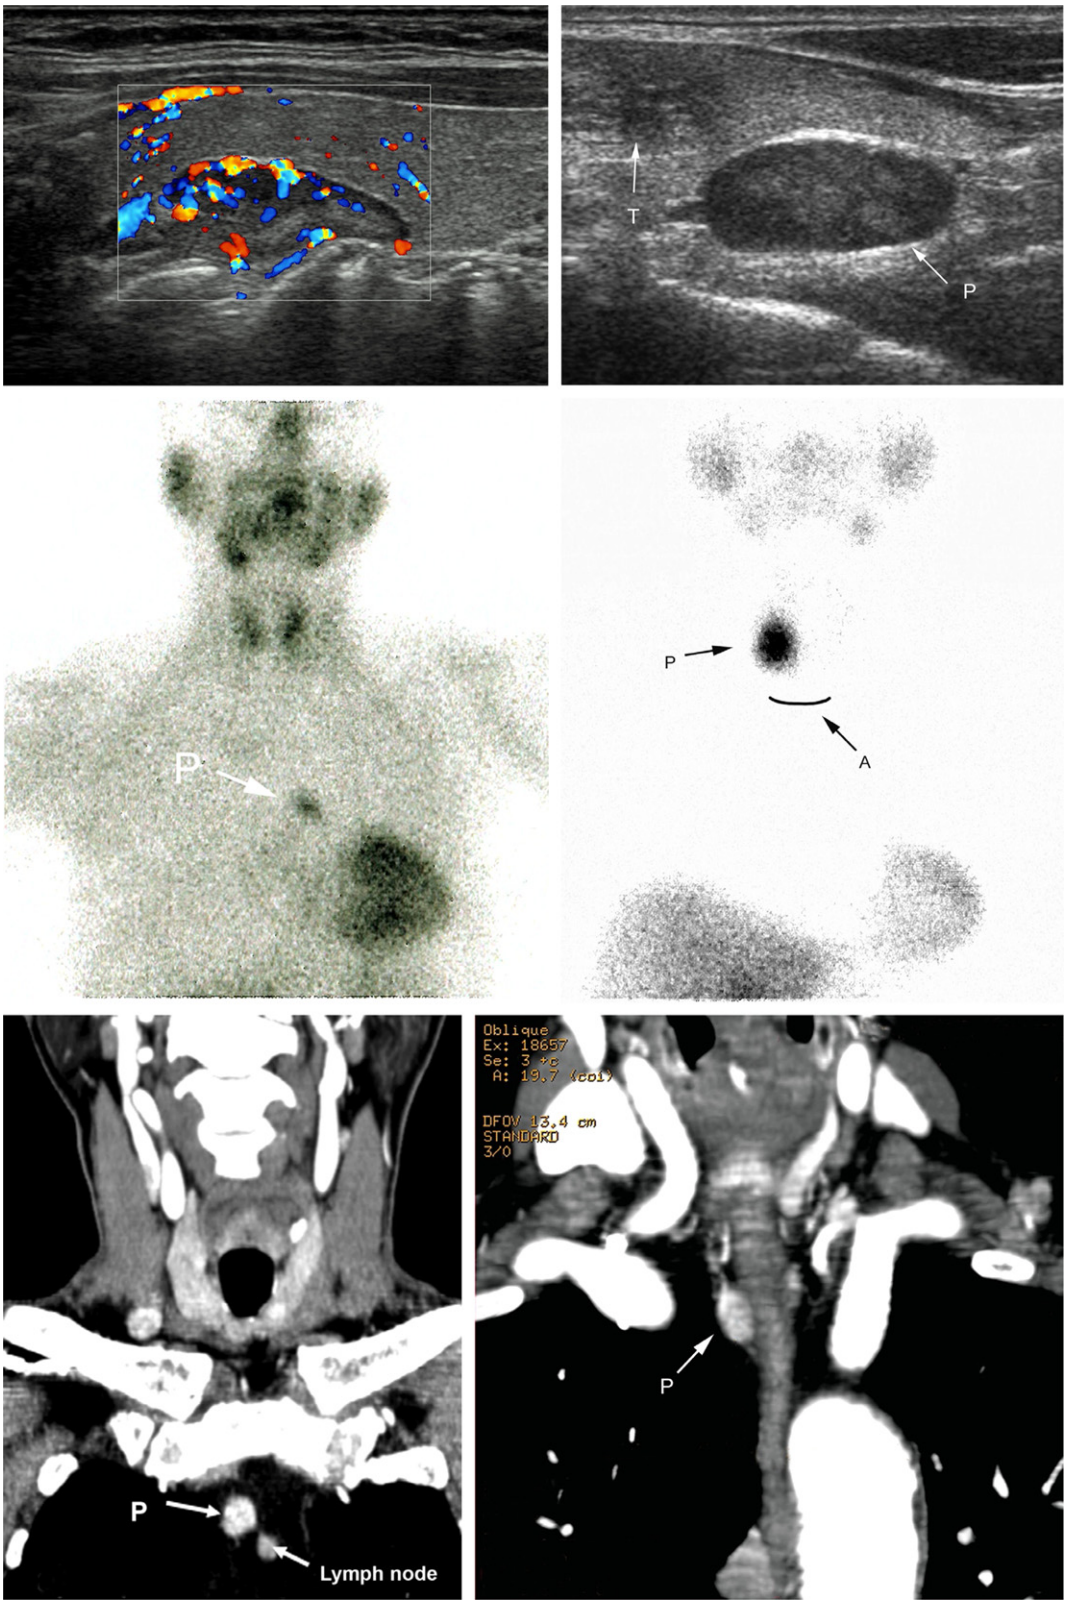

Fig. 3 Parathyroid imaging. *Upper panels*: Ultrasound. *Left:* Typical hypoechoic pattern and shape of a lower parathyroid adenoma (P) adjacent to the thyroid lobe (T). *Right*: Color power Doppler ultrasound pattern of a parathyroid adenoma, showing a diffuse intraparenchymal color flow signals. *Central panels*: ^{99}m-technetium-sestamibi scanning. *Left*: parathyroid adenoma (P) in the right lower neck; (A) indicates jugular dimple. *Right*: Parathyroid adenoma (P) located in the upper mediastinum (P). *Lower panels*. *CT scan*. *Left*: Coronal section showing a paraesophageal parathyroid adenoma (P). *Right*: Coronal section showing an ectopic parathyroid adenoma in the upper mediastinum (P) and an adjacent lymph node (L).

Patients with mild hypercalcemia [serum calcium <12 mg/dL (3 mmol/L) can proceed directly to surgery, following standard procedures. Conversely, when serum calcium is higher patients should receive preoperative treatment with iv saline eventually followed by loop diuretics, intravenous bisphosphonates, denosumab or cinacalcet to reduce serum calcium levels and, therefore decrease the risk of complications, particularly cardiac arrhythmias.

Surgery is also a reasonable option for patients with asymptomatic PHPT. Over the last 25 years four International workshops have provided guidance to select patients who should be referred for surgery or followed without surgery. The guidelines for surgery or monitoring according to the most recent guidelines are reported in **Table 5**. These guidelines mostly reflect the previous ones. New indications for surgery include: (i) silent vertebral fractures detected by X-ray, CT, MRI or DXA (vertebral fracture assessment, VFA), (ii) 24-h urinary calcium excretion >400 mg/dL and increased stone risk (evaluated by urinary stone risk profile) and subclinical kidney stone or nephrolcalcinosis detected by X-ray, ultrasound, and CT. PTx should be recommended to patients who meet one or more surgical criteria and it is estimated that about 60% of patients with asymptomatic PHPT meet the criteria for surgery. As mentioned before, some patients with mild PHPT may have subtle cardiovascular abnormalities and complain of psychological and cognitive symptoms. It is unclear whether and to what extent these abnormalities will be reversed after successful PTx; for the time being they are not considered as an indication for surgery. Nonetheless, in some cases the presence of one or more of these nonclassical manifestations associated with increased cardiovascular risk (metabolic syndrome, hypertension, ischemic heart disease) may contribute to advise surgery, if surgical risk is low. Randomized clinical trials have shown that also patients with sporadic asymptomatic PHPT and no surgical criteria may benefit from surgery, not only because it normalizes serum calcium and PTH, but also improves BMD and quality of life (QoL).

Particular attention should be paid in patients with hereditary forms of PHPT. In these patients multigland disease is common, occasionally with asynchronous involvement of the various parathyroid glands. Bilateral neck exploration, the classical surgical approach, carries an increased surgical risk and an increased recurrence/persistence of PHPT. Because of that in patients with mild hypercalcemia surgery can be temporarily postponed.

It is important to discuss with each individual patient the benefits and risks of PTx and the preference of the patients should be taken into account. Parathyroid surgery in experienced hands is safe, cost-effective, and associated with low perioperative morbidity. On the other hand, when performed by inexperienced surgeons, it may be associated with complications that could not be acceptable for a subject with a mild disease and a good QoL. In this regard, an initial advice of surgery may be reconsidered when preoperative imaging studies are negative in a patient with mild asymptomatic PHPT. As a matter of fact, under these circumstances the patient may feel uncomfortable to undergo a "blind neck exploration," which is a more extensive and risky surgical procedure.

Table 4 2013 guidelines for monitoring in patients with asymptomatic PHPT

- Serum calcium annually
- BMD (by DXA) at lumbar spine, hip or distal one-third distal radius every 1–2 years
- Vertebral fractures evaluation by X-ray, CT, MRI or VFA if clinically indicated (i.e., back pain, high loss)
- Serum creatinine (eGFR) annually
- 24-h urine biochemical stone risk profile, renal imaging by X-ray, ultrasound or CT if renal stones are suspected

Abbreviations: *BMD*, bone mineral density; *DXA*, dual X-ray absorptiometry; *CT*, computerized tomography; *MRI*, magnetic resonance imaging; *VFA*, vertebral fracture assessment (by DXA); *eFGR*, estimated glomerular filtration rate.

Nonsurgical Management

Most patients with asymptomatic PHPT do not meet the criteria for PTx. These patients as well as those who decline surgery or have contraindications to surgery need to be monitored and eventually treated medically.

Medical treatment

Currently there is no effective medical treatment of PHPT, but there are options to improve some manifestations of the disease. Medical treatment may be considered in patients with contraindications to surgery or are unwilling to undergo PTx, as well as in those in whom surgery was unsuccessful. The choice of treatment should be guided by the aim of therapy.

Calcimimetics

The calcimimetic cinacalcet can be used to decrease serum calcium. Cinacalcet has been approved by the Food and Drug administration (FDA) for the "treatment of severe hypercalcemia in patients with PHPT who are unable to undergo PTx," and by the European Medical Agency (EMA) for the "reduction of hypercalcemia in patients with PHPT, for whom PTx would be indicated on the basis of serum calcium levels (as defined by relevant guidelines), but in whom surgery is not clinically appropriate or contraindicated." Serum calcium typically declines over a few weeks and may normalizes in most patients with moderate hypercalcemia. In addition, cinacalcet increases serum phosphate, slightly decreases PTH, but has no effect on BMD. Adverse events are dose-related: modest and transient when low doses of cinacalcet are used (up to 30–60 mg twice daily), but rather frequent, particularly gastrointestinal symptoms, and occasionally severe to require treatment withdrawal, when higher doses are employed, such as in patients with parathyroid carcinoma. The benefits of cinacalcet are sustained over time as long as the drug is used. Long-term safety of cinacalcet has not been established. Its rather high cost is another important limit for its long-term use.

Bisphosphonates

If the aim is to increase BMD antiresorptive therapy can be considered. Alendronate is the bisphosphonate that has been more extensively used and shown to be effective in reducing bone turnover markers and increase BMD. In a 2-year placebo-controlled study patients treated with alendronate (10 mg/daily) showed an increase of BMD at the lumbar spine and hip (6.8% and 4.1%, respectively), associated with a sustained decline of urinary NTX and bone-specific alkaline phosphatase. Serum total and ionized calcium and PTH and urinary calcium excretion did not change. Similar results have been observed in men. Over a short period of time the increase of BMD is comparable to that observed after successful PTx.

Combined therapy with cinacalcet and bisphosphonates

If a patient has a low BMD and serum calcium concentration appropriate for the use of cinacalcet, is reasonable to use combined therapy with bisphosphonates and cinacalcet. Indeed, limited data demonstrate that the combined therapy is associated with both the calcium lowering effect of cinacalcet and the skeletal advantage of bisphosphonates.

Pregnancy

PHPT can occasionally be diagnosed in pregnancy by the finding of hypercalcemia on routine blood testing. It is important to keep in mind that there are some distinctive features in the diagnosis and management of PHP during pregnancy (i) serum ionized calcium should preferably be measured because pregnancy is associated with hemodilution and occasionally hypoalbuminemia; (ii) the possibility of a hereditary form of PHPT should be sought because of the young age of pregnant women; (iii) a conservative approach, mostly hydration, should be considered in women with mild elevation of calcium; in the case of more severe hypercalcemia PTx in the second trimester and, in selected cases, cinacalcet (nonapproved in pregnancy) may be considered.

Parathyroid Cancer☆

D Fink, New York University Medical Center, New York, NY, United States
Elizabeth Shane, Columbia University Medical Center, New York, NY, United States

Glossary

Bisphosphonates A group of drugs that inhibit osteoclast-mediated bone resorption.

Calcimimetics Allosteric stimulators of the calcium receptor that have been shown to lower serum parathyroid hormone and calcium concentrations in patients with primary hyperparathyroidism.

Hungry bone syndrome A period of hypocalcemia that ensues after successful parathyroidectomy, during which calcium is rapidly deposited into bone and usual intake may not be sufficient to maintain serum calcium within the normal range.

hypercalcemia Elevation of serum calcium to a point above the upper limit of normal for the particular laboratory performing the measurement.

Positron emission tomography A clinical technique that is reported to successfully localize parathyroid cancer deposits.

Preoperative localization Tests to localize the abnormal parathyroid gland prior to embarking on parathyroid exploration. The most common approaches are sestamibi scanning and ultrasonography.

Parathyroid carcinoma is an unusual neoplasm is characterized by a distinctive clinical profile that differs in several respects from that of hyperparathyroidism due to a benign parathyroid adenoma, which commonly presents with mild asymptomatic hypercalcemia (Shane and Bilezikian, 1982, Cohn *et al.*, 1985, Heath *et al.*, 1980, Silverberg *et al.*, 1989, Silverberg *et al.*, 1990, Parisien *et al.*, 1990). In this article, the clinical features, natural history, pathological features, diagnosis, and prognosis of parathyroid cancer are reviewed. Surgical approaches to parathyroid cancer are outlined as well as medical therapies of the hypercalcemia that accompanies recurrent or metastatic disease.

Incidence

In most series, parathyroid cancer accounts for less than 1% of patients with primary hyperparathyroidism (Brown *et al.*, 2011; Cohn *et al.*, 1985; Cryns *et al.*, 1994a; Hakaim and Esselstyn, 1993; Holmes *et al.*, 1969; Sandelin *et al.*, 1991; Schantz and Castleman, 1973; Shane and Bilezikian, 1982; Wang and Gaz, 1985; Wynne *et al.*, 1992) and 0.05% of all cancers (Hundahl *et al.*, 1999). It is possible that parathyroid cancer is somewhat more common in Japan and perhaps also in Italy, accounting for 5% of patients operated on for primary hyperparathyroidism in series reported from these countries (Fujimoto and Obara, 1987; Obara and Fujimoto, 1991; Obara *et al.*, 1993, 1997; Yoshimoto *et al.*, 1998). Approximately 400 cases of parathyroid carcinoma were reported in the English literature between 1930 and 1999. In 1999, the National Cancer Data Base reported 286 cases of parathyroid carcinoma (Hundahl *et al.*, 1999). In a recent study based upon the Surveillance, Epidemiology, and End Results (SEER) cancer registry, the incidence of parathyroid cancer increased between 1988 and 2003 (Lee *et al.*, 2007); 224 cases of parathyroid cancer were reported over the 16 years, with an incidence (per 10 million population) of 3.58 between 1988 and 1991 compared to 5.73 between 2000 and 2003. In addition, an Australian retrospective case series reported that 3 parathyroid carcinoma cases were reported between 1958 and 1990, while 11 were reported between 2001 and 2010 (Brown *et al.*, 2011). Possible reasons for this apparent rise in the incidence of parathyroid cancer include increased serum calcium screening, changing indications and increased surgical referrals for parathyroidectomy for asymptomatic hyperparathyroidism, and improvements in histopathological diagnosis.

Etiology

The etiology of parathyroid cancer is unknown. No clear pattern of predisposing factors has emerged in the cases that have been described. However, several clinical situations may predispose to the development of parathyroid cancer. Several cases of parathyroid carcinoma have been reported in patients with a history of neck irradiation (Christmas *et al.*, 1988; Ireland *et al.*, 1985; Mashburn *et al.*, 1987). Parathyroid cancer has also been reported within an adenoma or a hyperplastic parathyroid gland (Aldinger *et al.*, 1982;

This article is an update of Connie Taylor, Elizabeth Shane, Parathyroid Cancer, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 497–504.

Berland *et al.*, 1982; Desch *et al.*, 1984; Guazzi *et al.*, 1982; Haghighi *et al.*, 1983; Kramer, 1970; Murayama *et al.*, 1977; Parham and Orr, 1987), in the setting of end-stage renal disease (see below), and in association with prolonged secondary hyperparathyroidism due to celiac disease (Boyle *et al.*, 1999). Despite these associations, Shantz and Castleman, in an extensive review of 70 cases, found no evidence for malignant transformation of previously pathologic tissue (Schantz and Castleman, 1973).

Parathyroid cancer has been reported in patients with familial hyperparathyroidism (Dinnen *et al.*, 1977; Kakinuma *et al.*, 1994; Leborgne *et al.*, 1975; Mallette *et al.*, 1974; Streeten *et al.*, 1992; Yoshimoto *et al.*, 1998), particularly those with autosomal dominant isolated hyperparathyroidism that is not part of the multiple endocrine neoplasia type 1 (MEN1) syndrome (Wassif *et al.*, 1993). In one such family, there was no evidence of antecedent hyperplasia in unaffected glands and chromosomal abnormalities commonly observed in other solid tumors were identified (a reciprocal translocation between chromosomes 3 and 4, trisomy 7, and a pericentric inversion in chromosome 9; Streeten *et al.*, 1992). Analyses of tumor DNA from one family member with parathyroid carcinoma showed no evidence of *ras* gene mutations, PTH gene arrangement, or allelic loss from chromosome 11q13, the locus of the gene for MEN1. MEN1 is most commonly associated with benign parathyroid disease, but there have been several reports of parathyroid cancer in patients with MEN1 (Agha *et al.*, 2007; del Pozo *et al.*, 2011; Dionisi *et al.*, 2002; Sato *et al.*, 2000; Shih *et al.*, 2009). The risk of parathyroid carcinoma is also greatly increased (15% prevalence) in patients with the hyperparathyroidism–jaw tumor syndrome (HPT-JT) (Dinnen *et al.*, 1977; Kakinuma *et al.*, 1994; Wassif *et al.*, 1993), which results from inactivating germline mutations in the *Hyperparathyroidism 2* gene (HRPT2) gene (Carpten *et al.*, 2002) (**Table 2**).

In 1996, Miki *et al.* reported a case of parathyroid cancer in a patient with end-stage renal disease and also reviewed 12 additional cases published between 1982 and 1996 (Miki *et al.*, 1996). Hyperplasia of the other parathyroid glands was present in all (Berland *et al.*, 1982; Greenberg *et al.*, 1989; Ireland *et al.*, 1985; Iwamoto *et al.*, 1990; Kodama *et al.*, 1989; Krishna *et al.*, 1989; Miki *et al.*, 1996; Sherlock *et al.*, 1985) and one had a history of prior neck irradiation (Ireland *et al.*, 1985). The diagnosis was made an average of 6 years after the start of hemodialysis. In all cases, parathyroid carcinoma was diagnosed during or after parathyroidectomy on the basis of local invasion ($n=5$), tumor pathology ($n=4$), or distant metastases ($n=2$). Hypercalcemia was less severe than usually observed in patients with parathyroid carcinoma and parathyroid hormone (PTH) levels were not unusually high for patients on maintenance hemodialysis. Only one patient died of hypercalcemia. The authors concluded that no preoperative features distinguished hemodialysis patients with parathyroid carcinoma from those with parathyroid hyperplasia and that the clinical course may be more benign because of the tendency for renal insufficiency to lower serum calcium levels.

Molecular Pathogenesis

Oncogenes and tumor suppressor genes have been implicated in the development of parathyroid tumors. In the 21st century, there have been significant advances in the understanding of the molecular pathogenesis of parathyroid carcinoma. In 2002, Carpten *et al.* reported a germline mutation in the tumor suppressor gene, HRPT2, which is located at 1q25-q31 in hyperparathyroidism–jaw tumor syndrome (HPT-JT) (Carpten *et al.*, 2002). HRPT2 encodes the protein, parafibromin (referring to the parathyroid tumors and jaw fibromas) and acts as a gene transcription regulator. In 2003, Howell *et al.* were the first to describe the role of HRPT2 in sporadic parathyroid carcinoma (Howell *et al.*, 2003). Shattuck *et al.* demonstrated HRPT2 mutations in 10 of 15 patients with sporadic parathyroid carcinoma; three patients were identified as having germline HRPT2 mutations, suggesting that patients with sporadic parathyroid cancer may instead have underlying HPT-JT syndrome (Shattuck *et al.*, 2003). HPT-JT syndrome and sporadic parathyroid cancer are now associated with inactivating germline and or somatic mutations in HRPT2 (Howell *et al.*, 2003; Shattuck *et al.*, 2003). Additionally, Krebs *et al.* reported that HRPT2 mutations were not present in 60 patients with sporadic parathyroid adenomas (Krebs *et al.*, 2005). Despite compelling evidence for HRPT2 mutations in the pathogenesis of parathyroid carcinoma, they are not universally detected and therefore are not an ideal screening test. However, assessing for HRPT2 mutations may prove helpful in the preoperative assessment of patients with hyperparathyroidism who have clinical features suggestive of parathyroid cancer (see below), in order to guide the initial surgical approach. Additionally, there is increasing evidence that mutations in MEN1 may also be involved in sporadic parathyroid cancer (Haven *et al.*, 2004, 2007).

Cyclin D1 or PRAD1 (parathyroid adenoma 1) is an oncogene located on chromosome 11q13; its protein product is a cell cycle regulator. Rearrangement of the cyclin D1 gene with the regulatory region of the PTH gene has been reported in 5% of parathyroid adenomas and the cyclin D1 oncoprotein is overexpressed in 18–40% of parathyroid adenomas (Hsi *et al.*, 1996; Tominaga *et al.*, 1999). In one study, overexpression of cyclin D1 protein was found in 90% of parathyroid cancers (Vasef *et al.*, 1999). However, it is uncertain whether overexpression of cyclin D1 protein is a causative or an associative phenomenon.

There is also strong evidence that inactivation of the tumor suppressor gene RB (retinoblastoma) on chromosome 13 may contribute to the development of parathyroid carcinoma. Together with cyclin D1, RB is important in cell cycle control. In one study, 11 parathyroid cancers lacked a RB allele and most had a complete absence of nuclear staining for the RB protein (Cryns *et al.*, 1994b). In contrast, only one parathyroid adenoma lacked the allele and none had abnormal staining for the RB protein. Several other investigators have also reported that allelic deletions on chromosome 13 are more common in parathyroid cancer than in benign primary hyperparathyroidism. These data strongly support the presence of a tumor suppressor gene on the long arm of chromosome 13, critical for the development of parathyroid carcinoma. However, as the deleted portion of chromosome 13 is large, it remains to be determined whether RB or a different gene on 13q will prove to be the primary causative tumor suppressor. Another important cell cycle regulator, the p53 tumor suppressor gene, does not appear to be a major contributor to the pathogenesis of parathyroid carcinoma (Cryns *et al.*, 1994a; Hakim and Levine, 1994).

Table 1 Parathyroid carcinoma and benign primary hyperparathyroidism: typical features

	Parathyroid carcinoma	*Primary hyperparathyroidism*
Female:Male ratio	1:1	3.5:1
Average age (years)	48	55
Asymptomatic	$<5\%$	$>80\%$
Serum calcium	>14 mg dl^{-1}	≤ 1 mg dl^{-1} above upper limit of normal
Parathyroid hormone	Markedly elevated	Mildly elevated
Palpable neck mass	Common	Rare
Renal involvement[a]	32–80%	4–18%
Skeletal involvement[b]	34–91%	$<5\%$
Concomitant renal and skeletal disease	Common	Rare

[a]Includes nephrolithiasis, nephrocalcinosis, and impaired renal function in the absence of any other etiology.
[b]Includes osteitis fibrosa, subperiosteal resorption, 'salt and pepper' skull, and diffuse osteopenia on plain radiographs.

Several locations have been identified for potentially important oncogenes or tumor suppressor genes that seem to be preferentially or exclusively found in parathyroid carcinomas as compared with adenomas. Tumor-specific gains or losses of chromosomal material suggest that oncogenes on chromosomes 1q, 5q, 9q, 16p, 19p, and Xq and tumor suppressor genes on chromosomes 1p, 3q, 4q, 13q, and 21q may be involved in the pathogenesis of parathyroid carcinoma.

General Considerations

The clinical features of parathyroid cancer are due primarily to the effects of excessive secretion of PTH rather than to infiltration of vital organs by the tumor (Shane and Bilezikian, 1982). Thus, signs and symptoms of hypercalcemia dominate the clinical picture in addition to symptoms of hyperparathyroid bone disease and renal involvement (renal insufficiency, nephrolithiasis, or nephrocalcinosis). It is important to consider parathyroid cancer in the differential diagnosis of parathyroid hormone-dependent hypercalcemia, particularly in symptomatic patients, as often the diagnosis of parathyroid carcinoma is made in retrospect when hypercalcemia recurs due to local spread or distant metastasis of the tumor. The best outcomes for patients with parathyroid cancer occur when there has been complete resection of the tumor at the time of the first surgery (Shane and Bilezikian, 1982). Several features of the patient with primary hyperparathyroidism should suggest a malignant rather than a benign disease (**Table 1**).

Demographic Features

Benign primary hyperparathyroidism is considerably more common in women than in men (3–4:1). In contrast, there is no association of gender with parathyroid carcinoma and the ratio of affected women to men is 1:1 in most reported series. Patients with primary hyperparathyroidism typically present in their fifties or sixties, whereas the average patient with parathyroid carcinoma is in his or her forties, approximately 10 years younger. However, two reviews (the Mayo Clinic experience (Wynne *et al.*, 1992) and the National Cancer Data Base (Hundahl *et al.*, 1999)) found that the average age of their patients was in the middle fifties. Thus, although it is reasonable to consider the possibility of parathyroid cancer when primary hyperparathyroidism is diagnosed in a man and or a younger individual, gender and age are of limited assistance in the setting of the individual patient.

Symptoms and Biochemical Characteristics

Benign primary hyperparathyroidism usually presents with mild hypercalcemia (within 1 mg dl^{-1} above the upper limit of normal) that is often asymptomatic and usually discovered incidentally (Heath *et al.*, 1980; Silverberg *et al.*, 1989). In contrast, the serum calcium level in parathyroid cancer is much higher, generally above 14 mg dl^{-1} or 3–4 mg dl^{-1} above the upper limit of normal (Shane and Bilezikian, 1982). Signs and symptoms of hypercalcemia, including fatigue, weakness, weight loss, anorexia, nausea, vomiting, polyuria, and polydipsia are almost always present. Bone pain, fractures, and renal colic are much more common when primary hyperparathyroidism is due to a parathyroid cancer than an adenoma. Extremely high levels of parathyroid hormone are unusual in benign primary hyperparathyroidism, where circulating concentrations are commonly less than twice the upper limit of normal. In contrast, parathyroid hormone levels in patients with parathyroid cancer are generally much higher, ranging from 3 to 10 times above the upper limit of normal. Oxyphil parathyroid adenomas may manifest some clinical features of parathyroid carcinoma, with markedly elevated serum calcium and PTH levels as well as large tumor sizes (Fleischer *et al.*, 2004). On the contrary, non-functional parathyroid carcinomas do not present with hypercalcemia or hyperparathyroidism, and often present with a neck mass (Wilkins and Lewis, 2009). Serum alkaline phosphatase activity is often frankly elevated in patients with parathyroid carcinoma, whereas levels are usually in the normal or upper-normal range in patients with benign primary hyperparathyroidism (Silverberg *et al.*, 1990). In patients with parathyroid cancer, there may be increased production of the N-terminal molecular form of PTH, distinct from hPTH(1-84); measurement of PTH by both third and second generation assays may be helpful in diagnosis, as the Third/Second Generation PTH Assay Ratio may be inverted (>1) (Cavalier *et al.*, 2010,

Table 2 Hyperparathyroidism–Jaw tumor syndrome (HPT-JT)

– Parathyroid tumors 1st presenting sign
– Ossifying fibromas of the mandible and maxilla
– Renal lesions → renal hamartomas and cystic kidney disease
– Uterine tumors

2014; Rubin *et al.*, 2007). Finally, patients with parathyroid carcinoma may have elevated levels of α- and β-subunits of human chorionic gonadotropin, whereas patients with primary hyperparathyroidism do not (Rubin *et al.*, 2008; Stock *et al.*, 1982).

Physical Findings

A palpable neck mass has been reported in 30–76% of patients with parathyroid carcinoma, but is distinctly unusual in benign primary hyperparathyroidism (Levin *et al.*, 1988). This important clinical finding constitutes another striking difference between benign and malignant parathyroid disease. Recurrent laryngeal nerve palsy in a patient with primary hyperparathyroidism who has not had previous neck surgery suggests local spread of the tumor and is also very suggestive of parathyroid cancer. In a patient with characteristics suggestive of malignancy in whom HPT-JT is considered in the differential diagnosis, other components of the syndrome must be addressed (**Table 2**). For such patients, transvaginal ultrasound in women to evaluate for uterine tumors, jaw radiography to evaluate for ossifying fibromas, and abdominal ultrasound to evaluate for renal tumors should be included in the preoperative evaluation (Schulte and Talat, 2012).

Target Organ Involvement

The classical target organs of parathyroid hormone – namely, the kidney and the skeleton – are affected with greater frequency and severity in parathyroid carcinoma than is typically observed in benign primary hyperparathyroidism (Shane and Bilezikian, 1982). The prevalence of renal involvement in benign primary hyperparathyroidism, including nephrolithiasis, nephrocalcinosis, and impaired glomerular filtration, is less than 20% (Heath *et al.*, 1980; Silverberg *et al.*, 1990). In contrast, renal colic is a frequent presenting complaint of parathyroid carcinoma. The prevalence of nephrolithiasis was 56% and the prevalence of renal insufficiency was 84% in the Mayo Clinic series (Wynne *et al.*, 1992), somewhat higher than in previous reports in which the prevalence of renal involvement has ranged from 32% to 60%.

Bone pain and pathologic fractures are also common features of parathyroid cancer. Patients with benign primary hyperparathyroidism rarely have skeletal complaints and specific radiologic signs are found in less than 5% of patients (Heath *et al.*, 1980; Silverberg *et al.*, 1989, 1990). In contrast, specific radiologic signs of hyperparathyroid skeletal disease are commonly seen in parathyroid carcinoma, with osteitis fibrosa cystica, subperiosteal bone resorption, 'salt and pepper' skull, absent lamina dura, and diffuse osteopenia reported in 44% to 91% of cases. Another distinguishing feature is the development of concomitant bone and stone disease in parathyroid cancer, whereas simultaneous and symptomatic involvement of the kidneys and skeleton is distinctly unusual in primary hyperparathyroidism.

Recurrent severe pancreatitis, peptic ulcer disease, and anemia occur with greater frequency in patients with malignant disease than in those with benign primary hyperparathyroidism.

Acute Primary Hyperparathyroidism

Primary hyperparathyroidism occasionally presents as acute parathyroid crisis, with marked elevations in serum calcium and parathyroid hormone levels and prominent symptoms of hypercalcemia. In such cases, it can be difficult to distinguish clinically from parathyroid cancer (Rock *et al.*, 2010). However, whenever patients present with marked elevations of serum calcium and parathyroid hormone, the diagnosis of parathyroid cancer should be considered in the differential, since the surgical approaches differ.

Summary

Features that should lead a physician to suspect that a patient with hypercalcemia and elevated parathyroid hormone levels has parathyroid cancer are shown in **Table 1**. However, patients with parathyroid cancer may occasionally present with signs and symptoms that are quite mild. Whether this is because the disease is diagnosed at an earlier stage is unclear. Conversely, some patients with benign primary hyperparathyroidism may present with more severe disease than is commonly seen. In such patients, distinguishing between benign and malignant disease on clinical grounds may be difficult or impossible, since profound hypercalcemia, renal disease, and osteitis fibrosa or diffuse osteoporosis may occur and even concomitant kidney and bone disease may be present (Levin *et al.*, 1988). In either situation, it is preferable to have a high index of suspicion for parathyroid carcinoma than to miss the opportunity for surgical cure by failing to consider it in the differential diagnosis.

Pathology

Gross Pathology

Certain operative findings are helpful in distinguishing between benign parathyroid adenomas and parathyroid carcinoma. Parathyroid adenomas are usually soft, round or oval in shape, and reddish-brown in color. In contrast, parathyroid carcinomas are usually lobulated and firm to stony-hard in consistency. Approximately half are surrounded by a dense, fibrous, grayish-white capsule that adheres tenaciously to adjacent tissues and makes the tumor difficult to separate from contiguous structures. If there is gross infiltration of adjacent thyroid, nerve, muscle, or esophagus, or if there are cervical node metastases, the diagnosis of carcinoma is a simple matter. Unfortunately, any one or all of these operative findings may be absent. Additionally, it is also important to note that a normal parathyroid gland weighs 25–35 mg and an average parathyroid adenoma weighs 0.5 g. Parathyroid carcinomas are usually larger than adenomas (DeLellis, 2005; Schantz and Castleman, 1973).

Histology

As is the case with many endocrine neoplasms, the histopathologic distinction between benign and malignant parathyroid tumors is difficult to make. In 1973, Schantz and Castleman, based on an analysis of 70 cases of parathyroid carcinoma, established a set of criteria for the pathologic diagnosis of this malignancy (Schantz and Castleman, 1973). These histologic features are as follows: (1) uniform sheets of (usually chief but occasionally oxyphil) cells arranged in a lobular pattern and separated by dense fibrous trabeculae; (2) mitotic figures within tumor parenchymal cells that must be distinguished from endothelial cell mitoses; and (3) capsular or vascular invasion. Unfortunately, neither of the first two features is pathognomonic of parathyroid carcinoma, both having been reported in parathyroid adenomas (Levin *et al.*, 1988). However, capsular invasion and vascular invasion correlate well with subsequent tumor recurrence and their presence greatly increases the likelihood that the tumor is malignant. Finally, the overall histologic pattern is probably more useful than any single feature in differentiating parathyroid carcinoma from adenoma (Fujimoto and Obara, 1987; Obara *et al.*, 1997). Cellular atypia, including nuclear pleomorphism and enlargement and macronucleoli, has been associated with a greater likelihood of malignancy (Bondeson *et al.*, 1993). The presence of more than one of the above-mentioned characteristics in a lesion should alert the pathologist.

Other Histologic Markers

Although several histologic techniques have been used to improve the diagnosis of parathyroid carcinoma, none have proved consistently helpful. Electron microscopy of parathyroid cancer reveals nuclear and mitochondrial alterations and evidence of increased secretory activity but is not useful in distinguishing benign from malignant tumors (de la Garza *et al.*, 1985; Holck and Pedersen, 1981; Smith and Coombs, 1984). Nuclear diameter is larger in parathyroid carcinomas than in adenomas, but is not very useful in the individual case (de la Garza *et al.*, 1985; Holck and Pedersen, 1981; Jacobi *et al.*, 1986; Lloyd *et al.*, 1979; Schantz and Castleman, 1973; Smith and Coombs, 1984). Measurement of nuclear DNA content by flow cytometry is of limited value both in establishing the diagnosis of parathyroid carcinoma and in predicting the invasive potential of the tumor. Although mean nuclear DNA content is greater and an aneuploid DNA pattern is more common in parathyroid carcinoma than in adenomas, aneuploidy occurs too frequently in parathyroid adenomas to be useful in differentiating benign from malignant parathyroid tumors.

Loss of parafibromin nuclear immunoreactivity has high sensitivity and specificity for parathyroid cancer and was first reported as a molecular marker for parathyroid cancer in 2004 (Tan *et al.*, 2004). However, follow-up studies have noted both false positive and false negative results limiting universal application parafibromin immunochemistry (DeLellis, 2008; DeLellis *et al.*, 2008). Immunohistochemical staining of RB protein with polyclonal antibodies is usually absent in parathyroid carcinomas and almost always present in parathyroid adenomas (Cryns *et al.*, 1994b; Subramaniam *et al.*, 1995). However, staining for RB protein with monoclonal antibodies was not useful in distinguishing between benign and malignant parathyroid tumors in one study (Farnebo *et al.*, 1999a). Similarly, immunostaining for the cell cycle-associated antigen Ki-67, a marker of proliferative activity, is not consistently useful for distinguishing carcinomas from adenomas (Abbona *et al.*, 1995; Farnebo *et al.*, 1999a).

Invasive growth of various neoplasms may be facilitated by tumoral secretion of proteolytic enzymes, such as gelatinase A. Farnebo *et al.* have reported that gelatinase A mRNA was detected in 14 of 18 unequivocal and 4 of 13 equivocal parathyroid cancers (Farnebo *et al.*, 1999b). The strongest signal was detected in the fibroblasts and macrophages at the tumor border, rather than in the tumor cells.

Natural History

Parathyroid carcinoma is an indolent, albeit tenacious, tumor with rather low malignant potential. It tends to recur locally at the operative site and spread to contiguous structures in the neck. Metastases occur late in the course of the disease with spread via both lymphatic and hematogenous routes. Cervical nodes (30%) and lung (40%) are involved most commonly, followed by liver (10%). Occasional involvement of bone, pleura, pericardium, and pancreas has been reported.

Management

Initial Surgery

The most effective therapy for parathyroid carcinoma is complete resection of the primary lesion at the time of the initial operation when extensive local invasion and distant metastases are less likely (Shane and Bilezikian, 1982). Therefore, both preoperative suspicion and intraoperative recognition are of paramount importance in the management of this cancer. This is particularly important in the era of minimally invasive parathyroidectomy, when full neck exploration with identification of all four parathyroid glands is less common than it used to be. To assess preoperative risk of parathyroid cancer, Schulte *et al.* recently proposed the '$<3+<3$ rule,' which refers to the size of parathyroid lesion (<3 cm) and the serum albumin-corrected serum calcium level (<3 mmol l^{-1}) to risk stratify patients. They suggest that patients with parathyroid tumors less than 3 cm in diameter and serum calcium levels less than 3 mmol l^{-1} (12 mg dl^{-1}) are at low risk for parathyroid carcinoma and can be managed surgically with local resection (Schulte and Talat, 2012). However, we feel that caution is warranted in applying this rule. The <3 cm criterion was based on data from the National Cancer Data Base report of 286 cases of parathyroid cancer; only 37.4% of patients had lesions >3 cm, while 23.4% were <3 cm and in 39.2% the size of the lesion was not reported. Similarly, in more than 300 patients with parathyroid cancer reported by Talat *et al.*, only 17% had lesions >3 cm, while 17% had lesions <3 cm and in 66% the size was unknown (Talat and Schulte, 2010). Thus, while parathyroid lesions >3 cm suggest higher risk of carcinoma, we believe that there are insufficient data to reliably categorize lesions <3 cm as low risk. Moreover, recent data demonstrate a decrease in the proportion of patients with tumor sizes less than 4 cm, suggesting that earlier referral and diagnosis may result in patients with parathyroid cancers that are not as large as those seen previously (Lee *et al.*, 2007). Therefore, an algorithm which uses a <3 cm size rule as a cutoff may result in missed opportunities for preoperative consideration of parathyroid carcinoma. This is important because those patients in whom the clinical presentation is suggestive of parathyroid carcinoma should have a thorough exploration of all four parathyroid glands, since parathyroid carcinoma has been reported to coexist with benign adenomas or hyperplasia (Anderson *et al.*, 1983; Boyle *et al.*, 1999).

When the gross pathologic findings suggest malignancy, the following steps should be taken:

- The lesion should be removed *en bloc* together with the ipsilateral thyroid lobe and isthmus.
- The trachea should be skeletonized.
- Any contiguous tissues to which the tumor adheres should be resected.
- Great care should be taken to avoid rupture of the capsule of the gland, which increases the likelihood of local seeding of the tumor.
- If the recurrent laryngeal nerve is involved in the tumor, it must be resected.
- Tracheoesophageal, paratracheal, and upper mediastinal lymph nodes should be excised.
- Extensive lateral neck dissection is indicated only when there is spread to the anterior cervical nodes.

The situation is more complex when the diagnosis is made in the early postoperative period on the basis of pathology, particularly in view of the controversy surrounding the histopathology of parathyroid carcinoma. However, a second neck exploration is indicated under the following conditions:

- The gross characteristics of the lesion are typical of a parathyroid cancer.
- The histology appears to be aggressive with extensive vascular or capsular invasion.
- The patient remains hypercalcemic.

If any of these conditions apply, the structures adjacent to the tumor site should be resected in the manner described above. If none of these features are present and the diagnosis was made solely on the basis of the microscopic characteristics, immediate reoperation may not be necessary since a simple complete resection of the tumor may be curative. However, careful observation of the patient is essential and frequent measurement of parathyroid hormone and serum calcium levels is necessary.

Prognostic Classification

While parathyroid carcinoma has no predilection for gender, there is some evidence that male patients have a higher relative risk of recurrence (Schulte and Talat, 2012) and death (Lee *et al.*, 2007; Schulte and Talat, 2012). Talat *et al.* developed two prognostic classification systems for disease outcome in 2010, which were validated in 2012 (Schulte *et al.*, 2012; Talat and Schulte, 2010). The first system divided patients into high and low risk categories. Low risk was based on the presence of capsular and soft tissue invasion whereas high risk was based on the presence of vascular invasion, lymph node metastases, invasion of vital organs, or distant metastases. The second system classified high risk patients into classes I–IV. Class 1 includes low risk patients (capsular and soft tissue invasion). Classes II–IV are all high risk; class II includes patients with vascular invasion only, class III includes those with lymph node metastases or organ invasion, and class IV includes those with distant metastases (Schulte *et al.*, 2012). These classification systems were validated based on 82 patients with parathyroid cancer with follow-up ranging from 2 to 347 months. Mortality was seen only in the high risk groups.

Medical Management of the Postoperative Patient with Parathyroid Cancer

The postoperative management of a patient with parathyroid cancer must include careful attention to the serum calcium level. Prolonged severe elevation of parathyroid hormone is usually associated with increased bone resorption and formation. The

amount of unmineralized bone matrix (osteoid) may be greatly increased. Sudden withdrawal of excess parathyroid hormone will permit rapid deposition of calcium and phosphorus into the excess unmineralized osteoid. This process may be associated with severe and symptomatic hypocalcemia ('hungry bone syndrome'). Although hungry bone syndrome should be regarded as a sign that the surgery has been at least temporarily successful, it can be dangerous and must be managed aggressively. The hypocalcemia may be severe and protracted, requiring large doses of intravenous calcium. If hyperparathyroidism was severe and there is biochemical or radiographic evidence of skeletal involvement (elevated alkaline phosphatase, radiographic lesions of hyperparathyroidism), the patient should remain in the hospital until the hypocalcemia can be controlled with oral calcium supplements. Sufficient supplemental calcium and calcitriol should be prescribed to maintain the serum calcium at the low end of the normal range. As the bones heal and the remaining parathyroid glands recover, the requirement for calcium will decrease, permitting gradual reduction of the doses of calcium and withdrawal of calcitriol. After this point, serum calcium and parathyroid hormone levels should be monitored every 3 months.

Surgical Management of Recurrent or Metastatic Disease

The management of recurrent or metastatic parathyroid carcinoma reflects the rather indolent biology of this cancer and, in contrast to many other tumors, is primarily surgical (Shane and Bilezikian, 1982). Recurrent carcinoma in the neck should be treated with wide excision of the involved area, including the regional lymph nodes and other involved structures. Since even very small tumor deposits may produce sufficient parathyroid hormone to cause severe hypercalcemia, resection of accessible distant metastases in lymph nodes, lungs, or liver should be performed (Obara *et al.*, 1993). Resection, even if incomplete, may provide significant palliation, resulting in periods of normocalcemia that range from months to years. In addition, surgical debulking of tumor deposits may make it easier to control the hypercalcemia medically.

Preoperative Localization of Recurrent Parathyroid Cancer

In patients with recurrent hypercalcemia, preoperative localization studies should be performed. However, careful palpation of the neck should not be neglected, since recurrence occurs earliest and most often at the original site and such tumors are frequently palpable. Thallium-201–technetium-99m scanning is useful in locating tumors in the neck and upper mediastinum (Fujimoto *et al.*, 1986; Johnston *et al.*, 1996; Obara *et al.*, 1990). Technetium-99m–sestamibi used concurrently with a handheld, gamma-detecting probe may also be useful for the intraoperative localization of abnormal parathyroid tissue (Martinez *et al.*, 1995). Thallium-201 is also helpful for situations in which the thyroid has been partially or completely resected or when pulmonary metastases are suspected. Computerized tomography and magnetic resonance imaging are useful adjuncts to ultrasonography in evaluation of the neck and are superior for detection of distant metastases in the chest or abdomen. Positron emission tomography with a positron-emitting analogue of 2-deoxyglucose ([^{18}F]fluorodeoxyglucose) has also been reported to successfully localize parathyroid cancer deposits. If noninvasive testing does not yield results, arteriography or selective venous catheterization may be useful. Fine-needle aspiration biopsy should be avoided in order to avoid seeding deposits of malignant tissue.

Radiation Therapy

In the past, the use of radiation therapy to control tumor growth and decrease hormone production was ineffective in the majority of cases. However, radiation to the neck after surgery for recurrence may be helpful in preventing tumor regrowth (Chow *et al.*, 1998; Levin *et al.*, 1988; Munson *et al.*, 2003). In a series from Princess Margaret Hospital in Canada, 6 patients with microscopic residual disease who received adjuvant radiation therapy were followed for 12 to 56 months without recurrence (Chow *et al.*, 1998). Adjuvant radiotherapy has been shown to improve risk of recurrence (Busaidy *et al.*, 2004; Clayman *et al.*, 2004; Munson *et al.*, 2003). Additionally, parathyroid cancer lung metastases may respond to radiofrequency ablation (Tochio *et al.*, 2010).

Chemotherapy

Attempts to control tumor burden with chemotherapy have been disappointing. Because of the rarity of parathyroid carcinoma, experience with various chemotherapeutic regimens is limited to scattered case reports. Several regimens (nitrogen mustard; vincristine, cyclophosphamide, and actinomycin D; adriamycin, cyclophosphamide, and 5-fluorouracil; and adriamycin alone) were not effective (Anderson *et al.*, 1983; Golden *et al.*, 1965; Grammes and Eyerly, 1980). Two patients have been treated with synthetic estrogens with some success (Goepfert *et al.*, 1966; Sigurdss *et al.*, 1973). A single patient with pulmonary metastases responded to treatment with dacarbazine, 5-fluorouracil, and cyclophosphamide with a decrease in PTH and normalization of serum calcium for 13 months (Bukowski *et al.*, 1984). Another patient responded to dacarbazine alone with a brief but significant decline in her serum calcium level (Calandra *et al.*, 1984). An 18-month remission after therapy with a regimenof methotrexate, doxorubicin, cyclophosphamide, and lomustine, associated with regression of a mediastinal mass and pleural effusion was reported in a patient with a nonfunctioning parathyroid carcinoma by (Chahinian *et al.*, 1981). Such approaches are probably worth trying if surgical measures fail.

Management of Hypercalcemia

When parathyroid carcinoma has become widely disseminated and surgical resection is no longer effective, cure is impossible. However, even at this juncture, relatively prolonged survival can be achieved with adequate control of hypercalcemia, although the extremely elevated PTH levels and the intensity of the associated bone resorption often make this goal difficult to realize.

Acute hypercalcemia associated with parathyroid carcinoma is treated in the same way as hypercalcemia due to any other cause (Bilezikian, 1992). Management includes infusion of saline to restore fluid volume and enhance urinary calcium excretion. After this has been accomplished, loop diuretics may be considered to further increase calciuresis. Agents that inhibit osteoclast-mediated bone resorption are virtually always necessary.

Antiresorptive Agents

Bisphosphonates

The bisphosphonates are a group of drugs that inhibit osteoclast-mediated bone resorption. Several of these drugs have shown some promise in the therapy of parathyroid carcinoma.

Clodronate (Cl_2MDP) lowers serum calcium in parathyroid carcinoma when administered intravenously (Jacobs *et al.*, 1981; Shane *et al.*, 1982). It is widely available in Europe and the United Kingdom, but it is not available in the United States. Pamidronate, when infused for periods ranging from 2 to 24 h and at doses ranging from 45 to 90 mg per day, has been at least transiently effective in lowering serum calcium levels in several patients with parathyroid cancer (Depapp *et al.*, 1994; Mann, 1985; Obara *et al.*, 1993; Sandelin *et al.*, 1991; Vainas *et al.*, 1997; Weinstein, 1991). A more potent bisphosphonate, zoledronate, has been approved in the United States for the treatment of hypercalcemia. Zoledronate, at doses of 4 and 8 mg, has been shown to be superior to pamidronate (90 mg) in the treatment of hypercalcemia of malignancy, in terms of both the response rate and the duration of response (Major *et al.*, 2001). Though zoledronate has not been specifically evaluated in parathyroid cancer, it is a reasonable approach to controlling hypercalcemia in these patients.

Denosumab

Denosumab is a monoclonal antibody that inhibits receptor activator of nuclear factor kB ligand (RANKL) and potently inhibits osteoclast activity. Vellanki *et al.* reported the first patient with parathyroid carcinoma and refractory hypercalcemia who responded to denosumab, 120 mg subcutaneously every month, with a reduction in serum calcium (Vellanki *et al.*, 2014). Initially, the patient was receiving dacarbazine, pamidronate and cinacalcet but had recalcitrant hypercalcemia. After the denosumab was started, he was eventually able to stop the dacarbazine and pamidronate. His serum calcium was maintained in the normal range on denosumab and cinacalcet.

Other Treatments

Calcimimetics

Under normal circumstances, parathyroid hormone secretion is mediated by a cell surface calcium-sensing receptor and this regulatory response is generally retained in benign parathyroid tumors. An allosteric modulator of the calcium receptor with calcimimetic properties, R-568, was first shown to lower serum parathyroid hormone and calcium concentrations in patients with primary hyperparathyroidism (Silverberg *et al.*, 1997). This same first generation calcimimetic was used to treat a patient with parathyroid carcinoma (Collins *et al.*, 1998), with control of serum calcium for 2 years without adverse effects. This was followed by a report by Silverberg *et al.* of 29 patients with inoperable parathyroid carcinoma treated with cinacalcet HCl, a second generation agent with a longer half-life, with doses starting at 30 mg twice daily to 90 mg four times a day (Silverberg *et al.*, 2007). Approximately two thirds of patients responded with a decrease in serum calcium levels.

Calcitonin

Although calcitonin inhibits osteoclast-mediated bone resorption, increases urinary calcium excretion, and has been reported to lower serum calcium in two patients with parathyroid cancer, it is a weak antiresorptive agent and is not effective in parathyroid carcinoma (Shane and Bilezikian, 1982).

Plicamycin

Plicamycin (mithramycin), another specific inhibitor of bone resorption, lowers serum calcium levels in parathyroid carcinoma (Singer *et al.*, 1970). It is administered intravenously at a dose of 25 $\mu g\ kg^{-1}$ over 4–8 h and may be repeated at daily intervals for up to 7 days until the serum calcium falls into an acceptable range (Bilezikian, 1992). Unfortunately, plicamycin has toxic effects on the liver, kidneys, and bone marrow that increase with the number of exposures. Intravenous bisphosphonates have largely supplanted plicamycin in the therapy of hypercalcemia.

Immunization

In 1999, Bradwell *et al.* reported a patient with parathyroid carcinoma metastatic to lungs and pleura who had severe hypercalcemia that was resistant to oral clodronate, intravenous pamidronate, octreotide, 5-fluorouracil, and streptozotocin. The patient

was immunized with human and bovine PTH peptides, followed with booster doses at 4 and 11 weeks (Bradwell and Harvey, 1999). Antibodies against PTH were detected at 4 weeks. Before therapy, serum calcium varied between 3.5 and 4.2 mmol l^{-1}. Serum calcium levels remained significantly lower (2.5–3.0 mmol l^{-1}) throughout the 6 months of observation. There was rapid improvement in her clinical condition and no significant adverse effects were observed. In 2004, there was another report of immunotherapy in a patient with metastatic parathyroid carcinoma (Betea *et al.*, 2004). In addition to improvement in clinical, hormonal, and biochemical measures, they reported, for the first time, an antitumor effect with a decrease in size of the pulmonary metastases.

Prognosis

The prognosis of parathyroid carcinoma is quite variable. No single characteristic correlates predictably with outcome. Lee *et al.* noted that increased survival rate was associated with younger age, more recent year of diagnosis, female gender, and lack of distant metastasis (Lee *et al.*, 2007). Talat *et al.* also noted that increased survival and lower risk of recurrence was associated with female gender and the absence of vascular invasion or lymph node metastasis (Hundahl *et al.*, 1999; Talat and Schulte, 2010). Early recognition and complete resection at the time of the initial surgery offer the best prognosis. The average time between surgery and the first recurrence is approximately 3 years, although intervals of up to 20 years have been reported. Once the tumor has recurred, complete cure is unlikely. However, prolonged survival is still common in these circumstances with palliative surgery and control of hypercalcemia. Five-year survival rates vary from 40% to 86%. The National Cancer Database survey reported 10-year survival to be approximately 49% (Hundahl *et al.*, 1999). To improve diagnosis and survival rates, endocrinologists and surgeons must be aware of the clinical characteristics of parathyroid cancer, include parathyroid cancer in the differential diagnosis of markedly elevated serum calcium and parathyroid hormone levels, and communicate prior to surgery regarding high risk patients, so that the initial operation is more likely to result in a definitive cure.

Parathyroid Surgery☆

EF Garner and H Chen, University of Alabama at Birmingham, Birmingham, AL, United States

Glossary

Autotransplantation Transfer of parathyroid tissue from its normal location, usually to a muscle bed in the neck or forearm in order to preserve parathyroid function following total parathyroidectomy.

Four-dimensional computed tomography (4D-CT) Preoperative imaging technique that adds the timing of contrast perfusion to traditional computed tomography to assist in localizing parathyroid adenomas.

Gamma probe Handheld counter used intraoperatiely to measure radioactivity following intravenous technetium-99m administration prior to the operation and provide real-time localization during minimally invasive radioguided parathyroidectomy.

Minimally invasive parathyroidectomy (MIP) Procedure that involves preoperative localization and intraoperative parathyroid hormone assay to identify and remove the single abnormal gland with limited exploration and without identifying the remaining parathyroid glands.

Primary hyperparathyroidism Disease caused by the hypersecretion of parathyroid hormone from one or more of the parathyroid glands, resulting in hypercalcemia. The diagnosis is made based on elevated calcium levels, elevated parathyroid hormone levels, and elevated or normal urinary calcium concentration.

Secondary hyperparathyroidism Disease associated with increased production of parathyroid hormone in response to external factors, such as chronic renal failure, leading to hyperplasia of all of the parathyroid glands.

Sestamibi scintigraphy [+/− single photon emission computed tomography (SPECT)] Preoperative nuclear medicine study that is used to localize hyperfunctioning parathyroid tissue. Sestamibi is combined with SPECT for three-dimensional perspective and improved localization.

Tertiary hyperparathyroidism Disease that develops in patients with prolonged secondary hyperparathyroidism who develop autonomous parathyroid function. It also may occur following renal transplant. It is treated with subtotal parathyroidectomy or total parathyroidectomy with autotransplantation.

History

Parathyroid surgery has advanced over the years through the slow process of trial and error. The original description of the parathyroid gland came in 1850 when Sir Richard Owen, a conservator of the Hunterian Museum, identified "a small compact yellow glandular body attached to the thyroid" while dissecting the remains of an Indian rhinoceros. Three decades later, a Swedish medical student, Ivar Victor Sandström, more completely described the "glandulae parathyroideae" in a manuscript entitled "On a New Gland in Man and Several Mammals." Around the same time, Anton Wolfer reported a case of post-operative tetany in a patient that had undergone a total thyroidectomy (and incidental total parathyroidectomy) by Theodor Billroth. It was Eugene Gley in Paris who ultimately made the connection between the parathyroid glands and tetany in 1891. In the early 1900s, it was postulated that removal of a solitary enlarged parathyroid may be used to treat the underlying bone disease of patients. Felix Mandl is credited with performing the first successful parathyroidectomy in 1920s on Albert Gahne, a 34-year-old tram car conductor who likely had a parathyroid carcinoma. Another famous case involves Charles Martell, a merchant marine captain who underwent seven operations before a parathyroid adenoma was ultimately found in the superior mediastinum.

Several technological advances over the past half century have refined parathyroid surgery. The routine measurement of serum calcium levels became possible with the advent of the serum channel autoanalyzer in the 1960s. This invention allowed for the early detection of hypercalcemia and led to a sudden increase in the incidence of hyperparathyroidism and a new population of patients with asymptomatic disease. Rosalyn Yalow and Solomon Berson won the Nobel prize in 1977 for developing the radioimmunoassay (RIA) that allowed the measurement of parathyroid hormone (PTH). Other important technical advances, including improved preoperative localization [high resolution ultrasound, sestamibi ± single photon emission computed tomography (SPECT), and four-dimensional computed tomography (4D-CT)] and rapid intraoperative PTH (IOPTH) assay, have allowed for the current era of the minimally invasive parathyroidectomy (MIP).

Parathyoid Glands

Anatomy and Embryology

An understanding of the anatomy and embryologic variants of the parathyroid glands is critical for appropriate surgical management. During development the inferior and superior parathyroid glands arise from the third and fourth pharyngeal pouches, respectively. These glands migrate inferiorly and usually settle posterior to the thyroid. The inferior glands are typically located behind the inferior pole of the thyroid, while the superior glands are usually found behind the lateral lobes of the thyroid. However, the parathyroid glands may be found in an ectopic site in up to 16% cases (Phitayakorn and McHenry, 2006). The inferior glands are more likely to vary in location. It is important for the surgeon to be familiar with the common ectopic locations, including the mediastinum, intrathymic/intrathyroidal tissue, retroesophageal or paraesophageal space, within the carotid sheath, or high in the neck from failure of descent. One study found ectopic glands were most commonly found in the thymus (38%) followed by the retro/paraesophageal space (31%) (Roy *et al.*, 2013). Another study demonstrated that the retroesophageal space is the most common site of a missed parathyroid by low-volume surgeons (Chen *et al.*, 2010). Despite the variation in anatomy, the inferior parathyroid glands are generally located anterior and medial to the ipsilateral recurrent laryngeal nerve, while the posterior glands tend to be found posterior and laternal to this nerve.

Although the appearance of the parathyroid glands may vary, they are most commonly oval or bean-shaped with a yellow-brown color. The average weight of the normal adult parathyroid gland is 30-50 mg. The superior and inferior parathyroid glands typically receive their blood supply from branches of the inferior thyroid arteries. The venous drainage involves the superior, middle, and inferior parathyroid veins. The gland itself is composed of chief cells and oxyphil cells as well as adipose tissue and fibrovascular stroma.

Primary Hyperparathyroidism

Primary hyperparathyroidism is caused by the hypersecretion of parathyroid hormone (PTH) from one or more of the parathyroid glands. It can be caused by three different pathologic lesions: parathyroid adenomas, parathyroid hyperplasia, and parathyroid carcinoma. Parathyroid adenomas are benign neoplasms that are the source of most cases of primary hyperparathyroidism (80-90%). Adenomas usually involve a solitary gland, but occasionally involve more than one gland. The incidence of patients with primary hyperparathyroidism that have adenomas in two glands ("double adenoma") is between 2% and 15% (Abboud *et al.*, 2005; Alhefdhi *et al.*, 2014). Parathyroid hyperplasia, or the proliferation of parenchymal cells in all the parathyroid glands, is the second most common cause of primary hyperparathyroidism. Hyperplasia accounts for about 10-15% of cases. Parathyroid hyperplasia can be associated with multiple endocrine neoplasia (MEN) 1 (primary hyperparathyroidism, pancreatic tumors, and pituitary tumors) and MEN 2A (primary hyperparathyroidism, pheochromocytoma, and medullary thyroid cancer) syndromes. Parathyroid carcinoma is an invasive neoplasm that arises from the parenchymal cells of the gland and is an uncommon source of primary hyperparathyroidism ($<1\%$).

Clinical Presentation and Diagnosis

Historically, patients with primary hyperparathyroidism presented with the classic signs and symptoms of hypercalcemia, including the pentad of "painful bones, kidney stones, abdominal groans, psychic moans, and fatigue overtones." In recent years, due to the increased availability of laboratory testing, a biochemical diagnosis is often made prior to the development of symptoms during a routine health screening or workup for an unrelated medical condition. The development of the classic skeletal and renal complications is less commonly seen in modern times. The diagnosis is made based on an elevated serum calcium level and an elevated or inappropriately normal PTH level. A 24-h urine collection may help clarify the diagnosis and rule out familial hypocalciuric hypercalcemia (FHH). Patients with primary hyperparathyroidism will have normal or increased urinary calcium concentrations, while patients with FHH have low urinary calcium in the setting of high serum calcium levels.

Medical Alternatives

Whereas there is little question that the appropriate management of symptomatic primary hyperparathyroidism involves surgical excision of the involved gland, the management of the asymptomatic patient can be more challenging and the guidelines continue to evolve. There is still some debate regarding the role of parathyroidectomy for the asymptomatic patient with mild to moderate hypercalcemia. The primary question is whether these patients should undergo early parathyroidectomy or whether surveillance and medical therapy can be safely employed until the development of clinical sequelae. The most recent guidelines from the Fourth International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism published in 2014 have been included (Table 1). New indications for surgery continue to be added to the guidelines. For instance, sleep disturbance and insomnia are common problems associated with primary hyperparathyroidism that are improved with surgery, but these are not part of the current operative criteria (Murray *et al.*, 2014).

Although surgery remains the only curative treatment, calcimimetics (e.g. cinacalcet) are a medical alternative for lowering serum calcium levels. A recent phase 3 clinical trial demonstrated that cinacalcet is well-tolerated and normalizes serum calcium levels in patients with primary hyperparathyroidism who had contraindications to surgery (Khan *et al.*, 2015). Although cinacalcet

Table 1 2013 Guidelines for surgery in asymptomatic primary hyperparathyroidism*

Measurement	*Indication for surgery*
Serum calcium	>1 mg dL^{-1}(0.25 mmol L^{-1}) over the upper limit of normal
Skeletal	a. BMD by DXA: T-score ≤ 2.5 at lumbar, spine, total hip, femoral neck or distal 1/3 radius
	b. Vertebral fracture by x-ray, CT, MRI, or VFA
Renal	a. Creatinine clearance <60 cc min^{-1}
	b. 24-h urine for calcium >400 mg day^{-1} (>10 mmol day^{-1}) and increased risk by biochemical stone risk analysis
	c. Presence of nephrolithiasis or nephrocalcinosis by x-ray, US, or CT
Age	<50

*Adopted from Bilezikian et al. Guidelines for the Management of Asymptomatic Primary Hyperparathyroidism: Summary Statement from the Fourth International Workshop. 2014.

lower serum calcium levels, it does not have a significant effect on serum PTH levels and bone mineral density does not change. Bisphosphonates, particularly alendronate, may improve the bone mineral density without effecting serum calcium levels. The role for combination therapy with both cinacalcet and bisphosphonates to improve both serum calcium levels and bone mineral density has not been sufficiently evaluated (Marcocci *et al.*, 2014). There is no role for restricting dietary calcium intake in patients with primary hyperparathyroidism who do not undergo surgery. Vitamin D sufficiency should also be maintained.

Localization Procedures

Pre-Operative Localization

Localization with imaging studies has become routine prior to parathyroid surgery. In the case of primary hyperparathyroidism, preoperative localization of a solitary adenoma allows for a minimally invasive approach. In addition, the location of the parathyroid glands can vary and preoperative identification is useful for operative planning. Localization is absolutely essential prior to reoperation. Many techniques have been used to identify abnormal parathyroid glands preoperatively, including nuclear imaging, ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI). As the ability to perform a minimally invasive parathyroidectomy is dependent on accurate preoperative localization, careful selection of a localization technique is necessary and depends on several factors including surgeon preference, institutional factors, and patient characteristics (e.g. body habitus, contrast allergies).

Non-invasive techniques

The sestamibi scan remains the most widely used preoperative localization technique. Technetium-99m (^{99m}Tc) sestamibi accumulates in parathyroid adenomas as a product of the increased concentration of oxyphil cells which have high mitochondrial content. Sestamibi accumulates in both the parathyroid and thyroid glands, but washes out of the thyroid tissue more rapidly due to the lower mitochondrial activity. Parathyroid adenomas will have persistent sestamibi on delayed images (Fig. 1). Single-photon emission computed tomography (SPECT) has been added to the traditional planar images to provide a three-dimensional view and improved accuracy of localization. Sestamibi-SPECT is non-invasive, accurate and reliable. The sensitivity of sestamibi-SPECT can vary from 62% to 91% and the positive predictive value ranges from 84% to 96% (Cheung *et al.*, 2012). Surgeon interpretation and radiologist volume are factors that improve the success of sestamibi parathyroid localization (Zia *et al.*, 2012). One limitation of sestamibi scans includes low sensitivity with multigland hyperplasia and double adenomas. Another limitation is related to the presence of other metabolic active tissue (e.g., lymph nodes or thyroid pathology) that may cause a false positive with sestamibi scintigraphy.

Ultrasound may be used alone or in conjunction with sestamibi-SPECT. Parathyroid adenomas are often seen as hypoechoic masses on ultrasound. Localization with ultrasound has several advantages; it is easily performed, inexpensive, involves no radiation or contrast, and can also identify concomitant thyroid pathology. Ultrasound has a pooled sensitivity and positive predictive value of 76 and 93%, respectively (Cheung *et al.*, 2012). Ultrasound is limited by being operator dependent and its inability to evaluate mediastinal parathyroid tissue. There are several factors that may reduce the accuracy of ultrasound, including parathyroid hyperplasia, multiple gland adenomas, and thyroid nodules.

Computed tomography (CT) is another useful noninvasive technique used in preoperative localization. CT scanning can be helpful in identifying ectopic parathyroid glands. The sensitivity of this study for localizing parathyroid adenomas ranges from 46% to 87%. CT scans are readily available and allow for the possibility of needle-guided biopsy. The disadvantages of the technique include the use of intravenous contrast, radiation exposure, and cost. A newer technique known as four-dimensional computed tomography (4D-CT) involves the addition of timing of contrast perfusion to assist in localizing adenomas. In a meta-analysis of preoperative localization techniques, 4D-CT was demonstrated to have an improved sensitivity (89.4%) when compared with ultrasound (76.1%) and sestamibi-SPECT (78.9%) (Cheung *et al.*, 2012). 4D-CT may be useful when adenomas have not been localized on ultrasound or sestamibi-SPECT. A recent cost-analysis study revealed that the combination of sestamibi-SPECT and ultrasound with the addition of 4D-CT if necessary was the most cost-effective imaging method (Wang *et al.*, 2011). The availability and accuracy of these methods vary by institution, and thus, institutional factors often drive the preoperative imaging algorithm.

Magnetic resonance imaging (MRI) is typically used when other studies have been inconclusive. Unlike CT scans, MRI does not require ionizing radiation. However, MRI is expensive and interpretation can be difficult due to motion artifact. For this reason,

Fig. 1 Sestamibi scan localizing a left-sided, superior parathyroid adenoma (arrow) in the neck of a patient who subsequently underwent a MIP.

MRI should not be used as the first or only imaging study to evaluate parathyroid disease, but can be useful when added to the other studies mentioned.

Invasive techniques

Invasive localization techniques include parathyroid arteriography, selective venous sampling, and fine needle aspiration (FNA). These procedures are rarely used due to the capabilities of noninvasive imaging techniques and the potential complications associated with invasive procedures. Selective angiography of the inferior thyroid arteries can identify parathyroid adenomas as highly vascularized oval blushes and has a sensitivity of 60%. Selective venous sampling for PTH can help lateralize tumors. Bilateral internal jugular venous sampling for primary hyperparathyroidism has a sensitivity and positive predictive value of 80 and 71%, respectively (Ito *et al.*, 2007). This procedure has been shown to be safe and may be useful in the setting of negative sestamibi scanning and complex multigland disease (Ito *et al.*, 2007). Ultrasound-guided FNA can confirm parathyroid tissue through PTH sampling of a nodule, which is more sensitive than cytology. In addition, FNA may be useful in the evaluation of concomitant thyroid nodules identified on ultrasound.

Intraoperative Adjuncts

The rapid intraoperative PTH immunoassay has become an important tool to confirm all of the hyperfunctioning parathyroid tissue has been removed during the procedure. This assay was first used in the late 1980s, but has been refined over the years. The advantages of using intraoperative PTH (IOPTH) monitoring have been well described and include shorter operative times, less extensive dissection, decreased cost, and decreased failure rates for initial and reoperative parathyroidectomy. IOPTH testing is considered the most reliable perioperative adjunct. One study found that IOPTH monitoring has the highest sensitivity (99%), positive predictive value (99.6%), and accuracy (98%) when compared to other perioperative adjuncts (Chen *et al.*, 2005).

This laboratory test takes advantage of the short half-life of PTH (3-5 min) which allows for intraoperative monitoring. First, a PTH level is drawn prior to surgical incision to serve as a baseline level. The blood samples may be obtained through a peripheral intravenous catheter or arterial line. The equipment and the technician to run the assay are located within or close to the operating room to prevent delay due to transport of the sample. After gland excision, repeat PTH levels are measured at 5, 10, and 15 min post-excision. The surgery is concluded when the PTH drops by at least 50% of the baseline level. Several other algorithms for IOPTH monitoring have also been described. Propofol has traditionally been avoided because it was thought to alter intraoperative PTH levels. However, a randomized, prospective study demonstrated that propofol does not significantly alter PTH levels (Sippel *et al.*, 2004).

Radioguided minimally invasive parathyroidectomy requires the preoperative intravenous injection of 10 mCI technetium-99m sestamibi to be administered 1–2 h prior to surgery. Sestamibi remains in the hyperfunctioning parathyroid tissue longer and a handheld gamma counter is used to identify the abnormal parathyroid gland intraoperatively. Prior to incision, background counts are obtained over the thyroid isthmus to be used as a reference. Once the gland has been identified, in vivo counts are measured with the gamma probe. A parathyroid adenoma will generally produce an in vivo to background ratio of $>150\%$. The gland is then removed and an ex vivo count of the excised tissue is obtained by placing on the tip of the probe and directing the

probe away from the patient. The ex vivo count should be >20% of background levels. Any excised tissue containing radioactivity >20% of the background radioactivity is either a parathyroid adenoma or hyperplastic gland (">20% rule") (Murphy and Norman, 1999; Chen *et al.*, 2003). Most surgeons recommend confirming adequate excision with IOPTH.

Radio-guidance allows a more focused surgery and reduced operative time. While initially used for only well-localized parathyroid adenomas, the applications for radioguided parathyroid surgery continues to expand. This technique has now been applied to patients with multi-gland hyperplasia, secondary and tertiary hyperparathyroidism, and mediastinal adenomas with good results. In addition, radioguided techniques are even effective in patients with nonlocalizing setamibi scans (Chen *et al.*, 2009). Radioguided parathyroidectomy is safe for both the patient and operating room staff. Radiation exposure to the surgeon and staff has been shown to be minimal (Oltmann *et al.*, 2014).

Parathyroid Surgery

Surgery remains the only definitive treatment of primary hyperparathyroidism. Abnormal parathyroid glands are removed either through a bilateral neck exploration or a more focused parathyroidectomy if the abnormal gland is identified preoperatively. Cure rates with surgery are greater than 95%.

Bilateral Neck Exploration

The classic operation for primary hyperparathyroidism is a bilateral neck exploration with identification of all parathyroid tissue followed by the removal of any abnormal glands. This procedure is usually performed under general anesthesia, but may be performed under a regional cervical block. The patient is positioned supine with the neck extended. A 3-5 cm incision is made within a skin crease just below the thyroid isthmus centered on the midline. The strap muscles are dissected along the midline and retracted laterally. The surgeon then identifies all the parathyroid glands and removes any pathologically enlarged glands. IOPTH levels may be used to confirm adequate resection. The gamma probe can also be utilized. Failure to identify all four glands intraoperatively should prompt exploration of the common ectopic sites previously mentioned.

Bilateral neck exploration with parathyroidectomy provides a cure (defined as normocalcemia and normal PTH 6 months postoperatively) in greater than 95% of cases when performed by an experienced surgeon. This procedure is not as successful in less experienced hands as low-volume surgeons tend to have higher operative failure rates. Bilateral neck exploration provides the advantages of visualizing all of the glands and the potential to identify occult multiglandular disease. Complications include recurrent laryngeal nerve injury, hypoparathyroidism, hematoma and wound infection. When compared to a more focused parathyroidectomy, bilateral neck exploration is associated with longer operative times and higher rates of post-operative hypocalcemia (Bergenfelz *et al.*, 2002).

Minimally Invasive Parathyroidectomy

Primary hyperparathyroidism is the result of a solitary adenoma in about 85% of cases, and these cases are cured with the excision of the abnormal gland. Therefore, with the improvement in pre-operative localization studies, minimally invasive parathyroidectomy (MIP) has arisen as the standard of care for solitary adenomas with the goals of a more limited dissection, shorter operative times, and improved cosmesis. There is no difference in persistent or recurrent hyperparathyroidism in those undergoing MIP versus bilateral exploration. MIP can be performed under locoregional anesthesia in the ambulatory setting and is associated with shorter hospital stay and lower costs (Chen *et al.*, 1999). The complications of this procedure are similar to those seen with a bilateral exploration. In one series of 1065 patients that compared MIP to conventional exploration, MIP was associated with improvements in cure rates (99.4% vs. 97.1%) and complicate rate (1.45% vs. 3.10%) (Udelsman *et al.*, 2011).

While this procedure does not require the exposure of all the glands, it does rely on two important adjuncts: accurate preoperative localization and intraoperative PTH monitoring. Preoperative localization (i.e., sestamibi scanning or high resolution ultrasound) is critical for avoiding failure due to multiglandular disease. These studies should be reviewed by the operating surgeon prior to the operation. In addition, IOPTH monitoring is used to confirm the adequacy of the resection. Several criteria have been recommended for interpreting IOPTH values. If preoperative localization is negative or multiglandular disease is identified intraoperatively, the surgeon generally proceeds with a bilateral exploration as previously described. A radioguided technique may allow for a more focused surgery.

Prior to the operation, a large-bore peripheral intravenous catheter is placed for administration of medications and IOPTH monitoring. The procedure may be performed under general or locoregional anesthesia. The patient is positioned supine with the arms tucked. An inflated IV bag is placed to provide slight extension of the neck. A 1-4 cm transverse, slightly curved incision is made approximately one to two fingerbreadths below the cricoid cartilage in a skin fold centered along the midline. This incision may vary slightly based on localization. The dissection continues downward through the subcutaneous tissue and platysma. The strap muscles are then separated vertically along the midline and retracted laterally. Focused exploration is then performed based on preoperative localization studies and/or radioguidance. IOPTH values are monitored intraoperatively and results should be confirmed prior to completion of the procedure. If the IOPTH values fail to drop appropriately, further exploration for a second

adenoma or hyperplastic tissue is warranted. After confirmation the culprit gland has been excised, the strap muscles and platysma are reapproximated using absorbable suture.

Post-operative care includes calcium supplementation as well as counseling on the signs and management of hypocalcemia. Patients are instructed to take additional doses of calcium if they develop symptoms of hypocalcemia (e.g. numbness/tingling, muscle cramps). Postoperative pain can usually be managed with nonnarcotic medications. Most patients are discharge home the day of the procedure. Patients return to the clinic in 1-2 weeks after surgery where the serum calcium and PTH are checked. Vitamin D may be added for hypocalcemia refractory to calcium supplementation alone. The serum calcium and PTH values are rechecked at 6 months to confirm cure.

Variations on Minimally Invasive Parathyroidectomy

Endoscopic, video-assisted, and robotic approaches are variations on the minimally invasive parathyroidectomy. Similar to MIP, these techniques also rely on preoperative localization and IOPTH monitoring. These operations are typically performed under general anesthesia, but may provide the possible advantages of improved visualization of neck structures and improved cosmesis.

The first endoscopic parathyroidectomy was described by Michel Gagner in 1996 and has subsequently been modified by other surgeons. Access is gained at the manubrium where a 5-mm endoscope is introduced. Two or three additional trochars are added laterally in the neck for instruments. The procedure is performed under steady low pressure insufflation (<8 mmHg) to create an operative space. Disadvantages to this approach include the loss of operative space during suctioning, risk of hypercarbia from CO_2 absorption, longer operative times, and the development of subcutaneous emphysema. Due to some of these limitations, this approach has not gained widespread practice.

Minimally invasive video-assisted parathyroidectomy (MIVAP) is a procedure pioneered by Paolo Miccoli. A small 15 mm incision is made approximately 2 cm above the sternal notch. After dissecting the strap muscles off of the thyroid lobe, retractors are inserted to maintain the operative space. Traditionally, this procedure required a short period of insufflation to dissect out this space. Modifications have omitted this step such that it is now a gasless procedure. A 30°, 5-mm endoscope is then inserted into the incision followed by the introduction of small surgical instruments approximately 2 mm in size. The surgeon then proceeds by dissecting the thyroid gland from the strap muscles to gain exposure. A focused exploration is then performed based on pre-operative localization. The parathyroid gland is bluntly dissected under endoscopic vision and the vascular pedicle is ligated with either titanium clips or a ligature device. MIVAP has the advantages of improved cosmesis, decreased post-operative pain and improved patient satisfaction (Lombardi *et al.*, 2009). Robotic parathyroidectomy is a newer technique and has been successfully described at several centers. Although this approach provides adequate cure rates and improved cosmesis, it is limited by cost and longer operative times (Tolley *et al.*, 2014).

Re-Exploration

Persistent hyperparathyroidism is defined as the failure to achieve or maintain normocalcemia within 6 months following surgery. Recurrent hyperparathyroidism refers to hypercalcemia that reappears after 6 months of normalized serum calcium levels. The two most common reasons for failure of the initial parathyroid operation are failure of the surgeon to find the abnormal gland and missed multiglandular disease. Multi-gland disease accounts for up to 37% of patients undergoing reexploration. Double adenomas are also associated with a higher incidence of recurrent and persistent hyperparathyroidism (Alhefdhi *et al.*, 2014). Less commonly, a parathyroid carcinoma has not been recognized or adequately treated. The success of the initial operation is in part related to the experience of the operating surgeon (Chen *et al.*, 2010). An experienced surgeon is more likely to know the normal and ectopic site of parathyroid glands.

Reoperative parathyroid surgery is a more challenging operation and should be performed by a high-volume endocrine surgeon. Due to the increased complexity, patients should be selected for surgery based on an analysis of the risks and benefits. As the risk of complication increases with a second operation, surgery is typically reserved for symptomatic patients. Some surgeons recommend that patients who have undergone a prior neck operation or those with preoperative hoarseness should undergo fiberoptic laryngoscopy to document recurrent laryngeal nerve function.

Once the patient has been deemed to be a surgical candidate, the surgeon should review previous imaging studies, operative notes, and pathology reports. Additional imaging studies may be helpful in localizing the adenoma. Four dimensional-CT may be a useful tool for locating the hyperfunctioning tissue in the setting of the reoperative neck. One study evaluated 45 patients undergoing reoperative parathyroidectomy and found the sensitivity of 4D-CT localization was 88% compared to 54% with sestamibi localization (Mortenson *et al.*, 2008). Intraoperative adjuncts, including ultrasound, gamma probe and IOPTH monitoring may also be helpful in identifying the missing adenoma. A radioguided parathyroidectomy may be useful in the reoperative neck as it allows for a more focused approach and less dissection (Pitt *et al.*, 2009).

Secondary and Tertiary Hyperparathyroidism

Pathology and Clinical Presentation

Secondary hyperparathyroidism is the compensatory oversecretion of PTH in the setting of abnormalities in calcium metabolism. The majority of cases occur in patients with chronic kidney disease. Other causes of secondary hyperparathyroidism include

vitamin D deficiency, inadequate calcium intake, decreased intestinal absorption, and idiopathic hypercalciuria. Chronic kidney disease leads to hyperphosphatemia and decreased renal conversion of 24-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol, leading to a decrease in the intestinal absorption of calcium. As a result, hypocalcemia develops which leads to the stimulation of PTH secretion and parathyroid gland hyperplasia. Secondary hyperparathyroidism develops in approximately 90% of patients with chronic kidney disease. The clinical manifestations can be severe and include: skeletal symptoms (including classic osteitis fibrosa cystica), pruritis, extraskeletal calcifications, and calciphylaxis. Secondary hyperparathyroidism is typically managed with medical therapy directed at correcting serum calcium and phosphate levels into the physiologic range. Medical therapy consists of a low phosphate diet, administration of phosphate binders, calcium supplementation, vitamin D supplementation and dialysis. The recently developed calcimimetics, such as cinacalcet, function by increasing the sensitivity of the calcium-sensing receptor (CaSR) and thus lowering parathyroid hormone levels. These agents are typically added when patients on dialysis fail phosphate binders. Calcimimetics have been shown to effectively reduce PTH levels and decrease parathyroidectomy rates in this population (Ballinger *et al.*, 2014). Renal transplantation remains the definitive treatment for secondary hyperparathyroidism. However, emerging data suggest that a significant number of patients after renal transplantation still have hyperparathyroidism (Lou *et al.*, 2015).

Tertiary hyperparathyroidism develops as a result of the persistent stimulation of the parathyroid glands in patients with long-standing secondary hyperparathyroidism. These patients develop autonomous PTH production that is not suppressed even after correction of the abnormalities in calcium homeostasis. This scenario is most frequently encountered when a patient with renal failure and secondary hyperparathyroidism undergoes renal transplantation. Surgery remains the primary treatment for these patients.

Subtotal Versus Total Parathyroidectomy

Surgery is indicated for the management of secondary hyperparathyroidism when medical therapy fails (i.e., persistent hyperphosphatemia, hypercalcemia, or elevated PTH levels). Additional indications for parathyroid surgery include refractory symptoms of hypercalcemia (e.g., pruritus), intractable renal osteodystrophy (e.g., intractable bone pain, fractures), and calciphylaxis. Surgical therapy is the primary management of tertiary hyperparathyroidism after renal transplantation. The two accepted operations for the management of secondary and tertiary hyperparathyroidism include subtotal parathyroidectomy and total parathyroidectomy with parathyroid autotransplantation. Despite ongoing debate, neither procedure has been clearly distinguished as superior. The selection of an operative technique remains largely dictated by surgeon preference.

Subtotal parathyroidectomy involves identification of all four glands followed by the removal of "three and a half glands." A 40-60 mg remnant of normal-appearing parathyroid tissue is left in place and marked with nonabsorbable suture and/or a surgical clip in case reoperation is necessary. This procedure has the theoretical advantage of less postoperative hypocalcemia because the parathyroid remnant remains *in situ* and continues to function. One of the disadvantages of a subtotal parathyroidectomy is the need to perform a second cervical exploration for recurrent or persistent hyperparathyroidism, which can be challenging and carries the increased risk of recurrent laryngeal nerve injury. This is the most common operation for tertiary hyperparathyroidism.

Total parathyroidectomy with autotransplantation involves removal of all four glands followed by selection of the most suitable gland as an autograft. The most normal-appearing gland is chosen and a 40-60 mg portion of this gland is minced into small fragments for autotransplantation. This tissue may be confirmed as parathyroid gland on frozen section. Finally, approximately 10 gland fragments are autotransplanted into an acceptable site, most commonly the brachioradialis muscle of the nondominant forearm. This area should be marked with nonabsorbable or surgical clip in case future surgery is indicated for recurrence. The disadvantages of total parathyroidectomy include temporary post-operative hypocalcemia requiring aggressive medical therapy, risk of autograft failure, and difficulty in removing graft fragments at reoperation. Cryopreservation of the parathyroid tissue is an important adjunct and allows for future autotransplantation in the case of parathyroid transplant failure and persistent hypoparathyroidism. IOPTH monitoring and radioguided surgery may also be helpful to avoid missing a supernumerary gland during subtotal or total parathyroidectomy.

Parathyroid Cancer

Parathyroid carcinoma is a very rare malignancy with an incidence of <1 million population per year (Lee *et al.*, 2007). The majority of these tumors hypersecrete PTH and lead to symptoms similar to other causes of primary hyperparathyroidism. Parathyroid carcinoma accounts for less than 1% of cases of primary hyperparathyroidism. Preoperative diagnosis of this malignancy is often challenging as the clinical presentation can mimic that of benign disease. A high index of suspicion should accompany concerning features, including a very high serum calcium (>14 mg dL^{-1}) and a palpable neck mass. When these features are present, one should consider a metastatic workup prior to exploration. Intraoperatively, the parathyroid gland may appear grayish-white and is often adherent to the surrounding tissue. Fine-needle aspiration (FNA) is not recommended due to poor sensitivity as well as the risk of capsular rupture and possible seeding of the neck.

Surgery is the primary treatment for parathyroid cancer. If parathyroid carcinoma is suspected during the initial procedure, the surgeon should proceed with complete en bloc resection of the tumor with negative margins, including any of the locally invaded tissue such as the contiguous ipsilateral thyroid lobe. The most common operation involves a thyroid lobectomy. In the past, a

central lymph node dissection was recommended, but recent data suggest that this is not necessary for most patients with parathyroid cancer (Hsu *et al.*, 2014). Despite aggressive surgical management, tumor recurrence is common. Recurrence is best managed with reoperation as surgery is the most effective treatment in palliating the accompanying hypercalcemia. The multiple reoperations often result in higher rates of surgical complications. Mortality is usually secondary to the complications of uncontrollable hypercalcemia and not tumor burden.

Hypercalcemia: Other Causes than Primary Hyperparathyroidism

René Rizzoli, Geneva University Hospitals and Faculty of Medicine, Geneva, Switzerland

Introduction

The regulation of calcium homeostasis is aimed at maintaining extracellular calcium concentration and calcium balance as constant as possible, to protect the body against calcium overload and mineral deposition into soft tissues. Extracellular calcium concentration is thus maintained extremely stable, because of the high sensitivity of a variety of cell systems or organs, including the central nervous system, muscle, and exo-/endocrine glands, to small variations of extracellular calcium concentration (Rizzoli and Bonjour, 2006). Calcium homeostasis is controlled by a series of hormones and factors tightly interrelated in complex regulatory systems. The production of some of these agents is regulated by the concentration of the solute they are controlling, through negative feedback mechanisms.

Regulation of Extracellular Calcium Concentration

Extracellular calcium concentration is maintained in a dynamic equilibrium through fluxes occurring at the level of the intestine, bone and kidney (Rizzoli and Bonjour, 2006). At steady state, as in nongrowing individuals, the amounts of solutes entering the extracellular space are matched by the amounts leaving it. Approximately 50% of total calcium is bound to proteins, mostly albumin. To take into accounts variations in protein or albumin concentrations, when measuring total plasma calcium concentration, various corrections have been proposed. A simple one is Albumin-corrected calcemia = measured calcemia + 0.02 mmol/L per gram of albumin lower than 40 g/L. Alternatively, total protein can be used, provided there is no paraprotein, with the formula: Protein-corrected calcemia = measured calcemia/[(protein in g/L/160) + 0.55]. All the albumin or protein based corrections are not recommended for extreme values of albumin or protein. Furthermore they do not take into account variations in blood pH. Indeed, alkalosis is associated with a higher binding of calcium to albumin, hence a lower free calcium concentration. Acidosis is causing the reverse, that is, a higher unbound fraction.

To avoid the problem of the influence of albumin or protein concentration, the golden standard is the determination of the calcium bioactive form, that is, ionized calcium. However, the latter requires strict preanalytical conditions, without any contact of the blood sample with air, and measurement must be completed within 1 h after sampling. From an analytical point of view, ionized calcium determination is performed on blood gas analyzers with a specific electrode, which may complicate its utilization in large series of samples. A second sample (heparinated syringe or capillary sample) is generally required. Such a large volume to be collected in a child may preclude a routine ionized calcium determination in children. Because of the influence of pH on ionized calcium concentration, the latter must be interpreted at native pH, and not after an adjustment for pH 7.40.

Intestinal Fluxes

Net intestinal absorption of calcium represents the difference between the amounts of solutes absorbed and secreted into the gut lumen. In human, under normal conditions, fractional calcium intestinal absorption represents approximately 20% of ingested calcium. This percentage is higher during growth. Net intestinal absorption of calcium depends on dietary intakes, on the capacity of the intestinal wall to transport calcium, on the bioavailability of calcium present in the intestinal lumen, and on the secretory flux. The intestinal calcium active absorptive capacity is mainly controlled by calcitriol, which stimulates the transport through both genomic and nongenomic mechanisms (Rizzoli et al., 1977; Haussler et al., 2013). Parathyroid hormone is not exerting any direct effect on the intestinal cells for calcium absorption, but indirectly through calcitriol. The importance of bioavailability of calcium at absorptive sites is illustrated by the impairment of calcium absorption induced by the formation of complexes with anions, such as phosphate, sulfate, phytate or oxalate. For instance, the colonic mucosa is equipped with a powerful vitamin D-sensitive mechanism of calcium transport. However, the absorption is quantitatively little, since calcium in the large intestine lumen is under a form not available for absorption (Ammann et al., 1986). Modification of gut microbiota and lower intestinal content pH can increase distal tract calcium absorption (Ammann et al., 1988; Whisner and Castillo, 2018). At steady state, a 24 h urinary excretion of calcium is mainly the reflection of daily net intestinal calcium absorption.

Bone Fluxes

In average, about 1% of total bone calcium exchanges every month, through a mechanism involving bidirectional fluxes. The main regulators of these fluxes are parathyroid hormone and calcitriol, as well as numerous factors locally produced (Rizzoli and Bonjour, 2006; Manolagas and Parfitt, 2013; Bonewald, 2017). A large variety of substances either circulating or locally produced,

or present in the bone matrix, such as prostaglandins, thyroid hormones, glucocorticoids, sex hormones, growth factors, interleukins, lymphokines or myokines, components of the RANK-ligand/osteoprotegerin system, produced by the immune or hematopoietic systems, stromal or bone cells, are capable of influencing bone remodeling, and thereby the bidirectional calcium fluxes (Martin and Seeman, 2008; Martin and Sims, 2015). In fasting urine, calcium excretion related to creatinine is a direct reflection of net bone calcium exchange (Nordin and Peacock, 1969; Peacock et al., 1969). Indeed, after an overnight fast, calcium appearing in the urine mostly originates from bone. Multiplying the calcium to creatinine ratio by serum creatinine provides urinary calcium excretion per glomerular filtration rate unit.

Renal Fluxes

By controlling calcium excretion, the kidney plays a central role in calcium homeostasis (Rizzoli and Bonjour, 2006). At steady state, the amount of calcium appearing in the urine is the reflection of net fluxes into the extracellular fluid originating from intestine and bone. Approximately 75% of plasma calcium is ultrafiltrable. After filtration, more than 95% of calcium is reabsorbed. In proximal tubule, calcium reabsorption is tightly connected to that of sodium (Friedman, 2000). Then, 20% to 30% of filtered calcium are reabsorbed along the loop ascending limb, and 10% at the level of the distal tubule. Parathyroid hormone influences calcium reabsorption in the loop ascending limb and in the distal tubule (Friedman, 2000). Any change in renal tubular capacity to reabsorb calcium is able to induce variations of plasma calcium from 1.5 to 3.8 mmol/L (Nordin and Peacock, 1969; Peacock et al., 1969). This concept has been established by the study of the relationship between urinary calcium excretion and plasma calcium in patients suffering from a lack or an excess of parathyroid hormone.

Various situations or pharmacological agents can modulate the renal tubular reabsorption of calcium. Alkalosis stimulates renal tubular reabsorption of calcium, whilst acidosis decreases it. Thiazides and lithium salts increase the reabsorption of calcium, through mechanisms which are independent of parathyroid hormone (Rizzoli et al., 1981). Phosphate deficiency, pharmacological doses of calcitonin and loop diuretics are associated with an increase in calcium clearance (Friedman, 2000). Even large variations of the glomerular filtration rate do not cause major changes in calcemia, since the renal tubule can easily maintain the calcium excretion by modulating its reabsorptive capacity. A right shift in the relationship between urinary calcium excretion and calcemia indicates an increase in the renal tubular reabsorption of calcium, for instance through increased PTH levels. The latter can be quantified using an index calculated from a nomogram with fasting urinary and serum, calcium and creatinine values (Bonjour et al., 1988).

Calcium Homeostasis

A central role in the regulation of calcium homeostasis is played by parathyroid hormone produced by the parathyroid glands, which recognize small alterations in plasma calcium (Goltzman and Hendy, 2015; Hannan et al., 2016). Any change in plasma calcium is detected by a cell membrane-associated calcium-sensor/receptor, which can also be activated by other divalent cations. This 1078 aminoacid polypeptide belongs to the family of seven transmembrane domains cell membrane associated and guanine nucleotide binding protein-coupled receptors (Hannan et al., 2016).

Parathyroid hormone as well as a decrease in calcium and/or phosphate concentrations directly stimulate the synthesis of calcitriol at the renal level. The latter hormone contributes to an increase of plasma calcium through a mobilization of calcium from bone and a stimulation of intestinal calcium absorption (Haussler et al., 2013; Hefti et al., 1983).

Table 1 Mechanisms of hypercalcemia

	Increased bone resorption	*Increased renal tubular reabsorption of calcium*
Endocrine disorders		
Primary hyperparathyroidism	+	+
Hyperthyroidism	+ +	−
Malignancy (with or without bone metastases)	+ or + +	+ or −
Granulomatous disorders (calcitriol overproduction)	+ +	−
Immobilization	+ +	−

Milk-alkali syndrome	−	+
Thiazide diuretics	−	+
Lithium salts	−	+
Benign familial hypocalciuric hypercalcemia	−	+

Disorders of Extracellular Calcium Homeostasis (Table 1)

Any disturbance of the above described fluxes can result in an alteration of extracellular calcium homeostasis. An increase in intestinal absorption of calcium and in bone resorption can lead to hypercalcemia when the renal excretion capacity is overwhelmed (Buchs et al., 1991; Rizzoli et al., 1994b). When renal tubular reabsorption of calcium is stimulated, plasma calcium levels can rise, despite very minute changes of calcium influx into the extracellular fluid compartment (Nordin and Peacock, 1969; Peacock et al., 1969). Despite increased renal tubular reabsorption of calcium, urinary excretion is elevated as a consequence of a higher filtered load.

The predominance of stimulated renal tubular reabsorption of calcium or of increased bone resorption in determining an altered extracellular calcium homeostasis can be demonstrated in a variety of clinical disorders associated with hypercalcemia (Buchs et al., 1991) (**Fig. 1**).

Symptoms and Signs of Hypercalcemia

Hypercalcemia is associated with a variety of symptoms, for which there is no specific threshold of calcium concentration accompanied by clinical symptoms. Their severity is influenced by the rapidity of onset of hypercalcemia, age, comorbidities and

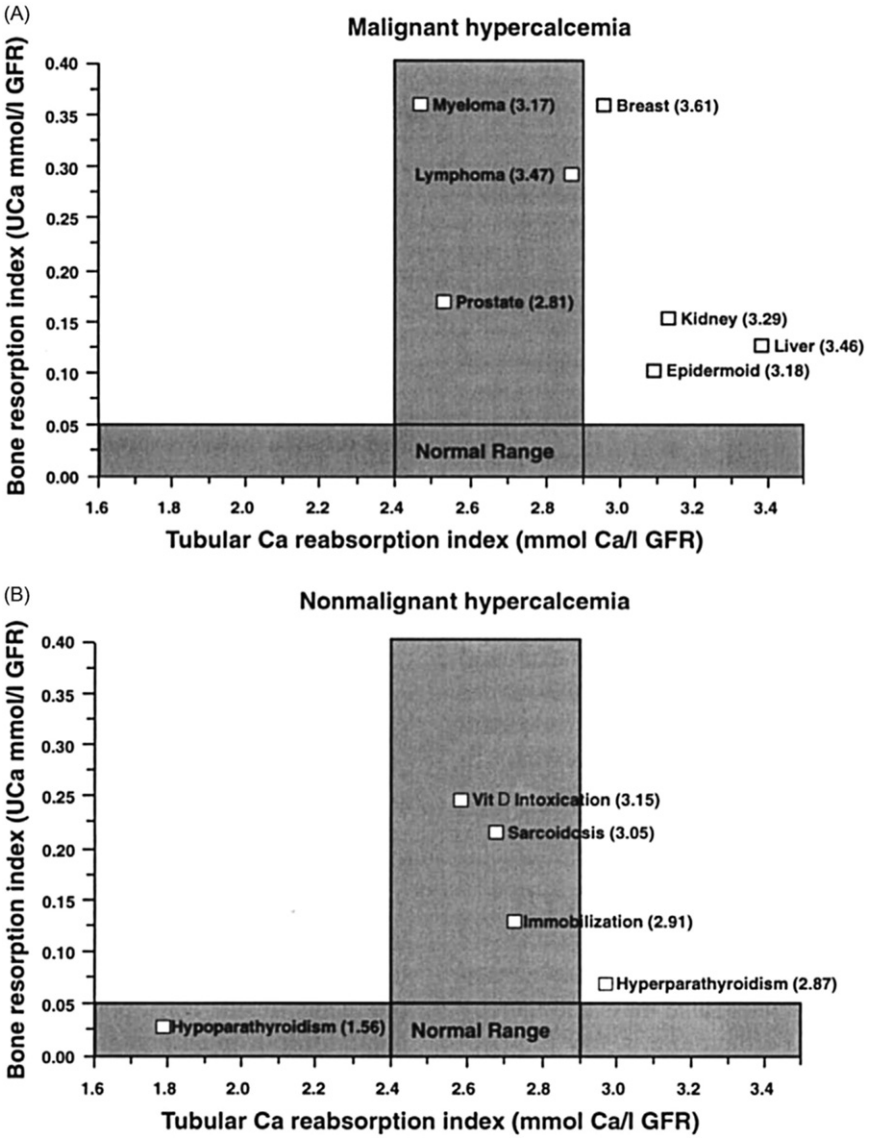

Fig. 1 Relationship between bone resorption, as evaluated by the bone resorption index (BRI) and tubular reabsorption of calcium index (TRCaI) in rehydrated patients with malignant (A) or nonmalignant (B) hypercalcemia. In parentheses is mentioned the mean plasma calcium concentration. This figure is taken from Buchs, B., Rizzoli, R. and Bonjour, J. P. (1991). Evaluation of bone resorption and renal tubular reabsorption of calcium and phosphate in malignant and nonmalignant hypercalcemia. *Bone,* **12**, 47–56.

concomitant medications. The symptoms can be divided into the four "O" categories. *Groan* (gastrointestinal tract): anorexia, dyspepsia, nausea, constipation, abdominal pain. *Moan* (neurological): fatigue, muscle weakness, poor concentration, confusion, irritability, even lethargy and coma. *Stone* (renal): dehydration, polydipsia, oliguria, renal function impairment, acute renal injury, nephrocalcinosis and vascular calcifications. *Bone*: this series of symptoms concerns more primary hyperparathyroidism, and is less prominent in other causes of hypercalcemia. Cardiac symptoms associated with elevated extracellular calcium concentrations comprises shortening of the QT interval in the electrocardiogram and increased risk of arrhythmia, particularly with concomitant hypokalemia.

Disorders Other Than Primary Hyperparathyroidism

In outpatients, the most frequent cause of hypercalcemia is primary hyperparathyroidism. Among other causes, malignancy accounts for the vast majority of hypercalcemia in hospitalized patients.

Endocrine Dysfunction: Hyperthyroidism

Mild elevation of serum calcium is frequently encountered in active hyperthyroidism. The mechanism is increased bone resorption (Baxter and Bondy, 1966). A feature of hyperthyroidism is a rather high phosphatemia, since thyroid hormone can directly stimulate renal tubular reabsorption of phosphate (Sorribas et al., 1995). Hypercalcemia resolves with correction of thyroid function.

Malignancy

Approximately one-half of people who die of cancer have bone involvement (Coleman, 2006). Different tumor types may have preferential sites of metastases; however, the vast majority of tumors metastases to bone. The term metastatic bone disease reflects the spread of a tumor to the bone. This term may be applied to solid tumors, as well as to multiple myeloma, where the tumor is intrinsic to the bone marrow (Rizzoli et al., 2013). In advanced breast or prostate cancer, metastatic bone disease is present in a large proportion of patients. Bone metastases may also be seen in 15%–30% of cancers of the lung, gastrointestinal tract (colon and stomach), and the genitourinary (bladder, kidney and uterus) (Roodman, 2004), as well as in advanced thyroid cancer and melanoma (Coleman, 2006). Skeletal related events include pathologic fractures (21%), spinal cord compression (1%), surgery (1%) and radiotherapy (8%) to bone and may or may not include hypercalcemia of malignancy. Hypercalcemia is a sign of advanced cancer disease. Only in neuroendocrine tumors or possibly in renal carcinoma, hypercalcemia may be detected before the tumor diagnosis.

Malignant cells release a number of molecules that favor osteoclastogenesis via the RANK/RANKL/OPG system like parathyroid hormone-related protein (PTHrP) detected by immunohistochemistry in about 90% of bone metastases from breast cancer (Powell et al., 1991; McCauley and Martin, 2012). RANKL has also been shown to trigger the migration to bone of melanoma and some epithelial cells that express the RANK receptor, such as breast cancer cells. Lytic bone lesions are observed on X-ray in about 95% of patients with advanced myeloma, in contrast to what is observed in lymphomas, although both entities are B-cells malignancies. Bone involvement is related to an excessive bone resorption through increased osteoclast number encountered in the close vicinity of myeloma cells (Bataille, 2015) together with a decreased osteoblast activity. In myeloma and lymphomas, there is a marked reduction in osteoblast activity. The plasma cells can release several factors such as DKK1, sFRP2 which act on the Wnt pathway and reduce the osteoblast number and activity (Tian et al., 2003). So the lesions observed in myeloma are predominantly osteolytic. In advanced metastatic bone disease, hypercalcemia reflects the release of large amounts of calcium mobilized due to breakdown of the calcified matrix. In some cases of multiple myeloma, the monoclonal immunoglobulin binds the calcium ion (Merlini et al., 1984). In these patients, the high total serum calcium is associated with normal ionized calcium and urinary calcium excretion, without symptoms or signs of hypercalcemia.

Hypercalcemia may occur even in the absence of bone metastases and is attributed to a humoral mechanism (Stewart et al., 1980) (**Table 2**). In humoral hypercalcemia of malignancy, increased renal tubular reabsorption of calcium represents the main pathogenetic mechanism, in which an effect of tumor-produced PTHrP is implicated (Stewart, 2005). Ectopic production of authentic PTH is a very rare phenomenon (Rizzoli et al., 1994a). The relative and quantitative contribution of calcium mobilization from bone, and of renal tubular reabsorption of calcium, to hypercalcemia induced by parathyroid hormone-related protein can be estimated in studying the model of thyroparathyroidectomized rats chronically infused with parathyroid hormone-related protein (Rizzoli et al., 1989). The elevation of plasma calcium is determined by both increased bone resorption and enhanced renal tubular reabsorption of calcium. However, the complete inhibition of bone resorption by a bisphosphonate, at a dose which fully normalizes fasting urinary calcium excretion, taken as a reflection of net bone resorption, is associated with an approximately 30% decrease, but not a correction of plasma calcium (Rizzoli et al., 1989). Thus, the residual hypercalcemia can be attributed to a renal tubular reabsorption effect, which accounts for more than two-thirds of the elevated plasma calcium in this experimental model. Indeed, it is well established that bisphosphonates are devoid of any direct effect on the renal handling of

Table 2 Bone invasion in hypercalcemia of malignancy.

Tumor type	*No. of subjects*	*% with bone invasion*	*Calcemia (mmol/L)*
Breast	35	100	3.61 ± 0.66

Table 3 Hypercalcemic disorders with elevated calcitriol production

Eutopic secretion	Tumors: seminoma, PTHrP producing tumors
Ectopic production	Tumors: B- or T-cell lymphomas, Hodgkin disease, T-cell acute leukemia, eosinophilic granuloma
	Infection: tuberculosis, histoplasmosis, candidiasis, leprosy
	Other granulomatous diseases: sarcoidosis, silicosis, berylliosis, lipoid pneumonia, foreign body granuloma (e.g., silicon implant)

calcium (Rizzoli et al., 1992). Elevated PTHrP levels can lead to an earlier relapse after treatment of hypercalcemia by a bone resorption inhibitor (Rizzoli et al., 1999).

Granulomatous Disorders

Ectopic production of calcitriol is a cause of hypercalcemia occurring in some malignancies of the hematopoietic system as well as in various ganulomatous diseases (Kallas et al., 2010) (**Table 3**). In active sarcoidosis, up to 10% of the patients may become hypercalcemic, and even more hypercalciuric. Granuloma macrophages develop an increased activity of 1-alpha-hydroxylase enzyme leading to higher production and circulating levels of calcitriol, hence to a markedly elevated intestinal absorption of calcium.

Immobilization

Very rapidly after immobilization, there are an increase in bone resorption and an inhibition of bone formation, leading to calcium release into the extracellular fluid (Stewart et al., 1982). Hypercalcemia occurs when the urinary excretion capacity is overwhelmed. There is a clear age-dependency since disuse-induced hypercalcemia is very rare in the oldest old whilst it is more frequent in children and young adults.

Drug-Induced

Vitamin D excess due to iatrogenic administration of pharmacological doses of vitamin D is a rare cause of hypercalcemia. Large doses used to be given in the treatment of hypoparathyroidism before the availability of active vitamin D metabolites. Vitamin D excess is associated with increased calcium intestinal absorption and bone resorption (Rizzoli et al., 1994b). The latter is responsive to bone resorption inhibitors. Because of the prolonged half-life of the metabolite 25-hydroxyvitamin D, hypercalcemic–hypercalciuric syndrome can persist for several weeks to months, with an important morbidity and even permanent soft tissues damages.

Vitamin A intoxication-mediated hypercalcemia is very rare and can result from vitamin A supplementation or retinoic acid treatment for various disorders (Valentic et al., 1983). The pathogenic mechanism mainly involves increased bone resorption.

Milk-alkali syndrome encompasses hypercalcemia, metabolic acidosis and renal failure (Orwoll, 1982). It was described in patients with peptic ulcer treated with large amounts of milk and antacids, such as calcium carbonate. Whilst hypercalcemia is usually corrected with hydration and reduction of calcium intakes, renal function alterations may persist.

Thiazide diuretics stimulate calcium reabsorption in the distal tubule through a PTH-independent mechanism, particularly in situations with high bone turnover (Rizzoli et al., 1981; Wermers et al., 2007).

Lithium increases both PTH secretion, through parathyroid cells hyperplasia, and renal tubular reabsorption of calcium, which appears to be reversible upon cessation of lithium treatment (Khandwala and Van Uum, 2006; Bendz et al., 1996). Mild hypercalcemia has been reported in as many as 5% of lithium-treated patients.

Benign Familial Hypocalciuric Hypercalcemia

Various mutations in the calcium sensing receptor have been reported, which account for hyper- or hyposecretion of parathyroid hormone in relation with variations of extracellular calcium concentration (Hu and Spiegel, 2003). In familial hypocalciuric benign hypercalcemia, circulating levels of parathyroid hormone are insufficiently suppressed for the degree of calcemia, and the renal tubular reabsorption of calcium is increased through a parathyroid hormone-independent mechanism (Marx et al., 1982; Hannan et al., 2016). This disorder appears to be due to mutations associated with hypofunction of the cell membrane calcium sensing mechanism (Hannan et al., 2016). Thus, higher plasma calcium levels are necessary to inhibit PTH secretion. Interestingly, the same biochemical pattern can be encountered in patients treated with lithium salts (Bendz et al., 1996). Under these conditions, parathyroid hormone production is not suppressed despite higher circulating calcium levels. Calcium sensing receptor activity can be modulated by calcimimetics, which enhance its sensitivity to extracellular calcium (Marx, 2017).

Management of Hypercalcemic Disorders

Severe symptomatic hypercalcemia requires rapid intervention since the condition may be life-threatening. The first aim of therapy is to correct dehydration (Rizzoli and Bonjour, 1992). Fluid therapy comprises the administration of 2–3 L of isotonic saline over the first 24–48 h, with repeated measurements of plasma electrolytes, particularly potassium, because of the risk of severe hypokalemia. Hypovolemia may be present and further worsened during diuresis. Plasma calcium decreases not only by restoring intravascular volume and correcting thereby the hemoconcentration but also by altering proximal tubule calcium hyperreabsorption, which is the consequence of dehydration and volume contraction (Hosking et al., 1981). Thus, it is mandatory to replenish extracellular fluid volume, possibly under the continuous control of central venous pressure, particularly in older subjects with compromized cardiac function, and urine output, to maintain sodium diuresis and promote calcium excretion. To avoid possible fluid overload, loop diuretics could be administered. Loop diuretics impair calcium reabsorption in the ascending limb of Henle's loop and may help to enhance urinary calcium excretion (Suki et al., 1970). But their effect is rather weak, since the calcium reabsorbed in the ascending limb represents a small fraction of the filtered load. By causing acute volume loss, diuretics could further aggravate the volume contraction dependent hypercalcemia. In the management of hypercalcemia states, the combination of massive saline infusion with high doses of furosemide is of dubious efficacy to markedly decrease renal tubular reabsorption and may be associated with life-threatening imbalances in electrolytes concentration and fluid volumes. This historical therapeutic approach should be avoided nowadays. In case of hypernatremia, 5% dextrose should be given instead of saline. Attention should be paid to prevent immobilization to avoid additional disuse-induced stimulation of bone resorption and impaired bone formation.

Clinical improvement usually occurs after rehydration. The next step of therapy requires the correction of the disturbed calcium flux(es): the decrease in net bone resorption and/or in renal tubular calcium reabsorption. To modify the latter, pharmacological doses of salmon calcitonin, 400–600 IU given intravenously in perfusion over 12 to 24 h can be administered (the effect is however transient), or the oral calcimimetic cinacalcet. Both are reducing the renal tubular reabsorption of calcium. The use of the former should be restricted to very severe hypercalcemia with neurological symptoms, requiring a rapid decrease in calcemia.

The most efficacious and used agents in the management of nonhyperparathyroid hypercalcemia are certainly the bone resorption inhibitors bisphosphonates (Rizzoli and Bonjour, 1992; Berenson, 2002; Body et al., 2007). Pamidronate is given at the dose of 90 mg intravenously in 250–500 mL of saline or 5% dextrose over 2 h. Zoledronate is given at a dose of 4 mg intravenously in 250 mL saline or 5% dextrose over 30 min. Ibandronate is given at the dose of 4 mg in 100 mL saline or 5% dextrose over 30 min. In response to intravenous bisphosphonates, calcemia begins to drop by 48 h and reach a nadir by 4 to 5 days.

Conclusions

The physiology of calcium homeostasis is regulated by coordinated bidirectional calcium fluxes, occurring at the levels of intestine, bone and kidney. These fluxes are influenced by calciotropic peptides or steroid hormones, and by a variety of locally produced factors. In the control of extracellular calcium concentration, the kidney tubule reabsorptive capacity plays a central role. Management of hypercalcemic disorders other than primary hyperparathyroidism, includes the treatment of the hypercalcemia causing disease and normalization of the abnormal calcium fluxes. Bisphosphonates are an efficacious option in case of increased bone resorption.

Introduction

The existence of a parathyroid hormone related (or like) protein was first postulated by Albright (1941), while discussing a patient with renal carcinoma, a solitary metastasis and severe hypercalcemia. Albright suggested that some of the tumors might be secreting PTH or something like it that induced the hypercalcemia (Albright, 1941). As with many of Albright's predictions, he was eventually proven correct, but not before the idea that the hypercalcemia was due to ectopic PTH production had become well-established (Omenn *et al.*, 1969). It was eventually the development of improved immunoassays in the 1970's, which revealed that the causative agent of the humoral hypercalcemia of malignancy (HHM) was distinct from *bona fide* PTH, with PTH even undetectable in numerous hypercalcemic patients (Benson *et al.*, 1974; Powell *et al.*, 1991; Roof *et al.*, 1971). In the late 1980s, parathyroid hormone related protein (PTHrP) was purified from a human lung cancer cell line, then cloned, sequenced and identified as the agent responsible for HHM (Moseley *et al.*, 1987; Suva *et al.*, 1987). Other confirmatory studies soon followed (Mangin *et al.*, 1988; Strewler *et al.*, 1987) that collectively demonstrated that this factor bound to the PTH receptor to induce cyclic-adenosine monophosphate (cAMP) production by activating adenylate cyclase downstream of the receptor (Horiuchi *et al.*, 1987; Kemp *et al.*, 1987), but was immunologically and genomically distinct from PTH. Thereafter, the gene encoding PTHrP, *PTHLH*, was isolated from multiple species, including human, rat, mouse (Mangin et al., 1989, 1990b; Suva *et al.*, 1989; Yasuda *et al.*, 1989) and more than 30 years of subsequent research have revealed a vast amount of information regarding the synthesis, metabolism, regulation and varied biological actions of PTHrP. Soon after its discovery, it became apparent that PTHrP was far more than an evolutionary accident that phenocopied the ability of PTH to regulate postnatal mammalian calcium and phosphate metabolism. If gene conservation across species and phyla is evidence of evolutionary and gene importance, then *PTHLH* clearly represents the ancestral gene and the basis for the subsequent gene duplication event yielding the *PTH* gene. Indeed, PTHrP has functions far beyond the limited physiologic role of PTH. This article will briefly consider PTHrP in the context of physiology and pathophysiology, and outline the gene structure, biosynthesis, metabolism, regulation and breadth of PTHrP's widespread biological functions.

PTHLH Gene

The PTHrP gene (*PTHLH*) has a more complex genomic organization than the *PTH* gene, but the two genes share similar intron-exon boundaries (**Fig. 1**). The amino acid sequence of PTHrP is highly conserved (up to amino acid 111) between human, mouse, rat, chicken and dog, suggesting important functions are likely residing in these regions. Studies over the past few decades, have demonstrated that PTHrP is the product of a single *PTHLH* gene localized on the p-arm of the human chromosome 12 (Suva *et al.*, 1989; Vasavada *et al.*, 1993; Yasuda *et al.*, 1989). Unlike the related human *PTH* gene, which is located on chromosome 11, the *PTHLH* gene is a complex transcriptional unit consisting of 9 exons and 3 unique promoters upstream of exons I, III and IV (**Fig. 1**) (Suva *et al.*, 1989; Vasavada *et al.*, 1993; Yasuda *et al.*, 1989). Transcription of the PTHLH gene can result in three mature human PTHrP peptides of 139, 141 and 173 amino acids. Multiple RNA transcripts of each of these peptides have been observed, validating the three peptides as the transcribed and translated products of the single human *PTHLH* gene. Gene splicing events result in the three variants of PTHrP: PTHrP(1–139), PTHrP(1–173), PTHrP(1–141) (Mangin *et al.*, 1988; Southby *et al.*, 1995).

Both PTHrP and PTH, as well as their shared common receptor, PTH receptor 1 (PTHR1), have been identified in teleost fish and in the cartilaginous elasmobranches (Devlin *et al.*, 1996; Trivett *et al.*, 1999; Danks et al., 1993, 1998). These data support the idea that *PTHLH* is indeed the original ancestral gene, with PTH and its subsequent control of postnatal calcium metabolism

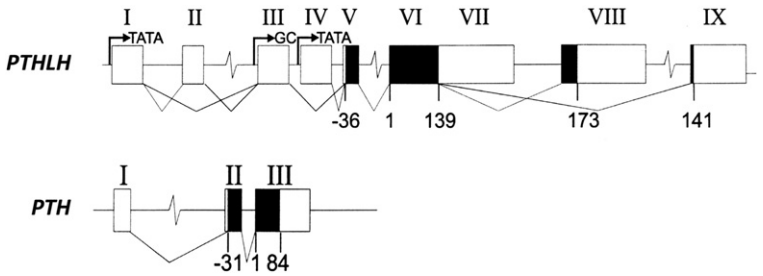

Fig. 1 *PTHLH* and *PTH* gene splicing. The nine exons of the human *PTHLH* gene are shown and three unique promoters upstream of exons I, III and IV. Transcription initiation position is at +1. During splicing three isoforms of PTHrP can be formed: PTHrP(1–139), PTHrP(1–173), PTHrP (1–141). The *lines* indicate different splicing events. Adapted from (Mangin, M., Ikeda, K., Dreyer, B. E. and Broadus, A. E. (1989). Isolation and characterization of the human parathyroid hormone-like peptide gene. *Proceedings of the National Academy of Sciences of the United States of America*, 86, 2408–2412; Suva, L. J., Mather, K. A., Gillespie, M. T., Webb, G. C., Ng, K. W., Winslow, G. A., Wood, W. I., Martin, T. J. and Hudson, P. J. (1989). Structure of the 5' flanking region of the gene encoding human parathyroid-hormone-related protein (PTHrP). *Gene*, 77, 95–105). The three exons of the human *PTH* gene are shown for comparison. Adapted from (Vasicek, T. J., Mcdevitt, B. E., Freeman, M. W., Fennick, B. J., Hendy, G. N., Potts, J. T., Jr., Rich, A. and Kronenberg, H. M. (1983). Nucleotide sequence of the human parathyroid hormone gene. *Proceedings of the National Academy of Sciences of the United States of America*, 80, 2127-2131). Transcription initiation position is at +1. During splicing 1 isoform of PTH, PTH(1–84) can be formed.

evolving by a gene duplication event. Interestingly, the structural organization of the chicken, mouse and rat PTHLH genes share substantial homology with the human *PTHLH* gene (Karaplis *et al.*, 1990; Mangin et al., 1990b; Moseley and Gillespie, 1995; Yasuda *et al.*, 1989; Thiede and Rutledge, 1990) although the rodent genes are considerably simpler than the human gene. The *PTHLH* gene in rodents appears to employ only a single TATA promoter and contains only four exons, suggesting that the greater complexity of the human PTHLH gene is a late evolutionary event (Karaplis *et al.*, 1990; Mangin et al., 1990a), given the relative simplicity of the mouse and rat genes.

In the human *PTHLH* gene, the presence of multiple promoters (**Fig. 1**) suggests that alternate promoter use maybe driving the tissue-specific and/or developmentally regulated expression of PTHrP. Since the *PTHLH* genes from all species described to-date have a functional proximal TATA promoter region, but may not have upstream promoters (**Fig. 1**), it is likely that the majority of the transcriptional regulation of PTHrP occurs through the proximal TATA promoter (5′ to exon IV).

The genomic organization and complexity of the human *PTHLH* gene that produces three splice variants of PTHrP with complex transcriptional regulation (**Fig. 1**) remains a scientific quandary. Indeed, there are currently only four reported situations in which PTHrP peptides are present in the circulation; (i) HHM where PTHrP expression by tumors stimulates bone resorption, (ii) lactation where PTHrP is made in the breast and enters the circulation (Grill *et al.*, 1992), (iii) fetal life where PTHrP regulates maternal-fetal calcium transport (Kovacs *et al.*, 1996; Abbas *et al.*, 1989; Rodda *et al.*, 1988), and (iv) breast cancer bone metastasis where PTHrP(12–48) has been measured in patient serum by mass spectrometry and likely regulates hematopoietic cell fate (Kamalakar *et al.*, 2017; Washam *et al.*, 2013). Since there is no evidence of PTHrP peptides in the circulation of normal humans, it appears that PTHrP actions, unlike PTH, are largely paracrine. It is these observations, along with the susceptibility of the PTHrP sequence to proteolysis, glycosylation and other posttranslational modifications that highlight the complexity of the molecule and its myriad functions, many of which we summarize below.

PTHrP Peptide(S) Biosynthesis, Metabolism and Nuclear Localization Motifs

In the context of diseases, the details and identity of circulating PTHrP is even more important. Less than 0.2 pmol/L of PTHrP peptides are detectable in the circulation in normal adult humans, although elevated levels (pg/mL) have been measured by mass spectrometry in the serum breast cancer bone metastasis patients (Washam *et al.*, 2013). PTHrP(12–48) has not been proposed or identified previously and thus may not have been detected by current PTHrP antisera. In fact, detection by existing PTHrP antisera is minimal (Washam *et al.*, 2013). Observations such as these, along with the finding that PTHrP is widely expressed in a variety of normal tissues drives the idea that PTHrP acts in a paracrine fashion. Sites of PTHrP expression represent both the regulated and constitutive pathways of protein secretion and suggest multiple modes of local release. Comparison of the human PTH and PTHrP peptide sequences reveals significant homology in the N-terminal region, with 8 of the first 13 amino acids identical and very little PTH homology observed through the rest of the sequence (Suva *et al.*, 1987). The N-terminal region (amino acids 1–14) comprises the PTH receptor (PTHR1) binding domain (**Fig. 2**). The extensive homology between PTH and PTHrP in this region accounts for the ability of PTHrP to bind to and activate PTHR1 in classic PTH target tissues (bone and kidney) and consequently to generate the paraneoplastic effects on calcium and phosphate metabolism characteristic of HHM. The amino acid sequence is conserved in various species from chicken, mouse and rat to dogs and humans indicating that PTHrP has an important evolutionary function.

In addition to PTHR1, a second human PTH2 receptor (PTHR2) has been identified (Behar *et al.*, 1996; Usdin, 2000; Usdin *et al.*, 1995) and which binds and is activated at high potency by PTH and by tuberoinfundibular peptide of 39 residues (TIP39)

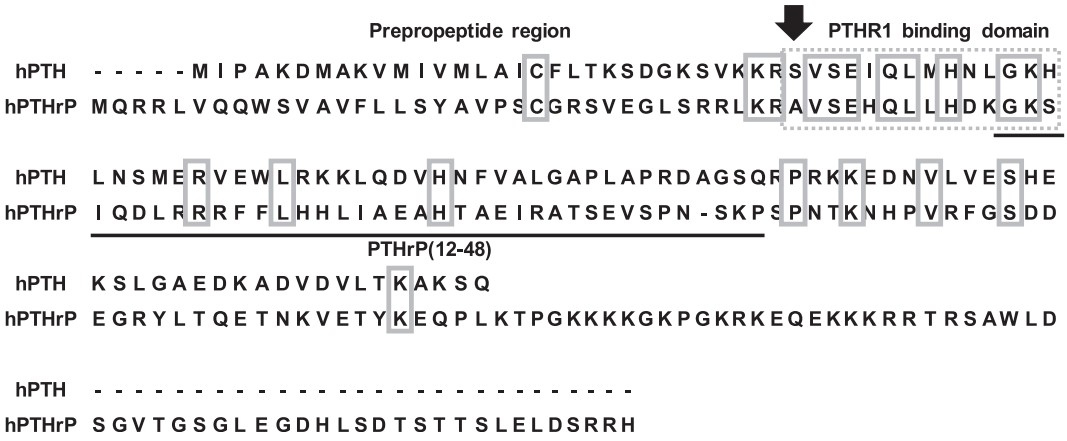

Fig. 2 *Comparison of human PTH and human PTHrP amino acid sequences.* The amino acid sequences of hPTH and hPTHrP are shown. Prepropeptide region is shown to the left of the *arrow*. *Arrow* identifies N-terminal amino acid of the secreted forms of both hPTH and hPTHrP. Amino acid sequence identity overlap between PTH and PTHrP enclosed in *gray*. Significant homology in the N-terminal, PTHR1 binding domain, enclosed in *dotted box*. Amino acid sequence of PTHrP(12–48) is underlined.

but not PTHrP (Usdin et al., 1995, 2002). Interestingly, despite the high homology at the N-terminus between PTH and PTHrP, the selective PTHR2 interaction with PTH and not with PTHrP is encoded by position 5 (Ile in PTH; His in PTHrP) (Behar *et al.*, 1996).

Interestingly, although the transcriptional control of *PTHLH* gene expression is complex, the regulation of individual PTHrP isoforms are also subject to a multitude of posttranslational modifications and enzymatic processing. Each PTHrP isoform; PTHrP (1–139), PTHrP(1–173) and PTHrP(1–141), can undergo numerous posttranslational modifications which are proteolytic and/or enzymatic in nature. These reactions result in various peptide fragments of PTHrP, and many fragments have been ascribed a known biological function (**Table 1**). In the amino acid sequence of PTHrP, the first 36 amino acids (− 36 to − 1) comprise of the prepropeptide region, (**Fig. 2**). The prepropeptide region is necessary for protein trafficking and secretion (Suva *et al.*, 1987). Proprotein convertases, which are a family of enzymes known to cleave peptides following basic amino acids or following an Arginine (R) (Constam and Robertson, 1999). Thus, proprotein or prohormone enzymes, PC1/3, Furin, PC2, PC4, PC5 and PACE4 were shown to cleave the prepropeptide region after the Arginine at position − 1 (**Fig. 3**). A proprotein enzyme-dependent endoproteolytic cleavage of Arginine at position 37 can give rise to the N-terminal fragment and other mid-molecule fragments like, 35–84, which have been associated with the transport of Ca2 + across the placenta to allow skeletal development of a fetus (Wu *et al.*, 1996; Hilliker *et al.*, 1996). The C-terminus 107–139 region (Valin *et al.*, 1999; Cornish *et al.*, 1997), formed by prohormone enzymatic cleavage of Arginine at 106, has been shown to inhibit osteoclast function and to increase osteoblast proliferation. An absence of any of these regions; N-terminal (Hilliker *et al.*, 1996), mid-molecule (Wu *et al.*, 1996) or the C-terminal, results in drastic bone abnormalities in vivo and decreased numbers and function of both osteoclasts and osteoblasts (Soifer *et al.*, 1992; Burtis *et al.*, 1992).

Potential enzymatic processing sites are scattered throughout the PTHrP primary amino acid sequence (**Fig. 3**), and it seems likely that processing of PTHrP takes place in an isoform- and tissue-specific fashion (Habener, 1981; Rholam and Fahy, 2009). The physiological implications of posttranslational processing of PTHrP are still poorly understood, however, it is clear that secreted forms of N-terminal, mid-regional, and C-terminal regions of PTHrP exist (**Table 1**). These peptides have a number of bioactivities that are presumably mediated via distinct receptors and signaling mechanisms to facilitate the broad spectrum of PTHrP effects (Rholam and Fahy, 2009; Deftos *et al.*, 2001). Despite this knowledge, the complex mechanisms driving the extensive endoproteolytic processing and/or metabolism of PTHrP are poorly defined, with even its native secretory forms having eluded precise identification (Burtis, 1992; Kamalakar *et al.*, 2017; Martin *et al.*, 1991; Orloff *et al.*, 1994).

However, although these specific peptide cleavage products have been predicted and/or demonstrated in transgenic animals and in vitro, no specific PTHrP peptide fragments, other than PTHrP(12–48), have been identified or sequenced from the circulation of patients (Kamalakar *et al.*, 2017; Washam *et al.*, 2013). PTHrP(12–48) is not a transcribed product, but is the result of proteolytic processing of the three known human PTHrP isoforms. Indeed, given the lack of direct information, in silico cleavage site analyses identifies the potential endoproteases involved in PTHrP(12–48) processing.

Lysyl endopeptidase (LysC) (Jekel *et al.*, 1983) and Peptidyl-Lys metalloendopeptidase (LysN) (Hori *et al.*, 2001) have cleavage specificities conducive to the N-terminal processing site of PTHrP(12–48) (**Fig. 4**). Although LysC and LysN are not expressed in humans, the chemical properties of these enzymes suggests that Lys11 may be a monobasic cleavage site. Indeed, the N-terminal processing at Lys11 follows the consensus rules and sequence motifs that typically characterize prohormone processing at monobasic sites (Devi, 1991; Schwartz, 1986). Thus, monobasic endoproteases with lysine substrate specificities likely participate in N-terminal processing of PTHrP at Lys11.

The C-terminus of PTHrP(12–48) ends in a proline residue at position 48 (**Fig. 4**). Proline contains a rigid pryrrolidine ring that imposes strong conformational restrictions on the peptide chain's structural architecture (Vanhoof *et al.*, 1995). Proline residues

Table 1 Reported PTHrP peptide fragments and their proposed functions

Peptide fragments	*Known functions*
Prepropeptide	
−36 to −1	Intracellular trafficking and polypeptide hormone secretion (Suva *et al.*, 1987)
N-terminal peptides	
1–14	Receptor binding and activation (Stewart *et al.*, 1987; Burtis *et al.*, 1992; Hilliker *et al.*, 1996)
14–36	Receptor binding and activation (Burtis *et al.*, 1992; Stewart *et al.*, 1987; Hilliker *et al.*, 1996)
12–48	Measured in patient serum by mass spectrometry and likely regulates hematopoietic cell fate (Washam *et al.*, 2013; Kamalakar *et al.*, 2017)
Mid-region peptides	
1–86	Ca^{2+} transport across placenta (Clemens *et al.*, 2001)
35–84	Ca^{2+} transport across placenta (Wu *et al.*, 1996; Hilliker *et al.*, 1996)
67–93	Nuclear localization sequence (NLS), brain development and function (Lam et al., 1999, 2002)
38–94	NLS +, Increases myeloma cell proliferation and survival (Caffario *et al.*, 2014)
C-terminal peptides	
1–108	Bicarbonate excretion from kidneys (Ellis *et al.*, 1990)
1–141	Bicarbonate excretion from kidneys (Ellis *et al.*, 1990)
107–139	Inhibits osteoclast activity, promotes osteoblast proliferation (Cornish *et al.*, 1997; Valin *et al.*, 1999)
142–173	Function unknown

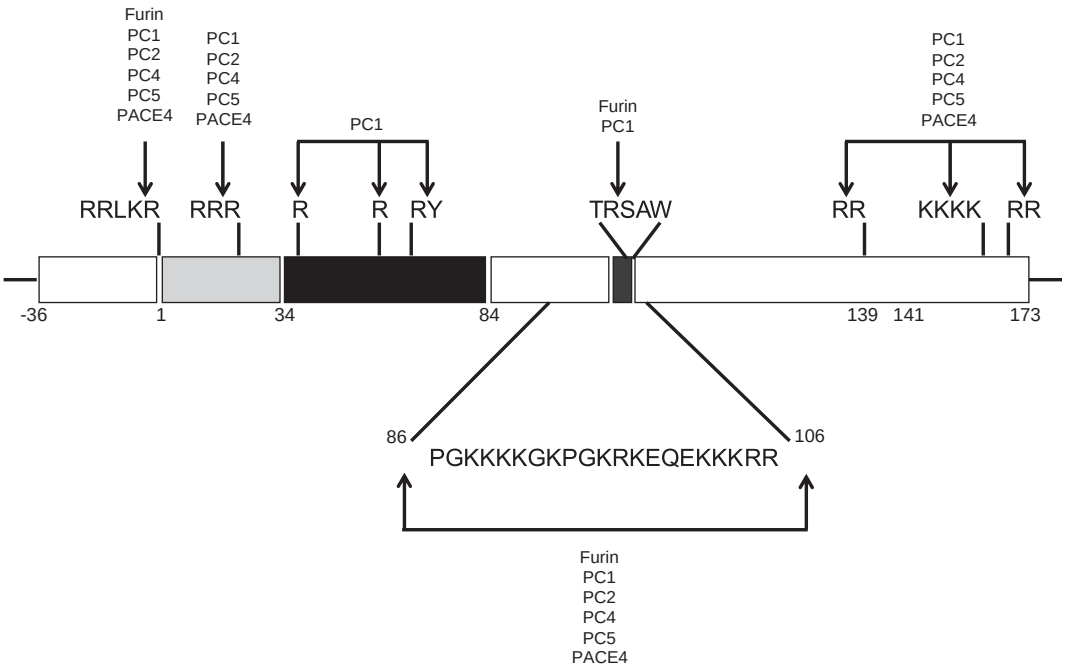

Fig. 3 Putative PTHrP processing sites. The PTHrP peptide from amino acid −36 to 173, including the prepropeptide region of PTHrP is shown. Furins, proprotein convertases (PC1,2,4, 5) and paired basic amino acid cleaving enzyme (PACE4) cleave at basic amino acid residues, Arginine (R), Lysine (K), Serine (S) and Prolines (P) to result in various *predicted* proteolytically and enzymatically cleaved active fragments of PTHrP.

are highly evolutionarily conserved, particularly in cytokines, neuropeptides, and growth factors, and are proposed to serve as beacons that mark biologically important protein regions associated with an array of regulatory, protective, destructive, and other biological activities (Kay *et al.*, 2000; Vanhoof *et al.*, 1995; Yaron and Naider, 1993). In this light, PTHrP proteolysis at position 48 is particularly intriguing. Prolyl endopeptidase (PEP) (Koida and Walter, 1976) or a related member of the serine type postprolyl dipeptidyl family of endoproteases, such as fibroblast activation protein-alpha (FAP-α) (Gass and Khosla, 2007), are strong candidates for the C-terminal processing of PTHrP(12–48) at Pro48 (**Fig. 4**). In sum, the in silico analysis suggests that lysine-specific monobasic and postprolyl endoproteases are likely involved in the N-terminal and C-terminal processing of PTHrP at positions Lys11 and Pro48. Since PTHrP(12–48) remains the only verified circulating PTHrP peptide, much interest still exists in determining the details of its processing and biologic function.

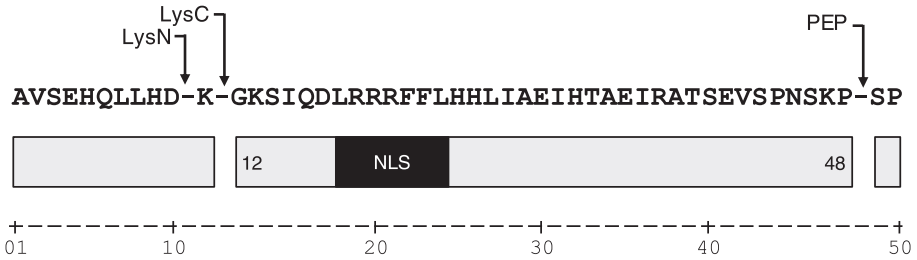

Fig. 4 *In silico PTHrP*(12–48) *Posttranslational Processing and Modification.* The PTHrP(1–50) amino acid sequence is shown. Lysine specific monobasic endoproteases (LysC/LysN) and postprolyl endoprotease family members (PEP) predicted to hydrolyze the Lys^{11} and Pro^{48} peptide bonds respectively. A noncanonical NLS between residues 19–21 suggests an intracrine function for PTHrP(12–48). *LysC* = Lysyl endopeptidase; *LysN* = Peptidyl-Lys metalloendopeptidase; *PEP* = proline endoprotease; *NLS* = nuclear localization signal.

In addition to the classical autocrine/paracrine actions mediated by the activation of PTHR1, mid-regional species of PTHrP have been shown to influence cell behavior through a nuclear pathway, involving endocytosis of PTHrP into neighboring cells and translocation to the nuclear compartment, where it functions to regulate cell death decisions (Luparello *et al.*, 2008) and proliferation in a variety of cell types (Lam *et al.*, 2002) Several noncanonical nuclear localization signals (NLS) have been proposed to exist in the various PTHrP isoforms, the most well-known being a bipartite nuclear/nucleolar localization sequence between residues 88 and 107 that mediates nuclear import of mid-regional species of PTHrP via importin-β1 (Fiaschi-Taesch and Stewart, 2003; Lam et al., 2001, 1999). A second tetrabasic (KKKK) nuclear localization motif spanning amino acid residues 147–150 has also been shown to have intracrine regulatory effects for PTHrP(1–173) in chondrocytes (Clemens *et al.*, 2001; Goomer *et al.*, 2000). In vitro studies have identified a CRM1-dependent leucine-rich nuclear export signal (NES) critical for nuclear export of PTHrP between residues 126 and 139 (Pache *et al.*, 2006). In addition to these motifs, the location of a nonconsensus NLS within PTHrP(12–48) (**Fig. 4**) raises some interesting possibilities that has been shown to target PTHrP(12–48) to osteoclasts (Kamalakar *et al.*, 2017). In sum, the precise actions of PTHrP in the nuclear compartment remain unclear, but are thought to include DNA binding transcription factor activity associated with regulation of gene transcription and/or nuclear organization (Luparello *et al.*, 2008), activation/suppression of the cell cycle via interaction with other nuclear proteins (Connell-Crowley *et al.*, 1997; Lam *et al.*, 2000; Swarthout *et al.*, 2002; Tovar Sepulveda *et al.*, 2002) as well as RNA/chromatin binding and nuclear trafficking (Aarts et al., 1999a, b; Sirchia *et al.*, 2007).

PTHrP Regulation and Function

Since its discovery, PTHrP has been shown to play major roles in a variety of fundamental biologic functions. Indeed, the observation that PTHrP is normally produced in a wide variety of tissues where it acts in a paracrine fashion has driven an intensive research effort. The following sections will summarize and highlight some of the most important advances.

Skeletal Development

The importance of PTHrP in the skeleton became evident when deletion of the *PTHLH* gene in mice resulted in early death due to respiratory failure, the result of defective rib formation (Karaplis *et al.*, 1994). In addition, this discovery also separated PTHrP from PTH, since the later deletion of the *PTH* gene revealed a much milder phenotype, (Miao *et al.*, 2002). Indeed, further interrogation of the role of PTHrP in skeletal development confirmed the important role of PTHrP in fetal bone development. *PTHLH* $-/-$ mice are early postnatal lethal, but haploinsufficient *PTHLH* $+/-$ mice are normal at birth and develop low bone mass at the age of 3 months. These mice demonstrated decreased recruitment of osteoblast precursors and increased osteoblast apoptosis compared to wild-type mice and as osteoblasts are crucial in osteoclastogenesis, an expected decrease in osteoclast formation was also observed in *PTHLH* $+/-$ mice (Amizuka et al., 1996, 1994; Karaplis *et al.*, 1994).

In the growth plate, differentiated chondrocytes produce Indian hedgehog (IHH) which signals undifferentiated chondrocytes to secrete PTHrP, which in turn signals to the differentiating hypertrophic chondrocytes to slow down the rate of chondrocyte differentiation, thereby, regulating developmental bone growth. This paracrine PTHrP/IHH signaling loop is fundamental to our understanding of endochondral bone formation and helped confirm the important role of PTHrP. In fact, PTHrP secretion is also regulated by TGF-β and IGF-1 (Alvarez *et al.*, 2002; Dexheimer *et al.*, 2016; Hilton *et al.*, 2005; Kronenberg, 2006), which are also active in the fetal growth plate. These findings have also been extended to articular joints, where PTHrP is produced in response to a variety of stimuli, including mechanical loading, to support the maintenance of articular cartilage in a similar paracrine PTHrP/IHH signaling loop (Broadus *et al.*, 1988; Ohta *et al.*, 2015; Pelosi *et al.*, 2013).

Tooth Eruption

PTHrP is produced by the enamel organ and loss of PTHrP leads to a lack of postnatal tooth eruption, a classic result of aberrant osteoclastogenesis (Philbrick *et al.*, 1998). Replacement of PTHrP in the enamel epithelial cells allows tooth eruption. Further studies have revealed that PTHrP drives osteoclasts to resorb bone to form crypts as a site for tooth eruption, in a paracrine manner. Interestingly osteoclasts do not express the PTH receptor, which warrants further investigation to uncover other receptors through which PTHrP presumably acts (Boabaid *et al.*, 2004). However, since PTHrP is a potent inducer of receptor activator of nf kappa b ligand (RANKL) is likely the regulatory mechanism. Currently, the periodontal ligament (PDL) is recognized to play an important role in root resorption of human deciduous teeth by odontoclasts (osteoclast-like cells) (Fukushima *et al.*, 2005), mediated by increased RANKL expression by the PDL. In addition, PTHrP induces Jagged1 expression in PDL cells, leading to both osteo- and odontoclastogenesis (Nakao *et al.*, 2009). The combined effects of PTHrP promotes tooth and alveolar bone resorption although the precise signaling mechanism for PTHrP in this setting remains unknown.

Smooth Muscle Relaxation

Next to a causal role in HHM, perhaps the most informative effect of PTHrP is its potent role relaxing effects in vascular smooth muscle. It has been known for almost 100 years that the injection of parathyroid extract in a variety of species induces dose-dependent increases in blood flow, resulting in decreased blood pressure (Charbon *et al.*, 1968; Collip and Clark, 1925; Collip *et al.*, 1925; Schleiffer *et al.*, 1979). Once PTHrP was identified, it became clear that the many reports of PTH and PTH peptides impact on smooth muscle beds (Mok *et al.*, 1987; Pang *et al.*, 1984; Qian *et al.*, 1999) was not the normal function of PTH, but the result of a local physiological role for PTHrP (Maeda *et al.*, 1999; Sutliff *et al.*, 1999). PTHrP is produced in the smooth muscle of the uterus, bladder, stomach and arteries where it acts a potent muscle relaxant (Francis *et al.*, 2003; Nishikawa *et al.*, 2013). Thus, following vasoconstriction, increased PTHrP synthesis and secretion provides a mechanism to limit or reverse the effect and relax smooth muscle. This mechanism is demonstrated in studies where vasoconstriction induced by angiotensin II elicits a rapid and dramatic increase in PTHrP production (Pirola *et al.*, 1993), a mechanism that is preserved in angiotensin II-induced kidney injury (Lorenzo *et al.*, 2002).

Mammary Gland Development and Calcium Transport

Much of our understanding of the role of PTHrP in mammary gland development comes from seminal studies rescuing the neonatal lethality of PTHrP $-/-$ mice (Wysolmerski *et al.*, 1995). The genetic rescue attained by targeting PTHrP expression to cartilage using the collagen II promoter, permitted study of PTHrP function in other tissues of the null phenotype (Wysolmerski *et al.*, 1995). In the absence of PTHrP expression, there is failure in the development of breast ducts. PTHrP stimulates calcium transfer from bone to breast milk during lactation as well as mother-to-fetus placental calcium transport (Ardeshirpour *et al.*, 2006; Kovacs *et al.*, 2002). Although the role of PTHrP in driving placental calcium transport is unquestioned, some controversy still remains regarding the identity of the primary driver(s) of postnatal breast development, with both PTHrP (Boras-Granic *et al.*, 2011) and RANKL (Gonzalez-Suarez *et al.*, 2010) potential candidates. These particular actions of PTHrP helped provide the original rationale for the misnamed "vicious cycle" of bone metastasis (Guise *et al.*, 1996), driven by PTHrP alone which has beleaguered the field for more than 20 years (Johnson and Suva, 2017).

PTHrP in Cancer

Although originally identified as the product of lung cancer cells, the importance of PTHrP expression in malignancy is not confined solely to the scenario of HHM. In many cancers, including lung, prostate and breast, patients with metastatic bone disease display an increase in serum calcium that is largely driven by PTHrP (Powell *et al.*, 1991; Soki *et al.*, 2012). Indeed, PTHrP expression and the activation of osteoclastogenesis and bone resorption is important, but there is significant evidence supporting the idea that tumor expression of a plethora of factors, in addition to PTHrP, is able to activate bone resorption (Johnson and Suva, 2017). These tumor-derived molecules exert a variety of effects on other cells residing in the local bone marrow micro-environment that favor tumor establishment and progression in bone (Johnson and Suva, 2017). In recent years it has become apparent that the bone and bone marrow compartment provides not only a receptive growth factor-enriched environment for arriving tumor cells but also favorable niches in which circulating/disseminated tumor cells can survive (Makhoul *et al.*, 2016). It is clear that the numerous interactions between invading tumor cells, host bone cells and the immune system that facilitate tumor progression in bone (and elsewhere) are the result of processes above and beyond the action of any single molecule. With the ongoing and intensifying focus on the mechanisms driving cancer development and bone metastasis, the future of effective therapy may well reside in the increased understanding of the common traits of bone metastatic breast cancer cells (Johnson and Suva, 2017) and not a simple reliance on any single agent, even if it is PTHrP.

Conclusion

Since the discovery of PTHrP in 1987, there has been significant efforts focused on gaining a deeper understanding of the physiological roles of both PTHrP and PTH. The data clearly indicate that endocrine PTH and paracrine PTHrP regulate bone and calcium metabolism in a cooperative fashion, with their interactions at their most complex during early development. It is also apparent that duplication of the *PTHLH* gene eventually gave rise to the *PTH* gene. This information provides an evolutionary argument to explain the many duplicated genes on chromosomes 11 and 12 as well as the many common regulators of both molecules. It goes without saying that PTHrP is a fundamental and essential regulatory hormone, significantly conserved across evolution. It plays a crucial role in physiology and pathophysiology yet, the identity of the specific PTHrP peptides in the circulation of patients has been elusive. As such, what specific PTHrP peptides are presented to the human PTHR1, the primary signaling receptor for PTH and PTHrP, in vivo remain largely unknown. Many important questions regarding the role of PTHrP in disease remain unanswered. Indeed, the questions perhaps most critical are *What is the importance of PTHrP entry into cells either receptor-mediated or not? What is the contribution of PTHrP* versus *other tumor-derived factors in the progression of cancer*? These and other unanswered questions will only be answered by continued efforts to uncover the underlying biology of this important molecule. Thus, the search to identify the PTHrP peptides and their biological characterization in both normal physiology and disease is an expanding and ongoing scientific endeavor, from which the results are eagerly anticipated.

Physiology of Calcitonin and Its Therapeutic Uses☆

Sunil J Wimalawansa, Cardio Metabolic Institute, New Jersey, NJ, United States

Glossary

Bone mineral density (BMD) An indirect estimate of bone mineral content that is inversely correlated with the risk of future fractures. BMD is measured using dual energy X-ray absorptiometry (DXA) and expressed as the amount of mineralized tissue in the area scanned (g/cm^2). The BMD in the hip is considered the best predictor of hip fracture. The spine is a good location for assessing BMD changes early in menopause and monitoring the response to therapy; however, the location is subject to interference with artifacts such as osteophytes and extraskeletal calcification.

Calcitonin (CT) A 32-amino acid-polypeptide hormone produced in C cells of the thyroid gland. It is a potent inhibitor of osteoclastic bone resorption. It plays an important role in maintaining calcium homeostasis during the periods of calcium stress. Worldwide, synthetic forms of CTs, such as human, eel, and salmon, are used in the treatment of several bone-related diseases, including osteoporosis, Paget's disease, and hypercalcemia. Because of its analgesic effect, CT can be used to alleviate pain associated with acute, vertebral crush fracture syndrome.

Calcitonin gene-related peptide (CGRP) Calcitonin gene-related peptide, a 37-amino acid polypeptide that has neuromodulatory, nociception, and vasodilator functions.

Medullary thyroid carcinoma (MTC) Malignancy arising from C cells of the thyroid gland.

Osteoporosis A chronic, progressive skeletal disease, characterized by low bone mass and fragility and deterioration of bone microarchitecture; it increases fracture risks.

Introduction

C cells derive from the neural crest and migrate rostrally to become the parafollicular cells in humans and the ultimobranchial bodies in lower vertebrates. Calcitonin (CT) is synthesized by C cells located in the thyroid in mammals and in the ultimobranchial glands in lower vertebrate animals, secrete to the circulation, and act as a hormone throughout the body (Wimalawansa, 1989; Foster *et al.*, 1964). During this forward migration, C cells are expected to concentrate in the thyroid and ultimobranchial body (Wimalawansa, 1993a). However, some C cells may not progress to the thyroid and could be manifest in extrathyroidal tissues in the path way of its migration upwards (Wimalawansa and MacIntyre, 1991).

Calcitonin is an endogenous regulator of calcium homoeostasis, especially during "calcium stresses" protecting the skeleton, acting principally on bone. It also has a direct action on the kidneys and gastrointestinal secretory activity as well as direct and indirect effects on the central nervous system in modulating pain. Investigations into its central nervous system role suggest that, in addition to having an intrinsic analgesic effect, it may exert a modulator effect on other neuronal activities, directly at the sites at which it is known to be present, and indirectly, by a mechanism yet to be elucidated at other locations.

Currently, the principal indications for the therapeutic use of calcitonin are disorders involving hypercalcemia, Paget's disease (osteitis deformans), acute pancreatitis, high-bone turnover osteoporosis, pain associated with osteoporosis or bone metastases, and Sudeck's atrophy. Various types are in use—natural porcine calcitonin (pCT), synthetic human calcitonin (hCT), synthetic salmon calcitonin (sCT) (Salcatonin), and a synthetic eel calcitonin (eCT) analog (Elcatonin). One difficulty with treatment is that, until few years ago, injection was the only possible mode of administration. However, dosage forms using other routes are being developed, and a calcitonin nasal spray is now commercially available.

Structure–Activity of CT

The CT gene has been relatively conserved during evolution. Over the past five decades, 11 different sequences of CT, from 9 different species have been identified (**Table 1**). Six of the invariant amino acid residues in the CT molecules are clustered in the amino terminal, and two are at the carboxy terminal end of the molecule (Wimalawansa, 1989). Furthermore, as with several other bio-active hormones, all CT molecules, irrespective of the species, have a disulfide bridge in the N-terminus of the molecule, between the first and seventh amino acids making a ring structure, and have a proline-amide at the C-terminus of the molecule (Wimalawansa and MacIntyre, 1991). Intact disulfide bridge is essential for its receptor docking and thus, biological activity.

For its key biological activities, hypocalcemic effects, and inhibition of osteoclasts, the intact molecule—all 32 amino acids—is required (Wimalawansa and MacIntyre, 1991). Nevertheless, substitution of some of these amino acids [e.g., some structurally (chemically) modified sCT and eCT molecules] is known to enhance their biological potency by delaying degradation (i.e., increases its circulatory and biological half-lives) but may enhance allergenicity (Wimalawansa and MacIntyre, 1991).

Calcitonin is produced within the C cells as a precursor molecule. Before secretion into the circulation, however, it undergoes a number of posttranslational modifications, including cleavage, disulfide bridge formation, and amidation of C-terminal amino acid, via converting proline into proline-amide. These highly conserved structural modifications are essential for the full biological activity of CT (Wimalawansa, 1989). The mature form of biologically active $CT_{(1-32)}$ that is secreted into the circulation has a short half-life.

Release of CT From C Cells and Its Measurement in Blood

The release of CT from C cells is stimulated by divalent cations, such as Ca^{2+} and Mg^{2+}, as well as by glucagon, dibutyryl cyclic AMP (cAMP), theophyllin, gastrin, cholecystokinin, and alcohol. Following the interaction of CT with its cell-surface receptors, second messenger cAMP dose-dependently increases, leading to its biological activity. Suppression of bone-resorbing activity occurs secondary to the cell surface CT receptor mediated increase of intracellular cAMP (Wimalawansa and MacIntyre, 1991). This function can be mimicked in organ and cell cultures by exogenous administration of its analogs, such as dibutyryl cAMP.

Immunoreactive calcitonin (i-CT) levels in plasma (or serum) can be measured accurately and precisely using various immunoassays, such as antibody-derived immunoassays or chemiluminescense. Immunoreactive CT levels in the blood have been

Table 2 Conditions associated with calcitonin underproduction and overproduction

Conditions associated with calcitonin underproduction	*Conditions associated with calcitonin overproduction*
Osteoporosis	Calcitonin-secreting tumors

	Posttraumatic stress disorder
	Hepatic surgery
	Toxic shock syndromes
	Acute myocardial infarctions and strokes
	Lithium intoxication

used as a screening and diagnostic test in conditions with hypersecretion of CT. Premalignant and malignant disorders of C cells (i.e., medullary thyroid carcinoma or MTC) are such conditions (Wimalawansa and MacIntyre, 1991).

Table 2 illustrates causes of elevated and suppressed serum i-CT levels in humans. For diagnosis of latent disease (in those with familial diseases) and patients with MTC before clinical manifestation (as in the cases with some multiple endocrine neoplasia syndromes) or postoperative thyroidectomy to remove MTC tumors, a number of in vivo stimulation tests have been used, including injection of pentagastrin and infusion of calcium (Wimalawansa, 1989).

The first intraoperative immunoreactive (i-CT and i-PTH) assays were developed by the author in 1982, and data were presented at the U.K. Bone and Tooth Society meeting in London. Immunoreactive CT measurement was used as a mode to demonstrate the feasibility of measuring interoperative hormonal levels for the first time. The practical utility of these assays later was demonstrated in several series of patients undergoing thyroidectomy for MTC and removal of adenoma in those with primary hyperparathyroidism (Wimalawansa and Bailey, 1995; Wimalawansa, 1991). A number of conditions are associated with low- and high-serum i-CT levels (**Table 2**).

Efficacy of Commercially Available CT Formulations

Calcitonin can be administered parenteral or intranasal routes. Miacalcin nasal spray (Novartis Co.) is a synthetic salmon CT that is more potent than human CT, in part because of its relatively longer half-life in circulation (Wimalawansa, 1989). Its primary action is mediated through inhibition of bone resorption by osteoclasts. Each osteoclast is estimated to have >6 million CT receptors on its cell surface, so it is a prime target for CT actions; the direct action of CT on osteoclast cell suppression is bone resorbing activity.

Miacalcin nasal spray, 200 IU administered once daily, is an approved treatment for postmenopausal osteoporosis. Nevertheless, CT is the weakest among all the FDA-approved antiosteoporosis pharmaceutical agent in the market (Wimalawansa and Cooper, 1997). Thus, it usually is reserved for patients who refuse or cannot tolerate other antiosteoporosis agents, with the exception of patients experiencing acute bone pain (see later for more details). In general, CT nasal spray is recommended in conjunction with an oral calcium intake of 1200 mg (diet + supplements; or 500 mg of oral calcium supplement taken after supper) and 1000 IU of vitamin D to retard the rate of bone mass (Arantes *et al.*, 2016; Weaver *et al.*, 2016a,b).

In some countries, the only available form of CT is an injectable preparation. Injectable CT formulations, a dose of 40–60 IU administered three or four times per week, have been used for the prevention or treatment of osteoporosis; however, this regimen is less effective than all other antiosteoporosis agents. A smaller dose of injectable sCT, such as 10–40 IU three times per week, may have the same beneficial effect on bone and also decrease the chances of the onset of antibody-mediated resistance to CT; such a dose is also economical. Salmon CT has fewer side effects than does human CT with reference to nausea, but the main drawbacks with sCT are its high cost and loss of efficacy caused by the formation of neutralizing antibodies (Wimalawansa, 1993a).

Side effects are greatest with intravenous administration, less with intramuscular and subcutaneous injections, and least with intranasal administration (Wimalawansa, 1993a; Wimalawansa and Cooper, 1997). The recommended dosage of intranasal CT is 200 IU (one puff) per day, and its biological effects are similar to those seen with subcutaneous injections of 50 IU a day (Wimalawansa and Cooper, 1997).

Being a peptide, calcitonin preparations should be refrigerated and protected from direct sunlight to prevent degradation. Shelf lives of CT formulations are approximately 2 years. Nonhuman CTs can be allergenic, with roughly 50% of patients developing antibodies over 3–5 years (Wimalawansa, 1993a). However, this leads to actual clinical resistance (e.g., generation of neutralizing antibodies) in less than one-third of such patients (Wimalawansa, 1989; Wimalawansa and MacIntyre, 1991).

Adverse Reactions

Potentially Life-Threatening Effects

Calcitonin is a safe drug with few side effects (Wimalawansa, 1993a; Wimalawansa and Cooper, 1997). There are no potentially life-threatening adverse effects related to CT. There are no reports of deaths or long-term side effects attributable to CT use over 48 years of clinical experience (Wimalawansa, 1993a, 2004). The main drawback of CT therapy is its cost, local irritation when administered intranasally, and pain, flushing and nausea after parenteral administration (Wimalawansa and MacIntyre, 1991). Compared with other FDA-approved therapies, CT therapy has little effect on bone mineral density (BMD) and fracture reduction (Wimalawansa and Cooper, 1997).

The absorption of nasally administered CT is variable and poor, and a third of those who use nonhuman CT develop neutralizing antibodies in the long term; consequently CT further loses its efficacy (Wimalawansa, 1993a). In such patients, the dose may need to be increased by two- to threefold or more than the recommended doses to achieve the desired effects. Alternative routes of administration have been investigated, such as pulmonary, rectal, buccal [liposomes], depot preparations, and oral forms, but no real breakthrough has been reported yet.

Acute overdose

No overdoses have been reported with CT. Flushing and transient nausea and vomiting are the only key notable short-term symptoms.

Severe or irreversible adverse effects

Anaphylactic reactions have been reported rarely in association with nonhuman forms of CT therapy. As with other medications, such reactions are thought to be caused by allergenicity to excipients rather than the peptide itself.

Symptomatic adverse effects

CT generally is well tolerated. With injectable CT, the most commonly encountered adverse effects are pain at the injection site and cutaneous flushing that affects the upper body, particularly the face. This is noticed by at least a third of patients and probably occurs to a certain extent in most who take this medication. Depending on the route of administration, onset may be within seconds to minutes after administration and may last as long as 1 h.

Although nausea is common, it is mild. If it is troublesome, the problem may be alleviated by finding a suitable time for the administration of CT injections (e.g., avoiding immediately before or after a meal; taking it just before going to bed) or, for some patients, administering an antiemetic for the first few days. Increased urinary frequency (diuretic effect) occurs in as many as 10% of patients, but diarrhea is rare.

As many as one in four patients discontinue therapy because of adverse effects. Nevertheless, no major side effects have been observed with long-term treatment with CT (Wimalawansa, 1993a). With reference to the commonly used preparation of intranasal CT, the most common adverse effects are nasal irritation and runny nose. Rarely use of intranasal CT may be associated with nasal bleeding and exacerbation of asthma (Wimalawansa, 1993a).

Interference with clinical pathology tests

Calcitonin has no known technical or chemical interferences or interactions with laboratory tests.

Drug interaction

There are no known specific drug interactions between CT and other drugs (Wimalawansa, 1993a).

Physiological Roles of CT

Physiological concentrations of CT are likely to have a tonic effect to restrict osteoclastic bone resorption. The physiological role of CT is to maintain skeletal mass, particularly during periods of calcium stress, such as during the period of growth (infancy and

childhood), pregnancy, and lactation (Wimalawansa and Cooper, 1997). These physiological actions are geared to preserving the skeleton (Wimalawansa, 1989).

Maintaining Calcium Homeostasis During Calcium Stress

During pregnancy, calcium is retained by the fetus in increasing amounts irrespective of the calcium status of the mother (Wimalawansa and Cooper, 1997). During the period of lactation, calcium is secreted into milk against a concentration gradient (i.e., active calcium secretion into milk); this occurs at the expense of the maternal skeleton. Thus, if the maternal calcium and vitamin D intake are suboptimal, mothers who breast-feed for prolonged periods may experience significant bone loss during lactation. While testosterone and estrogen are stimulants for the synthesis of CT by C cells, i-CT levels in the blood are significantly lower in postmenopausal women and in older men.

This increased mobilization of calcium from the maternal skeleton occurs via the enhanced gene expression and secretion of parathyroid hormone-related protein [PTHrP; simulating fetal parathyroid hormone (with equivalent functions)] during these periods. In these situations, parallel increases in secretion of CT seem to exert a protective effect in preserving skeletal mineral content by preventing excessive osteoclast-mediated bone resorption that is stimulated by PTHrP. For example, the somewhat rare condition, pregnancy-associated osteoporosis is caused by a relative CT deficiency (suboptimal or lack, or secretion of biologically inactive form of CT from C cells) or severe maternal calcium deficiency, usually secondary to or malnutrition.

Antiinflammatory Properties

The antiinflammatory effect of CT is dose dependent. In acute experiments, CT seems to be involved in reducing the first-phase reactions of the inflammatory process as well as an antipyretic effects. In long-term experiments (e.g., Freund's adjuvant arthritis), sCT reduced edema and the response to pain stimuli, reduced the number and severity of intraarticular lesions, and consequently improved the range of movement in the joints affected by the arthritic process (Wimalawansa, 2009). In carrageenan edema, the potency of sCT is three times greater than that of hCT or pCT at equivalent doses of biological activity.

Calcitonin exhibits antiinflammatory properties in several models of acute and chronic inflammation in rats and mice arthritic models: (A) dextran, carrageenan, nystatin edema; yeast hyperthermia; and Freund's adjuvant arthritis in rats, and (B) histamine edema; acetic-acid-induced abdominal constriction; and pain secondary to inflammation in mice (Wimalawansa, 2009).

The antiinflammatory mechanisms of action probably involve a reduction in vascular permeability, reducing the synthesis and secretion of inflammatory cytokines such as interleukin-1 (e.g., IL-1), and stimulation of lysine decarboxylase activity, as with many nonsteroidal antiinflammatory agents (Wimalawansa, 2009). This effect seems to be independent of changes in tissue/cellular calcium levels.

In addition, a dose-dependent inhibition of prostaglandin and thromboxane biosynthesis is reported to occur as a result of partial inhibition of the activity of cyclooxygenase, the enzyme responsible for the first stage of arachidonic acid metabolism. However, such has not been established in humans. In patients with hypercalcemia of malignancy and those with increased prostaglandin levels, CT exerted antihypercalcemic and analgesic effects but had no effect on prostaglandin levels.

Cardiovascular Effects

Although CT is thought to have little or no effect on the cardiovascular system, a number of observations are of interest. Facial flushing is one of the most common side effects of CT (Wimalawansa, 2004, 2009). This side effect is usually associated with the peak plasma level of CT, especially in the early stages of treatment; it also frequently occurs after intravenous and intramuscular administration of CT, but it occurs less often after subcutaneous administration.

This phenomenon occurs after stress and emotions (e.g., when confronted with an embarrassment) and in postmenopausal women, as well as in pathological conditions, such as those with multiple paraneoplastic diseases (**Table 2**). The reaction is thought to result from a preferential release of various vasodilatory cytokine factors, including vasoactive intestinal polypeptide. In a rabbit model of immunoarteriosclerosis, long-term administration of pCT reduced the arteriosclerotic process; this was thought to be induced by inhibition of the formation of calcium deposits in arteries, which prevented calcium entry into vascular smooth muscle cells.

In rats, high doses of calcitonin (e.g., sCT, 100 IU/kg) have been reported to inhibit the arrhythmic response to aconitine and ouabain but not to adrenaline. Intravenous sCT produced a pressor response in rats after induction of hypotension by bleeding but was without effect in normotensive rats or those made hypotensive by other means. This pressor effect seems to be attenuated by chemical sympathectomy, which seems to indicate that CT may be potentiating the sympathetic outflow.

Calcitonin is a weak, vasoactive hormone. Its beneficial effect is evident in those with bone pain, sometimes called "migraine of the bone"; this is predominantly due to restoration of normal bone blood flow (i.e., reduction of blood flow to the affected bone, as in the case with Paget's disease of bone). In addition, CT's diuretic and natriuretic effects might be the result of an increase in renal blood flow, supporting the hypothesis that CT is a renal, vasoactive peptide (Wimalawansa, 2004, 2009).

Miscellaneous Effects

Less well-known effects of CT include certain interactions with other hormones, which seem to occur with high doses and thus appear to have no practical or therapeutic implications. Such effects include antistress, antiulcerogenic, and perhaps antiinflammatory properties. Other rare effects of CT include reduction in the synthesis of prostaglandin, inhibition of breast cancer cells in vitro, stimulation of plasminogen activator, and amylase secretion by salivary glands. Adverse effects, such as flushing and diarrhea in those with multiple endocrine neoplasia, metastatic bone syndrome, and after parenteral demonstration of CT, may be the result of excess episodic release of CT into the circulation.

Clinical Pharmacology

Considering the millions of cell surface CT receptors on each mature osteoclast, it is considered the main target for this hormone. Calcitonin directly suppresses the bone resorption activity of osteoclasts and thereby decreases bone resorption. When serum-ionized calcium increases, CT is secreted from the C cells into circulation (Wimalawansa, 1989). Osteoclast cells are highly sensitive to pico-gram (nmol) quantities of circulatory CT. This feedback mechanism will lead to rapid decreases in bone resorption, and thus the amount of calcium leaching from the skeletal surfaces into the circulation will decrease. This will bring back the tightly controlled ionized calcium levels toward the normal range (Wimalawansa and Cooper, 1997).

Osteoclasts are multinucleated giant cells (**Fig. 1**) and constantly create resorption cavities on bone surfaces (**Fig. 2**). In addition, when administered over several months, CT also reduces the number of osteoclasts by decreasing the rate of recruiting

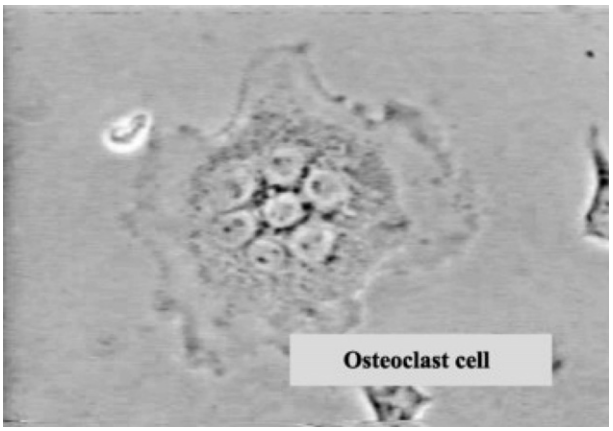

Fig. 1 An osteoclast cell: One of the largest cells in the body. Using their pseudopodia, osteoclasts move over the surface of bone, making resorption pits en route.

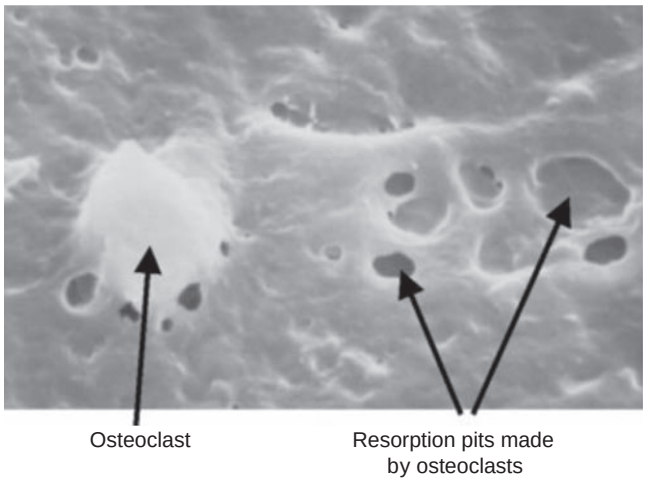

Fig. 2 Scanning electron micrograph of a bone slice illustrating an osteoclast and its movement path on the bone surface, showing a number of excavation pits made by the osteoclasts. These cells make a tight seal over the bone surface using its cell membrane pseudopodia, secreting acid and proteases to digest the underneath collagen matrix. Once a certain depth in a pit is formed, the osteoclast moves to a different site. Endogenous or exogenous CT will control this bone resorbing activity.

osteoclast progenitor cells into osteoclastic lineage (Wimalawansa, 1989). Considering its direct and potent actions in controlling osteoclasts, CT is a useful agent in patients with conditions associated with high bone turnover.

However, it is not clear whether the decrease in the number of osteoclasts is a consequence of an acute effect of CT on osteoclasts, an independent effect on its precursor cells, or both (Wimalawansa, 1991). Because of the rapid actions of CT on suppressing osteoclastic bone resorption, during the growth phase (also in growing rat models), administration of CT could lead to lowering of serum calcium levels and perhaps cause symptomatic hypocalcemia (Wimalawansa, 1989).

However, due to the relatively slow rate of bone turnover, a plasma calcium-lowering effect of CT is not seen in healthy adults. Therefore, the administration of CT has little or no effect on plasma calcium in ambulatory adults. Nevertheless, when bone turnover is high, as in children or in disease states (e.g., hypocalcemia of malignancy, Paget's disease, etc.), and during the first few days in those who are bedridden, the administration of CT may be followed by decreases in plasma calcium.

In the gastrointestinal system, several pharmacological actions of CT have been documented. CT enhances the intestinal secretion of sodium, potassium, chloride, and water, inhibits gastric acid secretion, and delays emptying (Wimalawansa, 1989). It also inhibits the secretion of several gastrointestinal regulatory peptides and hormones, including gastrin, insulin, pancreatic glucagon, motilin, pancreatic polypeptide, and gastric inhibitory peptide. Inhibitory effects on the secretion of pituitary hormones, including growth hormone, thyroid-stimulating hormone, and luteinizing hormone, also have been reported.

Pharmacokinetics

The most convenient and conventional analytical methods for i-CT are radioimmunoassay, chemiluminisum assays, and enzyme-linked immunosorbent assays. The usefulness of the radioimmunoassay and single site immunoassays are questionable because the testing may also detect inactive fragments and precursors. Pico-gram quantities of CT can be detected by such assays, and the biological activity of similar amounts can be detected using isolated osteoclast bioassay system (Wimalawansa, 1989, 1991).

Calcitonin is rapidly degraded by gastric contents and thus needs to be given parenterally. After CT is subcutaneously injected, the peak plasma concentrations are seen between 15 and 30 min. The plasma half-life of CT is short; approximately 4 min for porcine and hCT, but 15 min for sCT and eCT (Wimalawansa, 1989). Animal studies have shown that tissue uptake of labeled CT is greatest in the bone, liver, and kidney, but the volume of distribution varies widely. However, little information on plasma protein binding has been reported.

Loss of Efficacy of CT

The loss of efficacy following prolonged administration of CT is well known (Wimalawansa, 1989, 2009). This phenomenon is caused by a combination of downregulation of cell-surface CT receptors, development of neutralizing anti-CT antibodies (with nonhuman CTs), and enhanced catabolism of the synthetic peptide. This can be minimized with smaller doses of CT administered less frequently and switching nonhuman forms of CT to synthetic or genetically engineered human CT.

Primary Nonresponse

Some patients exhibit primary resistance to calcitonin, with little or no response to standard therapeutic doses. They may not have response or adverse effects even with high dosages of exogenously administered CT (e.g., 200–500 IU/day sCT or 2–5 mg/day hCT). Few people are in this category, but they may represent true nonresponders.

Secondary Resistance

Secondary resistance is having a good response at first but later failing to have a response or being unable to maintain the benefits of CT. Such secondary resistance occurs with all types of CTs, even in the absence of generating neutralizing antibodies. Those with Paget's disease treated for >3–4 years with CTs begin to experience a failure to respond to the therapy that is exhibited in serum alkaline phosphatase and urinary markers of bone turnover.

Another classic example is in those with malignancy-related hypercalcemia. Parenteral administration of 100–200 IU CT induced a decrease in blood calcium within the first 6–12 h. However, from day 3 or 4 onward, CT has little effect in maintaining serum calcium levels in those with hypercalcemia (i.e., lose its efficacy). The hypocalcemic response can be sustained in those patients only when CT is coadministered with a glucocorticoid or a potent, parenterally administered bisphosphonate or denosumab.

The Plateau Phenomenon

With prolonged administration of CT, some patients experience a "plateau" phenomenon. In many, this is attributable to downregulation of CT receptors and thus partial resistance to CT that requires higher dosages to obtain the same responses (e.g., reduction of serum alkaline phosphatase in those with active Paget's disease). However, it could also be caused by other complex

mechanisms, such as secondary hyperparathyroidism, development of anti-CT antibodies, and the development of a new lineage of calcitonin–nonresponsive osteoclasts (Wimalawansa, 1994a, 1997). Despite achieving a plateau phenomenon, for example, the inability to reduce serum bone-specific alkaline phosphates, some patients may continue to have symptomatic pain relief and histologic improvements.

Therapeutic Uses

Osteoporosis

Osteoporosis is a result of an imbalance between bone formation and resorption, resulting in a gradual, net loss of bone (decreased bone mass) and an associated loss of trabecular integrity and bone strength, which leads to fractures. CT has been used for more than four decades to treat various metabolic bone disorders that are characterized by accelerated bone resorption (Wimalawansa and Cooper, 1997; Chestnut, 1993). As in persons with postmenopausal osteoporosis, many persons with osteoporosis have increased bone turnover. While CT is a logical therapy for the prevention and treatment of osteoporosis (Wimalawansa, 1989, 1991), its effect in improving bone mass, bone strength, and fracture prevention is not striking (MacIntyre *et al.*, 1988; Toth *et al.*, 2005; Szucs *et al.*, 1992; Pontiroli *et al.*, 1991).

One of the first clinical studies suggesting the antifracture efficacy of nasally administered sCT was published by Overgaard and colleagues (Overgaard, 1994; Overgaard *et al.*, 1993; Overgaard and Christiansen, 1991); another study reported the results of analysis of rectally administered sCT (Overgaard *et al.*, 1992). The investigators studied the effects of intranasal sCT in a 2-year, double-blind, placebo-controlled trial of women 68–72 years randomized to receive 50, 100, or 200 IU CT or placebo daily. Among 162 women completing the study, spinal BMD increased by 1% (95% CI, 0.1–1.5) in the placebo group and 3% (95% CI, 1.8–4.2) in the group receiving 200 IU CT.

As with bisphosphonates, CT seems effective in patients with high bone turnover with little or no effects in those with normal bone turnover (Chestnut, 1993). Like other antiresorptive therapies, the administration of CT eventually decreases the bone formation phase, thereby producing a new, lower rate of bone turnover. Consequently, increases in bone mass are seen only during the first 2–3 years of treatment. Thereafter, a plateauing effect of BMD is observed. However, it may be possible to minimize this by administration of CT in a cyclical fashion (e.g., nasal CT, 200 IU/day, in cycles of 6 months). Although CT prevents bone loss associated with corticosteroid treatment, it is unclear how CT and other similar antiresorptive agents reduce bone loss because corticosteroids are thought to depress bone formation rather than stimulate bone resorption.

Although CT has been used for preventing bone loss and decreasing osteoporosis-associated fractures, its efficacy is much less than that of hormone replacement therapy, selective estrogen receptor modulator (SERMs) bisphosphonates, denosumab, and teriparatide. A reduction in the rate of bone loss, rather than a sustained increase in bone mass, is expected as the therapeutic goal with CTs. Nevertheless, for those who cannot tolerate or fail to have response to standard doses of Food and Drug Administration (FDA)-approved therapies, CT could be considered as an alternative therapy for the treatment of osteoporosis, especially when the potent agents are not appropriate, too costly, or cannot be tolerated because of adverse effects. CT is also an alternative therapy for women who cannot tolerate estrogen therapy for social, religious, or medical reasons (Pontiroli *et al.*, 1991).

Since the efficacy of CT is $<30\%$ that of other FDA-approved antiosteoporosis agents. Therefore, other FDA-approved drugs are recommended for the treatment of osteoporosis as the first line of treatment. CT also has been used for the treatment of osteoporosis in men (Wimalawansa and Cooper, 1997; Toth *et al.*, 2005; Szucs *et al.*, 1992).

Although its efficacy is questionable, its prolonged administration causes downregulation of receptors and/or the development of neutralizing antiCT antibodies (with nonhuman CT) and increased catabolism of CT (Wimalawansa, 1989). Administering small doses of CT less frequently and switching salmon or eel CT to a synthetic or genetically engineered human CT can minimize these problems.

Doses of injectable CT as small as 60 IU per week have been shown to have an effect in postmenopausal bone loss (Wimalawansa and Cooper, 1997; MacIntyre *et al.*, 1988). Calcitonin is more widely used in Southern Europe (e.g., Italy) and Japan than anywhere else in the world. In a small, 2-year dose-finding study using intranasal CT in postmenopausal women with osteoporosis, spinal BMD increased by 2% per year (MacIntyre *et al.*, 1988). There was no demonstrable effect on other skeletal sites, but compared with placebo a decreased vertebral fracture rate was observed.

Like other antiresorptive therapies, CT decreases the remodeling phase, thereby achieving a new lower rate of bone turnover (Wimalawansa and Cooper, 1997). Consequently, increases in bone densities generally are seen only during the first 2–3 years of treatment with CTs (Pontiroli *et al.*, 1985, 1989). At least in theory, it may be possible to overcome this by administering CT in a cyclical fashion.

Clinical studies

The Prevent Recurrence of Osteoporotic Fractures (PROOF) study is the only multicenter, randomized, controlled clinical trial (RCT) that demonstrates a fracture reduction with intranasal administered CT (Toth *et al.*, 2005; Szucs *et al.*, 1992; Chesnut *et al.*, 2000; Cummings and Chapurlat, 2000). It was a 5-year, multicenter, double-blind randomized study designed to test the efficacy of Miacalcin nasal spray. The objective was to test whether CT reduces the risk of new vertebral fractures in postmenopausal women with established osteoporosis (Chesnut *et al.*, 2008).

A total of 1255 women with at least one but not more than five vertebral compression fractures were randomized to receive Miacalcin nasal spray (doses of 100, 200, or 400 IU), or a placebo. All subjects received daily supplements of 1000 mg of calcium plus 400 IU of vitamin D (Chesnut *et al.*, 2000, 2008; Chestnut, 1996). **Fig. 3** illustrates the efficacy of sCT nasal spray on vertebral fracture reduction.

The results demonstrated that Miacalcin nasal spray, at the FDA-recommended dose of 200 IU daily, reduced the risk of new vertebral fractures as compared with placebo, but the doses of 100 and 400 IU did not. However, the study failed to demonstrate reduction of hip or nonvertebral fractures. The study also showed marginal reduction of a biochemical marker of bone resorption in the serum type I collagen cross-linked telopeptide (Silverman, 2003). Except for an increased incidence of rhinitis, the frequency of adverse events in all treatment groups was comparable to placebo.

Other studies that used CT as the interventional agent had small increments in spinal BMD and marginal antifracture efficacy (Chestnut, 1993; MacIntyre *et al.*, 1988). These studies using CT reported fewer fractures and consistently were underpowered to detect a statistical difference of fracture reduction. Synthetic salmon, human, and eel CTs have also been tested as a therapy for osteoporosis, but no conclusive human data exist on fracture reduction (Stevenson *et al.*, 1981). However, except for the PROOF study, no RCT data demonstrate a reduction of any type of fractures with CT.

There is some evidence to suggest that CT may prevent glucocorticoid-induced bone loss, but the efficacy is considerably less than that of bisphosphonates (Ezzat, 2010; Nakamuta *et al.*, 1996; Nishioka *et al.*, 1991; Roux and Dougados, 2002). However, in glucocorticoid-induced osteoporosis, it is unclear how CT and other antiresorptive agents reduce bone loss given that glucocorticoids predominantly suppress bone formation rather than stimulate bone resorption (Ezzat, 2010; Fudman, 1997). It is plausible that this is attributable to the effect of enhanced osteoclast apoptosis with CT, as demonstrated with amino-containing bisphosphonates.

In patients with established osteoporosis, CT may stabilize or modestly increase indexes of cortical and trabecular bone and total body calcium (MacIntyre *et al.*, 1988; Wimalawansa *et al.*, 1988). The increments in bone density seen with CT are small, appear to be transient, and likely are to be attributable to reduction in bone resorption with bone formation remaining unaffected until the remodeling spaces are filled. However, the reason for the reduction of fracture rate in light of the small increase in BMD is not yet understood.

In addition to their well-known effects on decreasing bone turnover, antiresorptive therapies such as estrogen, bisphosphonates, denosumab, and CT may have a positive effect on osteoblasts and osteocytes, enhancement of osteoclast apoptosis, and preservation of the microarchitecture of bone. This may result in a disproportionate reduction in fracture rates in comparison with a no or a small increase in true BMD.

New approach to reduce fracture rates

To improve the bone mass and strength and reduce fracture risks, it is logical to use an anabolic agent such as teriparatide first (once FDA approved, other bone-anabolic or biologics agent can also be used) and stabilize or maintain the gains achieved using a sequential use of an antiresorptive agent for a suitable duration (MacIntyre *et al.*, 1988). Such an approach could maximize the potential increase of the bone mass, strength, and microarchitecture, and the maintenance of such improvement with an antiresorptive agent for a few years should markedly reduce fracture rate. Nevertheless, this logical approach is not yet practiced in clinical setups.

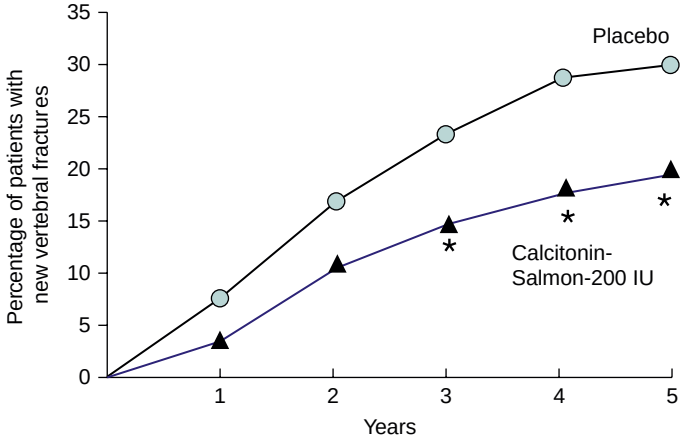

Fig. 3 Effects of intranasally administered sCT on new occurrence of vertebral fracture reduction. The cumulative percentages of subjects with vertebral fractures are indicated ($*P < 0.05$) Adapted from Chestnut III, C.H., Silverman, S., Andriano, K., *et al.*, (2000). A randomized trial of nasal spray salmon calcitonin in postmenopausal women with established osteoporosis: The prevent recurrence of osteoporotic fractures study. *The American Journal of Medicine* **109**, 267–276; Chestnut, C., 3rd, (1996). Postmenopausal osteoporosis: an overview. *American Journal of Therapeutics* **3**(10), p. 715–719.

Paget's Disease of Bone

Over the past few decades, CT has been used successfully as a treatment for Paget's disease of bone (Wimalawansa and Cooper, 1997). Several types of CT have been used for this purpose, but salmon CT is the most commonly used (Greenberg *et al.*, 1974; Woodhouse *et al.*, 1971). Paget's disease is a localized bone disease that is characterized by high bone turnover, so it is not surprising that CT is effective in decreasing the bone turnover in those with Paget's disease (Wimalawansa and MacIntyre, 1991). Calcitonin is particularly useful in this disease because it inhibits osteoclast activity and decreases the new osteoclast recruitment (Wimalawansa, 1989).

Inhibition of osteoclastic activity explains the short-term (or acute) effects of CT in reducing bone pain and deceasing markers of bone resorption, whereas long-term responses presumably are related to the decreased osteoclast numbers. In addition, CT alleviates Paget's-associated bone pain and improves clinical, biochemical, radiological, and histologic features of the disease. The major indication for CT therapy in Paget's disease is to control bone pain (Wimalawansa, 1991; Wimalawansa and Cooper, 1997).

One of the mechanisms by which CT relieves bone pain rapidly is via reducing the associated, excessive blood flow in Pagetic bones (Wimalawansa, 1989, 2009). It also alleviates some of the neurological signs and symptoms, such as the early spinal cord compression that is associated with Paget's disease (Wimalawansa and Cooper, 1997). Whether this is because of decreased local swelling or reduced inflammation is unknown. In general, treatment with CT decreases the biochemical markers of bone turnover, such as serum (bone-specific) alkaline phosphatase and N-telopeptide levels, by approximately 40%.

However, unlike potent agents such as bisphosphonates and denosumab, CT does not reduce the bone turnover markers (e.g., serum bone-specific alkaline phosphatase levels) into the normal range. Moreover, CT therapy is stopped, the levels go up again within a short period (Wimalawansa, 1989). Thus, the effectiveness of CT depends on its continued daily use; discontinuation of the drug rapidly reactivates the disease process, including the symptomatology. There are no major serious adverse effects associated with this treatment wit CT in patients with Paget's disease or any other disease.

Hypercalcemia

In patients with hypercalcemia caused by malignancy and hypercalcemic emergencies, CT produces a rapid reduction in blood calcium. However, its efficacy in controlling serum calcium levels lasts only 3–4 days (Cooper *et al.*, 1997; Wimalawansa, 1993b). A decrease in plasma calcium of 0.5–1.0 mmol/L is expected within 6–24 h of commencing parenteral CT therapy. However, in the absence of additional therapy, such as the concomitant administration of a bisphosphonate such as pamidronate or zoledronic acid, hypercalcemia recurs (Wimalawansa, 1997; Cooper *et al.*, 1997; Wimalawansa, 1995a).

Calcitonin is most likely to be effective in cases of hypercalcemia in which a generalized increase in bone resorption is a prominent feature. The calciuric effect of CT may also play a small role in reducing the increased plasma calcium (Cooper *et al.*, 1997). In patients with hypercalcemia, CT can be used to obtain an immediate calcium-lowering effect (Wimalawansa, 1994b,c, 1995a,b). However, for longer-term maintenance, the concomitant administration of intravenous bisphosphonate (e.g., pamidronate, zolendronate, etc.) is essential (Wimalawansa, 1993b, 1995a, 1997). In addition to controlling hypercalcemia, the latter agents also have an effect on controlling metastatic osteolysis.

Analgesic Action of CT

Use of CT to Control Bone Pain

Although the efficacy of CT in fracture reduction is a matter of controversy, there is convincing evidence for the efficacy of CT as an analgesic (Chiarini *et al.*, 1978) in patients with acute vertebral osteoporotic fractures (e.g., crush fracture syndrome) (Wimalawansa and Cooper, 1997). Because of its specific analgesic effect, CT can be useful as an adjunct therapy in the care of patients with acute osteoporotic fractures (Wimalawansa, 2009; Silverman and Azria, 2002).

Painful episodes in patients with osteoporosis are not caused by the osteoporotic process itself but by fractures. The presentation of such pain is acute, continuous, exacerbated by movement and ameliorated with rest. The pain can be severe and will ease with bed rest. Nevertheless, it is necessary to mobilize such patients as early as possible to avoid immobilization-associated complications, such as deep venous thrombosis (Wimalawansa, 2009). The short-term use of high-dose CT could assist pain relief in those with acute crush fracture syndrome and aid the early mobilization of such patients without resorting to opioid therapy (Wimalawansa, 2009).

In one double-blind placebo-controlled RCT, $>50\%$ of patients receiving daily nasal sprays of 200 IU CT had a significant response in mobility and functional capacity, whereas patients receiving placebo nasal spray experienced only a moderate response with respect to the same parameters (Wimalawansa, 2009). In addition, the analgesic actions of intranasal CT are rapid and lead to a meaningful reduction of pain in those with crush fracture syndrome (Wimalawansa, 2009).

A double-blind, double-placebo RCT examined for a period of 4 weeks the analgesic effect of daily administration of 200 IU intranasal CT, 100 IU CT administered intramuscularly, and a placebo ($n = 28$/group) in women with painful postmenopausal osteoporotic fractures. In the 24 patients receiving intranasal CT who completed the trial, a statistically significant reduction in pain score was measured by a visual analog scale by week two (Pontiroli *et al.*, 1985, 1989). For patients who received intramuscular CT and those who received a placebo, a significant decrease of pain scores was observed by 4 weeks (Wimalawansa, 2009).

The mechanism of the pain associated with acute fractures is different from that of the pain associated with fractures that happened a while ago. The most efficacious time to administer intranasal CT is immediately after a fracture (Wimalawansa, 2009). A significant pain reduction is observed within the first few hours and lasts for 4–5 days (Wimalawansa, 2009) (**Fig. 4**). The analgesic effect of CT diminishes over time as a consequence of tolerance or the spontaneous improvement that usually occurs over 4 weeks with most vertebral compression and wedge fractures.

Metastatic Bone Pain

Calcitonin has been used successfully for the treatment of bone pain in patients with metastatic bone disease. Analgesic effect has been observed in three-quarters of such patients. CT has also been used in the treatment of intractable pain from advanced malignancy, especially when injected into the subarachnoid space. In a series of 12 cancer patients, intrathecal injection of CT, together with chemotherapeutic agents, enabled reduction of opioid analgesic requirement by 80% (personal observation). It is likely that the main site of this analgesic action is in the hypothalamic "pain center," the central nervous system (Wimalawansa and Cooper, 1997; Wimalawansa, 1995a).

Although the mechanism of CT's analgesic action is not fully understood, it has been postulated to occur through direct action at the hypothalamic level and indirect action through interference with neurotransmitters such as serotonin and prostaglandin, independent of endorphin, and a peripheral action mediated via alteration of blood flow to the affected regions and inhibition of the factors such as inflammatory cytokines (Wimalawansa, 2009).

However, there have been no placebo-controlled studies conducted using CT in patients with metastatic bone pain. Jelic and colleagues used CT to treat 16 patients with pain caused by diffuse osteolytic or osteoblastic–osteolytic metastases who had not obtained satisfactory pain relief with opiate-type analgesics (Jelic *et al.*, 1995). Most of the patients on CT experienced a decrease in pain with an accompanying decreased intake of opiate-type analgesics (Jelic *et al.*, 1995; Kovcin *et al.*, 1994). Of the 16 patients, 2 were able to discontinue opiate intake completely, whereas 3 had no pain relief at all (Wimalawansa, 2009). Authors concluded that CT may be useful in relieving metastatic bone pain in some patients who experience resistance to opiate-type analgesics.

Pain Relief

Because of its effective pain-relief properties (analgesic effects), CT can be used as a treatment particularly for those with acute onset of back pain caused by vertebral crush fractures (Silverman and Azria, 2002). However, the use of the recommended,

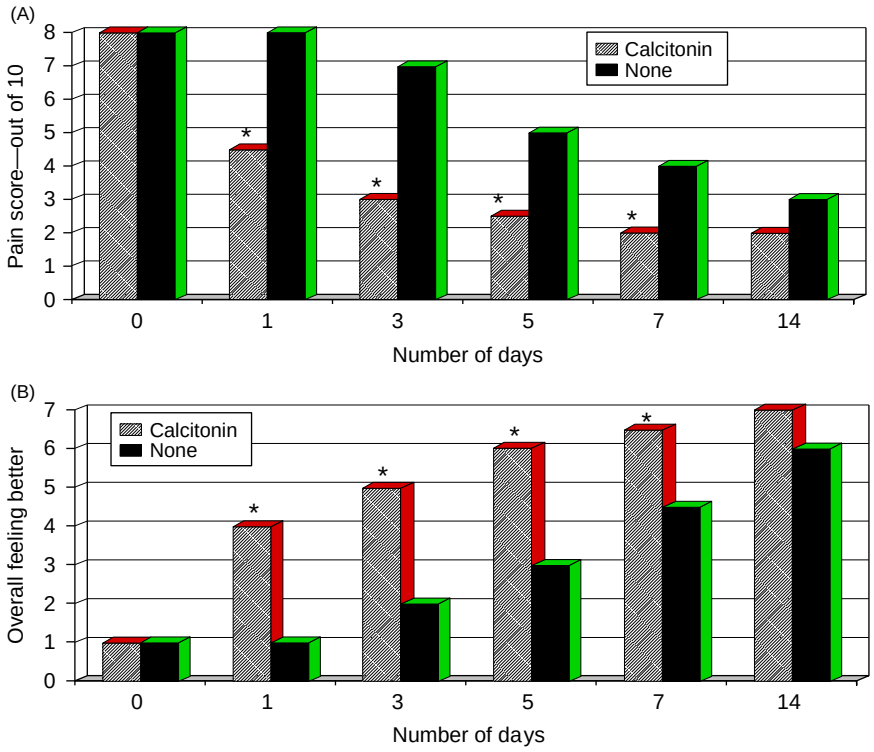

Fig. 4 (A) Effects of nasally administered sCT in reduction of pain after acute vertebral crush fractures ($n = 12$ per group; $^*P < 0.05$). (B) Overall feeling/well-being of patients after the use of nasally administered sCT after acute vertebral crush fractures ($n = 12$; $^*P < 0.05$). The data presented are inversely related to relief of pain after the administration of salmon calcitonin (Wimalawansa, 2009).

standard dosage of 200 IU CT administered intranasally daily does not relieve bone pain or pain associated with any other disorder. For this purpose, higher doses of intranasal CT, such as 800–1000 IU (i.e., 4–5 puffs), administered into alternative nostrils over a 10-min period is required (Wimalawansa, 2009).

As with its calcium-lowering effects in persons with hypercalcemia, the pain relief wears off after 3–4 days of use of high-dose intranasal CT. The goal is to reduce the pain quickly so that the patient can be mobilized out of bed, which prevents other complications, such as deep venous thrombosis. Therefore, such a condition requires a prescription of only one vial of Miacalcin (Wimalawansa and Cooper, 1997) (there is no reason to provide repeat prescriptions for this purpose) (Wimalawansa, 2009).

Continuation of CT beyond a few days is not beneficial because the agent loses its pain-relieving efficacy. The treatment regimen should change, and other reasons for continuation of pain when pain fails to subside should be sought. The principle of this approach is to mobilize patients to prevent inactivity-associated complications without resorting to using potent opioid analgesics that have additional adverse effects.

Miacalcin (CT) nasal spray is not approved for use as an "analgesic" by the FDA. Nevertheless, its analgesic actions of CT have been documented with the injectable forms and the nasal form (Wimalawansa and Cooper, 1997; Wimalawansa, 2009). The reduction in pain occurs significantly earlier than any demonstrated improvement in skeletal dynamics, and in some instances no objective improvement in the underlying skeletal condition can be observed.

Migraine

Migraine also reportedly responds to CT, but results are variable and the mechanism of action is unclear. However, CT has effects on vasoconstriction of certain atrial beds, which may indirectly help those experiencing migraine attacks. Daily intramuscular doses of 100 IU were significantly more effective than placebo in reducing the frequency, intensity, and duration of migraine (Brady *et al.*, 1991; Gennari *et al.*, 1986; Micieli *et al.*, 1988). Because of relatively less adverse effects, salmon CT has been investigated as a therapeutic agent for the treatment of migraine (Gennari *et al.*, 1986; Micieli *et al.*, 1988; Ustdal *et al.*, 1989).

However, administration of CT via injections is associated with a variety of gastrointestinal adverse effects, such as nausea, which in fact may worsen the situation. Thus, CT could aggravate certain migraine-associated problems, such as nausea. Salmon CT has also been administered prophylactically via the nasal route and shown to be effective in preventing attacks of migraine, and its actions are thought to be attributable to changes in local cytokines and hormones, such as ACTH, glucocorticoids, and endorphin (Ustdal *et al.*, 1989). However, disease-specific agents such as triptans have superseded therapies with CT.

Arthritis

There have been no placebo-controlled studies conducted using CT in patients with rheumatoid or osteoarthritis (Chiarini *et al.*, 1978; Manicourt *et al.*, 2005). However, anecdotal and corroborative evidence exists suggesting that pain and inflammation associated with various arthopathies may respond favorably to CT, at least partially (Manicourt *et al.*, 2005). An open-label study of 70 patients with osteoarthritis reported a decrease in spontaneous pain in those who were treated with 100 IU CT for a 40-day period (Dainotto *et al.*, 1985).

Eel- and salmon-CT have been shown to reduce inflammation and pain in persons with rheumatoid arthritis (Aida, 1991; Aida *et al.*, 1993, 1994). The mechanisms of action of these beneficial effects are thought to be mediated via regulation of immune responses through mononuclear cells/monocyte functions, and reduction of synthesis and release of immunoglobulins, and inflammatory cytokines, such as tumor necrosis factor-α and interleukin-1 (IL-1) (Aida *et al.*, 1993, 1994; Ide and Suzuki, 2001).

A small controlled clinical studies have demonstrated an increase of axial BMD on those with rheumatoid arthritis after treatment with calcitonin (Kotaniemi *et al.*, 1996). Others have shown a possible synergy between calcitonin and active forms and analogs of vitamin D (Dottori *et al.*, 1982), and improved bone histomorphometric findings, such as reduction of resorption surface of trabecular bone (Kroger *et al.*, 1992). In addition, a randomized control clinical study (Sileghem *et al.*, 1992) and an observation study (Siamopoulou *et al.*, 2001) reported possible beneficial effects of intranasal sCT on reducing bone resorption and pain relief in adults with rheumatoid and children with juvenile rheumatoid arthritis. However, not all studies agree with such benefits in persons with arthritis (Stuart *et al.*, 1982).

Other Clinical Use of CT

Calcitonin has also been used successfully in the treatment of Sudeck's atrophy (Wimalawansa and Cooper, 1997; Wimalawansa, 2009; Dainotto *et al.*, 1985). Clinical experience suggests that the administration of CT shortens the duration of pain and healing of fractures, but this has not been confirmed. CT can be administered intrathecally, allowing a decrease in the (e.g., postoperative) requirements of narcotics in patients undergoing surgical procedures, such as hip replacement, under spinal anesthesia, and in patients with metastatic bone disease.

Conclusion

The 32-amino acid polypeptide hormone CT is a potent inhibitor of the osteoclast cells: a key mechanism that has been exploited with drugs for the treatment of bone disease with increased bone turnover. Therapy with CT is particularly effective in controlling osteoclastic bone resorption in disorders characterized by high bone turnover, including Paget's disease of bone, osteoporosis, Sudeck's atrophy, and statuses of hypercalcemia.

However, the efficacy of CT in the treatment of osteoporosis is significantly less than all other FDA-approved antiosteoporosis therapies. However, CT can be used effectively to control bone pain (e.g., crush fracture syndrome) that requires the use of higher doses (e.g., daily use of 800–1000 IU intranasal for 2–5 days). This allows for early mobilization of patients and thus prevents immobilization-associated complications; it also enables decreases (or elimination) in the use of potent analgesia. The efficacy on pain relief and the reduction of raised serum calcium levels do not last >3–4 days of continuous use.

Hypoparathyroidism and Other Causes of Hypocalcemia

Bart L Clarke, Mayo Clinic, Rochester, MN, United States

Hypoparathyroidism

Grant *et al.* (2010) reported that postsurgical hypoparathyroidism is the cause of hypoparathyroidism in approximately 75% of adults with this disorder. Anterior neck surgery for thyroid or parathyroid disease is the usual explanation for postsurgical hypoparathyroidism. During anterior neck surgery, parathyroid glands may be damaged by compromised blood supply resulting from exploration of the neck structures, or their unexpected excision.

Patients usually develop postsurgical hypoparathyroidism manifest by hypocalcemia within a day or two after surgery. Postsurgical hypoparathyroidism is most often transient. Various hospitals have reported widely ranging rates of symptomatic hypoparathyroidism from 1% to 46% after thyroid cancer surgery (e.g., Lee *et al.*, 2010). Permanent postsurgical hypoparathyroidism only occurs in 1%–2% of cases on average, with a strong correlation with expertise of the surgeon.

Studies have shown that risk of postthyroidectomy hypoparathyroidism varies with staging of the thyroid cancer, and is dependent on extent of surgery. Roughly 50% of cases of stage IV thyroid cancer develop postsurgical hypoparathyroidism. Edafe *et al.* (2014) showed that patients undergoing thyroidectomy for autoimmune hyperthyroidism (Graves' disease) commonly experience both short- and long-term hypoparathyroidism. Most surgeries that lead to postsurgical hypoparathyroidism are done for thyroid or head or neck cancers, but the condition can also occur after surgery for benign causes such as goiter or primary hyperparathyroidism. Surgeons may use day 1 postoperative calcium and parathyroid hormone levels to assess patients for the likelihood of developing permanent hypocalcemia (e.g., Noordzij *et al.*, 2007).

Hypo- or hypermagnesemia may cause the appearance of biochemical hypoparathyroidism in patients who have not had neck surgery (Rude *et al.*, 1976; Cholst *et al.*, 1984). Typically low serum magnesium does not cause hypoparathyroidism unless it is reduced to 1.0 mg/dL or less. Wong *et al.* (1983) showed that as many as 11% of hospitalized patients may have hypomagnesemia, while as many as 9% may have hypermagnesemia. Hypomagnesemia commonly develops with gastrointestinal losses associated with vomiting due to increased alcohol intake, chronic diarrhea, steatorrhea, malabsorption, or intestinal resection. Rude (1997) summarized that hypomagnesemia also commonly develops due to renal tubular losses due to medications such as furosemide, aminoglycosides, cisplatin, cyclosporin, amphotericin B, pentamidine, tacrolimus, or proton pump inhibitors. Some patients have rare genetic disorders such as Gitelman syndrome causing renal tubular loss of magnesium and other analytes. Intensive care unit patients with serious illness often develop hypocalcemia due to multifactorial hypomagnesemia. Rude (2009) also described hypermagnesemia as not being unusual in the setting of late-stage chronic kidney disease in association with treatment with magnesium antacids, enemas, or infusions, or tocolytic therapy during labor, or acute renal failure due to rhabdomyolysis or tumor lysis syndrome.

Primary intestinal hypomagnesemia is a rare genetic cause of magnesium malabsorption leading to hypomagnesemia shortly after birth. This condition leads to deficient intestinal magnesium absorption, but some patients may also have defects in renal magnesium reabsorption. Affected individuals may develop tetany, muscle spasms, or seizures due to both hypomagnesemia and hypocalcemia, with biochemical evidence of hypoparathyroidism. Lifelong high oral magnesium supplementation is able to decrease symptoms and normalize serum calcium. This genetic disorder has been found to be due to mutations in the *TRMP6* gene on chromosome 9 (Schlingmann *et al.*, 2005; Voets *et al.*, 2004). The TRMP6 protein is a member of the transient receptor membrane potential channel family that associates with TRPM7, a calcium- and magnesium-permeable cation channel.

Other nonsurgical causes of hypoparathyroidism are less common. Toumba *et al.* (2007) showed that thalassemia major requiring multiple blood transfusions may lead to iron deposition in and destruction of the parathyroid glands, as may hemochromatosis on occasion. Carpenter *et al.* (1983) showed that Wilson's disease causing copper deposition in the parathyroid glands may sometimes result in hypoparathyroidism.

Goddard (1990) reported that metastases to the parathyroid glands may cause gland destruction leading to hypoparathyroidism in rare circumstances. External beam radiation therapy used to treat malignant disease in the neck may rarely cause hypoparathyroidism due to destruction of the parathyroid glands. Pauwels *et al.* (2000) demonstrated that high-dose radioactive iodine therapy for Graves' disease may also rarely cause hypoparathyroidism.

Inherited causes of hypoparathyroidism include autosomal dominant hypocalcemia (ADH), in which the CaSR is affected by an activating mutation, as shown by Egbuna and Brown (2008). This gain-of-function mutation alters the threshold for parathyroid hormone secretion by parathyroid cells in response to ambient ionized calcium, resulting in decreased or inappropriately normal PTH secretion despite hypocalcemia. Most of the activating mutations reported so far occur in the extracellular amino-terminal or transmembrane domains of the receptor. Mutant receptors evaluated so far show both increased sensitivity to extracellular calcium and increased signal-transduction capacity.

Since these activating mutations are also expressed in the CaSR on proximal renal tubular cells in the thick ascending limb of Henle, absolute or relatively increased 24-h urinary calcium is characteristic of the disorder. Most patients with ADH are

asymptomatic and have mild hypocalcemia with significant hypercalciuria. Occasionally patients may develop moderate or severe hypocalcemia. This form of CaSR-mediated hypoparathyroidism appears to cause increased risk of kidney stones compared to other forms of hypoparathyroidism. In one series by Lienhardt *et al.* (2001), almost half of the patients with ADH had kidney stones associated with their hypercalciuria. Because of the severity of hypercalciuria in this disorder, calcium supplements must be carefully monitored to prevent exacerbation of kidney stone risk.

Vargas-Poussou *et al.* (2002) demonstrated that occasional patients have CaSR activating mutations associated with a Bartter-like syndrome, suggesting that the CaSR also plays a role in sodium chloride regulation. These patients usually develop hypocalcemia, hypercalciuria, and kidney stones, associated with hypokalemic alkalosis, renal tubular sodium loss that may cause low blood pressure, hyperreninemic hyperaldosteronism, and increased urinary prostaglandin excretion.

Extensive burns occasionally lead to upregulation of the CaSR in affected tissues, resulting in lower than usual serum calcium and suppression of PTH secretion, resulting in hypocalcemia and hypoparathyroidism.

The second most common form of hypoparathyroidism after postsurgical hypoparathyroidism is thought to be autoimmune hypoparathyroidism. Michels and Gottlieb (2010) described that isolated antibody-mediated destruction of the parathyroid glands may occur, resulting in idiopathic hypoparathyroidism, or autoimmune destruction may occur in association with other autoimmune conditions as part of the autosomal recessive autoimmune polyglandular endocrinopathy candidiasis ectodermal dystrophy (APECED) syndrome. Shikama *et al.* (2009) noted that mutations in the autoimmune regulator gene *AIRE* lead to this syndrome, causing abnormal thymic expression of tissue self-antigens, generation of auto-reactive T cells, and ultimate loss of central tolerance to specific self-antigens, and the consequent development of multiple autoimmune disorders. CaSR antibodies have been identified in some individuals with idiopathic hypoparathyroidism or the APECED syndrome (Blizzard *et al.*, 1966; Li *et al.*, 1996), but Brown (2009) indicated that it is not yet clear whether these autoantibodies are causative or markers of disease. Idiopathic autoimmune hypoparathyroidism most often occurs in teen-aged youth or young adulthood, but it may occur at any age. APECED usually presents in childhood, and is characterized by hypoparathyroidism, chronic mucocutaneous candidiasis, and Addison's disease, in addition to variable expression of endocrine and other autoimmune diseases. Variation in the clinical phenotype of individuals with identical mutations in the *AIRE* gene is incompletely understood, but this observation suggests that other genetic loci or environmental factors are important in the expression of the disorder.

Hypoparathyroidism may be diagnosed at birth or during childhood due to a variety of genetic mutations causing congenital syndromes, the most widely known being the DiGeorge (velocardiofacial) syndrome, as described by Goldmuntz (2005). This disorder is caused by abnormal development of neural crest cells in the third and fourth branchial pouches. In 90% of cases the syndrome is caused by heterozygous chromosomal deletion of the *TBX1* gene in the region of chromosome 22q11. Thirty-five genes have been identified in this region, so deletion of other genes, alone or in combination, could also cause this syndrome, but the *TBX1* gene is a major determinant of cardiac, thymus, and parathyroid cell phenotypes. A region on chromosome 10p (DiGeorge critical region II) has also been linked to this syndrome. DiGeorge syndrome is associated with distinctive facial abnormalities, cleft lip and/or palate, conotruncal cardiac anomalies, and mild-to-moderate immune deficiency. McDonald-McGinn and Sullivan (2011) indicated that hypocalcemia due to hypoparathyroidism has been reported in 17%–60% of affected children. DiGeorge syndrome is estimated to occur in as many as 1:2000–1:3000 births, with the incidence rate of new mutations estimated at 1:4000–1:6000. Because the clinical phenotype varies, findings may be subtle and therefore be overlooked, and mild hypocalcemia may be easily missed. Bassett *et al.* (2005) showed that in adults with chromosome 22q11.2 deletion, about half were hypocalcemic, with a median age at presentation of 25 years, and a maximum age of diagnosis of up to 48 years. This disorder may rarely be diagnosed for the first time as late as the mid-60s, with late-onset mild hypocalcemia, and is not infrequently diagnosed in affected parents in their 20s or 30s after birth of an affected child.

Finally, a number of other rare genetic mutations may cause hypocalcemia most often detected in infancy or childhood. Familial isolated hypoparathyroidism due to autosomal recessive or dominant mutations in the *pre–proPTH* gene on chromosome 11p15 (Parkinson and Thakker, 1992; Arnold *et al.*, 1990), or isolated parathyroid gland dysgenesis due to mutations in a number of critical transcription factors regulating parathyroid gland development such as *GCMB* (glial cells missing B) (Thomée *et al.*, 2005) or *GCM2* (glial cells missing 2) (Baumber *et al.*, 2005), *GATA3* (Van Esch *et al.*, 2000; Ali *et al.*, 2007), or Sry-box 3 (*SOX3*) (Bowl *et al.*, 2005), are thought to be very rare. Syndromic forms of genetic hypoparathyroidism include autosomal dominant hypoparathyroidism associated with deafness and renal anomalies, associated with mutations in the *GATA3* gene on chromosome 10p14-10-pter (Parvari *et al.*, 2002; Cassandrini *et al.*, 2006). Hypoparathyroidism has been very rarely associated with X-linked recessive mutations on Xq26-27, leading to disruption of SOX3 transcription (Labarthe *et al.*, 2006). The syndrome of autosomal recessive hypoparathyroidism, growth and mental retardation, and dysmorphism due to mutations in the *TBCE* gene on chromosome 1q42-q43 is another very rare cause of syndromic hypoparathyroidism (Rubin and Levine, 2009). Hypoparathyroidism with metabolic disturbances and congenital anomalies has been associated with rare maternal mitochondrial gene defects (Levine, 1999; Lui *et al.*, 2000).

Hypocalcemia

Hypocalcemia occurs for a variety of reasons other than hypoparathyroidism in both inpatients and outpatients. Hypocalcemia has multiple causes, and may occasionally occur in asymptomatic patients, but more commonly causes symptomatic tingling paresthesias, muscle cramps, or tetany in those with moderate hypocalcemia. More severe hypocalcemia is associated with

seizures, bronchospasm, laryngospasm, cardiac rhythm disturbances, loss of consciousness, or sudden death. These varying symptoms are due to the fact that ionized calcium plays a critical role in many tissues, with roles as varied as regulation of cellular secretion, muscle contraction, nerve function, and blood clotting.

About 50% of serum calcium is found circulating in the ionized form, not bound to proteins or anions. The majority of the remaining 45%–50% is bound by proteins, largely to albumin, with the remaining 5% bound to anions. Although the ionized form of calcium is the biologically active form of calcium, measurement of ionized calcium is more difficult and often not routinely available. Most laboratories report serum total calcium as the only form of serum calcium available to clinicians trying to assess calcium physiology in patients with complex disorders.

Several factors alter the results obtained for serum total and ionized calcium. Decreases or increases in serum albumin increase or decrease serum total calcium without changing serum ionized calcium. Decreases in serum albumin below 4.0 g/dL decrease serum total calcium by 0.8 mg/dL for each 1.0 g/dL decrease in serum albumin, with albumin-corrected serum calcium felt to be a more accurate measure of serum calcium than total calcium. Correspondingly, increases in serum albumin above 4.0 g/dL increase total calcium by 0.8 mg/dL for each 1.0 g/dL increase. Dehydration increases serum total calcium due to increased concentration of the blood. Serum pH below 7.4 increases serum ionized calcium, and serum pH above 7.4 decreases ionized calcium, without affecting serum total calcium levels. Circulating citrate or phosphate in the blood decreases serum total calcium, whereas monoclonal proteins may increase serum total calcium by binding to the calcium. Because variations in intravascular volume and calcium-binding proteins affect serum total calcium, ionized calcium should preferentially be measured in complex clinical situations associated with changes in volume status, albumin concentration, and/or blood pH. Under less complex clinical circumstances, serum total calcium corrected for serum albumin should be adequate.

Hypocalcemia is present when serum total calcium, albumin-corrected total calcium, and/or ionized calcium are below the lower limit of the normal range. Serum total calcium below 8.5 mg/dL (2.13 mmol/L), or ionized calcium below 4.80 mg/dL (1.20 mmol/L), is considered below normal in most clinical assays. Before launching into an exhaustive investigation of hypocalcemia, calculation of albumin-corrected serum calcium should be performed, and serum ionized calcium should be checked, if possible, to verify that it is decreased. Situations in which serum total or albumin-corrected calcium are decreased, but ionized calcium remains normal, may be due to binding protein abnormalities.

Biochemical Features of Hypocalcemia

Shoback (2008) summarized that serum calcium concentration represents the balance between calcium influx into extracellular fluid coming from intestinal absorption, skeletal resorption, and renal reabsorption, and calcium efflux from extracellular fluid coming from intestinal secretion, skeletal uptake, and renal excretion. Shafer and Shoback (2013) emphasized that hypocalcemia most commonly results from decreased skeletal resorption or intestinal absorption, associated with normal or increased renal excretion, but it may occur with normal calcium influx associated with increased renal excretion or skeletal mineralization. Mundy and Guise (1999) summarized that decreased skeletal resorption usually results from decreased osteoclast recruitment and activation, most often because of decreased PTH secretion, parathyroid hormone-related protein (PTHrP) release, or 1,25-dihydroxyvitamin D levels. Deficiencies of other cytokines that stimulate osteoclast recruitment or function, including interleukin (IL)-1α, IL-1β, IL-6, tumor necrosis factor-α, lymphotoxin, or transforming growth factor-β, usually lead to decreased skeletal resorption, but by themselves may not cause hypocalcemia. Decreased intestinal absorption of calcium is not uncommon, either due to decreased 1,25-dihydroxyvitamin D or malabsorption from other causes. Regardless of the cause of decreased calcium influx into extracellular fluid, serum calcium levels do not typically decrease unless the kidneys fail to compensate with appropriately increased urinary calcium reabsorption.

Other factors indirectly affect serum calcium. Decreased PTH or PTHrP lead to decreased renal tubular reabsorption of filtered calcium, resulting in increased urinary calcium loss. Increased fluid intake may result in hemodilution, and volume overload may result in polyuria resulting in increased renal calcium clearance. Physical activity may directly decrease bone resorption and thereby reduce serum calcium.

Kantham *et al.* (2009) demonstrated that the seven-transmembrane segment G protein-coupled extracellular calcium-sensing receptor (CaSR) plays a major role in regulation of extracellular calcium. This receptor is found on parathyroid, renal tubular, osteoblast, intestinal mucosal, and adipocyte cells, as well as other cells in other tissues. The CaSR regulates secretion of PTH by parathyroid cells and renal tubular reabsorption of calcium, as it regulates bone turnover and intestinal absorption of calcium. The CaSR has a large extracellular portion that binds ionized calcium, and a shorter intracellular portion that interacts with a variety of G proteins and signal-transduction pathways.

Symptoms and Signs

Patients with mild hypocalcemia may be completely asymptomatic, whereas those with severe hypocalcemia may lose consciousness due to profound metabolic derangements. The magnitude of symptoms and signs present depends largely on the severity and chronicity of the hypocalcemia (**Table 1**). Patients with chronically low levels of serum calcium may be asymptomatic except for a positive Chvostek's sign. Chvostek's sign may be present in up to 15% of healthy subjects without hypocalcemia,

Table 1 Signs and symptoms of hypocalcemia

Signs
Chvostek's sign
Trousseau's sign
Prolonged QTc interval
Posterior subcapsular cataracts
Basal ganglia and intracerebral calcifications
Papilledema or pseudotumor cerebri
Symptoms
Tingling paresthesias affecting fingertips, toe tips, or lips/tongue
Muscle cramps, twitching, or tetany
Abdominal cramps
Bronchospasm
Laryngospasm
Seizures
Depression
Generalized weakness
Congestive heart failure
Coma

however, so it is not pathognomic of hypocalcemia. Neuromuscular irritability is the most common cause of symptoms, ranging from tingling paresthesias around the fingertips, toes, lips, or tongue tip to tetany, carpopedal spasm, extremity muscle twitching or cramping, or abdominal cramps. McGreal *et al.* (1995) indicated that neuromuscular irritability is often most clearly demonstrated by eliciting facial muscle twitching after tapping over the facial nerve just anterior to the ear (Chvostek's sign), and Rehman and Wunder (2011) showed that carpal spasm may be caused by inflation of an upper arm blood pressure cuff to 20 mmHg above systolic blood pressure for 3 min (Trousseau's sign). Trousseau's sign may be present in up to 1%–2% of healthy subjects without hypocalcemia, so it is not pathognomonic of hypocalcemia either.

More severe hypocalcemia may cause a broader range of more severe symptomatology including bronchospasm, laryngospasm, seizures, cardiac dysrhythmias associated with QT interval prolongation, coma, or sudden death. Patients often report feeling weak, fatigued, or depressed until hypocalcemia is corrected.

Chronic hypocalcemia may result in calcification of the basal ganglia and other intracerebral structures on head CT, MRI, or X-rays. Patients may develop posterior subcapsular cataracts related to long-standing treatment-related increases in the calcium $\times$ phosphate product, or pseudotumor cerebri. Prolonged severe hypocalcemia may cause congestive heart failure due to cardiomyopathy, which may be reversible with appropriate management of hypocalcemia.

Differential Diagnosis

Causes of hypocalcemia may be broadly divided into PTH-mediated and non-PTH-mediated causes (**Table 2**). PTH-related hypocalcemia is most often due to PTH deficiency or resistance. A large portion of non-PTH-related causes are due to vitamin D deficiency or resistance, with a wide variety of other less common causes. This section briefly reviews the multiple causes of hypocalcemia due to conditions other than PTH deficiency.

PTH Resistance

Brandi (2011) described pseudohypoparathyroidism (PHP) as a complex disorder with several recognized subtypes, characterized biochemically by hypocalcemia, hyperphosphatemia, and hyperparathyroidism due to tissue unresponsiveness to PTH (**Table 3**). Most often, hypocalcemia is not detected at birth, but rather develops gradually during childhood. The historical gold standard for diagnosis of PHP was the Ellsworth–Howard test, in which bovine PTH was infused to evaluate whether urinary phosphorus and cyclic AMP increased as they should. In most forms of PHP, urinary cyclic AMP does not increase as seen in healthy controls. The Ellsworth–Howard test is no longer performed today due to the unavailability of bovine PTH for diagnostic testing, and the diagnosis is largely based on the constellation of biochemical findings, family history when present, and genetic analysis. Recombinant human PTH 1–34 (teriparatide) may be used in place of bovine PTH in modified Ellsworth–Howard protocols at some centers.

PHP is further classified as types 1a, pseudo-PHP, 1b, 1c, or 2. PHP type 1a is the most common subtype, and due to loss-of-function mutations in the coding region of the maternally inherited *GNAS* gene encoding the Gsα subunit of G proteins. Mantovani (2011) noted that in this disorder, Gsα protein expression is reduced by half. PHP type 1a patients have isolated PTH resistance at the renal tubule, resulting in blunted phosphaturic and cAMP responses to infused PTH. The blunted response is due to lack of normal signaling by the PTH receptor 1 due to the reduced stimulatory G protein expression.

Table 2 Differential diagnosis of hypocalcemia

Hypoparathyroidism
Acquired
Postsurgical
Autoimmunity
Hemochromatosis or transfusion-dependent thalassemia
Wilson disease
Parathyroid metastases
Neck irradiation
Hypo- or hypermagnesemia
Inherited
APECED syndrome
Isolated hypoparathyroidism: familial or X-linked
Autosomal dominant hypocalcemia
Parathyroid agenesis
Parathyroid hormone gene mutations
Syndromic forms of genetic hypoparathyroidism
PTH resistance
Types 1a, 1b, 1c, and 2
Hypomagnesemia
Vitamin D deficiency
Nutritional deficiency
Malabsorption
Inadequate sunlight exposure
Hyperpigmentation
Anticonvulsant therapy
Pseudovitamin D deficiency rickets (vitamin D-dependent rickets type 1)
Chronic kidney disease
Severe liver disease
Vitamin D resistance
Hereditary vitamin D-resistant rickets (vitamin D-dependent rickets type 2)
Others
Hyperphosphatemia
Chronic kidney disease
Tumor lysis syndrome
Rhabdomyolysis
Acute pancreatitis
Burns
Hungry bone syndrome
Osteoblastic metastases
Transfusion with citrated blood
Critical illness
Pseudohypocalcemia due to MRI gadolinium contrast agents
Electroconvulsive therapy
Medications
Hypocalcemia with decreased PTH levels
Medication-induced hypomagnesemia: cisplatin, diuretics, aminoglycosides, amphotericin
Medication-induced hypermagnesemia: magnesium-containing antacids or laxatives, tocolytic therapy
Cinacalcet
Alcohol abuse
Hypocalcemia with increased PTH levels
Calcium-chelating agents: EDTA, citrate, foscarnet, hydrofluoric acid
Vitamin D deficiency or resistance: phenytoin, phenobarbital, carbamazepine, valproic acid, isoniazid, theophylline, glutethimide, rifampicin
Antiresorptive agents: bisphosphonates, denosumab, estrogens, raloxifene, calcitonin, plicamycin, colchicine overdose
Loop diuretics
Proton pump inhibitors and H2-blockers
Glucocorticoid therapy
Others: propylthiouracil, dobutamine, calcium channel blockers, strontium-89, deferasirox, bicarbonate therapy

PHP type 1a is associated with Albright's hereditary osteodystrophy (AHO), which is characterized by obesity, round facies, mild mental retardation, and a skeletal phenotype involving short stature, brachydactyly of hands and/or feet, and heterotopic ossifications in subcutaneous tissues. This disorder is frequently associated with multiple hormone resistance involving thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), calcitonin, and/or growth hormone-releasing hormone (GHRH).

Table 3 Classification of pseudohypoparathyroidism

Type	*Gsα activity*	*Albright's HO*	*PTH resistance*	*Urinary cAMP response*	*Multiple hormone resistance*	*Molecular defect*
1a	↓	Yes	Yes	↓	Yes	Heterozygous *GNAS* mutations
1b	N	No	Kidney	↓	No	Imprinted *GNAS* defect
1c	N	No	Yes	↓	Yes	Unknown
Pseudo-PHP	↓	Yes	No	Normal	No	Heterozygous *GNAS* mutation
2	N	No	Kidney	Normal	No	Unknown

PseuoPHP, pseudopseudohypoparathyroidism; N, normal; HO, hereditary osteodystrophy; PTH, parathyroid hormone; cAMP, cyclic adenosine monophosphate.

Patients with PHP type 1a have renal tubule PTH resistance because they inherit a mutated maternally imprinted *GNAS* allele. *GNAS* alleles undergo differential imprinting in mothers and fathers, with tissue-specific expression of alleles in offspring. Only the maternal allele is expressed in the kidney and in the relevant endocrine organs associated with hormone resistance in this form of the disorder, but the rest of the body expresses both maternal and paternal alleles. An affected allele in other body tissues leads to haploinsufficiency and AHO expression, but PTH resistance occurs only in the tissues expressing the maternal allele.

Patients with paternally inherited *GNAS* mutations who have AHO without renal or endocrine gland resistance are designated as having pseudopseudohypoparathyroidism (pseudo-PHP). Patients with pseudo-PHP have a normal urinary phosphorus and cAMP response to PTH, unlike PHP type 1a patients. Patients with both PHP type 1a or pseudo-PHP may occur in the same kindred. In some families both forms are found in the same generation, but more often the two forms are found in different generations.

Brandi (2011) indicated that PHP type 1b patients lack typical features of AHO, but may have mild brachydactyly. Levels of Gsα in accessible tissues are normal, but patients have renal tubular PTH resistance without resistance to other hormones, although some may have mildly increased TSH levels. Skeletal manifestations are similar to those seen in patients with hyperparathyroidism, with bone loss or changes of osteitis fibrosa cystica. Mantovani (2011) reported that most cases are due to switching of the maternal *GNAS* allele to a paternal pattern of methylation, caused by microdeletions in the *STX16* gene located 220 kB centromeric from *GNAS* exon 1A, or deletions removing the differentially methylated region involving exon NESP55 or exons 3 and 4 of the antisense transcript. In both situations, inheritance of a mutation from a female, or spontaneous mutation of a maternally derived allele, removes the maternal *GNAS* epigenotype, leading to transcriptional silencing of the Gsα promoter in imprinted tissues, with little or no expression of either *GNAS* allele in these tissues.

Patients with PHP type 1c have normal Gsα activity and lack identifiable mutations in *GNAS*, and are thought to represent a variant of PHP type 1a.

PHP type 2 patients have normal cAMP production in response to administered PTH, but lack a phosphaturic effect. Little is known about the mutations involved, but because the biochemical picture is similar to that of severe vitamin D deficiency, it may be that most, if not all, cases of PHP type 2 are due to unsuspected vitamin D deficiency.

PTH causes the distal renal tubule to decrease phosphate reabsorption and increase calcium reabsorption. In patients with PHP type 1a, PTH has less distal tubule phosphaturic effect and no hypercalciuric effect, so these patients have reduced risk of kidney stones. Mantovani (2011) reported that in this situation, calcium supplements may be taken with less risk of calcium nephrolithiasis than in other causes of hypoparathyroidism.

Low serum magnesium may also increase PTH resistance. Rude (2009) indicated that magnesium repletion results in normalization or an increase in PTH levels, leading to normalization of serum calcium after a delay.

Vitamin D-Related Hypocalcemia

Hypocalcemia may be due to vitamin D deficiency or resistance. Thacher and Clarke (2011) implied that lack of adequate intake of dietary vitamin D or sunlight exposure may be the most common cause of hypocalcemia worldwide. Even if dietary intake is sufficient, malabsorption of vitamin D by the intestine can result from many causes and lead to hypocalcemia. Rare forms of vitamin D resistance due to renal 1α-hydroxylase deficiency or tissue vitamin D receptor mutations often lead to hypocalcemia. Leboff *et al.* (1999) indicated that hypocalcemia due to vitamin D deficiency or resistance may be moderate to severe, and lead to increased risk of hip fracture.

Vitamin D Deficiency

Ergocalciferol (vitamin D2) is obtained from plant sources or dietary supplements derived from irradiated fungi, and cholecalciferol (vitamin D3) is produced by synthesis in the skin with ultraviolet B light exposure, from animal sources, or dietary supplements. Both ergocalciferol and cholecalciferol are transported by vitamin D-binding protein in the blood to the liver, where they are converted by liver 25-hydroxylase to 25-hydroxyvitamin D2 and D3, and then to the kidneys, where small amounts are

renally 1α-hydroxylated to 1,25-dihydroxyvitamin D2 and D3. Serum total 1,25-dihydroxyvitamin D is the biologically active form of vitamin D in the body because of its 1000-fold higher affinity for the vitamin D receptor than 25-hydroxyvitamin D. Serum 1,25-dihydroxyvitamin D2 and 1,25-dihydroxyvitamin D3 are thought to have equal affinity for the vitamin D receptor. Lieben *et al.* (2011) summarized that serum total 1,25-dihydroxyvitamin D is able to stimulate active transport of calcium and phosphorus from the intestinal lumen into the blood by upregulating a number of intestinal transport proteins, especially when dietary intake of calcium or phosphorus is low. Serum 1,25-dihydroxyvitamin D also acts directly via vitamin D-binding sites on the PTH gene to suppress PTH transcription in parathyroid cells, resulting in reduced secretion of PTH. PTH also directly stimulates osteoclast and osteoblast cell recruitment and activation on bone surfaces. Total 1,25-dihydroxyvitamin D is able to suppress its own synthesis by renal 1α-hydroxylase, and to increase renal 24-hydroxylase to cause its own breakdown. Because decreased serum PTH, increased serum calcium, or decreased serum phosphorus each independently downregulate renal 1α-hydroxylase, hypoparathyroidism leads to reduced renal 1α-hydroxylase activity and decreased 1,25-dihydroxyvitamin D synthesis if serum calcium and phosphorus do not change in response to the decreased PTH level. Because vitamin D deficiency may result in both hypocalcemia and hypophosphatemia, this normally triggers upregulation of PTH synthesis that stimulates renal 1α-hydroxylase activity. Persistently increased serum PTH secretion from any cause often stimulates serum total and bone alkaline phosphatase activity, resulting in increased bone turnover, which may lead to bone loss over time. Severe and prolonged vitamin D deficiency may ultimately lead to increased unmineralized collagenous and noncollagenous matrix production in the skeleton, resulting in osteomalacia in adults, or rickets in children.

Van Schoor and Lips (2011) reported that vitamin D insufficiency, defined as serum 25-hydroxyvitamin D levels less than 20 ng/mL, and vitamin D deficiency, defined as serum 25-hydroxyvitamin D levels less than 10 ng/mL, are common in adults and children in most countries. Thomas *et al.* (1998) showed these are common as well as in hospitalized patients. Priemel *et al.* (2010) reported that serum 25-hydroxyvitamin D is the best marker of nutritional vitamin D intake, with levels below 10 ng/mL (25 nmol/L) considered deficient because of the higher prevalence of osteomalacia or rickets at this level. Optimal levels due to nutritional adequacy of intake continue to be debated, with most specialists recommending 30 ng/mL (75 nmol/L) for treatment of osteoporosis or metabolic bone disease. The 2011 U.S. Institute of Medicine report (2011) concluded that 20 ng/mL (50 nmol/L) was adequate to maintain skeletal health in healthy adults, and emphasized that optimal vitamin D levels have not yet been established for most human diseases. In light of the ongoing controversy regarding vitamin D optimal levels, vitamin D insufficiency is most often defined as levels between 10 and 20 ng/mL (25–50 nmol/L).

Vitamin D overdosing by patients is increasingly common, frequently leading to increased urinary calcium levels leading to nephrocalcinosis, but frank vitamin D toxicity resulting in hypercalcemia remains relatively uncommon. Most bone specialists regard serum 25-hydroxyvitamin D levels over 80 ng/mL (200 nmol/L) with concern, but it is uncommon to develop hypercalcemia unless serum 25-hydroxyvitamin D increases above 150 ng/mL (375 nmol/L).

Shoback (2008) indicated that any disorder that interferes with vitamin D absorption, production, transport, binding to vitamin D receptors in target tissues, or degradation may reduce vitamin D activity in tissues. Vitamin D deficiency may result from low sunlight exposure, especially in the elderly, those with hyperpigmented skin, or those using high-grade sun block to reduce sun exposure. Malnutrition, intestinal malabsorption, chronic liver disease, or later stage chronic kidney disease may interfere with adequate vitamin D absorption or production. Liamis *et al.* (2009) summarized that medications upregulating cytochrome P450 enzymes that normally break down vitamin D, such as anticonvulsants, including phenytoin, phenobarbital, carbamazepine, or valproate, may result in vitamin D insufficiency or deficiency if sunlight exposure or dietary or supplemental intake does not make up for more rapid metabolism.

Mutations in the CYP27B1 gene responsible for synthesis of renal 1α-hydroxylase give rise to pseudovitamin D deficiency rickets, previously known as vitamin D-dependent rickets type 1 (VDDR1) (St Arnaud *et al.*, 1997; Kitanaka *et al.*, 1998). These mutations result in partial or complete absence or reduced activity of the 1α-hydroxylase enzyme, causing synthesis of very low levels of 1,25-dihydroxyvitamin D, with resultant significant hypocalcemia and hypophosphatemia. This disorder is typically diagnosed shortly after birth or in infancy due to tetany, seizures, rickets, and failure to thrive. Vitamin D deficiency due to inadequate nutritional intake results in decreased serum calcium, phosphorus, and 25-hydroxyvitamin D levels, but serum 1,25-dihydroxyvitamin D levels usually remain normal until serum 25-hydroxyvitamin D levels decrease to less than 4 ng/mL (10 nmol/L). At this level, lack of adequate 25-hydroxyvitamin D availability leads to decreased production of serum 1,25-dihydroxyvitamin D. Pseudovitamin D deficiency rickets results in low serum calcium and phosphorus, increased PTH causing increased total and bone alkaline phosphatase, normal 25-hydroxyvitamin D, and very low or undetectable 1,25-dihydroxyvitamin D levels due to the inadequacy of renal 1α-hydroxylase activity.

Vitamin D-Resistant Rickets

Brooks *et al.* (1978) first reported that hereditary vitamin D resistance rickets, previously known as VDDR type 2, is a rare autosomal recessive disorder caused by vitamin D receptor mutations leading to resistance to the action of 1,25-dihydroxyvitamin D. This condition has been reported in association with mutations in the ligand-binding domain, DNA-binding domain, and other domains of the receptor. Resistance to 1,25-dihydroxyvitamin D action may be partial or complete. Children with this condition are usually identified before their 2nd year, but Malloy *et al.* (1990) reported that some children may not be diagnosed until their teenage years, similar to children with pseudovitamin D deficiency rickets. Presenting features include tetany, seizures,

rickets, and failure to thrive. Laboratory data confirms low serum calcium and phosphorus, increased PTH, increased total and bone alkaline phosphatase, normal 25-hydroxyvitamin D, and increased 1,25-dihydroxyvitamin D levels. Increased PTH caused by the hypocalcemia stimulates renal 1α-hydroxylase production of 1,25-dihydroxyvitamin D. The main biochemical feature of this disorder is increased serum 1,25-dihydroxyvitamin D, distinguishing it from pseudovitamin D deficiency rickets. Patients have significant scalp alopecia, with partial or total scalp alopecia in two-thirds of the kindreds reported. Hypocalcemia varies between different kindreds also. Patients do not respond to usual replacement doses of vitamin D or calcium, but may respond to high doses of activated vitamin D in some cases, depending on remaining vitamin D receptor activity. Those with no residual vitamin D receptor activity are unresponsive to vitamin D therapy, and usually require treatment with intravenous calcium and/or high-dose oral calcium.

Other Causes of Hypocalcemia

Hypocalcemia may occur due to a variety of other causes beyond those due to hypoparathyroidism or vitamin D deficiency or resistance.

Hyperphosphatemia may occur in later stage chronic kidney disease, leading to reduction in serum calcium because serum phosphorus complexes to calcium in extracellular fluid and leads to deposition of calcium × phosphate complexes in soft tissues. Stage V chronic kidney disease results in hyperphosphatemia causing decreased 1α-hydroxylase activity, leading to decreased 1,25-dihydroxyvitamin D production. Medications may cause hyperphosphatemia when taken in excessive amounts, including phosphate-containing laxatives or enemas. While not used very often any more, intravenous phosphorus given to lower serum calcium may cause hyperphosphatemia. Tumor lysis syndrome or rhabdomyolysis may result in acute hyperphosphatemia, thereby decreasing serum calcium acutely.

Large quantities of transfused citrated blood products may complex calcium to citrate in the circulation, resulting in acute hypocalcemia. Pancreatic lipase released into surrounding tissue fluids during acute pancreatitis may increase free fatty acids that can saponify calcium in the blood as it flows through the pancreas, resulting in significant lowering of serum calcium. Rapid new bone formation may cause such significant rapid uptake of calcium from the blood that normal homeostatic mechanisms are not able to compensate, and hypocalcemia develops, as is often seen with "hungry bone" syndrome after surgical cure of severe, long-standing hyperparathyroidism. Brasier and Nussbaum (1988) reported that higher risk of "hungry bone" syndrome is seen in older patients with higher preoperative PTH and serum alkaline phosphatase levels, and larger weight of the resected adenoma. Rapid new bone formation may also occur in patients with extensive osteoblastic metastases, leading to significant hypocalcemia. Vivien *et al.* (2005) reported that critical illness is often associated with multifactorial hypocalcemia.

Medications may directly cause hypocalcemia by a variety of mechanisms (**Table 3**). Prince *et al.* (2003) reported that certain gadolinium contrast agents for magnetic resonance imaging studies may cause pseudohypocalcemia within several hours of administration. Several of these agents, but not all, may cause falsely low serum calcium levels at less than 6.0 mg/dL, as these may interfere with colorimetric serum calcium assays. If spuriously low serum calcium is suspected, serum calcium should be rechecked using a different assay method to clarify the diagnosis. Asymptomatic patients with critical hypocalcemia reported after an MRI scan should be suspected of having an inaccuracy in their reported serum calcium level.

Rosen and Brown (2003) reported that many patients being treated for osteoporosis who are given potent antiresorptive agents, including oral and intravenous bisphosphonates, denosumab, or raloxifene, may significantly decrease serum calcium on occasion. Patients beginning these agents should be treated with adequate vitamin D and calcium supplementation before taking their first dose to minimize their risk of hypocalcemia.

Laboratory Assessment

Diagnosis and management of hypocalcemia is critically dependent on the laboratory studies available to the clinician. Initial evaluation of patients suspected of having hypocalcemia should include measurement of serum total calcium, albumin for calculating albumin-corrected serum calcium, ionized calcium if available, phosphorus, creatinine, PTH, 25-hydroxyvitamin D, and magnesium levels. Interpretation of serum calcium values is enhanced considerably by knowledge of serum phosphorus levels. Serum 1,25-dihydroxyvitamin D does not need to be routinely measured, but knowledge of this analyte is very important in certain cases.

Tandem mass spectroscopy is used to reliably measure serum 25-hydroxyvitamin D, but because this is expensive, this technique is frequently not available in most laboratories. Many laboratories still use antibody-based assays, but these are quite variable, and on average tend to overestimate serum 25-hydroxyvitamin D levels by about 30%. Priemel *et al.* (2010) reported that serum 25-hydroxyvitamin D levels less than 10 ng/mL (25 nmol/L) are regarded as deficient because of the significantly increased likelihood of osteomalacia. The Institute of Medicine (2011) considers a level of 20 ng/mL (50 nmol/L) to be sufficient for skeletal purposes in healthy adults. Serum 25-hydroxyvitamin D between 10 and 20 ng/mL (25–50 nmol/L) is interpreted as insufficient by most bone specialists. The normal upper limit for serum 25-hydroxyvitamin D is considered to be 50 ng/mL (75 nmol/L) by many bone specialists because hypercalciuria may occur above this level. Vitamin D toxicity is associated with hypercalcemia, but

this most commonly does not occur unless serum 25-hydroxyvitamin D is above 150 ng/mL (375 nmol/L). Occasionally this may occur when serum 25-hydroxyvitamin D is above 80 ng/mL (200 nmol/L).

Measurement of intact PTH should be done by reliable second- or third-generation assays. Most laboratories now use these types of PTH assay. These assays can reliably detect PTH levels at the low end of the normal range in patients with hypoparathyroidism. PTH assays tend to be less variable than 25-hydroxyvitamin D assays.

Serum magnesium deficiency or excess may both limit secretion of PTH (Cholst *et al.*, 1984; Wong *et al.*, 1983), so patients with apparent hypoparathyroidism with the biochemical phenotype of low serum calcium, increased serum phosphorus, normal creatinine, normal 25-hydroxyvitamin D, and low PTH should always have serum magnesium checked as part of their baseline evaluation. Increased 24-h urine magnesium in the setting of hypomagnesemia strongly suggests renal tubular magnesium wasting, rather than gastrointestinal loss of magnesium.

The biochemical phenotype of pseudohypoparathyroidism is usually low serum calcium, increased serum phosphorus, normal creatinine, normal 25-hydroxyvitamin D, and moderately increased PTH levels. Vitamin D deficiency is characterized by low serum calcium, low phosphorus, normal creatinine, and increased PTH levels.

Measurement of 24-h urine calcium and creatinine are important in determining the cause of hypocalcemia. 24-h urine calcium is often moderately increased in idiopathic hypercalciuria in the untreated patient, but is likely due to high-dose calcium or vitamin D supplementation in treated hypocalcemic patients. Markedly increased 24-h urine calcium and usually asymptomatic mildly decreased serum calcium may be due to autosomal dominant hypocalcemia. Untreated hypocalcemic patients may have decreased or low–normal 24-h urine calcium levels.

Management

The purpose of hypocalcemia treatment is to improve or eliminate symptoms, reverse skeletal demineralization if it is present, heal osteomalacia if present, maintain acceptable serum total and ionized calcium, and avoid hypercalciuria. Hypercalciuria is often defined as 24-h urine calcium above 300 mg. Bilezikian *et al.* (2011) reported that hypercalciuria may lead to chronic kidney disease, nephrolithiasis, or nephrocalcinosis. Patients with a need for urgent treatment due to tetany, seizures, laryngospasm, bronchospasm, cardiac rhythm disturbances, altered mental status, or severe hypocalcemia, typically require bolus intravenous calcium, usually given as calcium gluconate, followed by a slower intravenous infusion of calcium, and then oral calcium when able to tolerate this. One approach is to add ten 10-mL ampules of calcium gluconate, with 93 mg elemental calcium per ampule, to 900 mL of D5W, with 10 mL of this solution infused slowly over 10 min to improve symptoms, with repeat infusions given once or twice more as needed. A maintenance infusion with this solution is then begun at 10–100 mL/h to control symptoms and improve serum calcium toward the lower end of the normal range at around 8.5 mg/dL (2.12 mmol/L), with ionized calcium of around 4 mg/dL (1.0 mmol/L). The infusion rate is usually titrated to give 0.3–1.0 mg elemental calcium/kg/h.

Once the patient becomes stabilized on the intravenous infusion over several hours, and is able to take oral intake, an oral calcium supplement regimen is begun, giving the patient at least 500 mg elemental calcium three to four times a day. The calcium gluconate infusion is gradually slowed and then stopped as serum calcium approaches the target level of 8.0–8.5 mg/dL (2.00–2.13 mmol/L) and symptoms improve, providing the oral calcium supplements are tolerated.

Conventional management of chronic hypocalcemia involves mainly oral calcium and vitamin D supplementation which is occasionally supplemented with thiazide-type diuretics or magnesium. Once serum magnesium is below the normal range, total body magnesium deficiency is usually very large. Serum magnesium is a poor reflector of total body magnesium level because the vast majority of total body magnesium is located inside cells. Supplementation with oral magnesium tablets usually takes several months to fully replete body stores. As total body magnesium is gradually repleted, serum calcium and PTH levels gradually return toward normal.

Oral calcium supplements of any type will help restore serum calcium toward normal. In general, oral calcium carbonate or calcium citrate is used most commonly for this purpose because they are easily obtained and relatively inexpensive. Calcium carbonate is 40% calcium by weight, and calcium citrate 21% calcium by weight, so that more calcium citrate tablets need to be taken to achieve the same intake or elemental calcium. Calcium supplements are usually given in at least two divided doses each day, but sometimes up to four to six times a day, with dosing usually recommended at mealtimes to enhance absorption. The usual starting doses recommended are usually 500–1000 mg elemental calcium given two to three times each day, and these are then increased further as needed based on tolerability, compliance, and the clinical target. It should be emphasized that the calcium doses uses in Europe are lower than those used in the United States.

Because calcium tablets alone may be insufficient to achieve serum calcium of 8.0–8.5 mg/dL (2.0–2.13 mmol/L), vitamin D supplementation is usually started simultaneously. If renal function is normal, ergocalciferol (vitamin D2) or cholecalciferol (vitamin D3) may be started at 1000–4000 International Units each day. With vitamin D deficiency, vitamin D 50,000 International Units once weekly to several times a week as needed, depending on intestinal absorption. Severe hypoparathyroidism or PHP typically require higher doses of vitamin D supplementation. Care must be taken with these longer-acting forms of vitamin D, however, as their half-life is prolonged due to storage in body fat, and toxic serum levels of 25-hydroxyvitamin D may take 6–9 months to come down after supplementation is stopped.

More often, because of concerns regarding toxicity, calcitriol (1,25-dihydroxyvitamin D) 0.25 mcg once or twice a day is started in place of vitamin D2 or D3 in the United States, whereas calcitriol or alfacalcidol (1α-hydroxyvitamin D) is used in Europe. The

half-life of these active forms of vitamin D is much shorter than vitamin D2 or D3, on the order of 1–3 days, so that improvement in absorption or offset of action occurs more rapidly. Patients with hypoparathyroidism in Europe are often treated with higher doses of active vitamin D than calcium. Commercial parenteral vitamin D is no longer available in the United States, but some hospital-compounding pharmacies produce intravenous vitamin D3 based on clinical need.

Patients who develop increased urinary calcium while on calcium and vitamin D supplementation, or who are unable to achieve or maintain serum calcium at or near their target range, may benefit from a thiazide-type diuretic to reduce their urinary calcium loss. Doses of hydrochlorothiazide or chlorthalidone of 12.5–25 mg a day may be useful, but some patients may require higher doses of 50 or 100 mg to reduce their 24-h urine calcium to the desired range of less than 300 mg.

Once- or twice-daily injections of PTH 1–34 (teriparatide; Forteo; Forsteo) have been used off-label in clinical trials lasting 1–3 years to more effectively control serum or urine calcium and phosphorus in patients with hypoparathyroidism (Bilezikian *et al.*, 2011; Winer *et al.*, 1996, 1998). This therapy is not approved by the FDA or European Medicines Agency (EMA) for treatment of hypoparathyroidism. Mannstadt *et al.* (2013) published the pivotal 6-month phase III clinical trial with recombinant human PTH 1–84 (Natpara; Natpar) in 2013, with FDA approval as an adjunct for treatment of hypoparathyroidism in January 2015, and similar approval by the EMA in April 2017. Several guidelines for use of recombinant human PTH 1–84 in hypoparathyroidism have been published (Brandi *et al.*, 2016; Bollerslev *et al.*, 2015).

Hasse *et al.* (1997) and Tolloczko *et al.* (1996) have reported a few patients who have received previous or simultaneous renal transplants have received parathyroid allograft transplants. Advances in stem cell technology may eventually permit induced pluripotent cells or stem cells to be used to create new parathyroid tissue in patients where it did not develop or has been removed.

Patients with pseudovitamin D deficiency rickets (VDDR1) require lifelong physiologic doses of 1,25-dihydroxyvitamin D3 and calcium therapy. Patients with hereditary vitamin D-resistant rickets (vitamin D-dependent rickets type 2) usually require pharmacologic doses of 1,25-dihydroxyvitamin D3 and calcium to overcome their resistance. Calcium supplements of up to 3000 mg elemental calcium each day may be required. High-dose therapy is continued until their undermineralized bones have mineralized, typically within 2–6 months. Lifelong close monitoring is required to monitor serum calcium and mineral metabolism measurements and clinical symptoms. Some patients do not respond to high-dose therapy despite serum 1,25-dihydroxyvitamin D3 levels more than 100 times the upper limit of normal. Long-term intravenous calcium infusions in combination with high-dose oral calcium supplements are usually used successfully in this case.

Calcitonin Gene-Related Peptide (CGRP)☆

AA Aubdool, X Kodji, and SD Brain, King's College London, London, United Kingdom

Glossary

Calcitonin receptor-like receptor (CRLR) G protein-coupled receptor (GPCR); pharmacology of this receptor is defined by its interaction with a group of accessory proteins called receptor activity-modifying proteins (RAMPs). CRLR receptor functions as a CGRP receptor when dimerized with RAMP1 and as an adrenomedullin (AM) receptor when dimerized with RAMP2 or RAMP3.

CGRP receptor component protein (RCP) Intracellular protein that facilitates signal transduction through the CGRP receptor.

Migraine Complex neurological disorder characterized by severe head pain, nausea, and exacerbated sensitivity to external stimuli such as light and sound. It presents in one of two forms, migraine without aura or migraine with aura, with the latter characterized by visual early disturbances such as zigzag lines and blind spots.

Receptor activity-modifying proteins (RAMPs) A family of three single type I transmembrane proteins, RAMP1, RAMP2, and RAMP3, required for the transport, glycosylation, and pharmacological classification of the calcitonin receptor-like receptor (CRLR) as CGRP1 or adrenomedullin (AM) receptor.

Introduction

Calcitonin gene-related peptide (CGRP) is a product of alternative splicing of the calcitonin (CT) gene. CGRP is primarily located within unmyelinated, small diameter sensory C-, and thinly myelinated Aδ-nerve fibers. Its dual occurrence in nerves and non-neuronal locations suggests potential functions as a neuromodulator and effector mediator (for a recent review, see Russell *et al.*, 2014). Its biological activity is mediated by type II G protein-coupled receptors (GPCRs), known as the calcitonin receptor-like receptor (CRLR or CLR), which forms a receptor complex with the accessory proteins: receptor activity-modifying proteins (RAMPs) and receptor component protein (RCP), to modulate both its ligand-binding selectivity and its signal transduction. Structural and functional analysis of these multiple associations is providing new insights into molecular determinants of multiple CGRP functions and allow the design of new drugs to regulate CGRP activity under pathological conditions.

CT/CGRP Gene, Alternative Splicing, and Transcriptional Regulation

CGRP is a 37-amino acid neuropeptide discovered by Amara *et al.* (1982) in thyroid tissue of aging rats, where alternative splicing of RNA transcripts from the CT gene resulted in distinct mRNAs encoding CGRP. CT and α-CGRP are coded for by the same gene (CALCA) found on chromosome 11p. Depending on the tissue localization, the CALCA gene is processed by different combinations of the six exons contained within the gene. In thyroid "C" cells/parafollicular cells, 95% of the CALCA gene is processed to include exons 1–3 (forming the common region, translated into N-terminal peptide), exon 4 (calcitonin-coding gene), followed by poly-adenylation (forming the extra 16 amino acid-containing C-terminal peptide). In contrast, neuronal CALCA pre-RNA is processed to include exons 1–3 (as previously), exon 5 (CGRP-coding region), and exon 6 (CGRP 3′ non-coding exon) followed by 3′ polyadenylation, which is translated into α-CGRP precursor containing 121 amino acids. Both CT and CGRP precursors undergo post-translational processing. The process that allowed tissue-specific inclusion of the alternative 3′-terminal exon 4 is modulated by factors that bind to an intronic enhancer element that contains both 3′ and 5′ splice site consensus sequence elements. Although factors involved in the tissue-specific alternative splicing of the CALCA gene have not been identified, members of the serine- and arginine-rich RNA-binding protein family may participate in multiple interactions that coordinate individual recognition events during the early steps of RNA processing (Fig. 1).

A second CGRP gene (CALCB coding for β-CGRP) was predicted from cDNA analysis in rat and human. The β-CGRP gene encodes a molecule closely related to α-CGRP. β-CGRP differs from α-CGRP in one amino acid in rat and in three amino acids in human and mouse, resulting in >90% homology. Unlike CALCA, CALCB gene lacked poly A signal within exon 4, preventing

☆*Change History:* April 2016. AA Aubdool, X Kodji, and SD Brain made changes in all sections previously written by Moreno and Stanimirovic. Some of the references have been deleted and further updated. Old figures were deleted and replaced with three new figures. CL has been replaced to CRLR, according to the updated nomenclature IUPHAR/BPS Guide to Pharmacology.

This article is an update of Mara J. Moreno, Danica B. Stanimirovic, Edith Hamel, Calcitonin Gene-Related Peptide (CGRP), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 425–435.

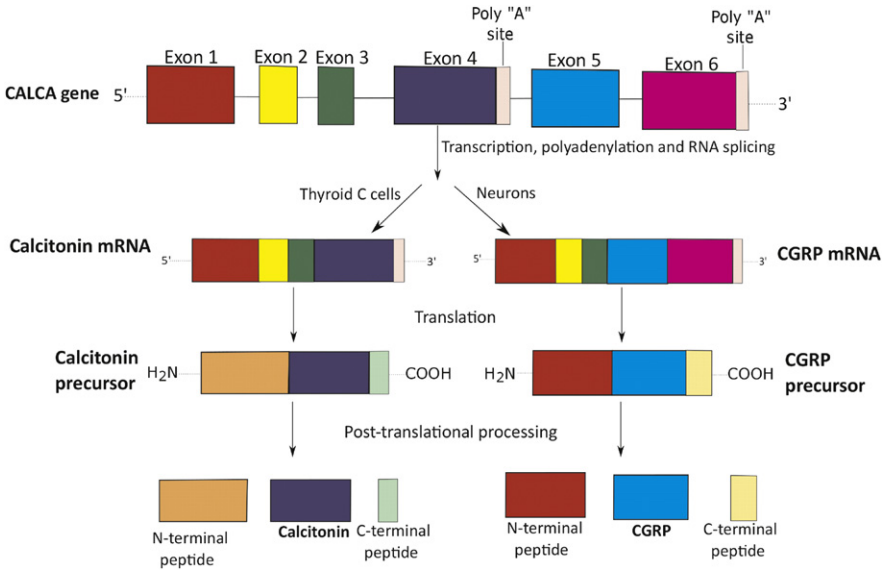

Fig. 1 CALCA gene processing yielding both calcitonin and α-calcitonin gene-related peptide (CGRP) in a tissue-specific manner. Boxes are exons; lines in between are introns. Adapted from Russell et al. (2014).

alternative splicing, hence β-CGRP is the only product of CALCB gene. Post-translational processing of α-CGRP and β-CGRP precursors resulted in the release of the bioactive peptides as well as non-functional N-terminal and C-terminal peptides. The structures of human α-CGRP and β-CGRP contain four clear domains: 1) The first 7 amino acids on the N-terminus, containing ring-like structure held by disulphide bridge between Cys2 and Cys7; 2) residues 8–18, consisting of an α helix; 3) residues 19–27 forming either a β- or γ- twist; 4) the last domain, made up of residues 28–37 including the C-terminus, forms the binding epitope. Traditionally, β-CGRP has been suggested to be localized to the CNS and gut, although a wider localization is now realized. However, as less is known about the specific function of β-CGRP, this chapter will only focus on the role of α-CGRP.

CGRP synthesis is upregulated in nerve damage and under inflammatory conditions. This is partly associated with nerve growth factor (NGF) release from keratinocytes and inflammatory cells, such as macrophages, playing an important role in nerve growth. The endogenous stimuli that drive CGRP release remain uncertain, although recent studies have focused on the role of various transient receptor potential (TRP) channels, such as TRP Vanilloid 1 (TRPV1) and TRP Ankyrin 1 (TRPA1), which are activated by a range of environmental (e.g. chemical, temperature) stimuli in addition to various endogenous stimuli (including reactive oxygen species and anandamide). The activation of these channels leads to an influx of cations, especially Ca^{2+} and Na^{+} resulting in Ca^{2+}-dependent exocytosis of CGRP from the nerve terminals.

Once released, the bioactivity of CGRP is partially dependent on its breakdown and removal system. Although the exact mechanism of CGRP metabolism remains unclear, studies in the skin has shown that CGRP is hydrolyzed by tryptase, which is released following mast cell activation or by neutral endopeptidases, which were identified in neurodegeneration field. Other enzymes involved in CGRP metabolism includes insulin-degrading enzymes (IDE) and endothelin-converting enzyme-1 (ECE-1). Independent of its breakdown, CGRP re-uptake into the nerve terminals has been proposed, especially in the mouse vas deferens, in guinea pig basilar artery and in rat dura mater encephali. Additionally, CGRP'S interaction with its receptor can lead to internalization and recycling. Hence, various removal mechanisms are important in regulating CGRP functions and may highlight future pharmacological targets in various disease conditions.

CGRP Receptors

Pharmacology of CGRP Receptors

CGRP is a member of a peptide family that also includes CT, amylin (AMY), adrenomedullin (AM) and intermedin. Although these peptides have only limited sequence identity, they share a number of structural features, including a six- or seven-amino acid ring formed by a disulphide bond at the N termini (implicated in triggering signal transduction), an amphipathic α-helix, and a C-terminal amide (responsible for the interaction of the molecule with the receptor). The structural convergence among these peptides results in a significant degree of cross-reactivity between receptors.

CGRP acts via type II GPCRs that primarily stimulate adenylate cyclase through the G_s subunit although full signaling pathway requires accessory proteins. CRLR was first isolated from rat pulmonary blood vessels. Despite initial transfection of human or rat CRLR into mammalian cells failing to elicit CGRP- or AM-induced responses, a stable expression of this gene in human embryonic kidney 293 cells resulted in increased density of high-affinity ^{125}I-CGRP binding sites and stimulation of intracellular cAMP levels

by CGRP. McLatchie *et al.* and Evans *et al.* showed the importance of two further accessory proteins on plasma membrane as well as cytoplasm to achieve full signaling function of CRLR.

Receptor Activity-Modifying Proteins

RAMPs are a family of single transmembrane domain proteins that are required for the transport, glycosylation and ligand specificity of CRLR (Fig. 2). They have a relatively long extracellular amino terminus, a single membrane-spanning domain and a short intracellular C terminus. Three members (RAMP1, RAMP2, and RAMP3) have been identified in this family by homology searches. They are 148, 175, and 148 amino acids long, respectively, with about 30% of sequence identity. RAMP1, although unable to bind CGRP on its own, can combine with CRLR to form a fully glycosylated receptor complex of 66 kDa. The crystal structure of human RAMP1 has been crystallized and residues on the extracellular domain important for cell-surface expression of CRLR.RAMP1 heterodimer have been identified (Kusano *et al.*, 2008). Interestingly, the combination of CRLR with RAMP2 or RAMP3 seemingly yields an AM receptor of 58 kDa (core glycosylated) that can cross-react with CGRP only at high concentrations.

RAMPs act as a chaperon for CRLR trafficking to the cell surface. When expressed individually, RAMPs and CRLR are retained intracellularly with CRLR sequestered in the endoplasmic reticulum (ER) and RAMP1 in both the ER and the Golgi system, predominantly as a disulfide-linked homodimer. When co-expressed, both proteins are detected on the cell surface, suggesting that the interaction between CRLR and RAMP1 facilitates their trafficking to the plasma membrane.

RAMP1 is also required for the terminal glycosylation of CRLR. Differential glycosylation of CRLR in the presence of RAMP1 or RAMP2 does not define receptor specificity for CGRP or AM. Moreover, core glycosylation is not sufficient for plasma membrane incorporation of CRLR in the absence of RAMPs. Human CRLR presents three asparagine (Asn) consensus glycosylation sites at positions 60, 112, and 117 of the amino acid sequence. Selective mutations of these sites have demonstrated that Asn117 is important for direct interaction of CGRP or AM with CRLR and RAMP1 or RAMP2 and, therefore, for the functionality of the receptor complex. However, Asn117 substitution does not affect N-glycosylation, association with RAMP1, and/or cell surface expression of receptor/RAMP1 heterodimers.

The extracellular N terminus of RAMP1 plays an important role in determining ligand specificity through association with the amino terminus of CRLR that results in formation of a CGRP-binding pocket. The observation that the first non-peptide CGRP receptor antagonist BIBN4096BS exhibits up to 200-fold higher affinity for human than rat CRLR, despite more than 90% sequence homology of CRLR between the two species, suggested that this selectivity is likely conferred by the interaction of BIBN4096BS with RAMP1 (homology ~71%). In support of this idea, tryptophan 74 in RAMP1 was shown to be responsible for the selective high-affinity binding of BIBN4096BS to the human CGRP receptor. Future structural analyses of CRLR/RAMP complexes are needed to map residues important for ligand recognition and provide a basis for designing therapeutics with high affinity and selectivity for these receptors.

RAMPs can also compete in regulating the function of CGRP/AM receptor function. For instance, co-expression of RAMP3 and RAMP1 results in reduced RAMP1-dependent CGRP receptor activity in a rabbit aortic endothelial cell line. Conversely, the expression of RAMPs is selectively regulated by different factors such as hypoxia and corticosterone. Therefore, balance of expression of various RAMPs, as well as their modulation by physiological or pathological conditions may affect the affinity, function, and "molecular switch" between CGRP and AM receptors. Many effects of AM are blocked by α-CGRP$_{8-37}$ and not by AM$_{22-52}$, a more selective AM receptor antagonist. In some cases, both α-CGRP$_{8-37}$ and AM$_{22-52}$ can partially inhibit CGRP- and AM-induced cAMP production. The first report documenting the interaction between CRLR and RAMP1 in neuroblastoma SK–N–MC cells showed that this complex selectively responds to CGRP but not to AM, suggesting that CRLR/RAMP1 heterodimers define a very selective CGRP1 receptor. Although α-CGRP has far lower affinity than does AM for CRLR/RAMP2 and CRLR/RAMP3

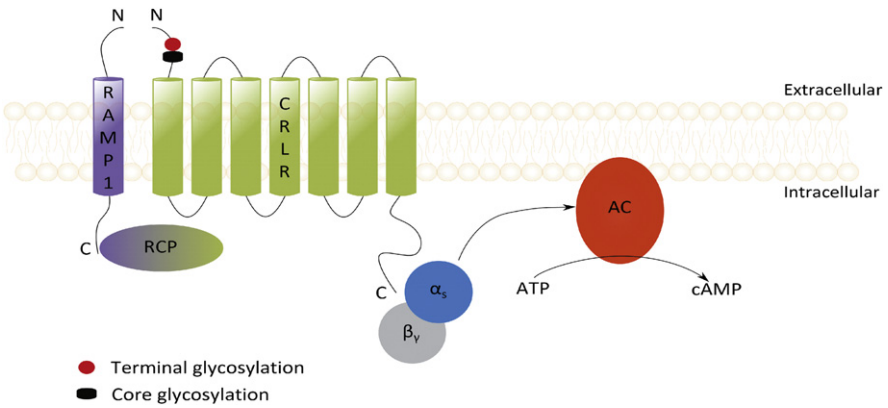

Fig. 2 A representative figure of Calcitonin Receptor Like Receptor (CRLR) and its interaction with associated accessory proteins Receptor Activity-Modifying Protein 1 (RAMP1) and Receptor Component Protein (RCP) which are vital for α-CGRP signaling. Activation of this receptor complex leads to a $G_{\alpha s}$ signaling pathway, activating adenylyl cyclase (AC) inducing cyclic adenosine monophosphate (cAMP) production.

complexes, the affinity of AM for CRLR/RAMP1 is comparable to that of αCGRP in some biological systems. Furthermore, in cells expressing higher levels of CRLR/RAMP1 than of CRLR/RAMP2 or-RAMP3, the effects of AM were blocked by $\alpha CGRP_{8-37}$ but not by AM_{22-52}. Hence, the CRLR/RAMP1 heterodimer defines a functional AM-sensitive receptor that is potently antagonized by $\alpha CGRP_{8-37}$ and distinct from CRLR/RAMP2, which is more sensitive to AM_{22-52}. This dual interaction of CRLR/RAMP1 complex with both αCGRP and AM may explain why many actions of AM are potently antagonized by $\alpha CGRP_{8-37}$. More recently, the possibility that CGRP may also act via CRLR and RAMP3 in human tissue has been investigated.

In summary, RAMPs contribute to various aspects of CGRP receptor biology: (1) trafficking of CRLR to the cell surface, (2) glycosylation of CRLR, (3) ligand specificity, and (4) receptor activity (see Hay and Pioszak, 2016 for more details). Furthermore, the importance of RAMPs in receptor pharmacology also extends to other members of the CT/CGRP family. As multiple AMY receptors arise from RAMP interaction with the CT receptor gene product, this indicates that the cellular profile of the CT/CGRP family of receptors, and potentially other class II GPCRs, can be dynamically regulated by the level and combination of these sets of proteins.

CGRP Receptor Component Protein (RCP)

In addition to RAMPs, the CGRP receptor complex seems to require another protein RCP for optimal function (Fig. 2). RCP is a 146-amino acid protein which is a peripheral membrane protein attached to the membrane by ionic interactions. RCP is expressed in CGRP-responsive tissues. CGRP binding and receptor density are not affected in RCP antisense-treated NIH3T3 cells, despite reduction in CGRP-mediated signal transduction, suggesting that RCP is not a chaperon protein for CRLR. The nature of the interaction between RCP and CRLR is unclear. It has been suggested that RCP may facilitate CRLR activation, couple the receptor to G proteins or other effector molecules, or coordinate the receptor–effector complex in the plasma membrane. The requirement for the expression of at least three proteins (CRLR, RCP, RAMPs) to form a functional CGRP receptor may explain the difficulty in determining the molecular identity of CGRP receptors. Structural analysis and antisense studies will allow determination of sites of interaction and assignment of functions to the emerging subset of accessory proteins that bind to and regulate the activity of GPCRs.

Signal Transduction

CGRP activates CGRP receptors, which stimulates adenylyl cyclase via $G_{\alpha s}$ increasing intracellular cAMP in a concentration-dependent manner. An increase in cAMP activates protein kinase-A (PKA), which then triggers multiple changes in the downstream signaling pathways. In some cases, the CGRP-induced increase in cAMP is followed by a membrane hyperpolarization associated with the activation of an adenosine triphosphate (ATP)-sensitive potassium channel. In blood vessels, CGRP increases nitric oxide (NO) production via two different pathways (Fig. 3): (1) stimulation of adenylyl cyclase followed by activation of PKA and subsequent phosphorylation of eNOS by PKB through a phosphatidylinositol 3-kinase (PI3K)-mediated mechanism or (2) induction of Ca^{2+} influx through voltage-gated calcium channels, an effect mediated by a cAMP-dependent PKA. Increased intracellular Ca^{2+} may stimulate eNOS and nNOS, leading to NO generation.

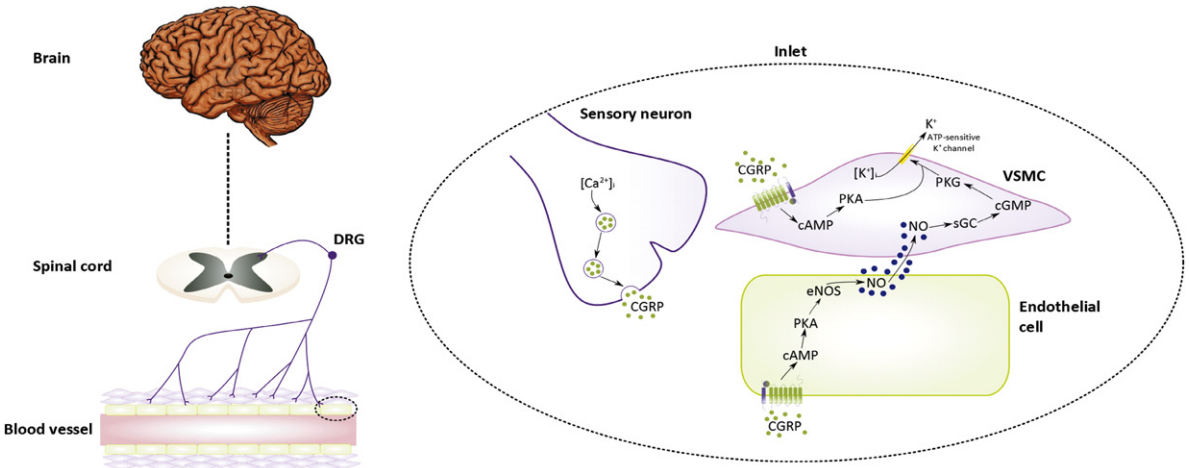

Fig. 3 A representative image of the role of CGRP in neurogenic vasodilation in peripheral and central nervous systems, which may play potential roles in migraine and other diseases, including inflammation and cardiovascular disease. Abbreviations: cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; CGRP, Calcitonin gene-related peptide; DRG, dorsal root ganglion; NO, nitric oxide; NOS, nitric oxide synthase; eNOS, endothelial NOS; PKA, protein kinase A; PKG, protein kinase G; sGC, soluble guanylyl cyclase; VSMC, vascular smooth muscle cell.

Sometimes CGRP receptor activation does not stimulate adenylyl cyclase but instead activates PLC-β1 via pertussis toxin (PTX)-insensitive $G_{\alpha q/11}$ protein. This induces the formation of diacylglycerol, a direct activator of PKC, and inositol 1,4,5-triphosphate (IP_3), which binds to receptors on the ER and causes a transient release of Ca^{2+}. There is also solid evidence that CGRP, at high concentrations, can signal through G_i coupled to either calcium or potassium channels in various tissues. In summary, it appears that CGRP activates various signal transduction pathways via its receptor complex and the relevance of the accessory proteins, RAMPs and RCP in determining signal cascades triggered by CGRP receptor activation remains to be clarified.

CGRP Antagonists and Antibodies

Structure–activity characterization of various human α-CGRP (hα-CGRP) fragments demonstrated the potent antagonist properties of C-terminal fragments such as $CGRP_{8-37}$. Shorter C-terminal fragments, including $CGRP_{19-37}$ and $CGRP_{23-37}$, also displayed competitive antagonist properties although with much lower potency when compared with $CGRP_{8-37}$. The use of peptide-based receptor antagonists resulted in limited use *in vivo* and bioassays due to its short bioavailability, until the discovery of the first small molecule CGRP receptor antagonist, developed by SmithKline Beecham (SB-273779), with both binding K_i and cAMP bioassay IC_{50} of 0.31 μM. This finding was followed by the development of BIBN4096BS or olcegepant with $\sim$20 times higher potency compared to $CGRP_{8-37}$, exhibiting $>$200-fold higher affinity at human CGRP receptors (SK-N-MC cell line $K_i = 14.4 \pm 6.3$ pM) than at rat CGRP receptors (spleen $K_i = 3.4 \pm 0.5$ nM). However, as this antagonist is not orally active, subsequent compounds were identified. This included Merck's "Compound 2" and its optimization into telcagepant resulted in an antagonist with good oral bioavailability and K_i of 1.1 nM in CGRP receptors-expressing HEK293 cells, with similar pattern of higher potency at primates and human CGRP receptors compared to rodent tissues. Other compounds include Merck's MK-3207, with improved K_i at 0.024 nM, Boehringer Ingleheim's "Compound 1" with pK_i of 7.8, a weak antagonist for CGRP responses in humans cerebral and guinea pig basilar arteries, and Bristol-Myers Squibb (BMS) BMS-694153 that can be administered intranasally which may be suitable for treating acute migraine attacks.

Despite promising results during Phases I and II clinical trials of olcegepant and telcagepant for migraine, showing no cardiovascular side effects, long-term study in Phase III showed that the administration of telcagepant administered for 3 months as a prophylactic treatment resulted in elevated symptomatic transaminase level in 2 patients. In contrast, a longer-term Phase III study at 300 mg for intermittent, but repeated administration only reported 3 patients with transient and temporal increase in enzyme levels. Regardless, Merck discontinued the development of telcagepant and another compound MK-3207 in July 2011 due to liver toxicity. Currently, there are other novel CGRP receptor antagonists undergoing clinical trials, with little evidence of liver toxicity in the early phases, highlighting an exciting time for small molecule CGRP antagonist.

An alternative approach to inhibiting CGRP is the development of antibodies against CGRP or CRLR, shown to inhibit neurogenic vasodilation, lasting for 7 days without cardiovascular effects, suggesting long duration of treatment. Despite initial concerns regarding its inability to cross the blood–brain barrier, clinical trials have shown promising results in migraine patients. Currently, there are four companies (Amgen, Teva Pharmaceuticals, Eli Lilly & Co, Alder Pharmaceuticals) investigating monoclonal antibodies against CGRP, each in the process of or recently having completed their Phase II clinical trials, showing positive improvement in migraine symptoms of, at least, a third of individuals tested. Little or no adverse effects have been currently reported. The longer-term use of the CGRP antibodies on both episodic and chronic migraine and pain conditions is awaited.

CGRP Functions in Physiological and Pathological Conditions

CGRP in Migraine and Headache

Migraine is a complex neurovascular disorder, affecting 8% of men and 18% women, with 13% of sufferers experiencing more than one attack per week. While the mechanisms triggering this condition are debated, the role of CGRP in migraine headache is widely supported by both clinical and experimental evidence. It is thought that the activation of the trigeminovascular system, releasing neuropeptides, including CGRP resulted in the pain experienced by sufferers. The trigeminal ganglion consists of bipolar neurons that send fibers to the meninges, to the meningeal (dural) and cerebral (pial) blood vessels involved in the manifestation of head pain and (centrally) to the caudal brainstem and upper cervical spinal cord. Activation of the trigeminovascular system causes peripheral release of neuropeptides that induce meningeal blood vessel dilation, blood flow increase and plasma protein extravasation, in part by central reflex activation of the perivascular parasympathetic system via the superior salivatory nucleus. This inflammatory process is also thought to cause sensitization of nerve fibers and, consequently lowering of the nociceptive threshold. Additionally, intravenous administration of CGRP can induce migraine-like attacks in sufferers while plasma CGRP levels in patients suffering an attack was elevated and normalized with anti-migraine agents, such as triptans. However, not all patients show such prominent response in CGRP levels, which may suggest that CGRP can be used as a biomarker to identify migraine patients who will benefit from inhibiting CGRP (as described in the "antagonist and antibodies" section).

CGRP in the Central Nervous System

CGRP immunoreactivity is widely distributed in the central nervous system (CNS), suggesting its involvement in various brain functions. Anatomical and functional studies in animal models showed that CGRP is involved in sensory, cognitive and motor

activities. A comprehensive review of biological roles of CGRP in the CNS was published by Van Rossum *et al*. CGRP participates in sensory functions such as olfaction, vision, hearing, and taste. CGRP-immunoreactive fibers are localized in the glomerular, mitral, and plexiform cell layers of the olfactory bulb as well as in other areas of the olfactory system, including the accessory and anterior olfactory nuclei. Although no functional evidence is available for a role of CGRP in audition and vision, the presence of immunoreactive CGRP cells in auditory structures or in visual areas, such as superior colliculus and lateral geniculate nucleus, strongly suggests that CGRP may be involved in these functions. CGRP is also expressed in sensory nerve endings in taste buds and in their central projections terminating in the rostral part of the solitary tract nucleus. CGRP neurons have been found in the amygdala and in circuits that project to the amygdala. Behavioral studies indicate that these projections may play an important role in learning by regulating gustatory, nociceptive, and acoustic information during aversive conditioning. CGRP plays an essential role in synaptic plasticity, erasing the fear memory and facilitating long-term potentiation in the central nucleus of the amygdala in rats.

A potential role for CGRP in neurological disorders such as dementia and depression has been supported by anatomical, biochemical, and clinical data. CGRP receptors are often localized in dopamine (DA)-containing neurons. Direct administration of CGRP into the brain markedly affects DA release and metabolism in selected brain regions as well as learning and memory. On the other hand, both psychomimetics and antipsychotic drugs influence regional brain concentrations and release of CGRP *in vivo*. Altogether, these findings support the involvement of CGRP in DA-related disorders. In dementia patients, cerebrospinal fluid (CSF) levels of both CGRP-LI and CT-LI are lower, but their concentration ratio is similar to that of age-matched healthy controls. This may be explained by a general neuronal loss or, alternatively, by a down-regulation of the CT/α-CGRP gene expression. In depressed patients, only CT-LI appears to be diminished, resulting in an increase of the α-CGRP/CT ratio. This most likely reflects an altered splicing mechanism favoring the formation of α-CGRP mRNA. Although more studies are needed to draw definitive conclusions, combined measurements of CGRP-LI and CT-LI in CSF may be of diagnostic and perhaps prognostic value in dementia and affective CNS disorders, including depression.

CGRP in the Cardiovascular System

CGRP and its receptors are found throughout the cardiovascular system, specifically in the media, intima and endothelial layer of blood vessels. CGRP-containing nerves form perivascular networks around blood vessels and the heart. CGRP participates in various functions, including modulation of vascular tone, microvascular permeability, cell proliferation, apoptosis and inflammation. In healthy subjects, CGRP plasma levels can vary between 2 and 35 pmol L^{-1} in a gender-independent manner and it possessed a circadian rhythm, with higher amounts released during nocturnal periods. CGRP is established as a potent microvascular vasodilator, 10-fold higher than prostaglandins and 10–100 times greater than acetylcholine and substance P. Brain *et al.* (1985) showed that local administration of CGRP caused reddening, due to increased blood flow in the cutaneous vasculature. Picomole amounts of CGRP results in an erythema lasting for 5-6 h. Positive chronotropic and inotropic responses in the heart are observed after intravenous CGRP administration. However, the physiological significance of circulating CGRP remains unknown. Various studies have supported the role of CGRP in regulating peripheral vascular tone and regional organ blood flow in physiological conditions through either endothelium-dependent or endothelium-independent mechanisms. Of note, plasma levels of CGRP are raised in pregnancy. Despite these responses, CGRP is not involved in regulating baseline blood pressure in normal individuals. Antagonism of CGRP receptor or inhibition of CGRP using antibodies had no effect on baseline cardiovascular hemodynamics in various animal species and humans. Additionally, the α-CGRP specific KO mice showed no changes in their baseline blood pressure and blood flow. Nevertheless, the commonly used CT/αCGRP KO mice displayed a significantly higher mean blood pressure at baseline, compared to WT counterparts.

Changes in CGRP levels have been reported with various cardiovascular pathologies including hypertension, obesity and cardiogenic shock associated with sepsis. The role of CGRP in obesity has been studied, with evidence that α-CGRP KO mice are protected from diet-induced obesity. CGRP levels are slightly raised in obese female humans and pre-obese Zucker rats. In some cases, increases in CGRP levels may be a compensatory mechanism to counteract pathological vasoconstriction or increased plasma volume such as that observed in myocardial ischemia or pregnancy, respectively. Nevertheless, other studies reported reduced or unchanged levels of CGRP in the plasma of patients with essential hypertension compared to normotensive controls. This discrepancy may be due to variations in treatment, sampling methods or stage/types of hypertension. There is increasing evidence that CGRP can play a protective role in the cardiovascular system but its precise protective mechanisms remain unclear (see Russell *et al.*, 2014).

Recently, a study demonstrated that α-CGRP KO mice have enhanced hypertension following continuous infusion of AngII for up to 28 days in mice, associated with worsened vascular dysfunction, inflammation and oxidative stress. Moreover, deletion of α-CGRP caused enhanced cardiac and renal damage in DOCA-salt induced hypertension, and exacerbated cardiac dysfunction in pressure overload-induced heart failure. Indeed, acute systemic administration of CGRP is beneficial in experimental models of hypertension and patients with congestive heart failure. Further research into the therapeutic potential of CGRP has been limited due to its peptide nature and short half-life ($\sim$10 min in plasma). Other ways of modulating endogenous CGRP release to influence blood pressure regulation have relied on the activation of TRP channels such as TRPV1 and TRPA1 expressed on sensory neurons. Whilst deletion of TRPV1 and TRPA1 has no effects on baseline cardiovascular hemodynamics and limited role in AngII-induced hypertension, activation of TRPV1 using its agonist rutaecarpine protects against phenol-induced hypertension in rats,

associated with increased vascular and neuronal CGRP. Other ways include the development of long lasting CGRP agonist. Notably, there is presently one stabilized α-CGRP peptide analogue from Novo Nordisk, with a half-life of ~10 h (patent number WO 2011/051312). Nilsson *et al.* (2016) recently demonstrated that 2-week treatment with this analogue had potential anti-diabetic effects and, reduced both food intake and body weight in diet-induced obese rats and the Leptin deficient mouse model (ob/ob mice). This suggests that long acting CGRP analogues may have a therapeutic potential in treating type 2 diabetes through positive metabolic effects. The effects of such analogues in cardiovascular diseases remains to be elucidated.

Role of CGRP in Vascular Disorders Associated With Aging and Raynaud's Phenomenon

Wimalawansa *et al.* demonstrated age- and circadian rhythm-related changes of CGRP tissue content. With aging, CGRP levels decrease in neural cells and increase in both the thyroid gland and circulation. The relevance of these changes in deteriorating hemodynamics in the elderly is unclear. CGRP content also decreases in major arteries such as aorta, carotid, cerebral and coronary arteries, a phenomenon likely linked to vasomotor dysfunction and higher risk of ischemic cerebrovascular and cardiovascular events in the elderly. An age-dependent reduction in CGRP nerve function, including decreases in neuronal CGRP mRNA levels, neurogenic CGRP release and CGRPergic nerve-mediated vasodilation were observed in spontaneously hypertensive rats, without any change in expression in normotensive rats. Chronic blockade of the angiotensin system using temocapril and losartan protects against the reduction in perivascular sensory nerve innervation in a blood pressure-independent manner. Hence, hypertension can modulate CGRP-containing nerves and availability of endogenous CGRP as one ages.

Local cold exposure causes a transient vasoconstriction followed by a gradual increase of blood flow back to baseline level, often referred to as vasodilation. This is important to protect against local cold-induced vascular injury. This phenomenon was first described by Thomas Lewis in 1930 and involved both the sensory and sympathetic nerves. There is recent evidence from Aubdool *et al.* (2014) showing that cold activates TRPA1 in the vasculature and sensory nerve denervation or pharmacological blockade of the CGRP receptor using BIBN4096 can impair the cold-induced vasodilator response. This highlights the major participation of CGRP which is released downstream of TRPA1 activation by cold from the nerves. A lack of reflex vasodilation in response to local cold exposure is normally observed in patients with Raynaud's phenomenon. Small unmyelinated nerves containing CGRP are extensively present in digital skin, where they are involved in nociception and modulating vascular tone. There is a deficiency in digital perivascular CGRP-containing nerves in Raynaud's phenomenon. Intradermal or intravenous administration of CGRP increase peripheral cutaneous perfusion as measured by laser Doppler flowmetry and cutaneous temperature. However, the numbers of patients studied have been small and further studies are required to understand the therapeutic potentials of CGRP in the Raynaud's phenomenon.

CGRP in Cutaneous-Neuroimmune Interactions

Interest in the role of CGRP in the skin arose from initial studies showing that it is a highly potent microvascular vasodilator. Endogenous CGRP is released from the sensory afferent nerve terminals and causes neurogenic vasodilation. However, emerging evidence has shown that CGRP can be released by other cells, including keratinocytes and immune cells, highlighting their potential role in mediating acute and chronic cutaneous immunity. Acute application of nanomolar concentration of CGRP in response to topical application of various inflammatory mediators, such as histamine and leukotriene B_4 onto hamsters' cheek pouch resulted in reduced edema responses to these substances, suggesting an anti-inflammatory effect of CGRP. The anti-inflammatory potential of CGRP was further highlighted in models of delayed-type and contact hapten-induced hypersensitivity, where epicutaneous pre-treatment of CGRP resulted in dose-dependent reduction in hypersensitivity, which was locally mediated. In contrast, pro-inflammatory effects of CGRP have been reported, especially in the role of CGRP in priming dendritic cells and T-cells in driving a Th2 response, increasing cytokines production, hence proposing an important role in atopic dermatitis and other skin inflammatory conditions.

In addition to immunomodulatory responses in the skin, CGRP can enhance keratinocytes proliferation and epidermal thickness *in vitro*. In support for this, sensory nerve denervation in a spontaneous psoriasis model (K5-Tie2 model) improve the skin symptoms which were later blunted by systemic CGRP administration. This suggests that CGRP is an important neuropeptide in driving psoriatic skin phenotype. However, it remains unknown whether CGRP acts directly by driving keratinocyte proliferation or through pro-inflammatory response. Indeed, CGRP plasma levels are elevated in both psoriatic and atopic dermatitis patients, although this trend does not necessarily indicate causality. While most research has mainly focused on the role of α-CGRP in the skin-sensory nerve interactions, recent study has shown the importance of *β*-CGRP, the main isoform expressed in keratinocytes, in skin samples from chronic pain patients as well as animal models of pain. Hence, our knowledge on the role of CGRP in skin has improved from its role in neurogenic vasodilation, to more complex interactions between the sensory nerve terminal-keratinocyte-immune responses, with multiple involvement of CGRP at each step of the interaction. Understanding these pathways may lead us to a novel indication of targeting CGRP in various skin conditions.

CGRP in Arthritis

Arthritic patients are known to have increased levels of CGRP in their plasma and synovial fluid, with increased sensory innervation throughout the arthritic joints. Modulation of CGRP activity can affect important disease components in both rheumatoid

arthritis (RA) and osteoarthritis (OA). CGRP receptors are expressed in the joint afferents and upregulated following arthritis induction in animal models of arthritis. When CGRP are released in the periphery, it activates the synovial vascular cells causing acute vasodilation, followed by endothelial cell proliferation and angiogenesis leading to chronic inflammation. Local administration of the TRPV1 agonist capsaicin and surgical denervation on arthritic ankle joints in rats reduced both peripheral and DRG levels of CGRP, and reduced the development of joint inflammation. Treatment with the CGRP receptor antagonist $CGRP_{8-37}$ inhibits the proliferation of synovial cells, cytokines production and MMPs expression in RA, in addition to reduced peripheral sensitization and decreased CRLR mRNA levels in both the DRG and large joint afferent neurons in both RA and OA animals. A high affinity neutralizing antibody to CGRP, LY2951742 has recently been shown to be efficacious in pre-clinical *in vivo* models of OA pain and remains to be studied in OA patients.

Concluding Remarks

There is sufficient evidence to highlight the potential therapeutic benefit of drugs modulating abnormal CGRP functions in pathological conditions. In the past few years, considerable progress has been made in understanding the complexity of CGRP receptor structure and pharmacology. The development of synthetic, non-peptide CGRP receptor antagonists and antibodies, and their apparent benefit in migraine, implies a major role of CGRP in migraine. This is an exciting stage where we are able to understand the complexity of CGRP in a range of physiological and pathological pathways, which may highlight the potential for targeting CGRP therapeutically. As the use of the antagonists and antibodies increases, it will continue to be important to monitor adverse effects, considering the multiple biological activities of this peptides. Separately, there is a potential possibility that CGRP agonists may also have a protective role in condition involving the cardiovascular system, but this is presently still at a research stage.

Epidemiology of Fractures

Nicholas R Fuggle, Elaine M Dennison, and Cyrus Cooper, MRC Lifecourse Epidemiology Unit, Southampton General Hospital, Southampton, United Kingdom

Introduction

Bones are rigid structures that provide architectural support for the body to allow mobility and locomotion. At a tissue level, bones are an intricate combination of mineralized connective tissue, bone marrow, endosteum, periosteum, blood vessels, and nerves. The connective tissue is composed of an organic matrix (composed of 95% type 1 collagen and 5% noncollagenous protein), inorganic mineral content (calcium phosphate and hydroxyapatite), and cells. There are two types of bone, cortical and trabecular bone of which contribute to bone structure and strength. Cortical bone is tightly compacted, forms the outer rim of long bones, and accounts for 80% of the adult bone mass (Augat and Schorlemmer, 2006). Trabecular bone is porous and less regular, being composed of plates and rods, and has a high turnover due to a massive surface area. It accounts for the remaining 20% of adult bone mass. The strength of a material is determined by the spatial distribution and the material composition. The latter is a fine balance between the material's ability to resist excessive strain and adequate elasticity to allow it to absorb energy. Generally, bone is 60% mineralized, but if this mineralization increases, it can lead to increased stiffness and thus brittleness, which increases the risk of fracture.

Fractures, defined as a crack or break in the cortex of a bone, occur due to excessive force being applied to the bone. They are a major cause of morbidity and mortality throughout the life course, and the resultant financial burden placed on global health economies is huge. In 27 European countries, fractures are estimated to account for €32 billion of direct and associated costs. In youth and early adulthood, they are more commonly caused by significant trauma; however, as aging occurs, the proportion of fractures occurring due to bone fragility increases, until predomination.

This chapter will review the epidemiology of fractures as a whole before focusing on hip, vertebral, and distal forearm fracture. We will then examine the morbidity, mortality, and wider financial implications of fragility fractures and peruse secular trends and geographic variation.

Fracture Epidemiology

Fracture incidence has a bimodal distribution with peaks in youth and older adulthood (Curtis *et al.*, 2016; Moon *et al.*, 2016). The young tends to experience long-bone fractures, around puberty, due to significant trauma that are more common in males than females. However, after the age of 50, the fracture incidence increases rapidly in the female population leading to a 1:2 (male-to-female) ratio. This growth in fracture incidence is due to an increase in hip, distal radial, and vertebral fracture. Risk factors for fracture in adult life include obesity, physical inactivity, vitamin D insufficiency, and possibly dietary calcium intake, tobacco smoking, alcohol consumption, and use of exogenous estrogens.

The prevalence of fractures, divided according to anatomical location, was recorded in the European POSSIBLE study (Freemantle *et al.*, 2010). Nearly 2000 fractures were sampled with 30% wrist, 23% vertebral, 11% ankle, 9% forearm, 8% foot, 7% hip, 7% rib, and 7% upper arm fractures. The remainder is depicted in **Fig. 1**. Hip, wrist, and vertebral fractures account for nearly two-thirds of prevalent fractures and are common sites for fragility fractures.

In the year 2000, the incidence of fragility fractures was approximately 9 million, and it was therefore extrapolated that a fragility fracture occurs once every 3 s (Johnell and Kanis, 2006). Of these, 1.6 million were hip, 1.4 million were clinical vertebral, and 1.7 million were distal forearm fractures (Johnell and Kanis, 2006). Other sites included humerus, rib, tibia, pelvis, and nonhip femoral fractures.

Global variation in fracture incidence is thought to be due to factors including the effect of ethnicity on BMD, bone geometry and microarchitecture, diet, and behavior (Curtis *et al.*, 2016). Incidence in fracture increases with increasingly northerly latitude (Oden *et al.*, 2014; Wahl *et al.*, 2012) that suggests a possible role for vitamin D.

In the United Kingdom, about half of women and a fifth of men, over the age of 50, will experience a fragility fracture during their lifetime (van Staa *et al.*, 2001). These fractures therefore represent an enormous issue for health-care systems and governments.

Hip Fracture

Examining hip fractures as a whole, 80% occur in females, and the incidence of hip fractures increases exponentially with age. Over the age of 50 years, fractures are considerably more common in females with a 2:1 (female-to-male) incidence ratio (Curtis *et al.*, 2016). This higher rate of hip fracture in women is due to an increased incidence and longer life span (Gallagher *et al.*, 1980; Cooper *et al.*, 1992b). There is a preponderance for middle and older age, with 80% occurring in those >35 years. Of the 1.6 million hip fractures in the United Kingdom in 1990, 1.19 million occurred in females and 463,000 in males (Cooper *et al.*, 1992b).

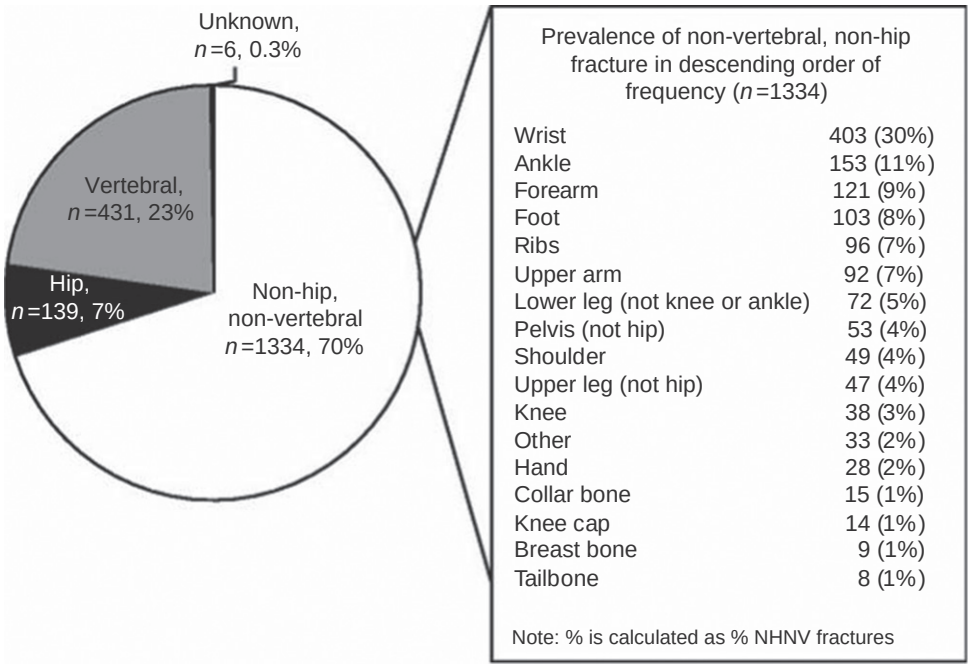

Fig. 1 Fracture frequency in clinical practice: result from the POSSIBLE study (Freemantle et al., 2010).

In terms of traumatic mechanisms, although, in youth, hip fractures are largely due to substantial trauma, the majority of hip fractures are generally the result of a fall from standing height (Blain *et al.*, 2016). The direction of fall is also important, with falls forward less commonly associated with hip fracture than falls sideways.

Seasonality also plays a significant role with a marked increase in winter months (in those countries with temperate climates). Many of these occur indoors and so may not be due to environmental hazards of increased precipitation or icy conditions but may be due to reduced efficacy of neuromuscular reflexes and a reduction in natural light during this season.

An American study investigating a wide range of ecological correlates of hip fracture found a significant relationship with latitude (hip fracture more common in the south), poverty level, rural land use, and fluoridated water and a negative relationship with water hardness and sunlight hours in January and nonsignificant relationships with activity level, cigarette smoking, alcohol consumption, Scandinavian heritage, and obesity (Jacobsen *et al.*, 1990).

Indeed, variation in the incidence of hip fracture is observed between populations of differing ethnicity and race both within nations (Curtis *et al.*, 2016) and internationally (Oden *et al.*, 2015). Across Europe, there is an 11-fold variation in the prevalence of hip fracture (depicted in **Fig. 2**) that is not explained by smoking, obesity, alcohol consumption, migration, and physical activity levels (Elffors *et al.*, 1994). Global variation in hip fracture is seen in **Fig. 3**.

Hip-fracture mortality is considerable, and the vast majority requires admission to hospital for surgical intervention. The potential, acute complications they may experience include surgical complications, anesthetic risks, postoperative infections, and pressure sores, leading to 8% of men and 3% of women dying during hospital admission for the condition (CotUS, 1993). In the United States, there are 31,000 excess deaths (of 300,000 fractures in the sample population) within a 6-month period post fracture. At 12 months, the postfracture survival is significantly less at 63.3% (vs. 90.0% expected) for females and 74.9% (vs. 91.1% predicted) for males (van Staa *et al.*, 2001). Hip-fracture patients continue to have an increased mortality for up to 10 years post fracture (Bliuc *et al.*, 2009). From these four time points, it can be observed that the risk of death from fracture peaks initially and then gradually reduces with time. Mortality is increased in those with poor prefracture functional status and comorbidities. Encouragingly, however, a US medicare database suggests that hip-fracture mortality rates are decreasing (Brauer *et al.*, 2009). This may be due to improved preoperative, operative, and postoperative care and better rehabilitation.

Hip fractures have a huge effect on independence, with 50% of patients who were walking prior to the fracture rendered nonambulatory afterward. This and other comorbid factors lead to 14% of 50–55 year olds and 55% of >90 year olds requiring nursing home placement after the fracture.

Vertebral Fracture

Vertebral fractures are the most common osteoporotic fractures globally affecting 30%–50% of people over the age of 50 years (Bouxsein and Genant, 2010). Establishing the precise epidemiology of vertebral fractures is complicated by two main factors. Firstly, between 65% and 75% are clinically silent (Kanis *et al.*, 2012; Fink *et al.*, 2005) and are picked up incidentally on

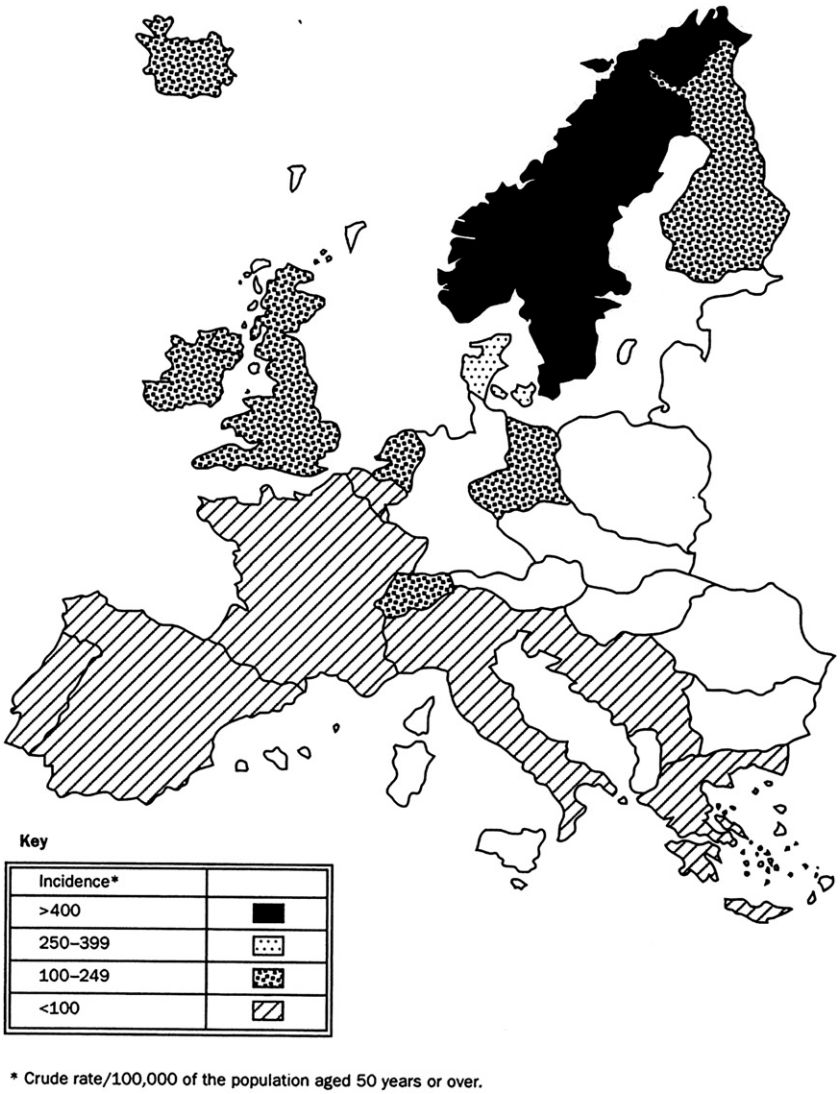

Fig. 2 The geographic variation in hip-fracture prevalence across Europe.

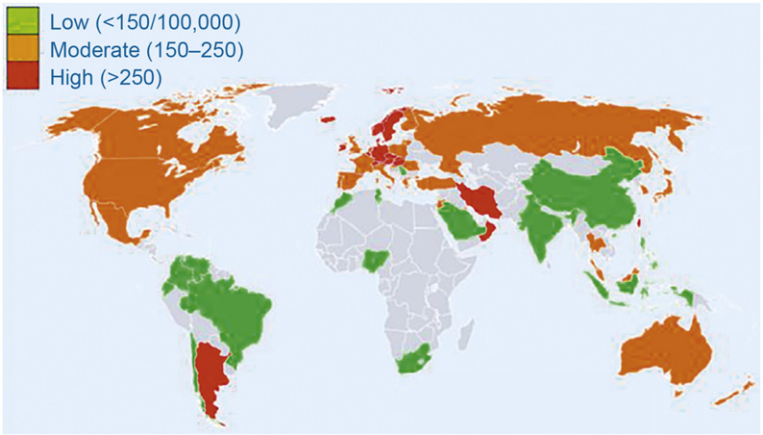

Fig. 3 The global variation in hip-fracture prevalence (Kanis et al., 2012).

radiography. Indeed, research shows that even on radiography, the presence of vertebral fractures is often not documented or even missed (Eastell *et al.*, 1991). Secondly, vertebral fractures can be defined clinically or morphometrically, with differing classifications of the latter being available. Morphometric analysis quantifies or semiquantifies the fracture according to measures of vertebral height, but there is variation concerning decision thresholds (O'Neill *et al.*, 1996).

The frequency of vertebral fractures divided according to vertebra affected is depicted in **Fig. 4**. As can be seen, the most commonly affected vertebrae are at T6–T8, the site of the most pronounced dorsal kyphosis (Cooper *et al.*, 1992a), and L1, at the thoracolumbar junction, the location of synthesis of the more rigid thoracic spine and the more mobile lumbar spine.

In terms of the etiology of vertebral fracture, males were found to have a higher prevalence than women aged 50–64, and it is postulated that this may be due to a higher incidence of trauma. Fractures in elderly women are commonly the result of normal activities, though they may be asymptomatic. Indeed, only 30%–40% of vertebral fractures come to medical attention (Cooper *et al.*, 1992a) as seen in **Fig. 5**.

The EVOS study, which is the largest study of vertebral fractures to date, included 15,000 individuals from 19 European countries. In this study, the age-standardized population prevalence was 12.2% in women and 12.0% in men (aged 50–79 years) (O'Neill *et al.*, 1996). There was marked variation across the continent with a threefold difference in the prevalence of vertebral fracture in different countries, the highest being in Scandinavia. This variation was partially explained by physical activity levels and measures of adiposity (O'Neill *et al.*, 1996). The CaMoS study, a five-year follow-up of over 9000 participants based in Canada, also found a similar prevalence of vertebral fractures between the sexes with a male-to-female prevalence ratio of 1:1 (Jackson *et al.*, 2000). The study of fractures (Kado *et al.*, 1999) and Rochester (Melton *et al.*, 1993) studies, based in the United States, were studies of females alone and found a prevalence rate of 20%–23% for vertebral fracture.

The age-standardized rates do vary by geography, with the highest (in studies combining hospitalized and ambulatory fractures of the vertebrae) seen in South Korea, the United States, and Hong Kong and the lowest rates in the United Kingdom (Ballane *et al.*, 2017). This variation can also be observed in the LAVOS study that found an overall prevalence of 14.8% across Latin America but a significant difference between the highest country rate in Mexico and the lowest in Puerto Rico (Clark *et al.*, 2009). Indeed, vertebral fracture prevalence is low in Latin America, with a study of osteoporotic women demonstrating a prevalence that was twice as low as that observed in EVOS (O'Neill *et al.*, 1996) and CaMoS (Jackson *et al.*, 2000).

In Asian studies, there is generally greater variation in prevalence rates across the region, with a 1.42 difference between the highest prevalence rates in Vietnam and the lowest rates in China (Ballane *et al.*, 2017). Heterogeneity was observed on an intranational and international basis. Interestingly, a pan-Asian study observed higher rates of vertebral fracture in men than women in Japan, Thailand, Indonesia, and Hong Kong at a female-to-male ratio of 0:6 (Kwok *et al.*, 2012). However, studies performed in individual countries have shown a preponderance for fractures in females with prevalence ratios of 1:24 in Korea (Shin *et al.*, 2012), 1:15 in Vietnam (Ho-Pham *et al.*, 2012), and 1:65 in Taiwan (Tsai *et al.*, 1996).

A recent study summarized the worldwide prevalence of osteoporotic vertebral fractures (Ballane *et al.*, 2017). The findings are summarized in **Table 1**.

The incidence of vertebral fractures in those aged 75–79 is 13.6 and 29.3 fractures per 100 persons per year for females and males, respectively (Felsenberg *et al.*, 2002). This does vary between studies, as demonstrated by the Rotterdam study of 3000 participants, followed up over 4–7 years, which found incidences of 1470 and 590 per 100,000 persons per year in women and men, respectively (Van der Klift *et al.*, 2002). The female-to-male ratio was 2:5, and interestingly, the presence of a fracture at baseline increased the incidence of vertebral fracture in women (26% vs. 5%) and men (9% vs. 3%).

Vertebral fractures are associated with an increased mortality that persists for >1 year post fracture (Bliuc *et al.*, 2009; Cooper *et al.*, 1993). The UK CPRD study observed a 12-month survival rate in women of 86.5% (vs. 93.6% expected) and 5-year survival of 56.5% (vs. 69.9% expected). Survival is reduced by the presence of comorbidities.

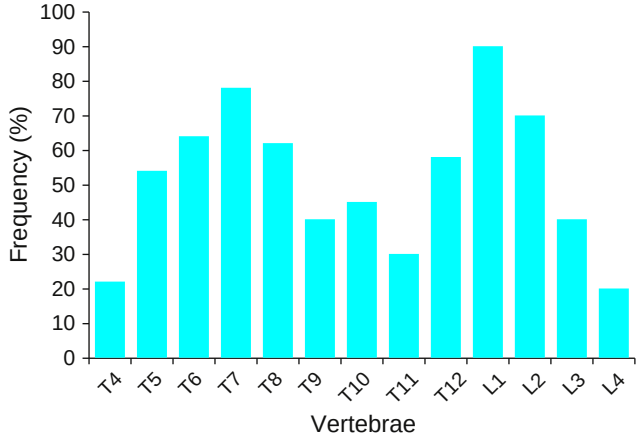

Fig. 4 Frequency of vertebral fractures according to vertebral level (Ismail et al., 1999).

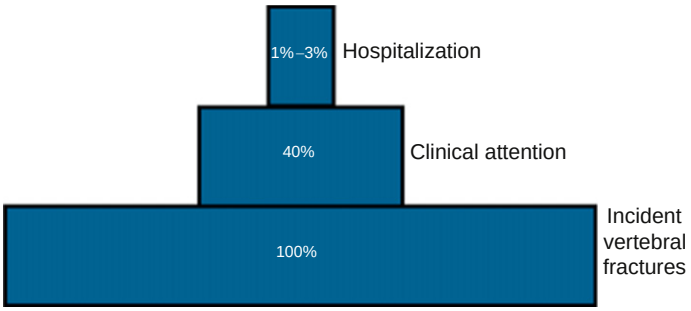

Fig. 5 The outcome of vertebral fractures (Cooper *et al.*, 1992a).

Table 1 Global prevalence rates of vertebral osteoporotic fracture (Ballane et al., 2017)

Geographic location	*Population demography*	*Prevalence rate (%)*
The Americas		
North America	White women ≥50 years	20–24
Latin America	Women ≥50 years	11–19
Asia		
Japan	≥65 years	24
Indonesia	≥65 years	9
Middle East		
Lebanon		20

Vertebral fractures lead to debilitating symptoms including back pain, kyphosis, and height loss that have significant effects on quality of life. Indeed, measures of quality of life reduce with increasing number of fractures.

Distal Forearm Fractures

Fragility fractures of the distal forearm are often the sequelae of a fall onto an outstretched arm. The incidence in men is relatively low and stable between the ages of 20 and 80 years. There is a marked preponderance for the female sex, with a larger sex prevalence ratio, of 1:4 (male to female) observed for distal radial fractures than for hip or vertebral fractures (van Staa *et al.*, 2001). Rates for those aged 50 and over are 39.7 and 8.9 per 10,000 persons per year for women and men, respectively (Curtis *et al.*, 2016).

Conversely to hip or vertebral fracture, there is no associated rise in mortality with wrist fractures, though increased morbidity does occur with only "fair to poor" function reported at 6 months after fracture (Chrischilles *et al.*, 1991).

Interfracture Relationships

Fragility fractures are thought to cluster with an increased risk of further fractures observed after the index fracture (Johnell *et al.*, 2004). A meta-analysis of 11 population-based cohort studies including 15,259 males and 44,902 females found that a history of prior fracture led to an 86% increase in the risk of a new fracture (Kanis *et al.*, 2004). Indeed, findings from the EVOS study of vertebral fracture found that vertebral fragility fracture was strongly predictive of incident hip fracture with a rate ratio of 2.8–4.5 (Ismail *et al.*, 2001). This risk increased with each new fracture.

Early Life

Early-life programming may affect an individual's predisposition to fracture. A low birthweight, which is taken as a surrogate measure for a poor quality of intrauterine environment, is associated with lower bone mass as an adult and subsequent increase in the risk of hip fracture (Harvey *et al.*, 2014; Cooper *et al.*, 2001; Javaid *et al.*, 2011; Baird *et al.*, 2011). There are also data to support a role for maternal vitamin D as the MAVIDOS trial demonstrated a benefit, in terms of childhood bone mass, if vitamin D supplementation was taken by the mothers of infants born in winter months (Cooper *et al.*, 2016). Certainly, peak bone mass is a significant contributor to the adult risk of osteoporosis (Hernandez *et al.*, 2003) and is likely determined by a genetic–environmental interaction that could be mediated by epigenetic factors.

Children

The epidemiology of fractures in children has been investigated in two studies, one based in Sweden and the other in the United Kingdom.

The Swedish study in Malmo investigated fracture in a pediatric population and found that the incidence of facture was 212 and 257 per 10,000 for females and males, respectively. Indeed, 27% of girls and 42% of boys had experienced a fracture by the age of 16 (Landin, 1983). Again, a dichotomy between the sexes is seen in this age group and is hypothesized to be due to a higher prevalence of trauma in males in this age group. The most common fractures were of the distal radius, followed by phalangeal fractures (Landin, 1983). Interestingly, a 10-year follow-up study found reduction in the incidence of fracture by 10% (Tiderius *et al.*, 1999).

The UK CPRD study of the incidence of pediatric fracture found 137 per 10,000 persons per year in total. In boys, fractures were more common occurring at 169 per 10,000 persons per year compared with girls at 103 per 10,000 persons per year. This extrapolates to 30% of UK boys having a fracture before their 18th birthday compared with 19% of UK girls. The most common fracture site, similar to the Malmo study, was the radius/ulna with 29.7 per 10,000 persons per year. There was also an ethnic discrepancy in the frequency of fractures, with a ratio of 1:2 black to white and South Asians at an intermediate risk as seen in **Fig. 6**.

Geographic variation in the rate of fracture is observed (**Fig. 7**) and is suspected to be due to concurrent variation in ethnicity and socioeconomic status (Moon *et al.*, 2016) The greatest fracture incidence was observed to be at the age of pubertal commencement, aged 14.5 years in males and 11.5 years in females (Kanis *et al.*, 2012). This may be due to this being the point at which there is the greatest discrepancy between vertical growth and gain in volumetric bone density (Walsh *et al.*, 2012; Holroyd *et al.*, 2016).

In terms of comorbid associations with fracture risk, childhood obesity increases the risk (Goulding *et al.*, 2000). Those children who fracture are more likely to have a lower bone mineral density than those who do not fracture, emphasizing the importance of this physiological variable in childhood and in old age. Physical activity, despite being associated with increased bone mass, is also associated with an increased risk of trauma and thus fracture (Clark *et al.*, 2008).

The Cost of Fragility Fractures

The cost of fragility fractures increases with increasing population size and thus increases with time.

In 1997, a conservative estimate for the costs of hip fracture alone was $131.5 billion worldwide by the year 2050 (Johnell, 1997).

In 2010, the cost of fragility fractures across 27 European Union countries was calculated to be €39 billion. Of this total, €26 billion were for the direct costs of treating the incident fracture, €11 billion for the cost of long-term care following fracture, and €2 billion for the cost of preventative strategies.

The cost of fracture varies by site with hip fracture accounting for 55% of costs, vertebral fractures 5%, wrist fractures 1%, and all other fractures 38%.

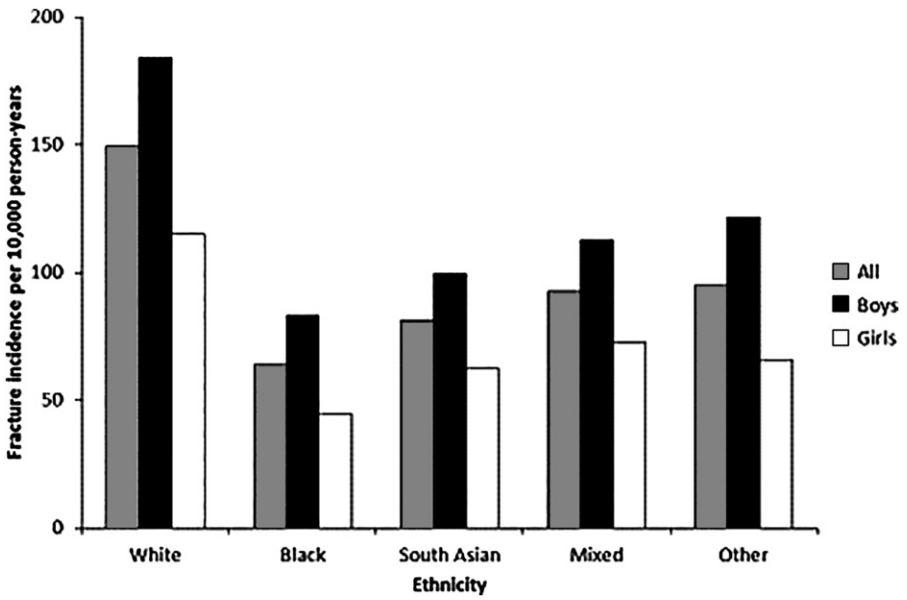

Fig. 6 Fracture incidence per 10,000 persons per year among UK children, 1988–2012, by ethnicity (Moon *et al.*, 2016).

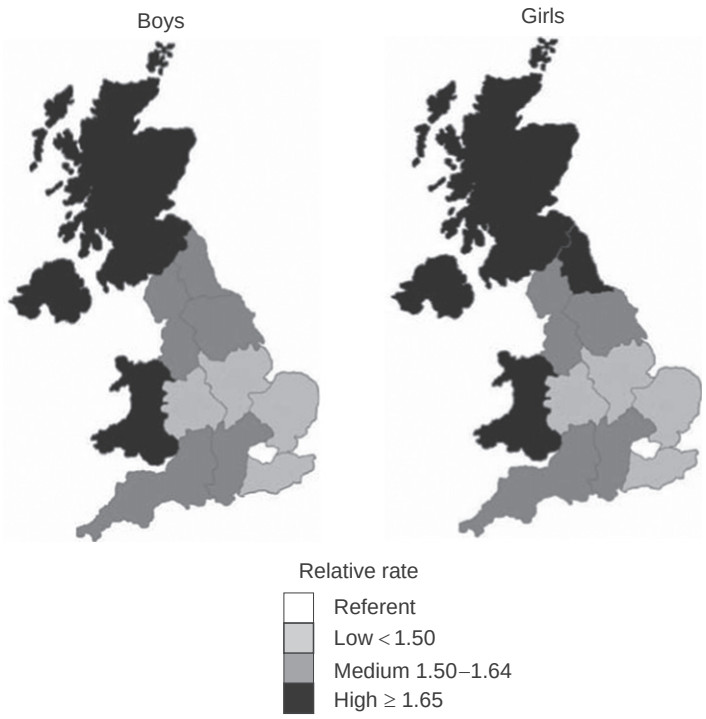

Fig. 7 The regional variation in pediatric fracture incidence across the United Kingdom (compared with Greater London) (Moon *et al.*, 2016).

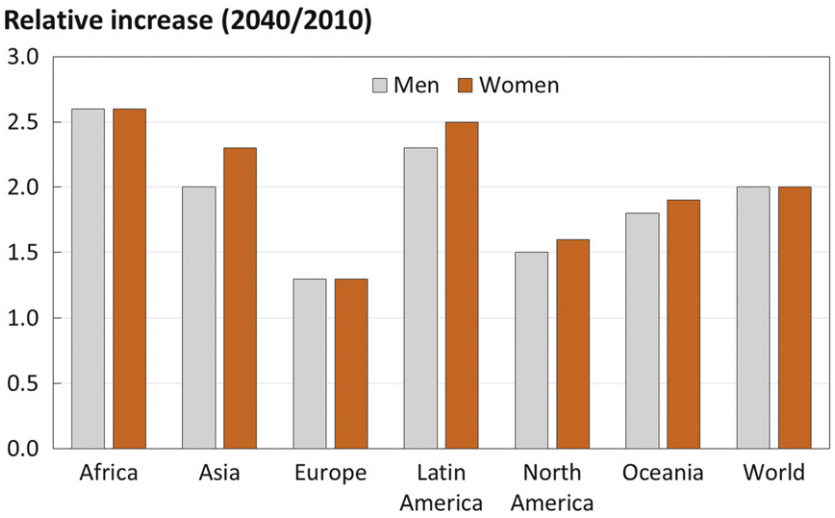

Fig. 8 Number of men and women at high fracture risk in 2040 relative to 2010, by continent (Oden *et al.*, 2015).

The Future

The number of fractures rose by 25% from the year 1990 to 2000 (Johnell and Kanis, 2006). Numbers are suspected to continue to rise, and the proportional increase in men is predicted to be higher than in women.

The total number of individuals currently aged 60 or greater is thought to be 901 million (equal to 12% of the global population). Europe has a higher proportion in this higher age bracket, likely due to increased life expectancy. However, by 2050, it is estimated that the majority of areas (except Africa) will have at least a quarter of their populations aged 60 or greater with a concurrent rise in the prevalence of hip fracture increasing form 1.66 million in 1990 to 6.26 million in 2050 (Gullberg *et al.*, 1997; Cooper *et al.*, 1992a).

Fracture risk will also increase with an estimated doubling of those at high risk of fracture aged greater or equal to 50 years by 2040 (see **Fig. 8**).

Interestingly, changes have been observed over time with regard to fracture site. From 1990 to 2012, there was no change seen in the rate of fracture; however, significant variation in the site of fracture occurred (van der Velde *et al.*, 2016).

Conclusion

As highlighted in this article, fragility fractures are common, often associated with increased mortality and manifold morbidity. They have an ever-rising financial cost, and therefore, the continued study and understanding of the epidemiology of fragility fractures are vital for coherent, rigorous, and effective health-care strategy.

Pathogenesis of Osteoporosis

Emma O Billington, University of Calgary, Calgary, AB, Canada
Ian R Reid, University of Auckland, Auckland, New Zealand

Introduction

The strength of the skeleton and its ability to withstand trauma is determined by a multitude of diverse factors. Skeletal development and homeostasis is a complex and tightly regulated process, and any condition that disrupts normal bone physiology has the potential to cause osteoporosis and increase the risk of fragility fracture. This article reviews the numerous determinants of skeletal strength and highlights the various scenarios in which osteoporosis can develop.

Fractures occur when the skeleton is subjected to a force that exceeds its resilience. Such force often results from trauma, such as a fall. Fragility fractures are fractures that result from minimal trauma (i.e., a fall from ground level). Many individuals with osteoporosis are at increased risk of falling, as the result of contributors such as frailty, impaired balance, sensory dysfunction (including poor vision and neuropathy), polypharmacy, and hazards in the home environment. This article will address factors that affect the intrinsic ability of the skeleton to resist fracture. However, extrinsic factors such as the force resulting from a fall should not be overlooked as important causes of fracture.

Definitions

Osteoporosis is a condition characterized by low bone mass and decreased bone strength, resulting in an increased propensity for fracture. Bone mass refers to the "quantity" of the bone mineral and is dependent on both the highest bone density that an individual achieves in their lifetime (i.e., peak bone mass), as well as the rate and duration of bone loss after peak bone mass has been attained, which is greatly dependent on bone turnover. Bone quantity can be assessed using dual-energy X-ray absorptiometry (DXA). DXA is a widely available, relatively inexpensive, and noninvasive technique that provides a two-dimensional estimate of an individual's bone mineral density (BMD) in a specific region of interest, usually the spine or the hip. Low BMD is predictive of fracture risk and has accordingly become recognized as a surrogate for the presence of osteoporosis (World Health Organization Study Group, 1994).

However, BMD by DXA does not take into account bone "quality," which is thought to be another important determinant of skeletal strength (Kanis, 2002). Bone quality encompasses the material properties of the bone matrix and bone mineral, as well as bone micro- and macro-architecture. These parameters are more challenging to assess clinically than bone quantity. The widespread use of techniques to assess the quality of the bone, such as high resolution peripheral quantitative computed tomography (HR-pQCT) and bone histomorphometry, is limited by several factors, including poor availability, high cost, and, in the case of histomorphometry, invasiveness. Although bone quality is not routinely assessed in the clinical setting, it is important to recognize that BMD alone does not capture the full picture of skeletal strength, and that the condition of osteoporosis encompasses abnormalities of both bone quantity and bone quality. Determinants of bone strength are outlined in **Table 1**.

The terms "primary osteoporosis" or "age-related osteoporosis" can be used to describe the development of skeletal fragility in the context of aging, which is largely mediated by a decline in circulating sex hormone concentrations. A more specific term, "postmenopausal osteoporosis," refers to the presence of primary osteoporosis in older women, resulting from the estrogen deficiency that accompanies menopause. The term "secondary osteoporosis" denotes osteoporosis that is not explained by age and/or age-related sex hormone deficiency alone and is often the consequence of underlying illness or medication use. Conditions that are associated with reduced bone mass and increased skeletal fragility are set out in **Table 2**.

Table 1 Components of skeletal strength

Component	*Contributors*
Bone mass	Peak bone mass
	Rate and magnitude of bone loss (bone turnover)
Material properties	Organic phase (collagen volume, cross-linking, advanced glycation end products)
	Mineral phase (hydroxyapatite, mineralization)
	Microcracks
Micro-architecture	Trabecular thickness, connectivity
	Cortical porosity
Macro-architecture	Hip axis length
	Diameter

	Thiazolidinediones
	Antiepileptic drugs
	Selective serotonin reuptake inhibitors
	Proton pump inhibitors
	Heparin

Determinants of Skeletal Strength

Peak Bone Mass

Peak bone mass is generally reached by the mid-20s and influences bone mass, and thus an individual's propensity to fracture, later in life (Heaney *et al.*, 2000). Gains in bone mass throughout childhood and adolescence are achieved largely via the process of bone modeling. Modeling involves formation of new bone on the periosteal (outer) surface, along with removal of old bone on the endosteal (inner) surface (Seeman, 2003), resulting in large changes in bone size and shape. Genetic factors have a large influence on peak bone mass, and studies of twins and families have repeatedly demonstrated that $>50\%$ of inter-individual variance in peak bone mass is genetic (Ralston and Uitterlinden, 2010; Krall and Dawson-Hughes, 1993; Pocock *et al.*, 1987; Hernandez-De Sosa *et al.*, 2014). Emerging evidence suggests a role for epigenetics in skeletal development (Marini *et al.*, 2016; Earl *et al.*, 2010), and the degree of DNA methylation in the perinatal period has recently been shown to be predictive of bone

mass in early childhood (Curtis *et al.*, 2017). In addition to genetic factors, bone development throughout adolescence is responsive to circulating sex hormones. Animal studies suggest that periosteal apposition is inhibited by estrogen and stimulated by testosterone (Turner *et al.*, 1989). Accordingly, at the time of puberty, periosteal apposition is reduced in girls, and increased in boys (Seeman, 2003).

The developing skeleton is also influenced by mechanical loading (Ruff, 2003), and both body weight and physical activity have been highlighted as modifiable environmental factors that have a strong impact on peak bone mass (Rubin *et al.*, 1999; McGuigan *et al.*, 2002; McKay *et al.*, 2005; Sundberg *et al.*, 2002). Dietary calcium intake has mostly been found not to play a significant role in determining peak bone mass (Rubin *et al.*, 1999; McGuigan *et al.*, 2002; Lanou *et al.*, 2005). Chronic systemic illness in childhood or adolescence can lead to arrested skeletal development (Soyka *et al.*, 2000), and the presence of growth hormone deficiency (Giustina *et al.*, 2008), type 1 diabetes (Pan *et al.*, 2014), and amenorrhea (Rubin *et al.*, 1999) have all been associated with failure to achieve expected peak bone mass, as has the use of glucocorticoid medications (Avioli, 1993).

Bone Turnover

The skeleton remains active following achievement of peak bone mass, undergoing constant change to repair damage, preserve structure, and maintain adequate circulating concentrations of bone minerals (Parfitt, 1982; Calvo *et al.*, 1996). After skeletal maturity is reached, such changes are primarily achieved through the process of bone remodeling, rather than modeling. Remodeling involves the removal of old bone from an area of the bone surface and replacement with new bone at the same site. At any given time, approximately 20% of the trabecular bone surface is undergoing remodeling (Hill, 1998), with the majority of the skeleton being replaced over the period of a decade in older adults (Manolagas, 2000).

Remodeling results from the concerted actions of the cells that resorb old bone (osteoclasts) and those that form new bone (osteoblasts). Together, these two cell types are known as a "basic multicellular unit," and their remodeling activities are largely orchestrated by osteocyte cells, which reside within the bone matrix and send signals to the osteoclasts and osteoblasts in response to mechanical loading and humoral stimuli (Neve *et al.*, 2011; Martin and Sims, 2005). The processes of bone resorption and formation are usually tightly coupled, although resorption generally starts to exceed formation beginning in the early 30s, leading to net losses in bone mass from that time onwards (Drake *et al.*, 2015). Factors that worsen this imbalance, such as the rapid decrease in estrogen that occurs in women at the time of menopause, can result in profound bone loss as well as reductions in bone quality. Many of the causes of secondary osteoporosis presented in **Table 2** also contribute to uncoupling of bone resorption and formation (Calvo *et al.*, 1996).

Resorption

Bone resorption is carried out by osteoclasts. Osteoclasts and osteoclast precursor cells express the receptor activator of nuclear factor-kappa B (RANK). Simulation of RANK by its ligand (RANK ligand [RANKL]), which is secreted by both osteoblasts and osteocytes (Nakashima *et al.*, 2011), results in osteoclast differentiation and recruitment to the region of the bone surface where resorption is to take place (Eghbali-Fatourechi *et al.*, 2003). Osteoclast recruitment is also facilitated by macrophage colony stimulating factor (M-CSF) (Tanaka *et al.*, 1993). Mature osteoclasts adhere to the bone surface and secrete hydrochloric acid and acidic proteases such as cathepsin K, resulting in degradation of the bone matrix and liberation of calcium, phosphate, and fragments of type I collagen (Ross, 2013).

Formation

Following resorption of bone by osteoclasts, deposition of new bone is carried out by osteoblasts. These cells arise from the mesenchymal cell lineage, and a number of signal transduction cascades are involved in their differentiation (reviewed in De Gorter and Ten Dijke, 2013). Activation of the transcription factor Runx2 and induction of the canonical wingless (Wnt) pathway are two particularly critical steps in the osteoblast differentiation process. Runx2 determines the fate of osteoblast precursor cells, promoting differentiation of mesenchymal stem cells into osteoblasts, rather than cartilage or adipose cells (De Gorter and Ten Dijke, 2013). Conditions that impair Runx2 activity can predispose to osteoporosis by promoting the differentiation of mesenchymal stem cells into adipose cells rather than osteoblasts (Grey, 2008; Benvenuti *et al.*, 2007; Rzonca *et al.*, 2004; Akune *et al.*, 2004). Activation of the canonical Wnt pathway is also required for osteoblast differentiation (De Gorter and Ten Dijke, 2013). The proteins sclerostin and dickkopf-related protein 1 (DKK-1) are antagonists of the Wnt pathway, and conditions that increase their presence result in suppressed bone formation (Cosman *et al.*, 2016; Pinzone *et al.*, 2009).

Osteoblasts initiate the formation of new bone by secreting type I collagen and noncollagenous proteins, including osteocalcin, osteopontin, and bone sialoprotein, onto the bone surface (Neve *et al.*, 2011), with type I collagen creating a scaffold onto which calcium and phosphate can deposit. After osteoblasts complete their part in the bone formation process, some become "buried" in the bone and undergo further differentiation into osteocytes (Dallas *et al.*, 2013).

In addition to depositing new bone, mature osteoblasts are involved in the regulation of osteoclast activity. Osteoblasts secrete RANKL, as well as another important regulatory protein, osteoprotegrin (OPG). While RANKL stimulates osteoclast differentiation and recruitment and promotes bone resorption (Eghbali-Fatourechi *et al.*, 2003), OPG does the opposite. OPG acts as a "decoy receptor" for RANKL, preventing binding of RANKL to RANK and thereby inhibiting osteoclast activity (Boyle *et al.*, 2003). Factors that alter the ratio of circulating RANKL and OPG can therefore lead to the uncoupling of bone resorption and formation.

Expression of RANKL is upregulated by interlukin-1 (IL-1), tumor necrosis factor α (TNF- α), glucocorticoids and vitamin D (Hadjidakis and Androulakis, 2006; Ross, 2013), and downregulated by estrogen (Eghbali-Fatourechi *et al.*, 2003). OPG expression is upregulated by estrogen and transforming growth factor β (Hadjidakis and Androulakis, 2006). Parathyroid hormone (PTH) also has an important influence on the RANKL to OPG ratio. Sustained elevations in circulating PTH concentrations lead to increased production of RANKL and M-CSF, promoting bone resorption (Ross, 2013), while intermittent cyclical exposure to PTH results in the stimulation of bone formation at a greater rate than resorption and leading to net gains in bone density.

Regulation of remodeling

Osteocytes are integral to the regulation of bone remodeling (Dallas *et al.*, 2013). Osteocyte cell bodies sit within the bone matrix, each extending several dendritic processes to form a network that connects these cells to the vasculature, the bone surface, and one another (Dallas *et al.*, 2013). These cells constantly assess for changes in the condition of the skeleton and signal to osteoclasts and osteoblasts to ensure that bone remodeling is adjusted accordingly. Like osteoblasts, osteocytes express surface receptors for PTH and Wnt, and have the ability to secrete RANKL and OPG (Xiong *et al.*, 2011). Mechanical loading of osteocytes, such as by weight-bearing exercise, results in the inhibition of sclerostin and activation of the Wnt pathway, as well as downregulation of RANKL. This leads to osteoblast differentiation and osteoclast inhibition (Tatsumi *et al.*, 2007; Dallas *et al.*, 2013). Mechanical unloading results in the reverse: increased expression of sclerostin and RANKL (Dallas *et al.*, 2013; Xiong *et al.*, 2011). Osteocyte apoptosis also serves a regulatory purpose, promoting bone resorption via recruitment of osteoclasts (Gu *et al.*, 2005). Several stimuli can trigger osteocyte apoptosis, including local bone microdamage, oxygen deprivation due to immobilization, withdrawal of estrogen, and glucocorticoid exposure (Gu *et al.*, 2005).

Material Properties

All bone is made up of both cellular and extracellular components. The cellular constituent is comprised of the osteoclasts, osteoblasts, and osteocytes, as described above. The extracellular component of bone ensures that the skeleton is both strong and flexible, and can be categorized into organic and mineral phases. The organic phase is mostly comprised of type I collagen (90%) (Young, 2003), and also contains many noncollagenous proteins ($\sim$5%), lipids ($\sim$2%), and water. Type I collagen provides a structural blueprint for mineral deposition (Young, 2003). Aberrations in collagen production and cross-linking are associated with reduced skeletal strength and increased risk of fracture (Saito *et al.*, 2006b). Collagen can undergo post-translational modifications via the process of non-enzymatic glycation. States of low bone turnover can lead to the accumulation of advanced glycation end products through non-enzymatic glycation, and this has been shown to contribute to skeletal fragility in animal models (Tang *et al.*, 2009). Although the specific roles of noncollagenous proteins, lipids, and water within the organic phase are incompletely understood, noncollagenous proteins appear to be important for maintaining the structural integrity of type I collagen, and are also involved in cell signaling and mineralization (Boskey, 2013).

The mineral phase of the extracellular matrix makes up 60%–70% of the dry weight of the human skeleton and lends hardness and rigidity to bone (Boskey, 2007). This phase is comprised of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$], which consists primarily of the minerals calcium and phosphorus (Boskey, 2007). Mineralization of bone is dependent on the presence of adequate amounts of calcium, phosphorus, and the enzyme alkaline phosphatase which breaks down the mineralization inhibitor, pyrophosphate (Neve *et al.*, 2011; Sapir-Koren and Livshits, 2014). Some osteoblast-secreted noncollagenous proteins, such as bone sialoprotein, have also been found to promote mineralization (Malaval *et al.*, 2008). In states of deficiency of one or more of these factors, under-mineralization of bone, known as osteomalacia, results. Prolonged exposure to drugs such as fluoride and high-dose etidronate can also interfere with the mineralization process (Jones and Sambrook, 1994).

Microdamage to the bone has been postulated as a potential mechanism by which skeletal fragility is increased. This term refers to small "microcracks" within the bone matrix, resulting from repeated loading of the skeleton (Seref-Ferlengez *et al.*, 2015). If not repaired via remodeling, these cracks have the potential to extend, leading to a reduced ability of the bone to withstand force (Seref-Ferlengez *et al.*, 2015). In animals, suppression of bone remodeling with alendronate has been shown to promote the development of microdamage (Allen *et al.*, 2006). In humans, the presence of microdamage appears to have little impact on the mechanical properties of the skeleton when compared to other parameters, such as trabecular volume (Follet *et al.*, 2011).

Micro-Architecture

Each bone in the body is composed of both a cortical and a trabecular compartment, and bone micro-architecture concerns the characteristics of each of these compartments. The cortical component forms the bone's hard outer layer. Cortical bone lends strength and stability to the skeleton, being relatively resistant to bending and torsion (Felsenberg and Boonen, 2005). This bone is laid down in a lamellar manner and has a smooth appearance. Inside the cortical shell sits a delicate network of trabecular bone, which has a spongy, cancellous appearance. The number, spacing, and thickness of the trabeculae are important determinants of skeletal strength (Felsenberg and Boonen, 2005), and trabecular bone is also the primary location for bone remodeling and mineral metabolism. The majority of bone turnover—around 70%—occurs at trabecular bone surfaces, although this type of bone only comprises 20%–30% of the skeleton. Cortical bone, on the other hand, comprises 70%–80% of the skeleton and accounts for only 30% of bone turnover (Felsenberg and Boonen, 2005). Different bones have differing trabecular and cortical compositions.

For instance, the vertebrae are >75% trabecular bone, whereas the neck of the femur is approximately 65% trabecular, and the proximal radius is >95% cortical (Riggs *et al.*, 2004).

Alterations in trabecular and cortical micro-architecture can be associated with increased skeletal fragility (Nishiyama *et al.*, 2013; McCloskey *et al.*, 2016). Age-related bone loss is associated with reductions in trabecular number, and loss of trabecular continuity, which are more frequently observed in patients with osteoporotic fractures than in controls (Parfitt *et al.*, 1983). States of high bone turnover contribute to thinning of the trabeculae, as activation of a greater number of basic multicellular units increases the likelihood that resorption lacunae will be in close proximity to one another or even directly opposite one another on the same trabeculae. This trabecular thinning represents an additional mechanism, beyond loss of overall bone mass, by which increased bone turnover might increase fracture risk (Garnero *et al.*, 1996; Rogers *et al.*, 2000). In conditions where bone resorption is increased, such as aging, loss of cortical bone is also observed, and eventually this lamellar bone develops a porous appearance (Zebaze *et al.*, 2010; Bala *et al.*, 2014). In the perimenopausal period, trabecular bone loss exceeds cortical bone loss. However, by 15 years after menopause, cortical remodeling exceeds trabecular remodeling, as a result of the development of cortical porosity or "trabecularization," which provides increased surface area for remodeling (Zebaze *et al.*, 2010). The development of cortical porosity is more profound in women than men (Macdonald *et al.*, 2011), and this parameter can be used to distinguish between postmenopausal women who have fractured and those who have not, independent of BMD by DXA (Bala *et al.*, 2014; Patsch *et al.*, 2013). Both diabetes and hyperparathyroidism have also been shown to promote the development of cortical porosity (Patsch *et al.*, 2013; Vu *et al.*, 2013).

Characteristics of cortical and trabecular bone can be assessed in detail with HR-pQCT, although this technique is not presently available for routine clinical use. While DXA does not permit detailed assessment of cortical and trabecular micro-architecture, it is possible to estimate trabecular bone quantity using DXA images from the lumbar spine, which is done via calculation of a "trabecular bone score." Trabecular bone score has been shown to independently predict fracture risk and was recently incorporated into the WHO FRAX fracture risk calculator (McCloskey *et al.*, 2016).

Macro-Architecture

Skeletal strength is also influenced by the macro-architecture, or geometry, of the bone. In particular, an evaluation of the Study of Osteoporotic Fractures cohort demonstrated that shorter hip axis length is associated with a lower risk of fracture (Faulkner *et al.*, 1993). Correspondingly, an increase in average hip axis length observed in New Zealand women between the 1950s and 1990s was found to correlate with increases in age-adjusted hip fracture rates throughout this timeframe (Reid *et al.*, 1994). Other macro-architectural parameters, such as outer diameter of the proximal femur and neck-shaft angle have been associated with fracture risk in some populations but not others (Broy *et al.*, 2015). Ahlborg and colleagues have demonstrated that periosteal apposition increases at the time of menopause, resulting in increases in the medullary and periosteal diameter of the radius (Ahlborg *et al.*, 2003). These geometric changes may help to offset the effects of rapid loss of bone mass in the early postmenopausal period.

Causes of Skeletal Fragility

Postmenopausal Osteoporosis

In most individuals, loss of bone mass begins in the early 30s, when the rate of resorption starts to exceed formation (Drake *et al.*, 2015). In women, bone loss accelerates around the time of menopause when ovarian estrogen production ceases, often exceeding 2%–5% per year in the perimenopausal period (Hannan *et al.*, 2000). This translates into losses of 20%–30% of bone density at trabecular sites and 5%–10% at cortical sites in the decade following menopause (Riggs *et al.*, 2004; Khosla and Riggs, 2005). Within 10 years of menopause, bone loss begins to slow again, continuing at a rate of 0.5%–1.0% throughout the remainder of the lifespan (Khosla and Riggs, 2005; Cummings, 1993). In addition to the losses in bone mass observed on DXA following menopause, postmenopausal osteoporosis is also characterized by alterations in bone micro-architecture, including reductions in trabecular number and thickness, and increasing cortical porosity (Zebaze *et al.*, 2010).

Postmenopausal osteoporosis primarily results from the estrogen deficiency that occurs at the time of menopause, which leads to the uncoupling of bone resorption and bone formation. Estrogen receptors are expressed by osteoclasts, osteoblasts, and osteocytes, and estrogen has been shown to exert effects on each of these cell types, primarily through the estrogen receptor α (Manolagas *et al.*, 2013). Estrogen suppresses the production of RANKL by osteoblasts (Eghbali-Fatourechi *et al.*, 2003) and upregulates OPG expression, in addition to suppressing the pro-osteoclast factors M-CSF, IL-1, IL-6, TNF-α, and prostaglandins (Drake *et al.*, 2015), and stimulating apoptosis of mature osteoclasts and osteoclast precursors (Drake *et al.*, 2015). The presence of estrogen also results in upregulation of growth factors such as insulin-like growth factor-1 and TGF-β in osteoblasts (Khosla and Riggs, 2005), differentiation of mesenchymal stem cells into osteoblasts rather than adipocytes, and suppression of osteoblast and osteocyte apoptosis (Khosla *et al.*, 2011). Estrogen may also play a role in osteocyte mechano-sensing. In a mouse model, knockout of the estrogen receptor α results in failure to evoke an anabolic bone response with mechanical loading (Lee *et al.*, 2003). Thus, the net effect of the estrogen deficiency that develops at the time of menopause is a rapid uncoupling of bone resorption and formation. This effect can be attenuated by the administration of exogenous estrogen (Cauley *et al.*, 2003, Eghbali-Fatourechi *et al.*, 2003).

Male Osteoporosis

Men ultimately lose less bone mass than women, as they do not undergo an accelerated period of loss as women do following menopause. However, older men experience gradual reductions in bone mass, at an average rate of 0.5%–1.0% per year (Drake *et al.*, 2015; Cummings, 1993). Although osteoporosis is related to a secondary cause in roughly half of men, the likelihood of straightforward age-related osteoporosis increases in men older than 65–70 years of age (Gennari and Bilezikian, 2013). Age-associated reductions in circulating sex hormone levels appear to impact upon the loss of bone mass and development of skeletal fragility in aging men. Over the course of the male lifespan, sex hormone binding globulin levels increase by >2-fold. This corresponds to decreases in the amounts of bioavailable testosterone and estrogen by approximately half (Khosla *et al.*, 1998). This reduction in estrogen concentrations is particularly important, as estrogen status appears to be more reflective of BMD than testosterone in men (Drake *et al.*, 2015), and correspondingly, estrogen replacement has been shown to have a more marked effect on reducing bone turnover than testosterone replacement in men who are deficient in both hormones (Falahati-Nini *et al.*, 2000).

Additional Causes of Age-Related Osteoporosis

The observation that both women and men begin to lose bone mass as early as the mid-30s (Drake *et al.*, 2015), in the absence of significant changes in endogenous estrogen and testosterone production, has led to the postulation that the development of age-associated osteoporosis cannot be attributed to sex hormones alone (Manolagas, 2010). Indeed, additional age-related factors have been shown to promote bone loss via mechanisms that appear to be at least partially independent of circulating sex hormones. Cellular senescence develops with aging as the result of multiple processes, including accumulation of oxidative stress, telomere shortening, and impairment of DNA repair mechanisms (Marie, 2014). Bone cell senescence is associated with reduced osteoblast and osteocyte differentiation, as well as alterations in the stiffness and quality of the bone matrix (Marie, 2014). One mechanism by which cellular senescence has been shown to affect the skeleton is through the increased production of mitochondrial reactive oxygen species, resulting in oxidative stress (Marie, 2014). The presence of oxidative stress attenuates Wnt signaling and promotes osteoblast and osteocyte apoptosis (Manolagas, 2010). A potential role for oxidative stress in the development of skeletal fragility is corroborated by the finding that genetic knockdown of NADPH oxidase 4, an enzyme involved in the production of reactive oxygen species, protected against bone loss in ovariectomized mice (Goettsch *et al.*, 2013). The effects of sex hormone deficiency and cellular senescence on the bone seem to be at least partially independent of one another, but existing evidence suggests that they are not mutually exclusive. For instance, the effects of oxidative stress on the skeleton appear to be augmented by estrogen deficiency (Almeida *et al.*, 2007), and can be at least partially attenuated via treatment with estrogen (Manolagas *et al.*, 2013; Almeida *et al.*, 2010).

Secondary Osteoporosis

Declines in bone quantity and alterations in bone quality are anticipated consequences of aging. However, changes that are more profound than expected for an individual's age and sex suggest the presence of a secondary cause. Although the majority of postmenopausal women with osteoporosis have primary disease, a secondary contributor may be identified in up to 50% of men and premenopausal women (Klibanski, 2001). Secondary causes of osteoporosis include lifestyle factors, underlying disease states, and the use of medications. As skeletal homeostasis is tightly intertwined with the regulation of other organ systems, it is not surprising that a diverse multitude of secondary causes exist. Here, the pathogenesis of some of the more common and well-characterized causes of secondary osteoporosis is reviewed.

Monogenic syndromes

While much of the hereditary contribution to bone mass and bone strength appears be polygenic (Xie *et al.*, 2015) or epigenetic (Marini *et al.*, 2016; Earl *et al.*, 2010), a few monogenic syndromes result in low bone mass and/or increased propensity to fracture. These include osteogenesis imperfecta, which most often results from mutations in the genes encoding one of the two alpha chains that form type 1 collagen (COL1A1 and COL1A2) (Marini *et al.*, 2007), although mutations in genes encoding proteins responsible for post-translational modifications of type 1 collagen can also lead to this disorder. While the severity of osteogenesis imperfecta is mutation-dependent, many individuals present with low bone mass and fractures in childhood (Ralston and Uitterlinden, 2010). Osteoporosis pseudoganglioma syndrome results from a loss-of-function mutation in LDL-receptor related protein 5 (LRP5), a receptor that is required for activation of the Wnt pathway (Gong *et al.*, 1996, 2001). Affected individuals have low bone mass and frequent fractures in childhood. Mutations in the gene encoding aromatase (Morishima *et al.*, 1995) (which is responsible for the conversion of androgens into estrogen in peripheral tissues) and of the estrogen receptor (Smith *et al.*, 1994), also result in the development of osteoporosis. These single gene disorders are rare, being present in a very small proportion of individuals with osteoporosis.

Lifestyle factors

Large observational studies have demonstrated that several lifestyle factors are associated with low bone mass and fracture risk, including smoking, alcohol use, low body weight, poor nutritional status, and immobility. Smoking and excess alcohol consumption (≥ 3 units per day) are two well-established fracture risk factors (Kanis *et al.*, 2007). Low body weight is also associated

with reduced BMD and fracture (Reid, 2010). In addition, nutrition has been highlighted as a determinant of fracture risk in observational studies, with both low protein intake (Langsetmo *et al.*, 2015) and low fruit and vegetable intake (Benetou *et al.*, 2016) being associated with increased risk (Bischoff-Ferrari *et al.*, 2011). Dietary calcium intake is not consistently related to bone density (Bischoff-Ferrari *et al.*, 2009; Tai *et al.*, 2015), bone loss (Reid *et al.*, 2015) or fracture risk (Bolland *et al.*, 2015). The mechanical loading of bone that results from weight-bearing physical activity has a stimulatory effect on osteocytes and promotes bone formation (Tatsumi *et al.*, 2007; Dallas *et al.*, 2013). Correspondingly, exercise has been associated with higher BMD and reduced likelihood of fracture (Farmer *et al.*, 1989; Gregg *et al.*, 1998), with immobility being associated with low bone mass and increased fracture risk (Holm and Hedricks, 1989).

Underlying diseases

Many diseases have been associated with the presence of osteoporosis and predisposition to fracture. Several of these conditions affect the skeleton via more than one mechanism, and in many cases the mechanism(s) remain incompletely elucidated. Some of these diseases are discussed in further detail below, grouped according to their principal effect on the bone. This topic has also recently been comprehensively reviewed elsewhere (Emkey and Epstein, 2014).

Diseases that result in excess bone resorption include those that lead to sex hormone deficiencies, as well as hyperparathyroidism, hyperthyroidism, inflammatory disorders, and some hematologic conditions. In keeping with the established effects of sex steroids on the skeleton, conditions that result in hypogonadism are associated with high bone turnover and net loss of bone mass. These include hypothalamic amenorrhea, hemochromatosis, Turner syndrome, and Klinefelter syndrome (Emkey and Epstein, 2014). In persons with hyperparathyroidism, sustained elevations in circulating PTH concentrations lead to increased production of RANKL and M-CSF, promoting bone resorption (Ross, 2013). Hyperparathyroidism preferentially affects areas rich in cortical bone, such as the distal radius (Khan and Bilezikian, 2000). In hyperthyroidism, activation of the thyroid hormone receptor by excess thyroid hormone (T3) results in high bone turnover; the increased incidence of osteoporosis in individuals with subclinical hyperthyroidism also suggests a direct effect of TSH on the bone (Emkey and Epstein, 2014). Pro-inflammatory conditions such as chronic obstructive pulmonary disease, rheumatoid arthritis and inflammatory bowel disease lead to upregulation of cytokines such as IL-6 and TNF-α, both of which promote bone resorption (Emkey and Epstein, 2014). Diseases that involve infiltration of the bone marrow, such as systemic mastocytosis and multiple myeloma, are also associated with increases in inflammatory mediators such as RANKL, M-CSF, and IL-6 at sites of bone marrow infiltration (Emkey and Epstein, 2014; Rossini *et al.*, 2014). In addition, thalassemia major has been associated with increased RANKL production and high bone turnover (Morabito *et al.*, 2007).

Conditions that result in impaired absorption of calcium and vitamin D from the digestive tract, such as inflammatory bowel disease and celiac disease have been associated with the development of secondary hyperparathyroidism (Lamb *et al.*, 2002; Keaveny *et al.*, 1996). These conditions also appear to contribute to bone loss and impaired skeletal strength via promotion of systemic inflammation and RANKL production (Fornari *et al.*, 1998; Moschen *et al.*, 2005). Malabsorptive bariatric surgery, particularly Roux-en-Y gastric bypass, has also been associated with the development of secondary hyperparathyroidism and a high bone turnover state (Switzer *et al.*, 2017).

Several conditions have been shown to reduce bone formation and lead to low bone turnover, including growth hormone deficiency, Cushing syndrome, and diabetes. Growth hormone has an anabolic effect on osteoblasts, and adult-onset growth hormone deficiency is characterized by low bone mass, primarily at cortical sites, and increased fracture risk (Emkey and Epstein, 2014). Excess endogenous glucocorticoid production, as in Cushing syndrome, is also associated with impaired osteoblast function (Emkey and Epstein, 2014). Individuals with diabetes are at increased risk of fracture (Sellmeyer *et al.*, 2016). Persons with type 1 diabetes have lower BMD than their disease-free counterparts, which may reflect failure to achieve peak bone mass (Pan *et al.*, 2014). HR-pQCT imaging of individuals with type 2 diabetes has demonstrated increased cortical porosity (Burghardt *et al.*, 2010; Farr *et al.*, 2014). Mounting evidence suggests that the skeletal abnormalities and increased risk of fracture observed in this population are the result of low turnover disease (Bouillon *et al.*, 1995). Animal studies have demonstrated that abnormal glucose uptake by osteoblasts results in reduced activity of the transcription factor Runx2 (Wei *et al.*, 2015), which is required to direct the differentiation of mesenchymal stem cells into osteoblasts rather than adipose and cartilage cells. In a rat model with insulin-dependent diabetes, expression of Runx2 was reduced, while expression of the Wnt pathway inhibitors DKK-1 and sclerostin was increased (Hie *et al.*, 2011), highlighting another mechanism by which this condition may impede bone formation. Beyond its effects on bone turnover, diabetes also appears to adversely affect the bone matrix. Prolonged hyperglycemia promotes the development of advanced glycation endproducts and alters collagen cross-linking in rats (Saito *et al.*, 2006a), which may explain why fracture risk in persons with diabetes is increased independently of BMD (Schwartz *et al.*, 2011).

Altered bone matrix has also been identified in other disease states, such as the connective tissue disorders Marfan syndrome and Ehlers–Danlos syndrome (Emkey and Epstein, 2014), and Paget's disease, which results in deposition of woven rather than lamellar bone at sites of disease activity (Ingram *et al.*, 1996).

Drugs

Several medications are associated with increased fracture risk. The mechanism(s) by which some of these agents, such as glucocorticoids, contribute to the development of skeletal fragility is well established. In other cases, the pathophysiology remains unclear. Some of the more widely used medications that impact upon bone density and fracture risk are briefly reviewed here. Drugs with adverse skeletal effects have also been extensively reviewed elsewhere (O'Sullivan and Grey, 2015).

Not surprisingly, medications that reduce circulating sex hormone levels also reduce bone density and increase fracture risk (Emkey and Epstein, 2014). These include aromatase inhibitors, which are used in the adjuvant treatment of hormone-receptor positive breast cancer, gonadotropin-releasing hormone agonists, most frequently used in the treatment of prostate cancer, and the injectable contraceptive agent depot medroxyprogesterone acetate (Emkey and Epstein, 2014).

Prolonged treatment with glucocorticoids is the most common iatrogenic cause of osteoporosis, and the principal effect of these agents on the skeleton is to impair bone formation (Reid, 2000). The use of these medications is associated with dose-dependent skeletal effects, including rapid declines in bone mass and an increased risk of fracture (Reid, 2000; Weinstein, 2011). Histomorphometric assessment has demonstrated reductions in trabecular bone mass of $>25\%$ over the first 6 months of glucocorticoid therapy (LoCascio *et al.*, 1990). An increased risk of fracture also becomes apparent within the first 3 months of therapy (Steinbuch *et al.*, 2004), and fracture incidence is higher than expected for the changes in BMD observed in individuals taking these medications (Weinstein, 2011). Glucocorticoids suppress osteoblast proliferation and stimulate osteoblast and osteocyte apoptosis (Reid, 2000). While glucocorticoid exposure also inhibits osteoclastogenesis, these agents extend the osteoclast lifespan and increase RANKL production while exerting a suppressive effect on OPG (Emkey and Epstein, 2014; Humphrey *et al.*, 2006), the net result being uncoupling of bone formation and resorption (Weinstein, 2011).

Treatment with thiazolidinedione (TZD) medications, used primarily for the treatment of type 2 diabetes, has been associated with a 1.5 to 2-fold increased risk of fracture (Dormandy *et al.*, 2009; Home *et al.*, 2009; Kahn *et al.*, 2008). The use of TZDs is associated with modest reductions in bone density that do not appear to be reversed with cessation of therapy (Billington *et al.*, 2015). These medications have inconsistent effects on bone turnover markers (Billington *et al.*, 2015). The mechanism(s) by which treatment with TZDs increase fracture risk are unclear at present, although preclinical data indicates that they might reduce osteoblast activity by promoting the differentiation of mesenchymal stem cells into adipose cells rather than osteoblasts (Grey, 2008; Benvenuti *et al.*, 2007; Rzonca *et al.*, 2004; Akune *et al.*, 2004).

The use of antiepileptic drugs has been associated with low bone density and increased fracture risk (Meier and Kraenzlin, 2011). In the case of anticonvulsants that induce the cytochrome P450 enzyme system in the liver (such as phenytoin, carbamazepine, primidone, and topiramate), the increased fracture risk has been attributed to increased conversion of 25-hydroxyvitamin D into inactive metabolites (Meier and Kraenzlin, 2011). This has the potential to lead to 1,25-hydroxyvitamin D deficiency and promote the development of secondary hyperparathyroidism (Meier and Kraenzlin, 2011). Accordingly, supplementation with 2000 or 4000 IU of vitamin D has been shown to stabilize BMD in adults taking longterm antiepileptics (Mikati *et al.*, 2006). The mechanism by which antiepileptic agents that do not induce cytochrome P450 impact the bone is unclear, although recent data suggest that some of the newer anticonvulsants (such as levetiracetam) may not have significant effects on the skeleton (Lee *et al.*, 2010).

Other commonly prescribed medications that have been associated with increased fracture risk include proton pump inhibitors and the selective serotonin reuptake inhibitor class of antidepressants (Bedimo *et al.*, 2012; Emkey and Epstein, 2014). The mechanisms by which these medications increase skeletal fragility remain poorly understood.

Summary

Skeletal strength and resilience to fracture is dependent upon both bone quantity and bone quality. Bone quantity is determined by an individual's peak bone mass and the subsequent rate and degree of bone loss, whereas bone quality reflects the micro- and macro-architecture of the bone, as well as the condition of the bone matrix. Conditions that influence these determinants of bone strength have the potential to promote the development of osteoporosis and increase the risk of fragility fracture. The most common cause of skeletal fragility is postmenopausal osteoporosis, which results primarily from rapid declines in endogenous estrogen production at the time of menopause. While men do not undergo a similar phase of accelerated bone loss, they do experience gradual age-related reductions in estrogen and testosterone concentrations, contributing to steady declines in bone mass with aging. Cellular senescence also contributes to the development of osteoporosis with advancing age. Beyond age-related contributors, several secondary causes of osteoporosis have been identified, although the pathogenic mechanisms remain unclear in many cases. Disease states and medications that result in hypogonadism or glucocorticoid excess are established causes of secondary osteoporosis, and their underlying pathophysiology is well understood. On the other hand, the presence of diabetes and the use of medications such as TZDs, proton pump inhibitors, and selective serotonin reuptake inhibitors represent emerging risk factors for osteoporosis and fracture for which a better understanding of pathogenesis is required.

Role of Estrogens and Androgens in Osteoporosis

Michaël R Laurent, University Hospitals Leuven, Leuven, Belgium

Introduction

Osteoporosis is a skeletal disease characterized by compromised bone strength, which predisposes a person to an increased risk of fracture (NIH Consensus Development Panel on Osteoporosis Prevention Diagnosis and Therapy, 2001). Bone strength is determined not only by bone mineral density (BMD) but also by bone size and macroarchitecture (particularly cortical bone area, but also cortical thickness and trabecular bone volume), microarchitectural features such as cortical porosity, trabecular thickness and perforations, as well as bone material properties (Seeman and Delmas, 2006).

As early as the 1940s, estrogen deficiency was blamed for post-menopausal osteoporosis and androgen deficiency for male osteoporosis (Albright *et al.*, 1941). However, by the late 1990s it was realized that estrogens also played an important role in the pathophysiology of male osteoporosis, and estrogens were even implicated in bone loss in old age as well as age-related secondary hyperparathyroidism (Riggs *et al.*, 1998). More recently however, there is growing awareness that aging has an independent and overriding influence on bone loss and fractures in both genders. Indeed, there is an exponential increase in fracture risk in elderly of both genders (see section "Fractures") resulting not only from an increasing risk of falls (Riggs *et al.*, 2006) but also from distinctive mechanisms of age-related bone loss such as oxidative stress, cellular senescence, hypercortisolism etc. (Farr *et al.*, 2017; Khosla *et al.*, 2011a; Khosla *et al.*, 2011b; Manolagas, 2010; Ucer *et al.*, 2017).

The aim of this chapter is to provide an overview of how estrogens, androgens and their receptors influence skeletal development and maintenance. However, their effects are gender-specific (estrogens play a key role in both genders whereas androgens may provide some additional benefit in young men), time-specific (i.e. due to enhanced development of peak bone mass, prevention of bone loss later in life, or both), compartment-specific (i.e. different in cortical vs. trabecular bone; see **Table 1**) and dose-dependent (i.e. estrogen levels below certain thresholds are associated with bone loss, whereas supraphysiological sex steroid levels generally confer no added skeletal benefits). Thus, to understand the role of sex steroids, we will first outline the effects of age and gender on cortical and trabecular bone as well as fracture risk.

Gender Differences in Bone Development, Bone Loss and Fracture Risk

Fractures

Gender is a key clinical risk factor for fractures, second only to age. The lifetime risk of osteoporotic fractures after the age of 50 years is as high as 45%–55% in women, compared to 20%–25% in men in high-risk Caucasian populations (Ahmed *et al.*, 2009; Lippuner *et al.*, 2009; Nguyen *et al.*, 2007). Also for hip fractures, the male: female incidence ratio is about 1:2 and remarkably constant worldwide despite >10-fold geographic differences in fracture incidence (Kanis *et al.*, 2012). Still, this means that men account for about one-third of the 9 million osteoporotic fractures worldwide, with some gender differences according to the fracture site (men accounting for 30% of hip and 39% of spine fractures, only 25% of humerus and 20% of forearm fractures, but 54% at other sites e.g. ribs) (Barrett-Connor *et al.*, 2010; Johnell and Kanis, 2006).

Fracture incidence starts to increase around the age of menopause in women, and then further accelerates in parallel in both genders after the age of 70 years (**Fig. 1**) (Bergström *et al.*, 2008; Curtis *et al.*, 2016; Laurent *et al.*, 2013). The gender difference in fracture risk can be explained by musculoskeletal sexual dimorphism i.e. the fact that men develop greater bone and muscle mass during puberty and adulthood, and do not experience accelerated bone loss after midlife as post-menopausal women do.

Table 1 Summary of the time-, gender- and compartment-specific (cortical vs. trabecular bone) effects of estrogens and androgens

	Estrogens				*Androgens*			
	Cortical bone		Trabecular bone		Cortical bone		Trabecular bone	
	Women	Men	Women	Men	Women	Men	Women	Men
PBM	++	++	++	+	−	+	?	+
Midlife	−	−	−	−	−	−	−	−
Old age	++	++	++	++	−	−	−	−

++ = very important role, + = important role, ? = uncertain role, − = no established role.

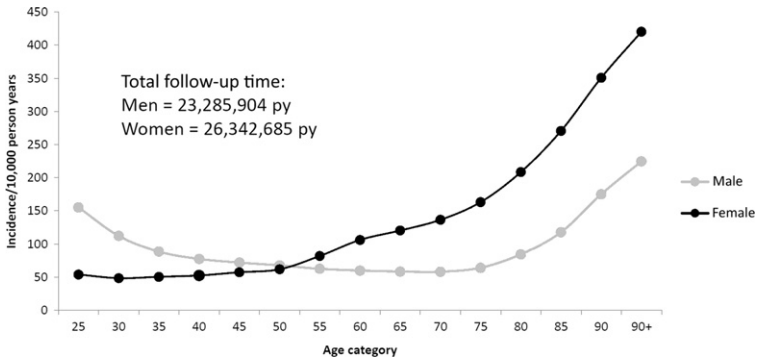

Fig. 1 Age- and sex-specific incidence rates of any fractures among adults in the United Kingdom, between 1988 and 2012, based on data from the Clinical Practice Research Datalink. Reproduced, with permission, from Curtis *et al.* (2016).

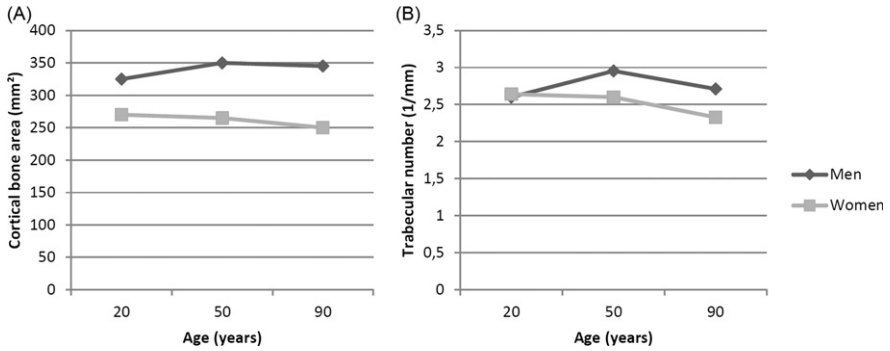

Fig. 2 (A) Cortical bone area at the tibia and (B) trabecular number at the distal radius, at the approximate ages of peak bone mass, middle age and in old age (20, 50 and 90 years, respectively), in men (dark gray) and women (light gray). Adapted and reproduced, with permission, from Khosla *et al.* (2006b) and Lauretani *et al.* (2008).

Cortical and Trabecular Bone Development and Maintenance

The structural development and maintenance of the skeleton can be divided into three phases: peak bone mass (PBM) acquisition, midlife, and old age. Men between 20 and 30 years have about 25% greater bone mass (whole body bone mineral content, BMC) (Boot *et al.*, 2010). However, this is not surprising given the fact that men are on average 8% taller than women (because dual-energy X-ray absorptiometry is a projectional technique and in 3D, $1.08^3 \approx 1.25$) (Almeida *et al.*, 2017). Gender differences in PBM are however not uniform, but time- and site-specific (e.g. PBM is reached earlier at the hip than at the spine). More importantly, these differences are explained almost entirely by the fact that young men develop *wider* cortical bone diameters, even after adjustment for height (Baxter-Jones *et al.*, 2011; Berger *et al.*, 2010; Henry *et al.*, 2004; Lorentzon *et al.*, 2005; Walsh *et al.*, 2009). Other determinants of bone strength also show sexual dimorphism (Almeida *et al.*, 2017) but the key determinant is bone width. The latter is determined by periosteal expansion and offers important biomechanical advantages, because bone strength scales to the fourth power with bone diameter. In fact, young men have similar cortical thickness as women, slightly lower cortical volumetric BMD, greater cortical porosity and lower trabecular bone volume in the spine, but these elements are outweighed entirely by greater cortical bone size (Berthold *et al.*, 2006; Burt *et al.*, 2016; Hansen *et al.*, 2014; Khosla *et al.*, 2006b; Kirmani *et al.*, 2009; Macdonald *et al.*, 2011; Nishiyama *et al.*, 2012; Riggs *et al.*, 2004).

Midlife may be a period during which men continue to consolidate their cortical bone assets. Trabecular bone volume declines early after PBM in both genders, but in men, some studies suggest that this is mainly due to loss of trabecular thickness (which is biomechanically less deleterious). Thus, both cortical bone cross-sectional area and trabecular number increase towards midlife in men, whereas they slightly decline in women (**Fig. 2**) (Khosla *et al.*, 2006b; Lauretani *et al.*, 2008; Riggs *et al.*, 2008). What drives these changes remains incompletely understood, but they occur independently of changes in sex steroids.

After menopause and in aging however, two pathophysiological alterations disturb the remodeling process (i.e. the resorption of bone by osteoclasts and bone formation at previously resorbed sites by osteoblasts). Collectively, the activities of these cells are coupled in basic multicellular units (BMUs). The first disturbance is an increased bone turnover with an increased number of BMUs. As a result, there are more osteoclasts resorbing pits at any given moment throughout the skeleton, even though osteoclast activity within each BMU is not more vigorous (Szulc and Seeman, 2009). Secondly, the osteoblasts in these BMUs fail to completely refill the resorption cavity. This leads to a small deficit in bone formation compared to resorption, which is amplified by the increased number of remodeling cycles. At the structural level, these two pathophysiological processes results in trabecular thinning and eventually

perforations and loss of trabecular number, widening of the medullary cavity with trabecularization of the cortex and increased cortical porosity. All of these structural features of skeletal decay are exaggerated in women compared to men (**Fig. 2**), in association with their greater bone turnover and lower estrogen levels after menopause (Khosla *et al.*, 2006a; Khosla *et al.*, 1998; Riggs *et al.*, 2006; Riggs *et al.*, 2004; Riggs *et al.*, 2008). Indeed, there is no "andropause" equivalent, and older men generally have higher serum estrogen concentrations than post-menopausal women. Periosteal expansion continues into old age and appears to represent a compensatory mechanism for bone loss from endosteal resorption (Pye *et al.*, 2017). This explains why periosteal apposition in old age may be even higher in women, nevertheless the net balance between endosteal resorption and periosteal expansion is more negative in women, leading to greater cortical thinning (Ahlborg *et al.*, 2013; Seeman, 2002; Zebaze *et al.*, 2010).

In conclusion, male gender is a protective factor that approximately halves the lifetime risk of osteoporotic fractures by both increasing PBM and decreasing subsequent bone loss. In the next section, we will discuss how sex steroids contribute to these gender differences.

Effects of Sex Steroids or Cortical and Trabecular Bone

Endogenous androgens and estrogens are C19 and C18 steroid hormone ligands of the androgen receptor (AR) and estrogen receptors (ERα and ERβ), respectively. Testosterone (T), the principal circulating androgen, can be converted by 5α-reductase enzymes to the more potent androgen dihydrotestosterone (DHT), and by the aromatase enzyme (CYP19A1) to 17β-estradiol (E2), the principal ligand of ERα. Thus, T has a dual mode of action, both androgenic as well as estrogenic.

Role of the Estrogen Receptors (ERα and ERβ)

Clinical evidence

Before bisphosphonates became available, estrogen replacement therapy together with calcium- and vitamin D-supplementation constituted the only therapeutic option for osteoporosis in post-menopausal women. Similarly, young men with hypogonadotropic hypogonadism are at increased risk for osteoporosis, which is reversible by T replacement therapy (Finkelstein *et al.*, 1987). Furthermore, surgical or pharmacological castration e.g. for breast or prostate cancer increases the risk of osteoporosis and fractures (Greenspan *et al.*, 2013; Hamilton *et al.*, 2010; Shahinian *et al.*, 2005). However, since hormone deficiency or deprivation results in both androgen as well as estrogen deficiency, the respective contributions of androgen- or estrogen-receptor signaling cannot be distinguished. Nevertheless, selective estrogen-receptor modulators (SERMs) are antiresorptive in men with low E2 levels (Uebelhart *et al.*, 2004), and prevent fractures in men receiving androgen deprivation therapy for prostate cancer, attesting to the importance of estrogen signaling even in men (Smith *et al.*, 2013). Also in male-to-female transsexuals, pharmacological E2 prevents bone loss, even despite androgen suppression (Lapauw *et al.*, 2008; Mueller *et al.*, 2011; Ruetsche *et al.*, 2005).

A more direct way of examining this issue is by animal or human models with genetic receptor or enzyme dysfunctions, discussed in the next paragraph. However, it is important to note that all of the effects in these knock-out animal models may be developmental, even though some phenotypes manifest at older age. Nevertheless, also after skeletal maturity, aromatase inhibition in adult animals or humans results in bone loss not only in women but also in men which cannot be compensated by AR actions alone (Falahati-Nini *et al.*, 2000; Finkelstein *et al.*, 2016; Leder and Finkelstein, 2005; Vanderschueren *et al.*, 2000). Finally, a large number of epidemiological studies (reviewed in Vanderschueren *et al.*, 2014) show that free or bioavailable E2 levels, are associated with bone loss and fracture risk in older men.

Genetic studies

Case reports of severe osteoporosis in men or women with aromatase or ERα deficiency attest to the importance of estrogens for bone health (Bilezikian *et al.*, 1998; Quaynor *et al.*, 2013; Smith *et al.*, 1994; Taes *et al.*, 2009). Notably, periosteal circumference was normal in an ERαKO man, supporting a role for the AR in periosteal bone formation (Smith *et al.*, 2008). Also in population studies, polymorphisms in the *ESR1* (ERα), *CYP19A1* (aromatase) or *COMT* (an estrogen-metabolizing enzyme) gene are associated with bone mass or fracture risk (Eriksson *et al.*, 2008; Gennari *et al.*, 2004; Limer *et al.*, 2009; Paternoster *et al.*, 2013; Van Pottelbergh *et al.*, 2003). In young rodent models, aromatase knock-out results in severely disturbed cortical and trabecular bone acquisition in both genders, despite increased T and IGF-1 levels (Matsumoto *et al.*, 2006; Öz *et al.*, 2001). In ERαKO mice, cortical bone development is impaired in both genders. Trabecular bone volume is also decreased by ERαKO in females but normal or even paradoxically increased in males, because of hypothalamic-pituitary feedback and high androgen levels signaling through the AR (Lindberg *et al.*, 2002; Sims *et al.*, 2003; Vidal *et al.*, 2000).

In female rodent models, ERβ seems to have a weaker opposite, inhibitory role on the stimulatory effects of ERα (Nicks *et al.*, 2016; Windahl *et al.*, 2001; Windahl *et al.*, 1999). However, any role for ERβ in males or in humans remains unconfirmed (Almeida *et al.*, 2017). G protein-coupled receptor 30 (GPR30) has also been proposed as an ER (and therefore renamed G protein-coupled ER 1 or GPER1), although this remains controversial. In any case, GPR30 appears redundant for the effects of estrogens on cortical and trabecular bone, although it may play a role at the growth plate (Vanderschueren *et al.*, 2014).

In summary, estrogens are indispensable for normal cortical and trabecular development as well as maintenance, not only in women but also in men (**Table 1**).

Target cells and genes

To identify whether the target cells for these effects of estrogens are osteoclasts, osteoblasts, osteocytes or other cell types, conditional KO models using Cre/LoxP technology have been used, in which ERs or AR can be deleted in specific cell types (Davey *et al.*, 2004). Based on such models, estrogens appear to stimulate cortical thickness through ERα in the osteoblast cell lineage in female mice, although only transiently in male mice (Almeida *et al.*, 2013; Määttä *et al.*, 2013a; Melville *et al.*, 2014). In female mice, it remains debated whether trabecular bone volume is maintained through actions of ERα in either osteoclasts (Almeida *et al.*, 2013; Martin-Millan *et al.*, 2010; Nakamura *et al.*, 2007; Seitz *et al.*, 2012) or osteoblasts and osteocytes (Kondoh *et al.*, 2014; Määttä *et al.*, 2013a; Melville *et al.*, 2014; Windahl *et al.*, 2013a). In male mice, the effect of estrogens on trabecular bone is not mediated via osteoclasts, but possibly via late osteoblasts or osteocytes (although not osteoblast precursor cells) (Määttä *et al.*, 2013a; Ucer *et al.*, 2015; Windahl *et al.*, 2013a).

The downstream actions of ERα can be mediated in four different ways. Firstly, translocation to the nucleus and regulation of target genes by direct binding to estrogen response elements (ERE), which are specific DNA sequences recognized by the ERα. This classical mode of action requires pioneer factors which modulate chromatin availability (such as GATA4; Miranda-Carboni *et al.*, 2011) and co-activators, of which SRC-1 is the best-known example. As a consequence, trabecular bone loss in SRC-1 knock-out mice is due to estrogen resistance in females and androgen resistance in males (Mödder *et al.*, 2004; Yamada *et al.*, 2004). Secondly, sex steroid receptors (both ERα and AR) may bind and influence (positively or negatively) the signaling of other transcription factors, e.g. NF-κB, AP-1 or RUNX2 (Baniwal *et al.*, 2009; Martin *et al.*, 2015; McCarthy *et al.*, 2003). Thirdly, both of the previous two (direct and indirect) genomic signaling mechanisms may be mediated by the unliganded ERα (but not the AR), and this ligand-independent effect can stimulate or repress gene expression (Almeida *et al.*, 2013; Rudnik *et al.*, 2008). Fourthly, both liganded ERα and AR may stimulate kinase-mediated extranuclear signaling at the plasma membrane, which is called non-genomic (or non-genotropic) signaling (Kousteni *et al.*, 2001; Kousteni *et al.*, 2002; Kousteni *et al.*, 2003). Knock-in mouse models in which the AR or ER are replaced by a mutant incapable of DNA binding demonstrate the physiological consequence of this mode of action, although these effects are modest and usually opposite to the classical genomic effects (Almeida *et al.*, 2010; Pang *et al.*, 2012; Syed *et al.*, 2011; Syed *et al.*, 2007; Syed *et al.*, 2005). The latter mode of action is involved in the ERα regulation of cortical bone mass and its regulation of oxidative stress in bone cells and their mechanoresponsiveness (see below) (Manolagas, 2010). An E2 dendrimer conjugate which selectively stimulates extranuclear estrogen signaling maintains protective effects on cortical bone without stimulating the uterus (Bartell *et al.*, 2013; Farman *et al.*, 2017), which supports further drug development selectively exploiting this pathway.

The direct target genes of ERα in osteoblasts, and even more so in osteoclasts or the target genes of AR in any target cell, remain poorly understood (Krum, 2011). Many target genes have been proposed, but few have been extensively validated (Almeida *et al.*, 2017; Vanderschueren *et al.*, 2014). Recent studies suggest that estrogens stimulate osteoblast expression and cleavage of Fas ligand to induce anti-resorptive effects via pre-osteoclast apoptosis, while other studies suggest involvement of SDF-1 (also known as Cxcl12) (Garcia *et al.*, 2013; Krum *et al.*, 2008; Ucer *et al.*, 2017; Wang *et al.*, 2015).

Rodent studies have suggested that female ERαKO mice also have an altered bone formation response to mechanical loading (Lee *et al.*, 2003). However, this seems to be a ligand-independent effect of ERα, while ERαKO in male mice, gonadectomy or ARKO has the opposite effect i.e. enhanced skeletal mechanoresponsiveness (Callewaert *et al.*, 2010a; Saxon *et al.*, 2012; Sinnesael *et al.*, 2015b; Windahl *et al.*, 2013b). Whether the altered mechanoresponsiveness in these models is explained by altered bone turnover (Vanderschueren *et al.*, 2014), altered background physical activity or whether these findings are generalizable to humans, remains unknown.

Collectively, these studies suggest that ERα actions are important for cortical and trabecular bone development in both genders, although more work is needed to fully elucidate the target cell(s) and molecular mechanisms of these effects.

Role of the Androgen Receptor (AR)

Rodent studies have demonstrated that androgens stimulate periosteal bone expansion in growing animals and have antiresorptive effects on trabecular bone through a direct effect of AR and independent of aromatization (Beck *et al.*, 2014; Movérare *et al.*, 2003; Venken *et al.*, 2006). In contrast to the strikingly osteopenic phenotypes resulting from selective estrogen deficiency, studies in androgen-insensitive or AR knock-out (ARKO) rodents reveal a milder cortical and trabecular bone phenotype (Callewaert *et al.*, 2009; Kawano *et al.*, 2003; MacLean *et al.*, 2008; Venken *et al.*, 2006; Yeh *et al.*, 2002), which is quite normal compared to female reference values. The same probably applies to XY women with androgen insensitivity syndrome, although less studies are available (Han *et al.*, 2008). Also in the general population, polymorphisms which negatively influence AR signaling such as long CAG repeats, have been not been negatively associated with male bone mass—in fact in some studies, a positive association due to hypothalamic-pituitary feedback and increased estrogen actions has been observed (Huhtaniemi *et al.*, 2009). In other words, androgens are responsible for the greater cortical bone expansion and trabecular PBM seen in young adult males compared to females, but they are not indispensable for normal cortical and trabecular bone development as estrogens are.

More recent cell-specific ARKO models have suggested that the effect of androgens on trabecular bone development is, at least partly, mediated through effects of the AR in osteoblasts and osteocytes. There is some evidence that the AR in osteoblasts enhances trabecular bone mass in female mice (Määttä *et al.*, 2013b), but whether or to what extent androgens promote bone mass in women (e.g. with hyperandrogenism due to polycystic ovary syndrome) remains unknown. Most likely, the effect of

androgens on trabecular bone involves reduced bone resorption, rather than an anabolic or increased bone formation effect (Chiang *et al.*, 2009; Notini *et al.*, 2007; Sinnesael *et al.*, 2013; Ucer *et al.*, 2015). The expression of the AR in osteoclasts as well as any direct contribution thereof to the antiresorptive effect of androgens remains questionable (Sinnesael *et al.*, 2015a; Ucer *et al.*, 2015). Remarkably, the key effect of androgens on periosteal bone expansion does not appear to be mediated by the AR in osteoblast-lineage cells either (Ucer *et al.*, 2015).

Hence, the quest to identify the—extraskeletal—target cell(s) responsible for the effect of androgens on cortical bone remains open. Although the AR exerts well-known anabolic actions on muscle, which may in turn positively influence bone mass, the effects of androgens on bone are certainly not entirely explained by muscle-bone interactions (Laurent *et al.*, 2016a; Laurent *et al.*, 2016c).

Similarly, it is known that rising serum T during early puberty in males indirectly regulate growth hormone and insulin-like growth factor 1 (IGF1) levels, which may partially (but not fully) explain the periosteal bone expansion induced by androgens in early puberty (Callewaert *et al.*, 2010b). The perinatal T surge on the other hand is a major regulator of pubertal growth hormone secretion and ultimate height, but it appears redundant for the inhibition of trabecular bone resorption and periosteal expansion induced by androgens (Sims *et al.*, 2006). Finally, there is some evidence that low IGF1 may contribute to fracture risk as well as frailty in older men (Boonen *et al.*, 2002; Ohlsson *et al.*, 2011). Still, the role of the somatotropic axis, by itself as well as its contribution to the effects of sex steroids in male or female osteoporosis, remain poorly understood.

Whether inducible AR deletion at later age has any direct detrimental skeletal effects in skeletally mature mice, remains yet unanswered. This is an important topic for future research because a direct role of androgens in the development of osteoporosis in older men has not been confirmed (Finkelstein *et al.*, 2016; Idan *et al.*, 2010; Laurent *et al.*, 2015). However, some epidemiological studies suggest that the combination of low serum E2 and T may be associated with higher fracture risk than low E2 alone (Amin *et al.*, 2006; Woo *et al.*, 2012). Although androgens may have a minor independent effect on bone turnover markers (Khosla, 2015), on risk of falls and fractures independent of BMD (Khosla, 2010; Meier *et al.*, 2008; Orwoll *et al.*, 2006), and on trabecular bone in the spine of mice treated with strong AR antagonists (Wu *et al.*, 2016), clearly more research is needed.

In summary, the beneficial skeletal effects of androgens mainly arise during puberty, by establishing greater trabecular PBM and greater radial bone expansion in young men. On the other hand, an independent effect of androgens in older men remains hitherto unconfirmed (**Table 1**). The development of osteoporosis in older men is mainly associated with estrogen deficiency, especially when serum T concentrations fall below 200 ng/dL and consequently, E2 serum levels below 10 pg/mL (Finkelstein *et al.*, 2016).

Other Players in the Gonadotropic Axis: SHBG and FSH

T, DHT and E2 are bound with high affinity to sex hormone-binding globulin (SHBG) and non-specifically to bulk carrier proteins such as albumin. Consequently, only about 1%–5% of these active sex steroids circulate freely i.e. not bound to proteins. According to the free hormone hypothesis however, this small percentage constitutes the active sex steroid because only non-protein-bound hormones are proposed to diffuse across cell membranes to active their nuclear receptors. Calculated or measured free T or E2 concentrations are often used in clinical practice as well as in studies related to osteoporosis, although many fundamental and practical concerns surround this approach (Laurent and Vanderschueren, 2014). Nevertheless, numerous studies show that higher SHBG levels are associated with greater BMD and cortical bone size in young men, but higher bone loss and fracture risk in older men and post-menopausal women (Cawthon *et al.*, 2016; Eriksson *et al.*, 2006; Hsu *et al.*, 2015; Hsu *et al.*, 2016; Lee *et al.*, 2008; Mellström *et al.*, 2008; Nielson *et al.*, 2017; Vanbillemont *et al.*, 2010; Vandenput *et al.*, 2016; Vanderschueren *et al.*, 2014). This may be explained by the fact that SHBG is sensitive metabolic marker rather than by its effect on free sex steroids, given the lack of a bone phenotype in SHBG-transgenic mice (Laurent *et al.*, 2016b).

Finally, there are experimental animal studies suggesting that increased follicle-stimulating hormone (FSH) levels per se contribute to (peri-)menopausal bone loss, although this remains controversial and evidence in humans remains limited (Allan *et al.*, 2010; Sun *et al.*, 2006; Zhu *et al.*, 2012).

Role of Estrogens and Androgens in the Diagnosis and Treatment of Osteoporosis

Role of Sex Steroids in Osteoporosis Work-Up

The role of sex steroids in the diagnosis of osteoporosis is generally limited. Osteoporosis is most commonly a disorder of post-menopausal women. Although all post-menopausal women have low E2 concentrations, those with the lowest serum E2 levels have the lowest cortical and trabecular volumetric BMD and the highest fracture risk (Khosla *et al.*, 2005; Lee *et al.*, 2008). However, there is no clinical utility of E2 or SHBG measurements in post-menopausal women, neither for fracture risk assessment nor to predict benefits of osteoporosis therapies, even in hormone-replacement therapy (Crandall *et al.*, 2015).

In contrast to post-menopausal women, most aging men retain relatively normal serum T concentrations, although free or bioavailable T concentrations decline more substantially because SHBG increases in older men (Bhasin *et al.*, 2011; Jardi *et al.*, 2018). Although low E2 and high SHBG (particularly at a threshold <16 pg/mL total E2 or <12 pg/mL of bioavailable E2 (Amin *et al.*, 2000; LeBlanc *et al.*, 2009; Mellström *et al.*, 2008; Woo *et al.*, 2012)) are associated with greater fracture risk in older men, the

clinical utility of measuring these sex steroids in older men is limited (Orwoll *et al.*, 2017). Still, current guidelines recommend measuring serum T concentrations in the work-up for male osteoporosis (Watts *et al.*, 2012). This may be useful in younger men with unexplained "idiopathic" osteoporosis, while it may have little usefulness in a geriatric population.

Sex Steroid Receptors as Treatment Targets in Osteoporosis

Estrogen replacement therapy

Since the Women's Health Initiative study, estrogen-replacement therapy (colloquially known as hormone replacement therapy, HRT) is no longer broadly recommended for the prevention of chronic diseases including osteoporosis in post-menopausal women, due to an increased risk of breast cancer, dementia, gallbladder disease, stroke, deep vein thrombosis (DVT), pulmonary embolism and urinary incontinence (Manson *et al.*, 2013). However, HRT is still a first-line treatment option for vasomotor symptoms. Excess adverse events were mainly observed with combination HRT with conjugated equine estrogen and medroxyprogesterone acetate (CEE + MPA). CEE alone still increased the risk of stroke, DVT, gallbladder disease and urinary incontinence relative to placebo, although mainly in older women. In women aged 50–59 years however, the risk/benefit ratio was favorable (Manson *et al.*, 2013).

Both CEE and CEE + MPA significantly prevented hip fractures (− 33% for both groups), vertebral fractures (− 36% and − 32% respectively) and total fractures (− 28% and − 24% respectively) (Manson *et al.*, 2013). In general however, HRT is not recommended for fracture prevention per se, given the availability of more effective treatments with less side-effects, such as bisphosphonates (Recker *et al.*, 2007). Nevertheless, in women with low or moderate fracture risk who use HRT for vasomotor symptoms, another antiresorptive therapy may not be required as long as HRT is continued. However, post-menopausal women at high risk for fractures should be treated with osteoporosis drugs such as bisphosphonates (Almeida *et al.*, 2017).

Selective estrogen receptor modulators (SERMs)

SERMs such as tamoxifen, raloxifene, bazedoxifene and lasofoxifene bind to the ERα ligand binding pocket and are thus estrogen antagonists in the presence of E2 and partial agonists in the absence of estrogens. Thus, they induce bone loss in premenopausal women but prevent bone loss in post-menopausal women. Notably, SERMs have tissue-specific effects: they have beneficial agonistic effects on bone and desirable antagonistic effects on breast tissue, but unwanted antagonistic vasomotor effects and adverse agonistic effects on the liver (promoting venous thromboembolism) and (in case of tamoxifen only) on the uterus. This tissue-specificity is explained by tissue-specific differences in recruitment of ERα co-activators and co-repressors (Shang and Brown, 2002). Full agonism of ERα requires two co-activator interaction surfaces, called activation function (AF)-1 and 2. The bulky side-chain of SERMs hinders approximation of helix 12 and recruitment of co-activators to AF-2, which is situated in the ligand-binding domain (Almeida *et al.*, 2017). Tissue-specificity is further determined by AF-1, which is situated on the ERα aminoterminal domain. Mice lacking ER AF-1 display a normal response to E2 in the liver and almost full responsiveness in cortical bone, but no response in trabecular bone and only weak effects on the uterus (Börjesson *et al.*, 2011). All available SERMs, as well as non-nuclear ER agonists such as estrogen dendrimer conjugate require a functional AF-1 (Börjesson *et al.*, 2013; Börjesson *et al.*, 2016; Farman *et al.*, 2017). Interestingly, ICI 182,780 (a potent ERα antagonist) works as an agonist on trabecular bone and on the uterus of ovariectomized ERα AF-2 null mice (Moverare-Skrtic *et al.*, 2014). Further work is needed to develop compounds that selectively exploit beneficial ERα effects on bone without unwanted effects on other organs.

Randomized trials have demonstrated that SERMs prevent vertebral fractures (Cummings *et al.*, 2010; Ettinger *et al.*, 1999; Silverman *et al.*, 2008). Lasofoxifene additionally reduces non-vertebral fractures as well as coronary heart disease and stroke (Cummings *et al.*, 2010), while for raloxifene and bazodoxifene only post-hoc analyses suggest prevention of non-vertebral fractures in high-risk subgroups (Delmas *et al.*, 2003; Silverman *et al.*, 2012). Hip fracture prevention has not been demonstrated however, and for bazedoxifene evidence of breast cancer chemoprophylaxis is lacking. In clinical practice, raloxifene or lasofoxifene may be useful in relatively young post-menopausal osteoporotic women with low risk of hip fractures or venous thromboembolism, or in women with contraindications to other drugs (Almeida *et al.*, 2017).

As mentioned above, SERMs appear to exert similar effects in men with severe hypogonadism and compromised E2 levels (Doran *et al.*, 2001; Uebelhart *et al.*, 2004), however they are not approved for men. In randomized trials, raloxifene and toremifene also reduced bone turnover and increased BMD in men receiving androgen-deprivation therapy for prostate cancer, while toremifene reduced incident vertebral fractures (Smith *et al.*, 2004; Smith *et al.*, 2013). However, due to an increased risk of venous thromboembolism, SERMs are not currently approved for this indication either (Alibhai *et al.*, 2017).

Testosterone

Several randomized trials have examined the effects of T therapy in post-menopausal women. Although a significant improvement in sexual function has been suggested by a recent meta-analysis, a deleterious effect on lipid profiles, increased risk of acne and hirsutism, and no effect on BMD was found, while long-term safety data remain lacking (Elraiyah *et al.*, 2014).

In recent years, there has been a tremendous increase in the prescription of T for adult or older men in some countries, particularly in the United States. While T replacement therapy has established benefits in men with congenital or acquired hypogonadism (Basaria, 2014; Finkelstein *et al.*, 1989), its use in so-called "late-onset hypogonadism" is much more controversial. Notably, the definition of a clinical syndrome associated with "low T" levels in older men remains controversial. According to the

European Male Aging Study criteria of total $T < 11$ nmol/L, free $T < 220$ pmol/L and at least three sexual symptoms, only 3.2% of men 60–69 years and 5.1% of those 70–79 years would classify as late-onset hypogonadism (Wu *et al.*, 2010). Secondly, not only adverse effects on the prostate but particularly adverse cardiovascular events have drawn much attention (Basaria *et al.*, 2010; Budoff *et al.*, 2017). The stimulatory effects on the prostate may be blunted by concomitant 5α-reductase inhibitors, without affecting the musculoskeletal benefits (Amory *et al.*, 2004; Bhasin *et al.*, 2012; Borst *et al.*, 2014; Matsumoto *et al.*, 2002).

T therapy has produced significant but modest BMD increases in some randomized trials (Amory *et al.*, 2004; Kenny *et al.*, 2010; Nair *et al.*, 2006) but not others (Christmas *et al.*, 2002; Emmelot-Vonk *et al.*, 2008; Snyder *et al.*, 1999). The benefits of T appeared limited to men with baseline low T levels and treated for longer duration with T at relatively high doses, with possibly greater effectiveness of i.m. injections (Borst and Yarrow, 2015; Giannoulis *et al.*, 2012; Snyder *et al.*, 1999; Tracz *et al.*, 2006).

More recently, the Testosterone Trials investigated the efficacy and safety of T therapy in men with late-onset hypogonadism. After 1 year, transdermal T increased the primary outcome of spine trabecular volumetric BMD by QCT by 6.8%. Additional significant increases were seen on femoral and spine cortical and trabecular bone and estimated strength; the effect was greater on trabecular than on cortical bone, and greater on the spine than on the hip (Snyder *et al.*, 2017). T gel increased lumbar spine areal BMD by only 1.2%, while femoral BMD was not significantly affected. Importantly however, evidence that T reduces fractures remains lacking. Therefore, current guidelines in male osteoporosis recommend that hypogonadal men with low T and low fracture risk may not need additional anti-osteoporotic medications, while men at increased fracture risk should be treated with approved fracture prevention drugs (Watts *et al.*, 2012).

Selective androgen receptor modulators (SARMs)

In contrast to the well-established tissue-specific agonistic/antagonistic effects of SERMs, the development of SARMs has been largely disappointing. Notably, SARMs maintain anabolic effects on bone and muscle with less agonistic effects on reproductive organs, but true tissue-specificity has hitherto not been demonstrated (Dubois *et al.*, 2012; Dubois *et al.*, 2015). Most SARMs cannot be converted to DHT, which may well explain why their deleterious effect on the prostate is diminished (but often not completely absent); they can be regarded more as "marginators" (greater dose-dependent margin between wanted and unwanted effects) than as true modulators (Almeida *et al.*, 2017). Unfortunately, SARMs are not aromatizable either, which is problematic given the key role of estrogens for osteoporosis in older men. In a randomized trial, DHT treatment in older men reduced BMD, probably because gonadotropins and E2 were concomitantly suppressed (Idan *et al.*, 2010). These results are in line with the Hypogonadism and Estrogen Removal (HER) trial, which has shown that the effects of T on cortical and trabecular bone and bone turnover in older men depends largely if not exclusively on estrogens (Finkelstein *et al.*, 2016). Despite beneficial effects in hypogonadal animal studies, few clinical trials with SARMs are available, and none have demonstrated positive effects on BMD (Dalton *et al.*, 2011; Dobs *et al.*, 2013; Papanicolaou *et al.*, 2013). Furthermore, the potential cardiovascular side-effects of T raise concern for further SARM development. Nevertheless, other therapies which could reverse muscle and bone loss (i.e. concomitant osteoporosis and sarcopenia) in elderly of both genders are eagerly awaited (Laurent *et al.*, 2016a).

Summary

At PBM, men develop wider bones due to greater periosteal bone expansion, as well as greater trabecular bone mass. Estrogens are essential for cortical and trabecular bone development in both genders; however, key elements of musculoskeletal sexual dimorphism are determined by androgen effects of periosteal bone formation and trabecular bone resorption. During midlife, men continue to consolidate their cortical and trabecular bone assets, likely independent of sex steroids. Cortical and trabecular bone loss with aging however is dependent on estrogen deficiency in post-menopausal women, as well as in some men (particularly those with serum $T < 200$ ng/dL and $E2 < 10$ pg/mL) and high SHBG. Although the clinical role of sex steroids in the diagnosis and treatment of osteoporosis in general is limited, there is growing interest and attention for bone loss and fracture risk in patients treated with hormone deprivation therapies for breast and prostate cancer. Further research is needed to investigate the cellular and molecular mechanisms by which sex steroid regulate bone metabolism, which could potentially lead to the development of new drugs to exploit their musculoskeletal benefits without adverse reproductive or cardiovascular effects.

Osteoporosis in Premenopausal Women☆

Serge Rozenberg, Free Universtiy of Brussels, Brussels, Belgium

Glossary

Aromatase inhibitors Compounds that inhibit Aromatase in order to reduce production of estrogenic steroid hormones. These drugs are used for the treatment of breast cancer.

Anorexia nervosa (AN) An eating disorder that is characterized by the lack or loss of appetite, known as anorexia. Other features include excess fear of becoming overweight; body image disturbance; significant weight loss; refusal to maintain minimal normal weight; and amenorrhea. This disorder occurs most frequently in adolescent females.

Amenorrhea Absence of menstruation for at least 6 months (primary: it never occurred,) Secondary. The absence of vaginal bleeding for at least 6 months in women who previously have had menstruations.

Bone mineral density (BMD) A measurement of the density of bone as determined by dual-energy X-ray absorptiometry (DEXA). It is generally measured at the hip and lower spine.

Bulimia A condition characterized by gorging and purging behaviors, where the purging is induced by vomiting, laxatives, or diuretic use.

DEXA Dual X-ray absorptiometry. A noninvasive method, based on the differential absorption of X-rays. It is primarily used for quantitating bone mineral content (BMC) and density (BMD), especially for the diagnosis of osteoporosis, and also in measuring body composition.

Depo Provera (DMPA; depot medroxyprogesterone acetate) An injectable progesterone contraceptive that works in part by inhibiting the pituitary gonadotropins, which in turn suppress ovulation and ovarian steroidogenesis.

Gonadotropin-releasing hormone (GnRH) agonist A synthetic version of the naturally occurring decapeptide: GnRH: A decapeptide that stimulates the synthesis and secretion of both pituitary gonadotropins, luteinizing hormone and follicle stimulating hormone. GnRH is produced by neurons in the septum preoptic area of the hypothalamus and released into the pituitary portal blood, leading to stimulation of gonadotrophs in the anterior pituitary gland.

Hypothalamic amenorrhea (HA) Lack of menses caused by impairment of normal hypothalamic function leading to absent or decreased secretion of GnRH. It is often related to anorexia nervosa, to intense exercise or stress.

Hyperprolactinemia Increased levels of prolactin in the blood, which may be associated with amenorrhea and galactorrhea. Relatively common etiologies include prolactinoma, medication effect.

Laurence–Moon Syndrome An autosomal recessive condition characterized by hypogonadism; spinocerebellar degeneration; mental retardation; retinitis pigmentosa; and obesity. This syndrome was previously referred to as Laurence–Moon–Biedl syndrome until Bardet–Biedl syndrome was identified as a distinct entity. (From *The New England Journal of Medicine* **1989**, *12*; *321*(15): 1002–1009).

Osteoporosis A systemic disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk. A condition characterized by a reduced amount of bone leading to an increased susceptibility to fractures (*T* score lower than 2.5 SD from the mean peak value on DEXA scan).

Osteopenia Decreased bone density (*T* score between 1 and 2.5 SD below the mean peak value on DEXA scan) (Figure).

Oligomenorrhea Abnormally infrequent menstruation.

Premature ovarian failure (POF) also called premature ovarian insufficiency (POI) menopause, premature The premature cessation of menses (Menstruation) when the last menstrual period occurs in a woman under the age of 40. It is due to the depletion of ovarian follicles. Premature menopause can be caused by diseases; ovariectomy; radiation; chemicals; and chromosomal abnormalities.

Prader–Willi Syndrome An autosomal dominant disorder caused by deletion of the proximal long arm of the paternal chromosome 15 (15q11-q13) or by inheritance of both of the pair of chromosomes 15 from the mother (Uniparental Disomy) which are imprinted (Genetic imprinting) and hence silenced. Clinical manifestations include mental retardation; muscular hypotonia; hyperphagia; obesity; short stature; hypogonadism; strabismus; and hypersomnolence. (Menkes, Textbook of Child Neurology, 5th edn., p. 229).

Turner syndrome A syndrome of defective gonadal development in phenotypic females associated with the karyotype 45,X (or 45,XO). Patients generally are of short stature with undifferentiated gonads (streak gonads), sexual infantilism, hypogonadism, webbing of the neck, cubitus valgus, elevated gonadotropins, decreased estradiol level in blood, and congenital heart defects. Noonan syndrome (also called Pseudo-Turner syndrome and Male Turner syndrome) resembles this disorder; however, it occurs in males and females with a normal karyotype and is inherited as an autosomal dominant.

☆*Change History*: February 2018. Rozenberg updated an article (from Kimberly Elford Paul Claman University of Ottawa and Ottawa Hospital, Ottawa, Ontario, Canada). The figures were not from that article but were referenced.

This article is an update of Kimberly Elford and Paul Claman, Osteoporosis in Reproductive Age Women: Impact of Sex Steroid Replacement, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 441–446.

 doi:10.1016/B978-0-12-801238-3.65818-X

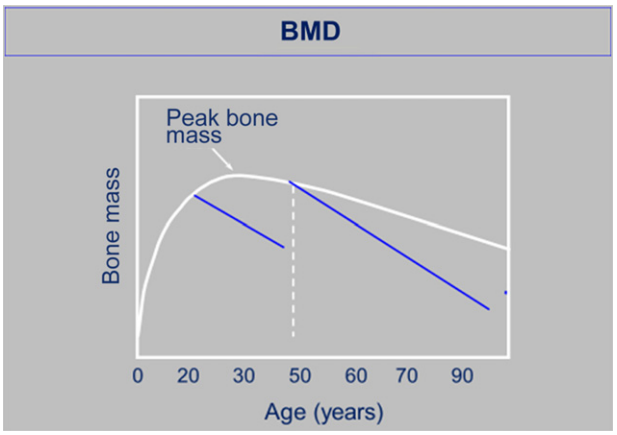

Fig. 1 It is essential to try to identify whether low bone mass in premenopausal women is related to failure to attain peak bone mass (which may for instance be of genetic origin, or have occurred during child development), to previous bone loss that has stopped, or ongoing bone loss, as the therapeutic attitude will differ.The white curb represents schematically the mean BMD evolution with age. The first *blue* line represents the BMD evolution of a patient suffering from BMD loss starting at a young age before the onset of menopause. The second blue line represents the BMD evolution of a patient suffering from BMD loss starting at the onset of menopause.

Introduction

Although osteoporosis is generally considered to be a disease mostly affecting older women after menopause, it can occur at any age, occasionally affecting premenopausal women. According to Callegari *et al.* (2017), about 2%–7% of young Australian women have a bone mass below 2 standard deviations for their age group (Z Score of less than -2).

Cauley *et al.* (2012) evaluated the value of bone turnover markers for predicting fracture risk in women across menopausal transition in 2305 women.

They observed that a higher urinary NTX excretion measured before menopause and across menopause is associated with a higher risk of fracture.

Premenopausal osteoporosis may result from insufficient bone accrual, premature bone loss or both. It is essential to try to identify whether low bone mass in premenopausal women is related to failure to attain peak bone mass (which may for instance be of genetic origin or have occurred during childhood development), to early bone loss that has been contained or ongoing bone loss because the therapeutic attitude will differ (**Fig. 1**). All of the etiological and risk factors that induce bone loss after menopause may also lead to premenopausal osteoporosis. One should strive to correct etiological and risk factors associated with osteoporosis (such as smoking, alcohol consumption, sedentary lifestyle). In the following article we will focus on reproductive factors associated with osteoporosis and occurring at a young age, that is, before the usual onset of menopause. We will not, however, discuss, steroid induced osteoporosis, cancer induced osteoporosis, hyperparathyroidism, Cushing syndrome, celiac disease and other forms of malabsorption, idiopathic hypercalciuria and connective tissue disorders, even though these conditions also need to be excluded when confronted with premenopausal women who have osteoporosis.

Assessment of Premenopausal Osteoporosis

The clinical investigation involves an osteoporosis assessment consisting of BMD measurements and determination of other risk factors for osteoporosis such as a personal history of low-trauma fractures, a family history of osteoporotic fractures, lifestyle factors, medications and serum level of 25OHD. In addition, since many women with premenopausal osteoporosis present reproductive dysfunction (often amenorrhea), clinical management will include the evaluation of its origin. Follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol, prolactin, thyroid-stimulating hormone (TSH), and human chorionic gonadotropin (hCG) will be measured to evaluate the cause of amenorrhea.

Etiologies

The major causes of hypo-estrogenemia induced osteoporosis in premenopausal women are documented in **Table 1**.

Hypothalamic Amenorrhea

Hypothalamic amenorrhea (HA) is a prevalent condition and the most common cause of young-adult-onset amenorrhea, with the exception of pregnancy. It can be precipitated by eating disorders, excessive exercise, anorexia nervosa (AN), hyperprolactinemia,

Table 1 Amenorrhea which may induce osteoporosis in the young premenopausal woman. The aetiologies in bold are the principal causes

Hypothalamic amenorrhea (HA)
Functional hypothalamic amenorrhea
Exercise
Stress induced
Eating disorders
Anorexia nervosa
Severe illness
Medically induced
GnRH agonists (used previously for endometriosis, previously for myomata or breast cancer treatment), eventually combined with aromatase inhibitors
Inflammatory or infiltrative diseases
Brain tumors—e.g., craniopharyngioma
Cranial irradiation
Traumatic brain injury
Other syndromes—Prader–Willi, Laurence–Moon–Biedl, leptin mutations
Pituitary dysfunction
Hyperprolactinemia
Other pituitary tumors—acromegaly, corticotroph adenomas (Cushing disease)
Other tumors—meningioma, germinoma, glioma
Genetic causes of hypopituitarism
Empty sella syndrome
Pituitary infarct or apoplexy
Ovarian dysfunction
Gonadal dysgenesis (Turner syndrome, 46,XY*)
Other causes of primary ovarian insufficiency (POI)
Post-surgery, inflammation endometriosis
Post chemotherapy, irradiation

Depo Provera use, gonadotropin-releasing hormone (GnRH) agonist use and functional hypothalamic amenorrhea. AN is the major concern for osteoporosis.

Osteoporosis in Patients With Anorexia Nervosa (AN)

Conservative estimates of the lifetime prevalence of anorexia nervosa (AN) range from 0.6% to 4.2% (Gielen *et al.*, 2017). AN is 10 times more common in women than in men and mainly affects young women (median age of onset 18 years old) (Grinspoon *et al.*, 2000; Gielen *et al.*, 2017). About half of these patients suffer from osteoporosis and almost all have osteopenia (Grinspoon *et al.*, 2000; Gielen *et al.*, 2017). Amenorrhea is common and the typical triad consists of low energy intake (generally related to eating disorders), osteoporosis and amenorrhea (**Fig. 2**).

Concerns should be raised if a patient's history reveals the absence of three or more cycles. Amenorrhea seems to be very common in athletes, affecting between 3% and 66% of them and about 15%–62% of young, female athletes are concerned by eating disorders. The incidence of osteoporosis in adults who presented the triad during adolescence and young adulthood is unknown (Grinspoon *et al.*, 2000; Gielen *et al.*, 2017).

AN is associated with marked endocrine changes that also impair healthy bone turnover. As mentioned before, amenorrhea is common. In adolescents with AN, menarche is often delayed, contributing to low BMD. However, the severity of bone loss in women with AN is greater than in those with normal-weight hypothalamic amenorrhea, indicating that, in addition to estradiol deficiency there are other factors including nutritional deficiencies and hormonal abnormalities that contribute to bone loss. GH resistance, low levels of IGF-1, hypercortisolemia and low levels of testosterone have all been implicated in AN-associated osteopenia and osteoporosis. Abnormalities in hormones regulating appetite (oxytocin, leptin and peptide tyrosine tyrosine (PYY)) may play an additional role. Therefore, the etiology of bone loss in patients with AN is multifactorial (Gordon, 2010; Gielen *et al.*, 2017).

Biological Markers of Bone Turnover, Bone Loss and Bone Fragility, Fracture Risk in AN Patients

Klibanski's team observed an uncoupling of bone turnover in adults with AN, with a decrease in markers of bone formation and an increase in markers of bone resorption. However, in adolescents with AN, there is a low bone turnover state with a decrease in levels of bone formation and resorption, as opposed to an increased bone turnover during normal adolescence (Misra and Klibanski, 2006). Veronese *et al.* conducted a meta-analysis of vitamin D status in AN patients and observed that AN patients who

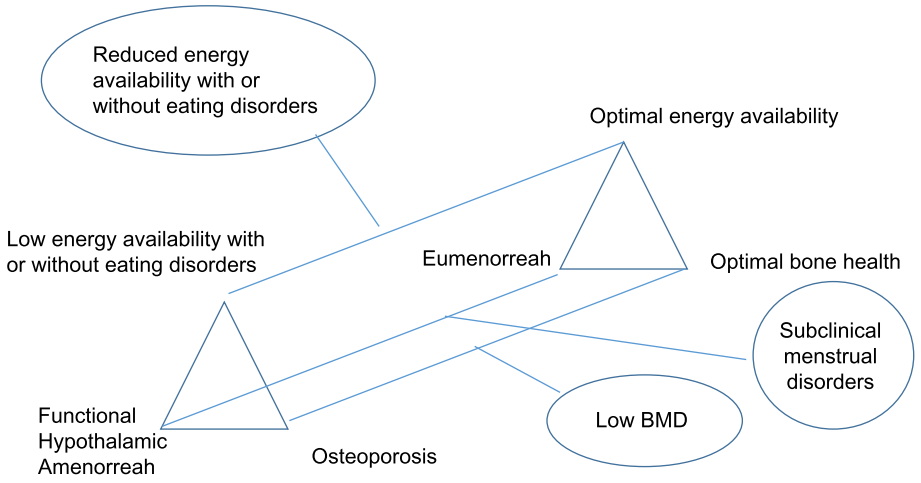

Fig. 2 The female athlete triad refers to the inter-relatedness of eating disorders, amenorrhea, and osteoporosis. Adapted from Catherine Gordon Meet the Professor course at the ASBMR Annual Conference 2012.

did not take vitamin D supplements had significantly lower levels of 25OHD and 1,25(OH)2D (Veronese *et al.*, 2015). Both trabecular and cortical bone sites are affected in AN, but since there is a marked estrogen deficiency component in these women, trabecular osteoporosis (such as at the lumbar spine) is more marked and common (Misra and Klibanski, 2014). Moreover, HR-pQCT studies reported that their bone microarchitecture, marrow adiposity and bone strength are affected (Misra and Klibanski, 2014). AN patients often have a reduced peak bone mass, increasing their risk of fracture (Theintz *et al.*, 1992).

Not surprisingly, therefore, a two- to sevenfold increase in fractures has been reported in patients with AN (Rigotti *et al.*, 1991; Vestergaard *et al.*, 2002; Strokosch *et al.*, 2006). Rigotti *et al.* followed a series of 27 women with AN for a median of 25 months and concluded that anorexic women may have an increased risk of fracture (RR 7.1; 95% CI 3.2–18.5) and that low BMD is not rapidly reversed after recovery from AN (Rigotti *et al.*, 1991). Vestergaard *et al.*, using a case control Danish Nationwide register study, also observed an increased fracture risk in AN subjects, which persisted more than 10 years after the diagnosis (Vestergaard *et al.*, 2002).

Assessment and Management of Osteoporosis in AN

AN patients need to be encouraged to gain weight. A restored, acceptable BMI (between 18 and 25 kg/m^2) will generally help to recover a normal reproductive function, which can be determined by a regular menstrual cycle (without hormone therapy). Restauration of body weight will also improve BMD although a complete catch-up does not always occur (Misra and Klibanski, 2006). In addition, AN patients should take adequate amounts of calcium (e.g., 1200 mg) and vitamin D (e.g., 800 IU) daily, from diet and supplements.

High-dose estrogen contraception is not an effective treatment option for AN-associated bone loss in adolescents or adults. Indeed, prospective trials have failed to show a benefit of combined estrogen–progestin oral contraceptives in treating AN-associated bone loss even though one may be tempted to restore menstruation in these patients using oral contraceptives. Unfortunately, several studies have failed to observe a protective effect of the "pill" containing 50 µg ethynilestradiol (Strokosch *et al.*, 2006). On the other hand, lower-dose physiological estrogen replacement, using MHT such as 100 µg transdermal 17-beta-estradiol with cyclic micronized progesterone, resulted in BMD gains at the spine and hip compared with placebos. The therapy did not, however, restore BMD to normal (Misra *et al.*, 2011). Although AN patients are also androgen-deficient, its replacement is currently not recommended.

Limited data suggest that bisphosphonates may benefit iwomen with AN-associated bone loss. For instance, 1 year of risedronate treatment resulted in a modest gain in BMD compared with placebo (Miller *et al.*, 2011). Another study, however, failed to report any improvement between alendronate and placebo (Golden *et al.*, 2005). Furthermore, there are safety concerns with bisphosphonates, especially in younger patients who may want to become pregnant. Bisphosphonates should only be prescribed to non-pregnant women of reproductive age and those who will not become pregnant during the treatment period. Bisphosphonates are usually not prescribed in such cases but can be used by older AN patients. Denosumab and teriparatide should also not be used as first line therapies in young patients suffering from AN-induced osteoporosis.

Conclusion

AN predominantly affects young women and results in the disturbance of most endocrine axes. This will lead to osteoporosis in about half of the patients and to osteopenia in almost all of them with added suffering due to fractures. Multidisciplinary management is needed, involving a gynecologist, an endocrinologist, a pediatrician (depending of the patient's age), a psychologist, a nutritionist and a bone specialist. BMD and an endocrine evaluation is mandatory in these patients. Other pathologies

associated with weight loss, amenorrhea and bone loss should be excluded. Optimal therapy aims to restore body weight and the recovery of a regular cycle. A healthy lifestyle is therefore mandatory. Calcium and vitamin D supplementation is recommended in all patients with AN. MHT is indicated in adolescent girls with sustained low body weight, low BMD and amenorrhea when other causes of amenorrhea have been excluded. The bisphosphonates, denosumab and teriparatide may be useful in adult women with severe bone loss.

Hyperprolactinemia

Hyperprolactinemia is a relatively common clinical problem. Its prevalence ranges from 0.4% in an unselected adult population to as high as 9%–17% in women with reproductive diseases. It was also found in 5% of women at a family planning clinic, 9% of those with young-adult onset amenorrhea and 17% among women with polycystic ovary syndrome. (Biller *et al.*, 1999). It may result from a micro (or less often macro) prolactinoma or be drug induced. The clinical spectrum involves anovulation, oligomenorrhea, amenorrhea, infertility, galactorrhea, and osteoporosis. Hyperprolactinemia leads to the inhibition of pulsatile secretion of hypothalamic GnRH with resultant hypothalamic amenorrhea or menstrual irregularity. Estrogen-deficient hyperprolactinemic women are at high risk for the development of osteoporosis. Klibanski and Greenspan (1986) and Schlechte *et al.* (1992), have shown that women with hyperprolactinemia have reduced bone densities compared to controls. Although loss of bone density worsens with lower estrogen levels, there is no correlation between prolactin levels and bone density. Prolactin receptors have been found in human bone, but it is unlikely that hyperprolactinemia exerts a significant, direct effect on calcium metabolism or bone mineral content. However, it is clear that the estrogen deficiency found in hyperprolactinemic women is directly responsible for osteopenia. Park and Song, 1995 showed that the decline in bone mass observed in hyperprolactinemic women follows a rapid course between ages 20 and 25 and then starts to slow down. Fortunately, bone loss partially recovers after the restoration of gonadal function with dopamine agonist therapy. Menstrual dysfunction and bone loss do not occur in all hyperprolactinemia women. Only 30% of the subjects in Klibanski and Greenspan's study in 1986, were found to suffer from bone loss. It is likely that only those women with increased prolactin and amenorrhea or menstrual irregularities (indicating a hypoestrogenic state) are at risk for osteoporosis.

Treatment

When hyperprolactinemia is found, a careful history must be taken to rule out the use of dopamine-inhibiting medications or hypothyroidism because these can cause hyperprolactinemia. Imaging of the pituitary gland using computed tomography or magnetic resonance imaging is indicated to rule out a pituitary adenoma. Normally, menstruating hyperprolactinemic women who do not have pituitary tumors and those in whom fertility is not desired may not require therapy. Indeed, some women suffer from hyperprolactinemia associated with the "big big molecule of prolactin" which is biologically inactive (called macroprolactinemia), and is detected by the same radioimmunoassay as the biologically active prolactin (Biller *et al.*, 1999). This may explain many cases of the very high prolactin levels sometimes found in normally ovulating women which require no treatment. Dopamine agonist is the mainstay of treatment. In women with menstrual irregularities, Bromocriptine and Cabergoline are the most commonly used dopamine agonists and are effective in normalizing serum prolactin, resulting in the resumption of menstrual regularity. Dopamine agonist therapy not only regulates menstruation but also helps to prevent bone loss and reduces long-term fracture risk in hypoestrogenic hyperprolactinemic women. However, the presence of a pituitary macroadenoma may require surgical or radiological management (Biller *et al.*, 1999).

Drug Induced

Depo Provera Use

Depot medroxyprogesterone acetate (DMPA) is a safe injectable contraceptive that works by inhibiting pituitary gonadotropin secretion with resultant suppression of ovarian steroidogenesis. Most DMPA users become amenorrheic within the first year of use. Circulating estrogen concentrations in women using DMPA are maintained at levels similar to those found in the early follicular phase of normally menstruating women. Controversy exists regarding whether a constant low estradiol level leads to bone loss in DMPA users.

Kaunitz *et al.* (2008) conducted a systematic review of studies published in PubMed from 1996 to 2006, evaluating changes in BMD after discontinuation of DMPA. Ten primary clinical or observational studies addressing this issue were identified. BMD consistently went back to baseline or near base-line values following DMPA discontinuation in women of all ages. This recovery in BMD was seen as early as 24 weeks after therapy cessation and persisted for as long as women were followed up. BMD in past DMPA users was similar to that in non-users. The authors concluded that bone loss occurring with DMPA use is reversible and is not likely to be an important risk factor for low bone density and fractures in older women, although data on fracture risk in DMPA users are lacking (Kaunitz *et al.*, 2008).

Some investigators have found significantly lower BMD in DMPA users than in controls. Others, however, have been unable to show significant deterioration in BMD after years of use. A long-term study by Tang *et al.* (1999) found significantly lower BMD of the lumbar spine and hip in women who used DMPA for more than 5 years compared to nonusers of the same age, body mass

index, smoking status and who had the same calcium intake. Longitudinal research needs to be undertaken to determine whether DMPA use causes significant loss in BMD and whether any deficit in bone density is carried forward into postmenopausal life thereby increasing fracture risk. Substantial recovery of bone mass was reported, in 1994, by Cundy *et al.* more than 1 year after discontinuation of DMPA. Candidates for injectable contraception should be informed that the use of DMPA is associated with a slight decrease in bone mineral density (BMD), which is largely, if not completely, reversible. There should be no specific limit to the length of time that the DMPA contraceptive is prescribed, regardless of the woman's age. Monitoring BMD is not recommended in users of DMPA for contraceptive purposes. Finally, the consensus statement declared that, although calcium and vitamin D supplements are beneficial in skeletal health for women in general, it should not be recommended solely based on a woman's use of DMPA (Guilbert *et al.*, 2009).

On the other hand, DMPA may not be indicated in women with suspected osteoporosis or with a high prevalence of osteoporosis risk factors. Similarly, DMPA may not be the first choice of contraception in adolescents who have not achieved peak bone mass.

Conclusion

Scientific evidence shows that DMPA is a valid contraceptive option for women. Its potential impact on BMD must be balanced against the significant individual, family and social consequences of unintended pregnancy.

Gonadotropin-Releasing Hormone Agonist (GnRHa or LHRHa) Use

Gonadotropin-releasing hormone agonists suppress ovarian function through the inhibition of the hypothalamic–pituitary axis and are used in the management of several conditions in women's health. They may be indicated for severe endometriosis, before surgery or before IVF. They also used to be indicated for the preoperative treatment of uterine fibroids but since the development of ulipristal acetate, they have largely been abandoned for such cases (Rozenberg *et al.*, 2017). They may be used to induce chemical castration in breast cancer patients (this subject will be covered in another chapter). Using GnRHa for more than 6 months may result in extreme bone loss. Data suggest that after 6 months of use, discontinuation of treatment is associated with a virtually complete recovery of any bone lost during the time of therapy. For long-term use, low-level estrogen and/or progesterone add-back therapy has been suggested. The concept of add-back therapy is that there may be a threshold level of estrogen that is high enough to prevent bone loss but low enough to attenuate the development of endometriosis.

Premature Ovarian Failure

Premature ovarian failure (also known as premature menopause) is defined as menopause before the age of 40. It can be "natural" or "iatrogenic" such as after bilateral oophorectomy. It may be either primary or secondary. In the majority of cases of primary POF, the cause is unknown. Chromosome abnormalities (especially X chromosome), follicle-stimulating hormone receptor gene polymorphisms, inhibin B mutations, enzyme deficiencies and autoimmune disease may be involved. Secondary POF is becoming more prevalent since survival rates following treatment of malignancies using surgery, radiotherapy and chemotherapy continue to improve. Diagnosis should be confirmed by an elevated FSH level, over 40 IU/L and an estradiol level lower than 50 pmol/L, in the absence of bilateral oophorectomy. Further assessments should include thyroid function tests, autoimmune screening for polyendocrinopathy, karyotype (below the age of 30) and bone mineral density. Untreated early ovarian failure increases the risk of osteoporosis, cardiovascular disease, dementia, cognitive decline and Parkinsonism. The mainstay of treatment is hormone therapy which must be continued until the average age of the natural menopause. With regards to fertility, while spontaneous ovulation may occur, the best chance of achieving pregnancy is through donor oocyte in vitro fertilization. It is essential that women receive adequate information as they may find it a difficult diagnosis to accept. It is recommended that women with POF be seen in a specialized unit capable of dealing with their multiple needs (Vujovic *et al.*, 2010).

Treatment

One should aim at treating the underlining disorder. Risk factors need to be corrected (alcohol, smoking). Calcium, vitamin D, and weight bearing exercise are recommended for most women with premenopausal osteoporosis. Exercise is not recommended in AN patients, however. Pharmacotherapy is not indicated in premenopausal women with low bone mineral density without fractures or without evidence of accelerated bone loss. There are very few data available to guide clinicians in the use of classical pharmacologic therapies used in postmenopausal women (bisphosphonates, selective estrogen receptor modulators (SERMs), teriparatide (parathyroid hormone [PTH] 1–34), and denosumab). These treatments should be reserved for rare patients with fractures or ongoing secondary causes of osteoporosis and bone loss. Women with fractures or accelerated bone loss in the setting of estrogen deficiency or amenorrhea may benefit from estrogen replacement. Replacement of estrogen in premenopausal women who are estrogen deficient may have beneficial effects on bone mass (women with POI and to a lesser extend women with AN) (Gielen *et al.*, 2017).

Conclusion

Bone density measurement is recommended for premenopausal women with known secondary causes of osteoporosis or history of a fragility fracture. During the evaluation of premenopausal women with osteoporosis, secondary causes of osteoporosis need to be excluded. One should determine whether there is ongoing excessive bone loss. Adequate calcium, vitamin D, and life style should be recommended. In women with a secondary cause of osteoporosis etiological treatment should be targeted. In the absence of evidence of accelerated bone loss or fractures, conservative management without specific other medical therapy and only follow up should occur. In rare cases of premenopausal osteoporosis, for instance those associated with amenorrhea and osteoporosis induced by chemotherapy, will other medication such as bisphosphonates or denosumab be used.

Secondary Osteoporosis

Gregory R Emkey, Pennsylvania Regional Center for Arthritis & Osteoporosis Research, Wyomissing, PA, United States

Introduction

Osteoporosis is a skeletal disease characterized by decreased bone mass and microarchitectural changes in bone tissue that increase the susceptibility to fracture. It is estimated that 10 million Americans over the age of 50 have osteoporosis, and tens of millions more are at risk. Bone mineral density testing has been the accepted standard for screening for this disease, and is routinely targeted at postmenopausal females by general clinicians.

Secondary osteoporosis is loosely defined as low bone mineral density or increased risk of fragility fracture caused by any factor other than aging or postmenopausal status. A wide array of diseases, treatments, and medications can affect bone quality in men and women of all ages, which is often not reflected in bone density testing. In light of the significant public health burden caused by osteoporosis, a recognition and understanding of these factors is of utmost importance. The following is an organ-system based review of the more common causes of secondary osteoporosis, with a focus on pathogenesis.

Endocrinology

Glucocorticoid Excess

Endogenous overproduction or systemic administration of glucocorticoids is a well-known cause of bone loss, and is the most common iatrogenic cause of osteoporosis seen in clinical practice (Weinstein, 2011). The pathogenesis includes diverse effects on three main cell types in bone biology, changes in calcium handling, as well as increased falls related to steroid-induced myopathy (Natsui *et al.*, 2006; Canalis *et al.*, 2007). As many as 30%–50% of patients receiving chronic glucocorticoid therapy will experience a fracture, making this a major contributor to the morbidity and mortality associated with steroid-responsive chronic diseases such as lupus, rheumatoid arthritis, giant cell arteritis, transplant recipients, inflammatory bowel disease, and COPD (Steinbuch *et al.*, 2004; Angeli *et al.*, 2006).

Glucocorticoids cause decreased production of osteoblast precursors and increased apoptosis of mature osteoblasts (Weinstein *et al.*, 1998; O'Brien *et al.*, 2004). Histomorphometric studies have confirmed decreased numbers of osteoblasts on cancellous bone in patients with glucocorticoid-induced osteoporosis (GIO) with associated thinning wall width. Decreased osteoblast differentiation is in part mediated through inhibition of wingless (Wnt)/B-catenin signaling, as the expression of Dickkopf-1 and sclerostin, both antagonists of Wnt signaling, can be enhanced by glucocorticoids (Ohnaka *et al.*, 2005; Gifre *et al.*, 2013). Enhanced apoptosis of osteocytes is also seen, which are the main mechanosensing cells of bone that contribute to the ability to withstand significant compressive forces.

While glucocorticoid therapy can decrease osteoclast production, the lifespan and activity of osteoclasts are increased, thereby maintaining their effect relative to the decreased osteoblastic number and activity. Studies have shown increased production of receptor activator of NF-kB ligand (RANKL) which promotes osteoclastic activity and survival, and suppression of osteoprotegerin (OPG), a natural decoy receptor for RANKL (Hofbauer *et al.*, 1999; Humphrey *et al.*, 2006). Additionally, glucocorticoids have been shown to confer a prosurvival effect directly to osteoclasts, independent of alterations in RANKL and OPG, in the early stages of steroid exposure in mice (Jia *et al.*, 2006). The bone abnormalities may also be enhanced by the decreased sex hormone secretion because of suppressed hypothalamic-pituitary function.

Bone loss occurs quickly with glucocorticoid therapy and appears to be biphasic, with as much as a 6%–12% loss in BMD within the first year, followed by a continued annual loss with ongoing therapy (LoCascio *et al.*, 1990). Biochemical markers of bone turnover are affected as early as 1–2 months following initiation of therapy, and the bulk of bone loss is seen within the first 6 months (Saag *et al.*, 1998). Addressing the deleterious effects of steroid therapy on bone is imperative early on in the course, particularly if long term use (i.e., 90 days or longer) or moderate to high dose (>7.5 mg/day) is planned. Risk factors associated with GIO include advanced age, low BMI, dose and duration of glucocorticoid, as well as other traditional factors (Weinstein, 2012). Bone density testing is recommended at the onset of therapy as a general screening, though changes in the mechanical qualities of bone may occur prior to any changes reflected in BMD testing. Treatment recommendations are based on dose, additional risk factors, prior fractures, and an updated guideline was recently published, and both anabolic and antiresorptive therapies may be used in addition to calcium and vitamin D supplementation (Buckley *et al.*, 2017; Saag *et al.*, 2007).

Primary Hyperparathyroidism

Parathyroid hormone (PTH) is critically involved in calcium and phosphorus homeostasis, and continuous exposure to elevated levels in primary hyperparathyroidism (PHPT) are known to be catabolic to the skeleton. The contribution to osteoporosis is so

well established that in patients with PHPT significant metabolic bone disease is generally considered an indication for parathyroidectomy (Bilezikian *et al.*, 2009). The majority of patients with PHPT are postmenopausal females, with an incidence as high as 1 in 500 reported in this population (Bilezikian *et al.*, 2009). PHPT preferentially affects areas rich in cortical bone more so than cancellous bone, therefore evaluating distal forearm and femoral neck BMD is recommended (Khan and Bilezikian, 2000). Vertebral fracture prevalence is increased, both in symptomatic and asymptomatic patients (Cipriani *et al.*, 2015).

The precise mechanism of bone loss in PHPT is not completely understood. Histomorphometrically, persistently elevated levels of PTH induce a state of high bone turnover and have been associated not only with a low BMD but also with alterations in the mineralization density distribution and collagen crosslinks affecting bone stiffness and quality (Roschger *et al.*, 2007; Zoehrer *et al.*, 2008). At the cellular level, compared with healthy controls, patients with PHPT had a low OPG/RANKL ratio favoring a state of bone resorption, which improves following parathyroid surgery (Szymczak and Bohdanowicz-Pawlak, 2013). The effects of PHPT on Wnt pathway signaling is still being elucidated. Taken together, the finding of increased bone turnover, low BMD, and reduced bone quality appear to confer an increased risk of fracture in PHPT, highlighting the need for proactive screening of bone disease.

Hyperthyroidism

Thyrotoxicosis is an established cause of high-turnover osteoporosis, and many studies have shown a consistent decrease in BMD and increase in fracture risk in patients with untreated hyperthyroidism (Vestergaard and Mosekilde, 2003; Ross, 1994). While bone loss has been documented at all skeletal sites, there is preferential involvement of cortical bone, suggesting the need to screen distal forearm BMD (Greenspan and Greenspan, 1999; Svare *et al.*, 2009). While the cause of the hyperthyroidism may not matter, the severity is an important factor, as a TSH of <0.1 mU/L was associated with a threefold increase risk of hip fracture and a fourfold increase risk of vertebral fracture in a cohort of postmenopausal females, even in subclinical thyroid disease (Blum *et al.*, 2015; Bauer *et al.*, 2001).

The effect of thyrotoxicosis on bone was felt to be mediated by the effects of T3 through its interaction with nuclear receptors TR-α and TR-β, and excessive stimulation of these receptors leads to accelerated bone remodeling and ultimately osteoporosis. Additionally, recent evidence has shown that thyroid stimulating hormone (TSH) may be a negative regulator of bone turnover, as decreased expression of TSH-receptor leads to a high turnover state and low BMD (Abe *et al.*, 2003). Bone-protective effects of TSH include increased osteoblastic differentiation, and inhibited osteoclast formation (Baliram *et al.*, 2017). This has important implications for other situations with low TSH such as subclinical hyperthyroidism and use of thyroid replacement medications in cancer, etc. In hypothyroidism the use of highly sensitive TSH measurements has allowed a more accurate control of patients on replacement therapy and it is recommended that values be kept in mid normal range to avoid bone sequelae (Garber *et al.*, 2012).

Growth Hormone Deficiency

Growth hormone (GH) is an important determinant of longitudinal bone growth and development of skeletal maturity, and children with GH deficiency exhibit short stature and reduced peak bone mass (Giustina *et al.*, 2008). The anabolic effect of GH on osteoblasts appears to be dependent upon insulin-like growth factor 1 (IGF-1), whose production by the liver and osteoblasts is stimulated by GH (Andreassen and Oxlund, 2001). The local interaction of IGF-1 and its binding proteins regulate GH receptor (GHR) on osteoblasts, mediating some effects of GH on bone (De Jesus *et al.*, 2009). A marked reduction in bone turnover is seen histomorphometrically in adult-onset GH deficiency, primarily affecting cortical bone (Bravenboer *et al.*, 1996). This is associated with a lower BMD, and a fracture risk two to three times that of osteoporotic patients without GH deficiency (Wüster *et al.*, 2001). Treatment with GH replacement has been associated with a decrease in the fracture rate (Mazziotti *et al.*, 2006).

Acromegaly

Acromegaly is associated with significant increase in markers of bone turnover due to the effect of excess GH and IGF-1 on osteoblasts and osteoclasts (Ueland *et al.*, 2006). Studies on the effect of acromegaly on BMD are nuanced due to the structural changes in bone influencing the accuracy of testing, as well as the common finding of concurrent hypogonadism. Overall, the BMD in acromegalics is generally preserved, with some showing a relative decrease in trabecular bone density (Kayath and Vieira, 1997; Scillitani *et al.*, 2003). Despite a preserved BMD, several studies document increased bone turnover and an increased incidence of vertebral fractures compared with a control population, influenced by factors such as the duration of active acromegaly, serum IGF-1 levels, and postmenopausal status (Mazziotti *et al.*, 2013, 2015; Bonadonna *et al.*, 2005).

Male Hypogonadism

Androgens are important for developing and maintaining skeletal health in men (Clarke and Khosla, 2009). Serum testosterone levels decline with aging starting around the 5th decade of life in men, a time after which approximately 85% of cortical bone loss occurs (Mohr *et al.*, 2005; Ebeling, 1998). In addition to aging, medications such as androgen deprivation therapy (ADT) cause an abrupt decline in androgen levels. In vitro studies have shown that androgens, via the androgen receptor, can stimulate

osteoblastic cell proliferation, upregulate TFG-b and IGF-1 (involved in bone formation), and downregulate IL-6 (involved in bone resorption) (Kasperk *et al.*, 1989, 1997). Testosterone also contributes to bone health indirectly in men via its conversion to estrogen by aromatase in peripheral tissues (including osteoblasts and osteocytes), and men with low estrogen, or decreased aromatase activity, can present with low BMD (Riggs *et al.*, 2002; Leder *et al.*, 2003; Miedlich *et al.*, 2016). Estrogens play a role in both bone resorption and bone formation in men. Several large studies have shown a relationship between low serum estradiol levels in men and low BMD (Amin *et al.*, 2000; Travison *et al.*, 2009). In addition to these direct effects on bone, low testosterone may also be associated with increased falls, a clear risk factor for fractures (Vandenput *et al.*, 2017).

Measurement of sex hormone levels can be valuable in the workup and prognostication of bone health in men with hypogonadism. While low testosterone levels are associated with decreased bone mass and muscle strength, a much stronger correlation with fracture risk is seen with low bioavailable estradiol levels or high sex hormone binding globulin (SHBG) levels (LeBlanc *et al.*, 2009; Barrett-Connor *et al.*, 2000; Vandenput *et al.*, 2016). The highest correlation with fracture was when both the bioavailable estradiol level was low *and* the SHBG level was high. Hypogonadism, whether from aging, surgery, or a medication, is a major cause of osteoporosis in men, and the relative contributions of alterations in estradiol, testosterone, and SHBG need to be better defined. In symptomatic patients, testosterone replacement therapy can also serve to improve the bone density at the spine and later the hip, though concern of side effects and lack of antifracture efficacy affect its primary use to treat hypogonadal bone disease (Seftel *et al.*, 2015).

Diabetes Mellitus

Both type 1 (T1DM) and 2 diabetes mellitus (T2DM) are increasingly associated with deleterious effects on the skeleton (Inzerillo and Epstein, 2004; Epstein and Leroith, 2008). Compared with healthy controls, there was a 12-fold increased risk of hip fracture in T1DM and a 1.7-fold increase in T2DM seen in the Iowa Women's Health Study (Nicodemus *et al.*, 2001). A similar increase in fracture risk was seen in the Women's Health Initiative in those with T2DM, even after adjusting for frequent falls and BMD changes (Bonds *et al.*, 2006). T1DM is associated with decreased BMD and failure to achieve peak bone mass (Pan *et al.*, 2014). In T2DM, however, there is often a normal or elevated BMD, implicating a decline in the quality of the bone as a contributor to fracture risk (Ma *et al.*, 2012). In T2DM, structural changes such as increased intracortical porosity, as well as decreased material strength seen in micro-indentation testing, may explain fracture risk despite lack of BMD changes (Burghardt *et al.*, 2010; Farr *et al.*, 2014).

The osteoporosis associated with DM is one of low bone turnover, with decreased markers of osteoblastic activity (Bouillon *et al.*, 1995). Insulin and amylin have anabolic effects on bone, and their decrease in T1DM may lead to impaired bone formation likely through decreased IGF-1 (Kemink *et al.*, 2000; Fowlkes *et al.*, 2011). Additionally, mouse models of insulin-dependent diabetic osteopathy have shown an increased expression of Dkk1 and SOST, both antagonists of Wnt signaling and osteoblastogenesis (Hie *et al.*, 2011). The accumulation of advanced glycation endproducts and lower enzymatic collagen crosslinks contribute to altered biomechanical features of diabetic bone showing the importance of glycemic control over time (Khosravi *et al.*, 2014).

In diabetes there is increased bone marrow adiposity which has been linked with osteoporosis (Rosen and Bouxsein, 2006). Peroxisome proliferator activator receptors (PPARs), especially PPAR-gamma, are transcription factors and nuclear receptors involved in glucose metabolism, and have been shown to be potent regulators of adipogenesis. The mesenchymal stem cells in the bone marrow microenvironment can experience an adipogenic or osteogenic fate, and PPARs and their ligands rosiglitazone and pioglitazone appear to drive the differentiation toward adipocytes and away from osteoblasts (Kawai and Rosen, 2010). This has important implications as these agonists are commonly used in the treatment of T2DM (see below under drugs). In addition to the above cellular mechanisms of bone compromise in DM, other factors such as retinopathy-induced visual impairment, neuropathy-induced balance problems, renal osteodystrophy from dialysis, and renal transplantation all add to the fracture burden. In addition, sarcopenia contributes to an increased risk for falls and fractures in this population (de Liefde *et al.*, 2005). Close attention should be given to bone health in diabetics of all ages, as fractures are an increasingly recognized complication.

Vitamin D Deficiency

Deficiency of vitamin D is leads to reduced intestinal absorption of calcium and phosphorus, resulting in secondary hyperparathyroidism and demineralization of bone (Sai *et al.*, 2011). The main sources of vitamin D are diet and sunlight exposure; lack of fortification of foods and increased appreciation of the harmful skin effects of excessive sunlight exposure have contributed to the amount of vitamin D deficiency seen in clinical practice. Serum 25(OH)D is best indicator for vitamin D status in clinical practice, and while 20 ng/mL is generally considered the threshold for defining insufficiency with regards to bone health, optimal calcium absorption and control of secondary hyperparathyroidism have been seen closer to 30 ng/mL (Sai *et al.*, 2011; Heaney, 2004). Extreme examples of the skeletal effects of vitamin D deficiency are seen in cases of osteomalacia, or rickets in children, where there is a softening of the bones caused by an increase in the unmineralized osteoid component of the bone matrix.

Due to the difficulty involved in isolating the effect of vitamin D on clinical outcomes, and the heterogeneity of the investigations, the magnitude of its effect on bone loss is debated, but most studies agree that levels of 25(OH)D below 20 ng/mL are associated lower BMD (Bischoff-Ferrari *et al.*, 2004a; Lips *et al.*, 2001). For similar reasons, the effect of vitamin D deficiency on fracture risk is difficult to quantify, but large population studies of both men and women agree that hip fracture risk is higher in those with a 25(OH)D level below 20–25 ng/mL (Cauley *et al.*, 2008, 2010; Looker and Mussolino, 2008). The contribution of vitamin D deficiency to muscle weakness and falls is debated, though recent review suggests supplementation can reduce falls in

adults (Bischoff-Ferrari *et al.*, 2004b; Kalyani *et al.*, 2010). While there is debate about the definition of optimal vitamin D level for bone health, there is agreement that levels below 20 ng/mL are associated with lower BMD, increased fracture risk, and decreased efficacy of pharmacologic and nonpharmacologic interventions for osteoporosis.

Rheumatologic and Inflammatory

Systemic Lupus Erythematosus

Low BMD is described in up to 50% of female patients with systemic lupus erythematosus (SLE) (Yee *et al.*, 2005). In addition to traditional risk factors, bones of SLE patients are affected by use of corticosteroids and other immunosuppressive drugs, physical inactivity, and vitamin D deficiency on the basis of sun avoidance (Yee *et al.*, 2005; Bultink, 2012; Lane, 2010). While HR-pQCT studies have documented decreased bone strength in SLE patients on glucocorticoids, a recent study saw similar changes in SLE patients without steroid exposure implicating effects of the disease rather than medications (Tang *et al.*, 2013). Osteoclast-inducing inflammatory cytokines are known to be elevated in SLE and contribute to bone loss (Walsh *et al.*, 2005). An elevated risk of fracture is seen, some citing as high as 12.5% of patient experiencing fractures, with age at diagnosis, duration of disease, and glucocorticoid use increasing that risk (Ramsey-Goldman *et al.*, 1999; Lee *et al.*, 2007). As SLE commonly affects premenopausal females, heightened awareness of the deleterious skeletal effects and fracture risk is important to prompt early screening.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory arthritis associated with several forms of skeletal remodeling including marginal joint erosions, periarticular osteopenia, and systemic osteoporosis. Low BMD and an increased risk for fracture have been seen in RA patients compared with control populations, though confounding variables make the underlying mechanism of bone loss somewhat difficult to elucidate. These include age, female sex, physical inactivity, disease severity, and use of medications such as glucocorticoids. An association between disease severity and bone loss has been observed, though there has been no consistent correlation between joint erosions and low BMD (Lodder *et al.*, 2004; Solomon *et al.*, 2009). Many of the cytokines and growth factors known to be involved in RA-associated inflammation, such as IL-1, IL-6, TNFa, can promote osteoclastic activity themselves or modulate the expression of the osteoclastogenic factor RANKL and its inhibitor OPG (Goldring and Gravallese, 2000).

Further insights into the control of bone turnover in RA have come from studies of RANKL and OPG. In early, active, untreated RA patients, an increased RANKL:OPG ratio, as well as increased CTX levels, were predictors of rapid and persistent bone damage over an 11 year follow up (Geusens *et al.*, 2006; van Tuyl *et al.*, 2010). Consistent with these findings, TNFa blockade, an effective treatment of the inflammatory process, has been associated with decreased systemic bone loss, and these effects correlate with a fall in serum RANKL levels (Vis *et al.*, 2006). In addition to an increased RANKL:OPG ratio, increased levels of Dkk-1 and sclerostin, inhibitors of bone formation, have been found in the serum of RA patients (Terpos *et al.*, 2011). Treatment with inhibitors of IL-6, was associated with a favorable decrease in the RANKL:OPG ratio as well as a drop in the Dkk-1 and sclerostin levels and less bone mass loss (Terpos *et al.*, 2011; Tanaka *et al.*, 2014). Clearly, monitoring for bone loss and instituting timely therapy is of utmost importance in RA.

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is a chronic arthritis characterized by inflammation in synovial joints as well as the entheses. In contrast to RA, the inflammation can be accompanied by increased bone formation, particularly at areas of entheseal inflammation such as at ligament insertion sites in the spine. Osteoporosis is a known complication of AS, which can often go undiagnosed because of the young, mostly male population affected. Osteoporosis is seen in up to 25% of patients with AS, with osteopenia seen up to 50% of the time, and is usually associated with disease activity and duration (Ghozlani *et al.*, 2009). The fact that bone loss can be seen early in the disease process argue that immobility is not the primary cause (van der Weijden *et al.*, 2012). Vertebral and nonvertebral fractures are seen with increased frequency in patients with AS contributing to the morbidity of the disease, and are associated with advanced age, longer disease duration, and degree of structural changes (Ghozlani *et al.*, 2009; Mitra *et al.*, 2000; Muñoz-Ortego *et al.*, 2014). Chronic systemic inflammation is apparent, as is progressive immobility, which both are thought to contribute to the bone loss. Recent data indicate that there are negative changes in the bone microarchitecture, bone strength, and vBMD in AS patients, which will prompt further investigations into the pathogenesis of bone loss in this group, and treatment directions (Nigil Haroon *et al.*, 2015). Bone health, activity levels, and fracture prevention are a significant aspect of caring for this disease, and need to be addressed early in disease course.

Neurologic

Spinal Cord Injury/Immobilization

Spinal cord injury (SCI), or any situation that results in prolonged immobilization and skeletal unloading, is associated with bone loss and an increased risk of fracture (Szollar *et al.*, 1998; Zehnder *et al.*, 2004). While DEXA is an important tool for screening for

low BMD, the most affected areas of the skeleton in SCI patients appear to be the distal femur and proximal tibia, areas not routinely accessible, limiting the value of the test. Initially following SCI there is massive mobilization of calcium from the mineral phase of bone, which can lead to complications such as hypercalcemia and hypercalciuria. Animal studies have shown an increase in osteoclasts and bone resorption surfaces after only 72 h of rat leg immobilization, and decreased trabecular bone volume at 10 days (Weinreb *et al.*, 1989). In human SCI patients, there is a minor initial increase in markers of bone formation with a profound and sustained increase in bone resorption markers that peaks at 10–16 weeks after immobilization (Chantraine *et al.*, 1986; Roberts *et al.*, 1998). Following a stroke and immobilization, sclerostin levels are elevated, implicating a role for antagonizing the Wnt pathway in the skeletal response to mechanical unloading (Gaudio *et al.*, 2010). Any situation where there will be prolonged offloading of the skeleton, such as with injuries or as extreme as with space travel, can cause profound bone density loss and needs to be addressed proactively (Vico *et al.*, 2000).

Parkinson's Disease

Parkinson's disease (PD) is a progressive neurologic disorder associated with reduced mobility and an increased risk of falling (Pickering *et al.*, 2007). Compared to age and sex-matched controls, there is a decrease in femoral neck and lumbar spine BMD, 25-OH vitamin D levels, and an increase in bone turnover markers in patients with PD (Abou-Raya *et al.*, 2009; Ozturk *et al.*, 2016). There is a significantly increased risk of bone fracture in PD, particularly at the proximal femur, which is likely affected by disease duration and severity and propensity for falls (Johnell *et al.*, 1992; Invernizzi *et al.*, 2009). In addition to traditional risk factors affecting this population, such as advanced age and female gender, contribution to bone loss by reduced mobility, low BMI, poor nutrition, and vitamin D deficiency appear to increase the risk of osteoporosis (Vaserman, 2005). Screening BMD and vitamin D levels are recommended at the onset of disease as appropriate therapy may prevent progression of bone loss and risk of fracture (Cummings and Eastell, 2016).

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic demyelinating neurologic condition often leading to profound disability and functional limitation. Low BMD, particularly at the hip, has been consistently shown in MS compared to a control population in both male and female patients (Ozgocmen *et al.*, 2005; Weinstock-Guttman *et al.*, 2004). While factors such as vitamin D deficiency, frequent courses of glucocorticoid therapy, and female gender are considered risk factors, the most important determinants of bone loss are degree of functional impairment, advanced age, and duration of disease (Ayatollahi *et al.*, 2013). In a large multinational longitudinal cohort of women (GLOW), MS was one of the comorbidities that appeared to contribute significantly to fracture risk, though quantifying the specific contribution of MS to fracture risk has yet to be done (Dennison *et al.*, 2012). Vitamin D deficiency is very prevalent in MS, though the extent of its role in the pathogenesis of bone loss in MS is unclear (Nieves *et al.*, 1994).

Hematologic/Oncologic

Multiple Myeloma/Monoclonal Gammopathy of Undetermined Significance

Hematologic malignancies can directly and indirectly affect bone contributing to generalized osteoporosis and pathologic fractures, bone pain, and hypercalcemia. Multiple myeloma (MM) has the highest incidence of bone involvement of all malignant diseases. It is estimated that 70% of patients present with bone pain in MM, and up to 60% of patients will develop a pathologic fracture during their course (Kyle *et al.*, 2003). The skeletal involvement of MM is a major contributor to the morbidity and mortality associated with MM, and up to 90% of patients will develop generalized osteoporosis or lytic bone lesions (Roodman, 2004).

The bone loss in MM is driven by the uncoupling of bone turnover, with marked increase in osteoclastic bone resorption and a decrease in the rate of bone formation, leading to generalized osteolysis. In the bone marrow microenvironment, MM cells produce multiple factors that increase osteoclast production, activity, and survival. By binding to bone marrow stromal cells, MM cells stimulate production of osteoclastogenic cytokines such as RANKL, M-CSF, and IL-6 by the stromal cells and production of osteoclastogenic factors IL-3 and macrophage inflammatory protein 1a (MIP-1a) by the MM cells (Gunn *et al.*, 2006; Giuliani *et al.*, 2004; Choi *et al.*, 2000). The RANKL:OPG axis is altered in MM, with an increase in the ratio observed favoring production and survival of osteoclasts (Giuliani *et al.*, 2001). Osteoblasts are involved in MM-related bone disease with normal or low levels of bone formation markers seen despite increased resorption, as well as decreased osteoid formation and osteoblastic activity observed histologically (Zangari *et al.*, 2011). Recent work has focused on over-expression of DKK-1, a Wnt signaling inhibitor, by plasma cells in MM patients with bone lesions, as well as increased levels of DKK-1 in MM cells and circulating in the plasma (Tian *et al.*, 2003). Consistent with this finding, anti DKK-1 treatment in a murine model of MM resulted in prevention of the suppression of osteoblast number and surface seen in MM, and an increase in the bone formation rate (Heath *et al.*, 2009).

Monoclonal gammopathy of undetermined significance (MGUS) is the most common plasma cell disorder with a prevalence of nearly 7% in the population age 80 or older (Bida *et al.*, 2009). MGUS is a premalignant condition, with roughly a 1% risk per year of progression to MM. Despite the lack of osteolytic lesions seen in MGUS, there is an increased risk of fracture particularly at

axial sites, and the level of the paraprotein in the blood does not seem to correlate with this increased risk (Melton *et al.*, 2004). RANKL levels are elevated in MGUS, and recent studies suggest that there could be bone architectural changes in MGUS, as well as a rise in serum DKK-1 and MIP-1a before progression to MM (Ng *et al.*, 2011; Politou *et al.*, 2004). Measurement of serum protein electrophoresis and immunofixation are important in the evaluation of elderly patients with osteoporosis, particularly those with unexplained fragility fractures, as that may be the first clue to an underlying plasma cell disorder that requires monitoring and potential treatment.

Thalassemia Major

Metabolic bone disease is a known complication of thalassemia major (TM), with the incidence of osteoporosis reported as high as 50%, and an additional 45% of patients have osteopenia (De Sanctis *et al.*, 2013). The precise pathogenesis of bone disease in TM is incompletely understood. Contributing factors include delay in sexual maturation, hypogonadism, decreased growth hormone and IGF-1 levels, diabetes, hypothyroidism, and vitamin D deficiency (De Sanctis *et al.*, 2013). There is a decrease in the activity of osteoblasts and an increase in bone resorption, leading to a decrease in BMD (Perisano *et al.*, 2012). Bone histomorphometry studies in adolescents with TM showed increased osteoid thickness, osteoid maturation time, and mineralization lag time, all of which indicate impaired bone maturation and mineralization (Mahachoklertwattana *et al.*, 2003). Voskaridou *et al.* showed elevated serum levels of Dkk-1 and sclerostin in thalassemic patients compared with healthy controls, as well as increased bone turnover markers, all of which correlated with low BMD (Voskaridou *et al.*, 2012). This may give clues to the pathogenesis of thalassemic bone disease, and sclerostin may make a reasonable therapeutic target. In terms of osteoclastic activity in TM, recent studies have shown elevated circulating levels of RANKL, a relatively preserved levels of OPG, yielding a shift in the RANKL:OPG ratio favoring bone resorption (Morabito *et al.*, 2007). Bone marrow expansion, another feature of TM, can have effects on cortical thickness of bone and increased fragility (Perisano *et al.*, 2012). Delays in recognition of TM-associated bone disease can lead to serious consequences of fractures and skeletal deformities as survival improves, making screening BMD and controlling associated risk factors very important early in the disease. Bisphosphonates are a reasonable starting place for treatment when warranted (Giusti *et al.*, 2016).

Systemic Mastocytosis

In systemic mastocytosis, there is diffuse infiltration of mast cells and their products such as histamine, prostaglandins, leukotrienes, and cytokines (IL-1, IL-3, IL-6) into various tissues of the body. Diagnosis is based on mast cells infiltration on a bone marrow biopsy as well as the finding of a c-kit point mutation or elevated serum tryptase levels. Osteoporosis at the spine, as well as vertebral compression fractures, is a common finding in both men and women with mastocytosis (Rossini *et al.*, 2011). Given the often mild or nonspecific symptoms in indolent mastocytosis, the true incidence of this disease and the magnitude of its contribution to idiopathic osteoporosis is unknown. One series of asymptomatic men with idiopathic osteoporosis showed bone marrow infiltration with mast cells in 9% of cases (Brumsen *et al.*, 2002). The role of mast cells in bone turnover is still being elucidated, but a deficiency appears to induce a low remodeling state, whereas an abundance is associated with accelerated bone loss (Chiappetta and Gruber, 2006). Older age, lower DKK-1 levels, and alcohol use have also been shown to be associated with increased fracture risk (Greene *et al.*, 2016). Serum IL-6 levels are elevated in patients with aggressive mastocytosis, as well as in those with bone pain and osteoporosis, implicating a role for this osteoclastogenic cytokine in the pathogenesis of the bone loss (Theoharides *et al.*, 2002). All patients with systemic mastocytosis warrant BMD testing and evaluation for vertebral fractures, and clinicians need to consider this disease in working up patients with idiopathic osteoporosis, and consider treatment when appropriate with bisphosphonates.

Infectious Disease

Human Immunodeficiency Virus (HIV)

Osteoporosis is common in HIV infection, and has become a more important issue as treatment advances have allowed the HIV-infected population to enjoy longer life expectancy. Up to 70% of patients with HIV have evidence of low bone density, and the risk appears to increase with exposure to antiretroviral therapy (Brown and Qaqish, 2006). Multiple factors contribute to the pathogenesis of bone loss in HIV infection, including smoking and alcohol use, low BMI, chronic inflammatory response, hypogonadism, decreased physical activity, and growth hormone deficiency. There is a significantly increased risk of fracture, with a more than fivefold higher risk of hip fracture compared with a healthy population (Güerri-Fernandez *et al.*, 2013). While bone loss is described independent of medications, use of highly active antiretroviral therapy (HAART) has been associated with higher incidence of osteopenia possibly driven by increased osteoclastic activity and bone resorption and vitamin D deficiency (Marques de Menezes *et al.*, 2016; Nylén *et al.*, 2016; Mastaglia *et al.*, 2017). Within as little as 2 years after initiating HAART, a 2%–6% loss in BMD is seen, as well as an increased risk of fracture, and this effect may stabilize over time (Yin *et al.*, 2012).

Recent attention has focused on the effect of the viral infection itself on pathogenesis of bone loss. Analysis of expression levels of miRNAs in HIV patients showed changes in genes involved in the TGFb and Wnt signaling pathways, implicating potentially

altered osteoblastogenesis and osteoclastogenesis, which requires further study (Del Carpio-Cano *et al.*, 2013). With regards to the effect of the infection, HIV viral protein R and HIV glycoprotein, gp120 can both upregulate RANKL (Fakruddin and Laurence, 2003, 2005). The proinflammatory cytokines induced by HIV infection include TNFa, and OPG, both of which can affect osteoclast development and function (Amorosa and Tebas, 2006). The infection itself can also increase TNF-related apoptosis-inducing ligand (TRAIL) which binds OPG, limiting the capacity of OPG to regulate RANKL-associated osteoclastogenesis (Herbeuval *et al.*, 2005). Combining this with experience of decreased BMD and increased fracture incidence, attention to bone health is of paramount importance in those infected with HIV.

Nephrology

Idiopathic Hypercalciuria

Idiopathic hypercalciuria (IH) is defined as urinary excretion of calcium >4 mg/kg/day in women and >4.5 mg/kg/day in men without any underlying metabolic cause. There is an association between hypercalciuria and low BMD, and the prevalence is increased among Ca-containing stone-formers (Sakhaee *et al.*, 2011; García-Nieto *et al.*, 2003). This is consistent with studies that report a fourfold increased risk of vertebral fracture observed among urolithiasis patients compared with healthy controls (Melton *et al.*, 1998). The deleterious skeletal effects of hypercalciuria in the absence of stone formation is not as well established as in stone formers, and consideration should be given to a radiographic evaluation for asymptomatic stones in osteopenic patients, as this could alter management decisions (Miller, 2012). Clearly bone loss needs to be aggressively addressed in stone forming IH, and the significance of increased urinary Ca in the absence of stone formation needs to be determined by the clinician on a case-by-case basis. Decreased BMD is even seen in children with IH, and is associated with decreased 25-OHD3 levels (Artemiuk *et al.*, 2015).

The precise mechanism of bone loss in IH remains incompletely understood despite recent advances. Bone histomorphometry studies have consistently documented decreased osteoblastic activity, mineralization rates, and osteoid surfaces (Sakhaee *et al.*, 2011; Malluche *et al.*, 1980). IH is characterized by increased intestinal calcium absorption, increased bone resorption, and decreased renal tubular calcium reabsorption (Heilberg and Weisinger, 2006; Pak *et al.*, 2005). In 40%–60% of hypercalciuric stone formers elevated circulating 1,25-dihydroxyvitamin D3 (1,25(OH)2D3) levels are found, as well as increased monocyte expression of vitamin D receptor (VDR) (Coe *et al.*, 1982; Favus *et al.*, 2004). Animal studies have confirmed role of 1,25(OH)2D3 in urinary calcium concentration and decreased BMD (Frick *et al.*, 2013; Ng *et al.*, 2014). The significance of these findings needs to be determined in humans, but they begin to provide insights into potential pathogenic mechanisms of IH-related bone disease.

Psychiatry

Anorexia Nervosa

Anorexia nervosa (AN) is an eating disorder characterized by an obsessive fear of gaining weight and refusal to maintain an adequate body weight, 10 times more common in females than in males. Significant caloric restriction and periods of amenorrhea are the norm. Low BMD is a near universal finding in AN, often occurring in young adolescent females during a time of critical bone mass accrual, with as many as 50% of young females with a z-score of less than -1 (Misra *et al.*, 2004). Studies have documented the detrimental effects of interruption of normal menstruation during adolescence on adult BMD (Wiksten-Almströmer *et al.*, 2009). The risk of fracture during childhood and early adult years is nearly 60% higher for AN females compared with healthy-weight controls (Faje *et al.*, 2014). Contributors to osteoporosis in this population include the low peak bone mass accrual, decreased muscle mass, hypogonadism, decreased IGF-1 levels, and increased cortisol (Misra and Klibanski, 2011). Increased bone marrow adiposity is seen in AN, despite decreased visceral adiposity, and this correlates inversely with BMD as it does in other disease states (Bredella *et al.*, 2009). During treatment of AN, bone density gains were more associated with increased fat mass, rather than increased total body weight (Achamrah *et al.*, 2017). Even in successfully treated AN, adults will have an increased risk of fracture due to the low peak bone mass achieved, and screening for osteoporosis should be considered at a younger age.

Gastrointestinal

Celiac Disease

Celiac disease affects around 1% of the world's population, and is characterized by inflammatory changes in the duodenum with loss of normal small intestinal villi affecting dietary absorption. While classically thought to begin in childhood, it is now more common to be diagnosed as an adult. The effect of celiac disease on bones has been established for a long time, with osteomalacia historically complicating childhood disease, and low BMD affecting all ages. There is as much as a 17-fold higher prevalence of

celiac disease among patients with osteoporosis as compared to controls, suggesting the need for more intensive screening in this population (Stenson *et al.*, 2005). It is estimated that 40% of adults diagnosed with celiac disease will have osteoporosis, affecting both women and men (Meyer *et al.*, 2001). Low bone mass complicates all ends of the celiac spectrum, from severe to asymptomatic disease (Mazure *et al.*, 1994). A recent systematic review reported an increased risk of hip and nonhip fractures in celiac patients compared with controls (Heikkilä *et al.*, 2015).

The pathophysiology of bone loss in celiac disease is multifactorial, centered around inflammation, malabsorption, and decreased intestinal absorption. Decreased absorption of calcium and vitamin D, as well as frequent avoidance of dietary calcium, contribute to a net negative calcium balance and compensatory elevation in PTH (Keaveny *et al.*, 1996; Chakravarthi *et al.*, 2012). The secondary hyperparathyroidism has been correlated with increased bone turnover and decreased BMD (Valdimarsson *et al.*, 2000). There has been a lot of attention recently on intestinal and systemic inflammation in celiac disease, with elevated levels of inflammatory cytokines detected and correlate with bone loss (Fornari *et al.*, 1998). The RANKL:OPG axis has been extensively studied in celiac, and an increased ratio is seen favoring bone resorption (Taranta *et al.*, 2004; Fiore *et al.*, 2006). In addition to the above factors, low BMI, hypogonadism, decreased physical activity often contribute to the bone loss associated with celiac disease. Gluten free diet can improve the status of the bone disease, though the magnitude of the improvement is less in adult patients than in children.

Inflammatory Bowel Disease

Crohn's disease and ulcerative colitis are two forms of chronic inflammatory bowel disease (IBD) and are associated with bone loss, with as many as 40% having evidence of osteopenia (Frei *et al.*, 2006). Risk of fracture appears to be elevated, though the magnitude varies in different epidemiological studies (Vestergaard and Mosekilde, 2002; Loftus *et al.*, 2002; Bernstein *et al.*, 2000). The pathophysiology is multifactorial, including the effect of osteoclastogenic inflammatory cytokines, intestinal malabsorption, low BMI, malnutrition, decreased physical activity, and use of glucocorticoids (Rodriguez-Bores *et al.*, 2007). Low bone mass has been described in new-onset disease prior to any steroid therapy (Lamb *et al.*, 2002). Lower BMD is associated with increased cumulative dose of prednisolone and lower weight in young adults with IBD (Laakso *et al.*, 2014).

Calcium intake and absorption is often poor in this population, and as many as 50% of patients with IBD are vitamin D deficient (Ulitsky *et al.*, 2011; Vernia *et al.*, 2014). In Crohn's disease, the primary tissue involved is at the terminal ileum, where the majority of absorption of fat-soluble vitamins occurs, and resection of the terminal ileum has been described as one of the most important determinants of developing osteoporosis (van Hogezand *et al.*, 2006). The RANKL/OPG system has been implicated in the metabolic bone effects of IBD, as elevated plasma levels of OPG are seen, as well as increased release of OPG from inflamed colonic mucosa (Moschen *et al.*, 2005). The elevated OPG levels correlate with lower BMD, and are felt to be a response to osteopenia and RANKL driven osteoclastogenesis. There is little debate about the development of bone loss in IBD, though the magnitude of the effect is still in question. Routine BMD testing, dietary questioning on calcium intake, and measuring of 25-OH vitamin D levels are recommended for all patients at the onset of disease.

Bariatric Surgery

Obesity now affects nearly 30% of the US population, and using bariatric surgery to treat morbid obesity has become increasingly popular (Ogden *et al.*, 2014; Buchwald and Oien, 2009). Malabsorptive and restrictive bariatric procedures are successful for weight loss and improvement in comorbid conditions such as diabetes and hypertension, but there has been growing recognition of the negative skeletal effects that occur following the surgeries. Decrease in BMD has been consistently demonstrated in the 1 year following bariatric surgery, as high as a 10% loss at the femoral neck and 3% loss at the lumbar spine (Vilarrasa *et al.*, 2009). The decrease in BMD is similar following Roux-en-Y gastric bypass and sleeve gastrectomy procedures (Vilarrasa *et al.*, 2013). Decreased calcium intake and absorption, low vitamin D, secondary hyperparathyroidism are common, though advanced age, menopausal status, and greater lean mass loss seem to correlate more with degree of bone loss. Most studies to date use areal BMD (aBMD) measurements to quantify bone density following surgery, a technique susceptible to artifactual changes in the setting of obesity and profound weight loss, but a recent systematic review showed a significant decline in hip BMD and a trend toward decrease at the spine at 1 year (Kalani *et al.*, 2017).

Bone turnover markers are elevated as quickly as 3 months following bariatric surgery and persist through an 18-month follow-up study (Sinha *et al.*, 2011). This indicates a high turnover state consistent with the effect of elevated PTH. The same study also showed that, even after a transient improvement in vitamin D and PTH levels following surgery (likely from aggressive repletion), they both return to preoperative levels by 1 year. Another intriguing observation is that following gastric bypass surgery plasma ghrelin levels fall, and the degree of this fall correlate with the degree of bone loss over 1 year (Carrasco *et al.*, 2014). Ghrelin is a gut derived peptide involved in energy homeostasis and growth hormone secretion, as well as a direct mitogenic and antiapoptotic effect on osteoblasts (Fukushima *et al.*, 2005). At this point, there are no consistent long-term data on fracture risk following bariatric surgery. In addition to maintaining adequate calcium and vitamin D intake, all patients should have screening BMD done at or before surgery, and have it closely monitored along with markers of bone turnover.

Pulmonary

Chronic Obstructive Lung Disease (COPD)

COPD and osteoporosis share many common risk factors such as smoking use, advanced age, and reduced physical activity (Xiaomei *et al.*, 2014). The addition of chronic steroid use, systemic inflammation, reduced muscle mass, hypogonadism, and vitamin D deficiency augment the risk of bone loss in COPD patients. In a large study of 2699 newly diagnosed COPD patients, the prevalence of osteoporosis was elevated compared to a non-COPD population (RR 3.1) (Soriano *et al.*, 2005). Radiographic emphysema, regardless of other factors or airway obstruction, is a risk factor for bone loss, indicating a possible common pathway between lung parenchymal damage and bone loss (Bon *et al.*, 2011). There is significant body composition change in COPD patients, and the loss of fat-free mass is associated with osteopenia (Bolton *et al.*, 2004). The increased risk of osteoporosis seems to be present in both steroid-users and nonusers, though the rate of fractures is likely higher among those that frequently use oral or inhaled corticosteroids, have more severe COPD, and low muscle mass (de Vries *et al.*, 2005; Loke *et al.*, 2011; Gonçalves *et al.*, 2017). Systemic inflammation in a feature COPD, including elevated levels of osteoclastogenic cytokines such as TNFa and IL-6 (Gan *et al.*, 2004). Vitamin D deficiency is reported in nearly half of patients with COPD, and the level is associated with both BMD and severity of the lung disease (Romme *et al.*, 2013). Adding to the importance of addressing bone health in COPD patients, is the fact that vertebral fractures negatively affect pulmonary function in general, thereby increasing the morbidity of both disease processes (Schlaich *et al.*, 1998).

Transplantation Medicine

Transplantation Osteoporosis

Transplantation is an increasingly viable option for the treatment of end-stage diseases of the kidney, heart, endocrine pancreas, liver, and lung as well as for many hematological disorders. Immunosuppressive medications have improved patient and graft survival, while at the same time allowing for better recognition of long-term complications of transplantation, including osteoporosis and fractures (Ebeling, 2009). Posttransplant bone loss is multifactorial. The primary contributors are the immunosuppressive medications, namely glucocorticoids and calcineurin inhibitors (CIs), though factors such as decreased mobility, poor nutrition, hypogonadism, and the underlying disease all play a role (Epstein *et al.*, 2003). High doses of glucocorticoids are often used, especially in the immediate posttransplant time period, causing significant deleterious effects to bone by mechanisms reviewed above. Cyclosporine (CsA) and tacrolimus (FK506) are the principle CIs used following a transplant, and both have been shown to cause acute, rapid, and severe bone loss (Movsowitz *et al.*, 1988; Kirino *et al.*, 2004). Histomorphometrically, a high-turnover state of bone remodeling was seen, with the resorption far exceeding the bone formation (Movsowitz *et al.*, 1989).

Clinically, the bulk of the bone loss is in the first 6–12 months following transplantation, a time when close monitoring of BMD and other risk factors is of utmost importance. BMD at the spine tends to improve especially at 1 year but cortical bone loss at the femur continues to decline. Fragility fracture rates are generally elevated, and vary depending upon the organ transplanted, osteoporotic BMD, underlying condition, dosage and duration of immunosuppression, and preexisting bone disease. Fractures add significantly to the morbidity associated with transplantation, and every effort should be made to address bone loss in a timely manner in this population.

Drugs Associated With Bone Loss

Depot Medroxyprogesterone Acetate (DMPA)

The injectable contraceptive DMPA (Depo-Provera) has been associated with decreased BMD which has received tremendous attention because of its popularity as an effective form of contraception. In 2004, the US Food and Drug Administration attached a black-box warning to its label, suggesting it should only be used as a long-term form of contraception only of other methods are inadequate despite lack of long term serious skeletal events (Cromer *et al.*, 2006). As a progestin-only contraceptive, it induces a state of estrogen deficiency, which is the primary mechanism of its effect on bones (Cundy *et al.*, 1991). A decrease in BMD is often seen in the first 2 years of therapy, though the loss has been shown to be mild and dose-dependent, worse with prolonged use, and reversible upon discontinuation (Curtis and Martins, 2006; Clark *et al.*, 2006; Kaunitz *et al.*, 2008; Lange *et al.*, 2017). While anything that can negatively affect bone mass, particularly during development and adolescence warrants caution and discussion with patients, the use of DMPA as an effective form of contraception should not be avoided solely on the basis of its mild skeletal effects.

Aromatase Inhibitors

Adjuvant treatment of hormone receptor positive breast cancer with an aromatase inhibitor (AI) is highly effective at decreasing the reoccurrence of the disease in postmenopausal women. By blocking the peripheral conversion of androgens to estrogen, they

reduce endogenous production of estrogen by nearly 90%. This reduction in circulating estrogen has a deleterious effect on the skeleton, and induces a state of increased bone turnover (Eastell *et al.*, 2006). For example, after 5 years of therapy in the Arimidex, Tamoxifen, Alone, or in Combination (ATAC), anastrazole was associated with a decline in BMD at the spine and total hip of 6.08% and 7.24%, respectively (Eastell *et al.*, 2008). A retrospective study of nonosteoporotic AI users over 3 years, not on bisphosphonate therapy, showed a steady decline in BMD as well as trabecular bone score, and altered hip geometry, indicating bone structural changes occur early on in therapy (Hong *et al.*, 2017). There is an increase in the fracture occurrence during AI therapy, that seems to decrease upon cessation of therapy (Forbes *et al.*, 2008). The presence of low BMD prior to treatment seems to affect the fracture incidence, as 9.8% of women with baseline osteoporosis had a fracture during 3 years of AI therapy, compared with 5.6% of those without baseline osteoporosis (Bouvard *et al.*, 2014). Denosumab is proving to be an effective alternative to bisphosphonate therapy for these patients (Nakatsukasa *et al.*, 2017).

Thiazolidinediones

Thiazolidinediones (TZDs) are ligands for PPARγ, and are commonly used in DM2 for improved glycemic control and insulin sensitization. Evidence for the effects of TZDs on bone come from several mouse models, where PPARγ deficiency is associated with increased bone mass, and activation of PPARγ with rosiglitazone resulted in increased marrow adipocytes, reduced bone formation, and decreased expression of osteoblastogenic transcription factors (Ali *et al.*, 2005). In the bone environment, PPARγ controls differentiation of cells of mesenchymal and hematopoietic lineages, and its activation can shift away from bone formation and osteoblastogenesis and increase adipogenesis (Beck *et al.*, 2013). The increase in bone marrow fat is similar to that which is seen with the aging process. Additionally, PPARγ activation can inhibit the Wnt/B-catenin pathway and decrease IGF-1 production, both of which have negative effects on bone formation (Moldes *et al.*, 2003; Lecka-Czernik *et al.*, 2007).

There is accumulating evidence that TZD use is associated with bone loss in humans, particularly in women. In the ADOPT study (A Diabetes Outcome Progression Trial), a randomized controlled trial of 4360 patients with DM2 comparing treatment with rosiglitazone, metformin, and glibenclamide, there was an increased incidence of fractures among women taking rosiglitazone (9.3%) compared with metformin and glibenclamide (5.1% and 3.5%, respectively) (Kahn *et al.*, 2008). In a subset of this study, a significant increase in a serum marker of bone resorption (C-telopeptide) was seen in women taking rosiglitazone, not with the other agents; there was no increase in markers of bone formation (Zinman *et al.*, 2010). A meta-analysis confirmed the increased risk of fracture among female long-term users of TZDs, along with decline of BMD at the total hip and spine of 1%–2% (Loke *et al.*, 2009). Evaluation of bone health should happen before prescribing TZDs for DM, and if fracture risk is elevated, other hypoglycemic medications are preferable.

Acid-Suppressive Medications

Acid-suppressive medications, proton-pump inhibitors (PPIs) and H2 receptor antagonists (H2RAs), are some of the most commonly prescribed medications worldwide. Studies have recently been reporting increased adverse consequences of chronic acid suppression, one of which has been an increased risk of fracture. In a 1997 study of male hip fractures, Grisso *et al.* found an increased risk in those that used cimetidine, an H2RA (Grisso *et al.*, 1997). Several case–control studies have been done since that time and have shown an increased risk of osteoporotic fractures among PPI users (Yang *et al.*, 2006; Vestergaard *et al.*, 2006; Gray *et al.*, 2010). The fracture data on H2RAs have been a bit more inconsistent, with some showing a slight increased risk, and others actually showing a slightly decreased risk. The length of time and dose used appear to increase the adverse skeletal events (Grisso *et al.*, 1997). The effect of chronic acid suppression on BMD is unknown, with stable or mild decreases seen over short-term follow up (Gray *et al.*, 2010; Yu *et al.*, 2008). In that study, females had a higher risk of nonspine fractures, and the increased risk in men was only seen in those with poor calcium intake.

The leading hypothesis for the mechanism of adverse skeletal events in the setting of acid suppression was that it induces a state of hypochlorhydria and affects calcium absorption leading to a negative calcium balance (Graziani *et al.*, 1995). Recent studies have refuted that finding that calcium absorption is the cause (Hansen *et al.*, 2010). The difficulty in controlling for multiple confounding factors has limited our understanding of the full scope of the effect of acid suppressive medications on bone health, and while the overall fracture risk may be small, the large number of people potentially affected make this a serious issue. There is a possible increased risk of fracture in patients cotreated with bisphosphonates and PPIs, and careful consideration of the need for PPIs should be given to these patients (Yang *et al.*, 2015). At this point, it is advisable to recommend optimal calcium intake in people that need PPIs, address other contributors to fracture risk, and limit the use to the lowest dose and shortest time possible. The calcium supplement which may be the most suitable is calcium citrate because of its better absorption profile (Heller *et al.*, 2000).

Antiepileptic Drugs

The association between antiepileptic drugs (AEDs) and metabolic bone abnormalities has been observed since the 1960s, when anticonvulsants and osteomalacia were linked together. Since that time there have been several cohort and prospective studies that have shown an association of AEDs with low BMD and increased fracture risk (Farhat *et al.*, 2002; Vestergaard *et al.*, 2004; Lee *et al.*,

2010). The pathophysiology was felt to be primarily through induction of the cytochrome P450 enzyme system in the liver, which would convert 25(OH)D to an inactive metabolite, leading to less active vitamin D, less calcium absorption, and increase in PTH levels (Meier and Kraenzlin, 2011). In fact, in a randomized trial, Mikati *et al.* showed that using high dose vitamin D supplementation in patients on AEDs could help stabilize the BMD at the spine and total hip compared with low dose vitamin D supplementation (Mikati *et al.*, 2006). Some studies have found an association of lower BMD even with AEDs that do not induce the cytochrome P450 system, suggesting an alternative mechanism. A recent retrospective study of some of the newer anticonvulsants (gabapentin, topiramate, levetiracetam) did not show any adverse effects on BMD (Lee *et al.*, 2012). A meta-analysis of 22 studies showed a significant increase in both enzyme-inducing and nonenzyme-inducing AEDs, particularly with phenytoin, phenobarbital, and topiramate (Shen *et al.*, 2014). Clearly more studies need to be done to definitively link AEDs with bone loss and fractures, and it is recommended to screen for vitamin D deficiency, particularly in those on enzyme-inducing AEDs, and address other aspects of bone health on an individual basis.

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are widely prescribed antidepressant medications that have recently received a lot of attention for negative effects on bone and fracture risk. They act by potently blocking the serotonin transporters (5-HTT) which are located in the CNS as well as in the periphery, such as bone (Bliziotes *et al.*, 2001). While depression itself has been linked with bone loss, cross-sectional studies have supported an association between decreased BMD and SSRI use in both men and women (Diem *et al.*, 2007; Haney *et al.*, 2007; Richards *et al.*, 2007). Longitudinal studies have documented a 1.6-fold greater decline in BMD in those using SSRIs compared with nonuser (Diem *et al.*, 2013). These studies, however, have been contrasted by investigations of several large databases (The National Health and Nutrition Examination Survey III, Women's Health Initiative, and Study of Women's Health Across the Nation) that did not reveal an association of BMD decrease with SSRI use (Spangler *et al.*, 2008; Kinjo *et al.*, 2005). Even though there is discrepancy on the effect of SSRI on BMD, most agree that there is an increased risk of fragility fractures among depressed individuals on SSRIs (Richards *et al.*, 2007; Spangler *et al.*, 2008; Moura *et al.*, 2014).

The exact mechanism of bone loss among users of SSRI is unknown, and recent focus has been on the effect of serotonin on osteoblasts. Circulating serotonin of gut origin was shown to reduce osteoblast proliferation, an effect modulated by LDL-receptor related protein 5 (LRP5) (Yadav *et al.*, 2008). The interaction of LRP5, serotonin, and the Wnt pathway is being elucidated, and will guide our understanding of SSRI use and bone effects (Warden *et al.*, 2010). While not always possible, use of SSRIs should be avoided in those at high risk of fracture.

Heparin

The long-term use of unfractionated heparin has been associated with reduced BMD, increased rates of bone loss, and an increased risk of fracture (de Swiet *et al.*, 1983; Barbour *et al.*, 1994). Using rat histomorphometry and bone turnover markers, it has been shown that extended us of heparin reduces bone formation and increases bone resorption; low molecular weight heparin (LMWH) only seems to reduce bone formation markers, possibly contributing to its lessened effects on bone (Muir *et al.*, 1997). However there has been a recent report of postpartum osteoporosis with fractures in women treated with LMWH during pregnancy (Ozdemir *et al.*, 2015). Recently, long-term use of heparin is mostly limited to treatment of thromboembolism during pregnancy, and as such bone loss should be a consideration in these women.

Antihypertensives

The frequency of use of antihypertensives increases with advanced age, as does the incidence of falling, which has led to numerous studies of the effects of these medications on BMD and fracture risk (Wiens *et al.*, 2006). There is an increased risk of falls when initiating any antihypertensive medication in an elderly patient, particularly within the first few weeks, which has obvious implications on fracture risk (Butt *et al.*, 2013). Diuretics appear to have differential effects on bone based on their mechanism of action, as loop diuretics increase urinary calcium excretion and are associated with elevated markers of bone turnover and lower BMD, while thiazide diuretics decrease urinary loss of calcium and may have protective effects on bone and the risk of fracture (Wiens *et al.*, 2006; Rejnmark *et al.*, 2006). Despite this, a recent prospective study identified increased fracture risk with both thiazide and loop diuretics (Paik *et al.*, 2016). Baseline osteoporosis status and fracture risk should be considered when placing a patient on an antihypertensive medication, especially with the elderly.

Summary

As outlined in this article, there are many disease states and medications that can affect the metabolic activity of bone and its relative strength and risk of fracture. It is important for the clinician to consider the scope of these conditions when evaluating a patient with osteoporosis, as well as keeping bone health in mind when treating patients with these diseases and medications,

even if they fall out of the normal scope of the elderly and postmenopausal women. This approach can help to limit the added morbidity and mortality an osteoporotic fracture to their other comorbid conditions.

Osteoporosis; Prevention and Ca—Vitamin D Treatment

Bo Abrahamsen, University of Southern Denmark, Odense, Denmark and Holbæk Hospital, Holbæk, Denmark

Physiology and Development

As the principal repository for calcium in the body, the skeleton is tasked not only with the role of protecting our inner organs and being a scaffold for locomotion but also serves as a necessary source of calcium to maintain normal serum calcium levels during fasting or other times of inadequate supplies of dietary calcium, including compromised active calcium absorption in vitamin D deficiency. Because of the safety implications it is useful to briefly reconsider how calcium homeostasis is regulated in normal physiology.

Keeping serum calcium concentrations within a narrow range is absolutely necessary for normal neuromuscular and cardiac function whereas the body is tolerant to relatively large decreases in bone mineral content, at least in the short term. Accordingly, the normal parathyroid'calcium axis is finely tuned through the sigmoid calcium-PTH curve to respond to small decreases in serum calcium by large and rapid increases in PTH which will increase mobilization of calcium from the skeleton and increase renal reabsorption of calcium. From a practical point of view this means that skeletal calcium content is the junior partner in the relationship between bone and the extracellular fluid, so that the calcium need of the skeleton is sacrificed to maintain adequate serum levels in circumstances of inadequate supply. It is possible to override part of this regulation by treating patients with potent anti-resorptive drugs, in which case the skeletal stores of calcium cannot be mobilized by an increase in PTH and in such circumstances patients may develop hypocalcaemia if not calcium and vitamin D replete.

As shall be briefly addressed below, incorporation of calcium and phosphate into osteoid is an active, vitamin D dependent process so increasing serum calcium will not in itself promote bone mineralization, let alone bone formation. The PTH axis is not so well tuned for dealing with increased serum calcium levels as PTH levels are fully suppressed at very modestly elevated serum calcium levels with no additional decrease possible. However, renal autoregulation responds to hypercalcemia with hypercalciuria and polyuria. The latter reduces the risk of nephrocalcinosis but comes with a risk of dehydration, which may ultimately worsen hypercalcemia. Apart from into the urine and into the skeleton, calcium can be deposited into plaques in atherosclerotic vessel walls or in extreme circumstances—such as renal failure with a high calcium phosphate product—into other soft tissues. It has become clear that vascular calcification, too, is not driven by passive diffusion but results from an active, highly regulated and incompletely understood process as reviewed in detail elsewhere (Evrard *et al.*, 2014).

As for vitamin D, 1,25-OH_2D is of course required both for the mineralization process in newly formed bone and for active calcium absorption from the gut. There are some safeguards in place, however. Firstly, conversion of 25-OHD to 1,25-OH_2D is increased by increasing PTH levels and thus by any declines in serum calcium. Second, given a large enough intake of calcium, the passive, non-vitamin D mediated, absorption of dietary calcium can be considerable though this can only be deposited in the skeleton if 1α-hydroxylated vitamin D and phosphate is present in the bone microenvironment in sufficient amounts. Interestingly, the micro-environment of bone contains a full local apparatus with regulation of hydroxylases in marrow stromal cells by substrate induction and feedback suppression (Zhou *et al.*, 2010), which does not only affect local availability of 1,25-OH_2D but also feeds forward into the FGF23 axis for global phosphate regulation (Nguyen-Yamamoto *et al.*, 2017). From a practical point of view, the buffering of 1,25-OH_2D makes this hormone non-informative as regards whether a person is vitamin D deficient or not. So while 1,25-OH_2D is arguably the most potent entity, serum 25-OH_2D is the clinical indicator of vitamin D status and vitamin D stores.

Mineralization of Bone and Osteomalacia

Osteomalacia denotes a delayed mineralization of newly formed bone tissue. This may have many causes but the most common one and the only one relevant to this article is vitamin D deficiency. By bone biopsy with tetracycline double labelling the diagnosis is simple and straightforward, with the delay in mineralization evident through increased thickness of the osteoid (above 12.5 μm) and a mineralization lag time of over 100 days (Parfitt *et al.*, 2004; Dempster *et al.*, 2013). Clinical clues generally included raised alkaline phosphatase though this can be missing (Bisballe *et al.*, 1991). Patients with nutritional osteomalacia are generally identified not by bone biopsy but by very low serum 25OHD, usually accompanied by raised alkaline phosphatase and PTH. Though a risk factor for development of osteoporosis as the secondary hyperparathyroidism accelerate thinning of trabeculae and cortices with time, osteomalacia is a distinct disease entity and one that is eminently treatable and where the response in terms of BMD increase far outstrips what we see in patients with osteoporosis proper.

Prevention of Development of Osteoporosis

Low calcium diets are unusual in Western Europe and the United States, except in persons with lactose intolerance, but such diets are prevalents in large parts of the world (Balk *et al.*, 2017). In theory, effects of calcium supplements on BMD in the vitamin D

 doi:10.1016/B978-0-12-801238-3.65371-0

replete, skeletally mature person should be limited to reversal of deficiency and consist of no more than a filling of resorption space brought about by a reduced PTH drive on bone resorption. A meta-analysis of 51 studies of BMD and calcium supplements, of which 13 studies used calcium in combination with vitamin D (Tai *et al.*, 2015) demonstrated an increase in BMD of 1%–2% with calcium supplementation, chiefly in the first study year. There was no appreciable difference between calcium alone trials and combined (CaD) trials. A similar analysis of vitamin D trials found marginal BMD effects only, with studies showing marked heterogeneity and a potential publication bias favoring positive studies (Reid *et al.*, 2014). In large population based cohorts (Swanson *et al.*, 2015; Cauley *et al.*, 2011), there were found inverse associations between serum vitamin D fracture risk, though interactions were reported with ethnicity in the latter study. Among Danish women, low vitamin D levels appear to be predictive of increases risk of fractures only if secondary hyperparathyroidism is present (Rejnmark *et al.*, 2011).

Interestingly, meaningful preservation of BMD in older persons after vitamin D treatment appear to be confined to those with 25OHD levels below 30 nmol/L at the start of treatment (Reid *et al.*, 2017). In children (Händel *et al.*, 2015), studies of the relationship between calcium intake and fracture risk have produced conflicting results with a possible interaction with race, though milk avoidance was linked to a higher occurrence of childhood fractures. However, it is far from clear that fractures in childhood are indicative of an increased likelihood of osteoporotic fractures in adulthood. Effects of calcium and vitamin D supplementation on BMD in healthy children appear to be small and transitory (Winzenberg et al., 2006, 2010). In adults, studies relating dietary calcium intake to the risk of osteoporotic fractures are dominated by observational studies and these have generally failed to show a clinically meaningful relationship (Bolland *et al.*, 2015).

Treatment of Osteoporosis and Prevention of Osteoporotic Fractures

As a sole treatment, calcium and vitamin D given in combination appears to marginally reduce the risk of osteoporotic fractures in older persons (Avenell *et al.*, 2014). Studies where subjects were recruited based on a prior osteoporotic fracture generally failed to demonstrate reduction in hip fracture risk with this intervention (Avenell *et al.*, 2004; Harwood *et al.*, 2004; Porthouse *et al.*, 2005; Grant *et al.*, 2005) while metaanalysis found a risk reduction averaging 18% (Avenell *et al.*, 2014) collectively for studies in persons not selected based on a prior osteoporotic fracture (Chapuy et al., 1992, 2002; Dawson-Hughes *et al.*, 1997; Salovaara *et al.*, 2010; Jackson *et al.*, 2006), though many of these studies were short of statistical significance for hip fracture outcomes when viewed separately. The risk reduction for fractures in general was much smaller (HR 0.95; 95% CI 0.90–0.99) but in contrast with hip fractures there was no appreciable difference according to prior osteoporotic fracture status (Avenell *et al.*, 2014). Vitamin D given without calcium did not significantly reduce the risk of fractures. We have recently learned that some of the inter-individual differences in anti-fracture efficacy may have a genetic basis. In the Women's Health Initiative (WHI) study (Wang *et al.*, 2017) calcium and vitamin D supplementation only resulted in significant benefits in a genetically defined subpopulation. This difference was seen despite limitations in study design in terms of parallel intake of personal supplements. While interesting, this does not provide useful guidance to physicians at present and of course requires replication in other studies or populations.

Table 1 shows the use of calcium and vitamin D supplements in pivotal trials of key osteoporosis medications in use today. Because calcium and vitamin D supplements were used as a mandatory adjunct to both active treatment and placebo in the great majority of trials there is a lack of high quality evidence that the treatments work equally well if given without supplementation. At the same time, the mandatory co-administration of supplements means that the fracture risk reduction seen with the osteoporosis

Table 1 Calcium and vitamin D used as adjuncts to osteoporosis medications in pivotal RCTs

		Calcium		*Vitamin D*		
Drug	*Trial*	*Mandatory*	*If low*	*Mandatory*	*If low*	*Percent supplemented*
No mandatory supplement						
Alendronate	FIT (Black, Lancet 1996)		500 mg		250 IU	82%
Calcium supplement mandatory						
Risedronate	VERT (Harris, JAMA 1999)	500 mg			500 IU	100%
Calcium and vitamin D supplement mandatory						
Raloxifene	MORE (Ettinger, JAMA 1999)	500 mg		400 + IU		100%
Teriparatide	Neer (NEJM 2001)	1000 mg		400 + IU		100%
Ibandronate	BONE (Delmas, OI 2004)	500 mg		400 IU		100%
Zoledronic acid	HORIZON (Black, NEJM 2007)	1000 + mg		400 + IU		100%
Bazedoxifen	Silverman (JBMR 2008)	<1200 mg		400 + IU		100%
Lasofoxifene	PERL (Cummings, NEJM 2011)	1000 mg		400 + IU		100%
Denosumab	FREEDOM (Cummings, NEJM 2009)	1000 mg +		600–800 IU		100%
Abaloparatide	ACTIVE (Miller, JAMA 2016)	1000 mg +		400–800 IU		100%[a]
Romosozumab	FRAME (Cosman NEJM 2016)	500–1000 mg		600–800 IU		100%

[a]Protocol allowed stopping supplements within certain limits.

medications in the trials represents what can be achieved over and above the effect of calcium and vitamin D supplementation. Finally, these trials of course provide no information on the safety of supplements as they were had to be given in both the active arm and the placebo arm of the studies. Biologically, it is hard to support the notion that dietary sources of calcium and vitamin D would not be equally effective and permit similar efficacy of specific anti-osteoporosis pharmaceuticals but this should be considered lower degree evidence that is, expert opinion rather than experimental evidence.

Safety Concerns

Aside from actual vitamin D intoxication, which remains a rarity, the safety concerns—justified or not—associated with calcium and vitamin D supplements at representative doses of 10–20 μg vitamin D and 500–1000 mg calcium daily are generally cardiovascular or renal (Abrahamsen, 2017). Much of the data available on the safety of calcium and vitamin D supplementation and the comparative safety of dietary intake comes from observational studies (Sluijs *et al.*, 2014; Li *et al.*, 2012; Adebamowo *et al.*, 2015; Yang *et al.*, 2016; Langsetmo *et al.*, 2013; Khan *et al.*, 2015; Paik *et al.*, 2014; Michaelsson *et al.*, 2013) that should not be dismissed but which are vulnerable to unmeasured confounding. We may use supplements because we are particularly health conscious and active, in above average health and with a low rate of disease events compared with that of the background population, or users may be those of us who rightly perceive themselves to be in poor health and nutrition and then try to ward off health consequences including osteoporotic fractures by taking the same supplements. Similar concerns apply to some extent also to dietary intake. Metaanalysis of RCTs suggests excess cardiovascular events in persons randomized to calcium and vitamin D supplementation (Bolland *et al.*, 2011), though the Womens Health Initiative CaD trial, which was the most influential trial in the analysis, was further restricted by exclusion of users who took own supplements. This removed the balancing created by the randomization process and essentially reduces the level of evidence to that of an observational study. There is an ongoing debate and controversy about how best to interpret the imperfect data on calcium and vitamin D safety collected in the clinical trials (Abrahamsen, 2017; Prince and Zhu, 2011; Abrahamsen and Sahota, 2011).

Fortification and the Public Health Perspective

It is important to be aware that vitamin D fortification is far from universal in the Western world and when in place it is generally there to prevent only severe rickets, not to achieve "normal" serum vitamin D levels of 50 or 75 nmol/L. Even so, many European countries have opted not to put in place mandatory food fortification programmes (Spiro and Buttriss, 2014). Hence, only infant milk formula and follow-on formula formally require fortification with vitamin D in the European Union. Sweden, Finland and Iceland fortify some food groups. Low-fat milks are fortified while in Sweden and Iceland while Finland has vitamin D fortification of fat spreads, milk, and milk alternatives. In the United Kingdom, most margarines and fat spreads are fortified with vitamin D though there is no mandatory fortification. Food fortification seeks to provide a small amount of vitamin D—about 5 μg. This is just enough to avoid rickets but will not lead to any risk of toxicity even in persons on highly unusual diets. Recognizing that it is very difficult to tailor fortification programmes to meet the vitamin D needs of housebound elderly people with low overall food intake, vitamin D supplements of 10 or 20μg daily are often recommended by health authorities in groups at particularly high risk of vitamin D deficiency.

Directions for Research

We are fortunate that some large vitamin D trials with multiple health outcomes are in progress and should be reporting in the next years. Hence, first reports from the New Zealand VIDA study—in which 5100 healthy volunteers aged 50–84 years were randomized to 100,000 IU cholecalciferol each month for up to 4 years—have been released in the past months demonstrating a threshold for BMD effects as discussed above (Reid *et al.*, 2017). The supplementation did not prevent falls or fractures (Khaw *et al.*, 2017). In the ongoing VITAL trial (Bassuk *et al.*, 2016; LeBoff *et al.*, 2015), 25,875 trial men and women were randomized in a 2 × 2 factorial design to a double-blind, placebo-controlled intervention consisting of cholecalciferol 2000 IU/d and Omacor fish oil (1 g/d) with the primary outcomes being prevention of cancer and CVD. Finally, the D-Health study in Australia has recruited 21,315 participants for a 5 years intervention study of 60,000 IU monthly cholecalciferol or placebo with 5 years additional register-based follow-up, aimed at capturing mortality and cancer outcomes (Neale *et al.*, 2016). These studies are likely to shed new light on the pros and cons of vitamin D supplementation on large disease areas but no studies are in place to better understand the role of calcium supplementation (Abrahamsen, 2017). This should be a major research priority given the considerable scientific uncertainty, which leaves clinicians at a loss of how best to advise their patients and the topic is also of importance in the light of low calcium diets being the order of the day in large parts of Asia and South America (Balk *et al.*, 2017).

How to Act in Daily Clinical Practice

There is ample evidence that very low vitamin D levels should be avoided as they translate to a higher risk of low BMD and fractures. Osteomalacia is imminently treatable and results in improvements in BMD that surpasses what can be achieved in osteoporosis. There is no consistent evidence that vitamin D supplementation given without calcium supplementation reduces the risk of osteoporotic fractures in the general population but some evidence that small reductions in fracture risk can be achieved in older people if supplemented by modest amounts of calcium and vitamin D, likely due to a large effect in a small number of people and no effect in the majority. Given the relatively low quality RCT evidence it is difficult to be dogmatic about the need for calcium and vitamin D supplements, at least in healthy people in the Western hemisphere with a varied diet. There seems to be a tendency for prescribers to use somewhat small calcium and vitamin D supplement amount as adjuncts to osteoporosis medications compared with what was used in the pivotal RCTs; this pragmatic approach is not unreasonable though it is nominally a deviation from the principles of evidence based medicine. If we have learned one thing from the past two decades of vitamin D and calcium research then it is that one size does not fit all and that supplements should be given according to individual requirements.

Osteoporosis Treatment: Bone-Forming Agents

Bente L Langdahl, Aarhus University Hospital, Aarhus, Denmark

Glossary

Antiresorptive osteoporosis treatments Treatments that improve bone mass and reduce fracture risk by inhibition of bone resorption. This group includes bisphosphonates, RANKL antibody, estrogen, testosterone, and selective estrogen receptor modulators.

Bone mineral density (BMD) The mineral content in bone measured by DXA (dual energy Xray absorptiometry) or quantitative computer tomography (qCT).

Bone remodeling A coupled process of bone resorption followed by bone formation, which maintains skeletal integrity throughout adulthood. In osteoporosis, bone resorption usually exceeds bone formation, leading to bone loss.

Osteoporosis Osteoporosis is a systemic skeletal disease, characterized by reduced bone mass and deteriorated bone architecture, resulting in an increased risk of fractures. Osteoporosis is defined by WHO as BMD more than 2.5 standard deviations below peak bone mass (T-score < -2.5).

Parathyroid hormone (PTH) An 84 peptide hormone produced by the parathyroid glands.

Sclerostin A peptide produced almost exclusively by the osteocytes. Sclerostin binds LRP5 and other agonists of the wnt-pathway, and thereby inhibits osteoblast activity and bone formation.

Introduction

Antiresorptive treatments are well established for the treatment of osteoporosis. They increase BMD and prevent fractures—vertebral fractures more so than hip and nonvertebral fractures. Some patients with severe osteoporosis, many fractures, and/or very low BMD or patients diagnosed at a young age with osteoporosis are difficult to treat optimally with antiresorptives, as fractures often reoccur in these patients. There is thus a need for new treatments that can increase bone mass and perhaps more importantly restore bone architecture (**Table 1**).

There are currently two approved treatments in this category: teriparatide and abaloparatide. At the time of writing, abaloparatide is only approved in the United States. A new treatment, romosozumab, has just recently finished the phase III clinical trial program and is undergoing evaluation by the authorities for approval.

Teriparatide

Both parathyroid hormone (PTH) and parathyroid hormone related peptide (PTHrP) exert their effects on bone by activating the PTH type 1 receptor (PTH1R) (Juppner *et al.*, 1991). It has been recognized that the effect of activation of the receptor differs whether the activation is sustained or intermittent. Sustained activation as seen in primary hyperparathyroidism activates both osteoblasts and osteoclasts, and increases bone formation as well as bone resorption. Intermittent activation, on the other hand, activates primarily osteoblasts and therefore primarily increases bone formation (Tam *et al.*, 1982). The first approved PTH-based treatment for osteoporosis is teriparatide (Dempster *et al.*, 1993). Teriparatide is the first 34 amino acids of the natural occurring PTH. Teriparatide is a peptide and therefore has to be administered parentally to avoid destruction in the stomach and proximal intestine if administered orally. The half-life of teriparatide is short; 60 min, and teriparatide is therefore administered as a daily subcutaneous injection, usually by the patients themselves (Satterwhite *et al.*, 2010). Teriparatide primarily stimulates recruitment and activity of the osteoblasts, and thereby increases bone formation. But since bone formation and bone resorption are physiologically coupled processes, bone resorption is subsequently stimulated, causing the net anabolic response to level off over time (McClung *et al.*, 2005).

The effects of teriparatide were first examined in a placebo-controlled study (Neer *et al.*, 2001) comprising women with severe osteoporosis, defined as having two or more vertebral fractures, or one vertebral fracture in combination with reduced bone mass (T-score < -1). The women were randomized to teriparatide in two different doses or placebo. All women received calcium and vitamin D substitution. The study was planned for 3 years but was stopped prematurely after a median study period of 21 months, because preclinical studies showing an increased risk for osteosarcoma in rats treated early in life or lifelong with teriparatide (Vahle *et al.*, 2004). The clinical study demonstrated robust increases in BMD: 9.7% at the lumbar spine and 2.8% at the femoral neck in women treated with teriparatide 20 μg daily. The risk of morphometric vertebral fractures and nonvertebral fractures was reduced by 65% and 53%, respectively. Adverse effects were hypercalcemia, dizziness, and leg cramps. Posthoc analyses revealed that the effect on nonvertebral fractures was positively correlated with treatment duration (Lindsay *et al.*, 2009). Since then, head-

Table 1 Summary of the main effects seen in clinical trials on bone mineral density (BMD) and fracture risk reduction of anabolic treatments of osteoporosis

Treatment	*Patients*	*Pharmacodynamics*	*Comparator*	*Increase in BMD*	*Fracture risk reduction*
Teriparatide	Postmenopausal women with prior vertebral fractures	Intermittent activation of the PTH type 1 receptor and thereby activation of osteoblasts	Placebo (21 months)	lsBMD 9.7%[a] fnBMD 2.8%[a]	Vertebral 65%[1] Nonvertebral 53%[a]
Teriparatide	Patients treated with glucocorticoids	Intermittent activation of the PTH type 1 receptor and thereby activation of osteoblasts	Alendronate (18 months)	lsBMD 7.2%[b] thBMD 3.8%[b]	NA
Abaloparatide	Postmenopausal women with osteoporosis	Intermittent activation of the PTH type 1 receptor and thereby activation of osteoblasts	Placebo (18 months) Teriparatide All had alendronate for additional 6 months	lsBMD 11.2%[c] thBMD 4.2%[c] lsBMD 12.8%[d] thBMD 5.5%[d]	Vertebral 84%[c] Nonvertebral 43%[c] Vertebral 87%[d] Nonvertebral 52%[d]
Romosozumab	Postmenopausal women with osteoporosis	Inhibition of sclerostin that inhibits the osteoblast and stimulates osteoclast recruitment	Placebo (12 months) All had denosumab during year 2	lsBMD 13.3%[e] thBMD 6.8%[e] lsBMD 13.3%[e] thBMD 6.8%[e]	Vertebral 73%[5] Nonvertebral ns[e] Vertebral 75%[5] Nonvertebral ns[e]
Romosozumab	Postmenopausal women with severe osteoporosis	Inhibition of sclerostin that inhibits the osteoblast and stimulates osteoclast recruitment	Alendronate (12 months) All had alendronate during year 2	lsBMD 13.7%[f] thBMD 6.2%[f] lsBMD 15.2%[f] thBMD 7.1%[f]	Vertebral 37%[6] Nonvertebral ns[f] Vertebral 48%[6] Nonvertebral 48%[f]
Combination therapy	Anabolic and antiresorptive	Inhibition of RANKL and thereby recruitment of osteoclasts (Denosumab) and intermittant activation of the PTH type 1 receptor and thereby activation of osteoblasts (Teriparatide)	Teriparatide (24 months) Denosumab (24 months)	lsBMD 12.9%[g] thBMD 6.3%[g]	NA

[a]Teriparatide 20 μg daily for 21 months (Neer *et al.*, 2001).
[b]Teriparatide 20 μg daily in comparison with Alendronate 10 mg daily for 18 months (Saag *et al.*, 2007).
[c]Abaloparatide 80 μg daily for 18 month (Miller *et al.*, 2016).
[d]Abaloparatide 80 μg daily for 18 month, all participants were treated with Alendronate for an additional 6 months (Cosman *et al.*, 2017).
[e]Romosozumab 210 mg monthly for 12 months, all participants received denosumab during the second year (Cosman *et al.*, 2016).
[f]Romosozumab 210 mg monthly in comparison with alendronate 70 mg weekly for 12 months, all patients were treated with Alendronate during the second year (Saag *et al.*, 2017).
[g]Denosumab 60 mg every 6 months in combination with teriparatide 20 μg daily for 24 months (Tsai *et al.*, 2013).
lsBMD: lumbar spine BMD, *fnBMD*: femoral neck BMD, *thBMD*: total hip BMD, *NA*: data not available.

to-head comparisons with antiresorptive treatments have been performed. Hadji et al. carried out a study investigating the effect of teriparatide in comparison with risedronate on back pain in postmenopausal women with prevalent vertebral fractures. The study demonstrated more robust increases in bone mass and a significant reduction in new vertebral fractures with teriparatide in comparison with risedronate (Hadji *et al.*, 2012). The VERO study compared the antifracture efficacy of teriparatide and risedronate in postmenopausal women with severe osteoporosis, and demonstrated that teriparatide is superior to risedronate for the prevention of vertebral, multiple vertebral, and clinical fractures (Kendler Dl *et al.*, 2017).

Histomorphometric and microCT-based investigations of bone biopsies from patients treated with teriparatide have demonstrated improvements in bone architecture (Jiang *et al.*, 2003). This has been confirmed by CT-based analyses of vertebrae and hips in patients. These analyses have revealed an increase in estimated bone strength by finite element analyses (Graeff *et al.*, 2009; Borggrefe *et al.*, 2010).

Teriparatide has also been investigated in men with severe osteoporosis (Orwoll *et al.*, 2003). This study, just like the study in postmenopausal women, was stopped prematurely and the median treatment duration was 12 months. No data on the effect on fracture are available; however, the changes seen in spine and hip BMD were similar to the increases seen in postmenopausal women, and teriparatide is therefore also approved for the treatment of male osteoporosis. Finally, the effect of teriparatide has been investigated in patients treated with glucocorticoids. Glucocorticoid-induced osteoporosis is pathophysiologically characterized by two phases. The first phase is characterized by stimulation of osteoclasts and bone resorption, whereas the second and permanent phase is characterized by inhibition of osteoblasts and osteocytes (Compston, 2010). In patients who had received glucocorticoids for more than 3 months and therefore are likely to be characterized by reduced bone formation, the effect of teriparatide in comparison with alendronate was investigated (Saag *et al.*, 2007). Bone mass at the spine and hip increased significantly more with teriparatide than with alendronate. Fractures were not an endpoint in this study; however, 10 vertebral fractures were seen in 165 patients (6.1%) treated with alendronate compared to 1 vertebral fracture in 171 patients (0.6%) treated with teriparatide. The difference was thus statistically significant.

In summary, teriparatide is a bone-forming treatment that increases bone mass at both trabecular and cortical sites, and prevents vertebral and nonvertebral fractures. The treatment duration is limited to 24 months and should be followed by an antiresorptive treatment. Teriparatide has been investigated in postmenopausal women, men, and patients treated with glucocorticoids.

Abaloparatide

The PTH1R has two different high-affinity conformations termed R^0 and RG, and responses of prolonged duration are observed with ligands that bind efficiently to the R^0 state, whereas short-duration responses are seen with ligands that bind more selectively to the RG state (Hoare *et al.*, 1999; Dean *et al.*, 2008). Abaloparatide is PTHrP (1–34) with some modifications (Hattersley *et al.*, 2016). Early studies showed that it induces bone formation without stimulating resorption and causing hypercalcemia (Culler *et al.*, 2001); it has also demonstrated that this effect may be due to a lower affinity for the RG conformation and thus a short activation period. The affinity to the RG conformation was shown to be lower than that of teriparatide (Hattersley *et al.*, 2016). In a phase III trial 2463 postmenopausal women were randomized to abaloparatide 80 μg daily, teriparatide 20 μg daily, or a placebo for 18 months (Miller *et al.*, 2016). Abaloparatide and teriparatide both increased BMD at the lumbar spine and hip sites compared to the placebo. Abaloparatide increased BMD more at the hip sites throughout the study period and initially also at the lumbar spine. In addition, the effect on biochemical markers of bone formation and resorption differed between the two treatments. Teriparatide stimulated bone formation and resorption throughout the study period, whereas the effect of abaloparatide on bone formation was less prominent after the first 6 months. Also, resorption was less increased with abaloparatide compared with teriparatide. Abaloparatide and teriparatide reduced the risk of new vertebral fractures by 84% and 80%, respectively. Abaloparatide reduced the risk of nonvertebral fractures by 43%, which was significant; however, the reduction was not different from the nonsignificant reduction seen with teriparatide. Abaloparatide and teriparatide reduced the risk of major osteoporotic fractures (upper arm, forearm including wrist, hip, shoulder, spine) by 67% and 30%, respectively. The reduction seen with abaloparatide was significantly different from the placebo and teriparatide, whereas the effect of teriparatide was not significantly different from the placebo. More women discontinued abaloparatide (9.9%) compared with the placebo (6.1%) and teriparatide (6.8%) due to adverse events. Hypercalcemia was less frequent with abaloparatide (3.4%) than with teriparatide (6.4%), but more common than with the placebo (0.4%).

The study was extended for an additional 6 months for the patients who had been treated with abaloparatide and placebo during the first 18 months. During the additional 6 months, all patients were treated with alendronate 70 mg weekly. BMD at the spine and hip sites increased in both groups (Cosman *et al.*, 2017). The reductions in vertebral, nonvertebral, and major osteoporotic fractures in women treated with abaloparatide/alendronate in comparison with women treated with placebo/alendronate were 87%, 52%, and 58%, respectively.

In summary, abaloparatide is a bone-forming treatment that increases BMD at both cortical and trabecular sites, and may be superior to teriparatide in preventing some types of fractures. Abaloparatide has not been investigated in men with osteoporosis or patients with glucocorticoid-induced osteoporosis.

Romosozumab

Bone formation by the osteoblasts can be stimulated via the canonical wnt-pathway in which lipoprotein-related peptide (LRP) 5 and −6 binds to the frizzled receptor and promotes bone formation (Poole *et al.*, 2005). The osteocytes are terminally differentiated osteoblasts that are imbedded within the bone matrix and control bone formation by producing sclerostin that prevents the binding of LRP5 and −6 to the frizzled receptor and thereby *inhibits* bone formation (Van Bezooijen *et al.*, 2004). Sclerostin also stimulates the release of RANKL by osteocytes and thereby the recruitment and activation of osteoclasts. Sclerostin was identified as the result of genetic analysis of families with sclerosteosis (Beighton *et al.*, 1976). Sclerosteosis is a recessive disease characterized by skeletal overgrowth, syndactyly, and nerve compression syndromes. Linkage analysis of families with sclerosteosis

and the related syndrome of Van Buchem disease localized both disease genes to chromosome 17q12–q21 (Balemans *et al.*, 1999) and subsequent positional cloning identified loss of function mutations in the SOST gene, which encodes sclerostin as the cause of sclerosteosis (Balemans *et al.*, 2001; Brunkow *et al.*, 2001). Given that individuals with loss of function mutations affecting SOST have a phenotype restricted to bone, sclerostin emerged as a highly attractive therapeutic target for the treatment of osteoporosis. Accordingly, neutralizing antibodies that act as inhibitors of sclerostin (McColm *et al.*, 2014; Padhi *et al.*, 2011) have emerged as highly promising agents for the treatment of osteoporosis.

Romosozumab is an antibody against sclerostin that has demonstrated bone-forming potential (Padhi *et al.*, 2011). The effect of romosozumab on bone turnover and BMD has been investigated in women in a phase II trial (McClung *et al.*, 2014). The women were randomized to treatment for 12 months with one of five different doses of romosozumab either monthly or 3-monthly, alendronate 70 mg weekly, teriparatide 20 mg daily, or a placebo. Treatment with romosozumab 210 mg monthly increased the bone formation marker, serum PINP by 91% after 1 month, but the increase leveled off over the following months, and at the end of the treatment period, serum PINP was 20% below baseline level. In addition, the bone resorption marker serum CTX decreased by 41% 1 week after administration of the first dose of romosozumab and then slightly increased to a level 26% below baseline at 12 months. Thus, romosozumab appears not only to stimulate formation but also to inhibit resorption. The fact that formation is decreased after 12 months is somewhat surprising, but it has been suggested to be caused by depletion of osteoblast progenitors or a compensatory increase in other inhibitors of bone formation such as dickkopf (Ferrari, 2014). The suppression of bone resorption is most likely caused by a reduction in the osteocyte production of RANKL due to the inhibition of sclerostin (Atkins and Findlay, 2012). Romosozumab 210 mg monthly increased lumbar spine BMD 11.3% which was significantly more than teriparatide, alendronate, and the placebo, which increased lumbar spine BMD by 7.1%, 4.1%, and 0.1%, respectively. A similar pattern was seen at the total hip where BMD changed by 4.1%, 1.3%, 1.9%, and -0.7% in women treated with romosozumab, teriparatide, alendronate, or a placebo, respectively. The effect of romosozumab and teriparatide on trabecular and cortical bone was further investigated in substudies of this phase II study using qCT of the spine and hip. These analyses demonstrated that romosozumab improves estimated bone strength both at the spine and hip more than teriparatide (Keaveny *et al.*, 2017; Genant *et al.*, 2017).

The effects of romosozumab have been further investigated in two phase III trials. The FRAME study investigated 7180 women with osteoporosis and found that treatment with romosozumab for 12 months increased BMD at the spine and total hip by 13.3% and 6.8%, respectively, and reduced the risk of vertebral and clinical fractures by 73% and 36%, respectively, in comparison with a placebo (Cosman *et al.*, 2016). The study was extended for a second year, where all patients received denosumab 60 mg every 6 months. This led to further increases in BMD, and the difference in fracture rates seen between the two treatment groups in the first year was maintained. The ARCH study included 4093 women with severe osteoporosis and investigated the effect of romosozumab in comparison with alendronate for 12 months. In the second year, all women received alendronate (Saag *et al.*, 2017). Romosozumab followed by alendronate increased BMD at the lumbar spine and total hip by 15.2% and 7.1%, respectively, and reduced the risk of vertebral, hip, and nonvertebral fractures by 48%, 38%, and 19%, respectively, in comparison with alendronate. A numeric imbalance in serious adverse cardiovascular events was observed during the first 12 months in the ARCH study, with more events seen in the romosozumab-treated women.

In the clinical setting, bone-forming agents are often not used first line, but only after insufficient response or treatment failure with antiresorptive treatments. The STRUCTURE study compared the effect of teriparatide and romosozumab for 12 months in women with osteoporosis previously treated with bisphosphonates (Langdahl *et al.*, 2017). The study demonstrated that both treatments substantially stimulated bone formation at the spine. At the hip sites, the responses to the two treatments were different. Romosozumab stimulated BMD and bone strength, estimated by finite element analysis of CT scans at the hip, whereas BMD and bone strength did not improve with teriparatide. This difference can probably be explained by the different mechanism of action of the two treatments: teriparatide stimulates bone formation and subsequently bone resorption, whereas romosozumab stimulates bone formation and at the same time inhibits bone resorption. The study duration was only 12 months and usually teriparatide is used for 24 months.

In summary, romosozumab represents a new treatment concept in osteoporosis: dual-acting as it appears to stimulate formation as well as inhibit resorption. It increases BMD substantially at both trabecular and cortical sites, and demonstrates strong antifracture efficacy that in one study was superior to the effect seen with alendronate.

Combination Treatment

Throughout the years, several treatments have been available for osteoporosis, and therefore an even larger number of combinations of therapies have been possible. Attempts have been made to demonstrate additive or synergistic effects of different combinations, but initially with disappointing results. Thus, in the PaTH trial, BMD in patients treated with a combination of teriparatide and alendronate did not increase more than with either drug alone. In fact, alendronate even appeared to impair the bone-forming effect of teriparatide (Black *et al.*, 2003; Finkelstein *et al.*, 2003). Similar results were found in a study combining risedronate and teriparatide (Walker *et al.*, 2013). In accordance with these findings, a rodent study showed that chronic exposure to a bisphosphonate blunted the response to teriparatide (Gasser *et al.*, 2000). It was suggested that this was caused by the osteoblasts being exposed to bisphosphonates while in the circulation. In accordance with this hypothesis, it was shown that a single infusion of zoledronic acid (which is rapidly cleared from the circulation) in combination with daily teriparatide for 1 year

increased lumbar spine and total hip BMD by 7.5% and 2.3%, respectively, whereas zoledronic acid alone resulted in increases of 4.4% and 2.2%, respectively, and teriparatide alone provided increases of 7.0% and 1.1%, respectively (Cosman *et al.*, 2011).

Recently, in the DATA trial the combination of teriparatide 20 μg daily and denosumab 60 mg every 6 months was compared with either treatment alone (Tsai *et al.*, 2013). After 24 months, BMD at the lumbar spine had increased by 12.9%, 9.5%, and 8.3%, and total hip BMD increased by 6.3%, 2.0%, and 3.2% in the combination, teriparatide, and denosumab groups, respectively. Taken together, the studies suggest that a combination of teriparatide and zoledronic acid gives "the best of both worlds," the significant increase in hip BMD seen with zoledronic acid combined with the significant increase in spine BMD seen with teriparatide, whereas the combination of denosumab and teriparatide appears even to have an additive or synergistic effect. None of the studies, however, was powered to allow for conclusions regarding antifracture efficacy.

Conclusion

A number of exciting drugs for the treatment of osteoporosis are emerging. In particular, the new anabolic options (romosozumab and abaloparatide) are promising, as they efficiently increase both hip and spine BMD and moreover may have greater antifracture efficacy than teriparatide.

The DATA trial demonstrated for the first time an additive effect of anabolic and antiresorptive therapy on BMD; however, antifracture efficacy with combination therapy remains to be demonstrated.

Osteoporosis Treatment: Sequential and Combination Therapy

Benjamin Z Leder and Joy N Tsai, Harvard Medical School, Boston, MA, United States

Glossary

Abaloparatide An anabolic drug that is a parathyroid hormone-related protein (PTHrP) analog.

Bisphosphonate A pyrophosphate analog compound with high affinity to hydroxyapatite that causes osteoclast inhibition.

Denosumab A monoclonal antibody that inhibits the receptor activator of nuclear factor kappa-B ligand (RANKL) and thereby inhibits the maturation of osteoclasts.

Romosozumab An anabolic monoclonal antibody that targets sclerostin, a Wnt antagonist that blocks osteoblast proliferation and function.

Teriparatide An anabolic drug that contains the first N-terminal 34 amino acids of human parathyroid hormone (PTH).

Introduction

Osteoporosis drugs may be categorized as either antiresorptive or anabolic, though these labels are not precise as all currently available antiresorptive agents also inhibit bone formation and all currently available anabolic agents also stimulate bone resorption. In contrast to many other chronic conditions, such as hypertension, that often warrant multidrug regimens, the standard of care for osteoporosis is monotherapy. It remains the case, however, that no single agent is curative for osteoporosis and thus potential combination treatment strategies continue to be actively investigated. Early trials combining two antiresorptives drugs (generally oral bisphosphonate with hormonal agents) were not found to be more effective than monotherapy and thus the more recent focus of study has been in combining antiresorptive and anabolic drugs, an approach that was hypothesized to benefit from their contrasting mechanisms of action (Bone *et al.*, 2000; Greenspan *et al.*, 2003; Harris *et al.*, 2001; Lindsay *et al.*, 1999; Palomba *et al.*, 2002; Sanad *et al.*, 2011; Tiras *et al.*, 2000; Tseng *et al.*, 2006; Wimalawansa, 1995). Notably, the past decade has also seen advances in our understanding of the importance of the order of antiresorptive and anabolic treatment and in how drug sequence may influence long-term efficacy. This article reviews the published clinical trials that have assessed the efficacy of various antiresorptive and anabolic combinations and sequences in the treatment of postmenopausal osteoporosis.

Combination Antiresorptive and Anabolic Treatment

Parathyroid hormone (PTH) analogs, such as teriparatide (PTH 1–34), increase bone mineral density (BMD), improve trabecular microarchitecture, and reduce fracture risk (Neer *et al.*, 2001; Black *et al.*, 2003; Tsai *et al.*, 2016; Hansen *et al.*, 2013). As discussed above, however, it has been hypothesized that limiting the bone-resorbing effects of PTH by the co-administration of an antiresorptive drug may improve its therapeutic effect, particularly in cortical bone (Uihlein and Leder, 2012). The combinations that have been investigated include combining PTH analogs (PTH 1–84 and teriparatide) with (1) estrogen and selective estrogen receptor modulators, (2) oral and intravenous bisphosphonates, and (3) denosumab, a monoclonal antibody that inhibits the receptor activator of nuclear factor kappa-B ligand (RANKL) (Deal *et al.*, 2005; Cosman *et al.*, 2001, 2011; Lindsay *et al.*, 1997; Ste-Marie *et al.*, 2006; Black *et al.*, 2007; Finkelstein *et al.*, 2010; Schafer *et al.*, 2012; Tsai *et al.*, 2013; Leder *et al.*, 2014).

Combination of Estrogen or Selective Estrogen Receptor Modulators and PTH Analogs

Combinations of PTH analogs with estrogens or raloxifene, a selective estrogen receptor modulator, have been studied in multiple small clinical trials, most of which examined the effect of adding a PTH analog to ongoing hormone replacement therapy (Deal *et al.*, 2005; Cosman *et al.*, 2001; Lindsay *et al.*, 1997; Ste-Marie *et al.*, 2006). Conclusions about the efficacy of this combination, however, are limited as these studies generally lacked monotherapy comparison groups. Similarly, in a double-blind, placebo-controlled trial study of 137 postmenopausal women randomized to receive teriparatide 20-mcg daily with either raloxifene 60-mg daily or placebo for 6 months, combination treatment increased total hip BMD more than teriparatide monotherapy but a raloxifene monotherapy control group was not included (Deal *et al.*, 2005). The short duration of this latter study also limits clinically relevant conclusions.

Combination of Bisphosphonates and PTH Analogs

The majority of combination therapy trials have focused on combinations of PTH analogs and bisphosphonates. In the parathyroid hormone and alendronate (PaTH) study, 238 postmenopausal women with osteoporosis were randomized to receive

Table 1 Comparison of 12-month BMD changes in three randomized controlled trials of combination therapy with concurrent initiation of antiresorptive and anabolic drugs

Study	*Sample size*	*Regimen*	*12-month % change at posterior-anterior spine*	*12-month % change at total hip*
Black et al. (2003)	119	PTH 1–84	6.3	0.3
	60	Alendronate	4.6	~3
	59	Both	6.1	1.9
Cosman et al. (2011)	138	Teriparatide (with placebo IV)	7.0	1.1
	137	Zoledronic acid	4.4	2.2
	137	Both	7.5	2.3
Tsai et al. (2013)	31	Teriparatide	6.2	0.7
	33	Denosumab	5.5	2.5
	30	Both	9.1	4.9

1 year of PTH 1–84100-mcg daily, alendronate 10-mg daily, or both (Black *et al.*, 2003). After 12 months, spine BMD increased similarly in all three groups (**Table 1**), whereas at the total hip, combination therapy increased BMD more than the PTH 1–84 alone but similarly to alendronate (**Table 1**). Importantly, PTH monotherapy increased spine trabecular volumetric BMD (vBMD) nearly twofold more than combination therapy (as assessed by QCT). At the hip, trabecular vBMD increased similarly among the three groups whereas cortical vBMD decreased with PTH 1–84, remained unchanged with combination treatment, and increased with alendronate. While early increases in bone formation marker type I collagen propeptide (P1NP) were observed with combination therapy, these increases were not sustained over 12 months. Moreover, combination treatment suppressed bone resorption marker serum c-telopeptide (CTX) significantly less than alendronate monotherapy. Qualitatively similar findings were also reported in separate studies assessing the combination of alendronate and teriparatide (at 40 mcg daily, double the FDA approved dose) and the combination of ibandronate and teriparatide (Finkelstein *et al.*, 2010; Schafer *et al.*, 2012). The combination of teriparatide and an intravenous bisphosphonate was assessed in a clinical trial of 412 postmenopausal women randomized to receive 12-months of teriparatide 20-mcg daily, zoledronic acid 5-mg, or both (Cosman *et al.*, 2011). While spine BMD increased more in the combination group at early time points, gains at 12-months were similar in the combination therapy and teriparatide monotherapy groups (**Table 1**). Combination therapy also demonstrated larger early BMD increases at the hip, though by 12-months gains were equivalent in the combination therapy and zoledronic acid monotherapy groups. Of note, in patients treated with combination therapy, serum CTX was suppressed initially but increased above baseline values at month-12.

Taken together, these trials demonstrate that combinations of PTH analogs and bisphosphonates do not provide significant additive skeletal effects in postmenopausal women. Based on the bone turnover marker results described above, it was hypothesized that the lack of benefit was due to the key role bone resorption plays in mediating the anabolic effects of PTH analogs, though the inability of bisphosphonates to fully inhibit PTH analog-induced bone resorption provides an alternate explanation.

Combination of Denosumab and Teriparatide

In contrast to combinations of PTH analogs and bisphosphonates, the combination of denosumab and teriparatide has clear additive effects on BMD. In the Denosumab and Teriparatide Administration (DATA) trial, 94 osteoporotic postmenopausal women were randomized to receive teriparatide 20-mcg daily, denosumab 60-mg every 6 months or both for 2 years (Leder *et al.*, 2014). Combination treatment increased spine, total hip, and femoral neck BMD more than either group after 1 year and this advantage was maintained during the second year (**Table 1** and **Fig. 1**) (Tsai *et al.*, 2013; Leder *et al.*, 2014). The 2-year net gains in spine and hip BMD realized with combined denosumab/teriparatide were larger than can currently be achieved with 2-year courses of any approved single drug (Neer *et al.*, 2001; Bolognese *et al.*, 2012; Cosman *et al.*, 2017; Black *et al.*, 1996; Harris *et al.*, 1999; Ettinger *et al.*, 1999). Similar additive effects of combined teriparatide/denosumab were observed in volumetric BMD, skeletal microarchitecture, and estimated bone strength of the distal tibia and radius as assessed by high-resolution peripheral QCT (HR-pQCT) (Tsai *et al.*, 2016). Specifically, combined teriparatide/denosumab increased total vBMD and cortical thickness more than both monotherapy groups whereas cortical porosity increased in the teriparatide monotherapy group but remained unchanged in the combination group. Together, these microarchitectural changes resulted in greater estimated bone strength (as assessed by micro-finite element analysis) in the combination therapy group as compared to the teriparatide monotherapy group at both peripheral sites.

The mechanisms underlying the unique efficacy of the specific teriparatide/denosumab combination remain unclear but the pattern of changes in bone turnover markers provides a possible explanation. Specifically, serum CTX was identically suppressed in women treated with combination therapy and denosumab monotherapy whereas bone formation markers in these two groups deviated. Bone formation remained stable in the combination therapy group for the initial 3-months of treatment and then declined modestly (though not to the level observed in the denosumab monotherapy group) (**Fig. 2**) (Leder *et al.*, 2014). The divergent pattern in bone resorption and formation marker changes in the combined teriparatide/denosumab group suggests that when given together, denosumab fully inhibits teriparatide-induced bone resorption while not interfering with teriparatide-induced "modeling-based" bone formation.

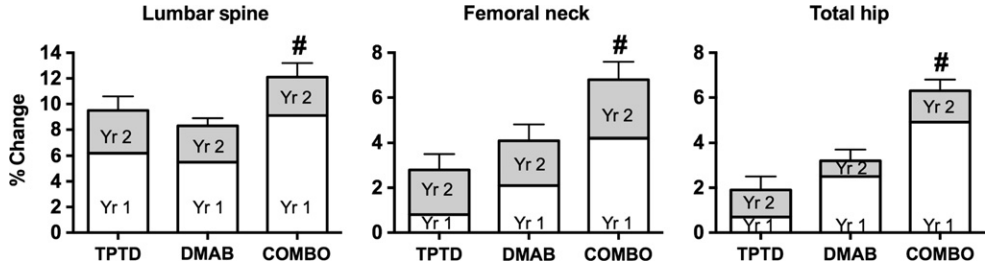

Fig. 1 Mean percent change (±SEM) in BMD from months 0–12 (in *white*) and 12–24 (in *gray*) in women treated with teriparatide (TPTD), denosumab (DMAB), or combination therapy (COMBO). #$P < .05$ versus both other groups at 24 months. Fig. 2 Mean percent change (±SEM) in serum osteocalcin and c-telopeptide from month 0–24 in subjects treated with denosumab monotherapy or combination teriparatide/denosumab. *$P < .05$ versus the other group at all time points for osteocalcin. Adapted from Leder, B.Z., Tsai, J.N., Uihlein, A.V., Burnett-Bowie, S.A., Zhu, Y., Foley, K., Lee, H. and Neer, R.M. (2014). Two years of denosumab and teriparatide administration in postmenopausal women with osteoporosis (the DATA extension study): A randomized controlled trial. *The Journal of Clinical Endocrinology and Metabolism* **99**, 1694–1700.

In summary, while bisphosphonate-containing combinations with PTH analogs do not lead to additive effects, the combination of denosumab and teriparatide appears to be is a promising approach that, even in the absence of fracture-efficacy studies, could be considered in patients with severe osteoporosis.

Sequential Treatment

Switching from Anabolic to Antiresorptive Therapy

Due to the observed increased risk of osteosarcoma in animal studies with PTH and parathyroid hormone-related protein (PTHrP) analogs, the use of teriparatide and abaloparatide (a PTHrP analog recently approved in the United States) is limited to 2 years (Langdahl *et al.*, 2017). And while the fracture risk reduction of teriparatide appears to be maintained for up to 18 months after discontinuation, BMD decreases almost immediately when the drug is stopped (Black *et al.*, 2005; Kaufman *et al.*, 2005; Lindsay *et al.*, 2004). Thus, the use of these agents should generally be followed by an alternate osteoporosis drug. In the extension of the PATH study discussed above, postmenopausal women who had received 1 year of PTH 1–84 were then randomized to receive either placebo or alendronate for an additional year (Black *et al.*, 2005). While alendronate increased BMD at the spine, total hip, and femoral neck, those who received placebo experienced no gain in femoral neck and total hip BMD and a −1.7% decline in spine BMD. In the separate EUROFORS (The EUROpean Study of FORSteo) study, postmenopausal women with severe osteoporosis who had received 1 year of teriparatide were randomized to continue teriparatide, switch to raloxifene, or stop treatment for an additional year (Eastell *et al.*, 2009). Spine BMD increased in those who received teriparatide, remained stable in those who received raloxifene, and decreased in those who did not receive treatment. Femoral neck BMD increased in all three groups (with greater gains in the teriparatide group compared to the no-treatment group) and total hip BMD increased only in those who received active treatment.

In an extension of the large double-blind placebo controlled abaloparatide registration trial, the 1139 postmenopausal women who had received either placebo or abaloparatide in the initial 18-month phase were all transitioned to open-label alendronate and spine, total hip, and femoral neck BMD increased in both groups (Cosman *et al.*, 2017). Additionally, the antifracture efficacy observed during the initial 18-month placebo-controlled portion of the trial was maintained during the open-label alendronate phase.

The transition from the as yet unapproved anabolic sclerostin inhibitor, romosozumab, to alendronate was also investigated in the recently published placebo-controlled ARCH trial (Active-Controlled Fracture Study in Postmenopausal Women with Osteoporosis at High Risk) (Saag *et al.*, 2017). In this study, postmenopausal women with osteoporosis who had received either romosozumab 120 mg monthly or alendronate 70 mg weekly for 12 months then received open-label weekly alendronate for 2 years. In the group who originally received romosozumab, alendronate maintained the comparative increases in spine and total hip BMD as well as the beneficial effect on vertebral, clinical, nonvertebral, and hip fracture incidence.

In the extension of the DATA study (DATA-SWITCH), women who originally received teriparatide or combined therapy were switched to 2-years of denosumab whereas those who originally received denosumab were switched to 2-years of teriparatide (Leder *et al.*, 2015). In the group who received 2 years of teriparatide followed by 2 years of denosumab, BMD continued to increase at all measured sites resulting in net 4-year gains of 14.0% at the spine and 6.6% at the total hip (**Fig. 3**). Women who received combination therapy followed by denosumab experienced mean 4-year gains of 16.0% at the spine and 8.6% at the total hip (**Fig. 3**). The transition from teriparatide-to-denosumab also significantly increased total vBMD, trabecular vBMD, cortical vBMD, cortical thickness, and estimated stiffness at both the distal tibia and distal radius (Tsai *et al.*, 2017).

Switching from Antiresorptive to Anabolic Therapy

Most patients who are treated with anabolic drugs have already been treated with antiresorptive agents for extended periods. Nonetheless, it has become increasingly clear that switching from a bisphosphonate to an anabolic drug may result in transient cortical BMD loss and diminished BMD gains at sites of predominately trabecular bone, such as the lumbar spine (Finkelstein *et al.*, 2003, 2010; Boonen *et al.*, 2008; Ettinger *et al.*, 2004; Cosman *et al.*, 2009; Miller *et al.*, 2008). An example of this phenomenon is illustrated in a clinical trial in which 59 women who previously received either alendronate or raloxifene for 18–36 months were then administered 18-months of teriparatide (Ettinger *et al.*, 2004). In these women, spine BMD increased more in those who had previously received raloxifene than those who had received alendronate and total hip BMD decreased by −1.8% in the initial 6-months of teriparatide therapy in those previously treated with alendronate and then reverted to baseline with continued therapy. In a separate substudy of the EUROFORS trial, 24-months of teriparatide was administered to postmenopausal women who were either treatment-naïve or had prior antiresorptive use and spine BMD increased more in the treatment-naïve group than those with prior antiresorptive exposure (87% of the prior antiresorptive drugs were bisphosphonates) (Obermayer-Pietsch *et al.*, 2008). This pattern of blunted increases in spine BMD and either stable BMD or transient mild hip BMD loss when an oral bisphosphonate is followed by teriparatide has also been observed in several additional studies (Boonen *et al.*, 2008; Ettinger *et al.*, 2004; Cosman *et al.*, 2009; Miller *et al.*, 2008).

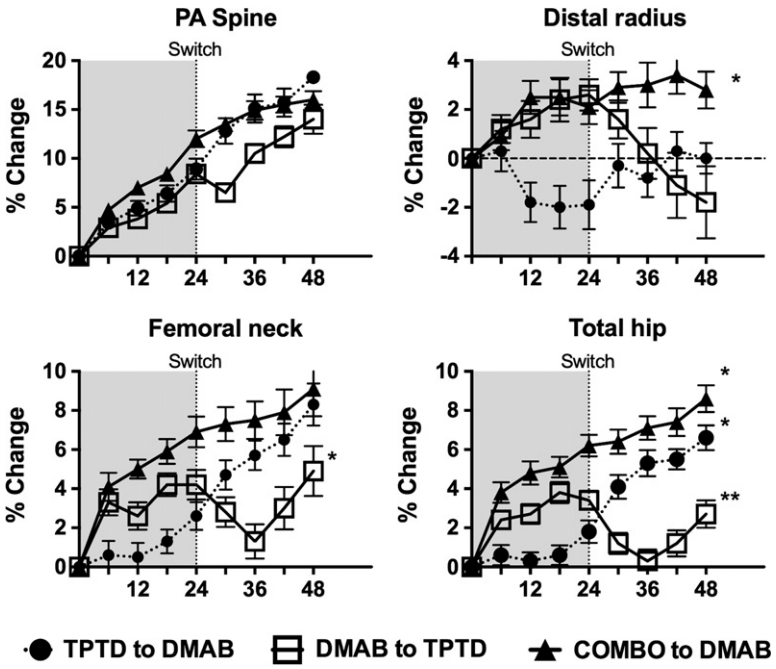

Fig. 3 Mean percent change (±SEM) in BMD from months 0–48 in subjects treated with teriparatide followed by denosumab (TPTD to DMAB), denosumab followed by teriparatide (DMAB to TPTD), and combination therapy followed by denosumab (COMBO to DMAB). $^{*}P < .05$ versus both other groups at month-48. $^{**}P < .0005$ versus both other groups at month-48. Adapted from Leder, B.Z., Tsai, J.N., Uihlein, A.V., Wallace, P.M., Lee, H., Neer, R.M. and Burnett-Bowie, S.A. (2015). Denosumab and teriparatide transitions in postmenopausal osteoporosis (the DATA-switch study): Extension of a randomised controlled trial. *Lancet* **386**, 1147–1155.

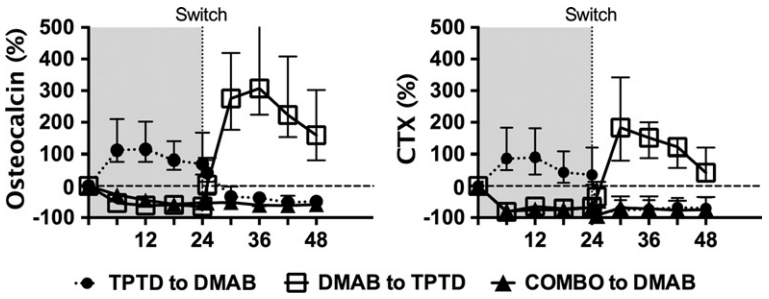

Fig. 4 Mean percent change (±SEM) in serum osteocalcin and c-telopeptide (CTX) from month 0–48 in subjects treated with teriparatide followed by denosumab (TPTD to DMAB), denosumab followed by teriparatide (DMAB to TPTD), and combination therapy followed by denosumab (COMBO to DMAB). Adapted from Leder, B.Z., Tsai, J.N., Uihlein, A.V., Wallace, P.M., Lee, H., Neer, R.M. and Burnett-Bowie, S.A. (2015). Denosumab and teriparatide transitions in postmenopausal osteoporosis (the DATA-switch study): Extension of a randomised controlled trial. *Lancet* **386**, 1147–1155.

In a recently published comparative efficacy clinical trial in which 436 postmenopausal women who had been previously treated with at least 3-years of bisphosphonate therapy were randomized to receive either 1-year of teriparatide or romosozumab, BMD at the spine, total hip, and femoral neck increased significantly more in patients treated with romosozumab than with teriparatide (Langdahl *et al.*, 2017). Despite this apparent comparative advantage, however, it should be noted that the romosozumab-induced increases in BMD appear to be lower than those observed in separate studies performed in treatment-naïve subjects, suggesting that the effects of romosozumab may also be blunted in the setting of prior bisphosphonate exposure (McClung *et al.*, 2014; Cosman *et al.*, 2016).

The transition from denosumab-to-teriparatide appears to result in a unique maladaptive pattern of high-turnover bone loss. In the DATA-Switch study previously described, women switched to teriparatide after 2-years of denosumab experienced 6-months of declining BMD at the spine, 12-months of declining BMD at the total hip and femoral neck, and progressive bone loss through all 24-months of treatment at the distal radius (**Fig. 3**) (Leder *et al.*, 2015). Notably, the decline in hip BMD after the switch resulted in the complete reversal of the denosumab-induced BMD increases achieved in the initial 2-years of denosumab monotherapy. At the distal tibia and distal radius, the transition from denosumab-to-teriparatide resulted in progressive decreases in total vBMD and cortical vBMD, increases in cortical porosity, and reduced bone strength as assessed by micro-finite element analysis (Tsai *et al.*, 2017). Moreover, the bone loss associated with this specific drug transition was accompanied by a dramatic stimulation of both bone formation and resorption. Specifically, levels of bone turnover markers increased 200%–300% 6–12 months after the drug transition and remained elevated even after 24-months (**Fig. 4**) (Leder *et al.*, 2015). This unprecedented stimulation of bone remodeling is concerning given that the more modest stimulation of bone turnover that occurs when denosumab is discontinued without a transition to teriparatide is associated with an increased risk of multiple vertebral compression fractures (Bone *et al.*, 2011; Cummings *et al.*, 2017).

Adding One Class of Drug to Another

When deciding to transition from one class of drug to another, an overlapping strategy may be preferable in some instances. In a trial of 198 postmenopausal women who received at least 18-months of alendronate or raloxifene, strategies of adding or switching to 18-months of teriparatide were compared (Cosman *et al.*, 2009). In the group who initially received raloxifene, spine and total hip BMD increased similarly in the add and switch groups whereas in the group who initially received alendronate, adding teriparatide increased spine BMD more than switching to teriparatide (hip BMD did not differ). Additionally, no early decreases in hip BMD were observed when teriparatide was added to either ongoing raloxifene or alendronate.

In a trial of 125 postmenopausal women with osteoporosis who had received 9-months of teriparatide, the effects of adding raloxifene, adding alendronate, or continuing teriparatide for 9 months were compared (Muschitz *et al.*, 2013). Spine BMD increased more in the raloxifene-add group than the group who continued teriparatide monotherapy whereas total hip BMD increased more in the alendronate-add group than both other groups during months 9–18. Additionally, in a 12-month extension to this study in which teriparatide was discontinued in all three groups, the greatest BMD gains were observed in women who consecutively received 9-months teriparatide, 9-months of combined teriparatide/alendronate and 12-months of alendronate monotherapy (Muschitz *et al.*, 2014).

Summary

In summary, when given sequentially, anabolic therapy should be given prior to bisphosphonates in order to achieve maximal gains in spine and hip BMD. The sequence of denosumab followed by teriparatide should be avoided due to high bone turnover BMD loss, especially given the known increased risk of vertebral fractures after denosumab alone is discontinued. While the

combination of bisphosphonates and PTH analogs do not result in additive effects, the combination of denosumab and teriparatide is uniquely effective. Lastly, approaches that overlap anabolic and antiresorptive therapy in either order deserve additional study.

Introduction

Despite many advances in the diagnosis of osteoporosis, the assessment of fracture risk, the development of therapies to reduce the risk of fractures, and the production of best practice guidelines, many studies indicate that a minority of men and women at high fracture risk actually receive treatment (Harvey *et al.*, 2017a). Even in patients who sustain a fragility fracture, fewer than 20% actually receive therapies to reduce the risk of fracture in the year following the fracture (Giangregorio *et al.*, 2006; Kanis *et al.*, 2014a), with particularly poor rates of treatment for older women and those who live in long term care. Disparities in use of fracture risk assessment tools such as FRAX® vary one thousand-fold worldwide, with a far greater variability than the 30-fold range of crude, or 10-fold range of age-standardized hip fracture worldwide, indicating a large gap in service provision (Kanis *et al.*, 2012, 2014b). Limitations in access to the internet, lack of national assessment guidelines for osteoporosis in many countries, and the availability of alternative assessment algorithms may partially explain these differences (Kanis *et al.*, 2014b). Not only is lack of assessment and lack of treatment of those at very high risk of further fracture such as hip fracture a concern, most worrying is the downward trend in people being treated after hip fracture, demonstrated both in the USA and UK populations (Solomon *et al.*, 2014; Hawley *et al.*, 2016). The precise causes for this trend are likely to be several, including the recent reimbursement changes in the US, and the massive inflation of concerns regarding potential rare side effects of long-term bisphosphonate treatment such as osteonecrosis of the jaw and atypical femoral shaft fractures. In this review, we give an overview of the treatment gaps at all levels, potential underlying reasons, and possible approaches to help reverse the situation.

The Osteoporosis Treatment Gap

There are now data, from both Europe and the United States, demonstrating substantial disparities between the number of individuals at high fracture risk, or who have experienced a low trauma fracture, and the number who receive appropriate assessment and treatment for osteoporosis (Harvey *et al.* 2017a). Thus in the UK, analysis of the Clinical Practice Research Datalink (CPRD) has demonstrated substantial gaps in both primary and secondary prevention. The probability of being prescribed any antiosteoporosis drug after hip fracture in the UK increased from only 7% in 2000 to 46% in 2010 (Klop *et al.*, 2014). This trend was more marked in patients $\geq$75 years. The increase in prescribing of antiosteoporosis drugs was complemented by a similar increase in vitamin D/calcium provision. The cumulative incidence of antiosteoporosis therapy was greater at any given point in time in women (8% in 2000, 51% in 2010) than in men (4% in 2000, 34% in 2010). Despite $<$50% of hip fracture patients receiving treatment, more recent data suggest a plateau and a possible decrease in prescriptions from around 2011 (Hawley *et al.*, 2016). Furthermore, there appears to be substantial geographic heterogeneity in the UK amongst treatment rates following hip fracture. For example, in a CPRD analysis based on the UK healthcare regions, the odds ratio for antiosteoporosis medication following a hip fracture was 1.29 (95% CI: 0.89, 1.87) for the North East and 0.56 (95% CI, 0.43, 0.73) in South Central regions, the North West being the referent. These geographic differences in prescribing persisted over the 5-years of follow-up (Shah *et al.*, 2017). Additionally, data from the GLOW study, a prospective observational study of over 60,000 older women recruited from primary care practices in 10 countries across US, Europe, and Australia, showed that $>$80% of women with a fragility fracture did not receive osteoporosis treatment (Greenspan *et al.*, 2012).

 doi:10.1016/B978-0-12-801238-3.99202-X

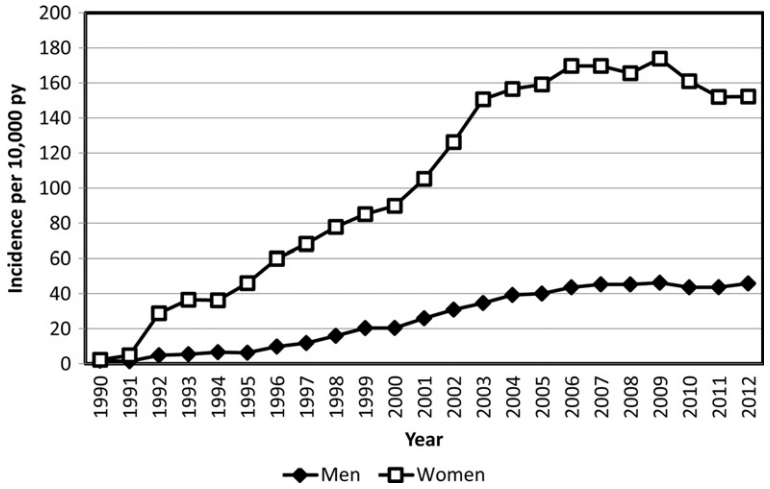

Fig. 1 Incidence of antiosteoporosis medication prescription from 1990 to 2012 in the UK population aged 50 years or over. Reproduced with permission from van der Velde, R.Y., Wyers, C.E., Teesselink, E., Geusens, P.P., van den Bergh, J.P., de Vries, F., Cooper, C., Harvey, N.C., van Staa, T.P. (2017). Trends in oral anti-osteoporosis drug prescription in the United Kingdom between 1990 and 2012: Variation by age, sex, geographic location and ethnicity. *Bone* **94**, 50–55.

These differences by geography, ethnicity and time for secondary fracture prevention are consistent with findings relating to primary use of antiosteoporosis medications. Between 1990 and 2012, rates of antiosteoporosis medication prescription in the UK rose from 2.3 to 169.7 prescriptions per 10,000 person-years amongst women from 1990 to 2006, but this was followed by a plateau and then a 12% decrease over 2009 to 2012 (**Fig. 1**). Prescription rates rose less steeply in men from 1990 to 2007 and plateaued from 2008 onwards. There were marked differences in prescription of antiosteoporosis medications according to ethnicity and geographic location (van der Velde *et al.*, 2017).

In Europe, treatment uptake for osteoporosis increased progressively up to 2008, thereafter plateaued, and has subsequently fallen in more recent years (**Fig. 2**). The phenomenon is most marked in the case of the bisphosphonates and is evident on a country by country basis (Svedbom *et al.*, 2013). The number of patients treated in each country was computed from IMS Health sales data for 2010, adjusted for suboptimal adherence, and expressed as treatment years (Hernlund *et al.*, 2013). The use of hormone replacement therapy was excluded since the majority of women take this treatment for menopausal symptoms rather than for osteoporosis. The proportion of patients eligible for treatment depended on defining an intervention threshold that is, the risk of fracture above which treatment can be recommended. In this report, the intervention threshold set was at the FRAX-based 10-year fracture probability equivalent to women with a prior fragility fracture without knowledge of BMD as adopted in several European guidelines (Kanis *et al.*, 2013a; Lekamwasam *et al.*, 2012a; Compston *et al.*, 2017). Thus, the intervention threshold can be likened to a "fracture threshold" expressed in terms of fracture probability. The study showed a very wide inter-country variation in the treatment penetration of individuals at high risk for osteoporotic fractures. The treatment gap varied from 25% in Spain to 95% in Bulgaria. Large treatment gaps were identified in countries with populations at both high and low risk of fracture. In total in the EU, it was estimated that, out of the 21.3 million men and women who exceeded the risk level, 12.3 million were untreated in 2010 (Hernlund *et al.*, 2013). These figures are conservative since an undetermined proportion of low risk women will have received treatment (Diez-Perez *et al.*, 2011). In an international prospective study, low uptakes of pharmacological intervention after hip fracture was also observed. Amongst 1795 patients who sustained a low-energy hip fractures in ten countries (Australia, Austria, Estonia, France, Italy, Lithuania, Mexico, Russia, Spain, and the United Kingdom), only 27% were prescribed pharmacological fracture prevention after the hip fracture (Svedbom *et al.*, 2013).

Data from the US suggest a similar pattern. In a large retrospective analysis of nearly 100,000 men and women aged 50 years or more who were hospitalized for hip fracture over a period of 1 year, based on U.S. administrative insurance claims data, the uptake of osteoporosis medication within 12 months after discharge from hospital was examined (Solomon *et al.*, 2014). The estimated probability of receiving osteoporosis medication within 12 months after discharge from hospital was 28.5% over this time period but varied by year. Indeed, the rates declined significantly over a 10-year interval, from 40.2% in 2002 to 20.5% in 2011 (Solomon *et al.*, 2014). Congruent findings come from analysis of the US Medical Expenditure Panel Survey, demonstrating a marked reduction in the prevalence of bisphosphonate use amongst women from 2007 onwards. Rates in men appeared to decline, albeit from a much lower baseline, over the same period (Jha *et al.*, 2015).

Reasons Underlying the Treatment Gap

There appear to be many factors in the poor rates of treatment for osteoporosis, including the insufficient implementation of strategies to effect primary and secondary prevention. Fundamentally, primary prevention is always made difficult by the concept

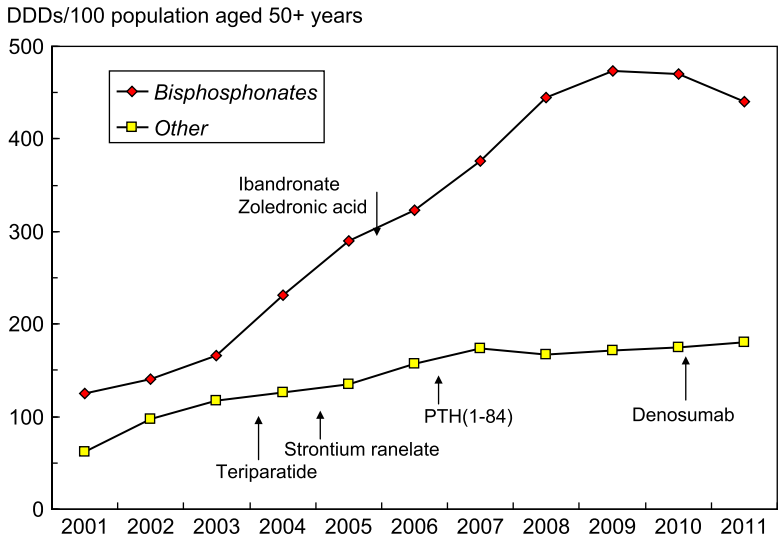

Fig. 2 Estimated sales (defined daily doses (DDDs)/100 population aged 50+ years) from 2001 to 2011 in the European Union. Reproduced with permission from Hernlund, E., Svedbom, A., Ivergard, M., Compston, J., Cooper, C., Stenmark, J., McCloskey, E.V., Jonsson, B., Kanis, J.A. (2013). Osteoporosis in the European Union: Medical management, epidemiology and economic burden: A report prepared in collaboration with the International Osteoporosis Foundation (IOF) and the European Federation of Pharmaceutical Industry Associations (EFPIA). *Archives of Osteoporosis* **8**, 136.

of managing a future "risk", rather than treating a disease event which has already happened. However, a hip fracture, for example, is a devastating life event, with a 20% associated reduced survival compared with non-fracture peers (Harvey *et al.*, 2010); in the analogous situation of an acute myocardial infarction, it is difficult to imagine a situation in the developed world in which it would be acceptable for <50% of such cardiac patients receiving preventative treatments such as aspirin, statins, and anti-hypertensives (Austin *et al.*, 2008). It is apparent that musculoskeletal disease may be viewed both by patients and policymakers as a lower priority than outcomes such as myocardial infarction and cancer (Harvey *et al.*, 2017a). Conversely, the Global Burden of Disease initiative has demonstrated musculoskeletal disease to be a leading cause of disability worldwide (Harvey *et al.*, 2014). These observations suggest a mismatch between the severity of the condition, and associated perceptions; this is well documented in the large international GLOW cohort, in which many women underestimated their fracture risk compared with their peers (Siris *et al.*, 2011). Against this backdrop, studies cited above have clearly demonstrated a successful increase in antiresorptive treatment rates both in primary and secondary prevention over the last 15 years. Advances in risk assessment and policy, for example through the use of risk calculators such as FRAX (Kanis *et al.*, 2011, 2016), guidance on intervention (Kanis *et al.*, 2013a), together with the availability of generic bisphosphonates, have helped to improve the clinical situation. It is therefore tragic in the context of this maturing field that treatment rates, both before and after a fracture, have declined in recent years, despite inexorable expansion of the population at risk (Oden *et al.*, 2015). Two studies have suggested possible reasons for this. Jha *et al.* examined relationships between medication use (data from the Medical Expenditure Panel Survey and National Inpatient Sample in the US), internet search activity for alendronate between 2006 and 2010, and media reports of safety concerns (Jha *et al.*, 2015). Against the backdrop of a decline in bisphosphonate use by >50% between 2008 and 2012, there were marked spikes of internet search activity corresponding to events such as a 2006 lawsuit filed against Merck for Fosamax allegedly causing osteonecrosis of the jaw, a major ABC World News feature on Fosamax and atypical femoral fractures in 2010, and several other media reports of such rare, but serious side effects. Similar findings have come from the Australian Longitudinal Study on Women's Health (Peeters *et al.*, 2014). Consistent with the US data, total use of antiosteoporosis medications increased over the period 2000 to 2007 but then decreased from 2007 to 2010. Despite relaxing indications for bone density testing and a subsidy for antiosteoporosis medications, the decline coincided with adverse media stories such as a major report on osteonecrosis of the jaw in 2007 (Peeters *et al.*, 2014).

Whilst serious long-term adverse side-effects of bisphosphonates are very rare in absolute terms (with incidences in the range of 1/100,000 to 1/10,000 per year) (Adler *et al.*, 2016), the approach to risk/benefit communication has largely amongst the media (as demonstrated above) and unfortunately amongst physicians and policymakers, been very much on the side of declaring risk. Recognition that the underlying disease is associated with substantial morbidity and increased mortality, with fracture risk markedly reduced by antiosteoporosis medications, seems largely under-articulated in these discussions. Indeed, the recent UK National Institute for Health and Care Excellence (NICE) guidance on multi-morbidity (Farmer *et al.*, 2016) specifically targeted bisphosphonates for review after 3 years treatment despite evidence for longer term efficacy and safety being more reliable than for other treatments considered. Such concerns do very little to improve osteoporosis care in the setting of declining treatment rates overall. Reassuringly in terms of the risk-benefit ratio, a recent study in the Danish population has demonstrated that users of alendronate still have a reduced risk of fracture compared with matched controls even after 10 years use, and that the number of

Table 1 Number of central DXA units available in the EU27 countries per million of the general population

Country	*DXA units/million*	*Country*	*DXA units/million*	*Country*	*DXA units/million*
Austria	28.7	Germany	21.1	Netherlands	10.7
Belgium	53.0	Greece	37.5	Poland	4.3
Bulgaria	1.2	Hungary	6.0	Portugal	26.9
Cyprus	23.9	Ireland	10.0	Romania	2.4

Finland	16.8	Luxemburg	2.0	Sweden	10.0
France	29.1	Malta	9.7	UK	8.2

hip fractures prevented is still substantially greater than the number of subtrochanteric fractures occurring even by the end of a decade of bisphosphonate treatment (Abrahamsen *et al.*, 2016). It is patently clear that the field needs to dramatically improve its approach to communicating the risks and benefits of treatments, and to robustly counter ill-informed adverse media stories in a timely fashion.

Healthcare Policies and Osteoporosis Assessment

Osteoporosis, in comparison with comparable non-communicable diseases, has rarely attracted proportionate levels of attention from healthcare providers and governments, and an individual nation's policy on access to bone densitometry with dual-energy X-ray absorptiometry (DXA) and its reimbursement will greatly influence the assessment and treatment of this disease. The International Osteoporosis Foundation (IOF) has published various regional audits (https://www.iofbonehealth.org/regional-audits) covering the European Union, Eastern Europe and Central Asia, Latin America, North America, the Middle East and Africa, Asia Pacific in terms of epidemiology, burden and costs of osteoporosis. Taking Asia Pacific as an example, whilst Australia, Hong Kong, Japan, New Zealand, Republic of Korea and Singapore had 12–24 DXA machines per million of population, China, India, Indonesia, Pakistan, Philippines, Sri Lanka and Vietnam were greatly under-resourced with less than 1 DXA machine per million of population. In addition, BMD testing and osteoporosis treatment were not fully reimbursed by insurance or healthcare policies in many countries, which served as a barrier to accessing treatment.

In Europe, it was assumed that 11 DXA machines per million of population were needed to provide adequate osteoporosis care. 16 European countries fell into this category of adequate provision, and 9 countries were considered to have very inadequate provision with <8.4 DXA units per million (Bulgaria, Czech Republic, Hungary, Latvia, Lithuania, Luxembourg, Poland, Romania, and the United Kingdom). **Table 1** shows the number of DXA units per million of population in the EU27 countries as estimated in 2010 (Kanis *et al.*, 2013b). Reimbursement for DXA scans was extremely variable between EU member states in terms of the criteria required and level of imbursement awarded—interestingly in some countries reimbursement for DXA was only offered if the BMD measurement demonstrated osteoporosis (Bulgaria and Switzerland), only if after fracture (Germany), or only if seen by a specialist (Poland).

Though no official IOF audit is available for North America, reimbursement for treatment also varies greatly, depending on each individual patient's health insurance plan. However, healthcare reform is evolving in the USA from fee for service to supporting improved quality, prevention and care coordination with financial incentives to encourage healthcare professionals or systems to report on or improve patient outcomes. However, performance measures on osteoporosis assessment remain low compared to other major chronic diseases, and a major drop in reimbursement for DXA scans in the office setting has led to a fall in the number of DXA providers and more than 1 million fewer DXA scans performed per annum (Overman *et al.*, 2015). Recent evidence suggests that this coincides with a plateau in the secular decline in age- and sex-adjusted hip fracture rates which had been apparent up until 2012 (Lewiecki *et al.*, 2016).

Approaches to Closing the Gap

Identification of Patients at High Risk of Fracture

It is apparent from the evidence described above, that osteoporotic fractures place a huge burden on societies across the world. It is well known that osteoporosis is a silent disease until a fracture occurs. Patient perception of fracture risk is often underestimated (Grover *et al.*, 2014; Gregson *et al.*, 2014), so initiation of primary prevention is usually reliant on health care practitioners. It is unsurprising therefore that secondary prevention (identifying individuals for treatment on the basis of a low trauma fragility fracture occurring) is the approach most often taken as the starting point for fracture prevention. However, whatever approach is taken to the reduction of fracture risk, it is critically important to place this within the context of local factors, such as the

background population fracture risk, prevalent patterns and risk factors, funding constraints and willingness of healthcare providers to pay for treatment.

Secondary Fracture Prevention

Following attendance to a healthcare practitioner with a new fracture, it is important to assess fracture risk in a straightforward way, and to treat if appropriate. Several methods have been explored—some staff based, some IT-based and others a combination of the two. The most successful systems usually focus on a multi-disciplinary Fracture Liaison Service (Eisman *et al.*, 2012; Mitchell, 2013), incorporating orthogeriatricians, rheumatologists, other physicians and clinical nurse specialists. They work in a multi-disciplinary team to ensure that medical management of patients admitted with fracture is optimized, both whilst in hospital and for future fracture prevention, ideally with a lead clinician responsible for coordinating the team (Drew *et al.*, 2016). The International Osteoporosis Foundation has recently instituted "a global campaign to facilitate the implementation of coordinated, multi-disciplinary models of care for secondary fracture prevention." The "Capture the Fracture®" (http://www.capturethefracture.org/) initiative has provided guidance on secondary fracture prevention, and also a global map, with a quality grading scheme, on which, subject to application, secondary fracture prevention services can be documented (Akesson *et al.*, 2013). There is currently huge variation, not only between, but also within countries, and in the availability, scope and quality of secondary prevention facilities. The Capture the Fracture initiative, aimed at raising the quality and coverage of fracture liaison services providing secondary prevention for osteoporosis, should provide a clinically valuable and cost-effective contribution to service improvement (Mitchell *et al.*, 2016).

Further important initiatives around case finding of fragility fractures centre around vertebral fractures—around 12% of postmenopausal women with osteoporosis have at least one vertebral deformity, with less than a third of these individuals coming to clinical attention (Cooper *et al.*, 1992). Primary care based screening strategies (Clark *et al.*, 2012), and history-taking strategies distinguishing back pain likely to relate to vertebral fracture from other types of back pain may facilitate detection of these fractures (Clark *et al.*, 2016). In addition, consistent reporting of radiographs, CT scans and the incorporation of vertebral fracture assessment in DXA scans will help with secondary fracture prevention in individuals with prevalent osteoporotic vertebral fracture.

Primary Fracture Prevention

In osteoporosis, as in any non-communicable chronic disease, there is clearly a balance between the benefits of a systematic screening approach leading to widespread treatment, with associated increased cost and risk of side-effects, and a case-finding strategy focused on those at greatest individual risk, with associated problems of under-treatment. Although, DXA screening is standard in the US (at the age of 65 years in women, and age 70 in men, and in individuals over the age of 50 years who have suffered an adult fracture) (Cosman *et al.*, 2014), in the majority of countries population screening is not judged to be cost-effective and primary prevention is focused more on opportunistic case-finding, triggered by the presence of clinical risk factors (Kanis *et al.*, 2013a; Lekamwasam *et al.*, 2012a,b; Compston *et al.*, 2017). A seven-centre randomized controlled trial of the effectiveness and cost-effectiveness of screening older women in primary care for the prevention of fractures (the UK SCOOP study), in which approximately 12,500 older women were randomized to either normal care or screening and subsequent treatment (based upon the FRAX risk assessment tool), has recently demonstrated that this intervention leads to a reduction in hip fracture risk (Shepstone *et al.*, 2012, 2017).

Health Economic Considerations

There are two major approaches to the health economic assessment in a particular condition. Firstly, one can assess the cost-effectiveness of the intervention, and set the threshold for intervention, for example FRAX probability, accordingly. Alternatively, one can derive a clinically informed and appropriate intervention threshold, and use cost-effectiveness analysis to validate a threshold. The 2017 National Institute for Health and Care Excellence (NICE) updated Multiple Technology Appraisal (MTA) on bisphosphonate use in osteoporosis (NICE, 2017) illustrates how, for a common disorder, the former approach, with strict application of cost-effectiveness thresholds for relatively inexpensive drugs, may lead to counter-intuitive and potentially harmful guidance (Sims, 2017; Harvey *et al.*, 2017b). The MTA incorporates the development of fracture risk calculators based on individualized clinical risk factors, such as FRAX and QFracture, (both recommended by NICE for the assessment of fracture risk in certain sections of the population (NICE, 2012)), and also the widespread availability of low-cost generic forms of the main oral and intravenous bisphosphonates. This latter development has led, in the NICE analysis, to cost-effectiveness at very low risk thresholds, resulting in an appraisal which recommends that, amongst individuals who qualify for osteoporosis assessment on the basis of the NICE Clinical Guideline CG146 on fracture risk assessment (NICE, 2012), treatment with oral bisphosphonates may be instituted above a 1% probability of major osteoporotic fracture (hip, spine, wrist or humerus) over 10 years, or above 10% for intravenous bisphosphonates. These health-economic-derived thresholds create a real danger of excessive bisphosphonate prescription in the general population (Sims, 2017), with treatment of substantial numbers of people who are at very low individual fracture risk; for example, every person eligible for assessment under CG146, including all women aged ≥ 65 and men ≥ 75 years,

would be recommended treatment if the MTA recommendations were interpreted as intervention thresholds (Kanis *et al.*, 2008). Very rare, but serious, side-effects of bisphosphonate treatment, such as atypical femur fracture and osteonecrosis of the jaw, would be observed far more commonly in the population than at present. Furthermore, the risk/benefit balance for individuals at low risk would be adversely affected, in contrast to the very clearly positive benefit/risk ratio associated with intervention at more clinically appropriate treatment thresholds (Adler *et al.*, 2016; Compston *et al.*, 2017; Rizzoli *et al.* 2011). In contrast, whilst the derivation of treatment thresholds is necessarily arbitrary, the UK National Osteoporosis Guideline Group (NOGG) used the second approach, developing its guidance on the basis of clinical appropriateness, setting the threshold at the age-specific 10-year FRAX probability of fracture equivalent to women having already sustained a fracture. Thus, economic thresholds were not used to set intervention thresholds but, more appropriately, to validate the use of clinically driven intervention thresholds. This approach, which avoids inappropriate over-treatment of older individuals and under-treatment of younger individuals, has been shown to be cost-effective (Kanis *et al.*, 2008), and has been adopted in many countries (Kanis *et al.*, 2016).

The cost effectiveness of individual therapies for osteoporosis have recently been comprehensively reviewed (Hiligsmann *et al.*, 2015). Of the 1794 articles identified across a range of databases, 39 studies fulfilled the inclusion criteria. These covered 14 different countries and within them 9 active interventions were assessed. When the interventions were compared with no treatment, active antiosteoporosis drugs were generally cost-effective in postmenopausal women aged over 60–65 years with low bone mass, especially amongst those with prior vertebral fractures. Factors which increased cost-effectiveness included higher individual fracture risk and medication adherence.

Summary

Whilst assessment for fracture risk, and use of antiosteoporosis medications, have increased markedly over the last 20 years, there is evidence from the United Kingdom, United States, and continental Europe that treatment rates have declined substantially in the last 5 years. Concerns amongst patients and clinicians around rare side effects of anti-resorptives, compounded by dramatic and widespread media reports, have been complemented by adverse changes in reimbursement in the US, and reflected in new guidance. Indeed, many doctors, dentists, and patients are now more frightened of the rare but serious side effects than they are of the disease and the fractures that arise. Notwithstanding, the lay press is simply the messenger bringing news and opinion from the scientific community, some or much of which may be ill-judged. The paradox arises that we seek to treat individual patients to the highest standards but at the same time bring disservice and disadvantage to the wider osteoporosis community. It is now time for us all to accept a long overdue collective responsibility for our failures and to work cohesively to improve the management of our patients.

Cancer Treatment-Induced Bone Loss (CTIBL)

Catarina Abreu, Maria R Dionísio, and Joana C Silva, Hospital of Santa Maria, Lisbon, Portugal
Luís Costa, Hospital of Santa Maria, Institute of Molecular Medicine, Faculty of Medicine, University of Lisbon, Lisbon, Portugal

Introduction

Bone loss is associated with an increased risk of fractures and comorbidities. Osteoporosis is defined as a skeletal disorder characterized by compromised bone strength predisposing to an increased risk of fractures. Furthermore, recent evidence suggests that the process of bone loss may play an important role in implanting tumor cell aggregates in bone (metastatic niche) (Ibrahim *et al.*, 2013; D'Oronzo *et al.*, 2015).

Drugs used in cancer treatment (like endocrine therapy, androgen deprivation therapy, and chemotherapy) may induce bone resorption, bone loss and a consequently high risk of bone fractures.

Therefore, assessing which patients are at risk, performing an early detection of bone loss, and implementing preventive measures and treatment is critical. Measures to secure bone health should be implemented early in the course of disease (Ibrahim *et al.*, 2013).

Risk Factors

Identification of patients at risk for cancer treatment -induced bone loss (CTIBL) is key to prevent further bone loss. In this setting, the following risk factors should be considered (D'Oronzo *et al.*, 2015; Doo and Shapiro, 2013; Hadji, 2015).

- Endocrine factors, such as hyperparathyroidism, vitamin D deficiency and menopause.
- Immobility, which prevents osteocyte-regulated bone turnover.
- Genetic factors, since certain gene polymorphisms (of IL-6, IL-1 receptor, and IL-1R antagonist) have been associated with a lower bone mass density (BMaD) in post-menopausal women.
- Family history of osteoporosis.
- Smoking history.
- Alcoholism.
- Chronic corticosteroid treatment (>6 months).
- Older age (>65 years).
- Body mass index <24.
- Low calcium and vitamin D dietary intake.
- Family and/or personal history of previous vertebral/hip fractures.

Diagnosis

Several diagnostic exams can be performed to better characterize bone loss and the risk of fractures.

Initially, a detailed medical history, physical exam, and medication review is required to look for risk factors.

A comprehensive laboratory assessment is necessary and should include serum levels of calcium, phosphate, 25-hydroxyvitamin D, parathyroid hormone, hemoglobin, C-reactive protein, alkaline phosphatase, thyroid-stimulating hormone, creatinine clearance and protein electrophoresis (serum and/or urine).

A dual energy X-ray absorptiometry (DEXA) scan of the hip, lumbar spine and femoral neck is the best way to determine BMaD and a predictor of fracture risk. It is highly precise, with a moderate cost and low radiation exposure. Periodic BMaD evaluations are recommended in women with iatrogenic ovarian failure (those that have treatment-related amenorrhea for >1 year should have BMaD assessed), in postmenopausal women treated with aromatase inhibitors (AIs), and in all breast cancer patients with fracture risk factors. BMaD detection is also mandatory in men on ADT. (D'Oronzo *et al.*, 2015) Z-scores ≤ -2.0 are considered below the expected age range, whereas Z-scores > -2 are within the expected age range (Doo and Shapiro, 2013).

The World Health Organization (WHO) provides a clinical tool—the Fracture Risk Assessment tool (FRAX)—to evaluate the 10-year probability of major osteoporotic fractures based on several risk factors. However, anticancer treatments are not included as a specific risk factor (D'Oronzo *et al.*, 2015; Doo and Shapiro, 2013). Also, current fracture risk assessment tools are based on data from healthy postmenopausal women and do not properly address treatment risks in younger premenopausal women (Coleman *et al.*, 2014).

 doi:10.1016/B978-0-12-801238-3.66136-6

BMaD-based osteoporosis treatment guidelines in postmenopausal women do not generally apply to premenopausal women, as the relationship between bone mass and fractures is not the same in both groups. Nevertheless, it is an indication for further evaluation in premenopausal women (Becker and Cohen, 2017).

Cancer Treatments Leading to Bone Loss

Endocrine Therapy (Figs. 1 and 2)

The early days of endocrine therapy (ET) for breast cancer date back to 1896, when Beatson performed the first oophorectomy in premenopausal women. Today, after >100 years of investigation, ET plays a major role in breast cancer treatment, both in early disease and metastatic setting. Indeed, most breast cancer diagnosis belong to the ET-responsive subtype, accounting for 70% of all cases.

According to the European and American Guidelines, ET is indicated in patients with detectable estrogen receptor (ER) expression (defined as ≥1% of invasive cancer cells) (Senkus *et al.*, 2015). The choice of agent is primarily determined by patient's menopausal status. It is acknowledged that in premenopausal women estrogen production is dependent on ovarian tissue, whereas in postmenopausal women aromatase enzyme converts androgens to estrogens in the adrenal gland, inhibiting CYP-19 cytochrome P450 enzyme.

Although bone loss induction differs according to ET regimen, 78% of women with breast cancer have at least one secondary cause of bone loss besides cancer or cancer-related therapies. Among secondary causes, the most common is vitamin insufficiency, with 38% of women presenting with vitamin D below 30 ng/mL [74.9 nmol/L]. Other causes of bone loss include idiopathic hypercalciuria and normocalcemic hyperparathyroidism (Camacho *et al.*, 2008).

The mechanisms by which estrogen regulates bone remodeling are not fully understood. Estrogen is known to affect osteoclastogenesis and osteoclast function through its effects on local cytokines and growth factors (produced by either bone cells or adjacent marrow cells estrogen). Furthermore, it regulates the life span of mature osteoclasts via induction of the Fas/Fas-ligand (FasL) system, thereby providing a rational for the osteoprotective function of estrogen, as well as of selective estrogen receptor modulators (SERMs). Both estrogen and SERMs primarily act by regulation of gene transcription via estrogen receptors (estrogen receptor alpha [ERα] and estrogen receptor beta [ERβ]) (Couse and Korach, 1999; Shang and Brown, 2002).

Several ETs are currently available, including aromatase inhibitors (AIs)—which include steroidal (exemestane) and non-steroidal inhibitors (letrozole, anastrozole)–, SERMs—like tamoxifen and raloxifene–, and estrogen receptor downregulators—like fulvestrant.

Anastrozole was the first selective non-steroidal AI to be used in clinical practice. It works by inhibition of conversion of androstenedione or testosterone to estrone, causing a decrease in bone mineral density (BMiD). Exemestane and letrozole are more recent, third-generation, agents of this class.

In vivo animal studies suggest that, due to its androgenic structure, exemestane may be more bone-sparing than letrozole (Lønning *et al.*, 2005).

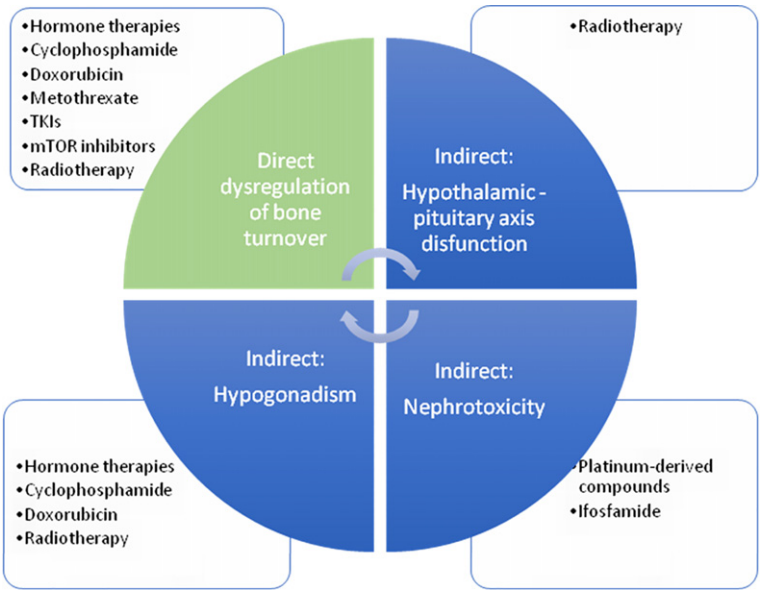

Fig. 1 Mechanisms of cancer treatment-induced bone loss. Adapted from D'Oronzo, S., et al. (2015). Cancer treatment-induced bone loss (CTIBL): Pathogenesis and clinical implications. *Cancer Treatment Reviews* **41**(9), 798–808.

Drug	Mechanism of boneloss
Hormone therapies	Hypogonadism, decrease OB proliferation, increase OB apoptosis
Platinum-derived compounds	Nephrotoxicity (hypomagnesemia)
Ifosfamide	Nephrotoxicity (oxidative stress) tubular damage with hypophosphatemia
Cyclophosphamide	Hypogonadism, decrease bone formation and resorption
Doxorubicin	Hypogonadism, decrease OB formation, increase OC formation and activation
Methrotexate	Decrease OB proliferation, osteocyte apoptosis
TKIs	Bone-damaging effect: hypocalcemia and secondary hyperparathyroidism Bone sparing effect: decrease OC differentiation and activity, increase OB activation
Radiotherapy	Hypogonadism, imbalanced activities of OBs and OCs
OB: osteoblast; OC: osteoclast; TKIs: tyrosine kinase inhibitors	

Fig. 2 Type of treatment and respective mechanisms of cancer treatment-induced bone loss. Adapted from D'Oronzo, S., et al. (2015). Cancer treatment-induced bone loss (CTIBL): Pathogenesis and clinical implications. *Cancer Treatment Reviews* **41**(9), 798–808.

Tamoxifen, a type II competitive inhibitor of estradiol at its receptor, acts as an inhibiting agent (anti-estrogen) in the mammary tissue, but as a stimulating agent in cholesterol metabolism, bone density, and cell proliferation in the endometrium (Shang and Brown, 2002).

Osteoprotection observed with SERMs is, at least partially, mediated by osteoclastic ERα in trabecular bone, and life span of mature osteoclasts is regulated through activation of the FasL signaling.

SERMs ERα-activated seem to truncate the already short lifespan (approximately 2 weeks) of differentiated osteoclasts, by inducing apoptosis through activation of the Fas/FasL system (Takashi Nakamura, 2007).

As an increasing number of women is exposed to AIs, these agents' adverse effects on the skeleton are important to understand. AIs lead to a marked increase in bone resorption, with a two to fourfold increase in bone loss compared to the postmenopausal physiologic BMiD loss (Hadji, 2009). Randomized controlled trials (RCTs) including an AI for 5 years showed an increase in the absolute fracture risk of around 10%, suggesting that one in every 10 women will eventually experience a bone fracture. Real world data indicate 18%–20% fracture risk after 5 years of follow-up. After conclusion of AI treatment, bone turnover normalizes and BMD and fracture risk can partially recover.

For those advocating an AI treatment extension for up to 10 years, a further increase in fracture risk, corresponding to 2%–3% per year, has been registered and should be taken into account.

For most pre-menopausal women eligible for ET, a 5-year tamoxifen 20 mg/day treatment, with or without ovarian suppression, is the option. The exception is for premenopausal women with HR-positive breast cancer at higher risk of recurrence 5 years, for whom the indication is for AIs plus ovarian suppression. The more sudden and severe estrogen deprivation, the greater the magnitude of bone loss. Bone loss is more rapid in premenopausal women receiving both ovarian suppression therapy (GnRH agonist) and an AI.

Patients undergoing ovarian suppression and those taking AIs are at an increased risk of bone loss and should be advised to have an adequate calcium and vitamin D3 intake. Additionally, a periodic assessment of BMD (by dual energy X-ray absorption [DEXA] scan) should be undertaken by these patients.

Some clinical studies investigated the impact of osteoporosis in clinical fractures. The MA-27 trial compared exemestane and anastrozole as adjuvant treatment in postmenopausal women and did not find a difference in the frequency of new clinical fractures between both treatments (4% for each) (Goss *et al.*, 2013). In the ATAC (Arimidex [anastrozole], Tamoxifen, Alone or in Combination) trial, 9366 postmenopausal women with invasive operable breast cancer who completed primary therapy were randomly assigned to receive anastrozole, tamoxifen, or both. More fractures were observed in patients on anastrozole compared with patients on tamoxifen. Also when looking at BMD in trials with AIs, BMD of the lumbar spine (LS) and total hip (TH) was significantly reduced in postmenopausal women receiving AIs versus tamoxifen or placebo. In the ATAC substudy, there was a 6% and 7.2% BMD loss with AI, and a 2.8% and 0.74% increase with tamoxifen, respectively. The annual fracture incidence was higher in women receiving anastrozole (11% vs. 7.7%) throughout the 5-year treatment period; at the sixth year, fracture rate decreased in women previously assigned to anastrozole; and in years 7–9, fracture rates were similar with both treatments, suggesting that AI-related fracture rates will not be a major event when treatment cessation occurs (Howell *et al.*, 2005).

The Intergroup Exemestane Study (IES) also demonstrated that postmenopausal women receiving tamoxifen for 2–3 years who continued on tamoxifen or switched to exemestane experienced a greater decline in BMD at the lumbar spine (2.7%) after 6 months compared with those who remained on tamoxifen (no change at either site) (Coleman *et al.*, 2007).

In the MA-17 trial, 5149 postmenopausal women were randomized to letrozole versus placebo after completion of 5 years of tamoxifen treatment. A total of 256 women registered a clinical fracture (5.3% of patients assigned to letrozole compared with 4.6% assigned to placebo) (Perez *et al.*, 2006).

Overall, analysis of data on the use of AIs, both continuously or with switch, shows that ET is associated with a significant bone mass density and that it correlates with treatment extent. Discussion about the trade -off between quality of life (Qol) and treatment duration, considering risk of fracture, osteoporosis management, and cancer-associated risk, is a matter of concern and debate in daily clinical practice.

Androgen Deprivation Therapy (ADT) (Figs. 1 and 2)

Androgen deprivation therapy (ADT) is a standard prostate cancer treatment. ADT was initially accomplished by orchiectomy, but it is currently increasingly performed by medical castration with gonadotrophin releasing hormone (GnRH) agonists (e.g., Leuprolide, Goserelin) and antagonists (e.g., Degarelix), given alone or in combination with androgen receptor antagonists (e.g., Flutamide, Bicalutamide, Nilutamide) (Saad *et al.*, 2008).

Hormone therapies are not equivalent concerning bone loss. Non-steroidal anti-androgens monotherapy, although not standard, provides some degree of bone protection. To evaluate the effects of anti-androgens on bone health, Smith and colleagues randomized 52 prostate cancer patients without bone metastases to receive Leuprolide or Bicalutamide, a nonsteroidal anti-androgen that competitively binds to androgen receptors. Results showed that bone loss is more relevant with Leuprolide and suggested a potential protective effect of Bicalutamide in bone fracture onset (Smith *et al.*, 2004; D'Oronzo *et al.*, 2015; Sieber *et al.*, 2004).

Patients under castration for a prolonged period of time can have long survival, and the impact of treatment becomes particularly important at this stage. BMaD declines within months of initiation of ADT, reflecting the rapid decrease in sex steroid levels, which reach nadir within 2–4 weeks. Rates of annual bone loss reported in prospective studies range from 2% to 8% at the lumbar spine and from 1.8% to 6.5% at the femoral neck, compared with 0.5%–1.0% in the general population of aging men, and with 2.0% in women undergoing early menopause (Grossman *et al.*, 2011).

Testosterone reduction to castrate levels is associated with a decline in serum estrogens (which result from testosterone conversion by peripheral aromatization). Estrogens are essential in bone formation and resorption in men, and low levels are associated with BMaD loss, increased fracture risk, increased body fat and decreased muscle mass (Saad *et al.*, 2008; D'Oronzo *et al.*, 2015). Estrogens also stimulate osteoclast apoptosis and suppress osteoblast apoptosis. As a result, in an estrogen deficiency setting, as the one elicited by ADT, osteoclast numbers increase and osteoblast numbers decrease, resulting in bone resorption. Estrogen deficiency is also associated with increased levels of cytokine -promoting bone resorption, including TNF-α and IL-1α. These cytokines increase RANKL expression, further stimulating bone resorption (Lipton *et al.*, 2012).

Overall, long-term ADT is associated with significant and progressive BMaD decline, which correlates with treatment extent, and the risk of frailty fractures increases as BMaD decreases. Fracture events significantly correlate with shorter survival in men with prostate cancer (Brufsky, 2008).

Chemotherapy (Figs. 1 and 2)

Chemotherapy may induce bone loss due to premature ovarian failure and to direct effects of cytotoxic treatment. Brufsky, 2008).

By inducing ovarian failure, chemotherapy reduces endogenous estrogens and leads to an increased bone turnover, bone loss, and fracture risk. These effects are associated with deregulation of osteoblast (OB) and/or osteoclast (OC) differentiation and activity.

Indirect effects of chemotherapy include the development of chronic renal disorders and electrolyte abnormalities, as well as a pro-apoptotic effect on both osteoblasts and osteocytes, and accelerated differentiation of bone marrow stromal cells into adipocytes (D'Oronzo *et al.*, 2015). Small observational trials have confirmed that, irrespective of ovarian function, postmenopausal women also experience chemotherapy-associated bone loss (Robinson *et al.*, 2005; Saad *et al.*, 2008).

Chemotherapy-associated bone loss has been reported in breast cancer within 1 year of initiation of adjuvant chemotherapy (Brufsky, 2008). Among premenopausal women receiving chemotherapy, the rate of bone mineral density (BMiD) loss may approach 3%–8% at the lumbar spine within 12 months of initiating chemotherapy. In postmenopausal women, data suggests that patients receiving adjuvant chemotherapy can lose 1%–10% bone mass within 1 year of chemotherapy (Van Poznak, 2017).

Risk factors for chemotherapy-induced ovarian failure include age—older premenopausal women are at higher risk–, chemotherapy type—risk associated with alkylating drugs, such as cyclophosphamide, is higher than with taxanes–, genetic factors, and higher doses and longer extent of chemotherapy (Shapiro, 2017; Doo and Shapiro, 2013).

Several bone loss mechanisms can be considered regarding the type of chemotherapy (D'Oronzo *et al.*, 2015):

– Platinum compounds, especially cisplatin, may induce kidney failure. Kidney impairment impacts bone health as a result of electrolyte disorders, which include acute and chronic hypomagnesaemia. Low magnesium serum levels affect bone turnover

by impairing the H + /K + ATPase pathway, involved in regulation of bone extracellular pH and the VitD synthesis enzyme 1,a-hydroxylase;
- Ifosfamide is a nephrotoxic drug, potentially affecting bone health;
- Cyclophosphamide exerts direct effects on bone turnover by suppressing bone formation and resorption and also induces ovarian failure;
- Doxorrubicin may compromise bone health by increasing osteoclast differentiation and reducing fibroblast and osteoblast-forming units. Doxorubicin may further impair bone health through dose-dependent ovarian failure.
- Metotrexate affects osteoblast proliferation and differentiation.

Other Treatments (Figs. 1 and 2)

Glucocorticoids are used in Oncology as an integral part of antiemetic chemotherapy regimens, as infusion reaction preventive medications, and as analgesics. Long term treatments can be responsible of iatrogenic osteoporosis. Furthermore, in patients with brain primary and secondary tumors, glucocorticoids are used to manage neurological symptoms associated with peritumoral edema. They mainly affect the trabecular bone, inducing an early and rapid decline of BMaD due to bone resorption, followed by a slower demineralization phase due to the impaired osteoblast activity (D'Oronzo *et al.*, 2015).

Radiotherapy can induce bone loss through multiple mechanisms, including indirect ones, such as iatrogenic hypogonadism, hyperparathyroidism and electrolyte disorders, and direct toxicity based on the imbalance between osteoblasts and osteoclasts (D'Oronzo *et al.*, 2015).

Prevention

Lifestyle measures, such as weight exercises, avoiding alcohol and smoking, limiting caffeine consumption, and achieving and/or maintaining a normal body weight, are beneficial to prevent CTIBL (Finkelstein and Wu, 2017; Ibrahim *et al.*, 2013; D'Oronzo *et al.*, 2015; Hadji *et al.*, 2008; Becker and Cohen, 2017).

Supplementation with calcium (1200 mg/day) and vitamin D (800 IU) to reach serum levels of at least 30 ng/mL should also be ensured to maintain bone turnover. Furthermore, maintaining these levels is known to reduce the risk for hip fractures in elderly women (Brufsky, 2008; Ibrahim *et al.*, 2013; D'Oronzo *et al.*, 2015; Hadji *et al.*, 2008).

Treatment

There are currently no FDA-approved agents for CTIBL prevention or treatment. However, conventional therapies for osteoporosis management have been successfully used to date.

An expert consensus recommends antiresorptive therapy for patients receiving AIs and having a T-score < -2.0 or two or more clinical risk factors for fracture (**Fig. 3**) (Coleman *et al.*, 2014).

A number of clinical trials have shown efficacy of bisphosphonates in preventing chemotherapy- and AIs-induced BMaD reduction in premenopausal women (**Table 1**) (Vehmanen *et al.*, 2004; Delmas *et al.*, 1997; Gnant *et al.*, 2008; Ellis *et al.*, 2008). Dosing and administration route is usually different for preventive and treatment purposes. Patients should be warned about contraindications for invasive dental procedures during bisphosphonate treatment, as this can be a risk factor for osteonecrosis of the jaw (ONJ). This treatment should not be offered to patients with esophageal disorders (if taken po), chronic kidney disease (eGFR <30–35 mL/min) or who have undergone certain types of bariatric surgery (if taken po). Calcium and vitamin D serum levels should be corrected, and supplementation should be used even with normal serum levels, as bisphosphonates can cause hypocalcemia.

Types of Bisphosphonates (Table 2)

- Oral (Clodronate, Alendronate, Risedronate, Ibandronate): Patients should be instructed to take these medications in an empty stomach, with plenty of water and in the upright position. Afterwards, they should stay upright for an hour time due to the limited oral bioavailability of these medications (0.5%–1%), which can be severely impaired by food. Oral bisphosphonates can be associated with (sometimes severe) esophagitis, constipation, or stomach discomfort. Alendronate improves bone mass density and reduces the risk of fractures in men with osteoporosis, although conflicting results have been reported for the oral bisphosphonates Alendronate and Risedronate (Ringe *et al.*, 2004; Brufsky, 2008; Saad *et al.*, 2008). Clodronate showed efficacy in bone loss prevention in premenopausal breast cancer patients with chemotherapy-induced ovarian failure (Saarto *et al.*, 1997).
- Intravenous: Intravenous (IV) bisphosphonates include Pamidronate and Zoledronic acid. Like oral bisphosphonates, although not formerly approved in this indication, they are sometimes used to treat CTIBL. IV bisphosphonates can also be used in men (Boonen *et al.*, 2012; Brufsky, 2008; Saad *et al.*, 2008). A 2007 phase III trial conducted by Gnant *et al.* revealed that Zoledronic

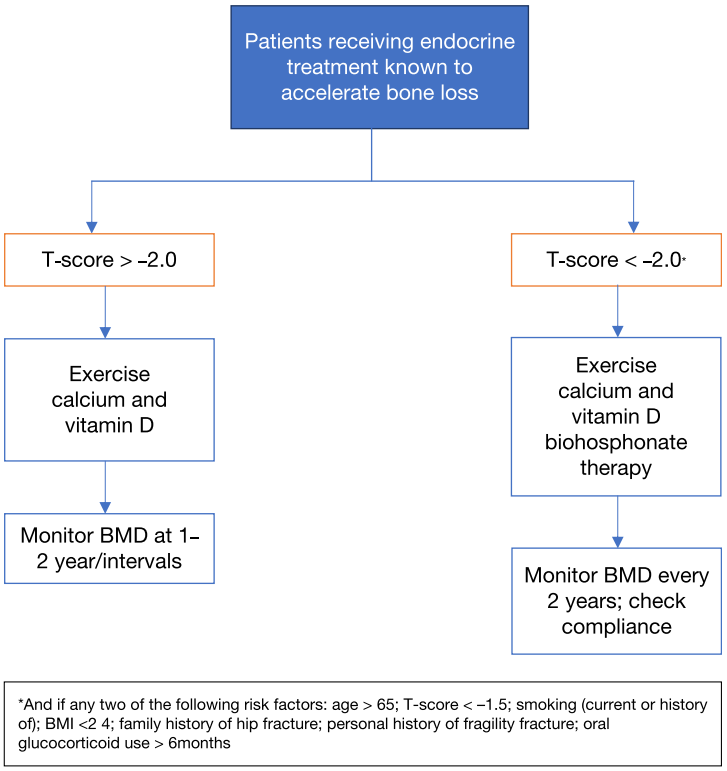

Fig. 3 Recommended bone health management algorithm in women receiving aromatase inhibitor (AI) therapy for breast cancer. Adapted from Coleman, R., *et al.* (2014). Bone health in cancer patients: ESMO Clinical Practice Guidelines, *Annals of Oncology* **25** (Supplement 3), iii124–iii,137.

Table 1 Trials of antiresorptive agents for preventing CTIBL in postmenopausal women with breast cancer

Antiresorptive agent (trial)	*N*	*BMaD study, n°*	*Dosing*	*Treatment duration, years*
Zoledronic acid (ZO-FAST)	1065	1065	4 mg iv q6mo	5
Zoledronic acid (*Z*-FAST)	602	602	4 mg iv q6mo	5
Zoledronic acid (*E*-ZO-FAST)	527	527	4 mg iv q6mo	5
Zoledronic acid (N03CC)	558	395	4 mg iv q6mo	5
Denosumab (HALT-BC)	252	252	60 mg sc q6mo	2
Risedronate (SABER)	154	111	35 mg po/week	2
Risedronate	87	87	35 mg po/week	5
Clodronate	61	61	1600 mg po/day	3
Risedronate (ARBI)	213	70	35 mg po/week	2
Risedronate (IBIS-II)	613	59	35 mg po/week	5
Ibandronate (ARIBON)	131	50	150 mg po/month	2
Risedronate	118	11	35 mg po/week	1

BMaD: Bone mass density; iv: intravenous; sc: subcutaneous; po: per os; q6month: every 6 months.

Adapted from Hadji, P., et al. (2011). Management of aromatase inhibitor-associated bone loss in postmenopausal women with breast cancer: practical guidance for prevention and treatment. Annals of Oncology 22, 2546–2555.

Acid (4 mg every 6 months) can prevent adjuvant endocrine therapy-associated bone loss in premenopausal patients. Results showed that endocrine treatment without Zoledronic acid led to significant ($P = 0.001$) overall bone loss after 3 years of treatment (BMaD, 14.4% after 36 months; mean T score reduction, 1.4). In contrast, BMaD remained stable in Zoledronic acid-treated patients compared with endocrine therapy alone ($P = 0.0001$). No interactions with age or other risk factors were observed (Gnant *et al.*, 2007). Zoledronic acid should be infused for a period of 15 min. The dosage of 5 mg yearly has also been shown to prevent osteoporosis fractures (D'Oronzo *et al.*, 2015; Zhang *et al.*, 2012; Gnant *et al.*, 2007).

– Denosumab, marketed under the brand name *Prolia* (60 mg every 6 months), is approved to increase bone mass in patients with increased risk of fractures in several indications, including (i) postmenopausal women with osteoporosis; (ii) men receiving ADT for non-metastatic prostate cancer; and (iii) women receiving adjuvant AI therapy for breast cancer (Lipton *et al.*,

Table 2 Bisphosphonates dosing

Agent	*Indication/dose (prevention CTIBL)*
Alendronate	70 mg oral weekly
Ibandronate	150 mg oral monthly
Risedronate	35 mg oral weekly
Zoledronic acid	5 mg IV yearly 4 mg IV q6month
Clodronate	1600 mg PO id
Pamidronate	60 mg IV every 12 weeks
Denosumab	60 mg every 6 months sc

CTIBL: cancer treatment induced bone loss; iv: intravenous; sc: subcutaneous; po: per os; q6month: every 6 months.

2012; Ellis *et al.*, 2008). In one trial, Denosumab (60 mg every 6 months) was also associated with an increase in BMaD and a reduction in new vertebral fractures incidence among men receiving ADT for non-metastatic prostate cancer (Smith *et al.*, 2009).

Regarding safety concerns, both bisphosphonates and denosumab are well tolerated, although Zoledronic acid is associated with more acute phase reactions and renal dysfunction, and less hypocalcemia episodes. Frequency of ONJ is equivalent with both treatments. Nevertheless, a less intensive schedule of bisphosphonates and Denosumab for bone mass preservation is associated with a lower rate of side effects (D'Oronzo *et al.*, 2015).

Bone Turnover Biomarkers

Although fracture risk rises exponentially as the BMaD declines, many frailty fractures occur in individuals who are not at risk according to the conventional densitometric criteria for osteoporosis, suggesting the need for a complementary assessment with biochemical markers of bone turnover. Markers of bone formation include bone alkaline phosphatase (ALP) and procollagen type I N-terminal propeptide (PINP), whereas serum C-terminal cross-linked telopeptide of type I collagen (S-CTX), urinary C-terminal telopeptide of type I collagen (U-CTX), and urinary NTX (U-NTX) are bone resorption markers. Concurrent dosage of plasmatic VitD, PTH, and calcium increases the accuracy of bone health assessment. Several studies have shown that levels of S-CTX and bone ALP could be predictive of vertebral and hip fractures, although their high individual variability due to age, gender, ethnicity, comorbidities and diet prevents routine application in clinical practice (D'Oronzo *et al.*, 2015; Lipton *et al.*, 2012).

Bone turnover markers are not yet established as routine clinical markers in any population, and their value for management of individual patients is not determined to date (Doo and Shapiro, 2013).

Bone Metastases; Basic Aspects

Margaux Bernard, Paola Di Mauro, Caroline Reynaud, Chantal Diaz-Latoud, and Philippe Clézardin, INSERM, Faculty of Medicine Lyon East, Lyon, France

Nomenclature

BMP-7	Bone morphogenetic protein 7
CaSR	Calcium-sensing receptor
CDH11	Cadherin 11
CTGF	Connective tissue growth factor
CTSK	Cathepsin K
CX43	Connexin 43
CXCL12	C-X-C motif chemokine ligand 12
CXCR4	Couple chemokine (C–X–C) receptor type 4
DKK1	Dickkopf-1
DTC	Disseminated tumor cell
ET-1	Endothelin-1
ERK 1/2	Extracellular signal-regulated kinase ½.
FGF9	Fibroblast growth factor 9
GAS6	Growth arrest-specific 6
HIF	Hypoxia-inducible factor
HSC	Hematopoietic stem cell
IHH	Indian Hedgehog
LIF	Leukemia inhibitory factor
LOX	Lysyl oxidase
MAPK	Mitogen-activated protein kinase
MSK1	Mitogen- and stress-activated kinase 1
OPG	Osteoprotegerin
PDGF	Platelet-derived growth factor
PTH-rP	Parathyroid hormone-related peptide
RANK	Receptor activator of nuclear factor kappa-B
RANKL	Receptor activator of nuclear factor kappa-B ligand
RUNX2	Runt-related transcription factor 2
SIBLINGs	Small integrin-binding ligand N-linked glycoproteins
SNO	Spindle-shaped N-cadherin + osteoblast
SOST	Sclerostin
TGFβ-2	Transforming growth factor-β2
TRAIL	Tumor necrosis factor-related apoptosis-inducing ligand
TSP-1	Thrombospondin-1
VCAM-1	Vascular cell adhesion protein 1
Wnt	Wingless/int

Introduction

Bone metastases, the spread of cancer to the bones, occur in more than 1.5 million patients with cancer world-wide and are most commonly associated with cancers of the prostate, lung, and breast, with incidence rates as high as 75% of patients with metastatic disease (Weilbaecher *et al.*, 2011). Metastatic cancer cells residing in the bone marrow alter the functions of bone-resorbing (osteoclasts) and bone-forming (osteoblasts) cells (Weilbaecher *et al.*, 2011). By disrupting the physiological balance between bone resorption and bone formation, metastatic cells promote skeletal destruction (Weilbaecher *et al.*, 2011). Weakened bones due to skeletal metastases can then lead to occurrence of skeletal-related events, such as fractures and compression of the spinal cord, bone pain and disability, contributing substantially to morbidity and mortality in patients with advanced cancer (Weilbaecher *et al.*, 2011). Here we provide an overview of the mechanisms of bone metastasis formation.

Bone metastasis is a stepwise sequence of events that include tumor cell colonization of the bone marrow, construction of a cancer niche, tumor cell interactions with bone cells (osteoclasts, osteoblasts) and release of signals from the resorbed bone matrix that promote skeletal tumor growth. Molecular mechanisms that mediate each of these events are described below.

Bone Colonization by Tumor Cells

Pre-metastatic Niche

Experimental studies suggest that, even before becoming clinically detectable, primary tumors release soluble factors into the bloodstream that induce the formation of a tumor growth-favoring microenvironment (called "pre-metastatic niche") in distant organs in order to attract tumor cells to these sites (Peinado *et al.*, 2017). Among these soluble factors, exosomes may play a prominent role. Exosomes are small vesicles (30–120 nm) containing DNA, RNA [messenger RNA (mRNA), microRNA (miRNA) and other noncoding RNAs], lipids and proteins that are secreted by all types of cells in culture, including tumor cells. Exosomes are also found in body fluids (blood, urine, saliva, and breast milk) (Vlassov *et al.*, 2012). In cancer, tumor-derived exosomes express distinct cell surface receptors (integrins) that are addressing them to specific organs (Hoshino *et al.*, 2015). Specifically, tumor-derived exosomal integrins $\alpha6\beta4$ and $\alpha6\beta1$ are associated with lung metastasis, while exosomal integrin $\alpha v\beta5$ is linked to liver metastasis in animals (Hoshino *et al.*, 2015). These tumor-derived exosomes are up-taken by organ-specific cells (S100A4-positive fibroblasts and Kupffer cells in lungs and liver, respectively), which then produce promigratory and proinflammatory

 doi:10.1016/B978-0-12-801238-3.65819-1

molecules within pulmonary and hepatic tissues, thereby preparing the soil to facilitate the arrival of tumor cells at these sites (Hoshino *et al.*, 2015). We, and others, showed that tumor cell integrins ITGBL1, $\alpha 2\beta 1$, $\alpha v\beta 3$ and $\alpha v\beta 6$ are associated with breast or prostate cancer bone metastasis (Zhao *et al.*, 2007; Sottnik *et al.*, 2013; Dutta *et al.*, 2014; Li *et al.*, 2015), suggesting that they could address exosomes to bone. Integrin-independent exosomal mechanisms are also involved. In melanoma, the transfer of the MET oncoprotein from tumor-derived exosomes to bone marrow progenitor cells promotes the metastatic process in lungs and bone (Peinado *et al.*, 2012). Tumor-derived exosomal miRNAs can also reprogram or educate target cells that take up exosomes toward a pro-metastatic and proinflammatory phenotype, thereby creating a pre-metastatic niche (Peinado *et al.*, 2017). The main action of miRNAs is the negative regulation of gene expression by base-pairing to the 3′-UTR of target mRNAs, resulting in translational repression or mRNA degradation (Beermann *et al.*, 2016). In cancer, miRNAs function either as tumor suppressors or as oncogenes, and their dysregulation contributes to metastasis in specific organs, including the skeleton (Beermann *et al.*, 2016). With regards to bone metastasis, there are evidence that exosomal miR-141 and miR-940 produced by prostate cancer cells promote the osteogenic differentiation of mesenchymal cells in the bone marrow microenvironment, which then facilitates the formation of bone metastases with an osteoblastic phenotype (Hashimoto *et al.*, 2018; Ye *et al.*, 2017).

Another important class of molecules involved in the formation of the pre-metastatic niche is the lysyl oxidase (LOX) family whose primary function is to drive collagen crosslinking and extracellular matrix stiffness (Peinado *et al.*, 2017). Hypoxia-inducible factor-1 (HIF-1) induces the expression of LOX in breast tumors and secreted LOX catalyzes collagen crosslinking in the lungs, facilitating the recruitment of bone marrow-derived cells and the subsequent colonization of the pulmonary tissue by breast cancer cells (Erler *et al.*, 2009). In bone, we and others have shown that tumor-derived LOX from breast and colon cancer cells generates pre-metastatic osteolytic lesions in animals by impairing bone homeostasis through the stimulation of osteoclast formation induced by RANKL and the inhibition of osteoblast formation (Cox *et al.*, 2015; Reynaud *et al.*, 2017). Thus, by acting systemically, LOX contributes to the formation of a pre-metastatic niche in the bone marrow.

Factors Promoting the Homing of Tumor Cells to the Bone Marrow

Chemokines, which are small proteins (8–14 kDa) belonging to the cytokine family, play a crucial role in promoting the migration of tumor cells to the bone marrow and, more specifically, to the pre-metastatic niche (Weilbaecher *et al.*, 2011). They are produced by stromal cells, which are associated with the pre-metastatic niche, and released in the bloodstream. For instance, the chemokine C-X-C motif chemokine ligand 12 (CXCL-12) is produced in large amounts in the bone marrow, lungs, and liver. Metastatic cells from breast or prostate cancers that express CXCR-4, the CXCL-12 receptor, migrate preferentially to these three organs due to the chemotactic properties of CXCL-12 (Weilbaecher *et al.*, 2011). Several other chemokines (CXCL-10, CXCL-13, CXCL-16, CX3CL-1, CCL22) are also produced by the bone microenvironment and have been implicated in the homing of tumor cells to bone (Weilbaecher *et al.*, 2011; Lee *et al.*, 2012; Lee *et al.*, 2012).

Construction of a Cancer Niche in the Bone Marrow

The fate of tumor cells after they enter the bone marrow remains the most elusive aspect of metastasis formation. Disseminated tumor cells (DTCs) in the bone marrow may be nonproliferative and remain dormant for several years, therefore never develop into overt bone metastases (Weilbaecher *et al.*, 2011). What enables DTCs in the bone marrow to remain dormant and how do they acquire the competence to form overt metastases? These questions come under intense scrutiny. Current hypotheses gaining ground are that DTCs must build a cancer niche by producing their own niche components to anchor and survive in the bone microenvironment, or bind to extracellular matrix components of the pre-metastatic niche that are produced by recruited stromal cells and/or occupy native bone marrow niches in which hematopoietic stem cells reside (Oskarsson *et al.*, 2014). By building this cancer niche, DTCs can enter dormancy and thus survive treatment with chemotherapeutics, which only target proliferating tumor cells.

Extracellular Matrix Niche and Tumor Survival

The extracellular matrix components tenascin C and periostin have been shown to play important roles in the construction of cancer niche in mouse models of cancer. Tenascin C is a hexameric protein produced by tumor cells that acts in an autocrine manner to support tumor cell survival. Periostin is a protein produced by stromal cells from the pre-metastatic niche that supports in a paracrine manner tumor cell survival. Tenascin C and periostin bind tightly to each other and to tumor cell surface integrins $\alpha 9\beta 1$ and $\alpha v\beta 3$, respectively, which leads to the activation of Wnt- and Notch-dependent intracellular signaling pathways (Oskarsson *et al.*, 2014; San Martin *et al.*, 2017). Other extracellular matrix components, including SIBLINGS (osteopontin, bone sialoprotein, dentin matrix protein 1), osteonectin, connective tissue growth factor (CTGF, CCN2), and nephroblastoma overexpressed (Nov, CCN3), have also been associated with bone metastasis formation (Trotter and Yang, 2016). Osteopontin has been involved in early bone colonization through binding to tumor cell surface integrin $\alpha v\beta 3$ (Trotter and Yang, 2016). Other SIBLINGs, osteonectin, CTGF and Nov are involved at a late stage in the bone metastatic disease, promoting tumor cell invasion and growth (Trotter and Yang, 2016; Croucher *et al.*, 2016).

Bone Niches and Tumor Dormancy

Osteogenic and vascular niches are crucial regulators of hematopoietic stem cell (HSC) behavior in the bone marrow. During homeostasis, signals coming from the osteogenic niche keep HSCs dormant, which preserves their long-term self-renewal potential, whereas the vascular niche is oxygenated and stimulates proliferation and differentiation of HSCs to maintain hematopoiesis (Winkler *et al.*, 2012). A current hypothesis gaining ground is that common mechanisms are likely to be involved in maintaining HSC and DTC dormancy in the osteogenic niche. "Dormancy is a stage in cancer progression where the cells cease dividing but survive in a quiescent state while waiting for appropriate environmental conditions to begin proliferation again. Quiescence is the state where cells are not dividing but at arrest in the cell cycle in G0-G1" (https://en.wikipedia.org/wiki/Cancer_dormancy). Quiescent DTCs are therefore protected against chemotherapy-induced apoptosis.

The osteogenic niche is home to a particular spindle-shaped N-cadherin + osteoblast (SNO) cell population. SNO cells regulate dormancy of HSCs through interaction with N-cadherin. It has been shown that E-cadherin-expressing breast cancer cells home to SNO cells through interactions with N-cadherin (Sosa *et al.*, 2014; Kan *et al.*, 2016). Another molecule that regulates HSC dormancy is growth arrest-specific 6 (GAS6), which is an osteoblast-derived ligand of the MER, TYRO3 and AXL (also known as UFO) tyrosine kinase receptors. When prostate cancer cells bind to osteoblasts in the niche they increase their expression level of AXL and GAS6 signaling inhibits tumor cell proliferation (Sosa *et al.*, 2014; Kan *et al.*, 2016). Osteoblasts also express the chemokine CXCL-12, which mediates adhesive interactions with HSCs by binding to CXCR4, the receptor for CXCL-12. It has been observed that prostate cancer cells, which express CXCR4, can directly compete with HSCs for osteogenic niche support (Shiozawa *et al.*, 2011).

The vascular niche is composed of endothelial cells that express specific cell adhesion molecules (*E*- and P-selectins), E-selectin being a crucial component that mediates HSC attachment and proliferation (Winkler *et al.*, 2012). Using real-time in vivo microscopy of breast tumor xenografts, it has been shown that dormant tumor cells were preferentially located in E-selectin-rich vascular regions in which they were anchored through SDF-1/CXCR4 interactions (Price *et al.*, 2016). These results (Price *et al.*, 2016) are in contrast with previous findings showing that dormant prostate cancer cells, which express CXCR4, compete with HSCs for osteogenic niche support (Shiozawa *et al.*, 2011). Ghajar *et al.* (2013) also reported that the bone marrow microvasculature might constitute a dormant niche for breast cancer cells. Specifically, they showed that the endothelium-derived extracellular matrix protein thrombospondin-1 (TSP-1) induces sustained dormancy of breast cancer cells in vivo. Overall, these experimental data suggest the concept of niche support for DTCs is still in the early stages of investigation, and warrants further investigation.

Other factors produced by osteoblasts or bone marrow mesenchymal stem cells, including bone morphogenetic protein 7 (BMP-7), transforming growth factor-β2 (TGFβ-2), leukemia inhibitory factor (LIF), and exosomal miR-23b, can also induce tumor dormancy in different types of cancer (Ono *et al.*, 2014; Sosa *et al.*, 2014; Johnson *et al.*, 2016).

Osteomimicry

During the time DTCs are in the bone marrow, they are able to adapt, exiting and re-entering a dormant state, and undergoing further selection to acquire a full complement of metastasis-colonization functions that they did not express before. In this context, tumor cells in the bone marrow express bone-associated genes (*RUNX2*, *CTSK*, *OPG*, *SPARC*, *CDH11*, *CX43*, *DKK1*), which are normally expressed by osteoblasts or osteoclasts (Bellahcène *et al.*, 2007; Le Gall *et al.*, 2007; Fradet *et al.*, 2011; Weilbaecher *et al.*, 2011). This process is called osteomimicry. For instance, the disruption of *RUNX2* activity in breast cancer cells abolishes their ability to form osteolytic lesions in vivo (Pratap *et al.*, 2011). Similarly, the incidence of prostate cancer bone metastasis is reduced greatly when cadherin-11 (CDH11) expression by tumor cells is silenced (Weilbaecher *et al.*, 2011). Moreover, paired immunochemistry on primary breast tumor samples and associated liver, lung or bone metastases showed that only bone metastatic cancer cells express bone proteins such as cathepsin K, osteonectin, cadherin-11, connexin-43 and RUNX2, demonstrating the clinical relevance of this process (Bellahcène *et al.*, 2007; Le Gall *et al.*, 2007; Fradet *et al.*, 2011).

Dormant Cell Reactivation

Two mitogen-activated kinases (MAPKs), namely p38 and extracellular signal-regulated kinase (ERK), control the switch of tumor cells between dormancy and active growth, respectively (Sosa *et al.*, 2014). Some of the molecular mechanisms that regulate this switch in the bone marrow have been identified. For example, mitogen- and stress-activated kinase 1 (MSK1), a downstream effector of the p38 and ERK1/2 signaling pathways, has been involved in the regulation of tumor dormancy in estrogen receptor (ER)-positive breast cancer cells that are metastatic to bone (Gawrzak *et al.*, 2018). Specifically, p38 depletion in tumor cells decreases MSK1 expression, and MSK1 depletion increases the capacity of poorly metastatic ER-positive breast cancer cells to form overt metastasis in animals (Gawrzak *et al.*, 2018). Thus, MSK1 is a dormancy enforcer and a negative regulator of metastasis initiation.

Bone might also provide an environment that enables dormant cell reactivation. Within a mouse bone metastasis model, indolent breast cancer micrometastases were found to overexpress adhesion protein vascular cell adhesion protein 1 (VCAM-1), which promotes the recruitment of osteoclast precursors by binding to osteoclast integrin $\alpha4\beta1$, leading to osteoclast formation and osteoclastic bone resorption (Sosa *et al.*, 2014). The mechanisms underlying VCAM-1 silencing and re-expression in these indolent bone marrow micrometastases are unknown. However, bone resorption likely creates an environment that promotes

tumor cell reactivation (Croucher *et al.*, 2016). In this respect, TGFβ1 and TGFβ2 exhibit competing functions on behavior of tumor cells in the bone marrow (Sosa *et al.*, 2014). TGFβ2 promotes tumor cell dormancy through Smad1/5 and p38 signaling, whereas TGFβ1 switches off dormancy, leading to rapid tumor growth in vivo (Sosa *et al.*, 2014). Thus, TGFβ1 released from resorbed bone could contribute to dormant cell reactivation (Weilbaecher *et al.*, 2011).

As exemplified with VCAM-1 and TGFβ1, there is a growing body of evidence suggesting that osteoclasts may be responsible for the reactivation of dormant DTCs (Weilbaecher *et al.*, 2011; Sosa *et al.*, 2014; Croucher *et al.*, 2016). It is well known that manipulating the bone microenvironment in mice by stimulating osteoclast activity through vitamin D deficiency, or through estrogen or androgen deprivation enhances skeletal tumor burden and bone destruction (Weilbaecher *et al.*, 2011; Croucher *et al.*, 2016). In this context, TGFβ1 that is released from resorbed bone not only switches off DTC dormancy, but also plays a central role in most of the events leading to tumor expansion in bone and bone destruction (Weilbaecher *et al.*, 2011). For instance, bone-derived TGFβ1 stimulates the expression of the Notch ligand Jagged-1 in bone metastatic tumor cells, which in turn promotes bone metastasis by activating the Notch pathway in supporting bone cells. Specifically, Jagged-Notch signaling directly promotes osteoclast differentiation and bone resorption, and it stimulates the release of IL-6 from osteoblasts to promote tumor cell proliferation (Sethi *et al.*, 2011). In addition, the therapeutic targeting of Jagged-1 with a monoclonal antibody inhibits bone metastasis formation in animals (Zheng *et al.*, 2017). Thus, osteoclastic bone resorption is likely to play an important role at an early stage in the establishment of bone metastasis.

Tumor-Derived Factors Mediating Osteolytic or Osteoblastic Bone Metastases

At a late stage in the progression of skeletal lesions, the patterns of bone metastases ranged from mostly destructive or osteolytic (in breast cancer, lung cancer, or myeloma), to mostly bone-forming or osteoblastic (in prostate cancer). There is however always an imbalance between bone formation and bone resorption. Bone metastasis is therefore a spectrum between these two extremes where, at one end, predominantly osteolytic lesions are associated with high osteoclast activity and reduced osteoblast activity and, at the other end, bone metastases that are predominantly osteoblastic have a high osteoblast activity and a reduced osteoclast activity (Weilbaecher *et al.*, 2011). Different molecular mechanisms associated with these different patterns of bone metastasis have been identified and are described below.

Osteolytic Lesions

Several factors secreted by tumor cells during the course of development of malignant osteolytic lesions stimulate osteoclast activity and bone resorption. Among them, parathyroid hormone-related peptide (PTHrP) was the first to be recognized as involved in malignant osteolysis. PTHrP stimulates in osteoblasts the expression of the cytokine receptor activator of nuclear factor-κB ligand (RANKL), which binds to its receptor RANK on osteoclast precursors, leading to the formation of new osteoclasts and therefore to osteoclastic bone resorption (Weilbaecher *et al.*, 2011). The transcription factor RUNX2 contributes to the ability of tumor cells to activate osteoclasts by upregulating Indian Hedgehog (IHH) expression, which in turn stimulates PTHrP-induced RANKL in osteoblasts and subsequently promotes RANK/RANKL-dependent activation of osteoclasts (Pratap *et al.*, 2011). Likewise, the transcription factor MAF mediates breast cancer bone metastasis through the control of PTHrP (Pavlovic *et al.*, 2015). Subsequent studies, described below, showed that TGFβ released from resorbed bone induces PTHrP production from tumor cells that results in enhanced bone resorption (Weilbaecher *et al.*, 2011). Overall, these studies (Pratap *et al.*, 2011; Weilbaecher *et al.*, 2011; Pavlovic *et al.*, 2015) demonstrate the importance of PTHrP in the pathogenesis of osteolytic lesions. Several other molecules produced by tumor cells, including interleukins (IL-6, IL-8, and IL-11) and granulocyte macrophage-colony stimulating factor (GM-CSF), stimulate osteoclast activity through the activation of the RANK/RANKL pathway (Weilbaecher *et al.*, 2011). Platelet-derived lysophosphatidic acid (LPA) also supports progression of osteolytic bone metastases in breast cancer. We showed that LPA, by binding to its receptor LPA1 at the tumor cell surface, promotes tumor cell proliferation and the LPA1-dependent secretion of IL-6 and IL-8, which in turn promotes osteoclast-mediated bone resorption (Boucharaba *et al.*, 2004). Moreover, the functional blockade of LPA action on its receptor, using a LPA1 antagonist, substantially reduces progression of osteolytic bone metastases in animals (Boucharaba *et al.*, 2006).

Tumor cells not only stimulate osteoclast activity, but also inhibit osteoblast activity, thereby worsening the imbalance between bone formation and bone resorption, and promoting bone destruction (Weilbaecher *et al.*, 2011). Specifically, tumor cells secrete activin A (a member of the TGF-β superfamily of growth factors), noggin (a BMP antagonist), and dickkopf-1 (DKK-1) and sclerostin (SOST-1) [two Wingless/int (Wnt) protein antagonists], all of them suppressing osteoblast differentiation (Weilbaecher *et al.*, 2011; Zhu *et al.*, 2017). For instance, MDA-MB-231 and MCF-7 breast cancer cells express SOST-1 and an anti-SOST antibody reduces tumor cell migration and invasion in vitro, and prevents formation of osteolytic lesions in animals (Zhu *et al.*, 2017).

Osteoblastic Lesions

One of the most well studied mediators is endothelin-1 (ET-1), which stimulates osteoblast proliferation and inhibits osteoclast activity and motility. Among patients with prostate cancer, those with bone metastases have far higher circulating levels of ET-1,

compared to those with localized cancer (Weilbaecher *et al.*, 2011). Gene expression analysis in mouse primary osteoblasts revealed that treatment with ET1 upregulates multiple osteoblast-stimulatory factors (e.g., IL-6 and RANKL) and downregulates DKK-1 (Rosano *et al.*, 2013). Stimulatory effects of ET-1 on osteoblasts are mediated by two receptors, ETAR and ETBR, which activate similar signaling pathways. Osteoblast proliferation and bone metastasis are both inhibited by ETAR antagonists atrasentan and zibotentan, as well as by the dual ETAR and ETBR antagonist bosentan, highlighting the prominent role played by ET-1 in the formation of osteoblastic lesions (Rosano *et al.*, 2013). Other osteoblast-stimulatory factors (VEGF, BMP-6) have also been shown to participate to the formation of osteoblastic lesions (Dai *et al.*, 2005; Kitagawa *et al.*, 2005). Osteoblasts express VEGF membrane receptors Flt1 and KDR and the treatment of animals with the Flt1 receptor inhibitor PTK787 blocks the formation of prostate cancer osteoblastic lesions in animals (Kitagawa *et al.*, 2005). Likewise, the treatment of animals with an antibody to BMP-6 decreases the formation of osteoblastic bone metastases induced by prostate cancer cells (Dai *et al.*, 2005). The osteoblast-stimulatory factors BMP-2, adrenomedullin, Wnt, and fibroblast growth factor 9 (FGF9) have been also involved in the formation of osteoblastic lesions (Logothetis and Lin, 2005). In addition, prostate-specific antigen (PSA), as a serine protease that cleaves PTHrP in the PTH-like domain, could also indirectly contribute to the formation of osteoblastic lesions by neutralizing osteoclast-stimulatory effect of PTHrP (Cramer *et al.*, 1996).

Osteoprotegerin (OPG) is a soluble RANKL inhibitor produced by osteoblasts that inhibits RANKL/RANK interaction. OPG levels are increased in patients with prostate cancer bone metastases. In addition, OPG can be expressed in breast and prostate cancer cells. OPG expressed by prostate cancer cells inhibits bone resorption, thereby contributing to the osteoblastic trait of most prostate cancer bone lesions (Corey *et al.*, 2005). In addition, OPG can promote tumor cell survival by binding to tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) (Croucher *et al.*, 2016).

Contribution of Bone to Metastasis Progression

Bone tissue is an abundant reservoir for growth factors, including TGFβ, insulin-like growth factors (IGFs) and platelet-derived growth factors (PDGFs) (Weilbaecher *et al.*, 2011). When released from the resorbed bone matrix, TGFβ acts on tumor cells, via SMAD- and COX2-dependent signaling pathways, which stimulates the expression of factors such as PTHrP, Jagged-1, IL-11, and prostaglandin E2 (Weilbaecher *et al.*, 2011; Sethi *et al.*, 2011; Croucher *et al.*, 2016). Bone-derived IGFs and PDGFs stimulate tumor growth (Weilbaecher *et al.*, 2011). Calcium is another factor released from bone during osteoclastic resorption. Calcium binds on tumor cells (breast, prostate) via a calcium-sensing receptor (CaSR) and promotes tumor cell proliferation and migration and secretion of PTHrP and epiregulin (Weilbaecher *et al.*, 2011; Boudot *et al.*, 2017). Epiregulin is an EGF-like ligand whose expression is increased in osteolytic lesions in vivo. It decreases *OPG* expression in osteoblasts, thereby contributing to the progression of osteolytic lesions (Boudot *et al.*, 2017).

Summary and Conclusion

In this review, we described early events that allow tumor cells to disseminate and colonize in the bone marrow and we highlighted the prominence of pre-metastatic and metastatic niches in mediating homing and dormancy of tumor cells, respectively. We also discussed the importance of the osteoclast activity for reactivation of dormant tumor cells. Finally, we explained how, at a later stage, tumor cells induce osteolytic or osteoblastic lesions. To date, no effective treatments for bone metastasis exist, only therapies that aim to limit the bone degradation such as denosumab (anti-RANKL monoclonal antibody) and bisphosphonates. The future challenge will lie in our ability to develop therapeutics targeting dormancy in order to address residual disease in patients.

Bone Metastases; Clinical Aspects

Steven Wood, Azeez Salawu, Helen Kroening, Stella D'Oronzo, and Janet Brown, University of Sheffield, Sheffield, United Kingdom

Incidence and Clinical Features of Bone Metastasis

Metastasis to the skeleton represents a serious and, currently irreversible, step in the progression of solid and hematological malignancies. Both the incidence of bone metastases and median survival after their diagnosis vary according to the primary tumor (**Table 1**). Due to the high incidence of breast and prostate tumors and the relatively long survival following bone metastasis development (typically 2–3 years for breast cancer, but potentially improving with immunotherapy, and 2–4 years for prostate cancer), these tumors account for up to 70% of the prevalence of cancer-related skeletal lesions (Coleman, 2006). Hernandez *et al.* (2015) estimated the 2012 prevalence of patients with bone metastases in the United States as approximately 300,000. The primary malignancies were represented by breast cancer in approximately one third of cases and prostate tumors in more than a quarter. In approximately 40% of breast cancer patients who develop distant metastasis, bone is the first site of relapse and, ultimately, more than 70% of patients who die from breast cancer have evidence of skeletal metastasis (Coleman, 2006). In advanced prostate cancer, the frequency of bone metastasis is even higher, probably greater than 80%, whereas in advanced lung cancer, the frequency of bone metastasis is much less at around 30%. Since survival after bone metastasis development in lung cancer is relatively short (typically 12–18 months) (Chen *et al.*, 2016), skeletal complications have represented less of a long-term health issue than for patients with breast or prostate cancer, though again survival is potentially improving with immunotherapy.

Regardless of the primary tumor, the axial skeleton (i.e., spine, ribs, pelvis and skull) is more frequently involved than the appendicular one. Among long bones, femora and humeri are commonly affected by bone metastases.

How Do the Clinical Features of Bone Metastases Arise?

Normal bone homeostasis is maintained by the continuous action of specialized bone resorbing cells (osteoclasts) and bone forming cells (osteoblasts) which, together, act to maintain and continuously renew the skeleton. In healthy individuals, bone resorption and bone formation are coupled and perfectly balanced in location, time, and amount. Osteoblasts are activated by numerous diverse cytokines and growth factors including Wnt-family members (Takada *et al.*, 2009), endothelin-1 (Clines *et al.*, 2007), bone morphogenetic proteins (Zhang *et al.*, 2009), fibroblast growth factor (Bosetti *et al.*, 2010) and transforming growth factor-β, TGFβ (De Gorter *et al.*, 2011) resulting in the increased deposition of new bone matrix. Bone resorption results from the action of osteoclasts which differentiate from osteoclast precursors to form active osteoclasts and this occurs in response to the action of Nuclear Factor-κB ligand (RANKL) binding to the receptor activator of nuclear factor-κB (RANK) upon osteoclast precursor cells (Suda *et al.*, 1999). This balance between bone-formation and bone-resorption, which depends on a range of diverse cytokines and growth factors is perturbed in differing ways by bone-metastatic cancer cells.

The mechanisms which lead to colonization of bone by metastatic cancer cells are the subject of active research. Recent data has provided a molecular basis for the "seed and soil" hypothesis, originally proposed by Stephen Paget in 1889 (Paget, 1989). The progress of tumor cells from initial colonization to tumor growth appears to require distinct niches within the bone, including the bone remodeling compartment (BRC)—a site of active bone resorption (Parfitt, 2001).

Active tumor cells in bone cause disruption of the fine-tuned balance between osteoblast and osteoclast activity, either causing excess bone resorption and bone destruction (as associated with lytic bone lesions), for example, in most breast cancers, renal cell carcinoma, multiple myeloma, thyroid cancer, melanoma (Macedo *et al.*, 2017; Selvaggi and Scagliotti, 2005; Taube *et al.*, 1994), or increased levels of bone formation (as in osteosclerotic bone lesions, e.g., in prostate cancer and lung cancers), though the new

Table 1 Incidence of bone metastases from different primary tumors and relative median survival (Macedo *et al.*, 2017; Coleman, 2006)

Primary tumor site	*Incidence of bone metastases*	*Median survival after bone metastasis diagnosis*
Breast	65%–75%	19–25 months
Prostate	65%–75%	12–53 months
Thyroid	60%	48 months
Lung	30%–40%	6–7 months
Bladder	40%	6–9 months
Kidney	20%–25%	12 months
Skin (Melanoma)	14%–45%	6 months

 doi:10.1016/B978-0-12-801238-3.64945-0

bone is formed with an irregular structure (Macedo *et al.*, 2017). In many cases (e.g., in breast cancer), mixed lesions are present having both osteolytic and osteosclerotic character. In all cases of bone metastases, the rates of bone resorption are increased and bone formation is often increased in response, even in lytic disease.

Several mechanisms promote osteolytic lesions including the release by cancer-cells of PTHrP, which in turn promotes the release of RANKL by osteoblasts and the RANKL-RANK mediated activation of osteoclasts. Osteoclast activation in turn releases growth factors and cytokines trapped within the bone matrix which then act upon the cancer cells to promote their further proliferation in a "vicious cycle" of bone destruction (Guise, 2010; Guise, 2013). The secretion of PTHrP by cancer cells which metastasize to bone may be intrinsic to the cancer cells themselves, as gene copy-number analysis recently identified amplification of the gene encoding Musculoaponeurotic Fibrosarcoma (MAF) transcription factor within bone-metastatic breast cancer cells, and an identified target of gene activation by MAF was PTHrP (Pavlovic *et al.*, 2015).

The mechanisms involved in osteoblastic lesions are still poorly understood. Prostate-specific antigen (PSA) has the ability to cleave PTHrP thus inhibiting osteoclast activation and switching the balance over towards bone formation (Keller *et al.*, 2001). More recently evidence has been obtained that prostate cancer secreted bone-morphogenetic protein-4 (BMP4) can convert tumor-associated endothelial cells within the bone marrow into osteoblasts, and this phenotypic conversion may account for the abnormal bone formation observed within prostate cancer (Lin *et al.*, 2017).

Skeletal Related Events and Bone Turnover Markers

Once bone metastases are established, patients may experience serious skeletal complications during the subsequent course of the disease, with consequent progressive disability. These complications of bone metastases are collectively termed skeletal related events (SREs) and have been widely used in clinical trials for assessing bone metastasis-induced skeletal complications and their response to bone-targeted therapies. SREs include pathological fractures (such as in long bone and vertebral fracture), the need for radiation to bone for pain relief, the need for surgery to bone and development of spinal cord compression. Some studies have included hypercalcemia of malignancy within the SRE definition. In most cases, hypercalcemia is associated with osteolytic bone metastases being, thus, more frequent in breast and lung malignancies than in prostate tumors (Coleman, 2006).

The frequency of SREs is relatively independent of the tumor of origin, with the most common being the need for radiation in patients with bone metastasis from breast, lung or prostate malignancies (Kuchuck *et al.*, 2013; Ulas *et al.*, 2016; Klaassen *et al.*, 2017). Pathological fractures are the second most frequent SRE, while spinal cord compression is relatively uncommon; however, this represents a medical emergency requiring urgent attention.

The socio-economic impact of SREs is very high. A multicenter observational study involving four European countries (UK, Germany, Italy and Spain) investigated the use of healthcare resources by patients with bone metastases from solid or hematologic malignancies who developed SREs. Approximately one-third of patients needed hospitalization, whose median duration reached 41.1 days in case of spinal cord compression (Hoefeler *et al.*, 2014). Another observational study investigated the need for palliative radiotherapy in both breast and prostate cancer patients, showing a total cost for each patient of $7,457US and $7,553US respectively; spine and hip were the most frequently irradiated sites (Hess *et al.*, 2012).

Normal bone metabolism (bone resorption and equivalent bone formation) results in release of a variety of intermediates into the circulation or urine. Many of these are derived from the breakdown or formation of type I collagen and have been evaluated as markers which can report in a "real time" manner on the current rates of bone formation and bone resorption and how these differ from normal. Originally these markers were developed for use in assessment of benign bone diseases such as osteoporosis. However, they are being used increasingly in oncology, either to give information on the skeletal effects of cancer treatments (e.g., in the bone loss induced by aromatase inhibitors in breast cancer or androgen deprivation therapy, ADT, in prostate cancer) or to reflect the effects of cancer cells on bone function in metastatic bone disease. A list of the most commonly used bone turnover markers is included in **Table 2**.

Table 2 Commonly used bone turnover markers

Turnover marker	*Formation/resorption*	*Urine/serum*
Bone-specific alkaline phosphatase	Formation	Serum
P1CP	Formation	Serum
P1NP	Formation	Serum
Osteocalcin	Formation	Serum
NTX	Resorption	Urine
α/β CTX	Resorption	Urine
Calcium	Resorption	Serum/Urine
1-CTP	Resorption	Serum
CTX	Resorption	Serum

1-CTP, type 1 collagen C telopeptide; NTX, N-telopeptide of type 1 collagen; P1NP, N-terminal propeptide of type 1 procollagen; P1CP, C-terminal propeptide of type 1 procollagen; CTX, C-telopeptide of type 1 collagen.

Whilst bone turnover markers have proved extremely valuable as surrogate efficacy endpoints, especially in early trials of bone-targeted agents, and are widely accepted as evidence of efficacy in this context (see below), it should be noted that they are not approved by regulators as endpoints for registration in Phase III studies.

Several studies have analyzed correlations between bone turnover markers and the risk of SREs. In 121 unselected, consecutive patients with histologically proven malignancy and bone metastases (mainly from breast and prostate cancer), NTX levels were correlated with the number of skeletal-related events and/or death ($r = 0.62$, $P < .001$ for 0–3 months and $r = 0.46$, $P < .001$ for 4–6 months, respectively) (Brown *et al.*, 2003). This study was the first to indicate a strong correlation between the rate of bone resorption and the frequency of skeletal complications in metastatic bone disease, demonstrating the utility of NTX in the prediction of patients most likely to experience skeletal complications and thus benefit from bisphosphonate treatment. In a further study (Brown *et al.*, 2005), baseline and recent bone marker levels were found to be predictive of negative clinical outcomes in patients with bone metastases secondary to prostate cancer and to nonsmall cell lung cancer and other solid tumors (breast cancer not included in this study). NTX levels were more consistent prognostic indicators than bone-specific alkaline phosphatase for all tumor types, reflecting the key role of osteolysis in the development of skeletal complications.

In a study involving 1824 patients, a significant correlation was described between high sBALP levels and the risk of SREs, especially in prostate cancer, while moderate-high levels of uNTX were associated with doubled risk of skeletal complications ($P < .001$ in both instances) (Coleman *et al.*, 2005). By exploring data deriving from placebo-controlled phase III trials of zoledronate in advanced tumors, Brown *et al.* (2010) observed a significant correlation between high baseline levels of the two markers and the risk of SREs. On the other hand, normal baseline NTX correlated with lower risk of pathological fractures ($P < .0001$) in patients with bone metastases receiving zoledronate. Furthermore, patients whose NTX remained permanently within the normal range, exhibited a significant reduction of skeletal complications ($P \leq .0005$), as compared to those with raising NTX (Lipton *et al.*, 2013). Interestingly, normalization of NTX during the first 3 months of bisphosphonate therapy, in patients with high baseline levels of this marker, was associated with reduced risk of skeletal complications, as well as improved survival (Lipton *et al.*, 2008).

A number of clinical variables have been also investigated for their correlation with SRE occurrence. In particular, Wang *et al.* analyzed 1143 patients with bone metastases and developed three different prediction models, identifying the visual analog scale (VAS) for pain as the strongest predictor of SREs. Other clinical variables, such as Mirels score, Frankel classification of spinal cord injuries and serum calcium levels, contributed to SRE prediction (Wang *et al.*, 2016).

More recently, a related terminology termed symptomatic skeletal events (SSE) has been used in clinical studies. The SSE definition is almost identical to SRE but excludes asymptomatic pathologic fractures (Parker *et al.*, 2013). Although clinically more relevant than SREs, SSEs have not been widely investigated so far. Two recent studies analyzed the incidence and economic impact of SSEs in patients with bone metastases from breast and prostate cancer, respectively. In both cases, the need for radiotherapy was the most common event, occurring in 59.5% of breast cancer patients and 84.1% of men with prostate cancer (Yanae *et al.*, 2017; McKay *et al.*, 2017).

Cancer-induced bone pain is one of the most significant causes of morbidity and quality of life (QoL) deterioration, that should be periodically monitored through specific scales (e.g., VAS). Pain features and presentation may vary from vague and intermittent discomfort to severe, sharp and persistent aches, progressively worsening and exacerbated by physical activity (Milgrom *et al.*, 2017). Sometimes, patients describe bouts of intermittent, severe pain (i.e., breakthrough pain) whose management requires specific expertise in palliative care. Bone pain pathogenesis is multifactorial and includes periosteum stretching by space-occupying masses, nerve root compression, endosteal nerve ending stimulation by chemical agents (e.g., cytokines, bradykinin, prostaglandins, histamine, etc.) secreted by both tumor and stromal cells, which stimulate ion channels and sensitize afferent neurons. Pathological fractures further contribute to bone pain, whose features vary according to the skeletal site. Moreover, back pain represents the first symptom of spinal cord compression, generally localized in the overlying area and worsened by activities that increase intradural pressure, such as sneezing, coughing and straining. Local pain may precede the onset of other neurological signs (i.e., weakness and paralysis) by weeks or even months (Milgrom *et al.*, 2017; Coleman, 2006).

Patients' QoL should be routinely assessed, especially when bone metastases have been detected. Tharmalingam *et al.* (2008) reviewed data from 47 studies which applied 24 different questionnaires, aimed at QoL evaluation, to 10,844 patients with bone metastases. Most studies employed the European Organization for Research and Treatment of Cancer QoL Questionnaire version 3 (EORTC QLQ-C30), consisting of 30 questions related to global health, systemic symptoms, limitation in daily functions and potential financial difficulties. More recently, a supplement of the abovementioned questionnaire has been developed, which focuses more specifically on bone metastasis-related symptoms (EORTC QLQ-BM22) (Chow and Bottomley, 2009; Lin and Pakpour, 2016).

Diagnosis of Bone Metastases

Although bone metastasis is usually identified during follow up in patients with a known cancer history, patients may present with bone metastases with no previous cancer diagnosis. Also, diagnosis of bone metastasis can be difficult in elderly patients, in whom osteoporosis and degenerative skeletal diseases can mimic cancer-related conditions. Thus, a careful clinical evaluation of the patient is always necessary, together with a record of the past medical history.

The radiographic features of bone metastases vary according to the osteoblastic, osteolytic or mixed pattern primary tumor from which they arise. Among imaging techniques, plain radiograph is usually the first to be performed following symptoms of bone pain. It is cheap, fast and specific, although its sensitivity is low (44%–50%) and lesions smaller than 1 cm might be undetected, especially when bone mineral content is almost unaffected. Medullary lesions are even more difficult to be identified because of poor contrast (Vinholes *et al.*, 1996).

Following plain radiograph, bone scintigraphy with technetium-99m is widely used to diagnose bone metastasis and to assess progression. It is much more sensitive than plain radiograph (except for multiple myeloma bone lesions), but it is poorly specific (Macedo *et al.*, 2017). The bone-seeking technetium-99m is absorbed onto the hydroxyapatite in bone, to an extent reflective of osteoblastic activity, with preferential uptake of tracer at sites of active bone formation. The bone scan therefore reflects osteoblast activity (as well as bone vascularity), thus highlighting active osteogenesis areas, regardless of their neoplastic, inflammatory or traumatic nature. False-negative scans might occur in the presence of pure lytic metastases, such as those associated with multiple myeloma, as well as in rapidly evolving osteolytic lesions. On the other hand, osteoblastic bone metastases are clearly visualized, unless they are very slow growing (Algra *et al.*, 1991).

Both computed tomography (CT) and magnetic resonance imaging (MRI) have higher sensitivity than plain radiograph (70%–100% and 80%–100%, respectively) and are useful to characterize spinal lesions. The former clearly shows both osteolytic and osteoblastic lesions, while describing any extensions to surrounding tissues. Notably, CT scan is very useful to localize lesions for biopsy (Rosenthal, 1997). MRI enables the entire spine evaluation, as well as the demonstration of spinal cord compression/infiltration (Shah and Salzman, 2011).

18F-Fluoro-D-glucose positron emission tomography (18F-FDG-PET) is another functional technique showing all those metastatic sites, including bone metastases, with high glycolytic rate. It is superior to bone scintigraphy for the detection of skeletal lesions from multiple myeloma, breast cancer (Jambor *et al.*, 2016) and lung cancer (Marom *et al.*, 1999). However, it is less reliable in detecting renal and prostate cancer bone metastases, possibly due to their low glycolytic rate (Cook *et al.*, 2016).

Measurement of bone turnover markers (BTM) has been widely attempted to detect the presence of early-stage skeletal lesions, before they become radiologically evident (Lumachi *et al.*, 2016; Elfar *et al.*, 2017; Klepzig *et al.*, 2009; Kong *et al.*, 2007; Du *et al.*, 2014; Zhang *et al.*, 2016). Although some diagnostic utility has been reported in detecting bone metastasis in lung cancer (Coleman *et al.*, 2011a; Lumachi *et al.*, 2013), this has not been supported in other cancers and their use in detecting the presence of bone metastases is not approved in clinical practice (Van Poznak *et al.*, 2011).

Bone Targeted Agents and Treatment of Bone Metastases

A more detailed account of treatment of bone metastases may be found in Chapter XX.

The discovery and development of pharmaceutical agents which specifically target bone has transformed the treatment of bone metastases and continues to do so. Bone-targeted agents have become standard of care for the systemic treatment and prevention of skeletal complications in patients with bone metastases from a range of solid tumors as well as multiple myeloma. Their current use is based on the results of large randomized controlled clinical trials over the last 20 years. They include the bisphosphonates, the fully humanized synthetic antibody denosumab and the radiopharmaceutical, radium-223. Whilst none of these currently has curable implications for established bone metastasis, they have greatly improved quality of life in terms of reduction in skeletal complications and extended survival in the case of radium-223 in prostate cancer. A summary of the key trials which supported the development of bone-targeted agents is included in **Table 3**.

Bisphosphonates are pyrophosphate analogs which are relatively safe, have few interactions and are usually well tolerated. Having homed to bone, bisphosphonates are internalized by osteoclasts resulting in disruption of osteoclast function and increased osteoclast apoptosis with the overall effect of reducing bone resorption. The bisphosphonate family contains variable side chains which determine their relative potency and precise mechanism of action (Roelofs *et al.*, 2010). Nitrogen-containing bisphosphonates (e.g., ibandronate and zoledronic acid) are especially potent, as they inhibit enzymes of the mevalonate pathway, further slowing down bone turnover. Nonnitrogen containing bisphosphonates, such as clodronate and alendronate, act via the formation of adenosine triphosphate analogs, which cause osteoclast apoptosis.

In oncology, in addition to their standard use in hypercalcemia of malignancy, bisphosphonates are being increasingly employed in the treatment of bone metastases and, more recently, in the adjuvant setting in prevention of metastasis in breast cancer. Studies in both benign disease (Eastell *et al.*, 2010) and in patients with cancer (Brown *et al.*, 2007), have shown that the effects of even a single dose of zoledronic acid on suppression of bone resorption, is extremely long-lasting, potentially out to several years.

Like bisphosphonates, denosumab acts to decrease osteoclast activity and thus reduce bone resorption. Denosumab inhibits receptor activator of nuclear factor κ ligand (RANKL), which is expressed on osteoblasts and released into the bone microenvironment where it activates its receptor [RANK] on osteoclast precursors. Since denosumab directly blocks osteoclast activity, it thereby reduces bone loss. Radium-223(as radium chloride), is an α particle-emitting radiopharmaceutical, chemically in the same periodic group as calcium. It binds strongly to bone, where it interacts with the hydroxyapatite in metabolically active areas such as bone metastases. It emits high linear energy transfer radiation, but with a relatively small range, which results in highly localized effects, acting directly at the site of bone metastases with minimal damage in adjacent tissues. It is associated with minimal toxicity

Table 3 Key trials for the development of bone targeted agents in metastatic bone disease

Agent/trial	*Accrual*	*Population*	*Intervention*	*Comparator*	*Primary outcome*
Clodronate					
Paterson *et al.* (1993)	173	Breast cancer with bone metastases	Oral Clodronate 1600 mg daily	Placebo	Skeletal morbidity rate 218.6 vs. 304.8 per 100 patient-years ($P < .001$)
Tubiana-Hulin *et al.* (2001)	144	Breast cancer with bone metastases	Oral Clodronate 1600 mg daily	Placebo	Time to new SRE 244 vs. 180 days ($P = .05$)
Ibandronate					
Body *et al.* (2004)	564	Breast cancer with bone metastases	Oral Ibandronate 50 mg daily	Placebo	Skeletal morbidity period rate 0.95 vs. 1.18 ($P = .004$)
Body *et al.* (2003)	466	Breast cancer with bone metastases	IV Ibandronate 2 or 6 mg daily	Placebo	Skeletal morbidity period rate 1.19 vs. 1.48 ($P = .004$)
Pamidronate					
Hortobagyi *et al.* (1996)	380	Breast cancer with ≥ 1 bone metastasis	IV Pamidronate 90 mg every 4 weeks	Placebo	Proportion of patients with SRE 65% vs. 46% ($P < .001$)
Theriault *et al.* (1999)	372	Breast cancer with ≥ 1 bone metastasis	IV Pamidronate 90 mg every 4 weeks	Placebo	Skeletal morbidity rate 56% vs. 67% ($P = .027$)
Berenson *et al.* (1996)	392	Multiple myeloma Stage III with ≥ 1 bone metastasis	IV Pamidronate 90 mg every 4 weeks	Placebo	Proportion of patients with SRE 24% vs. 41% ($P < .04$)
Zoledronate					
Barrett-Lee *et al.* (2014)	1404	Breast cancer with ≥ 1 bone metastasis	IV Zoledronate 4 mg every 3–4 weeks	Oral ibandronate 50 mg daily	Rate ratio for SRE 1.148 (95%CI 0.967–1.362)
Rosen *et al.* (2003)	1648	Breast cancer or multiple myeloma with bone metastasis	IV Zoledronate 4 mg (or 8 mg) Every 3–4 weeks	IV Pamidronate 90 mg every 3–4 weeks	Proportion of patients with ≥ 1 SRE 47% vs. 51% Multiple SRE risk HR 0.84 (0.72–0.98) ($P = .003$)
Morgan *et al.* (2010)	1970	Multiple myeloma newly diagnosed	IV Zoledronate 4 mg every 3–4 weeks	Oral clodronate 1600 mg daily	Overall survival HR 0.84 (0.74–0.96) $P = .0118$
Saad *et al.* (2004)	643	Metastatic castrate-resistant prostate cancer	IV Zoledronate 4 mg (or 8 mg) every 3–4 weeks	Placebo	Proportion of patients with ≥ 1 SRE 38% vs. 49% ($P = .028$)
Rosen *et al.* (2004)	773	Lung cancer and other solid tumors (excludes breast and prostate cancer)	IV Zoledronate 4 mg (or 8 mg) every 3–4 weeks	Placebo	Proportion of patients with ≥ 1 SRE 39% vs. 48% ($P = .039$)
Denosumab					
Fizazi *et al.* (2011)	1904	Castrate-resistant prostate cancer	SC Denosumab 120 mg every 4 weeks	IV Zoledronate 4 mg every 4 weeks	Time to first SRE 20.7 vs 17.1 months HR 0.82 (0.71–0.95) (superiority $P = .008$)
Stopeck *et al.* (2010)	2046	Breast cancer with ≥ 1 bone metastasis	SC Denosumab 120 mg every 4 weeks	IV Zoledronate 4 mg every 4 weeks	Time to first SRE HR 0.82 (0.71–0.95) (superiority $P = .01$)
Henry *et al.* (2011)	1776	Solid tumors with bone metastases (excluding breast or prostate primary)	SC Denosumab 120 mg every 4 weeks	IV Zoledronate 4 mg every 4 weeks	Time to first and subsequent SRE HR 0.84 (0.71–0.98) (noninferiority $P = .0007$)

and is well-tolerated. Currently approved for treatment of bone metastatic prostate cancer, extensive current trials are exploring its use in combination with chemotherapy and endocrine treatments in breast and prostate cancer.

The definitive criterion for clinical assessment of response of bone accepted by regulators is the reduction in SREs, as used in the large randomized trials of bone targeted agents discussed above. However, for development of new therapies, including combination of agents, bone turnover markers have been extensively used as surrogates in early trials and in selection of patients for clinical studies. Since increased bone resorption is the hallmark of bone metastasis, reductions in bone resorption markers such as NTX and CTX (and often consequent reduction also in formation markers such as P1NP and BSAP) have been widely interpreted as success criteria in early studies (Coleman *et al.*, 2011a). A major advantage for such studies is that the response is very fast (usually within 6 weeks), much more rapid than assessment via SREs or imaging.

This approach has proven to be reliable when later assessed in larger studies using SRE endpoints. For example, in the SRE breast cancer studies which demonstrated superiority or noninferiority of denosumab to zoledronic acid (see **Table 3**), the early change in bone markers induced by the two bone targeted agents reflected these differences (Stopeck *et al.*, 2010).

Adverse Effects of Bone Targeted Agents

The most serious adverse effect of bisphosphonates and denosumab is the occurrence of osteonecrosis of the jaw (ONJ), which involves painful bone destruction and potential infection. Treatment of ONJ can be challenging with only slow healing despite measures such as local debridement and antibiotic therapy. At the therapeutic doses of potent bisphosphonates (e.g., zoledronic acid) and denosumab used in metastatic bone disease, the incidence risk is about 1% per annum during therapy (Van Poznak *et al.*, 2011). The risk of developing ONJ can be mitigated by improved awareness of ONJ among oncologists, dental practitioner and oral surgeons, good dental hygiene and avoidance of dental procedures during therapy. Essential dental work should be completed before commencing bisphosphonates or denosumab. Based on our now much improved understanding of ONJ, comprehensive guidelines have been produced for its prevention, diagnosis, and management (Ruggiero *et al.*, 2014).

With the exception of ONJ, the adverse effects of bone-targeted agents are relatively mild and include a transient acute phase response and the possibility of renal impairment with intravenous bisphosphonates and gastrointestinal effects or diarrhea with oral agents. In the metastatic setting, there is consensus that the benefits of treatment with bisphosphonates or denosumab almost always outweigh the risks (Coleman *et al.*, 2014).

Bone Targeted Agents and Prevention of Bone Metastases

Preclinical and early clinical studies of bone targeted agents such as bisphosphonates in bone metastatic cancers showed that, in addition to modulating the bone microenvironment, these agents have direct antitumor, antiangiogenic and immunomodulatory effects (Aviles *et al.*, 2007; Daubine *et al.*, 2007; Mystakidou *et al.*, 2005; Santini *et al.*, 2007). There is therefore a rationale for the use of bisphosphonates in early disease in a strategy to prevent or reduce development of bone metastasis.

In one trial involving early breast cancer patients with proven micro-metastases (on bone marrow evaluation), adjuvant use of oral clodronate appeared to delay and prevented the development of bone metastases (Diel *et al.*, 2008). Similarly, Powles *et al.* (2006) showed that daily treatment with clodronate 1600 mg for two years significantly reduced the 5-year incidence of bone metastases (HR 0.59, 95%CI 0.398–0.887; $P = .009$) and overall survival (HR 0.77, 95%CI 0.591–0.999; $P = .048$).

Large studies of zoledronic acid have shed new light on the utility of bisphosphonates in the adjuvant setting in preventing bone metastasis. The ABCSG12 trial included 1803 premenopausal women with endocrine-receptor positive early breast cancer and showed that the addition of 6-monthly intravenous zoledronate for 3 years to ovarian suppression and tamoxifen/anastrozole prevented around a third of disease recurrences (HR 0.64, 95%CI 0.46–0.91; $P = .01$) after 7 years follow-up (Gnant *et al.*, 2009). A subsequent trial (the AZURE study), was performed in a wider subpopulation of early breast cancer patients, in which pre- and postmenopausal patients with Stage II and III breast cancer received standard adjuvant therapy $\pm$ an intensive schedule of zoledronic acid. Whilst this study failed to show a significant benefit in disease recurrence in the overall population studied (HR 0.98; $P = .73$), preplanned analysis of the postmenopausal subgroup showed a significant reduction in disease-free survival at 5 years (HR 0.75, 95%CI 0.59–0.96; $P = .02$) (Coleman *et al.*, 2011b). These results were mirrored by those of the NSABP-34 trial that showed that addition of oral clodronate led to disease-free interval improvement in women >50 years (HR 0.75, 95%CI 0.57–0.99; $P = .045$) (Paterson *et al.*, 2012).

This benefit from adjuvant bisphosphonates among older, postmenopausal women was confirmed in a meta-analysis of data from all randomized clinical trials evaluating adjuvant bisphosphonate use in the early breast cancer. Among a total of 18,766 patients (pre- and postmenopausal), there was a significant reduction in the rate of recurrence in bone (RR 0.83, 95%CI 073–0.94; $2P = .004$) (Coleman, 2016). This effect was found to be greater among the 11,767 postmenopausal women (RR 0.72, 95%CI 0.60–0.86; $2P = .0002$), who were also found to derive a breast cancer-specific overall survival benefit (RR 0.82, 95%CI 0;73–0.93; $2P = .002$). Neither benefit was demonstrated among premenopausal women (HR 0.92; $2P = .42$ and HR 1.00; $2P = .35$, respectively).

Mounting evidence of their benefit in the postmenopausal setting has now led to the recent consensus recommendation that adjuvant bisphosphonates be considered in the adjuvant treatment of early breast cancer in postmenopausal women, as well as

premenopausal women for whom ovarian suppression is a planned component of their adjuvant endocrine therapy (Hadji *et al.*, 2016).

The RANKL-inhibitor, denosumab was shown in the ABCSG18 trial to reduce the incidence of fractures in postmenopausal women receiving adjuvant aromatase inhibitors (Gnant *et al.*, 2015) and preliminary analysis of data from 3425 women in this trial suggests a disease-free survival benefit (HR 0.816, $P = .051$) that is comparable to the use of adjuvant bisphosphonates (Gnant *et al.*, 2015). The ongoing Phase 3 double-blind placebo-controlled D-CARE trial that is evaluating adjuvant denosumab in locally advanced breast cancer (Goss *et al.*, 2011) is expected to provide more-definitive evidence. This is expected to report in 2018.

Preventing prostate cancer bone metastasis using bone targeted agents has also been evaluated in a number of studies, though with mixed success. In the STAMPEDE trial for example, addition of zoledronic acid to androgen deprivation ± docetaxel did not show survival benefit (James *et al.*, 2016). A randomized, placebo-controlled trial involving 2406 castrate-resistant nonmetastatic prostate cancer patients, showed that administration of subcutaneous denosumab 120 mg every 4 weeks led to a significant increase in bone-metastasis free survival (HR 0.85 95%CI 0.73–0.98 $P = .028$) (Smith *et al.*, 2012). There was however no overall survival benefit seen (HR 1.01 $P = .91$) and a notable increased risk of osteonecrosis of the jaw (cumulative incidence of 4.6% at 3 years) in the denosumab arm resulted in its failure to obtain a license for routine adjuvant treatment in prostate cancer.

Prognostic and Predictive Biomarkers

As outlined above, biomarkers of bone turnover have proved valuable in assessing the current bone resorption and bone formation status of patients with established bone metastases and in monitoring response to bone targeted therapy. Several studies have also demonstrated their value in predicting risk of impending SREs in patients with established bone metastases. For example, (Brown *et al.*, 2005) showed that, patients with prostate cancer and high NTX levels, had a higher risk of skeletal complications.

(RR = 3.25, 95% CI = 2.26 to 4.68, $P < .001$) compared with patients with normal NTX levels. For nonsmall cell lung cancer and other solid tumors, excluding breast cancer (combined analysis), the corresponding figures were RR = 1.79, 95% CI = 1.15 to 2.79, $P = .010$). The association of bone marker levels with SRE risk persists was also observed in patients treated with bisphosphonates (Coleman *et al.*, 2005).

Could these bone turnover markers also have a role in early cancer, in assessing the future risk of developing bone metastasis and the response to bone-targeted treatment? Early studies suggested this may be possible in lung cancer (Papotti *et al.*, 2006), but it is only more recently that this possibility has been addressed in large, breast cancer studies, which open up exciting possibilities for biomarker development.

Lipton *et al.* (2011) investigated β-CTX in 621 postmenopausal early breast cancer patients in a 5-year phase III trial of tamoxifen ± octreotide. Over 7.9 years median follow-up, higher pretreatment β-CTX was associated with shorter bone-only recurrence-free survival (HR 2.8, 95%CI 1.05–7.48, $P = .03$). However, there was no significant association with first recurrence at other distant sites.

Very recently, Brown *et al.* (2018) have carried out a preplanned analysis of data from the AZURE trial to determine whether serum bone turnover markers in early disease have clinical utility in identifying patients at high risk of developing bone metastasis. When considered as continuous variables, pretrial values of P1NP, CTX and 1-CTP were each prognostic for future bone recurrence at any time ($P = .006$; $P = .009$; $P = .008$ respectively). In categorical analyses based on the normal range, high baseline P1NP (>70 ng/mL) and CTX (>0.299 ng/mL), but not 1-CTP (>4.2 ng/mL) were also prognostic for future bone recurrence ($P = .025$; $P = .033$; $P = .099$ respectively). None of the markers were prognostic for overall distant recurrence that is, they were bone metastasis-specific and none of the markers were predictive of treatment benefit from zoledronic acid.

In a proteomics-based study (Westbrook *et al.*, 2016) identified the proteins macrophage-capping protein (CAPG) and PDZ domain–containing protein (GIPC1) as being associated with the development of bone metastasis and this was subsequently tested clinically in an analysis of pretrial tissue samples from patients in the AZURE study. When analyzed as a novel composite biomarker (CAPG/GIPC1) the results showed that high expression of both CAPG and GIPC1 was associated with a higher risk of development of bone metastasis (HR 4.5, 95%CI = 2.1 to 9.8, $P < .001$) and death (HR 1.8, 95%CI 1.01 to 3.24, $P = .045$). The composite biomarker was bone metastasis-specific, that is, it was not associated with nonskeletal relapse. Moreover, the composite biomarker was predictive for treatment benefit since, in patients with high CAPG and high GIPC1, adjuvant zoledronate reduced the risk of first disease recurrence in bone by a 10-fold factor.

In another study using the AZURE trial tissue resource, absence of 16q23 (MAF) amplification was associated with improved disease outcomes in patients treated with zoledronic acid (Pavlovic *et al.*, 2015). In patients with MAF-negative tumors, but not in patients with MAF positive tumors, zoledronic acid was associated with higher invasive-disease-free survival than was control treatment (HR 0.74, 95%CI 0.56–0.98), but in patients with MAF-positive tumors who were not postmenopausal at randomization, zoledronic acid was associated with lower invasive-disease-free survival (HR 2.47, 95%CI 1.23–4.97) and overall survival (2.27, 95%CI 1.04–4.93) than control treatment (Coleman *et al.*, 2017).

Bone Metastases; Medical Treatment

Robert Coleman, University of Sheffield, Sheffield, United Kingdom

Introduction

The aim of treatment for bone metastases is typically palliative with cure only rarely a realistic aim in highly chemo-sensitive tumors such as lymphoma and germ cell malignancies. The choice and sequence of therapies varies, depending on the underlying disease and the extent of disease beyond the skeleton. External beam radiotherapy, endocrine and cytotoxic treatments, targeted therapies, radioisotopes and, in some tumors, immunotherapy are all relevant. In addition, orthopedic intervention may be necessary for the structural complications of bone destruction. Optimal management requires a multidisciplinary team that includes not only medical and radiation oncologists but also orthopedic surgeons, radiologists, nuclear medicine physicians and specialists in palliative medicine. Local therapy is frequently relevant throughout the clinical course of the disease while multiple lines of systemic therapy are likely to be necessary to regain control of the disease as resistance to each treatment develops.

Localized external beam radiotherapy is effective in relieving bone pain and may promote bone healing and improved bone structure. Overall, response rates of around 85% are reported, with complete relief of pain achieved in half of patients (Agarawal *et al.*, 2006). However, systemic treatments to reduce tumor burden and/or improve bone structure are the mainstay of management.

Systemic Treatment of Bone Metastases

Therapy for bone metastases should be directed against the tumor cell to reduce tumor cell proliferation and at normal osteoclasts to inhibit the tumor induced osteoclastic bone resorption. Chemotherapy, biologically targeted agents, and endocrine treatments have direct antitumor effects, whereas the bisphosphonates and denosumab target osteoclasts in order to improve the structural integrity of affected bones and reduce skeletal morbidity. In general, direct systemic anticancer treatment for metastatic bone disease is similar to that indicated for other metastatic manifestations of the malignancy and will be dictated by the underlying tumor type. Chemotherapy can be more hazardous for patients with extensive bone disease, because of both poor bone marrow tolerance after replacement of functioning marrow by tumor and the effects of previous irradiation. Primary prophylaxis with hematopoietic growth factors may be required to enable chemotherapy to be administered safely.

Bone metastases are most prevalent in patients with breast, prostate and lung cancers and most patients will experience bone pain and skeletal complications including pathologic fracture. The developments in systemic therapy for solid tumors including the emergence of a range of targeted treatments for patients with specific mutations (e.g., b-raf in melanoma, epidermal growth factor receptor and ALK in lung cancer) as well as immunotherapy with immune checkpoint inhibitors across multiple tumor types appear to be as relevant for patients with bone metastases as they are for those with metastatic disease at other sites.

Skeletal morbidity is also a major problem in patients with multiple myeloma, and either widespread lytic metastases or diffuse osteopenia can occur. Most patients with myeloma respond rapidly to treatment and can now expect a median survival of around 5 years. However, despite these dramatic tumor responses, bone healing is rare, with lytic lesions persisting despite control of the disease due to persistent inhibition of osteoblast function.

Targeted Radionuclide Therapy

The therapeutic use of radioactive-labeled tracer molecules is an area of considerable interest and research. Because the radiation dose can be delivered more specifically to the tumor across multiple sites and normal tissues partially spared unnecessary irradiation, radionuclide therapy has a number of advantages over external beam radiotherapy.

Radionuclide therapy began with the treatment of bone metastases from thyroid cancer with radioiodine (^{131}I) and is now well established for the treatment of patients with significant uptake of ^{131}I into the metastases. Long-term palliation may be possible (Qiu *et al.*, 2011) and other than a radiation reaction within the salivary glands and a low but not insignificant 1%–2% incidence of radiation-induced leukemias, ^{131}I treatment is generally well tolerated.

Currently, radionuclide therapy is most widely used for bone metastases from prostate cancer. Strontium-89, a β emitter that imitates calcium and is taken up preferentially at sites of new bone formation, has been shown to localize at the sites of prostatic bone metastases and deliver between 10 and nearly 100Gy to an individual bony metastatic site (Jansen *et al.*, 2010). The dose of radiation to the bone marrow is only about one tenth of that to the bone metastases; however, significant bone marrow suppression may occur and limit subsequent use of chemotherapy. Pain relief occurs in up to 80% of patients, with 10%–20% becoming pain free and a median duration of symptomatic response of around 6 months (Jong *et al.*, 2016). Samarium-153 is

 doi:10.1016/B978-0-12-801238-3.65211-X

both a β- and a γ-ray emitter and, through linkage of the isotope to ethylene diamine tetramethylene phosphonate (EDTMP), concentrates preferentially in skeletal metastases. ^{153}Sm-EDTMP can provide excellent palliation of pain in both breast and prostate cancer and, because of its short half-life and more limited adverse effects on bone marrow function, is easier to administer on a repeated basis (Sartor *et al.*, 2004).

Most recently the bone-seeking, α particle–emitting radiopharmaceutical ^{223}radium chloride (Ra-223) has been developed primarily for the treatment of metastatic prostate cancer. Ra-223 mimics calcium and preferentially forms complexes with the bone mineral hydroxyapatite in areas such as bone metastases where there is usually increased osteoblast activity. The radiation emitted from Ra-223 is of high linear energy and has ultra-short penetration (<100 μm; 2–10 cell diameters) resulting in a highly localized antitumor effect in tumor cells adjacent to the bone surface with little adverse effects to the surrounding normal tissue (Nilsson *et al.*, 2005). Following a placebo controlled randomized phase 3 trial in castration resistant prostate cancer (CRPC) which produced a 3.6 month improvement in median survival over best supportive care, Ra-223 has been approved for the treatment of bone metastases from CRPC. Skeletal morbidity was also reduced by Ra-223 over and above that achieved by a bisphosphonate (Parker *et al.*, 2013). Treatment with Ra-223 was well tolerated and improved quality of life with no significant long-term toxicities identified (Nilsson *et al.*, 2016). Ra-223 is now being studied earlier in the course of the disease, as well as in other diseases including metastatic breast cancer, in combination with both endocrine and cytotoxic agents.

Bone Targeted Agents

In the past three decades bone targeted agents have become established as a valuable additional approach to the range of current anticancer treatments. Most experience has been with the bisphosphonates but, in the past decade, antibody treatment directed at inhibiting RANK ligand has become the treatment of choice in a number of disease settings.

The bisphosphonates are pyrophosphate analogs, characterized by a P-C-P–containing central structure that promotes their binding to the mineralized bone matrix and a variable R′ chain that determines the relative potency, mechanism of action and adverse effect profile (Roelofs *et al.*, 2010). After administration, bisphosphonates bind rapidly to exposed bone mineral around resorbing osteoclasts. Then, during bone resorption, bisphosphonates are internalized by the osteoclast, disrupt several biochemical processes involved in osteoclast function and ultimately result in apoptotic cell death.

The molecular mechanisms of action of the bisphosphonates are well established, with nitrogen-containing bisphosphonates shown to inhibit enzymes of the mevalonate pathway that catalyze the posttranslational modification of several proteins including the small guanosine triphosphatases such as Ras and Rho (Roelofs *et al.*, 2010). Bisphosphonates that do not have a nitrogen atom in the R′ chain, such as clodronate, induce osteoclast apoptosis through the generation of cytotoxic adenosine triphosphate analogs (Xu *et al.*, 2013).

After intravenous administration of a bisphosphonate, the kidney excretes approximately one third of the injected dose, and the remainder is taken up by bone (Daley-Yates *et al.*, 1991). Oral bisphosphonates are poorly and variably absorbed from the gut and must be taken on an empty stomach and food and drink avoided for an hour after taking.

Bisphosphonates have been used successfully in the treatment of a wide range of bone conditions characterized by increased osteoclastic bone resorption. In oncology they have become the standard treatment for tumor-induced hypercalcemia and the prevention of skeletal morbidity and, as shown below, they now also have a role in prevention of metastasis in the adjuvant setting of postmenopausal women with early breast cancer (Coleman *et al.*, 2014).

Bisphosphonates to Prevent Skeletal Morbidity and Relief of Bone Pain

Osteoclast activation is the key step in the establishment and growth of bone metastases. Biochemical data indicate that bone resorption is of importance not only in classic “lytic” diseases such as myeloma and breast cancer but also in prostate cancer with its osteoblastic looking metastases on radiographs. Despite the osteoblastic appearance, values of resorption markers are at least as high as those seen in breast cancer and other solid tumors reflecting the importance of osteoclastic bone resorption in this disease setting as well (Brown *et al.*, 2005). As a result, the osteoclast is a key therapeutic target for skeletal metastases irrespective of the tissue of origin.

Although radiotherapy has been the treatment of choice for localized bone pain for decades, the bisphosphonates provide an additional treatment approach for the relief of bone pain across a range of tumor types. The effects seems to be independent of the nature of the underlying tumor or radiographic appearance of the metastases, with sclerotic lesions responding similarly to lytic metastases (Wong and Wiffen, 2002). In a randomized trial, the effect of a single intravenous dose of the bisphosphonate, ibandronate, was similar to that achieved by an 8 Gy dose of external beam radiotherapy (Hoskin *et al.*, 2015).

During the 1990s and early 2000s, the bisphosphonates became the standard of care for the treatment and prevention of skeletal complications associated with bone metastases in patients with solid tumors or multiple myeloma (Coleman *et al.*, 2014). Randomized, placebo controlled trials used skeletal related events (SREs) as the primary end point for these studies; either the number of patients experiencing one or more SREs, or the time to the first SRE or the rate of SREs as determined by either a simple annual rate or more complex multiple event analysis techniques. SREs included the occurrence of pathologic long bone and vertebral fractures, the need for radiation for pain relief or to treat or prevent structural bone damage, development of spinal cord

compression or a requirement for surgery to bone. Episodes of hypercalcemia of malignancy were also included in some definitions.

Breast Cancer

The greatest experience with bisphosphonates is in the management of bone metastases from breast cancer, where the value of the agents is undisputed (Van Poznak *et al.*, 2011). Both the oral agents, clodronate and ibandronate, as well as the intravenous formulations of pamidronate, ibandronate and zoledronic acid have useful clinical efficacy (Coleman *et al.*, 2014). Oral ibandronate has obvious practical attractions over intravenous treatments to both patients and health care providers (Body *et al.*, 2004). However, in a randomized comparison with intravenous zoledronic acid, ibandronate did not meet the strict statistical criteria for noninferiority defined in the study protocol (Barrett-Lee *et al.*, 2014). Pamidronate was the first intravenous bisphosphonate to be systematically evaluated and has clinically important efficacy on skeletal morbidity, quality of life, pain and analgesic use in metastatic breast cancer (Hortobagyi *et al.*, 1996; Theriault *et al.*, 1999) and multiple myeloma (Berenson *et al.*, 1996).

Zoledronic acid is the most potent bisphosphonate available and is the bisphosphonate of choice in most clinical settings and health care systems. A placebo-controlled trial of zoledronic acid showed that the percentage of patients with at least one SRE after 1 year on treatment was reduced from 50% in the placebo group to 30% with zoledronic acid ($P = 0.003$). Zoledronic acid also significantly delayed the time to first SRE ($P = 0.007$) and reduced the overall risk of SREs by 41% ($P = 0.019$) (Kohno *et al.*, 2005). When compared to pamidronate, zoledronic acid reduced the overall risk of experiencing an SRE by a further 20% ($P = 0.025$) (Rosen *et al.*, 2003). Additionally, control of bone resorption was greater at all time points with the more potent zoledronic acid. The increased potency, however, did not influence either time to progression or overall survival.

Multiple Myeloma

Myeloma is exemplified by a marked increase in osteoclast activity and suppression of osteoblastic activity. Early studies of bisphosphonates for myeloma evaluated oral clodronate and showed beneficial effects on disease progression and a reduction in skeletal morbidity. However, intravenous bisphosphonates are the treatment of choice for most patients with multiple myeloma. 3–4 weekly intravenous pamidronate significantly reduced the proportion of patients developing SRE(s), time to first SRE and skeletal morbidity rate in comparison to placebo (Berenson *et al.*, 1996). Additionally, QOL scores, performance status and pain scores were all favorably influenced by pamidronate therapy. Zoledronic acid has similar activity to pamidronate in terms of control of skeletal morbidity (Rosen *et al.*, 2003). However, zoledronic acid also appears to modulate the course of the underlying disease. In a large randomized trial conducted in the United Kingdom by the Medical Research Council in newly diagnosed patients with myeloma who were receiving chemotherapy (including stem cell transplantation where appropriate) and either intravenous zoledronic acid or daily oral clodronate, patients treated with zoledronic acid had a better chance of survival, with an improvement in median OS of 5.5 months ($P = 0.04$) (Morgan *et al.*, 2010).

Prostate Cancer

Despite early evidence of pain relief and inhibition of biochemical markers of bone resorption in patients with osteoblastic bone lesions associated with advanced prostate cancer, the role of bisphosphonates in prevention of skeletal morbidity was slow to evolve. After, unimpressive results with either oral clodronate (Dearnaley *et al.*, 2005) or intravenous pamidronate (Small *et al.*, 2003), zoledronic acid was investigated in patients with CRPC and bone metastases; the increased potency of this compound translated into improved clinical benefit with a 36% reduction in the overall risk of skeletal complications. Bone pain was also reduced at all time points (Saad *et al.*, 2004).

Other Tumors

The pathophysiology of bone metastases has many similarities across tumor types and bisphosphonates likely to be of value in preventing skeletal morbidity across the range of tumors involving the skeleton. A randomized trial in each individual tumor type with bone metastases was not feasible and so a placebo controlled "basket trial" of all solid tumor types with bone metastases other than breast or prostate cancer with zoledronic acid was performed. This showed that zoledronic acid reduced the proportion of patients with at least one SRE (39% vs. 48%, $P = 0.039$), almost doubled the time to the first SRE (314 days vs. 168 days, $P = 0.021$) and reduced the risk for SRE(s) by about 30% ($P = 0.003$) compared with placebo (Rosen *et al.*, 2004).

RANKL Inhibition to Prevent Skeletal Morbidity and Relief of Bone Pain

RANKL is a member of the TNF superfamily and is the ligand for OPG. RANKL is expressed on the surface of osteoblasts and released into the bone microenvironment, where it binds to and activates its receptor, RANK, on immature osteoclasts to increase

the number and activity of functional osteoclasts. Denosumab is a fully human, synthetic antibody that specifically binds to RANKL preventing its interaction with RANK in a way similar to that of OPG (Brown and Coleman, 2012).

A single subcutaneous dose of denosumab causes rapid suppression of bone turnover; the maximal amount of urinary NTX suppression (about 70%–80%) was reached after 7 days and was sustained over the observation period of 84 days of the study (Body *et al.*, 2006). In a dose-finding study in patients with breast cancer and bone metastases, doses between 60 mg and 180 mg and dosing intervals of 4–12 weeks were evaluated (Lipton *et al.*, 2007). Differences between treatment groups in bone resorption responses were small, but following modeling of the pharmacodynamic profiles, treatment with 120 mg of denosumab every 4 weeks was selected to provide the optimal balance of efficacy and tolerability. Additionally, a randomized, phase 2 study in patients with bone metastases and urinary NTX levels >50 nmol/mmol creatinine despite treatment with an intravenous bisphosphonate, showed that switching to denosumab was more likely to normalize NTX levels than continuing with bisphosphonate treatment (Fizazi *et al.*, 2009). Moreover, considerably fewer patients treated with denosumab experienced a first SRE during time on study.

Subsequently, three identically-designed double-blind, phase 3, registration studies of denosumab were performed (Stopeck *et al.*, 2010; Fizazi *et al.*, 2011; Henry *et al.*, 2011). These studies included patients with bone metastases resulting from breast cancer ($n = 2046$) (Stopeck *et al.*, 2010), CRPC ($n = 1901$) (Fizazi *et al.*, 2011), and other advanced solid tumors or multiple myeloma ($n = 1776$) (Henry *et al.*, 2011). Patients were randomly assigned to receive four weekly subcutaneous injections of denosumab (120 mg) or intravenous zoledronic acid (4 mg), with supplements of calcium and vitamin D. The primary end point was the time to first SRE.

In patients with bone metastases resulting from breast and prostate cancers, denosumab was statistically superior to zoledronic acid in delaying the first SRE (Stopeck *et al.*, 2010; Fizazi *et al.*, 2011). In patients with bone metastases resulting from other advanced solid tumors and myeloma, denosumab was not inferior to zoledronic acid but failed to demonstrate statistical superiority over bisphosphonates (Henry *et al.*, 2011). Overall, denosumab treatment delayed the occurrence of all types of SREs.

Recently, a formal comparison of denosumab and zoledronic acid in multiple myeloma was completed. This study met its primary endpoint, demonstrating noninferiority to zoledronic acid in delaying the time to first on-study SRE ($P = 0.01$) and benefits in a number of secondary endpoints including an increase in time to progression with denosumab (Raje *et al.*, 2017). This study is likely to lead to regulatory approval and more widespread use of denosumab in myeloma.

Disease Modifying Effects of Bone Targeted Agents in Metastatic Disease

Other than the beneficial effect of zoledronic acid on survival in multiple myeloma described earlier, no significant effects on disease-related end points such as time to progression and survival have been demonstrated in individual trials within the metastatic disease setting, despite the favorable effects on skeletal morbidity. Similarly, in the trials comparing denosumab to zoledronic acid no differences in either disease progression or survival were seen, despite the improved efficacy of denosumab in prevention of skeletal morbidity. Interestingly however, exploratory analyses performed using data from three randomized trials of zoledronic acid versus placebo suggested a beneficial effect of zoledronic acid on survival in patients with highly aggressive or advanced metastatic bone disease (Coleman *et al.*, 2013). It was thought most likely that these possible survival benefits result from prevention of SREs such as fractures and hypercalcaemia that are likely to preclude or delay introduction of effective anticancer treatments rather than any direct effects on the underlying cancer.

Adverse Events

The severity of adverse events related to bisphosphonates is generally mild and the benefits of treatment almost always outweigh the risks (Coleman *et al.*, 2014). With the exception of the acute phase response, causing transient fever, myalgia, and bone pain, adverse effects after administration of intravenous bisphosphonates are infrequent, provided the drug is infused at the recommended dose and duration. Intravenous bisphosphonates are associated with renal damage, notably when administered by rapid infusion. With use of the recommended infusion times, renal monitoring with dose reductions or delays as appropriate and adequate hydration of the patient, renal adverse events are uncommon. With oral agents, upper gastrointestinal toxicity (esophagitis and dyspepsia) or diarrhea may occur and may compromise adherence to treatment.

Denosumab does not impact on kidney function, which obviates the need for renal monitoring. Acute-phase reactions are also less common but hypocalcemia is more frequent and can be severe. All patients should be encouraged to take calcium and vitamin D supplements, and monitoring of serum calcium levels is advised, particularly in patients with impaired renal function.

The more serious potential adverse event from long-term treatment with bone-targeted agents is the development of osteonecrosis of the jaw (ONJ), particularly when administered parenterally on a monthly schedule. ONJ is characterized by painful bone destruction, secondary infection, and delayed healing in the mandible and/or maxilla (Ruggiero *et al.*, 2006). The risk of ONJ appears to be related to duration of treatment, occurring at around 1% per year on therapy (Migliorati *et al.*, 2011). As with intravenous bisphosphonates, the most important adverse event associated with the intensive dose schedule of denosumab used in oncology settings is ONJ. In the phase III registration trials ($n = 5677$), a similar proportion of patients treated with zoledronic acid and denosumab experienced ONJ (1.3% vs. 1.8%, respectively) (Saad *et al.*, 2012).

Treatment of ONJ is difficult and the management focus should be on prevention by increasing awareness amongst oncologists, dentists and maxillo-facial surgeons. Good dental hygiene and avoidance of dental procedures during therapy significantly reduce the risk of ONJ. Comprehensive guidelines now exist for prevention, diagnosis, and management of ONJ (Ruggiero *et al.*, 2014).

Optimum Use of Bone-Targeted Agents in Persons With Metastatic Bone Disease

Consensus guidance recommendations indicate that all patients with radiologically confirmed bone metastases from breast cancer should start taking a bisphosphonate or denosumab at the time of diagnosis of bone metastasis and continue with this treatment indefinitely (Coleman *et al.*, 2014; Van Poznak *et al.*, 2011). The development of an SRE is not necessarily a sign of treatment failure or a signal to stop treatment; evidence is now available to confirm that bone-targeted agents delay second and subsequent complications, not just the first event.

Bisphosphonate treatment—specifically zoledronic acid—or denosumab is also appropriate for patients with CRPC. In hormone sensitive prostate cancer, bisphosphonates may be indicated to prevent treatment induced bone loss but, because initial treatment of prostate cancer is so effective at controlling the underlying disease, the risk of SREs from metastatic involvement is low and does not usually justify routine use of monthly denosumab or zoledronic acid. Patients with other tumors and metastasis to bone should be considered for bone-targeted treatment if bone is the dominant site of metastasis or the patient has bony symptoms or a raised level of a biochemical marker of bone metabolism.

Despite the clinical benefits of bone-targeted treatments, only a proportion of events is prevented, and not all patients will experience a skeletal event despite the presence of metastatic bone disease. Accurate prediction in an individual patient of the need for and likely benefit from bone-targeted treatments is lacking; elevated bone marker levels, a previous SRE, increasing numbers of lesions, and lytic rather than sclerotic appearance of lesions on radiograms are associated with a higher risk for SREs and may be taken into consideration (Coleman *et al.*, 2014; Lipton *et al.*, 2008).

Several trials have investigated whether the interval between bisphosphonate infusions can be increased to take advantage of the prolonged pharmacologic effect in bone, improve convenience, reduced treatment costs and potentially minimize the risk of ONJ. Several small trials have suggested that reducing the frequency of administration did not significantly diminish the efficacy of zoledronic acid. However, these trials were underpowered to show noninferiority of the less intensive schedules with any reliability (Hutton *et al.*, 2013; Hortobagyi *et al.*, 2017). More recently, the noninferiority of less frequent zoledronic acid administration was shown in the much larger CALGB 70604 trial ($n = 1822$) (Himelstein *et al.*, 2017). No statistically significant differences in efficacy were seen between zoledronic acid monthly or every 3 months for 2 years. 29% of patients in both treatment groups experienced ≥ 1 SRE and there were no differences in time to first SRE or pain scores. These data support the use of the three monthly schedule, potentially from the outset as tested in the trial and certainly after loading of the skeleton with a few months of treatment with zoledronic acid. It is not known if the frequency of administration of denosumab can also be reduced. The mechanism of action is completely different, with no accumulation of the antibody in the skeleton, and there are data to show that both bone resorption biomarker levels and vertebral fracture rates increase within a few months of stopping treatment (Tsourdi *et al.*, 2017).

Prevention of Bone Metastases

Breast Cancer

The potential for bone targeted agents to modify the process of metastasis and have important effects on disease outcomes has been the focus of extensive laboratory and clinical research for several decades (Wilson and Coleman, 2012). The early metastasis prevention trials with oral clodronate in early breast cancer produced apparently inconsistent results in terms of disease recurrence. Then, the disease modifying impact of adding zoledronic acid every 6 months for 3 years to ovarian suppression therapy (plus tamoxifen or anastrazole) was shown to reduce disease recurrence by about one third ($P = 0.01$) (Gnant *et al.*, 2009), benefits that were confirmed with longer follow up at a median of 84 months (Gnant *et al.*, 2015a).

Subsequently the AZURE trial, performed in a broader patient population showed no overall benefit for the addition of an intensive schedule of zoledronic acid to standard adjuvant therapy and limited the clinical application of the ABCSG-12 results (Coleman *et al.*, 2011). Nevertheless, in a prespecified subgroup analysis, postmenopausal women receiving zoledronic acid showed improved disease-free and overall survival and these data, alongside the results of ABCSG 12, formulated the hypothesis that the benefits of adjuvant bisphosphonates may be restricted to women with low levels of reproductive hormones, either through the occurrence of menopause or induced by ovarian suppression therapy. This hypothesis was strengthened by both preclinical data (Ottewell *et al.*, 2014) and the results of the NSABP-B34 trial evaluating the addition of daily oral clodronate to standard adjuvant therapy; improved disease-free survival was seen in an exploratory subset analysis of women >50 years at trial entry (Paterson *et al.*, 2012).

To address this hypothesis systematically, the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) collected individual patient data from all randomized trials to evaluate in a meta-analysis the effects of adjuvant bisphosphonates on disease outcomes

and, specifically, whether menopausal status influenced treatment efficacy (Early Breast Cancer Trialists' Collaborative Group (EBCTCG) *et al.*, 2015). Data from 18,766 randomized women were collected and included 3453 and 2106 breast cancer recurrences and deaths respectively. Bisphosphonates reduced first distant recurrence in bone by about one sixth ($2P = 0.004$) and confirmed a significant interaction between treatment efficacy and menopausal status. There were no demonstrable benefits in premenopausal women but in 11,767 postmenopausal women highly significant reductions, not only in bone recurrence (RR = 0.72; 95%CI 0.60–0.86, $2P = 0.0002$) but also, most importantly, in breast cancer mortality (0.82; 95%CI 0.73–0.93, $2P = 0.002$) were seen. Treatment effects appeared to be similar irrespective of the estrogen receptor status or grade of primary tumor, and consistent across the different bisphosphonate agents tested or the dosing schedule employed (Early Breast Cancer Trialists' Collaborative Group (EBCTCG) *et al.*, 2015). The recently reported SWOG trial that compared adjuvant treatment with oral clodronate, oral ibandronate or intravenous zoledronic acid supports the meta-analysis suggestion of a probable class effect with no differences in disease recurrence between the three treatments (Gralow *et al.*, 2015).

The meta-analysis findings are changing clinical practice and both European (Hadji *et al.*, 2016) and North American (Dhesy-Thind *et al.*, 2017) consensus panels of breast cancer experts have recommended use of adjuvant bisphosphonates in post-menopausal women with early breast cancer, especially those at intermediate or high risk of relapse.

Denosumab is clearly an effective intervention to prevent fracture (Gnant *et al.*, 2015b) and preliminary data suggest it may also reduce disease recurrence (Gnant *et al.*, 2015c). However we do not know if this agent also reduces breast cancer mortality and await the results of the placebo controlled D-CARE trial (NCT01077154) for an answer.

Prostate Cancer

Prostate cancer spreads almost exclusively to bone and provides the ideal clinical setting for the evaluation of bone-targeted treatment to modify the course of the disease. In a placebo controlled trial of denosumab in men with nonmetastatic CRPC who were at high risk for bone metastasis by virtue of either a high PSA ($\geq$8.0 ng/mL) and/or short PSA doubling time ($\leq$10.0 months), denosumab significantly increased bone metastasis-free survival by a median of 4.2 months compared with placebo ($P = 0.028$) and delayed time to symptomatic first bone metastases (Smith *et al.*, 2012). However, this benefit was offset by the relatively high cumulative incidence of ONJ (4% at 3 years) and has not led to regulatory approval of denosumab in this clinical setting or changed clinical practice.

In the STAMPEDE trial in men starting ADT for prostate cancer, the impact of zoledronic acid alone or in combination with chemotherapy on disease recurrence was assessed. Docetaxel had a major impact on relapse and overall survival but zoledronic acid, despite extending the time to first skeletal complication, had no impact on survival (James *et al.*, 2016). Other studies of bisphosphonates to prevent bone metastases in prostate cancer have also failed to show benefit (Wirth *et al.*, 2015; Denham *et al.*, 2014); the biological rationale for lack of efficacy in the context of men with prostate cancer on androgen deprivation therapy when clear benefit has been seen in postmenopausal breast cancer requires further investigation.

Lung Cancer

Exploratory studies testing the potential use of bone targeted agents to prevent bone metastases in lung cancer have not identified any impact on the subsequent course of the disease (Scagliotti *et al.*, 2012). An ongoing trial with denosumab (SPLENDOR) has completed accrual and will report in the near future.

Treatment of the Skeletal Complications of Bone Metastases

Bone metastases cause considerable morbidity including pain, impaired mobility, hypercalcemia, pathological fracture, spinal cord or nerve root compression, and bone marrow infiltration. In two randomized trials that included patients with breast cancer and multiple myeloma receiving chemotherapy, the mean skeletal morbidity rates (number of skeletal events per year) in the absence of bisphosphonates were 3.5 and 2.0, respectively (Hortobagyi *et al.*, 1996; Theriault *et al.*, 1999; Berenson *et al.*, 1996). However, despite the clinical importance of metastatic bone disease and the huge expenditure on medical care for skeletal complications, relatively little thought has been given until recently as to how best to coordinate clinical management and deliver optimum care for patients with bone metastases.

Bone Pain

Bone pain is the most common type of pain from cancer. It is usually the manifesting symptom and is caused by a variety of factors, including periosteal stretching, compression or infiltration of nerve roots, reflex muscle spasm, and the local effects of cytokines. Appropriate analgesics and coanalgesics are essential to promptly relieve pain in addition to radiotherapy, systemic anticancer therapy and bone targeted treatments. A low threshold for seeking expert advise from a palliative care specialist is recommended.

Hypercalcemia of Malignancy

Hypercalcemia is an oncologic emergency that is typically associated with metastatic bone disease although, in tumors producing significant amounts of parathyroid hormone related peptide, it can occur in the absence of bone involvement. Clinical features include nausea, vomiting, dehydration, and confusion. The signs and symptoms vary considerably from patient to patient and are often nonspecific, affecting many systems in the body; they may easily be mistaken for symptoms of the underlying cancer or associated treatment if there is not an astute awareness of the possibility of hypercalcemia. If untreated, a progressive rise in serum calcium leads to deterioration in renal function and level of consciousness. Death ultimately ensues as a result of cardiac arrhythmias and renal failure.

Intravenous bisphosphonates, in conjunction with rehydration, are well established as the treatment of choice for hypercalcemia. Approximately 70%–90% of patients will achieve normocalcemia, resulting in relief of symptoms and improved QOL. Zoledronic acid is the most effective bisphosphonate for the acute treatment of this metabolic emergency (Major *et al.*, 2001). Denosumab is an alternative therapeutic option having been shown to be effective in around two thirds of patients with persistent hypercalcemia after recent bisphosphonate treatment (Hu *et al.*, 2014).

Summary

The management of bone metastases requires an experienced multidisciplinary team to ensure timely diagnosis and the appropriate integration of local and systemic treatments. The effects of tumor cells on bone cell function (especially on osteoclast activity) underpin the rationale for the use of bone-targeted treatment to reduce skeletal morbidity (Weilbaecher *et al.*, 2011). These bone-specific treatments are now an accepted part of routine clinical management. Additionally, the disruption of bone remodeling results in release of collagen fragments, which seems to have value in predicting skeletal events, prognosis, and monitoring of response.

Further developments in our understanding of the pathophysiology of bone metastases can be expected to provide new therapeutic strategies. Already, improved knowledge of the signaling molecules involved in regulating osteoclast function—notably OPG and RANKL—has led to the development of highly active targeted therapies for cancer-induced bone disease, and other novel therapeutic approaches are in clinical development. During the next 5 years, several of these compounds can be expected to gain regulatory approval, and ultimately combinations of bone-targeted therapies may be recommended to further reduce the clinical burden of metastatic bone disease.

Multiple Myeloma Bone Disease

Evangelos Terpos and Maria Gavriatopoulou, National and Kapodistrian University of Athens, Athens, Greece

Introduction

Multiple myeloma is a plasma cell dyscrasia characterized by bone marrow infiltration by monoclonal plasma cells and the presence of a monoclonal immunoglobulin in serum. It is the second most common hematological malignancy (Kyle and Rajkumar, 2004; Palumbo and Anderson, 2011). Symptomatic disease is characterized by one or more myeloma defining events including anemia, renal impairment, hypercalcemia, and bone disease (Greipp *et al.*, 2005). Approximately 85% of the patients present with osteopenia at diagnosis, while the degree of bone disease is correlated both with the extent of the tumor burden and prognosis (Palumbo and Anderson, 2011; Kyle *et al.*, 2003; Terpos *et al.*, 2003a,b). Bone metabolism is maintained by the balance between bone resorption and bone formation, however in multiple myeloma this balance which is mainly regulated by osteoclasts and osteoblasts is impaired. Myeloma cells secrete several factors that inhibit osteoblast bone formation and enhance osteoclast activity, while the microenvironment supports tumor expansion (Quail and Joyce, 2013; Podar *et al.*, 2009). Animal studies have demonstrated that increase of bone formation or inhibition of osteoclasts not only reduce myeloma burden but reduce the risk for myeloma bone disease as well (Choi *et al.*, 2001; Edwards *et al.*, 2008). Therefore, since disease progression depends on the interactions of myeloma cells with the microenvironment, treatment agents are aiming to restore bone homeostasis by targeting either osteoclasts or osteoblasts, or both.

Bone Marrow Mesenchymal Stromal Cells

Bone marrow stromal cells (BMSCs) is compiled by several hematopoietic (red and white blood cells) and mesenchymal (osteoprogenitors, osteoblasts, chondrocytes, adipocytes, fibroblasts, and endothelial cells) cells (Mendelson and Frenette, 2014) and participate indirectly in hematopoiesis by secreting chemokines, cytokines, and growth factors such as IL-6, G-CSF, GM-CSF, CXCL12, IL7, and LIF. These factors are involved in proliferation and differentiation of hematopoietic stem cells and progenitor cells (Mendelson and Frenette, 2014; Morrison and Scadden, 2014; Panaroni *et al.*, 2014; Panaroni and Wu, 2013). Mesenchymal cells originate from a mesenchymal stem cell (MSC), while B lymphocytes are differentiated in the bone marrow (Fridenshtein *et al.*, 1968). This explains that if, deficiency of osteoprogenitors and preosteoblasts is induced in vivo, the common lymphoid precursor cells are depleted (Visnjic *et al.*, 2004), while deletion of the α subunit in the G can lead to B cell differentiation at the pro-B cell stage arrest (Wu *et al.*, 2008a,b). In contrary, deletion of the parathyroid hormone (PTH) receptor, arrests the differentiation of a pro-B cell into a mature one. Following that, mature B cells are accumulated in the bone marrow and this occurs along the bone surface. This phenomenon is mainly due to overexpression of the vascular cell adhesion molecule 1 (VCAM1) by bone and stromal cells (Panaroni *et al.*, 2015). Myeloma cells interact with BMSCs either directly with cell–cell contact or via secretion of paracrine factors. These interactions stimulate secretion of BMSC-derived factors that upregulate the expression of antiapoptotic and cell cycle regulating proteins (Hideshima *et al.*, 2004; Neri *et al.*, 2007; Tai *et al.*, 2006; Asano *et al.*, 2011). More specifically, cell–cell interactions are mediated via adhesion molecules, such as intercellular adhesion molecule 1 (ICAM-1) and VCAM-1and very late antigen 4 (VLA-4). These interactions enhance MM cells retention and lead to increased osteolytic bone lesions (Michigami *et al.*, 2000; Markovina *et al.*, 2010; Hao *et al.*, 2011). Other factors such as interleukin 6 (IL-6) also promote of myeloma progression (Hideshima *et al.*, 2007). IL-6 is secreted by both MM and BMSCs as a result of different signaling pathways (such as NF-kB and Notch) stimuli (Chauhan *et al.*, 1996; Urashima *et al.*, 1995; Radtke and Raj, 2003; Nefedova *et al.*, 2004). Furthermore, other secreted cytokines like TNF-α and IL-1β can lead to bone disease by osteoblast inhibition, IL-6 upregulation, and osteoclast activation (Galson *et al.*, 2012; Lee *et al.*, 2013). Other factors secreted include vascular endothelial growth factor (VEGF), IL-1, insulin-like growth factor (IGF-1), TGF-β, angiopoietin-1 (Ang-1), platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), and basic-fibroblast growth factor (bFGF) (Hideshima *et al.*, 2005; Gupta *et al.*, 2001). These factors are associated with osteoclastogenesis, increased angiogenesis, and tumor growth (Giuliani *et al.*, 2011). Levels of serum Activin A have been shown to be increased in patients with advanced bone disease (Terpos *et al.*, 2012; Vallet *et al.*, 2010). Activin A is a factor activating osteoclasts and inhibiting osteoblast differentiation. However, it is not secreted by MM cells (Vallet *et al.*, 2010). MSCs from myeloma patients were found to secrete activin A, therefore suggesting a possible genetic defect in BMSCs of these patients (Vallet *et al.*, 2010). In preclinical models it has been demonstrated that targeting activin A can reverse osteoblast inhibition and improve this way myeloma bone disease. Furthermore, lenalidomide which is an immunomodulatory agent increases the levels of activin A secreted from the BMSCs, leading to osteoblastogenesis inhibition. Therefore, the combination an antiactivin A antibody with lenalidomide based regimens could represent a potential new therapeutic strategy for the management of myeloma bone disease (Scullen *et al.*, 2013). BMSCs in myeloma patients secrete growth differentiation factor 15 (GDF15), which supports stem cell survival and regeneration (Corre *et al.*, 2007, 2012; Tanno *et al.*, 2014; Reagan *et al.*, 2014). All the above-

mentioned findings highlight the important role of the microenvironment in the myeloma disease progression (Corre *et al.*, 2012; Tanno *et al.*, 2014; Feng *et al.*, 2010; Eda *et al.*, 2016). Proteasome inhibitors target the interactions between MM cells and BMSCs, inhibit cell growth and reduce the secretion of cytokines necessary to enhance myeloma cells survival (Hideshima *et al.*, 2001). Furthermore, bortezomib increases osteoblast differentiation by acting directly on MSCs (Mukherjee *et al.*, 2008). A different way to decrease myeloma cell adhesion to stromal cells involves the inhibition of CXCL-12/CXCR-4 axis, which is upregulated by VLA-4/VCAM-1 interaction, by using a CXCR4 inhibitor named AMD3100. Sensitivity to chemotherapy can be achieved by mobilization mechanisms (Azab *et al.*, 2009).

Cells of the Osteoblast Lineage

Osteoblasts are mononuclear cells which originate from mesenchymal stem cells. They contain alkaline phosphatase, which is a marker of osteoblastic activity (George *et al.*, 2006). Osteoblasts normally locate near the bone surface and their main function is bone formation (McSheehy and Chambers, 1986; Owen *et al.*, 1991). The osteoblasts that become part of mineralized matrix are called osteocytes (Giuliani *et al.*, 2006; Holtrop, 1990). Osteolineage cells affect primarily myeloma bone disease via the activation of two transcription factors: the runt-related transcription factor 2 (RUNX2) and the osterix (OSX) (Zaidi, 2007). These factors are essential for osteoblasts maturation and depend on the canonical Wnt signaling pathway.

Transcription Factor Runx2/Cbfa

Runx2/Cbfa1 is a transcription factor involved in formation and differentiation of osteoblasts from BMSCs and mesenchymal stem cells. The activation of Runx2/CBFA1 increases the expression of osteoblastic markers. In preclinical models, mice Runx2/CBFA1-negative do not have osteoblastic activity (Giuliani *et al.*, 2005). The expression of Runx2/CBFA1 in myeloma patients with bone disease is significantly lower than that in normal subjects or patients without bone disease. Myeloma cells inhibit osteoblast formation via cell-to-cell interactions and by suppressing Runx2/Cbfa1 activity.

Wingless-Related Integration Site (Wnt) Signaling Pathway

Wnt pathway is critically involved in bone remodeling (Giuliani *et al.*, 2005) via activation, gene expression, cell proliferation, migration, and differentiation (Albers *et al.*, 2013; van Amerongen *et al.*, 2012). Furthermore, Wnts control embryogenesis, organ formation and development, and regeneration of human tissues (Wan *et al.*, 2013). Wnts are classified as canonical when they have the capacity to inhibit phosphorylation of β-catenin and its degradation and as noncanonical when β-catenin levels remain the same (Bartis *et al.*, 2013). Wnt proteins bind to Wnt receptor and its co-receptors LRP5/LRP6 (low-density lipoprotein receptor-related protein) leading to β-catenin stabilization. Consequently, β-catenin accumulates in cytoplasm, translocates into the nucleus, and stimulates the expression of osteoblastic related genes (Westendorf *et al.*, 2004). When the Wnt signal is absent, the proteasome phosphorylates and degrades β-catenin. β-Catenin is the main factor regulating OPG expression from osteoblasts. Actually, it is demonstrated that inactivation of gene for LRP5 leads to an osteoporosis-pseudoglioma syndrome in humans while gain of function mutations in LRP5 leads to a syndrome of hereditary high bone density (Boyden *et al.*, 2002). Wnt pathway is regulated by extracellular soluble antagonists (Kawano and Kypta, 2003). Members belonging to the Dickkopf (DKK) family bind to LRP5/LRP6 while secreted frizzled-related proteins (sFRP), such as sFRP-2 and sFRP-3 bind to Wnt proteins. This results in suppressed Wnt signaling and reduced osteoblast function.

Dickkopf-1 (DKK-1) Protein

DKK1 is mainly expressed by osteoblasts and BMSCs, and antagonizes the Wnt pathway. This results in inhibition of osteoblasts maturation and increased bone formation. DKK-1 is also produced by myeloma cells and inhibits differentiation of osteoblast precursor. In patients with lytic lesions, DKK-1 was shown to be overexpressed in bone marrow biopsies. Furthermore, DKK-1 was also increased in the serum of MM patients (Politou *et al.*, 2006), while gene expression levels and serum levels of DKK-1 have been correlated with the extent of bone disease (Kaiser *et al.*, 2008; Tian *et al.*, 2003). The high expression of DKK1 has as a result that mesenchymal stem cells do not differentiate to osteoblasts (Tian *et al.*, 2003). Antibodies against DKK-1 (BHQ880) have shown encouraging results in patients with myeloma (Iyer *et al.*, 2014), however their development seems to be currently discontinued.

Secreted Frizzled-Related Protein-2 (sFRP-2)

sFRP-2 is produced from myeloma cells and inhibits osteoblast differentiation induced by bone morphogenetic protein 2 (BMP-2) (Oshima *et al.*, 2005). It is considered as a decoy receptor interfering with Wnt by binding to its receptor, frizzled. It has been demonstrated that patients with advanced bone disease have elevated levels of sFRP-2 in myeloma cells (Oshima *et al.*, 2005).

Sclerostin

Sclerostin is a Wnt inhibitor, produced by osteocytes which inhibits osteoblast-induced bone formation (Moester *et al.*, 2010). The production of sclerostin is upregulated by glucocorticoids, while intermittent parathyroid hormone (PTH) inhibits the production by osteocytes. Furthermore, sclerostin inhibits the canonical Wnt pathway by antagonizing Wnts for binding to LRP-5/6 receptor, leading to beta-catenin degradation. Patients with myeloma have elevated levels of circulating sclerostin and this correlates with adverse disease characteristics features and extensive bone disease. Patients with pathological fractures at diagnosis have extremely high levels of sclerostin compared with all the others, whereas sclerostin seems to correlate with bone-specific alkaline phosphatase and with C-telopeptide of collagen type 1 (Terpos *et al.* 2012a,b). Sclerostin seems to be the most appropriate target in myeloma bone disease. Romosozumab, is a monoclonal antibody against sclerostin, that increased the bone mass in patients with post-menopausal osteoporosis (McClung *et al.*, 2014). Clinical trials in myeloma setting are highly anticipated.

Interleukin-7

IL-7 increases osteoclastic activity and at the same time inhibits osteoblast maturation. IL-7 levels are increased in samples from bone marrow plasma in myeloma patients compared to healthy controls. IL-7 inhibits osteoblast differentiation by decreasing the promoter activity of Runx2/Cbfa1 in osteoblasts (Giuliani *et al.*, 2005).

Transforming Growth Factor-Beta (TGF-β)

TGF-β is a growth factor that is released from bone matrix during bone resorption and inhibits osteoblastic differentiation via Runx2 and remote deletion homoeobox 5 (DLX-5) pathways (Takeuchi *et al.*, 2010). It has been demonstrated that myeloma cells growth might be suppressed by TGF-b inhibition leading to promotion of the differentiation and maturation of osteoblasts (Lu *et al.*, 2016).

Growth Factor Independence-1 (Gfi1)

Gfi1 is a multifunctional transcription factor that binds DNA via specific Zn-finger domains mediating this way chromatin remodeling. This may result to long-term changes regarding gene expression. Elevated levels of Gfi1 block Runx2 induction by osteogenic signaling. MM cells increase Gfi1 expression, inhibit osteoblastogenesis, and reduce bone formation in MM bone disease (D'Souza *et al.*, 2011).

Adipocytes

Adipocytes are not directly implicated in bone disease. Wnt signaling suppresses adipocyte lineage which is regulated by PPARγ signaling pathway (Kang *et al.*, 2007; Fairfield *et al.*, 2018). Furthermore, adipocytes accumulation in the marrow increase with age from 30% to 70% in elderly people (Scheller *et al.*, 2015). Respectively, bone formation decreases with aging. Obesity has been shown to be correlated with increased risk of myeloma and is also associated with increased levels of adipocytes (Landgren *et al.*, 2010; Islam *et al.*, 2005; Wallin and Larsson, 2011). Patients with MM have higher abdominal fat and increased fat metabolic activity by FDG-PET/computed tomography (CT) when compared to MGUS (Veld *et al.*, 2016). Recent preclinical data suggested that an unhealthy diet may be involved in tumor progression (Lwin *et al.*, 2015). Adipocytes seem to support myeloma growth by secreting adipocyte-specific cytokines (adipokines) (such as leptin, adipsin, insulin, and resistin) and growth factors (IL-1β, IL-6, IL-10, IL-12, TNFα, monocyte chemoattractant protein 1 (MCP-1), IGF-1, VEGF, SCF, and bFGF) (Caers *et al.*, 2007; Sprynski *et al.*, 2009, 2010; Greco *et al.*, 2015; Sakurai *et al.*, 2013). Furthermore, adipocytes have a protective effect on myeloma cells against apoptosis induced by chemotherapy through autophagy mechanisms (Liu *et al.*, 2015). Bone marrow adipocytes secrete lipids that can be used as energy bank for cell proliferation (Zub *et al.*, 2015). Increased serum levels of free fatty acids were found in myeloma patients when compared to healthy controls (Jurczyszyn *et al.*, 2015). Some fatty acids had antimyeloma effect (Nagata *et al.*, 2015; Abdi *et al.*, 2014), however a recent study involved lysolipids in the origin of monoclonal gammopathies (Nair *et al.*, 2016). This probably is due to an extensive underlying immune activation that could represent an initiation mechanism in sporadic monoclonal gammopathies. Furthermore, increased levels of free fatty acids are correlated with upregulation of PPARγ signaling, which enhances adipogenesis and therefore myeloma survival and osteoblast inhibition. A recent in vitro study showed direct lipotoxic effect on human osteoblasts (Wang *et al.*, 2013; Gunaratnam *et al.*, 2014). Moreover, adipogenesis during aging and obesity affects bone renewal (Ambrosi *et al.*, 2017). To conclude, marrow fat seems to represent an important emerging regulator of tumor growth and bone disease development and, therefore, in the future it might play crucial role in the upcoming therapeutic strategies.

Osteoclasts

The underlying pathophysiology of myeloma bone disease consists of upregulation of osteoclast activity resulting in increasing bone resorption and therefore to bone lesions (Bataille *et al.*, 1989). The amount of osteoclast has been associated with disease progression (Terpos *et al.*, 2003a,b Valentin-Opran *et al.*, 1982 Taube *et al.*, 1992). Myeloma cells secrete osteoclastogenic cytokines, including IL-1, IL-3, IL-6, TNFα, MIP-1α, MIP-1β, and decoy receptor 3 (DcR3) (Roodman, 2009 Lee *et al.*, 2004a,b Nanes, 2003 Kitaura *et al.*, 2004 Abe *et al.*, 2002a,b Colucci *et al.*, 2009). Furthermore, bone cells and MSCs and bone cells also produce osteoclastogenic cytokines. BAFF, activin A, CXCL12, IL-6, and VEGF play critical role in osteoclast differentiation through the receptor activator of nuclear factor kappa-B ligand (RANKL) and osteoprotegerin (OPG) (Giuliani *et al.*, 2001; Pearse *et al.*, 2001; Roux *et al.*, 2002).

RANK

RANK is a transmembrane signaling receptor, which belongs to the tumor necrosis receptor superfamily. RANKL is mainly expressed by the surface of osteoclast precursors, while it is produced by BMSCs, osteoblasts and activated T-lymphocytes (Hsu *et al.*, 1999; Nakagawa *et al.*, 1998). MM cells adhesion to BMSCs acts as stimuli for RANKL expression by osteoblasts. Osteoblasts promote osteoclast differentiation through activation of NF-κB and JunN-terminal kinase pathways (Ehrlich *et al.*, 2005). Moreover, RANKL inhibits osteoclast apoptosis. RANKL has direct effects on mature osteoclasts resulting to actin ring formation and cytoskeletal rearrangements. The TNF receptor associated factor 6 (TRAF6) is a regulatory molecule which promotes osteoclasts formation when RANK binds to RANKL (Häcker *et al.*, 2011). TRAF6 binds to RANK and leads to the activation of the downstream NF-Kb (Jules *et al.*, 2010) and activation of MAPK pathways (JNK, p38). The activation of NF-Kb pathway increases c-Fos expression, which consequently binds and interacts with the nuclear factor of activated T cells (NFAT-c1) initiating osteoclast gene transcription. Denosumab is a humanized monoclonal antibody that binds to RANKL resulting in inhibition of B136 bone resorption (Body *et al.*, 2006). Denosumab currently is approved for the treatment of bone metastases due to solid tumors. In a phase 3 clinical trial which enrolled >1700 patients with newly diagnosed MM, denosumab was compared to zoledronic acid. The first available data of this study revealed that denosumab is not inferior to zoledronic acid while it seems to have a safer renal profile while it possibly increases progression-free survival (Terpos *et al.*, 2017).

OPG

OPG is a soluble decoy receptor for RANKL and member of the tumor necrosis factor receptor superfamily (Lacey *et al.*, 1998). It is produced by osteoblasts and BMSCs and reduces osteoclastogenesis by blocking the interactions of RANKL with RANK. Its expression IL-1b, TNF-a, TGF-b, estradiol, and 17b-oestriol regulate OPG expression. In preclinical studies OPG-deficient mice developed severe osteopenia and osteoporosis (Bucay *et al.*, 1998; Mizuno *et al.*, 1998; Simonet *et al.*, 1997). In healthy subjects, the RANKL/OPG ratio is very low. In contrary in MM patients osteoprotegerin (OPG) is decreased and correlates significantly with advanced bone disease (Seidel *et al.*, 2001).

RANKL/OPG Ratio

Several studies demonstrate that myeloma cells induce the RANKL expression by stromal cells in the bone microenvironment through direct cell-to-cell interactions (Giuliani *et al.*, 2001) and also express directly RANKL (Farrugia *et al.*, 2003; Heider *et al.*, 2003). In contrary, myeloma cells decrease OPG levels via reduced OPG secretion by stromal cells and osteoblasts (Qiang *et al.*, 2008). Furthermore, they produce syndecan-1 (CD138) which is a transmembrane proteoglycan binding to the heparin-binding domain of OPG mediating its lysosomal degradation by myeloma cells (Standal *et al.*, 2002). All these result in an increased RANKL/OPG ratio in the bone marrow microenvironment that increases osteoclast activity. The increased ratio of RANKL/OPG ratio has been associated with poor prognosis and severity of bone disease (Terpos *et al.*, 2003a,b). Agents targeting the normalization of the RANKL/OPG by reducing RANKL and increasing OPG managed to delay bone resorption and tumor growth in preclinical models (Croucher *et al.*, 2001a,b; Terpos *et al.*, 2004, 2005; Heath *et al.*, 2007).

Chemokine (C–C Motif) Ligand 3 (CCL3) (Also Known as Macrophage Inflammatory Protein 1-Alpha—MIP-1α)

CCL3 belongs to the CC chemokine family and is involved in the recruitment and activation of monocytes and monocyte-like cells, including osteoclast precursors (Wolpe *et al.*, 1988). It induces differentiation of osteoclast progenitors and increases osteoclast formation (Abe *et al.*, 2002a,b; Choi *et al.*, 2000; Oyajobi *et al.*, 2003). This is performed dose-dependently via the receptors CCR1 and CCR5, which are expressed by osteoclasts. CCL3 also enhances the effect of IL-6 and RANKL on osteoclast formation (Han *et al.*, 2001). CCL3 levels were elevated in the both in bone marrow and plasma of myeloma patients and correlated with disease features and activity. Furthermore, CCL3 was elevated in the blood of myeloma patients with extensive bone disease, but not in MGUS patients (Politou *et al.*, 2004; Terpos *et al.*, 2003a,b). Moreover, CCL3 gene was shown to be the

gene most highly correlated with advanced bone disease in multiple myeloma (Magrangeas *et al.*, 2003) CCL3 also acts directly on myeloma cells, promoting their growth, survival, and migration (Lentzsch *et al.*, 2003).

Interleukin-3

IL-3 is secreted from activated lymphocytes. IL-3 levels were increased in myeloma cells and in bone marrow plasma from patients with myeloma. IL-3 along with CCL3 and RANKL increase osteoclast activity and therefore bone resorption. Furthermore, IL-3 enhances the growth of myeloma cells independently of IL-6 (Ehrlich *et al.*, 2005; Lee *et al.*, 2004a,b).

Interleukin-6

IL-6 is produced by BMSCs and is involved in inflammatory and immune procedures and in bone metabolism through the Ras/mitogen-activated protein (MAP), extracellular signal-regulated kinase (ERK) cascade, signal transducer and activator of transcription3 (STAT 3) and phosphoinositide 3-kinase/Akt cascade pathways. IL-6 promotes survival and growth for both myeloma cells and osteoclasts. IL-6 mainly increases the early osteoclast precursors that differentiate into mature osteoclasts. Serum levels of IL-6 are increased in myeloma and correlate with progression free survival, disease stage and activity (Kyrstsonis *et al.*, 1996). IL-6 levels were elevated in patients with osteolytic bone lesions when compared with those without bone disease or with patients with MGUS (de la Mata *et al.*, 1995). Preclinical studies have shown reduction in RANKL expression with anti-IL-7 and anti-IL-6 (mAb-1339) antibodies (Fulciniti *et al.*, 2009). However, no osteoclastogenic inhibition and antimyeloma effect was demonstrated.

Vascular Endothelial Growth Factor (VEGF)

Vascular endothelial growth factor (VEGF) is a glycoprotein that plays a critical role in MM migration and survival (Taylor *et al.*, 2012). Recently it has also been implicated in osteoclastogenesis. VEGF activates the osteoclasts by binding to VEGFR-1 receptor which is predominantly expressed on osteoclasts. Myeloma cells, on the other hand secrete VEGF stimulated by IL-6 and therefore activates osteoclasts (Tanaka *et al.*, 2007). Furthermore, VEGF enhances bone resorption and increases survival of mature osteoclasts (Tanaka *et al.*, 2007). Moreover, VEGF induces IL-6 production from BMSCs, while IL-6 stimulates VEGF secretion by myeloma cells. This mechanism suggests the existence of paracrine interactions between BMSCs and myeloma cells which is triggered by VEGF and IL-6 (Dankbar *et al.*, 2000).

Osteopontin

Osteopontin is a protein that presents normally in the human bone, kidney, teeth, and epithelial tissues. It is involved in adhesion, apoptosis, angiogenesis, and tumor growth (Standal *et al.*, 2004). Increased levels of osteopontin were identified in patients with advanced myeloma disease when compared with asymptomatic MM or MGUS subjects. Furthermore, increased levels of OPN were correlated with increased bone destruction.

Stromal-Derived Factor-1a (SDF-1α)

SDF-1a is produced by BMSCs and mediates its activity through CXCR4 receptor which is expressed on hematopoietic stem cells, lymphocytes, osteoclast precursors, and malignant cells. SDF-1a upregulates the expression of the matrix degrading enzyme, matrix metalloprotease 9 (MMP-9), which promotes recruitment, activation, and migration of the osteoclasts and is crucially involved in hematopoietic stem cells homing, migration, and tumor proliferation (Alsayed *et al.*, 2007). Plasma levels of SDF-1a are elevated in myeloma patients when compared with healthy subjects and are correlated with the presence of bone lesions. A CXCR4 inhibitor, BKT140, has shown that induces myeloma cells apoptosis and reduces osteoclast activity (Beider *et al.*, 2011).

Activin-A

Activin-A is a dimeric glycoprotein, which belongs to the transforming growth factor-β (TGF-β) family. It regulates several biological functions, including hormonal homoeostasis, gonadal functions, muscle growth, immunity, inflammation, and bone remodeling (Hedger *et al.*, 2011). Activin-A which is produced by osteoblasts and its antagonist lead to autocrine regulation of extracellular matrix mineralization and formation (Eijken *et al.*, 2007). Activin-A stimulates osteoclasts and probably inhibits osteoblasts (Fuller *et al.*, 2000; Kawabata *et al.*, 2007). It is elevated in myeloma patients with advanced disease and correlates with adverse disease features, extensive bone disease, and poor prognosis (Terpos *et al.*, 2012). Sotatercept, is an activin-A inhibitor, which was administered in patients with MM in a phase 2 study and showed that it could probably increase bone mineral density (Abdulkadyrov *et al.*, 2014).

Similarly, increased expression of Bruton's tyrosine kinase (BTK) in osteoclasts and tumor cells has been correlated with tumor growth and bone destruction (de Weers *et al.*, 1994; Shinohara *et al.*, 2008). Therefore, a BTK inhibitor, ibrutinib, has demonstrated satisfying results in reduction of osteolytic bone disease by inhibiting NF-κB pathway (Rushworth *et al.*, 2013; Tai *et al.*,

2012). The in vivo combination of another BTK inhibitor, CC-292, with carfilzomib demonstrated synergistic activity and increased bone formation (Eda *et al.*, 2014). Osteoclasts originate from the monocyte/macrophage lineage and share similar immune receptors and functions (Charles and Aliprantis, 2014; Wu *et al.*, 2008a,b) and interact with T lymphocytes in a direct way (Takayanagi, 2009). T cells secrete osteoclastogenic cytokines (such as RANKL and IL-1β), however osteoclasts suppress T lymphocyte proliferation maintaining this way bone remodeling balance (Grassi *et al.*, 2011). Other cells of the myeloid lineage such as macrophages, dendritic cells, and myeloid-derived suppressor cells (MDSCs), are considered to create a protective environment for tumor cells by preventing apoptosis and by T cells suppression (Gorgun *et al.*, 2013; Leone *et al.*, 2015; Zheng *et al.*, 2009). Recently, it was demonstrated that osteoclasts enhance myeloma cell survival via direct inhibition of T cells proliferation and therefore T-cell-mediated cytotoxicity (An *et al.*, 2016). This results to tumor escape from immunological surveillance (Topalian *et al.*, 2015), and highlights the critical role of osteoclasts in osteolytic bone disease. Therefore, osteoclasts should be considered as potential therapeutic targets for multiple myeloma.

Osteocytes

Osteoblasts and osteoclasts are the major compounds of bone remodeling, however osteocytes are considered to be the main regulators of bone homoeostasis (Bellido, 2013). Osteocytes are approximately 90%–95% of all bone cells, while osteoclasts and osteoblasts fewer than 10%. The osteocyte is defined as a cell surrounded by mineralized matrix. Osteocyte apoptosis is linked to bone remodeling as a result of what is called the osteocyte cell death (Plotkin, 2014). The regions that contain apoptotic osteocytes are targets for bone resorption, resulting in increased bone formation (Noble, 2005). The available data suggest that osteocytes are the major source of RANKL driven osteoclast formation (Xiong and O'Brien, 2012). Myeloma patients with bone disease seem to have fewer viable osteocytes and increased osteoclasts compared to than healthy controls or patients without bone lesions, and this is mainly the result of increased osteocyte apoptosis. Moreover, the expression of OPG is downregulated in the osteocytes by myeloma cells, and this leads to a more pro-osteoclastogenic RANKL/OPG ratio. Furthermore, the osteocytes seem to be the exclusive source of sclerostin production (Westendorf *et al.*, 2004). In murine models the inhibition of the osteocyte-produced sclerostin led to increased bone mass and prevented bone destruction (McDonald *et al.*, 2017). Bortezomib, which is a proteasome inhibitor, has demonstrated bone formation effect (Mohty *et al.*, 2014), by maintaining the viability of osteocytes by reducing their apoptosis rate (Toscani *et al.*, 2016).

Bone Disease Management

Bone disease which is mainly due to increased osteoclastic activity accompanied by decreased osteoblastic function leads to skeletal-related events (SREs). Bisphosphonates, radiotherapy, balloon kyphoplasty and orthopedic surgery, and very recently denosumab are the main therapies used for the management of myeloma bone disease.

Bisphosphonates

Based on the results of phase 3 studies, pamidronate and zoledronic acid (ZA) have demonstrated reduction in SREs compared to placebo (Berenson *et al.*, 1996, 2001; Rosen *et al.*, 2001a). In the first study, ZA was as effective as pamidronate in SREs reduction for patients treated with conventional chemotherapy (Rosen *et al.*, 2001a, 2003). In the second study, 30 mg versus 90 mg intravenous pamidronate monthly demonstrated similar results regarding time to SRE and SRE-free survival time (Gimsing *et al.*, 2010). The third study, compared intravenous ZA with oral clodronate, and it was found that ZA reduced the SRE risk compared to clodronate in all patients included, irrespectively of the presence of lytic bone lesions at diagnosis. Furthermore, ZA improved overall survival (OS) by 10 months in patients with lytic bone lesions at diagnosis (Morgan *et al.*, 2010, 2011). A more recent meta-analysis revealed survival advantage of ZA versus placebo (Mhaskar *et al.*, 2012). Therefore, the European Myeloma Network (Terpos *et al.*, 2013) recommends that all myeloma patients with adequate renal function (creatinine clearance >30 mL/min) and osteolytic bone disease at diagnosis should be treated with ZA (4 mg, over an at least 15-min infusion, every 3–4 weeks) or pamidronate (90 mg, in a 2–4-h infusion, every 3–4 weeks), intravenously. However, symptomatic patients, without bone disease as assessed by conventional radiography, can be treated with ZA as well.

Management of Bisphosphonates Side-Effects

Intravenous BPs can cause acute phase reactions, inflammatory reactions at the injection site, hypocalcemia, hypophosphatemia, renal impairment (RI), and osteonecrosis of the jaw (ONJ) (Terpos *et al.*, 2013; Berenson *et al.*, 1997; Dimopoulos *et al.*, 2006). For hypocalcemia prevention, all patients should receive calcium with vitamin D3 supplementation (at least 600 mg calcium per day and 400 IU vitamin D3 per day).

Renal impairment is due to acute tubular damage and can be observed with both pamidronate and ZA, but the true incidence of this adverse event remains unknown, considering that renal dysfunction is also a common myeloma complication (Morgan

et al., 2010; Terpos *et al.*, 2013; Dimopoulos *et al.*, 2006). Thus, patients with mild or moderate renal impairment need dose adjustments of ZA, according to the summary of the product characteristics.

Osteonecrosis of the jaw is an uncommon complication (ONJ) of BP. Retrospective studies suggest that ONJ is usually observed with ZA, after dental procedures, and seems to be associated with the prolonged administration of the BP (Dimopoulos *et al.*, 2006). Preventive dental measures may reduce ONJ incidence (Dimopoulos *et al.*, 2009). In cases of ONJ, BP should be discontinued and can later be re-administered whenever ONJ has healed.

Denosumab

The most promising agent targeting RANK/RANKL/OPG signaling pathway is the humanized monoclonal antibody denosumab. Due to its high affinity and specificity for RANKL, it can prevent RANK activation, osteoclastogenesis, and osteoclast activation. Recently, denosumab met the primary endpoint of a randomized, double blind, phase 3 study by demonstrating no inferiority compared with zolendronic acid in delaying time to first on-study SRE in patients with newly diagnosed MM. Furthermore, it was proven superior to zolendronic acid regarding time to first on-study SRE in a 15-month landmark analysis. Interestingly, a PFS advantage was seen in denosumab arm; something that needs further investigation as this was an exploratory endpoint in the study. Denosumab is not cleared though the kidneys, providing patients with renal impairment a novel therapeutic modality. Compared with zoledronic acid, patients treated with denosumab had lower rates of renal adverse events (17.1% vs. 10.0%, respectively; $P < 0.001$) (Terpos *et al.*, 2017). Based on these results FDA approved on 5th January 2018 denosumab for the prevention of skeletal-related events in patients with multiple myeloma.

Radiotherapy

Radiotherapy is mainly used for solitary plasmacytomas, symptomatic spinal cord compression, extremely painful lytic lesions, and to prevent pathological fractures. For painful osteolytic lesions, a dose of 3000 cGy in 10–15 fractions seems to be adequate.

Balloon Kyphoplasty and Vertebroplasty

These techniques are used for the management of painful vertebral compression fractures, and approximately 80% of patients with pain which does not respond to pain killers, experience pain relief A (Berenson *et al.*, 2011). All recent data, including a phase III study and a meta-analysis, suggest that balloon kyphoplasty is the treatment of choice for the reduction of pain due to cancer-related vertebral fractures and may be associated with reduced rates of cement leakage (Berenson *et al.*, 2011; Bhargava *et al.*, 2009).

Surgery

The administration novel antimyeloma treatment regimens has reduced the need for surgery during the past decade. Currently, surgery should be used only to fix pathological fractures of the long bones, to prevent and restore axial skeleton in cases of unstable spinal fractures and for spinal cord compression with bone fragments within the spinal route.

Conclusions

Osteolytic bone disease is one of the most common feature of multiple myeloma and is caused by factors produced by myeloma cells that consequently stimulate osteoclasts and inhibit osteoblasts. The cross talk between myeloma cells and the bone marrow stromal microenvironment is extremely complex. Although both overall survival and quality of life of patients with MM has dramatically improved the past decade after the incorporation of novel therapeutic agents, myeloma still remains an incurable disease. Progressive disease depends on the interactions within the stromal compound, therefore agents targeting these interactions are essential for disease treatment and bone disease. Bisphosphonates are the cornerstone of treating and preventing bone disease in MM. Other novel agents, such as denosumab represent promising potential therapeutic tools in the treatment of MM-induced bone disease. These novel agents alone or in combination with bisphosphonates and antimyeloma treatment are expected to extend our therapeutic options for myeloma bone disease in the near future. Further understanding of the underlying pathophysiology is needed.

BMD Bone mineral density
HRpQCT High resolution peripheral quantitative computerized tomography
PTH Parathyroid hormone
T1D Type 1 diabetes
T2D Type 2 diabetes

Introduction

Diabetes is a condition with increased glucose levels in the blood (hyperglycemia). Usually glucose is transported into the cells via the glucose transporters (GLUT) mediated for some of the GLUT (GLUT4) by insulin. Diabetes may occur when insulin is absent (type 1 diabetes—T1D) or when transportation of glucose is diminished due to insulin resistance type 2 diabetes (T2D), that is, in T2D insulin is present, but not in sufficient quantities. The glucose levels are roughly speaking determined by intake of glucose, glucose transport into and from the tissues (i.e., storage as glycogen in the liver or muscles mediated by insulin and degradation of glycogen by glycolysis mediated by say glucagon). Glucose may also be lost in the urine either through increased filtration brought about by high glucose levels in the blood or alterations in the GLUT in the kidney—these transporters differ from the GLUT by also transporting sodium (SGLT2—or sodium glucose transporters type 2).

In T1D insulin is mandatory for treatment, otherwise ketoacidosis may occur. In T2D a number of subcutaneous (s.c.) and oral treatment alternatives are available. Metformin may decrease glucose absorption, improve insulin resistance, and affect glycogen storage in the liver. Sulphonylureas and glinides increase insulin secretion from pancreas, and are thus dependent on functioning beta-cells.

Insulin may be used in insulin secretion is decreased.

Glucagon-like peptide increases feeding-related insulin release. GLP1 may either be given as injection as an analogue or the amounts in plasma may be increased by inhibiting the degradation of GLP by inhibiting the enzyme that degrades GLP (dipeptidyl peptidase 4 inhibitors).

The thiazolidinediones may improve insulin sensitivity by affecting the peroxisome proliferator-activated receptor gamma (PPAR-gamma). SGLT2 inhibitors may increase glucose loss in the urine and thus decrease blood glucose levels.

Diet is essential in order to control glucose delivery, for example, is starch a complex carbohydrate, which is slowly turned into glucose by amylase in the intestine, whereas pure glucose demands more insulin in order to process it quickly. Exercise is encouraged in order to metabolize glucose (usage in the muscles) as this improves insulin sensitivity. Fat deposition especially in the liver may increase insulin resistance by increasing degradation of the insulin produced in pancreas and transported to the blood through the liver via the portal vein. Exercise further diminished fatty depositions in the liver, gut omentum and peripherally thus improving insulin sensitivity.

Diabetes may be accompanied by a number of complications such as impaired eye sight (diabetic retinopathy), decreased kidney function (diabetic nephropathy), and atherosclerosis. Impairment of bone function may be a further complication of diabetes, and the impairment of collagen structure and function may share some features in the vessel walls and in the collagen in bone. Atherosclerosis is brought about by deposition of cholesterol and fatty acids in the vessel walls, which may then calcify, either directly or by vascular smooth muscle cells transforming into bone forming cells.

Bone consists of a mineralized matrix (mainly hydroxyapatite, which is a calcium–phosphorous compound), an unmineralized matrix (mainly consisting of collagen, osteocalcin—which in turn mediates signaling with the pancreas and insulin, and a number of other proteins), and cells that mediate bone turnover (formation, i.e., creation of new bone and resorption, i.e., degradation of old bone).

The density of the mineralized matrix (bone mineral density—BMD) may be assessed by sending two weak X-ray beams through the body (DXA or dual X-ray absorptiometry—dual for two, X-ray for radiation, and A for absorptiometry, as the fraction of the X-ray absorbed is measured).

Phosphate is absorbed passively from the intestine in abundant quantities and filtrated into the urine. Parathyroid hormone (PTH) may increase loss of phosphate in the urine. Vitamin D may increase phosphate absorption in the intestine.

Calcium is absorbed from the intestine either passively or actively mediated by vitamin D. Both vitamin D and PTH may increase reabsorption of calcium from the urine.

Calcium and phosphate are then built into the mineralized matrix as hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$). Collagen is formed as a triple helix from protein chains. First it is formed as pro-collagen, from which N- and C-terminal fragments may be measured in blood (P1NP is the N-terminal fragment of pro-collagen of type 1 collagen). The chains are hydrolyzed, glycosylated, and bonded by disulfate bridges. Each triple helix chain is then bound to other chains by cross-linking. Degradation of cross-linked collagen may thus release fragments such as CTX (C-terminal fragment of cross linked collagen).

Collagen is rich in glycine and proline. The hydroxylation forms hydroxylysine, which is likely to undergo glycation by nonenzymatic glycation (the Maillard reaction), **Fig. 1**. This is one form of advanced glycation end products (AGE). These AGE in turn have their own receptor (RAGE).

Diabetes has been associated with an increased risk of fractures (Vestergaard, 2007; Janghorbani *et al.*, 2007) disproportionate to the changes in bone mineral density (BMD) (Vestergaard, 2007). Especially in patients with T2D where an increased BMD was accompanied by an increased risk of fractures. In fact a decreased risk should be expected (Vestergaard, 2007). In T1D a much higher increase in hip fracture risk was seen than predicted from the observed decrease in BMD (Vestergaard, 2007). A special bone phenotype may thus be proposed in patients with diabetes.

In order to understand changes in bone, bone biomechanical competence, turnover, and fracture risk in diabetes, it is necessary to comprehend bone turnover and bone biomechanical competence.

Normal Bone Turnover and Competence

In order to understand normal bone biomechanical competence (Burr and Turner, 2003), one may contemplate the hypothetical example why it is relatively easy to break a piece of chalk for writing on a blackboard, while the phalanx of the fifth finger—which holds similar dimensions—may not be broken so easily despite containing less calcium and thus in theory on a DXA scans would seem less strong.

Several reasons for this exist; the bone contains both a mineral matrix and collagen. The mineral matrix (hydroxyapatite in bone and calcium carbonate in the chalk) adds strength but at the same time fragility. Like an atypical femur fracture the chalk will usually break in a relatively right angle while the fracture of a phalanx more likely will be a spiral fracture.

Unlike the chalk, bone contains collagen fibers which—like rebar in concrete—adds bending and compressive strength (**Fig. 2**). Cross-linking of collagen may further add to bone strength. Like re-bar the addition of collagen (a soft material) to a rigid material like the calcified material (like concrete in a building) created a composite material, which is much stronger and lightweight than the individual components would suggest.

Besides collagen, the unmineralized matrix contains osteocalcin and a number of other proteins.

Bone (Fig. 2)

In addition to collagen, the macro-architecture (cortex and marrow cavity) and micro-architecture (trabeculi, Haversian system) adds biomechanical competence.

Further to this, crystal structure and cross-binding adds to the biomechanical competence (**Fig. 3**). A similar cross-binding is not seen in the calcium carbonate crystals of chalk which may be less perfect hexagons than hydroxyapatite, and thus be less densely packed with less cohesion between the individual crystals and is thus easier to crush.

The architecture with a solid shell—the cortex—and a hollow marrow filled with trabeculi, which criss-cross the marrow cavity, further adds to bone biomechanical competence. The criss-crossing of trabeculi is a much stronger structure than a solid beam, especially the cross-linking and triangular structures created add strength (**Fig. 4**).

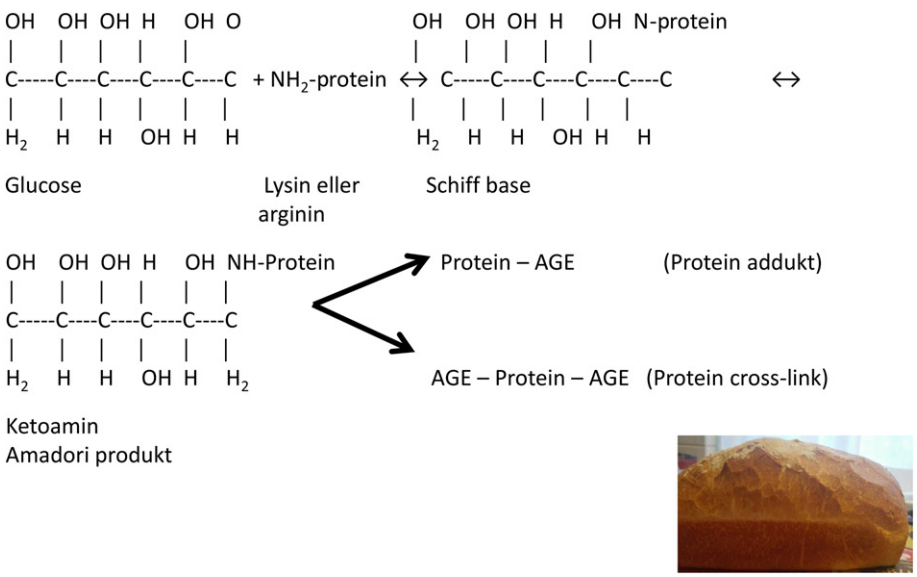

Fig. 1 The Maillard reaction and formation of advanced glycation end-products. This is the same reaction that turns bread yellow during baking.

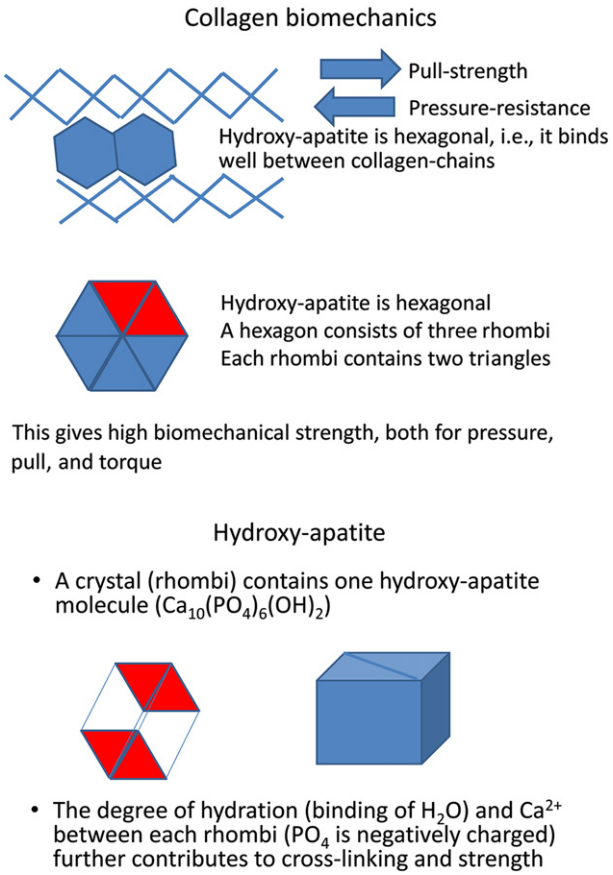

Fig. 2 The Maillard reaction and formation of advanced glycation end-products. This is the same reaction, which makes bread golden during baking.

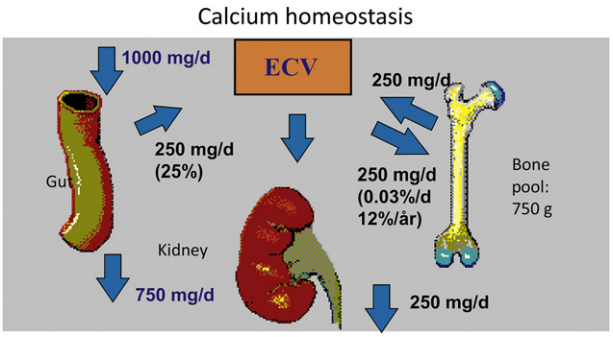

Fig. 3 Shows the normal calcium balance in adults.

This micro-architecture with trabeculi and fenestrations of the cortex (cortical porosity) may be visualized with modern high-resolution CT scanners (High-resolution peripheral quantitative computerized tomography—HrpQCT).

Bone is a living tissue, which contains osteoclasts, osteoblasts, and osteocytes. These contribute to turnover of bone and the way crystals are formed from hydroxyl-apatite, collagen is produced, and the mineralized and unmineralized matrixes are laid down. Diabetes may affect all of these processes.

Effects of Diabetes on Bone Biomechanical Competence

Diabetes may modify several of the processes mentioned above, and other factors associated with diabetes (obesity in T2D) and insulinopenia in T1D may also contribute,

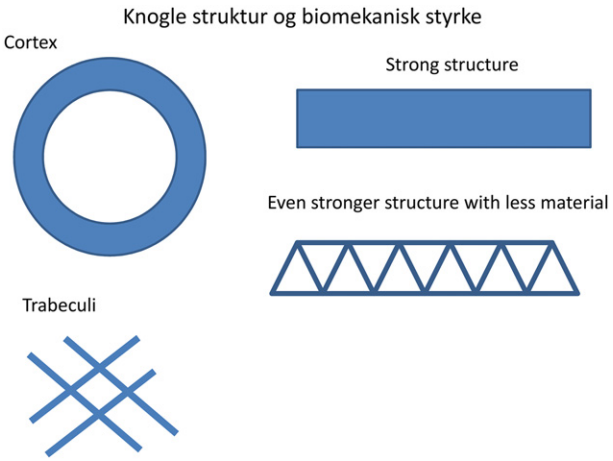

Fig. 4 Bone structure and biomechanical competence.

Turnover

In general dynamic histomorphometric studies on patients with diabetes are few in humans, especially in patients with T1D.

Animal studies (Follak *et al.*, 2004; Abbassy *et al.*, 2010; Fujii *et al.*, 2008; Glajchen *et al.*, 1988; Hamada *et al.*, 2007; Picke *et al.*, 2016) and studies in T2D in humans have suggested a low-turnover state in patients with diabetes (Manavalan *et al.*, 2012). Manavalan *et al.* (2012) in five T2D patients found reduced mineralizing surface, bone formation rate, osteoid surface, and osteoblast surface. Mineral apposition rate decreased with increasing blood glucose. Krakauer *et al.* in a mixed population of T1D and T2D patients among eight osteopenic patients reported markedly reduced bone formation rate and other histological indexes of osteoblast recruitment and function compared with those in nondiabetic control subjects (Krakauer *et al.*, 1995). On the other hand did Armas *et al.* not find any differences in dynamic or other histomorphometric parameters in patients with T1D (Armas *et al.*, 2012).

The disturbances in dynamic histomorphometry seem reversible with good metabolic control (Follak *et al.*, 2004; Fujii *et al.*, 2008; Picke *et al.*, 2016). In humans, markers of bone turnover in general have pointed at a reduced turnover expressed as osteocalcin (Starup-Linde *et al.*, 2015; Hygum *et al.*, 2017), CTX (Hygum *et al.*, 2017), and P1NP (Hygum *et al.*, 2017).

Bone Density and Structure (Micro and Macro-Architecture)

The findings using HRpQCT have differed. One study using HRpQCT in T2D showed similar trabecular and cortical architecture compared to normal controls, and the same increase in cortical porosity with fractures in T2D and controls (Patsch *et al.*, 2013; Heilmeier *et al.*, 2016).

One study reported increased cortical porosity and thus decreased density in the radius in T2D after adjustment for body weight (Yu *et al.*, 2015). Similarly a study in T2D patients with microvascular complications showed a decreased cortical porosity and cortical bone density, while T2D patients without microvascular complications had HRpQCT parameters comparable to controls (Shanbhogue *et al.*, 2016).

One further study showed an increased pore volume, but not statistically significantly increased porosity (Paccou *et al.*, 2016).

Increased trabecular number and cortical thickness have been reported in T2D without adjustment for weight (Patsch *et al.*, 2017), which was confirmed in a further study in T2D which showed a better microarchitecture in T2D than in controls (Nilsson *et al.*, 2017).

In T1D patients without microvascular complications had similar HRpQCT parameters to controls, while patients with microvascular complications had larger total and trabecular bone areas, lower total, trabecular, and cortical volumetric BMD, and thinner cortex at the radius, and lower total and trabecular vBMD, at the tibia in comparison to controls with microvascular complications after adjustment for weight (Shanbhogue *et al.*, 2015).

From these results it seems less likely that architecture as such lend a major contribution to the increased frailty at least in T2D and T1D, although a contribution may be seen with the presence of microvascular complications.

As an alternative to traditional DXA and HRpQCT, trabecular bone score (TBS) has been shown to be decreased in T1D (Neumann *et al.*, 2016) as well as in unspecified diabetes (Kim *et al.*, 2015; Leslie *et al.*, 2013) and TBS is related to fracture risk in nonspecified diabetes (Leslie *et al.*, 2013) and T2D (Choi *et al.*, 2016; Bonaccorsi *et al.*, 2017). One feature that deserves attention is that TBS—in contrast to areal BMD—may decrease with increasing BMI (Langsetmo *et al.*, 2016), which may interact with the high body-mass phenotype of T2D. This may be due to bone marrow adiposity as also shown by MRI to be altered in T1D (Abdalrahaman *et al.*, 2015).

Bone Quality

Studies using microindentation have shown a reduced biomechanical competence both in T2D (Farr *et al.*, 2014) and in adipose subjects (Sundh *et al.*, 2016). As mentioned patients with T2D have an increased areal BMD, but also an increased risk of fractures, and patients with T1D have an elevated risk of hip fractures not mirroring the decrease in BMD seen in these patients (Vestergaard, 2007). Both of these findings indicate a decrease in bone biomechanical competence as also found with microindentation.

The reasons for this decrease in biomechanical competence may be several. Einhorn *et al.* (1988) in an animal experimental study found a decrease in the perfection of crystal formation in diabetic rats, decreased calcium/phosphorus ratio of the ash, and decreased ash content in the tibial metaphyses with increased ash content in the tibial diaphyses compared to control animals. Bone osteocalcin content was increased in the metaphyses of the diabetic rats. Absolute measures of stiffness, torsional strength, and energy absorption were decreased in the bones of the diabetic rates. The latter is in accordance with the findings from the studies using micro-indentation.

In humans studies by Starup-Linde have suggested that mineralization may be disturbed with an increased formation of mineralized matrix to unmineralized matrix (Starup-Linde, 2015), which—like the chalk mentioned above—may make the bone look dense on DXA but frail on biomechanical testing. High sclerostin levels indicate that the bone tries to counter the hypermineralization (Hygum *et al.*, 2017; Heilmeier *et al.*, 2015), and with very high levels a decreased risk of fractures is actually seen in T1D (Starup-Linde *et al.*, 2016a) possibly indicating a successful balancing of mineralized versus nonmineralized matrix. However, similar findings were not seen in T2D (Heilmeier *et al.*, 2015; Starup-Linde *et al.*, 2016a), possibly indicating that the balance was not obtained in these patients.

A further important contributor to decreased biomechanical strength is glycation of collagen and formation of advanced glycation end products such as pentosidine.

In animal experimental diabetes, pentosidine and other advanced glycation end products are abundant in bone and the biomechanical competence of bone is reduced (Saito *et al.*, 2006a; Saito and Marumo, 2010). Similar findings have been done in human femur specimens (Saito *et al.*, 2006b).

In humans, serum markers of advanced glycation end products such as pentosidine (Yamamoto *et al.*, 2008) have associated with increased risk of fractures, whereas the opposite was the case for their receptor (esRAGE) (Neumann *et al.*, 2014; Yamamoto *et al.*, 2009; Yamamoto and Sugimoto, 2016).

The glycation of collagen and formation of AGE may alter the way bone cells interact with it (Hein *et al.*, 2006) so that increased AGE formation decreased the number of osteoblasts thus leading to a decreased formation of new bone.

Hyperglycemia may alter the function of bone cells. In osteoclasts, high glucose levels inhibited RANKL-induced osteoclastogenesis (Xu *et al.*, 2015) and decreased Tartrate resistant acid phosphatase (TRAP) activity and the pit resorption area for osteoclasts (Xu *et al.*, 2013). For the osteoblasts, high glucose levels increase mineralization at 12 mM levels and especially at 24 mM levels (Garcia-Hernandez *et al.*, 2012). PPAR-gamma expression may also be upregulated by hyperglycemia (Botolin and McCabe, 2006), which may induce an osteopetrotic phenotype. Hyperglycemia and high osmotic pressure for 24 h increased the production of collagen type I in osteoblasts and decreased the expression of BAP; (Cunha *et al.*, 2014) thus the effects of glucose on mineralization are unclear. Osteocyte like cells exposed to high glucose levels decrease expression of sclerostin protein, but not RANKL (Tanaka *et al.*, 2015) in contrast to what is seen in humans.

However, these are isolated cells and due to the complex interaction between osteocytes, osteoclasts, and osteoblasts, differences may be seen in vivo.

Body Weight and Feeding

T2D patients are often overweight, whereas T1D patients usually are normal weight or even underweight. The obesity in T2D may be brought about by increased energy intake (more meals and/or higher amounts of food per meal) and/or decreased physical activity with decreased energy consumption.

Higher BMI is associated with higher BMD (De Laet *et al.*, 2005), and the higher BMI in T2D may thus to some degree explain the higher BMD in these patients. The increased sclerostin levels may this partially explain the body's attempt to halt the increased mineralization induced by the higher body weight.

Ingestion of food is followed by a decrease in both resorptive and formative markers of bone formation (Henriksen *et al.*, 2003). In general the reduction in bone resorption is larger (around a factor of two to four depending on food item) than the reduction in bone formation following oral ingestion of any food item including oral glucose (Henriksen *et al.*, 2003). This response is brought about by GLP-2 (Henriksen *et al.*, 2003) and can be abolished using somatostatin, which inhibits GLP-2 (Clowes *et al.*, 2003). Intravenous (i.v.) Administration of glucose does not elicit a similar response despite release of insulin (Westberg-Rasmussen *et al.*, 2017), indicating that the response with decreased resorption and formation is strictly limited to oral feeding.

If T2D patients feed excessively and frequently this may induce a prolonged decrease in bone resorption favoring bone formation, which is then sought countered by sclerostin. Also as old bone may not be resorbed properly, the ratio between collagen and mineralized matrix may change.

The fact that similar changes are seen in HRpQCT in T2D and obesity may support the effects of obesity (Farr *et al.*, 2014; Sundh *et al.*, 2016).

Obesity may thus be a double-edged sword, increasing BMD, but decreasing bone quality. Inflammation from the adipose tissue and fat-rich diet may contribute to this (Cao, 2011).

Calcitropic Hormones and Other Biochemical Markers

As mentioned, sclerostin levels are markedly higher in both T1D and T2D (Heilmeier *et al.*, 2015; Starup-Linde *et al.*, 2016a). However, in animal models the role of sclerostin has been debated (Pereira *et al.*, 2017).

With hyperglycemia, hyperglycosuria usually leads to an increased loss of calcium in the urine. This can—in the absence of compensatory increased intake of calcium and vitamin D—lead to a negative calcium balance and thus bone loss (McNair *et al.*, 1979). Poorly controlled diabetes thus may lead to bone loss from increased calcium loss (McNair *et al.*, 1981). Usually this should be accompanied by secondary hyperparathyroidism, which is not the case in diabetes (McNair *et al.*, 1981). Especially the PTH response to hypocalcemia may be blunted (Schwarz *et al.*, 1992). However, as BMC and BMD are not decreased in T2D, this mechanism probably plays a minor role.

Vitamin D levels tend to be lower in T2D (Starup-Linde and Vestergaard, 2016), while PTH levels are not elevated (Starup-Linde and Vestergaard, 2016). Some of the decrease in vitamin D in T2D may perhaps be related to obesity—vitamin D being fat soluble and thus potentially deposited in the fatty tissue and not being available for normal feedback on PTH.

Proportionally lower than expected PTH may affect the bone anabolic properties of this hormone (Campbell *et al.*, 2016).

Usually low PTH should lead to decreased calcium absorption in the gut and reabsorption in the kidneys. However, as BMC and BMD are not decreased in T2D, this mechanism probably plays a minor role.

Effects of Treatments

Diet and exercise

Usually weight loss is encouraged in obese patients with T2D. A randomized controlled trial in overweight patients with T2D showed that weight loss was associated with a decrease in BMD (Daly *et al.*, 2005), while exercise training seemed to prevent the loss of BMD (Daly *et al.*, 2005). In patients treated by gastric by-pass, which is used for weight reduction in morbidly obese patients with T2D, a decrease is seen in BMD (Giusti *et al.*, 2005).

Hypoglycemia, falls, and fractures

An additional explanation for more fractures with normal to high BMD could be more traumas related to, for example, more falls due to hypoglycemia. However, the increased risk of fractures in diabetes is present even after adjustment for this, and although a relationship between hypoglycemia and fracture exists, this is weak (Vestergaard *et al.*, 2005).

Among the drugs used to treat diabetes, insulin and sulphonylureas may induce hypoglycemia and this fractures (Starup-Linde *et al.*, 2017), whereas most other oral and s.c. treatment principles usually do not induce major hypoglycemia.

Other causes for falls in diabetes may be impaired eyesight, neuropathy with impaired postural control, and sequelae to say cardiovascular problems and stroke. However, these seem to be of minor importance (Vestergaard *et al.*, 2009).

Effect of drug for glucose control

In animal studies insulin may revert the negative effects on bone following diabetes. However, in humans the picture is somewhat more unclear. Insulin (Vestergaard *et al.*, 2005), metformin (Vestergaard *et al.*, 2005; Josse *et al.*, 2017), and sulphonylureas (Vestergaard *et al.*, 2005) may along with dipeptidyl peptidase four (DPP-4) inhibitors (Monami *et al.*, 2011; Dombrowski *et al.*, 2017) show a trend toward lowering fracture risk. For GLP-1 agonists, the effect on fracture risk may depend on the type, with a decreased risk following use of liraglutide and an increased risk following use of exenatide (Su *et al.*, 2015). SGLT2 antagonists do not seem to affect fracture risk (Ruanpeng *et al.*, 2017; Zinman *et al.*, 2015).

Thiazolidinediones (glitazones) are associated with an increased risk of fractures (Loke *et al.*, 2009), although differences exist between the various types of glitazones (Josse *et al.*, 2017).

TZDs act by improving insulin sensitivity through activation of the nuclear receptor, peroxisome proliferator-activated receptor γ (PPAR-γ) (Yki-Jarvinen, 2004). The TZDs affect the differentiation of mesenchymal stem cells (Tornvig *et al.*, 2001). Normally the common mesenchymal progenitor stem cell can differentiate into among others osteoblasts and bone marrow adipocytes (Nuttall *et al.*, 1998). TZDs increase adipogenesis at the expense of osteoblasts, leading to bone loss (Lecka-Czernik *et al.*, 2002; Ali *et al.*, 2005). Other effects by PPARγ agonists include decreased circulating IGF-I concentrations (Lecka-Czernik *et al.*, 2007), and a decrease in estrogen levels, as treatment has been shown to affect the synthesis of sex steroids by inhibiting the aromatase pathway which is the main source for estrogen in postmenopausal women (Rubin *et al.*, 2005).

However, as mentioned the picture is not uniform (Palermo *et al.*, 2015), as insulin may be associated with an increased risk of fractures possibly linked to hypoglycemia, especially seen with short acting insulins (Josse *et al.*, 2017). Also some studies fail to find a decreased fracture risk with the use of DPP-4 inhibitors and GLP-1 agonists, including a recent meta-analysis (Driessen *et al.*, 2017).

For other types of drugs against diabetes, no change in fracture risk was seen (Vestergaard *et al.*, 2005).

Other effects of drugs used to treat patients with diabetes

Many patients with diabetes receive antihypertensive drugs. In general these do not increase, but may rather decrease the risk of fractures (Rejnmark *et al.*, 2006a).

Also statin use is frequent among patients with diabetes, and statins have been associated with a decreased risk of fractures (Starup-Linde *et al.*, 2016b). However, newer research have pointed at an increased fracture risk with very low LDL levels (Starup-Linde *et al.*, 2016b; Peña *et al.*, 2015) possibly from interference with the LRP5 and Wnt signaling system.

Effects of Drugs Against Osteoporosis in Diabetes

Bisphosphonates

Diabetes is a low-turnover condition and antiresorptive drugs reduce turnover. Concern has thus been raised about the safety of such drugs in diabetes. However, the fracture reducing potential seems similar in patients with and without diabetes for antiresorptive drugs (Vestergaard *et al.*, 2011).

Osteonecrosis of the jaw and other inflammatory jaw events—although rare—are associated with bisphosphonate use (Vestergaard *et al.*, 2012), and diabetes is per se a risk factor for osteonecrosis of the jaw and other inflammatory jaw events (Vestergaard *et al.*, 2012). However, these events seem rare (Vestergaard *et al.*, 2012).

The relationship between atypical femur fractures and diabetes is not known in detail (Saita *et al.*, 2015) although diabetes and long-term bisphosphonates share low bone turnover as a common risk factor.

PTH

Diabetes is a low turnover condition in terms of bone and interest has thus been shown on the bone anabolic properties of PTH or analogues. One study indicated that teriparatide may increase insulin resistance (Anastasilakis *et al.*, 2007). Like for bisphosphonates, the relative fracture risk reduction and increase in BMD were similar between patients with or without T2D (Schwartz *et al.*, 2016).

Conclusions

Diabetes seems associated with an increased risk of fractures, which may prove yet a complication of this disease. Changes in micro-architecture may neither explain the increase except in patients with microvascular disease, nor may increase risk of falls especially those related to hypoglycemia. Changes in calcitropic hormones may also play a minor role. This leaves changes in bone biomechanical competence as the presumed main cause of the increased risk of fractures. Some antidiabetic drugs may to some degree modify the risk of fractures.

Paget's Disease of Bone

Stuart H Ralston, University of Edinburgh, Edinburgh, United Kingdom

Glossary

Etiology The study or theory of the factors that cause disease and the method of their introduction to the host; the cause of origin of a disease or disorder.

Giant cell tumor A rare but benign bone tumor comprised of mesenchymal stromal cells and multinucleated giant cells with characteristics of osteoclasts.

Osteoblasts The cells responsible for bone formation, derived from differentiation of mesenchymal stem cells.

Osteoclasts Multinucleated bone resorbing cells formed by differentiation and fusion of mononuclear precursor cells of hematopoetic origin.

Osteosarcoma A malignant primary neoplasm of bone derived from cells of the osteoblast lineage. Almost all osteosarcomas in adults are secondary to Paget's disease of bone.

Epidemiology

Three major determinants of susceptibility to PDB have been identified; increasing age, ethnicity and male gender (van Staa *et al.*, 2002). Age is by far the strongest risk factor. Paget's disease is uncommon below the age of 50 but the prevalence doubles with each decade thereafter to affect about 5% of women and 8% of men aged 80 in the United Kingdom. The prevalence of PDB also varies widely in different countries (Corral-Gudino *et al.*, 2013). The disease occurs most commonly in the United Kingdom where it is estimated to affect about 2% of people over the age of 55 as assessed radiographically. The disease is also common in other European countries such as France, Spain and Italy and in people of European descent who have emigrated to other regions of the world, such as Australia, New Zealand, the United States of America, and Canada. In contrast Paget's disease is rare in Scandinavian countries, the Indian subcontinent, and Asian countries. These ethnic differences in prevalence of PDB persist after migration highlighting the importance of genetic factors in etiology. Archeological studies of skeletal remains in the UK have been performed and are consistent with a model whereby susceptibility to PDB arose as the result of genetic mutations that predispose to the disease in North West Europe many centuries ago, with spread to other regions of the world through emigration (Mays, 2010).

Pathophysiology

At a tissue level, active PDB is characterized by a marked increase in bone remodeling at affected sites (**Fig. 1**). Osteoclasts are increased in number and size and contain many more nuclei than normal. Some contain nuclear inclusion bodies which were

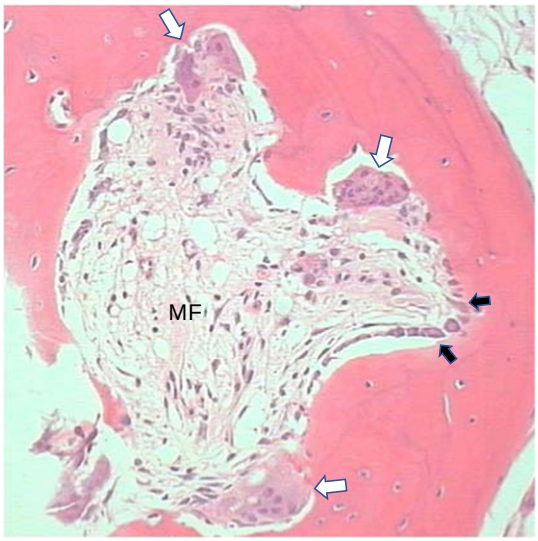

Fig. 1 Bone histology in active Paget's disease. Hematoxylin and eosin stained section of bone from a patient with active Paget's disease. Several large osteoclasts are visible (*white arrows*) as well as osteoblasts forming new bone (*black arrows*). There is extensive marrow fibrosis (MF).

 doi:10.1016/B978-0-12-801238-3.95769-6

originally considered to represent viral nucleocapsids (Rebel *et al.*, 1974). However more recent evidence suggests that these structures could be aggregates of undegraded proteins due to defects in the autophagy pathway in PDB (Daroszewska *et al.*, 2011; Helfrich and Hocking, 2014). Osteoblast numbers and new bone formation is also markedly increased in PDB but the bone is laid down in a disorganized fashion (woven bone) which is mechanically weak. Other histologic abnormalities characteristic of active PDB include increased vascularity of bone and bone marrow fibrosis.

Genetic factors play a key role in the pathogenesis of PDB (Ralston and Albagha, 2014; Cundy, 2018; Singer, 2015). Familial clustering is common and there is a sevenfold increases risk of developing the disease in first degree relatives of patients as compared with controls (Siris *et al.*, 1991). In a proportion of families, the disease is inherited in an autosomal dominant trait with an age-dependent increase in penetrance (Morissette *et al.*, 2006; Hocking *et al.*, 2000; Morales-Piga *et al.*, 1995). There are marked ethnic differences in susceptibility to PDB. These disease is common in people from North West Europe, Italy, and Spain. The ethnic differences in susceptibility persist in European migrants to countries such as Australia, New Zealand, and Canada where PDB occurs rarely in the indigenous population (Ralston and Albagha, 2014; Gardner *et al.*, 1978). This is consistent with a founder effect due to carriage of genetic variants that predispose to PDB across the world (Lucas *et al.*, 2005). At the present time 12 genes or loci with robust evidence for association with PDB have been identified as summarized in **Table 1**. However, for some of these variants, PDB is only one component of a multisystem proteinopathy which is characterized by myopathy and neurodegeneration as well as PDB.

Research into the genetic basis of PDB has provided several insights into the molecular pathways that regulate bone remodeling (reviewed by Ralston and Albagha (2014)). For example, discovery of mutations in *SQSTM1* as a cause of PDB uncovered a previously unsuspected role for this gene in regulating osteoclast activity through effects on RANK induced NFκB signaling and its interaction with the signaling protein CYLD. Similarly, studies of the 10p13 locus identified *OPTN* as an important gene in the regulation of bone metabolism through effects on the NFκB pathway and interferon signaling (Obaid *et al.*, 2015).

Other loci associated with PDB lie close to genes that play a role in osteoclast differentiation or activity. For example, the susceptibility locus on the 1p13 locus is 87Kb upstream of *CSF1* which encodes macrophage colony stimulating factor, a protein that is essential for the early stages of osteoclast differentiation. The 8q22 locus lies close to the *DCSTAMP* gene which is essential for the formation of multinucleated osteoclasts. At present, it seems likely that predisposition to PDB at these loci is mediated by variation in expression of these genes, or by linkage disequilibrium with rare variants within the genes themselves but further research is needed to clarify this. For other loci such as 7q33 (*NUP205*), 14q32 (*RIN3*), and 15q34 (*PML*), but the mechanism by which PDB occurs is unclear since these genes have not previously been implicated in bone metabolism. Mutations of the *HNRNPA1/HNRNPA1B1* and *VCP* genes result in a multisystem disease characterized by accumulation of abnormal protein aggregates in muscle and neurones. This supports the hypothesis that abnormalities of protein degradation play a key role in PDB the mechanisms by which osteoclast activation occurs in these diseases remains unclear.

Although susceptibility to PDB is strongly influenced by genetics, environmental factors also play a role. Evidence of this comes from epidemiological studies which have shown significant decreases in disease prevalence and severity in most countries over the past 25 years (Corral-Gudino *et al.*, 2013). It is of interest, however, that in the Campania region of Italy, the severity has increased and in some regions of Spain, no major changes in prevalence or severity of PDB have been observed. Various factors have been suggested as possible triggers for PDB including dietary calcium and vitamin D deficiency; exposure to environmental toxins; repetitive biomechanical loading of affected bones; and local trauma. The only environmental factor that has been studied experimentally is chronic paramyxovirus infection. This was suggested as a possible disease trigger based on the identification of nuclear inclusions in osteoclasts that were thought to resemble measles virus (Rebel *et al.*, 1974). However, more recent work has shown that these structures are morphologically distinct from measles virus particles on ultrastructural analysis (Helfrich *et al.*, 2000). Furthermore, attempts to detect evidence of paramyxovirus nucleic acids and proteins in patient material have yielded

Table 1 Genes and loci for PDB

Locus	*Syndrome*	*Discovery*	*Effect size*	*Allele frequency*[a]	*Likely gene(s)*	*Mechanisms of PDB*	*Author*
1p13	PDB	GWAS	Moderate	Common	*CSF1*	Unknown	Albagha *et al.* (2011)

inconclusive results and a recent large scale study showed no evidence of an enhanced immune response to paramyxoviruses in PDB as one would expect if a slow virus infection was the cause (Visconti *et al.*, 2017). Although experimental studies have shown that targeted over expression of measles virus nucleocapsids protein to osteoclasts can result in abnormalities of osteoclast function and bone turnover (Kurihara *et al.*, 2011) over-expression of other viral proteins can do the same (Ruddle *et al.*, 1993). Currently therefore the role of viral infection as a trigger factor or perpetuating factor in PDB remains controversial.

Clinical Features

Many individuals with PDB do not suffer symptoms related to the disease and it has been estimated from radiological survey data that between 7% and 14% of patients come to medical attention (van Staa *et al.*, 2002; Tan and Ralston, 2014). In those that do, musculoskeletal pain is the single most common presenting complaint affecting 38% of individuals, followed by bone deformity (20.3%), pathological fractures (10.6%), and deafness (5.9%) (Tan and Ralston, 2014). In one case series about 20% of patients who had presented clinically were truly asymptomatic. In these patients, the disease had been picked up on the basis of a raised alkaline phosphatase (ALP) on blood testing or an X-ray performed for other reasons. It is important to emphasize that the causes of musculoskeletal pain in PDB are often multifactorial; they included pain associated with increased metabolic activity of the disease; and pain secondary to osteoarthritis which is more common in PDB that age-matched controls (van Staa *et al.*, 2002) and pain associated with nerve compression syndromes. It was previously assumed that deafness in patients with PDB of the skull is due to auditory nerve compression but evaluation of the mechanisms of deafness in case series of patients with PDB has revealed that in most cases, the auditory nerve is intact and the deafness is of a conductive type due to involvement of the cochlea (Monsell *et al.*, 1995).

Most patients with PDB do not have clinical signs. Deformity of the facial bones, skull and femurs can occur but this is only detectable clinically when the disease is quite advanced. Paget's disease of the tibia can often be detected clinically and in patients with active disease there may be warmth in the overlying skin. Clinical signs related to nerve compression syndromes of spinal stenosis may also be evident in some patients. Osteosarcoma is a rare complication of PDB which is estimated to affect about 0.01% of patients. The presentation is usually with a sudden increase in pain and swelling of an affected site. The prognosis of osteosarcoma in PDB is poor even with aggressive treatment unless the lesion can be surgically excised (Ruggieri *et al.*, 2010). Giant cell tumors may also be observed in PDB and these are associated with mutations in the *ZNF687* gene (Divisato *et al.*, 2016). Rare complications of PDB that are seldom seem nowadays include high output cardiac failure and hypercalcemia in patients that have been immobilized. Vascular calcification is more common in patients with PDB as compared with controls and there is evidence that the risk of cardiovascular disease is increased (van Staa *et al.*, 2002).

Investigations

The diagnosis of PDB can usually be made on plain radiographs which show coarsening of the trabecular pattern in cancellous bone, cortical thickening, areas of osteolysis alternating with osteosclerosis, pseudofractures, and bone expansion (**Fig. 2**). Predominantly

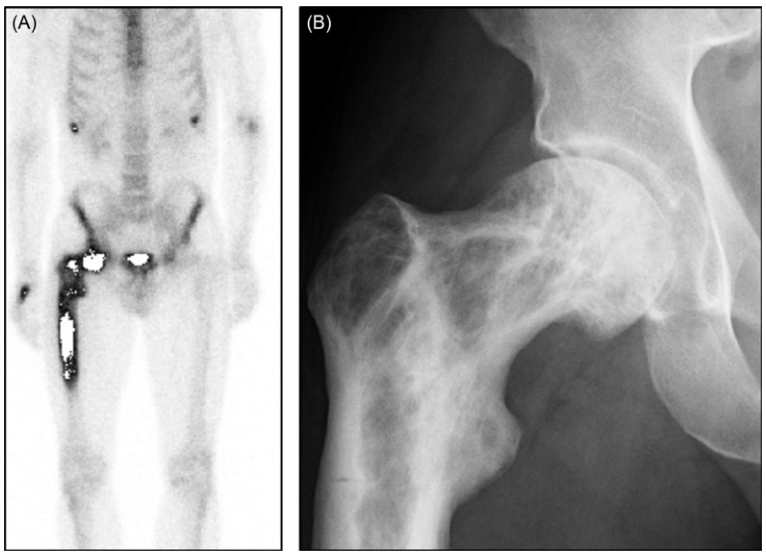

Fig. 2 Radiologic and scintigraphic features of Paget's disease. Panel A: Radionuclide bone scan of a patients with Paget's disease affecting the upper right femur. There is intense tracer uptake affecting the upper two-thirds of the femur. Panel B: X-ray of the upper femur from then same patient showing coarsening of trabeculae throughout the upper femur with areas of osteosclerosis alternating with areas of osteolysis. The right femur is enlarged and a pseudofracture is just visible on the lateral aspect of the femoral shaft at the level of the lesser trochanter.

osteolytic lesions may be observed in the early phase of the disease. Radionuclide bone scans are more sensitive that plain X-rays at detecting early lesions and are the preferred means of documenting the extent of PDB. The typical picture is one of a homogenous increase in tracer uptake affecting a whole bone or part or an affected bone (**Fig. 2**). In the long bones, tracer uptake typically starts at the metaphysis and extends proximally or distally to affect the diaphysis. Bone scans can be negative in PDB which is metabolically inactive however, and it's important to consider performing both forms of imaging in the assessment of patients suspected to have the disease. Routine biochemical screening in patients with PDB typically shows an isolated elevation in serum total alkaline phosphatase (ALP) with otherwise normal liver function tests and calcium biochemistry. Vitamin D deficiency is common but this simply reflects the fact that PDB tends to affect older people where vitamin D deficiency is common. Specialized biochemical markers of bone turnover are typically raised in patients with active PDB. Recently, Al-Nofal and colleagues (2015) conducted a systematic review of the clinical value of several biochemical markers in PDB including serum total alkaline phosphatase (ALP), serum bone specific alkaline phosphatase (BSALP), urinary collagen type 1 cross-linked N-telopeptide (uNTX), urinary collagen type 1 cross-linked C-telopeptide (uCTX); serum CTX and procollagen type I N-terminal propeptide (P1NP). This showed that in untreated patients, levels of all markers were associated with extent of PDB as determined by bone scans with no significant difference in performance between individual markers. Following bisphosphonate treatment, the bone formation markers BSAP, ALP, and P1NP showed the greatest changes and the best correlation with indices of disease activity on bone scan.

Management

Optimal management of PDB requires a multidisciplinary approach. All patients should be carefully assessed for the presence of symptoms that might be due to increased bone turnover as well as for complications such as spinal stenosis, secondary osteoarthritis and fracture that might need surgical treatment. It's also important to consider the possibility that pain in a patient with PDB might be due to an unrelated musculoskeletal condition.

Bisphosphonates

Bisphosphonates are the treatment of first choice for bone pain that is thought to be due to increased metabolic activity in PDB. Bisphosphonates are potent inhibitors of osteoclastic bone resorption which have been shown to be significantly more effective than placebo in relieving bone pain associated with PDB (Corral-Gudino *et al.*, 2017). Nitrogen containing bisphosphonates (aminobisphosphonates) are now used in virtually all patients since they are more effective at reducing bone turnover than simple bisphosphonates such as etidronate and tiludronate and have a longer duration of action (Corral-Gudino *et al.*, 2017). Comparative studies have suggested that zoledronic acid is superior to pamidronate and risedronate in improving bone pain secondary to PDB. Vitamin D deficiency should always be corrected prior to administration of bisphosphonate therapy to reduce the risk of hypocalcaemia. Bisphosphonates are contraindicated in patients with renal impairment; zoledronic acid and alendronic acid are licensed for use in patients with a GFR of >35 mL/min whereas pamidronate and risedronate are licensed to a GFR of >30 mL/min. Treatment regimens and common adverse effects of the bisphosphonates that are used most frequently in PDB are shown in **Table 2**. In addition to the common adverse effects shown in **Table 2**, bisphosphonate therapy has been associated with atypical femoral fractures, uveitis, and osteonecrosis of the jaw. Symptomatic atrial fibrillation has also been reported as an adverse effect of zoledronic acid.

There is no evidence to support the use of prophylactic bisphosphonate therapy to prevent complications of PDB although a trial is in progress to address this issue in carriers of *SQSTM1* mutations (http://www.isrctn.com/ISRCTN11616770).

Table 2 Bisphosphonates in Paget's disease

Drug	*Posology*	*Most common adverse effects*
Oral		
Risedronate	30 mg/day orally for 2 months	Dyspepsia, esophagitis
Alendronic acid[a]	40 mg/day orally for 6 months	Dyspepsia, esophagitis
Intravenous		
Pamidronate	30–60 mg/day i.v. for 3 days	Acute phase response, hypocalcaemia
Zoledronic acid	5 mg i.v.	Acute phase response, hypocalcaemia

[a]Not licensed in the UK or Europe for Paget's disease.

Attempts to normalize bone turnover by repeated courses of bisphosphonate therapy confers no advantage over symptom-directed treatment in PDB and there is evidence that with long term therapy, this approach may be harmful by increasing the risk of fracture and requirement for orthopedic surgery (Tan *et al.*, 2017; Langston *et al.*, 2010).

Analgesics

Many patients with PDB require analgesic therapy with paracetamol, non-steroidal antiinflammatory drugs and antineuropathic agents, either as an adjunct to bisphosphonate therapy in the treatment of pain due to increased metabolic activity or to control symptoms associated with secondary osteoarthritis or other conditions.

Calcitonin

Calcitonin can be effective at improving bone pain and reducing biochemical markers of bone turnover in PDB. It is now seldom used due to the fact that bisphosphonates are more convenient to administer, cheaper and have fewer side effects.

Denosumab

Denosumab is an osteoclast inhibitor which is a monoclonal antibody that neutralize RANKL. It is a powerful inhibitor of bone resorption. Although Denosumab is not licensed for PDB it has been found to be effective in isolated cases and represents a potential treatment option for patients where other drugs are contraindicated (Reid *et al.*, 2016).

Surgery

Orthopedic surgery is frequently required in PDB patients for fracture fixation, correction of deformity, treatment of spinal stenosis and for the treatment of co-existing osteoarthritis. Clinical experience indicates that the outcome of orthopedic surgery is good in PDB, although the presence of bone deformity increases complexity of the surgery and blood loss is increased, even with preoperative bisphosphonate therapy (Wegrzyn *et al.*, 2010).

Monitoring and Retreatment

It is usual to keep patients with PDB under periodic review every 6–12 months at which point the patient can be assessed clinically and biochemical markers of bone turnover checked. Total ALP concentrations are the most widely used biochemical marker of disease activity in routine clinical practice, although P1NP and BSALP are slightly more sensitive. Some patients may require repeated courses of treatment for PDB. The most common reason for retreatment is recurrence of bone pain thought to be due to recurrence of metabolic activity in PDB. This should be suspected clinically if the patient presents with pain localized to an affected site and there is biochemical evidence of increased bone turnover (such as an elevated ALP value). It should be noted however that if only a single bone is affected (monostotic PDB) there may be increased metabolic activity in the presence of normal biochemistry. In this circumstance, a therapeutic trial of bisphosphonate can be considered. It should be noted that the availability of potent bisphosphonates such as zoledronic acid with a prolonged duration of action has meant that biochemical recurrences of disease activity are now relatively rare especially in elderly patients with PDB (Cundy *et al.*, 2017).

Summary

Paget's disease of bone is a skeletal disorder characterized by focal increases in bone remodeling affecting one or more bones. Genetic factors play a key role in pathogenesis of PDB and many cases are caused by mutations in the *SQSTM1* gene. Bone pain is the most common symptom, affecting up to 38% of those who present clinically. Bisphosphonates are indicated for the treatment of bone pain thought to be due to increased metabolic activity of PDB.

Heterotopic Ossification and Calcification

Chen Kan and Na Ding, Anhui Medical University, Hefei, China
Lixin Kan, Anhui Medical University, Hefei, China and Northwestern University, Chicago, IL, United States

Glossary

Abnormal injury/immune response (AIR) The aberrant activation and suppression of the immune system, often follows a bimodal pattern, i.e., the activation of the innate immune responses is often followed by an anti-inflammatory adaptive immune response. The AIR and the subsequent abnormal release of endogenous mediators can lead to secondary insults and/or other dysfunctions.

Acquired HO A common clinical complication following traumatic events, such as spinal cord injury (SCI), traumatic brain injury (TBI) and joint arthroplasty.

Bone morphogenetic protein (BMP) A member of transforming growth factors-β (TGF-β) superfamily.

Endochondral ossification An indirect ossification that requires cartilage as an intermediator.

Hereditary HO Hereditary HO such as fibrodysplasia ossificans progressiva (FOP) and progressive osseous heteroplasia (POH) is rare but debilitating genetic disorders. FOP is characterized by progressive heterotopic endochondral ossification in connective tissues, while *POH* is characterized by intramembranous ossification inside skin and subcutaneous tissues.

Heterotopic calcification (HC) The deposit of calcium-based salts and crystals within tissues other than normal bone and enamel. HC can be considered as an atypical HO.

Heterotopic ossification (HO) The process by which bone tissue forms outside of the skeleton.

Intramembranous ossification A direct ossification, i.e., bone formation in the primitive connective tissue by direct differentiation of mesenchymal stem cells (MSCs).

Mesenchymal stem cells (MSC or marrow stromal cell) Adult multipotent stem cells that derived from the mesoderm, and have the capacity to differentiate into osteocytes, chondrocytes and adipocytes.

Introduction

Heterotopic ossification (HO) is the pathologic transformation of soft tissue into structurally normal bone through either endochondral or intramembranous ossification. Acquired HO is often a serious and costly complication of traumatic tissue damage whereas hereditary HO, such as fibrodysplasia ossificans progressiva (FOP) and progressive osseous heteroplasia (POH), is fatal genetic disorder characterized by progressive ossification in soft tissues.

Heterotopic calcification (HC, also called heterotopic mineralization), on the other hand, is abnormal deposition of calcium salts in tissues other than bone and enamel. HC can be considered as an atypical HO. Vascular calcification, a specific HC, is a frequent complication of atherosclerosis and diabetic vasculopathy.

All forms of HO are serious heterogeneous medical complications that could be costly or even fatal, but these disorders have not received due attentions. As a result, the current understanding of the mechanism of HO formation is very limited, and there is no effective treatment for these disorders either.

The purpose of this article is to raise the attention by updating our current understanding and identifying key knowledge gaps; however, since it is almost impossible to cover all aspects of HO at reasonable depth, this article will focus only on highly conserved or highly impact aspects of HO. Hopefully, our discussion will not only raise the attention of general audience but also identify potential knowledge gaps for professionals in this area.

Classification and Incidence

HO can be divided into different categories. Based on etiology, HO can be divided into acquired HO (aHO) and hereditary HO. aHO is the most common form of HO, which was first described in World War I and was frequently reported following the traumatic events (Shehab *et al.*, 2002; Garlan, 1991; Potter *et al.*, 2006, 2010), including (1) the spinal cord injury (SCI) induced HO, which affects about 22%–29% patients, often forming HO around hips, knees and shoulder joint (Ohlmeier *et al.*, 2017; Potter *et al.*, 2006; Brady *et al.*, 2017); (2) the traumatic brain injury (TBI) induced HO, which affects about 5%–20% patients, often forming HO around shoulders, elbows and knees (McAuliffe *et al.*, 1997; Ranganathan *et al.*, 2015; Brady *et al.*, 2017); (3) the severe burn injury induced HO, which affects up to 60% patients (Thefenne *et al.*, 2017; Schneider *et al.*, 2017; Foster *et al.*, 2017); (4) the hip arthroscopy induced HO, which affects 4.7%–60% patients (Bedi *et al.*, 2012; Beckmann *et al.*, 2014); and (5) the major elbow trauma induced HO, which affects 14%–35% patients (Cai *et al.*, 2015; Park *et al.*, 2010).

Hereditary HO, including fibrodysplasia ossificans progressiva (FOP) and progressive osseous heteroplasia (POH), is rare but life-threatening disease. The incidence of FOP is about one in two millions (Kaplan *et al.*, 2008; Pignolo *et al.*, 2011, 2016; Zhang

 doi:10.1016/B978-0-12-801238-3.66152-4

et al., 2013), and POH is even rarer (only about 60 confirmed patients worldwide) (Job-Deslandre, 2004; Jüppner, 2002; Kaplan *et al.*, 2004; Elli *et al.*, 2016).

HC can be considered as an atypical HO. vascular calcification, a specific type of HC, affects about 30% patients with peripheral vascular disease (Kusumbe *et al.*, 2014; Mizobuchi *et al.*, 2009; Fuery *et al.*, 2017).

Pathophysiology of HO

HO is an injury induced pathological process, and typical HO includes the sequential stages of inflammation, fibro-proliferation/angiogenesis, condensation, and final endochondral ossification (Davies *et al.*, 2017; Thilak *et al.*, 2015; Culbert *et al.*, 2014; Pignolo *et al.*, 2015).

Inflammation

Inflammatory response, triggered by injury, is responsible for the initial tissue degeneration and the subsequent events. Various cytokines, such as TNF-a, IL-1 and IL-6, secreted by the innate and adaptive immune cells, such as macrophages, mast cells and T cells, are pro-inflammatory cytokines that are able to facilitate the immune response and accelerate the death of damaged cells. On the other hand, IL-4, IL-10 and TGF-β1 were reported to be anti-inflammatory cytokines and contribute mainly to tissue repairing (Serra *et al.*, 2017; Netea *et al.*, 2015; Shintani *et al.*, 2017; van Dyken and Locksley, 2013; Mauri and Bosma, 2012; Josefowicz *et al.*, 2012). This normal inflammatory/injury response generally plays beneficial role and is essential for normal wound healing; however, this process could be dysregulated, especially in the context of traumatic injuries.

Abnormal inflammation/injury response (AIR) is commonly considered as a key common mechanism of both acquired and genetic HO (Kraft *et al.*, 2016). For example, Thilak *et al.* (2015) reported that the increased level of C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR), two clinical indicators of inflammation, were closely associated with HO following total hip arthroplasty. Citak *et al.* (2016) also suggested that elevated level of serum creatine kinase (CK) was recommended as a novel biomarker of HO. Forsberg *et al.* (2014) tested the expression of 24 inflammatory cytokines in the patients with high-energy trauma and found interleukin (IL)-3 promoted HO formation while serum IL-12 and IL-13 showed negative correlation with HO. Evans *et al.* (2012) found that pro-inflammatory cytokine, IL-6 was rapidly up-regulated within 6 days of high-energy penetrating war injuries, but after this acute stage, anti-inflammatory cytokine IL-10 exhibited significant trend of upregulation. Consistently, numerous trauma-induced animal models confirmed the crucial role of AIR in HO (Genêt *et al.*, 2015; Huang *et al.*, 2014; Kan *et al.*, 2009, 2011, 2014).

In FOP, a hereditary HO, AIR is thought to be responsible for flare-up, which is a pre-condition and crucial for subsequent HO (Pignolo *et al.*, 2016). Consistently, several FOP mice models, either gain-of-function of BMP receptor (ACVR1) or overexpression of ligands, demonstrated that AIR dramatically facilitates HO process (Kan *et al.*, 2004; Kan and Kessler, 2011; Yu *et al.*, 2008; van Dinther *et al.*, 2010). For example, inflammation-associated cytokines, such as IL-1, monocyte chemoattractant protein-1 (MCP-1) and TNF-a, were all elevated either in saliva or serum of FOP mouse model (Nfatc1-Cre/caAcvr1$^{fl/wt}$) (Sung Hsieh *et al.*, 2017), and activin A, a member of TGF-β superfamily which is strongly associated with AIR, was reportedly up-regulated in FOP model (Alessi Wolken *et al.*, 2017; Hino *et al.*, 2017; Upadhyay *et al.*, 2017; Hino *et al.*, 2015; Hatsell *et al.*, 2015). However, strangely, Hildebrand *et al.* (2017a) showed no significant difference of pro-inflammatory cytokines in FOP patients serum compared to unaffected healthy children. This could be due to inappropriate sample collection time (since AIR usually occurred immediately after injury); alternatively, inconspicuous change in systemic level might not reflect the local inflammation.

It is worthy to mention that even though HC only partially recapitulates the complex process of HO, the degree of inflammation is also closely associated with HC. However, the role of inflammation in HC is probably a bit different from that in the typical HO process. For example, in vascular calcification, the initial pro-inflammatory promotes microcalcification, which, in turn, induces further inflammation, and this vicious cycle can be broken by adaptive immune response, which, instead, promotes fibrosis and osteogenic transdifferentiation, and ultimately leads to macrocalcification (Hildebrand *et al.*, 2017a).

Fibrosis and Angiogenesis

One feature of normal wound healing is fibro-proliferation of local stem/progenitor cells and the ingrowth of new capillaries or angiogenesis; however, this normal process may also exceed what is needed for optimal repairing. In fact, both HO and HC suffered from pathologic fibrosis and angiogenesis. Although it is still unclear how fibrosis and angiogenesis are regulated, it is believed that abnormal cell–cell interaction and tissue microenvironment directly lead to activation of tissue-specific pluripotent stem/progenitor cells which eventually leads to fibrosis (Kan *et al.*, 2009; Dey *et al.*, 2017; Ranganathan *et al.*, 2016; Kaplan *et al.*, 2016). High level of local trophic factors, such as EGF and FGF, might not only facilitate the fibro-proliferation but also up-regulated neovascularization. Consistently, Agarwal *et al.* (2017a) showed the closely association of vasculature with HO by in vivo imaging through combining reflectance and Raman spectroscopy and indicated HO formation depended on angiogenesis. Interestingly, Cocks *et al.* (2017) also demonstrated that vascularity of HO was closely associated with maturity of bony lesion, i.e., less vasculature was observed in early stages of HO, but in mature HO, blood vessel numbers (BVN) are much higher.

Endochondral Ossification

In typical HO process, following AIR and fibrosis/angiogenesis, progenitor cells initiate the chondrogenic differentiation, under the influence of microenvironment factors, including factors of biophysical (mesenchyme condensation) and biochemical (osteogenic factors, such as BMPs), into terminal differentiated cells and form mature ectopic bone through endochondral ossification (Kan *et al.*, 2013, 2017). Alternatively, mesenchymal stem/progenitor cells directly differentiate into osteoblasts and osteocytes through intramembranous ossification (Cairns *et al.*, 2013; Pignolo *et al.*, 2015), such as in POH.

Cellular Origin of HO

One key knowledge gap is that the exact cellular origin of HO is still unclear (Kan and Kessler, 2014). Few investigators proposed that endothelia-derived progenitors contribute to HO via endothelial-mesenchymal transition (EndMT) mainly in the context of FOP (Medici *et al.*, 2010; Barruet *et al.*, 2016; Pang *et al.*, 2016). Others also indicated that EndMT participated in acquired HO formation (Sun *et al.*, 2016; Zhang *et al.*, 2016). However, Wosczyna *et al.* (2012) demonstrated that Tie2-cre labeled multipotent stem cells (originally thought to be endothelial progenitors) were mesenchymal origin. Consistently, study of another putative endothelial marker, VE-cadherin, did not support the idea that endothelial cells are involved in HO formation.

Hematopoietic cells were also reported to contribute to HO (Kaplan *et al.*, 2007). For example, Suda *et al.* (2009) first demonstrated that CD45 + circulating osteogenic progenitor cells expressed both hematopoietic and osteoblastic marker in vitro, and contribute to fibro-proliferative region in vivo, and even directly differentiation into osteoblasts. However, recent study found that CD45 + cells did not give rise to mature osteoblasts either in normal skeletogenesis or HO in triple transgenic mouse model (CD45-cre;Z/RED;Col2.3GFP) (Otsuru *et al.*, 2017).

Overall, the current consensus is that mesenchymal stem cells (MSCs) (Friedenstein *et al.*, 1966; Frenette *et al.*, 2013) are probably the main cellular origin of HO. For example, Kan *et al.* demonstrated that both Glast-creERT and Gli1-creERT labeled mesenchymal progenitors contribute to HO (Kan *et al.*, 2013, 2017). Dey *et al.* (2016) also suggested that tissue-specific mesenchymal progenitors contributed to distinct aspects of HO, i.e., SCX + tendon-derived progenitors participate in endochondral HO of tendon and MX1 + cells contribute to HO in muscle.

Molecular Mechanisms

Another key knowledge gap is that the exact molecular mechanism of HO is still unclear, even though various conserved signaling pathways have been implicated. The emerging picture seems to support the idea that dysregulation of BMP and activin A signaling might play a central role in HO, and that other conserved signaling pathways, such as Hedgehog (HH), Wnt/β-catenin and fibroblast growth factors (FGF), are also involved, either through cross-talk with BMP signaling or through other independent mechanisms (**Fig. 1**).

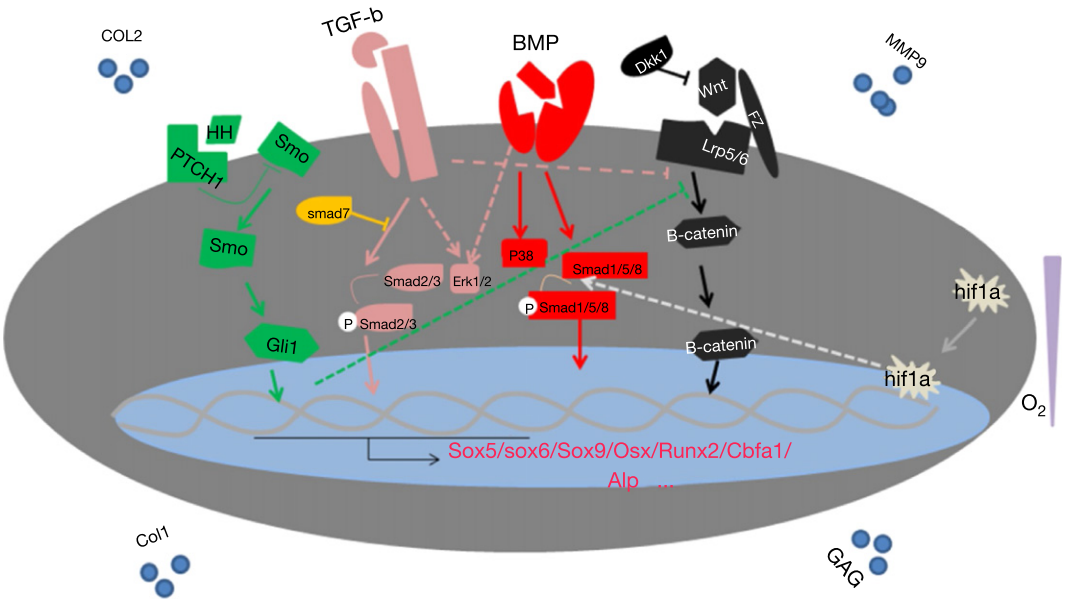

Fig. 1 Current working model of HO.

BMP/TGF-β Signaling

Even though BMP signaling is the most extensively studied pathway in HO, the exact roles of BMP in HO, either in acquired HO or hereditary, is still unclear; nevertheless, current data seem to suggest that the roles of BMP signaling could be very complicate and context-dependent.

For example, in FOP, at least three mechanisms have been proposed: (1) activates BMP signaling without exogenous BMP ligands (Kaplan *et al.*, 2009; Agarwal *et al.*, 2015). (2) Gain-of-function of BMPRI (Bagarova *et al.*, 2013), and hyperactivity of BMP signaling after ligand stimulation (Katagiri *et al.*, 2017; Bragdon *et al.*, 2011). (3) Mutant ACVR1 abnormally transduces BMP signaling in response to activin-A, which in turn, causes abnormal phosphorylation of smad1/5/8, and eventually leads to cartilage and bone formation in vivo (Hildebrand *et al.*, 2017b). This specific mechanism is proposed based on Hatsell *et al.*'s surprising finding that activin A could triggers ectopic ossification in an animal model of FOP (Hatsell *et al.*, 2015).

In aHO, BMPs were also thought to be critical for HO, but the detailed mechanism of BMP signaling in aHO is still largely unknown; however, Jackson *et al.* found that the expression of BMP ligands and BMPR1A are all elevated in a traumatic HO model. Kang *et al.* also showed that BMPR1A synergistically with BMPR2A, responding to high level of BMP ligands, phosphorylated SMADs and promoted osteogenesis. (Kang *et al.*, 2014; Peterson *et al.*, 2014, 2015; Liu *et al.*, 2014; Jackson *et al.*, 2011). Recently, Agarwal *et al.* (2017b) suggested that BMP ligands expression is essential for HO formation, however, loss of single type I BMP receptor, i.e., ACVR1, ALK2, or ALK3 are not sufficient to block HO; nevertheless, loss of both ACVR1 and ALK3 significantly reduces HO. Consistently, TGF-βs were also thought important for traumatic HO. For example, TGF-β2 is highly expressed in the HO lesion following total hip arthroplasty (THA) (Jackson *et al.*, 2011; Toom *et al.*, 2007; Suutre *et al.*, 2009; Sato *et al.*, 2007).

HH Signaling

HH signaling was also an important regulator of HO. For example, in POH, loss of GNAS encoding Gαs, were reported to enhance HH signaling, since Gαs is an activator of PKA which is an inhibitor of HH signaling (Cairns *et al.*, 2013; Regard *et al.*, 2013; Zhang *et al.*, 2012). In aHO, up-regulation of BMPs will promote IHH expression and lead to activation of ptch1 and eventually cause endochondral bone formation (Stoeger *et al.*, 2002; Sugita *et al.*, 2013; Yasuda *et al.*, 2010). Collectively, it seems safe to assume that HH signaling plays crucial roles in HO, but the exact roles of HH signaling or the crosstalking between HH and BMP or other signaling pathways are still largely unknown.

Wnt Signaling

Wnt pathway is also important for HO, especially for chondrocytes maturation and osteoblast differentiation (Gu *et al.*, 2015; Guerrero *et al.*, 2014; Su *et al.*, 2015). In the context of POH, Wnt signaling was demonstrated to be a downstream of HH signaling, and further studies found that Wnt/β-catenin target gene expression inversely correlates with HH signaling (Ptch1, Gli1 and Hip1). Thus disruption of the balance between Wnt/β-catenin and HH signaling may contribute to POH. In vitro experiment also demonstrated that BMP and Wnt signaling also coordinately regulate osteogenic differentiation of MSCs, i.e., both Smad1/5/8 and LRP5 (a ligand of wnt pathway) were up-regulated during osteogenic differentiation of MSC.

Diagnosis

The early diagnosis of HO is still challenging. Soft tissue swelling, severe pain, and joint restriction, could be pre-conditions, therefore suggestive of HO, but the definite diagnosis is dependent on cutting edge imaging technology and the development of specific early metabolic biomarkers of HO.

For imaging-based diagnosis, radiography (X-ray), ultrasonography, three-phase bone scanning and computed tomography (CT), magnetic resonance imaging (MRI) and Raman spectroscopy were all reported to be useful as tools (Onat *et al.*, 2017; Mercuri and Saltzman, 2017). Each technique has its own advantages and disadvantages. X-ray is often used to provide rough evaluation of mature HO. CT and MRI are commonly used in HO quantification other than early detection. Three-phase bone scanning is sensitive for early HO detection but lack of specificity. Ultrasonography appears to be the most suitable first-line imaging modality for the diagnosis of HO. Of note, a novel imaging technology, Raman spectroscopy has potential to define earlier mineralized collagen within HO lesion (Agarwal *et al.*, 2017a; Peterson *et al.*, 2013).

Additionally, the studies of earlier HO markers at metabolic level attract more attention recently. Serum alkaline phosphatase were shown to increase after 6 weeks in patients with HO (Evans *et al.*, 2014; Lee *et al.*, 2016). Matrix metalloproteinase-9 (MMP-9) are elevated in HO and suggested to be a in vivo HO marker (Evans *et al.*, 2014; Davis *et al.*, 2011; Shi *et al.*, 2017). Levels of inflammatory factors, chemokines, calcium, phosphorous, ESR, CRP and CPK were also demonstrated to be closely associated with HO (Qin *et al.*, 2014; Yang *et al.*, 2017; Edsberg *et al.*, 2017).

Table 1 Characterization of the therapeutic strategies to prevent HO

Therapeutic strategies	*Advantages*	*Disadvantages*	*Clinical application?*
NSAIDs	Simple, cheap, extensive effects on various HO and higher efficiency in HO reduction	Uncertainty adverse effects, such as chronic pain and impaired physical function	Yes
Radiation	Simple, noninvasive and higher efficiency	High expense, undetermined radiotherapeutic dose and higher adverse effects	Yes
Biphosphonates	Simple, wide use in HO. broader effects in each HO stage	Limited efficiency, occur after treatment cessation, higher adverse effects	Yes
Surgical resection	Clearly resection of HO lesions	Restricted surgical location, HO recurrence, invasive and high expense	Yes
Small molecular drugs	More specific, artificially synthesized. Easily absorbable and degradation	A certain adverse effects	Part of drugs
Specific neutralized reagents	More specific, artificially synthesized, easily absorbable and degradation, lower adverse effects	Limited effective range	No
Gene modification	Simple, cheap and most specific	Limited effective target, unstable and uncertain adverse effects	No

Treatment

There are no efficient treatments for either acquired or genetic HO (**Table 1**). However, nonsteroidal anti-inflammatory drugs (NSAIDs), radiation, bisphosphonates and surgical resection were commonly used to relieve or prevent HO. NSAIDs is first line treatment, because of its anti-inflammatory role in early stage of HO (Rath *et al.*, 2016; Beckmann *et al.*, 2014). Radiation therapy was also helpful for reducing local inflammatory response after injury and preventing MSCs osteogenic differentiation (Hoff *et al.*, 2013; Popovic *et al.*, 2014). Bisphosphonates are anti-absorptive agents, and several studies demonstrated it could induce osteoclast apoptosis and inhibit calcification (McClure, 1983; Taravati *et al.*, 2017). Operative intervention is limited to acquired mature HO resection but not for FOP. Although clinical improvement after operation is appreciated, there is still significant risk of recurrence (Agarwal *et al.*, 2017c).

Recently, preclinical studies showed that gene modification, potential small molecular drugs/inhibitors and several neutralizing reagents were also beneficial to HO. For example, specific and efficient inhibition of osteogenic genes, such as sox9, runx2, osterix and ALP were reported to be potential HO therapy. microRNAs, 18–25 nucleotide RNA molecules that target messenger RNA (mRNA) for cleavage or translational repression, showed enormous potential in HO prevention (Guérit *et al.*, 2013; Zhang *et al.*, 2017). It was reported that miR-203, miR-132-3p, miR-499, miR-563 and miR-574-3p alleviate ectopic bone formation either by targeting runx2 or sox9 or other related osteogenic genes (Tu *et al.*, 2016; Sun *et al.*, 2016; Xu *et al.*, 2016; Qu *et al.*, 2016; Lim *et al.*, 2016). Moreover, short interfering RNAs (siRNAs) which facilitate posttranscriptional silencing of target genes, also prevent HO via decreasing expression of runx2 and osterix (Shrivats *et al.*, 2015a; Shrivats *et al.*, 2015b). Overexpression of smad7 in injured tendon will downregulate EndMT and inhibited HO formation.

Small molecular drugs or inhibitors repress several conserved signaling pathways of HO could also be potential HO therapy. Dorsomorphin and its derivatives are BMPR inhibitors, such as LDN193189 and LDN212854, significantly decreased HO formation (Yu *et al.*, 2008; Peterson *et al.*, 2014). But the use of LDN212854 in HO prevention is also at great risk of adverse effects (Agarwal *et al.*, 2017b). PX478 and rapamycin, were reported to inhibit hif1a signaling to efficiently alleviate both genetic and acquired HO (Agarwal *et al.*, 2016). Imatinib, an inhibitor of platelet-derived growth factors (PDGF) signaling pathway, recently are also considered as a desirable inhibitor of hif1a, c-kit and MAPK, to effectively ameliorate HO symptoms (Werner *et al.*, 2013; Kaplan *et al.*, 2017). Chakkalakal *et al.* (2016) showed palovarotene, an inhibitor of retinoic acid receptor γ (RARγ), significantly prevented HO as well corrected skeletal defect. Interestingly, Cromolyn, an inhibitor or stabilizer of mast cells, recently were demonstrated to be a great help to HO reduction through specifically diminishing the number of de-granulating mast cells in pre-osseous lesions (Brennan *et al.*, 2017).

Other, more specific drugs, such as neutralizing antibodies, showed favorable effects in HO treatment via targeting abnormally activated signals. For example, Hino *et al.* and hatsell *et al.* proposed that activin a-specific-neutralizing antibody or broad-acting BMP and activin blockers like ACVR2A-Fc and ACVR2B-Fc could be a new strategic regime for FOP (Hino *et al.*, 2017). Agarwal *et al.* (2017b) also indicated ALK3-Fc is a translational drug to HO treatment with reduced risk of adverse effects. However, none of above-mentioned approaches have been commonly accepted in clinics, and further studies are needed to clarify the potential issues.

Kidney Stones☆

S Dizon, EA Iliescu, and A Ross Morton, Queen's University, Kingston, ON, Canada

Glossary

Lithotripsy The crushing of a calculus.
Nephrolithiasis The presence of calculi in the kidney.
Oxalate A salt of oxalic acid; an end product of metabolism.
Struvite Crystals of magnesium ammonium phosphate.
Supersaturation The presence of more substance in a solution than can be dissolved permanently.

Stones of the urinary tract have plagued humankind since antiquity, with the oldest recorded stone having been found in an Egyptian mummy. Hippocrates himself warned against the unskilled management of bladder calculi. In industrialized societies, upper renal tract stones predominate, with bladder stones being relatively rare. The passage of a kidney stone is associated with significant morbidity and expense. Indeed, the current estimated annual cost to the health care system in the United States is $5 billion. For the most part, the major burden of the disease is borne by young and otherwise healthy individuals. Knowledge of the composition of the stone, coupled with an understanding of the physicochemical and physiological principles underlying stone formation, can guide timely and appropriate investigation and intervention.

Epidemiology of Kidney Stones

The majority of urinary tract stones are kidney stones. The change from bladder to kidney as the site of lithiasis has paralleled national wealth. The frequency of kidney stones is also linked to the prosperity of the nation, as indicated by the significant reduction in stone formation in Europe temporarily associated with World War I and World War II. The common factor may be the increase in dietary protein intake (particularly meat) resulting in an increased acid load for the kidney to handle. Bladder stones remain a problem in Developing World children and in older men with urinary stasis. In North America, a proportion of the increase in rates of kidney stones has been linked to obesity, with a higher prevalence seen in people with a BMI exceeding 30 kg m^{-2}.

There is wide geographic variation in the rates of nephrolithiasis. The lifetime risk of developing a kidney stone is ~3% in Asia, 10% in Europe and North America, and 20% in Saudi Arabia. In addition to dietary variations in the countries, there is a potential role for climate effects. Stone formation appears to be more common in warmer climes; indeed, there is a 'Stone Belt' in the southern United States. Occupations associated with increased sweating, and reduced fluid intake also appear to predispose to renal tract stones. The presumptive mechanism relates to the development of more concentrated urine with an increased likelihood of crystal formation.

Stones are more common in men than in women, with a prevalence of 10.6% and 7.1%, respectively, however the incidence of stone formation in females is on the rise. The peak age for stone formation is the third decade of life for both sexes; there is a second, smaller peak during the sixth decade of life for women. It has been postulated that this may be associated with the increased renal calcium throughput associated with menopause. The recurrence rate for stone formation is high but relatively unpredictable. Nonetheless, ~75% of patients who have formed a kidney stone can be expected to have a recurrent episode within 20 years. Table 1 shows the relative frequency of kidney stones based on their chemical composition.

Stones are not always chemically pure; for example, many calcium stones contain small amounts of hydroxyapatite and uric acid.

Etiology of Kidney Stones

The majority of cases of renal stone disease are idiopathic in origin. Despite this, a family history of kidney stones can be found in 30–45% of patients. Although this may be the result of shared environmental factors (e.g., climate, diet), there has been substantial interest and progress in the understanding of genetic causes of stone disease. Furthermore, it is well established that several medical conditions predispose to stone formation. Table 2 shows those conditions associated with an increase risk of renal stone disease.

Calcium-Containing Stones

Calcium-containing stones account for more than 70% of all renal tract stones. From a physicochemical point of view, the fact that they form is hardly surprising given that urine is almost always in a state of supersaturation for calcium salts. Factors that

predispose to the development of idiopathic calcium stones include increased urinary concentrations of calcium and oxalate, alterations in inhibitors of stone formation, and nidus for stone formation.

The concentration of urinary calcium is increased by low urine volume and hypercalciuria. Low urine volume promotes stone formation by increasing the concentration of urinary calcium and by decreasing the urine flow rate. Hypercalciuria is commonly transmitted in an autosomal dominant fashion. Absorptive hypercalciuria is the most common cause of hypercalciuria and is postulated to be due to hyperresponsiveness to vitamin D in the jejunal mucosa. Resorptive hypercalciuria due to primary hyperparathyroidism occurs in ~5% of individuals with recurrent stone formation. Primary renal hypercalciuria due to a defect in renal tubular calcium reabsorption occurs in 5% of individuals with recurrent stone formation. A diet high in sodium is associated with increased urinary calcium excretion.

The sources of oxalate are the metabolism of amino acids (e.g., serine, glycine, hydroxyproline), metabolism of ascorbate, and dietary intake (10–20%). Oxalate is excreted by the kidney. The urinary concentration of oxalate is much lower than that of calcium. Increases in absolute excretion of oxalate result in larger proportional changes in urinary oxalate concentration when compared with calcium. Increased absorption of oxalate is seen with a low-calcium diet and enteric hyperoxaluria. The latter occurs with malabsorption syndromes associated with small bowel resection, chronic diarrhea or inflammatory bowel diseases. Calcium is bound by free fatty acids allowing increased colonic absorption of unbound oxalate. Inherited hepatic enzyme defects, primarily hyperoxaluria types I and II, are associated with severe hyperoxaluria that commonly presents during childhood with multiple kidney stones and may lead to renal failure.

Citrate is an important inhibitor of stone formation. Urinary citrate forms a soluble complex with calcium and decreases the concentration of free calcium available for crystal formation. Citrate also inhibits crystal propagation by unknown mechanisms. Hypocitraturia can occur as an isolated finding or may be due to chronic systemic metabolic acidosis, renal tubular acidosis, hypokalemia, a high-protein diet, and possibly a high-sodium diet.

Urinary glycoproteins inhibit stone formation at various stages. These proteins include Tamm–Horsfall protein, bikunin, nephrocalcin, and a urinary form of prothrombin fragment 1. The possible role of abnormal glycoproteins in recurrent stone formation is under investigation.

Uric acid is the product of purine metabolism. A diet high in purines can lead to hyperuricosuria and uric acid crystals that act as nidus for calcium oxalate precipitation and promote calcium stone formation. One third of patients with isolated hyperuricosuria have endogenous uric acid overproduction. In these cases, dietary restriction of protein does not affect uric acid concentrations in the urine.

Alterations in urinary pH, including both acidic ($pH < 5.5$) and alkaline ($pH > 6.7$), can predispose to calcium stones. Acidic pH increases the amount of undissociated uric acid available for calcium oxide stone formation. Conversely, alkaline urine increases monohydrogen phosphate available for formation of calcium monohydrogen phosphate (brushite) stones.

Uric Acid Stones

Pure uric acid stones are uncommon. They are radiolucent. The factors that predispose to the development of uric acid stones are the urine concentration of uric acid and low urine ($pH < 5.5$). Low urine volume increases the risk for uric acid stones by the same mechanisms discussed previously for calcium stones. Chronic hyperuricosuria is associated with gout, a high-purine diet, and inborn errors of metabolism. Acute hyperuricosuria may occur during treatment of myeloproliferative disorders.

Over the last ten years, the increasing prevalence of metabolic syndrome has been highlighted as the leading cause of uric acid stone formation. The proposed mechanism suggests that renal steatosis and lipotoxicity leads to decreased ammonia (NH_4^+) excretion, thereby dropping urinary pH.

Struvite Stones

Struvite stones are composed of magnesium ammonium phosphate. These stones develop in the context of urinary tract infection with organisms that produce urease (e.g., Proteus, Klebsiella, Serratia, Mycoplasma). The urinary pH and concentration of ammonia are increased by the breakdown of urea. Struvite stones grow rapidly, particularly in areas of the pelvicalyceal system that do not drain adequately, and may form stag-horn calculi. These stones usually present with symptoms of urinary tract infection. Struvite stones are difficult to treat because they are themselves infected.

Cystine Stones

Cystine stones develop as a result of cystinuria, an autosomal recessive trait or autosomal dominant with incomplete penetrance, associated with decreased proximal tubular reabsorption of cystine and other amino acids. Cystine stones develop due to the low solubility of cystine in the urine. Low urine volume and acidic urine promote stone formation.

Investigation of Patients with Kidney Stones

There is some controversy as to how extensively to investigate patients who have passed a single kidney stone. The controversy is centered around the low mortality and relatively low morbidity of the condition as well as the lack of specific therapy for most

forms of renal stone disease. Many clinicians favor the institution of general therapeutic maneuvers without investigation. The European Association of Urology has suggested a classification for stone formers based on frequency of stone passage and relative risk of recurrence. This classification can be adapted to direct investigation.

Analysis of the calculus, where possible, is the cornerstone of the investigation and rational therapy of nephrolithiasis. Patients with infection-related (struvite) stones and cystine stones can be readily identified and treatment can be planned. Patients who make uric acid stones are at high risk for recurrence and require detailed investigations as to the cause of their hyperuricosuria. For calcium stone formers, the European Association of Urology classification divides patients according to whether they are first-time or recurrent stone formers, whether or not there are residual stone fragments, and (for those recurrent stone formers) whether their disease results in rare (mild) or frequent (severe) passage of stones. Also highlighted for aggressive management is a group of patients who are at a predetermined specific risk for recurrence (e.g., primary hyperparathyroidism).

Table 3 suggests a rational approach to investigation in patients who have passed a single stone. This will detect patients with hyperuricemia and hypercalcemia as well as those with infected urine. The presence of a low bicarbonate level with a urine pH that is not maximally acidified would suggest the presence of renal tubular acidosis.

For patients who have frequent stone passage or a significant number of residual stones visible on radiographs, an attempt to establish the lithogenicity of the urine is a reasonable strategy. Commercially available software can calculate the relative supersaturation for calcium oxalate and calcium phosphate if required. **Table 4** outlines those additional 24-h urinary investigations that may be useful for recurrent stone formers. Optimal values for these parameters for minimal lithogenicity are shown in parentheses.

Rational Therapy for Kidney Stone Disease

The treatment of kidney stones can be divided into general and specific measures. The power of general advice in terms of fluid intake and diet should not be underestimated. It has been suggested that the 'stone clinic effect' can result in a 5-year reduction in new stone passage of 60%.

Dietary Intervention

Given that stone formation is the end result of the process of crystal formation, aggregation, and growth from a supersaturated solution, the most rational therapy would be to modify the solution such that the potential energy for crystal formation within the solution is lowered. The logical way in which to do this is to increase fluid intake. Consumption of enough fluid such that the daily urine volume is >2.5 l has been associated with significantly reduced rates of stone formation in large observational studies over prolonged periods of time. Furthermore, a randomized prospective study performed by Borghi and colleagues at the University of Parma, Italy, demonstrated that kidney stone patients randomized to drink enough fluid to generate a urine volume >2.5 lday^{-1} had a significantly lower rate of recurrence of their stones than did the group of patients randomized to receive no strict fluid prescription. In addition, the time to recurrence was significantly longer in the fluid-treated group.

From large observational studies, it appears that many different beverages provide some protection against stone formation. Data exist to support the beneficial effects of coffee (both caffeinated and decaffeinated), tea, beer, and wine in this regard. In contrast, the ingestion of grapefruit juice and apple juice was shown to increase the risk of stone formation in men followed in the Health Professionals Follow-up Study. Grapefruit juice also increased the risk of stone formation in women observed as part of the Nurses' Health Study; however, the mechanism of this effect is unclear.

Although it would seem to be intuitive that a reduction of calcium in the diet would reduce the frequency of kidney stones, that is not the case. The most compelling evidence of the failure of a low-calcium diet to ameliorate renal stone disease came from a prospective randomized study in men performed by Borghi and colleagues. This landmark study compared a diet containing 100 mmol day^{-1} of calcium with a diet containing 30 mmol day^{-1} of calcium. Members of the latter group were also required to lower their sodium intake to $\sim$50 mmol day^{-1} and their animal protein intake to 52 g day^{-1}. The group on the normal-calcium,

Note. Number in parentheses indicate desirable values for low urine lithogenicity.

low-sodium, low-protein diet had a significantly reduced risk of recurrent stone formation, although the effect took more than 3 years to manifest. The American Urological Association (AUA), recommends limiting sodium and non-dairy protein intake while maintaining a calcium intake of 1000–1200 mg day^{-1} in patients with calcium stones.

Few well-designed studies have addressed other dietary components. The combination of a low-protein, high-fiber diet was not shown to be preventive of recurrent calcium oxalate stones in a prospective study performed under the auspices of the Kaiser Permanente Medical Care Program.

Pharmacological Intervention

Calcium stones

The optimal initial treatment for idiopathic hypercalciuria is the administration of a thiazide diuretic such as hydrochlorothiazide or chlorthalidone (12.5–50.0 mg day^{-1}). Thiazide diuretics indirectly and directly increase calcium reabsorption in the proximal and distal tubules. Randomized trials have shown a 20% risk reduction for the development of new calcium oxalate stones. Routine monitoring for serum electrolyte abnormalities is necessary. Hypokalemia can lead to hypocitraturia and so must be avoided. If hypercalciuria persists, amiloride (5 mg day^{-1}) may be added to further reduce calcium excretion and correct hypokalemia. Potassium citrate (30–80 mEq day^{-1}) is indicated for patients with hypocitraturia or those with recurrent calcium stones in whom other metabolic abnormalities have been addressed. Urinary citrate is increased by decreased reabsorption induced by alkalinization. Patients with hyperuricosuria are at risk for the development of uric acid crystals that serve as a nidus for calcium oxalate crystal formation and have been shown to benefit from administration of allopurinol. Oral calcium and cholestyramine have been considered to bind oxalate and diminish urinary oxalate; however, there is no strong evidence for their use in idiopathic calcium oxalate stones. Oral calcium to bind oxalate and potassium citrate to correct acidosis may be beneficial in enteric hyperoxaluria.

Uric acid stones

The most important aspect of the pharmacological management of uric acid stones is alkalinization of the urine to a range of 6.0–6.5. Potassium citrate (30–80 mEq day^{-1}) is preferable to sodium bicarbonate because it avoids the sodium load. During potassium citrate therapy, the urine pH must be monitored and not allowed to rise above 7.0 because this will promote the formation of calcium phosphate stones.

Struvite stones

Struvite stones are chronically infected. Treatment of struvite stones with antibiotics may help to reduce the rate of growth of the stones; however, definitive therapy for struvite stones usually involves surgical excision of the stones. In patients whom surgery is not feasible or has failed, a trial of acetohydroxamic acid (AHA), a urease inhibitor, can provide benefit in patients where residual or recurrent struvite stones are present.

Cystine stones

Cystine stones are treated with the usual general measures of increased fluid intake and restriction of sodium intake. Alkalinization of the urine to a pH above 7.0 using potassium citrate increases the solubility of cystine. If these measures are not effective in reducing the rate of stone formation, α-mercaptoproprionylglycine (tiopronin), penicillamine, and captopril may be effective. These medications cleave the disulfide bond and increase the solubility of cystine.

Table 5 Situations where alternatives to ESWL may be required

Situation	*Explanation*	*Alternative*
Cystine stones	Resistant to fragmentation	Medical management
Struvite stones	Infected, hardcore	Combined strategy
Ectopic kidney (including renal transplant)	Targeting problem	PCNL
Pregnancy	Safety concerns	Conservative management until after delivery
Large stones (>2.5 cm)	Risk of steinstrasse or multiple residual fragments	PCNL
Bleeding diathesis	Risk of hemorrhage	Correction of problem, medical management, or direct surgical approach

Surgical Intervention

The surgical management of renal stone disease has been revolutionized by the advent of extracorporeal shock wave lithotripsy (ESWL) and the growth of endourological procedures. Invasive surgery is rarely required except in cases of complicated infected stones. The success rate of ESWL is close to 95% for individual cases. Concerns about the procedure relate to possible long-term complications (although the procedure has been in use for more than 25 years) and to the fact that failure to clear all of the stone fragments after lithotripsy will inevitably lead to an increased risk of recurrence. For ESWL to be effective, the patient must not be too large or too small for the machine. The stone must be targetable and amenable to fragmentation by the shock wave. Once the stone has been broken, there must be a clear drainage pathway given that the presence of ureteric obstruction is a contraindication to ESWL. Not infrequently, ancillary procedures, such as ureteric stenting and endourological fragment removal, are required after ESWL. **Table 5** details several other situations where ESWL may be less suitable.

Although the shock wave can be delivered externally (as in ESWL), direct application of the shock to the stone is possible using minimally invasive techniques such as percutaneous nephrolithotripsy (PCNL). Under these circumstances, a scope is passed through a percutaneous nephrostomy and fragmenting energy is applied directly to the stone. For ureteric stones, endourological procedures using rigid or flexible ureteroscopes are more likely to be successful than is ESWL alone. Larger kidney stones, >2 cm, could be managed with flexible ureteroscopy and laser lithotripsy if PCNL is contraindicated (in cases of morbid obesity, anticoagulation or bleeding disorders).

Acute complications of ESWL are infrequent. Loin pain and ureteric obstruction from stone fragment passage (steinstrasse) occur in ~6% and 2.5% of cases, respectively. Rarer complications include renal hematomata and direct shock wave damage to other viscera. Long-term development of hypertension has been reported by several groups and is the subject of ongoing investigations. Similarly, reduction in renal function following bilateral ESWL has led to recommendations that a period of months be allowed to pass before a second kidney is treated by this method.

The removal of stones by ESWL or other surgical methods should not be considered a cure of the renal stone disease. Close attention to medical management is required to prevent recurrence, either from growth of residual stone particles or from de novo stone formation in a susceptible individual.

Management of Acute Renal Colic Due to Stone Passage

The passage of a kidney stone is usually associated with severe pain, hematuria, and nausea and vomiting. Frequently, the person is unable to find a comfortable position and can be seen to be writhing on the bed. This is in contradistinction to persons with severe peritonitis who usually lie very still and resist movement. Despite being called 'colic,' the pain of stone passage is usually constant and may be in the flank or radiate to the groin. Radiation to the groin area suggests that the stone is in the middle or lower part of the ureter.

If the stone is passed, it should be sent for analysis. Other important investigations in the acute setting should be designed to rule out urosepsis and obstruction as well as to exclude other diagnoses. Helical computed tomography scanning offers high sensitivity and specificity for the diagnosis of ureteric stones and can provide significant information if nephrolithiasis is not the correct diagnosis. Investigations aimed at determining the cause of the kidney stones can be delayed until the acute episode is over.

Patients with acute renal colic can be managed supportively. Kidney stones smaller than 4 mm can be expected to pass spontaneously over the course of 48 h with symptomatic relief. It should be remembered that disappearance of symptoms does not always imply stone passage, and a confirmatory test is required if the stone is not voided. Indications for surgical intervention during the acute phase include nonpassage of an obstructing stone, urosepsis with obstruction, and ongoing pain. Acute interventions may include percutaneous nephrostomy followed by ESWL, percutaneous lithotripsy, and cystoscopy with retrieval of the stone. Invasive surgery is rarely required.

Pseudohypoparathyroid States

A Tsatsoulis, A Fountas, and E Laspa, University Hospital of Ioannina, Ioannina, Greece

Introduction

Pseudohypoparathyroid (PHP) states are a heterogeneous group of rare metabolic disorders that are characterized by end-organ resistance to parathyroid hormone (PTH) action. In PHP disorders, plasma PTH levels are elevated in the face of hypocalcemia and hyperphosphatemia, whereas these are low or absent in true hypoparathyroidism (PTH deficiency) (Mantovani and Spada, 2006; Kelsey, 2010; Weinstein *et al.*, 2001).

The syndrome was described for the first time in 1942 by Albright *et al.*, who reported three patients with hypocalcemia and hyperphosphatemia, along with skeletal abnormalities, including short stature, brachydactyly, and obesity. The diagnostic basis of these cases was their reduced calcemic and phosphaturic response to the administration of parathyroid extract. This was the first recognized hormone resistance syndrome, and was named "pseudohypoparathyroidism," as opposed to primary hypoparathyroidism (Albright *et al.*, 1942).

The constellation of developmental and skeletal abnormalities was further expanded to include mental retardation, round facies, dental hypoplasia, subcutaneous calcifications, shortening of metacarpal (particularly the third, fourth, and fifth) and metatarsal bones, and were collectively called Albright's hereditary osteodystrophy (AHO) (Thakker, 2011). Further reports described the presence of AHO without hypocalcaemia, and this variant was called pseudopseudohypoparathyroidism (PPHP).

Further developments in the understanding of PTH resistance syndromes came from the identification of the PTH receptor and its coupling to the α-subunit of the stimulatory G protein (Gsα), thereby activating cAMP levels (Chase *et al.*, 1969; Aurbach *et al.*, 1992).

Measurement of urinary cAMP, in response to synthetic PTH administration, permitted the differentiation between PHP type 1 (PHP1) and type 2 (PHP2). In PHP1 patients a blunted cAMP response to PTH was observed whereas in PHP2 the cAMP response was preserved. However, in both types the phosphaturic response was deficient, indicating a defect distal to cAMP generation in the PTH-signaling transduction pathway (Drezner *et al.*, 1973).

Recent applications of molecular biology techniques have allowed the distinction of PHP1 into PHP1a, which results from heterozygous inactivating mutations of the *GNAS*, and PHP1b, which is due to methylation defects in *GNAS* locus, known to be an imprinted gene (Turan *et al.*, 2015). Finally, PHP1c appears to be a variant of PHP1a, in which a specific mutation disrupts receptor-mediated activation of adenyl cyclase but does not affect receptor-independent activation of the enzyme (Turan *et al.*, 2015) (Table 1).

The aim of this article is to provide an overview of the current understanding of the pathophysiology, the genetic biology and phenotypes of the PTH resistant states.

Physiology of PTH Action

PTH is an 84-amino acid peptide that is secreted from the parathyroid chief cells and plays an important role in the maintenance of calcium homeostasis. The secretion of PTH is regulated by specific calcium-sensing receptors (CaSR) on the surface of the chief cells that monitor serum calcium levels (Tfelt-Hansen and Brown, 2005).

Table 1 Classification and characteristics of the various pseudohypoparathyroid disorders

Disease	*AHO*	*PTH resistance*	*Additional hormone resistance*	*Erythrocyte Gsa activity*	*PTH infusion*	*Parental origin*	GNAS *defect*
PHP1a	Yes	Yes	Yes	Reduced	Blunted urinary cAMP and phosphate excretion	Maternal	Inactivating mutations
PHP1c	Yes	Yes	Yes	Normal	Blunted urinary cAMP and phosphate excretion	Maternal	Inactivating mutations
PPHP	Yes	No	No	Reduced	Normal response	Paternal	Inactivating mutations
POH	No	No	No	Normal or reduced	Normal response	Paternal	Inactivating mutations
PHP1b	No	Yes	No	Normal	Blunted urinary cAMP and phosphate excretion	Maternal	Methylation defects
PHP2	No	Yes	No	Normal	Normal cAMP Blunted phosphate excretion	NA	None

PHP, pseudohypoparathyroidism; *PPHP*, pseudopseudohypoparathyroidism; *POH*, progressive osseous heteroplasia; *AHO*, Albright's hereditary osteodystrophy; *PTH*, parathyroid hormone; *Gsα*, G protein stimulating α-subunit; *cAMP*, cyclic adenosine monophosphate.

 doi:10.1016/B978-0-12-801238-3.95772-6

The hormone binds to a seven-transmembrane G-protein-linked receptor that is usually referred as the PTH/PTHrP receptor, because it also binds PTH-related peptide (PTHrP). This receptor is coupled to a Gs signaling pathway that leads to increased intracellular cAMP production and phospholipase C, which mediate the systemic actions of PTH on its target tissues (Juppner *et al.*, 1991; Gensure *et al.*, 2005).

The main targets of PTH action are the kidney and bone. In the kidney, PTH rapidly increases fractional reabsorption of calcium in the distal renal tubules. The renal effects of PTH are reinforced by low calcium levels, as sensed by the CaSR. This receptor is also present within the renal tubule, where it increases calcium reabsorption when serum calcium levels are reduced.

Additionally, PTH and low calcium concentrations directly stimulate 1α-hydroxylase expression in the proximal renal tubules and increase the production of 1,25-dihydroxyvitamin D ($1.25(OH)_2D$). The latter, acting in the small intestine, stimulates calcium absorption.

PTH is also an important regulator of phosphate metabolism. It acts on the proximal renal tubule and inhibits the activity of the sodium-dependent phosphate transporter (NPT-2), thereby increasing phosphate excretion (Lee and Partridge, 2009).

At the bone, PTH stimulates osteoblasts to secrete receptor activator of nuclear factor kappa-B ligand, which increases osteoclast activity, leading to increased bone resorption and the release of calcium and phosphate into the blood (Datta and Abou-Samra, 2009).

Thus, calcium homeostasis is regulated in a coordinated way by PTH, $1.25(OH)_2D$, and calcium itself in order to ensure the maintenance of its levels within the physiologic range.

Pathophysiology of PTH Resistance

The hallmark of all forms of PHP is the defect in renal response to PTH action. Specifically, PTH resistance appears to occur only in the proximal renal tubule, whereas the thick ascending tubule remains unaffected (Stone *et al.*, 1993). Therefore, the renal phosphaturic effect of PTH is reduced, leading to hyperphosphatemia, and the production of $1.25(OH)_2D$ is also decreased, contributing to hypocalcemia (Chase *et al.*, 1969).

Since the anticalciuric action of PTH is exerted in the distal tubule, this effect appears to remain intact in all PHP patients. This explains the hypocalciuria, the preservation of renal function and the absence of renal stones that are seen in PHP patients. The cell-specific defect in PHP is consistent with the cell-specific imprinting of *GNAS*. In accordance with this, the response to vasopressin that also acts in the distal tubule appears to be preserved in patients with PHP (Moses *et al.*, 1986).

The bone remodeling response to PTH appears to be intact in patients with PHP (Ish-Shalom *et al.*, 1996). However, the clinical effects on bone density are variable ranging from reduced bone mineral density to osteitis fibrosa cystica and to osteosclerosis (Burnstein *et al.*, 1985; Jacobson, 1985; Balkissoon and Hayes, 1999; Sbrocchi *et al.*, 2011). Whether this variability is due to differences in the skeletal response to PTH or to differences in the circulating levels of PTH and/or $1.25(OH)_2D$, that may have a predominant resorptive or anabolic effect in PHP, remains unknown (Long *et al.*, 2010).

In addition to changes in the regulation of calcium and phosphate homeostasis, PTH resistance appears to cause also perturbations in uric acid excretion. In particular, hypouricemia due to inappropriate increase in urinary excretion of uric acid has been reported in a Greek family with PHP1b (Laspa *et al.*, 2004). Uric acid is secreted and reabsorbed along the proximal renal tubules by the action of a urate-anion exchanger, which is expressed in tubular epithelial cells and involved in the regulation of uric acid excretion. It appears, therefore, that PTH is likely involved in the renal handling of uric acid excretion and this effect is disturbed in PHP patients.

Molecular and Clinical Characteristics of PHP States

Molecular Structure and Expression of *GNAS*

The *GNAS*, located on the long arm of chromosome 20, is a complex transcriptional locus that, in addition to Gsα, gives rise to multiple gene products through the use of alternative promoters and alternative splicing of downstream exons (Blatt *et al.*, 1988; Turan and Bastepe, 2013).

Gsα is encoded by exons 1–13 (Kozasa *et al.*, 1988). Exons 2–13 can also be used with three other alternative first exons, located upstream of exon 1, in order to produce additional novel transcripts. These include extra-large Gsα (XLas), which are expressed only from the paternal allele, the neuroendocrine secretory protein 55 (NESP55) and the noncoding A/B (Swaroop *et al.*, 1991; Kehlenbach *et al.*, 1994; Ischia *et al.*, 1997; Ishikawa *et al.*, 1990). There are also shortened neural transcripts of Gsα and XLas, termed GsαN1 and XLN1, respectively, which terminate prematurely before exon 4 (Crawford *et al.*, 1993; Pasolli *et al.*, 2000). In addition to these transcripts the *GNAS* locus also encodes a noncoding transcript in the opposite direction, termed *GNAS* antisense transcript (GNAS-AS1), which consists of five distinct exons and is involved in the imprinting of the *GNAS* locus (Hayward and Bonthron, 2000; Wroe *et al.*, 2000) (Fig. 1).

Genomic imprinting results in the expression of a gene according to its parental origin. Genes subjected to parental imprinting contain a number of differentially methylated regions (DMRs). Is seems that the methylated promoter is associated with non-expressed transcripts, whereas the non-methylated promoter drives the expression (Ideraabdullah *et al.*, 2008; Barlow and Bartolomei, 2014).

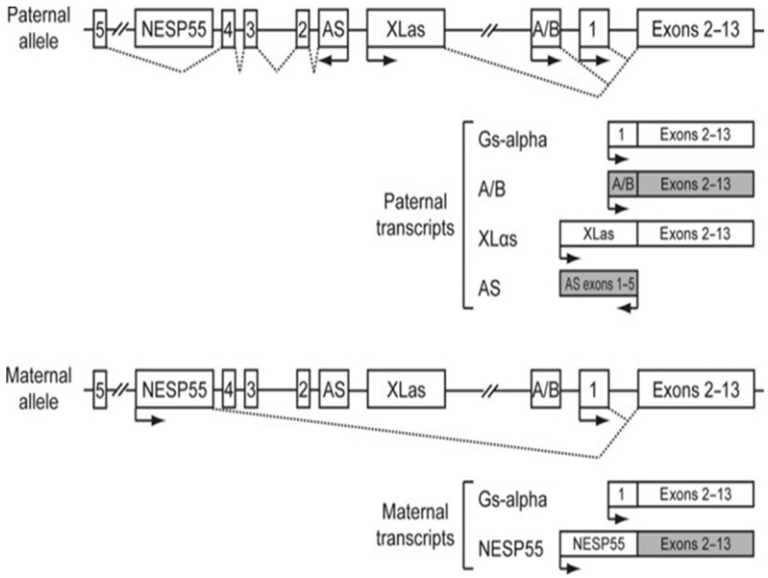

Fig. 1 *GNAS* genomic structure and encoded transcripts. Gsα is encoded by exons 1–13. Other transcripts produced by using alternative first exons that splice on to exons 2–13 are A/B, XLαs, and NESP55. An AS noncoding transcript is also produced in the opposite direction using distinct exons. Gsα is transcribed from both the paternal and maternal allele, except in selected tissues (proximal renal tubules, thyroid, gonads, and pituitary), in which expression occurs only from the maternal allele. A/B, XLαs, and AS transcripts are paternally expressed, and NESP55 transcripts are maternally expressed. Exons are represented by boxes. Arrows indicate the direction of transcription of the different paternal and maternal transcripts. Dashed lines join exons that are spliced to produce the different transcripts. Shaded boxes represent noncoding transcripts. Reproduced from Lemos, M. C., Thakker, R. V. (2015). GNAS mutations in pseudohypo-parathyroidism type 1a and related disorders. *Human Mutation* **36**, 11–19.

The *GNAS* is an imprinted locus and contains a number of DMRs that enclose the promoters of the different transcripts. Due to differential methylation of their promoter, most transcripts originate from one parental allele only. The XLαs, A/B *και GNAS-AS1* promoters are methylated on the maternal allele and are exclusively paternally expressed. Conversely, the NESP55 transcript that is methylated on the paternal allele shows exclusively maternal expression (Plagge *et al.*, 2008; Hayward *et al.*, 1998a,b).

Gsα promoter lacks methylation and is biallelically expressed in most cells. However, in some cells (pituitary somatotrophs, proximal renal tubular cells, thyroid epithelial cells, gonadal cells, neonatal brown adipose cells) paternal Gsα expression is silenced. The mechanisms of this silencing effect are still undetermined. Cis-acting elements that control tissue-specific paternal imprinting of Gsα appear to be located within the exon A/B which is imprinted (Yu *et al.*, 1998; Williamson *et al.*, 2004; Mantovani *et al.*, 2002; Germain-Lee *et al.*, 2002; Liu *et al.*, 2003; Chen *et al.*, 2009; Hayward *et al.*, 2001).

In humans, two imprinting control regions (ICRs) of *GNAS* have been identified within or close to the *GNAS* locus. One is located within the syntaxin 16 gene (*STX16*) that controls the imprinting of the A/B DMR only (Bastepe *et al.*, 2003). The other, encompassing exons 3 and 4 of the *GNAS-AS1*, controls the imprinting over the entire *GNAS* locus (Bastepe *et al.*, 2005; Richard *et al.*, 2012; Chillambhi *et al.*, 2008).

Genetic Disorders Resulting from *GNAS* Mutations

Pseudohypoparathyroidism type 1α (PHP1a)

PHP1a is an autosomal dominant disease caused by heterozygous inactivating mutations on the maternal allele of *GNAS* that involve exons 1–13 encoding Gsα (Patten *et al.*, 1990; Weinstein, 1998) (for a list of mutations, please see OMIM entry 139320 at http://www.ncbi.nlm.nih.gov). Homozygous mutations that disrupt completely Gsα activity are not compatible with life (Yu *et al.*, 1998, 2000).

Patients with PHP1a have renal PTH resistance, manifested as hypocalcemia, hyperphosphatemia, elevated serum PTH levels and a blunted cAMP and phosphate excretion following administration of PTH, together with the features of AHO (Chase *et al.*, 1969). The same individuals may also have resistance to other hormones which act via G-protein-coupled receptors and whose target tissues show predominant expression of Gsα from maternal allele, such as thyrotropin stimulating hormone (TSH), gonadotrophins and growth hormone releasing hormone (GHRH). Primary hypothyroidism without goiter, hypogonadism and growth hormone deficiency are commonly associated endocrinopathies (Weinstein *et al.*, 2001; Mantovani *et al.*, 2002; Germain-Lee *et al.*, 2002; Liu *et al.*, 2003). By contrast, responsiveness to other hormones (eg, adrenocorticotropic hormone and vasopressin) is normal in tissues in which both parental alleles are expressed (Moses *et al.*, 1986). Clinical features depend on the mono- or biallelic transcription of Gsα in tissues.

Individuals with PHP1a demonstrate a 50% reduction in Gsα activity in erythrocyte membranes, although this Gsα deficiency appears to have no adverse effect on red cell function (Levine *et al.*, 1983a,b). The 50% decrease in Gsα activity in patients with inactivating mutations in *GNAS* is utilized as a diagnostic test for making the distinction of the PHP subtypes (Turan *et al.*, 2015; Brix *et al.*, 2014).

The reported *GNAS* mutations are scattered in the entire coding region, with one hot spot in exon 7 accounting for 17.8% of cases (Lemos and Thakker, 2015). In general, there is no correlation between type or location of the Gsα mutation and onset of the disease or severity of the endocrine resistance in patients with inactivating *GNAS* mutations. However, a temperature sensitive Gsα mutant (A366S) that causes testotoxicosis due to constitutive activity at the lower temperature of the testes, but instability at body temperature, has been described in two boys (Nakamoto *et al.*, 1996).

PTH resistance usually develops during the first year of life, with hyperphosphatemia and elevated PTH preceding hypocalcemia. The severity of PTH resistance varies significantly between patients, even within the same family, and some of them remain normocalcemic throughout life (Gelfand *et al.*, 2006; Maupetit-Méhouas *et al.*, 2008). In addition, PHP patients are not prone to hypercalciuria, unlike patients with primary hypoparathyroidism, and maintain normal renal function. The delayed onset of PTH resistance may be explained by recent studies in knocked out mice, which demonstrated that the manifestation of PTH resistance caused by the maternal loss of Gsα occurs after early postnatal life, due to gradual development of paternal Gsα silencing in renal proximal tubules (Germain-Lee *et al.*, 2005; Turan *et al.*, 2014). However, nutritional factors and the involvement of Gsα-independent signaling pathways, may also contribute to the latency of PTH resistance, and this awaits further elucidation.

The associated TSH resistance also becomes clinically manifest over childhood and adolescence, but may occasionally present as hypothyroidism at neonatal screening. Hypogonadism, particularly in females, usually manifests as delayed or incomplete sexual maturation, amenorrhea or oligomenorrhea, and/or infertility. Growth hormone deficiency due to resistance to GHRH has also been reported, and appears to be more frequent in adults than in children.

Pseudohypoparathyroidism type 1c (PHP1c)

PHP1c individuals develop the same clinical and laboratory abnormalities as patients with PHP1a, including AHO and peptide hormone resistance. However, in contrast to PHP1a, *in vitro* assessment of Gsα activity reveals no abnormality (Mantovani and Spada, 2006; Weinstein, 1998; Linglart *et al.*, 2002). In a subset of designated PHP1c patients, there have been documented inactivating mutations on the maternal allele of the *GNAS* gene. These mutations are located in the α5-helix concerning the extreme carboxyl-terminus of Gsα, whereas usually PHP1a-associated mutations are distributed throughout the gene. This region contains the major sites for interaction between Gsα and G-protein-coupled receptors. It appears that mutations located at the carboxy-terminal end of Gsα (encoded by exon 13) can disrupt or strongly impair the ability for receptor-coupling, yet preserve cAMP generation through the activation of the adenyl cyclase (Thiele *et al.*, 2011).

Up to date there have been reports about two PHP1c patients in whom the disease is caused by epigenetic changes involving the *GNAS* locus. However, several patients with the diagnosis of PHP1c neither show epigenetic nor molecular genetic changes in *GNAS*, demonstrating that PHP1c may be caused by a variety of pathogenetic mechanism (de Nanclares *et al.*, 2007).

Pseudopseudohypoparathyroidism (PPHP)

Patients with PPHP exhibit the somatic features of AHO in the absence of PTH resistance. Both PHP1a and PPHP results from the same inactivating mutations of the *GNAS* and coexist in the same kindred, but never in the same sibship. The development of one or the other type of the disorder depends on the gender of the parent transmitting the molecular defect. Thus, paternal transmission leads to PPHP, whereas maternal transmission of the same mutation causes PHP1a (Wilson *et al.*, 1994; Davies and Hughes, 1993).

This parent-of-origin mode of inheritance for hormone resistance could be explained by the tissue-specific paternal imprinting of Gsα. In some, but not all tissues, the paternal allele is silenced and Gsα expression is predominantly maternal. This has been documented for the renal proximal tubule, thyroid gland, gonads and pituitary. On the other hand, expression of Gsα in the adrenal gland is biallelic. In the case of a maternal mutation, a significant loss of Gsα activity exists in those tissues in which paternal Gsα is silenced, thus leading to hormone resistance. When inherited paternally, the same mutation, does not severely affect the Gsα activity in tissues where the allele is already silenced.

Heterozygous inactivating mutations of Gsα lead to 50% loss of protein activity in non imprinted tissues where Gsα expression is biallelic, such as skin, fibroblasts, erythrocytes, white adipose tissue, bone and growth plate chrondrocytes (Yu *et al.*, 1998; Linglart, 2007; Long *et al.*, 2007; Wang *et al.*, 1992; Mantovani *et al.*, 2004; Mantovani *et al.*, 2003). Clinical findings related to those tissues are due presumably to Gsα haploinsufficiency and are present independently of the parental origin of the mutation. Thus, it is thought that AHO features result primarily from Gsα haploinsufficiency in tissues where Gsα expression is biallelic. Growth plate chondrocytes, that lack either the paternal or the maternal Gsα allele, differentiate into hypertrophic chondrocytes earlier than wild-type chondrocytes in a chimeric mouse model (Bastepe *et al.*, 2004). However, obesity and cognitive impairment occur predominantly in patients with PHP1a rather than PPHP, indicating involvement of Gsα imprinting in these AHO features (Mouallem *et al.*, 2008; Long *et al.*, 2007).

A recent study has provided evidence of hormone resistance in a PPHP patient with a novel paternal mutation in *GNAS*. This finding suggest that PTH and other hormone resistance may not be an exclusive feature of PHP1a and could also be observed in patients with PPHP (Turan *et al.*, 2014).

Progressive osseous heteroplasia (POH)

POH is a rare manifestation of AHO, characterized by severe heterotopic ossifications, which is progressive and affects skeletal muscle and deep connective tissues (tendons, ligaments, fascia), leading to ankylosis of affected joints and growth retardation of affected limbs later in life (Sanchez *et al.*, 2011).

Patients with POH have germline *GNAS* mutations, in the absence of hormone resistance and features of AHO. In the majority of cases, paternally inherited mutations have been detected, suggesting that the deficiency of a paternally expressed *GNAS* product in the development of POH (Shore *et al.*, 2002; Ahmed *et al.*, 2002; Adegbite *et al.*, 2008; Lebrun *et al.*, 2010).

Recent studies suggest that POH frequently follows dermomyotomes and shows bias of lesions towards one side or the other, similar to the lesions observed in McCune-Albright syndrome, which is due to mosaic mutations of *GNAS* that cause constitutive GSα activity. These observations suggest that the underlying cause of POH may be second-hit postzygotic mutations affecting tissues in patients with inherited heterozygous inactivating Gsα mutations (Cairns *et al.*, 2013; Pignolo *et al.*, 2015). In this context, it was recently shown that Gsα ablation causes heterotopic ossification through activation of Hedghoc signaling (Regard *et al.*, 2013). Further studies in human samples are awaited in order to better understand the mechanisms of the disease.

Hormone Resistance due to Epigenetic Alterations of *GNAS*

Pseudohypoparathyroidism type 1b (PHP1b)

Individuals with PHP1b lack typical features of AHO, and hormone resistance is confined to the actions of PTH in renal proximal tubules. Recent studies, however, have shown that some AHO features, as mild brachydactyly, may also be present in such patients. In addition, some PHP1b patients may also have mildly elevated TSH levels, indicating TSH resistance, whereas GH secretion appears to be conserved (Liu *et al.*, 2003; Mantovani *et al.*, 2007).

Most PHP1b cases are sporadic (80–85%) but some cases are familiar and show an autosomal dominant mode of inheritance (AD-PHP1b). PTH resistance in PHP1b is inherited only from female obligate carriers in a manner similar to that of type PHP1a (Linglart *et al.*, 2007; Juppner *et al.*, 1998; Bastepe *et al.*, 2001).

PTH infusion in patients with this syndrome results in deficient stimulation of nephrogenous cAMP or urinary phosphate excretion, whereas Gsα bioactivity in erythrocyte membranes is normal (Levine *et al.*, 1983a,b). Furthermore, *GNAS* mutations are not found in PHP1b. However, the AD-PHP1b gene maps to a telomeric region on chromosome 20q containing the *GNAS* locus (Juppner *et al.*, 1998; Levine *et al.*, 1983a,b). Subsequently, *GNAS* imprinting defects have been identified in patients with familiar and sporadic forms of PHP1b resulting in the absence of expression of the maternal Gsα. As the paternal allele is normally silenced in proximal renal tubules, the maternal allele silencing results in marked reduction of Gsα levels leading to PTH resistance.

The most consistent finding in these patients is the loss of methylation at the exon A/B DMR in the maternal allele, leading to silencing of the downstream maternal Gsα promoter (Izzi *et al.*, 2012).

In familiar cases of PHP1b, microdeletions of the *STX16* have been identified and are associated with loss of methylation at the A/B DMR. These include a recurrent 3 kb (Bastepe *et al.*, 2003) and a 4.4 kb (Linglart et al, 2005) and more recently a 24.6 kb deletion all within the *STX16* (Elli *et al.*, 2014). It seems that *STX16* harbor a cis-acting control element crucial for the establishment of the methylation imprint at exon A/B. Recently, deletions within the *NESP55* and/or the *GNAS-AS1* regions have been identified in some AD-PHP1b kindreds, in whom affected individuals show loss of methylation of all the maternal *GNAS* imprints, in addition to the A/B DMR (Bastepe *et al.*, 2005; Chillambhi *et al.*, 2010; Richard *et al.*, 2012).

Sporadic forms do not present deletions within the *GNAS* or *STX16* loci but show broad loss of imprinting at the *GNAS* locus including loss of methylation of the A/B DMR and loss of imprinting affecting at least one additional DMR (gain of methylation at NESP55, loss of methylation at GNAS-AS1 and/or XLas) (Izzi *et al.*, 2012). A few cases have been shown to be due to paternal uniparental disomy involving whole or part of chromosome 20 encompassing the *GNAS* locus (Dixit *et al.*, 2013; Bastepe *et al.*, 2011; Fernandez-Rebollo *et al.*, 2010). In this situation, two normal copies of *GNAS a*re both inherited from the father causing absence of maternal Gsα expression, hence PHP1b. However, the genetic causes of most cases of sporadic PHP1b remain unknown (Fig. 2).

In conclusion, there are no differences between the phenotypes of patients affected with familiar or sporadic forms of PHP1b. Therefore, diagnosis of PHP1b relies on the identification of loss of methylation at the A/B DMR of *GNAS*, the characterization of the methylation pattern of the entire *GNAS* locus, and the existence of deletions within the *STX16* or *GNAS* or paternal uniparental disomy (Linglart *et al.*, 2013).

Recently imprinting defects in *GNAS* were also reported in a large proportion of patients with PHP1a phenotype in which no mutations were found in Gsα coding exons, suggesting that the clinical and genetic features of PHP1a and PHP1b may overlap (Elli *et al.*, 2014; Fernandez-Rebollo *et al.*, 2013; Mantovani *et al.*, 2010a).

Diagnostic Aspects and Therapy

The presence of PTH resistance (hypocalcemia, hyperphosphatemia, and elevated PTH), in association with the features of AHO, are the basis for the clinical diagnosis of PHP1a. The demonstration of a blunted response of cAMP and phosphate excretion after PTH administration may contribute to diagnosis, although it is rarely necessary in clinical practice. Patients with PHP1a should

Fig. 2 Genetic and epigenetic defects causing PHP1b: Maternal *STX16* deletions cause isolated *A/B* loss of methylation, maternal deletion of *NESP55* leads to isolated *A/B* loss of methylation with hemizygosity in NESP55. However, maternal deletions affecting *AS* exons 3 and 4 result in a loss of methylation at all maternal *GNAS* imprints. Sporadic PHP-Ib cases show loss of methylation at exon *XL*, the promoter of *AS*, and exon *A/B*, and a gain of methylation at *NESP55*. Note that the methylation changes at the NESP55, AS promoter, and XL in sporadic PHP-Ib cases are often, but not always, partial. Please note that the figure is not drawn to scale. Reproduced with permission by Turan, S., Bastepe, M. (2013). The GNAS complex locus and human diseases associated with loss-of-function mutations or epimutations within this imprinted gene. *Hormone Research in Paediatrics* **80**, 229–241 (http://dx.doi.org/10.1159/000355384), S. Karger AG, Basel.

also be screened for any associated endocrinopathy, in particular hypothyroidism and hypogonadism. Patients with PPHP exhibit most of the somatic features of AHO, in the absence of PTH resistance, and their diagnosis may be facilitated in the context of a family history of PHP1a (Mantovani, 2011).

In general, PHP1a patients should be monitored annually with blood testing (PTH, calcium, phosphate, TSH) and urinary calcium excretion. Particular attention should be given to height, growth velocity and pubertal development in children as well as screening with provocative tests for GH deficiency. Careful physical examination should be performed annually to detect the presence and follow up the evolution of specific AHO features, including radiological evaluation of brachydactyly.

Several tests have been developed to assess Gsα *in vitro*, but are not used for routine analysis. These include semi-quantitative immunoblot analysis as well as functional assays of Gsα. The application of these assays to patients with PHP1 showed that patients with AHO and multihormone resistance had about 50% reduction in Gsα activity (PHP1a), whereas patients without clinical features of AHO and hormone resistance that was limited to PTH (PHP1b) had normal levels of Gsα activity. On the other hand, patients with PPHP or POH, who carry *GNAS* mutations on their paternal allele were also found to have a similar 50% reduction in Gsα activity (Levine, 2012).

These findings reflect the effect of *GNAS* haploinsufficiency in erythrocytes, which normally express both copies of *GNAS*, leading to a 50% reduction in Gsα activity regardless of the parental origin of the *GNAS* defect. The normal Gsα activity in PHP1b indicates the absence of paternal imprinting of Gsα in erythrocytes, so both alleles are expressed regardless of an epigenetic methylation defect.

However, the recent description of PHP1b patients with *GNAS* methylation defects who have mild features of AHO and partial resistance to TSH supports the notion that PHP1a and PHP1b may share overlapping phenotypes. Indeed, a recent study found that Gsa activity was partially reduced in patients with mild AHO but normal in those without these features. Taken together, these findings indicate that features of AHO are manifestations of Gsα deficiency in relevant tissues and argue against the association of AHO with a specific *GNAS* genotype. Thus, a threshold level of Gsa activity is necessary to assure a normal phenotype (Mantovani, 2011; Lemos and Thakker, 2015).

Genetic testing, through DNA sequencing of the *GNAS* will identify a mutation in most cases of PHP1a, PPHP, and POH, and rarely in PHP1c. However, it cannot distinguish between these disorders or determine the paternal origin of the mutation.

In patients with PHP1b, epigenetic defects can be identified by methylation analysis of DMRs in the *GNAS* locus. Familiar and sporadic forms of PHP1b have different patterns of methylation of the three DMRs, but loss of methylation at the maternal exon A/B DMR is a consistent finding in all patients (Turan and Bastepe, 2015).

Treatment of PTH resistance is similar to that of hypoparathyroidism and consists of administration of active vitamin D metabolites (eg, calcitriol) and oral calcium supplements to maintain normocalcemia. Additional endocrine disorders, in patients with PHP1a or PHP1c, in particular hypothyroidism and hypogonadism, should be screened for and corrected if necessary. There are no specific treatments for the various AHO features (Mantovani, 2011).

Regarding GH deficiency in patients with PHP1a, to date there is no conclusive evidence indicating that GH replacement therapy is beneficial. The observation that individuals with PPHP have short stature as their relatives with PHP1a, without having any endocrine abnormalities appears to challenge the primary role of GH deficiency in determining growth in PHP1a. However, a pilot study in a group of prepubertal short PHP1a children, treated with GH, reported a significant increase in height velocity, providing the first evidence that treatment of GH deficiency, if started early, would be a potentially effective therapy (Mantovani *et al.*, 2010b). Further studies are needed to clarify this matter.

Conclusions and Future Perspectives

Recent advances in the molecular genetic characterization of patients with PTH resistance have revealed novel pathogenic mechanisms that explain the phenotypes of the various forms of PHP disorders and provided insights into the understanding of *GNAS* function and epigenetic regulation. These advances have also led to the recognition of the complexity of the *GNAS* locus and the understanding that the various forms of PHP share overlapping characteristics.

However, further work in this interesting field remains to be done. This must address the allelic imbalance in *GNAS* expression, and in particularly, clarify the mechanism of tissue-specific expression of maternal or paternal *GNAS* alleles. The genetic modifiers that account for the development of POH in some patients and PPHP in others require further investigation. Research is also needed in order to clarify the genetic basis for the imprinting defects in patients with PHP1b.

Finally, the possible involvement of the imprinted *GNAS* locus in the development of obesity and the regulation of energy balance opens up new research avenues for the investigation of the role of imprinted genes in energy metabolism.

Thyroid Gland: Anatomy and Physiology☆

Salvatore Benvenga, University of Messina, Messina, Italy and University General Hospital "G. Martino" of Messina, Messina, Italy
Giovanni Tuccari, Antonio Ieni, and Roberto Vita, University of Messina, Messina, Italy

Glossary

Follicle A hollow sphere lined by a single layer of epithelial cells called thyrocytes, and filled with colloid.

Iodotyrosines Precursors of thyroid hormones resulting from iodination of tyrosyl residues of thyroglobulin. They include monoiodotyrosine and diiodotyrosine.

Iodothyronine Thyroid hormones resulting from coupling of two iodotyrosines.

Thyrocyte (follicular cell) The cell type that takes up iodide from the bloodstream and incorporates it in the thyroglobulin, the backbone of the colloid, thus producing iodotyrosines and iodothyronines.

Thyronamines Compounds with a chemical structure similar to thyroid hormones, in which the carboxylate group is replaced with the alanine side chain. Compared with thyroid hormones, their biological actions are either in the same or in the opposite direction.

Embryology

It is beyond the scope of this article to provide a detailed review of the embryological development of the hypothalamic thyrotropin-releasing hormone (TRH)-secreting neurons and the pituitary thyrotrophs. Concerning the hypothalamus, suffice it to say that, similarly to the releasing factors for other pituitary hormones, TRH is synthesized in parvocellular, not magnocellular, neurons of the paraventricular nucleus. On a historical note, the identification and characterization of TRH in 1970 and other releasing hormones by Roger Guillemin and Andrew Schally permitted these two scientists to share the Nobel Prize in Medicine 7 years later.

Concerning pituitary organogenesis, suffice it to say that it is dictated by the orderly expression of cell-specific transcription factors, including Titf1/Nkx2.1, Rpx/Hesx-1, Pax-6, Sox-3, Lhx-3, Prop-1, Pit-1, and TEF. Some of these genes are involved in the formation of other specific populations in the adenohypophysis. Accordingly, depending on the mutated gene, congenital secondary hypothyroidism may or may not be accompanied by other pituitary hormone deficiencies. Adenohypophysis anlage is recognizable at 4–5 weeks of gestation, but the hypothalamic-pituitary unit becomes mature only by 20 weeks. Within the anterior pituitary, the thyrotrophs are placed anteromedially and anterolaterally, and account for less than 10% of all the cell types (Aaron *et al.*, 2007).

The thyroid gland is the first endocrine gland to develop in humans. The thyroid gland originates from a diverticulum located in the median ventral wall of the pharynx (called the thyroid diverticulum). During the fourth week of embryonal development, an endodermal thickening (thyroid placode) appears in the midline floor of the primitive pharynx between the first and second pharyngeal pouches, dorsal to the aortic sac (Fancy *et al.*, 2010). This primitive thyroid tissue is hollow at first, but soon becomes solid (thyroid bud) and penetrates the underlying mesenchymal tissue, descending anteriorly through the thyroglossal duct to the hyoid bone and laryngeal cartilages in order to reach the lower neck. As the thyroid tissue migrates downward, it passes just anteriorly to the hyoid bone and laryngeal cartilages. The thyroid gland is initially spherical and then assumes a more bi-lobed configuration as it enlarges; a major increase regards its lateral portions (lobes) in comparison to the median connecting portion (isthmus) (Fancy *et al.*, 2010). Whereas in mice thyroid organogenesis takes about 1 week, in humans it takes a much longer time, and thyroid hormones synthesis is not evident before the 11th week of gestation (Szinnai *et al.*, 2007).

Whereas the epithelial cells, the most abundant cell type in thyroid, derive from endostyle, an endodermal area containing iodine-concentrating cells, C-cell precursors derive from the neural crest bilaterally to the fourth pharyngeal pouches and are located in the ultimobranchial bodies. Epithelial cells' differentiation is assumed to be the consequence of signals from the heart primordium, which is close to the ventral pharyngeal endoderm during the early embryogenesis. This hypothesis is supported by the frequent association of congenital cardiac malformations with congenital hypothyroidism. In addition, the close association of the thyroid and heart partly accounts for thyroid migration, which ends at day 45–50 (Santisteban, 2013). Differentiated follicular cells (thyrocytes) are polarized cells with a basolateral and an apical surface; the first faces the extrafollicular space, while the second faces the follicular lumen. This polarity is functionally paramount, as iodine uptake occurs at the basolateral side, whereas thyroid hormone secretion occurs at the apical side (Nilsson and Fagman, 2017).

☆*Change History*: July 2017. A Ieni and G Tuccari have edited the sections Embryology, Anatomy and Histology. S Benvenga and R Vita have contributed to edit the subsection on Embryology, and have edited the section Physiology, which has been divided into subsections. Figs. 1–3 have been added. Fig. 4 corresponds to former Fig. 1, and was maintained in its original version; the corresponding legend has been slightly edited. Fig. 5 corresponds to former Fig. 2, and was completely re-drawn. All the authors have re-written the glossary and have added keywords and abstract.

This article is an update of Wilmar M Wiersinga, Thyroid Gland, Anatomy and Physiology, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, pp. 453–455.

 doi:10.1016/B978-0-12-801238-3.96022-7

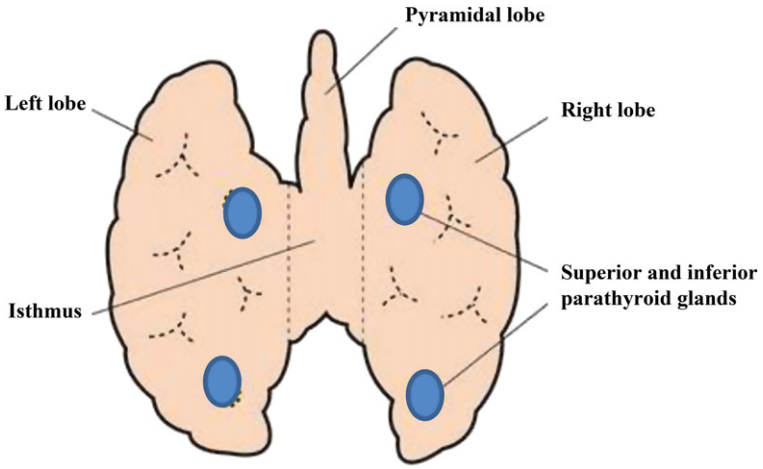

Fig. 1 Macroscopic posterior view of the thyroid.

During embryogenesis, thyroid development depends on the expression of a number of transcription factors, the most important being TTF-1 (thyroid transcription factor-1), PAX8 (paired box gene 8), FOXE-1 (forkhead box E1), and HHEX (hematopietically expressed homeobox). TTF-1 (also called NKX2–1) is a single polypeptide in humans and regulates the transcription of thyroglobulin, thyroid peroxidase (TPO), and thyrotropin (TSH) receptor genes in the follicular cells (Kratzsch and Pulzer, 2008). Moreover, TTF-1 promotes the expression of HHEX, FOXE1, and (weakly) PAX8. In turn, HHEX, PAX8, and FOXE1 regulate each other (Nilsson and Fagman, 2017). PAX8 plays a fundamental role in cell differentiation, in maintenance of the differentiated state, and in proliferation. FOXE-1 is essential in promoting migration of the follicular cells and seems to be involved in their survival and/or differentiation. HHEX is an early marker of thyroid cells with a putative effect in maintaining the expression of TTF-1 and PAX8 during thyroid organogenesis (Kratzsch and Pulzer, 2008). Hence, deletion of any one of the genes encoding HHEX, TTF-1, PAX8, or FOXE1 inevitably confers athyreosis or severe thyroid hypoplasia (Nilsson and Fagman, 2017). Currently available data indicate that gene expression undergoes significant changes during thyroid organogenesis and confirm the existence of unknown factors at least as critical as TTF-1, PAX8, FOXE-1, and HHEX (Kratzsch and Pulzer, 2008).

Anatomy

The thyroid gland is a highly vascularized organ located anteriorly in the neck between the C_5 and T_1 vertebrae, deep in the platysma, sternothyroid, and sternohyoid muscles. The thyroid weighs 15–20 g and weighs more in men than in women; the thyroid weighs approximately 1 g in a newborn and increases by about 1 g/year until age 15. It is an H-shaped, soft and reddish parenchymal organ, consisting of two lobes (left and right) and one isthmus that binds them together (**Fig. 1**). Each lobe is approximately 4 cm in length, 2 cm in width, and 2–3 cm in thickness. The isthmus measures about 2 cm in width, 2 cm in height, and 2–6 mm in thickness.

The superior extremity (called the superior horn) lies lateral to the inferior constrictor muscle and posterior to the sternothyroid muscle, while the inferior part (inferior horn) extends to the levels of the fifth or sixth tracheal ring. In the posterolateral section, the gland overlaps the carotid sheath and its components. About 50% of individuals present a pyramidal lobe (Morgagni's or Lalouette's pyramid), arising from either lobe or the superior portion of the isthmus and directed upward, usually to the left (**Fig. 1**) (Braun *et al.*, 2007).

The thyroid is enveloped by the layers of the deep cervical fascia and covered by the strap muscles anteriorly and the sternocleidomastoid muscle more laterally. The true thyroid capsule is firmly adherent to the gland, developing projections into the thyroid, forming septae and dividing it into lobes and lobules. The posterior layer of the thyroid capsule is thick. Posteriorly, the middle layer of the deep cervical fascia condenses to form the posterior suspensory ligament of Berry, connecting the thyroid lobes to the cricoid cartilage and the first two tracheal rings. In the posterior surface of the lateral lobes are located the parathyroid glands; normally there are four (two superior and two inferior), and these are roundish, and about the size of a grain of rice (**Fig. 1**).

Histology

Microscopically, thyroid is divided into lobules; each lobule consists of 20–40 round follicles that vary considerably in size, with a diameter ranging from 45 to 250 μm. In the newborn, follicles are small and grow slowly (**Fig. 2**).

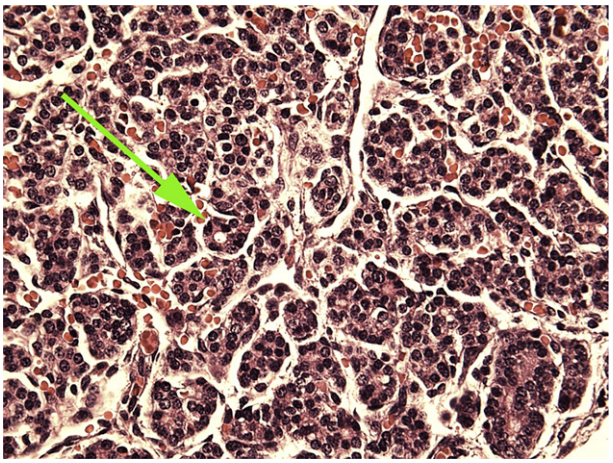

Fig. 2 Thyroid follicle of a newborn (*green arrow*), greatly different in size from that observed in adult ones (see **Fig. 3**).

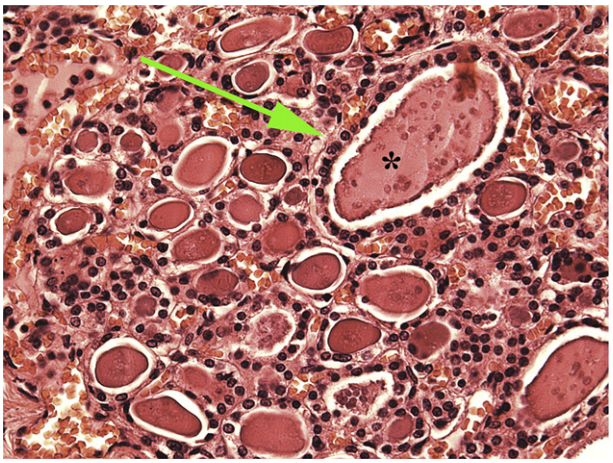

Fig. 3 Evident thyroid follicles in the adult (*green arrow*) lined by a single epithelium filled with colloid (*).

Each follicle is lined by a single cuboidal layer of epithelium (9–13 μm) with a thin basement membrane filled with acidophilic colloid-core. Thyrocytes have a definite polarity, with their apices directed toward the lumen of the follicles and their basis toward the basement membrane. The apical surface of the epithelial cells has numerous microvilli extending to the colloid, while the spheroid nuclei are located at the same level in all cells, mainly near to their basis (**Fig. 3**). Thyroid is the only human gland in which the hormonal product is stored extracellularly (viz. in the colloid).

Mitoses are infrequent, being evident only in young people. Thyrocytes are characterized by a pale acidophilic or amphophilic cytoplasm in which lysosomal bodies, granules, and secretory vacuoles are evident. Immunohistochemistry shows that normal follicular epithelium contains thyroglobulin, low-molecular weight keratin, epithelial membrane antigen, and vimentin. Follicles are embedded in a small amount of a loose connective tissue that forms the gland stroma, in which blood vessels, nerves, and lymphatics are present.

C-cells are dispersed between follicles, mainly in the posterolateral portion of the lobes, or are located beyond the basement membrane within the follicles, close to thyrocytes (Nilsson and Fagman, 2017). As noted above, C-cell precursors derive from the neural crest. They constitute about 0.1% of thyroid cells, and their identification is possible only using immunohistochemical methods for calcitonin. Moreover, the numerous dense-core granules of C-cells show immunoreactivity for neuron-specific enolase (NSE), chromogranins A and B, synaptophysin, and carcinoembryonic antigen (CEA). The stromal compartment surrounding follicles consists of fibroblasts derived from the neural crest (Kameda *et al.*, 2009), and includes also macrophages and mast cells, which recently were reported to have a role in thyroid cancer development (Visciano *et al.*, 2015).

Vascular supply of the thyroid gland is conspicuous, bilaterally represented by the superior thyroidal artery (from the external carotid) and inferior thyroid artery (from the succlavia). Exceptionally, another artery, the thyroid IMA artery (also known as Neubauer's artery), originating from either the common carotid or the anonymous troncus, may be present (Mohebati and Shaha, 2012). The thyroid contains a rich network of capillaries surrounding follicles. Venous blood drains through two sets of vessels:

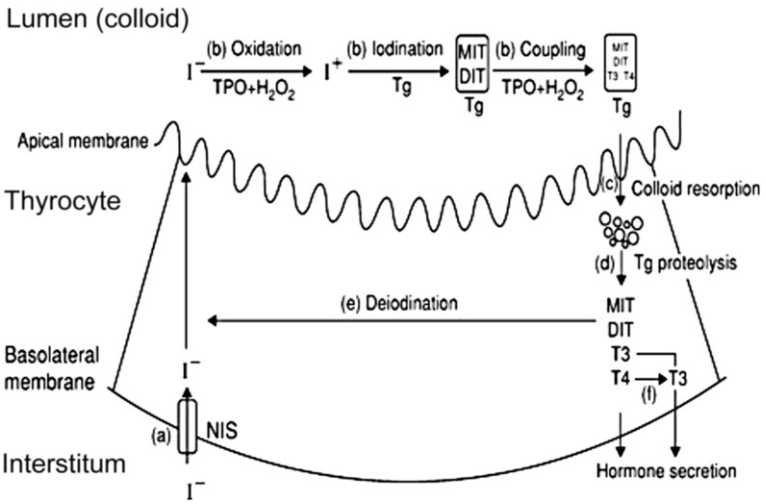

Fig. 4 Schematic diagram of thyroid hormone biosynthesis in and release from the thyrocyte. Subsequent metabolic steps are: (a) iodide transport via the Na^+/I^- symporter (NIS) inhibited by ClO_4^- and SCN^-; (b) oxidation of I^- to I^+ and iodination of tyrosine residues in thyroglobulin (Tg), and coupling of monoiodotyrosine (MIT) and diiodotyrosine (DIT) to thyroxine (T_4) or triiodothyronine (T_3), catalyzed by thyroid peroxidase (TPO) and inhibited by propylthiouracil and methimazole; (c) colloid resorption, inhibited by lithium and I^-; (d) proteolysis of Tg, inhibited by I^-; (e) deiodination of MIT and DIT; and (f) deiodination of T_4, inhibited by propylthiouracil.

superior and medial thyroidal veins realize a plexus, which drains into the external jugular vein, whereas inferior thyroidal veins realize a plexus in front of the trachea joining the brachiocephalic vein (Mohebati and Shaha, 2012).

A rich lymphatic network is present in the thyroid. Intraglandular and subcapsular lymphatics drain into the internal jugular lymph nodes. In particular, the superior lymph node group drains the upper gland and medial isthmus, while the inferior group drains the lower gland.

The thyroid nerves originate from the superior and middle cervical sympathetic ganglia. These fibers are vasomotor, indirectly influencing thyroid secretion (Mohebati and Shaha, 2012). Moreover, adrenergic fibers realize a network, which ends near the follicular basement membrane; adrenergic receptors are also present in follicular cells.

Physiology

Hormonogenesis in the thyrocyte can be subdivided into three main steps: iodide uptake; iodide oxidation and organification; and secretion of thyroid hormones. These steps are summarized in **Fig. 4**.

First Step: Iodide Uptake

All living beings are capable of taking up iodine and incorporating it into proteins. Iodinated compounds are of the utmost importance in regulating diverse functions in invertebrates devoid of the thyroid gland (Nilsson and Fagman, 2017). In humans and most vertebrates, the thyroid gland has evolved to save and store iodine. The thyroid produces iodinated molecules, iodotyrosines, and iodothyronines, the latter including thyroid hormones (T4 and T3) (Nilsson and Fagman, 2017).

Iodine is ingested with a number of food including dairy products, grains, and meat. Upon ingestion, organic iodine is reduced to inorganic iodide (I^-), the chemical form needed for the biosynthesis of thyroid hormones. Approximately 150 μg iodide are required by the thyroid gland for its daily activity, but in certain conditions, such as pregnancy and breastfeeding, iodide requirements are greater (Pennington and Young, 1991).

The thyroid and kidney are the most iodine-hungry organs. Indeed, the thyroid actively takes up iodine from the bloodstream, where its concentration is approximately 30 times lower than in the thyroid (Eskandari *et al.*, 1997). Particularly, the sodium/iodide symporter (NIS), located in the basolateral membrane of the follicular cell, entraps iodide from the circulation into cytoplasm against its electrochemical gradient, together with sodium ions. Unlike iodide, sodium entry into the cell is down its gradient, and results in energy production, which is required for the inward translocation of iodide. In turn, the sodium/potassium pump maintains the sodium gradient (Ferreira *et al.*, 2005). The next step is iodide efflux, namely its passive (down its electrochemical gradient) translocation from the cytoplasm to the apical side of the polarized thyrocyte, and the subsequent transport through the apical membrane. Crossing of the apical membrane was previously assumed to depend on pendrin and a putative apical iodide transporter, but the latter was recently ruled out. Nevertheless, a chloride channel was shown to mediate iodide efflux together with pendrin (Twyffels *et al.*, 2014; Rodriguez *et al.*, 2002).

Second Step: Iodide Oxidation and Organification

Upon its entry into the cytoplasm of the polarized thyrocyte, iodide moves apically, where it is oxidized and covalently bound to thyroglobulin (Tg). This step requires TPO and H_2O_2.

TPO is a 100 kDa heme-containing protein that belongs to the same family of human peroxidase, together with lactoperoxidase, myeloperoxidase, and eosinophil peroxidase (Godlewska *et al.*, 2017). Posttranslational modifications including glycosylation, heme fixation, proteolytic trimming, and dimerization are essential to obtain the mature protein (Godlewska *et al.*, 2017).

TPO acts as an H_2O_2 donor and oxidizes iodide. The resulting compound may be I^+ or OI^- (hypoiodite); both are capable of interacting with Tg (Kopp, 2013). H_2O_2 is generated by a NADPH oxidase system including DuOX (or thyroid H_2O_2-generating enzyme, THOX).

Tg, the most abundant protein of the thyroid, is a large glycosylated protein with more than 2700 amino acids and molecular mass of 660 kDa, representing the largest 1% of proteins in the vertebrate proteome (Lee *et al.*, 2008; Di Jeso and Arvan, 2016). Tg contains at least 66 tyrosyl residues, with slight differences between species. The number of tyrosines that are iodinated varies with iodine intake. Particularly, there is a hierarchy in iodination of tyrosines, so that tyrosine at position 5 is one of the most favored (see below) (Di Jeso and Arvan, 2016). There is evidence that Tg antigenicity depends on post-translational modifications, including iodination and glycosylation (Targovnik, 2013; Benvenga *et al.*, 1997).

Glycosylation of 10% of the total Tg weight occurs in the rough endoplasmic reticulum and in the Golgi apparatus, where N-linked oligosaccharides are acquired. Glycosylation is essential for the tertiary structure and the normal folding of Tg, which occurs also by interaction of Tg with endoplasmic reticulum oxidoreductase and molecular chaperones, such as calnexin and calreticulin (Di Jeso and Arvan, 2016). Within the endoplasmic reticulum, but before intracellular transport to the Golgi complex, two 12S (330 kDa) monomers are dimerized into a stable 19S (660 kDa) molecule. Tg represents the scaffold of the colloid in the follicular lumen, and acts as a depot of thyroid hormones and iodine (Targovnik, 2013; Di Jeso and Arvan, 2016). From this point of view, thyrocytes are more similar to exocrine cells than to the other major endocrine glands (Nilsson and Fagman, 2017).

Iodination of Tg results in monoiodotyrosine (MIT) and diiodotyrosine (DIT), depending on the number of iodine ions incorporated in Tg. Subsequently, when a MIT (donor) is coupled to a neighboring DIT (acceptor), 3,5,3′-triiodothyronine (T3) is generated, whereas when a DIT (donor) is coupled to another neighboring DIT (acceptor), 3,5,3′,5′-tetraiodothyronine or thyroxine (T4) is generated. Coupling of noniodinated tyrosine donor to a DIT acceptor forms 3,5-diiodothyronine (T2), whose effects on adiposity and body weight are still a matter of debate (Lanni *et al.*, 2005; Vatner *et al.*, 2015). Finally, 3,3′,5′-triiodothyronine (reverse T3 or rT3) accounts for only 0.9% of thyroid hormones released in the circulation. This results from either unfavorable coupling of a donor DIT to an acceptor MIT, or deiodination of T4 by type 1 or type 3 deiodinases (Bianco *et al.*, 2002). Structures of iodotyrosines and iodothyronines are shown in **Fig. 5**.

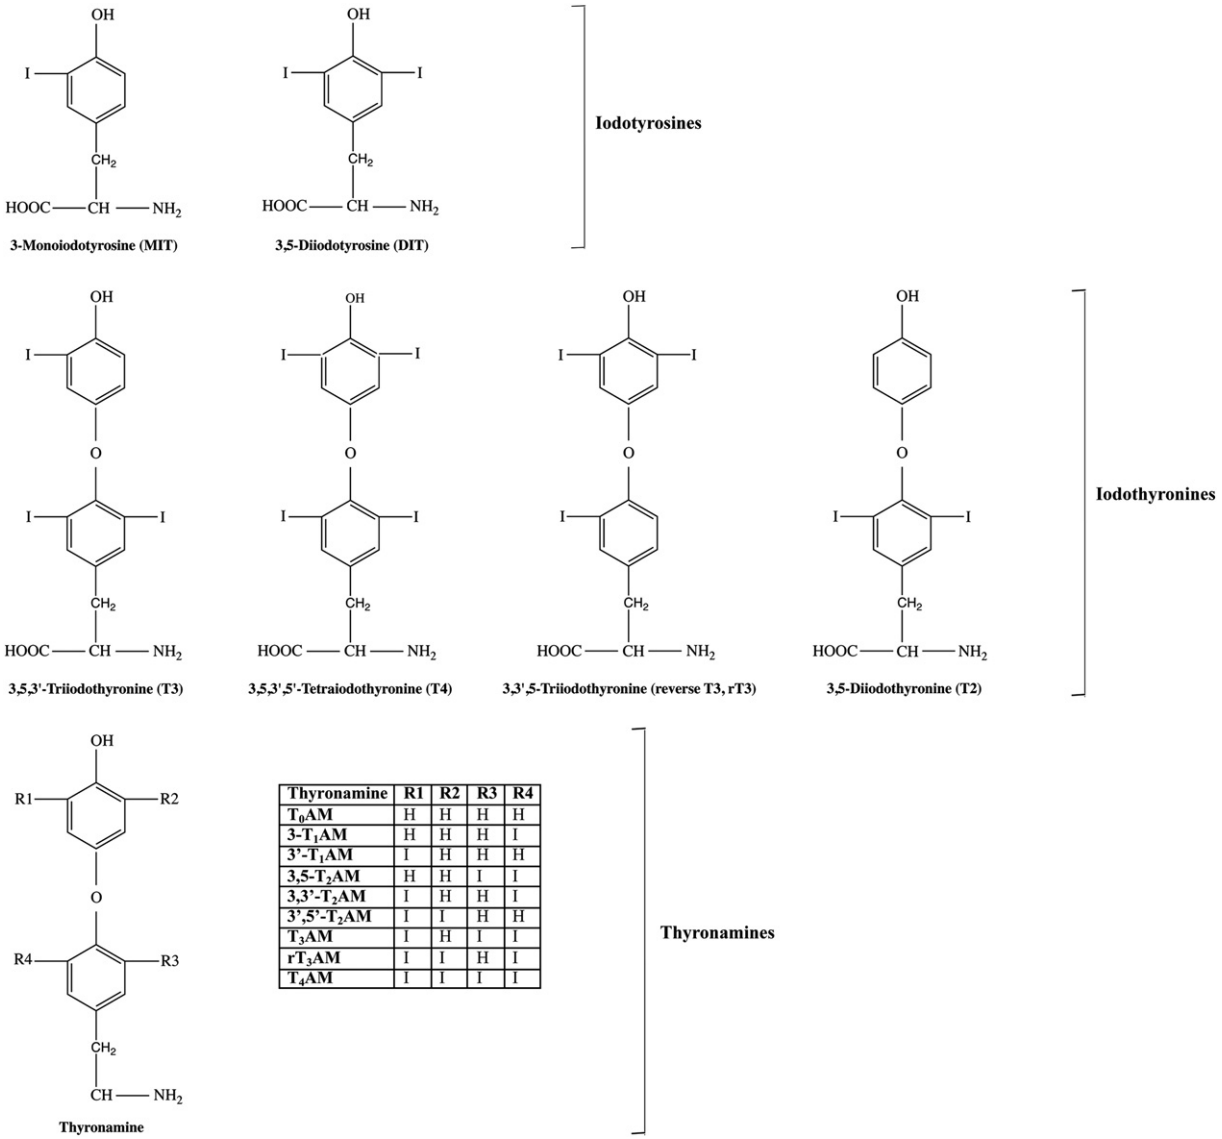
The major thyroid hormones forming sites are at the extreme N-terminus (T4) and C– terminus (T3 and T4) (Di Jeso and Arvan, 2016). Indeed, four main hormonogenic DIT-acceptor tyrosines were identified at position 5, 2554, 2747, and 1291, the first being the most efficient in T4 formation, while the third was the most efficient in T3 formation (Di Jeso and Arvan, 2016; Lamas *et al.*, 1989). Furthermore, formation of DIT and T4 are favored over MIT and T3, respectively. In iodine-sufficient areas the ratio of DIT:MIT:T4:T3 per molecule of Tg is 5:5:2.5:0.7, whereas in iodine-deficient areas, DIT:MIT and T4:T3 ratios are increased. Even if three or four thyroid hormones are synthetized per molecule of Tg, this process is warranted at extremely low levels of iodination (even 4 mol I^-/mol Tg) (Di Jeso and Arvan, 2016). The thyroid produced T3 accounts for only 20% of total T3; the remainder was obtained peripherally by T4 deiodination.

The iodide pool of the follicular unit includes also that resulting from deiodination of MIT and DIT. This part of the pool is recycled or further organified, or alternatively moved to the bloodstream (Rosenberg *et al.*, 1961). The daily turnover rate of the iodide pool is about 1% (Delange, 1998).

Although thyronamines were discovered in the 1950s, only in 2004 were they identified as ligands of a class of G protein-coupled receptors called trace-amine associated receptors. Thyronamines are structurally related to thyroid hormones as they have an identical carbon skeleton, but differ from the thyroid hormones in terms of the absence of the carboxylate group of the alanine side chain, which is replaced by an ethylamine chain (**Fig. 5**) (Chiellini *et al.*, 2017). Thyronamines include nine compounds differing for either the number or the position of the iodine atoms, the most abundant being 3-T_1AM (**Fig. 5**) (Chiellini *et al.*, 2017). These compounds were initially considered catabolites of thyroid hormones. However, recent observations suggest that thyronamines result from decarboxylation of thyroid hormones by ornithine decarboxylase, not by the aromatic amino acid decarboxylase as first reported (Hoefig *et al.*, 2015). Biosynthesis of 3-T_1AM occurs also in the intestine via the intermediate metabolite 3,5-T2, as demonstrated in thyroid cancer patients after thyroidectomy or radioiodide treatment (Hoefig *et al.*, 2011). So far, only two thyronamines (3-T_1AM and T_0AM) have been detected in vivo, particularly in the blood, heart, liver, adipose tissue, thyroid, and brain of rats and other animals. The other thyronamines are synthetically derived (Piehl *et al.*, 2011).

Third Step: Secretion of Iodothyronines

Tg is internalized in the thyrocytes through the apical membrane via micropinocytosis, namely vesicle-mediated endocytosis. Thus, invaginations of the apical membrane by pseudopods formation form colloid droplets (Bernier-Valentin *et al.*, 1991). These droplets release their content into endosomes, where Tg is sorted based on iodine content: whereas the highly iodinated molecules are fused with prelysosomes and then to lysosomes, those that are poorly iodinated are recycled and return back to the apical



Thyronamine	R1	R2	R3	R4
T_0AM	H	H	H	H
3-T_1AM	H	H	H	I
3'-T_1AM	I	H	H	H
3,5-T_2AM	H	H	I	I
3,3'-T_2AM	I	H	H	I
3',5'-T_2AM	I	I	H	H
T_3AM	I	H	I	I
rT_3AM	I	I	H	I
T_4AM	I	I	I	I

Fig. 5 Structures of the main iodotyrosines, iodothyronines, and thyronamines. Concerning thyronamines, only two (3-T_1AM and T_0AM) have been detected in vivo so far.

membrane, where they are secreted into the follicle lumen (Kostrouch *et al.*, 1993). Lysosomal endopeptidases, such as cathepsins B, D, and L, cleave Tg, thus releasing T3 and T4 (Dunn *et al.*, 1991). Direct cleavage within the follicle lumen has been also proposed (Tepel *et al.*, 2000). Proteolytic cleavage of Tg occurs at four major cluster sites, called A, B, C, and D, which fall at around residue 500, 990, 1800, and 2515, respectively (Dunn *et al.*, 1991). Three additional cleavage sites have been also found at residue 240, between residues 1142 and 1184, and at residue 597 (Gentile and Salvatore, 1993).

Upon their release into the cytoplasm, thyroid hormones reach the basolateral membrane with unknown mechanisms, and finally enter the circulation (Vickers *et al.*, 2012).

Regulation of Thyroid Hormones Biosynthesis

Thyroid hormones biosynthesis and metabolism is regulated by at least three factors: TSH-induced stimulation, iodine availability, and deiodinases activity.

TSH stimulates most if not all steps of thyroid hormones biosynthesis, from the uptake of iodine (by enhancing NIS expression) to internalization of Tg from the follicular lumen and consequent secretion of thyroid hormones into the bloodstream. TSH secretion is stimulated by TRH, which is in turn produced by neurons of the paraventricular nucleus of the hypothalamus, and prevents thyroid undersupply (Hoermann *et al.*, 2015). In order to prevent hyperstimulation by TSH, and to restore the individual set point of the hypothalamus–pituitary–thyroid axis, there are multiple negative feedback loops. Indeed, the

thyroid hormone inhibits both TRH and TSH secretion (Hoermann *et al.*, 2015). Concerning the inhibition of TRH release, it involves TRH-secreting neurons and tanycytes (Hoermann *et al.*, 2015). Also, the homeostatic relationship between TSH and FT4 is defined by a kite-shaped curve (Dietrich *et al.*, 2012). In addition, there is an ultrashort feedback loop by TSH on its own secretion by the thyreotrophs (Prummel *et al.*, 2004).

Iodine availability regulates thyroid hormones biosynthesis and secretion (Song *et al.*, 2010). When iodine availability is insufficient, T3 and T4 are inadequately synthetized, TSH increases, and goitrogenesis occurs. In addition, conversion of T4 to T3 is enhanced. In contrast, excessive iodine exposure leads to inhibition of thyroid hormones' biosynthesis by blocking H_2O_2 production and Tg iodination (the Wolff-Chaikoff effect) (Wolff and Chaikoff, 1948).

Thyroid hormone activation and inactivation are regulated by the deiodinases. Type 2 deiodinase (D2) acts on the outer ring of T4, converting it into T3; by contrast, type 3 deiodinase (D3) inactivates T4 and T3, deiodinating their inner ring and converting them into rT3 and T2, respectively. In addition, type 1 deiodinase (D1) acts both on the outer and inner ring. Thyroid contains especially D1 and D2 (Bianco, 2013).

Thyroid Hormones Circulation in the Bloodstream and Biological Actions

Similarly to steroid hormones, thyroid hormones are hydrophobic molecules, and therefore have to be carried in plasma by transporter proteins. Indeed, the free fraction of thyroid hormones is very low (0.03% of T4 and 0.3% of T3). The three major carriers are thyroxine binding globulin (TBG), transthyretin, and albumin. In addition, there are a number of minor carriers, such as lipoproteins, immunoglobulins, and serine protease inhibitors (serpins) (Benvenga, 2013).

TBG is the most important carrier of the thyroid hormone in blood in most mammals. It is a four-carbohydrate-chain glycoprotein that belongs to the serpin family, and peaks between α_1 and α_2 at zone electrophoresis (Benvenga, 2013). Other minor serpins that bind to thyroid hormones are α_1-antitripsin, α_1-chymotripsin, antithrombin III, and cortisol binding globulin. All the serpins have one thyroid hormone binding site with a relative higher affinity for T4 compared with T3 (Benvenga *et al.*, 2002). α_1-acid glycoprotein and sex hormone binding globulin are nonserpin proteins demonstrated to be minor T4 carriers (Benvenga, 2013).

Transthyretin is a homotetramer forming a cylindrical channel, which carries thyroid hormones and vitamin A in distinct sites. There are two sites for thyroid hormones, but only one is available, due to the much lower K_a of the second site (Neumann *et al.*, 2001).

From a phylogenetical point of view, serum albumin is the most ancient carrier. It has five binding sites for the thyroid hormones in its two subdomains (A and B). Albumin also binds sterol-derived hormones. Interestingly, other two homologues of albumin, vitamin D binding protein and α-fetoprotein, are capable of binding thyroid hormones (Benvenga, 2013).

All classes of lipoproteins can bind T4, T3, and rT3. Particularly, thyroid hormones interact with apoA, apoB100, apoC, and apoE, and this interaction is inhibited by lipids (Benvenga and Robbins, 1996).

Transport of thyroid hormones into cells relies on monocarboxylate transporters (MCT) 8 and 10, which are responsible for both the influx and the efflux of the thyroid hormones, and are ubiquitous. Another transporter of the thyroid hormones is the organic anion transporting polypeptide 1C1 (OATP1C1), which is particularly expressed in the astrocytes, where it is involved in T4 uptake (Mayerl *et al.*, 2014).

Upon its entry into the cell, T3, not T4, binds the thyroid hormone receptor (TR), which is a member of the nuclear receptor superfamily. There are two isoforms of TR (α and β), encoded by different genes located in different chromosomes (chromosomes 17 and 3, respectively) (Cheng *et al.*, 2010). Each isoform has three variants (α1, α2, α3 and β1, β2, β3). Of note, TRα2 and TRα3 are splicing variants of TRα1 that do not retain T3-binding activity. TR expression is spatially and temporally specific, as TRα is expressed mainly in the brain from the early stages of embryonic development, while TRβ is expressed mainly in the brain, liver, kidney, thyroid, heart, and retina (TRβ2) at a later stage of development (Cheng, 2000).

TR is a single polypeptide with a carboxyl-terminal ligand-binding domain (LBD), which interacts with coregulators (either activators or repressors) and participates in homodimerization (dimerization between two TR) and heterodimerization (dimerization between TR and retinoid X receptor). The binding of T3 to TR induces structural changes that lead to displacement of corepressors, recruitment of coactivators, and transcription activation, which is also regulated by other molecules, such as p53 and β-catenin (Cheng *et al.*, 2010). TR contains also a central, highly conserved domain, which interacts with the thyroid hormone response elements (TRE) (Wagner *et al.*, 1995).

For the purpose of this article, suffice it to say that mutations may occur in genes encoding either TRα or TRβ. Mutations of the TRβ gene lead to resistance to the thyroid hormone, which is a syndrome characterized by signs of various degree, including goiter, tachycardia, short stature, decreased IQ, and elevated thyroid hormone concentrations in serum together with nonsuppressible TSH (Weiss and Refetoff, 2000). Only a few cases of homozygosity for TRβ mutations have been reported so far (Ferrara *et al.*, 2012). Mutations of the TRβ gene have been also found in thyroid cancer and TSH-secreting pituitary adenoma (Cheng *et al.*, 2010). Concerning TRα, in mice, mutations in both alleles lead to death shortly after birth, while mutation of one allele results in dwarfism and abnormal lipid metabolism, and a phenotype different from that found in mutations of TRβ (Kaneshige *et al.*, 2001). Indeed, no mutation of TRα1 has been found in patients with resistance to thyroid hormones, indicating that TRα1 and TRβ have distinct functions. The phenotype resulting from TRα1 mutations is variable according to the location and type of mutation. These differences in the resulting phenotype might stem from the different interaction of TRα1 with various corepressors, with variable repression of different target genes (Cheng *et al.*, 2010).

In addition, thyroid hormones act directly in mitochondria stimulating cellular respiration. T3 or T2 binds a specific site in the mitochondrial inner membrane. Even if T2 is as potent as T3, it has a more rapid action (Horst *et al.*, 1989), and therefore its therapeutic use has been recently proposed (Lanni *et al.*, 2005). Thyroid hormones also induce mitochondrial heat generation, which depends on both basal proton leak and inducible proton leak; the latter is regulated by the uncoupling proteins, whose synthesis is stimulated by the thyroid hormone (Brand and Curtis, 2002).

The effect of the thyroid hormone in inducing thermogenesis had been used to treat obesity until 1978, when the US Food and Drug Administration issued a warning against it, due to severe heart and bone side effects. Subsequently, analogs of the thyroid hormone maintaining its thermogenic action, called thyromimetics, were synthetized (Yehuda-Shnaidman *et al.*, 2014). The main strategies to obtain stable thyromimetic molecules are the introduction of a bulky group at 5′ position for antagonism for TR, the replacement of iodine atoms to achieve resistance to metabolic deactivation, the change of bridging oxygen, and the replacement of the polar amino acid group at position 1 to change binding to TR (Hirano and Kagechika, 2010). Thyromimetics are TRβ-selective compounds that do not bind to TRα, which mediates the cardiac activity of the thyroid hormones. Some of these thyromimetics were proven efficient in treating obesity and dyslipidemia (Yehuda-Shnaidman *et al.*, 2014). However, despite TRβ selectivity, they can still interact with TRα, giving rise to heart and bone side effects (Unnikrishnan *et al.*, 2012). Also, because TRβ mediates the hepatic effects of the thyroid hormone as well as the negative feedback of the thyroid hormone in the hypothalamus, thyromimetics may induce both hepatic hyperthyroidism and systemic hypothyroidism due to hypothalamus–pituitary–thyroid axis suppression (Yehuda-Shnaidman *et al.*, 2014).

Except for direct action of the thyroid hormone in the mitochondrion, its effects have been long ascribed to genomic mechanisms. Only in the past decade the existence of a number of nongenomic effects of thyroid hormone has been demonstrated. These effects are, by definition, not mediated by the interaction of T3 with its nuclear receptor and protein synthesis, and therefore they have a much more rapid onset (minutes or hours) (Hammes and Davis, 2015). Furthermore, nongenomic actions are initiated by T3, T4, or rT3 binding to nontruncated TR, or truncated TR, or integrin $\alpha v\beta$ at the level of cell membrane, cytoplasm, and cytoskeleton. Activation of certain kinases (protein kinase C, mitogen activated protein kinases) ensues, with gene transcription or activation of the Ca-ATPase (Davis *et al.*, 2016). Nongenomic actions of the thyroid hormone might mimic the effects of estrogens in certain tumors by supporting cell proliferation and angiogenesis (Hammes and Davis, 2015).

Finally, recent investigations have highlighted a neural route of action of the thyroid hormone, originating in the hypothalamus at the level of T3-responsive nuclei, such as the paraventricular, ventromedial, and arcuate nucleus, and the preoptic and anterior areas. The activation of these areas, via the sympathetic and parasympathetic branch of the autonomic nervous system, regulates metabolism in liver and brown adipose tissue (Zhang *et al.*, 2017).

Thyronamines in the blood bind with high affinity to apoB100, with consequent very low free concentrations in serum, and interact with a class of G protein-coupled receptors called trace-amine associated receptors, but also with adrenergic receptors (Chiellini *et al.*, 2017). Biological effects of thyronamines are partly in the opposite direction of T3, since they reduce heart rate, cardiac output, metabolic rate, and body temperature. However, thyronamines also have actions that are synergic to T3, as they stimulate lipid metabolism over the carbohydrates one and neurological responses (Chiellini *et al.*, 2017). Like monoamine neurotransmitters, thyronamines have an ethylamine chain, and may also act as neuromodulators (Ianculescu and Scanlan, 2010).

Glossary

Congenital hypothyroidism Alteration of thyroid functions in newborns; when this condition is associated with a primary thyroid disease, it is characterized by an elevated thyroid-stimulating hormone (TSH) level and decreased thyroxine (T4) in the bloodstream.

DNA-binding domain Protein domain capable of recognizing and binding to specific DNA sequences.

Epigenetics The study of changes in gene function that are mitotically and/or meiotically heritable and that do not entail a change in DNA sequence.

Gene targeting A complex of methods that allows a defined gene to be modified; in cultured embryonic stem (ES) cells, it provides a tool for the generation of genetically modified mice.

G protein-coupled receptor A transmembrane receptor that interacts with a G protein associated with the cytosolic surface of the cell membrane; G proteins are so named for their ability to bind guanine nucleotides.

Knockout (null) mouse Genetically modified mouse in which both alleles of an endogenous gene have been inactivated.

Penetrance The frequency with which a genotype manifests itself in a given phenotype.

Transcription factor DNA-binding protein required for a promoter to function at full level; it recognizes and binds to a specific sequence located in regulatory elements of a target gene and exercises its function by interacting with other components of the transcription apparatus.

Introduction

The thyroid gland displays a peculiar architecture characterized by the presence of spheroidal structures, called follicles, composed of a single layer of epithelial cells (thyroid follicular cells, TFCs) surrounding a closed cavity (follicular lumen). TFCs are highly specialized cells responsible for the production of thyroid hormones and express a specific set of genes, whose protein products perform functions essential for hormonogenesis such as thyroglobulin (Tg), thyroperoxidase (TPO), sodium–iodide symporter (NIS), thyrotropin receptor (Tshr), pendrin, and thyroid oxidase (THOX). In adults, TFCs are found in the thyroid gland, located in front of the trachea at the base of the neck. However, they are originally derived from a group of endodermal cells, located in the posterior portion of the mouth cavity, in the primitive pharynx. These cells migrate caudally, reach their definitive position, and finally accomplish their terminal differentiation. In humans, this process requires approximately 7 weeks; a thyroid primordium is visible at the beginning of the 3rd week, whereas follicular organization appears by the 10th week.

The thyroid also contains a second population of hormone producing cells named parafollicular cells or C cells, which are neuroendocrine in nature and primarily synthesize calcitonin, a natural antagonist to parathyroid hormone. C cells are also of endoderm origin and arise from the ultimobranchial bodies (De Felice and Di Lauro, 2004).

The organogenesis of the thyroid follows the same pattern in all mammals. Hence, it was possible to use animal models to define the various steps involved in thyroid morphogenesis in detail and to understand the molecular mechanisms underlying the development of the thyroid gland.

This article focuses on the results obtained from both mouse models and patients affected by congenital hypothyroidism, results that have demonstrated how a complex network of factors is required for a correct morphogenesis of the thyroid.

Morphological Aspects of Thyroid Gland Development

During mouse development, the thyroid primordium is visible by embryonic day (E) 8.0 to 8.5. At this stage, the thyroid primordium, called thyroid anlage, appears as a thickening of the endodermal epithelium in the midline of the floor of the primitive pharynx, in the presumptive sublingual region. At E 9.5, the thyroid primordium buds from the primitive pharynx and begins to migrate caudally, forming an endodermal-lined diverticulum that descends in the tissue in front of the neck. At this stage,

☆*Change History:* December 2017. Marina Muzza and Laura Fugazzola updated the sections "Molecular Aspects of Thyroid Gland Development" and "Molecular Genetics of Thyroid Dysgenesis", including novel predisposition genes identified in thyroid dysgenesis, added the section "Thyroid Specification", included updated References within the text and added the section "References", modified Conclusion in accordance with the novel findings available in the literature, added an item in the Glossary.

This article is an update of Mario De Felice, Roberto Di Lauro, Thyroid Gland Development, Molecular Biology, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 456–461.

the migrating thyroid primordium is still connected to the pharyngeal floor by a narrow channel, the thyroglossal duct. At E 11.5, the thyroglossal duct disappears and the thyroid primordium loses all connections with the floor of the pharynx and reaches its final destination, in front of the trachea, by E 13.5. Then, the thyroid expands and follicular organization appears. By E 14.0, the differentiation process of TFCs begins and thyroid-specific genes are expressed. Finally, 2 days later, thyroxine is detected in the fetal thyroid (De Felice and Di Lauro, 2004).

Molecular Aspects of Thyroid Gland Development

During the past years, it has become possible to identify a number of genes expressed in various stages of thyroid development and their role(s), as deduced by the phenotypes obtained in mouse models where such genes have been mutated (inactivated) by gene targeting.

The discovery that the transcription factors TTF-1 (thyroid transcription factor-1), Foxe1 (forkhead box e1, formerly called TTF-2), Pax8 (paired box gene 8), and Hhex (hematopoietically expressed homeobox) are expressed not only in mature thyroid cells but also in their precursors offered a useful tool for the exploration of the genetic basis of the developmental process of the thyroid gland (Lazzaro *et al.*, 1991; Plachov *et al.*, 1990; Thomas *et al.*, 1998; Zannini *et al.*, 1997).

At E 8.5, in the primitive pharynx, the endodermal cells fated to become TFCs are univocally specified by the expression of TTF-1, Foxe1, Pax8, and Hhex. These factors are also present in other embryonic tissues, but all four are coexpressed only in the presumptive thyroid bud from the moment a thickening composed by proliferating cells appears in the midline of the floor of the primitive pharynx. When the thyroid diverticulum forms and begins its migration, the thyroid primordium still expresses TTF-1, Foxe1, Pax8, and Hhex, and the simultaneous presence of these four factors will remain for the rest of the life as a hallmark of differentiated TFCs.

The expression of TTF-1, Foxe1, Pax8, and Hhex is necessary but not sufficient to guarantee the morphogenesis of the thyroid. Other genes also are required for the correct development of the gland. Among these, Tshr (thyroid-stimulating hormone receptor) seems to be involved in the final steps of differentiation of TFCs (**Table 1**).

TTF-1

TTF-1, also known as Nkx2.1, was first identified as a nuclear factor able to bind to specific sequences that are present in both *Tg* and *TPO* genes. TTF-1 is a transcription factor that recognizes and binds to specific DNA sequences via a 60-amino acid DNA-binding domain called homeodomain. The protein is encoded by a single gene, *Titf1* in mice and *TITF1* in humans, located on chromosomes 12 and 14q13, respectively.

During embryonic life, TTF-1 is expressed in the developing thyroid, lungs, diencephalon, and posterior pituitary. Studies in *Titf1* knockout mice have demonstrated that this factor is absolutely necessary for the correct development of the thyroid. *Titf1* null mice display a perinatal lethal phenotype characterized by severe defects in both lung and forebrain development as well as a lack of thyroid and posterior pituitary. At an early stage of development, in the absence of TTF-1, the thyroid primordium forms in its correct position, but already by E 10.0 the thyroid primordium appears to be smaller than that in wild-type embryos and soon undergoes degeneration, probably due to an apoptotic process. Hence, TTF-1 is dispensable for the initial commitment of thyroid cells but is required for the survival and subsequent differentiation of these cells. Because in the absence of TTF-1 thyroid cells disappear before the gland accomplishes its final differentiation, it is not possible to assess the role of TTF-1 in vivo in the adult thyroid. However, experiments performed in cultured differentiated thyroid cells have demonstrated that TTF-1 is relevant for the expression of thyroid-specific genes. The role of TTF-1 in embryonic life is being investigated. TTF-1 is present in organs derived from the ventral wall of the anterior foregut (thyroid and lungs) but is absent in the esophagus, which derives from the dorsal wall of the gut. Furthermore, in the absence of TTF-1, there is no septation between the trachea and esophagus. Hence, a possible role of TTF-1 could be to contribute to the specification of the anterior part of the gut. However, we do not know which genes TTF-1

Table 1 Timing and Molecular Phenotype of Thyroid Development in Humans and Mice

Embryonic stage		*Histological feature*	*Gene expression*[a]			*Hormonogenesis*
Mice(day)	*Humans (week)*		*TTF-1 Foxe1 Pax8 Hhex*	*Tg TPO Tshr*	*NIS*	
8.5	3.0	Thyroid anlage	+	−	−	−
9.5	3.5	Thyroid primordium migration initiates	+	−	−	−
11.5	4.0–5.5	Thyroglossal duct disappears	+	−	−	−
13.5	6.5–7.0	Thyroid reaches final destination				
14.5	8.5	Expansion and functional differentiation	+	+	−	−
16.5	10.0	Onset folliculogenesis	+	+	+	+

[a]The expression of the indicated genes has only been studied in the mouse embryo.

controls during thyroid morphogenesis. TTF-1 appears to act in both early and late stages of morphogenesis through phosphorylation on multiple serine residues. Studies on the phenotype of *Titf1* null embryos or in the absence of phosphorylated TTF-1 indicate that this transcription factor regulates the expression of some signaling molecules. TTF-1, presumably in its phosphorylated form, is also required for the maintenance of an ordered follicular architecture and function in the differentiated thyroid. Finally, it should be noted that TTF-1 is also expressed in the ultimobranchial bodies and embryonic C cells.

Pax8

Pax8 is a transcription factor characterized by the presence of a 128-amino acid DNA-binding domain (paired domain) that recognizes and binds to a single site present in *Tg* and *TPO* promoters. The gene encoding Pax8 (called *Pax8* in mice and *PAX8* in humans) is located on chromosome 2 in both species. During embryonic life, Pax8 is expressed since E 8.5 in the kidneys, brain, and thyroid primordium. In *Pax8* knockout mice, the thyroid is severely affected, follicular cells cannot be detected, and the mice die within a few weeks. In the absence of Pax8, at an early stage of embryogenesis, the thyroid primordium forms, buds from the gut, and begins its migration. However, the thyroid primordium is nearly undetectable by E 12.0. Hence, like TTF-1, Pax8 is required for the survival of thyroid precursor cells.

Experiments in cultured cells have demonstrated that Pax8 can activate transcription of thyroid-specific genes at their chromosomal locus. The coexpression of Pax8 and TTF-1 in thyroid cells only has suggested that these factors can cooperate in the stimulation of thyroid genes. Indeed, studies have provided us with the demonstration that Pax8 and TTF-1 directly interact in vivo in differentiated thyroid cells. Our knowledge of the function of Pax8 in the developing thyroid is still scarce. Based on the reported anti-apoptotic function of *PAX* genes, it has been proposed that the loss of TFCs through apoptosis might be the underlying mechanism of the observed thyroid dysgenesis in Pax8 null embryos. It has been demonstrated that in the absence of Pax8, the expression of both Foxe1 and Hhex is strongly reduced in the precursors of follicular cells. Pax8 could then have a specific upper role in the regulatory pathway controlling the development of the thyroid.

Foxe1

Foxe1 is a transcription factor characterized by the presence of a forkhead domain as a DNA-binding domain. It is encoded by the *Foxe1* gene in mice and the *FOXE1* gene in humans, located on chromosomes 4 and 9q22, respectively. Early during development, at E 8.5, Foxe1 is expressed along the whole foregut, at variance with TTF-1 and Pax8, whose presence in the gut is restricted to the thyroid anlage. *Foxe1* knockout mice display a perinatal lethal phenotype characterized by a severe cleft palate and athyreosis or ectopia of the thyroid. Analysis of thyroid development shows that in the absence of Foxe1 at E 8.5, the thyroid anlage is specified, but at E 9.5, thyroid precursor cells are still on the floor of the pharynx, showing a clear defect of migration. At E 15.0, the *Foxe1* knockout embryos exhibit either a small sublingual thyroid remnant or no thyroid gland at all. Hence, Foxe1 is absolutely necessary to promote migration of TFC precursors. Furthermore, Foxe1 also could be implicated in the control of the survival of thyroid cells, as shown by the absence of thyroid in many *Foxe1* knockout mice.

Hhex

Hhex is a homeodomain containing the transcription factor encoded by the *Hhex* gene in mice and the *HHEX* gene in humans, located on chromosomes 19 and 10q23, respectively. During embryonic life, Hhex is present in the developing thyroid and in several organs derived from the foregut endoderm. In *Hhex* null embryos at E 8.5, the thyroid anlage is visible, but already at E 9.5 the thyroid primordium is absent or hypoplastic and the expression of TTF-1, Foxe1, and Pax8 is down-regulated.

It is possible that Hhex is implicated in the regulation of the expression of TTF-1, Foxe1, and Pax8 in the thyroid primordium. Hhex could then be required to maintain the expression of these transcription factors in the thyroid.

Tshr

Tshr is a protein that belongs to the superfamily of G protein-coupled receptors encoded by the *Tshr* gene in mice and the *TSHR* gene in humans, located on chromosomes 12 and 14q31, respectively. Tshr is detected in the developing thyroid after the completion of the migration of the primordium, during the same stage at which Tg appears and before the first evidence of follicular organization in the gland.

In adults, thyroid-stimulating hormone (TSH) is the main physiological agent implicated in the regulation of the main functions of the thyroid and exerts its cellular effects by binding to Tshr. Inactivating mutations in this receptor cause severe hypothyroidism during postnatal life. During the early stages of thyroid development, a functional Tshr is not required but is necessary for the final step of follicular cell differentiation. Indeed, in the absence of a correct TSH/Tshr signaling, the expression of both TPO and NIS in TFCs is strongly down-regulated.

Table 2 Mouse and human phenotypes following inactivation of some genes normally expressed during thyroid development

Protein	*Gene*		*Tissue expression*	*Phenotype*		*Inheritance in humans*
	Mouse	*Human*		*Null mice*	*Patients carrying inactivating mutations*	
TTF-1	*Titf1*	*TITF1*	Thyroid Lung Brain Posterior pituitary	Thyroid and pituitary absent; severe defects in lung and diencephalon	Mild thyroid hypoplasia; respiratory distress; atassia	Dominant
Pax8	*Pax8*	*PAX8*	Thyroid Kidney	Thyroid absent	Thyroid hypoplasia	Dominant
Foxe1	*Foxe1*	*FOXE1*	Thyroid Esophagus Palate Hair follicles Anterior pituitary	Thyroid absent or ectopic; cleft palate	Athyreosis; cleft palate; spike hair; choanal atresia	Recessive
Tshr	*Tshr*	*TSHR*	Thyroid	Thyroid hypoplasia	Thyroid hypoplasia	Recessive

Thyroid Specification

Studies in mouse, Xenopus and zebrafish have identified key roles for fibroblast growth factors (Fgfs) and bone morphogenetic proteins (Bmps), presumably derived from the cardiogenic mesoderm, in inducing thyroid fate in competent but yet undifferentiated anterior endoderm cells. These studies indicated that Fgf2 and Bmp4 are key players of an evolutionarily conserved mechanism for thyroid specification (Nilsson and Fagman, 2017). Moreover, when conditioned in 3D culture and stimulated with TSH, cells derived from mouse embryonic stem cells overexpressing Nkx2-1 and Pax8 are able to generate fully functional thyroid follicular, capable of rescuing thyroid hormone levels in athyreotic mice (Antonica *et al.*, 2012). This exciting discovery opens the door to regenerative therapy for patients with CH, though the field needs further advances to make this a realistic possibility.

Molecular Genetics of Thyroid Dysgenesis

In 85% of cases, permanent congenital hypothyroidism (CH) detected in newborns is due to impaired development of the thyroid. Defects in the mechanisms that allow the growth, survival, migration, or differentiation of the thyroid primordium can result in thyroid dysgenesis (TD). This term indicates an ectopic or hypoplastic thyroid (or both) as well as the absence of the gland (athyreosis). It has been demonstrated that in some patients, TD is due to mutations in genes involved in thyroid development and already identified in mouse models such as *TITF1*, *PAX8*, *FOXE1*, and *TSHR*. These results confirm that the products of these genes are required for a correct thyroid morphogenesis (**Table 2**). Moreover, newly discovered predisposing genetic factors are described in familial CH cases associated mainly with a normal or small thyroid in situ.

TITF1

Some patients affected by a syndrome characterized by severe neurological disturbances, respiratory distress, and thyroid alterations have been found to carry heterozygous mutations within the *TITF1* gene. Nevertheless, the signs and symptoms of the three disorders are not always observed in combination and moreover, their severity varies greatly (Abu-Khudir *et al.*, 2017). When tested in vitro, the various mutations described encode for proteins that do not display either functional activity or a dominant negative effect on the wild-type form. These data indicate that a reduced expression of TTF-1 is not compatible with the normal development of lungs, brain, and thyroid in humans. On the contrary, mice carrying only a functional allele of *Titf1* show a very mild, possible strain-dependent phenotype.

PAX8

Mutations in *PAX8* have been described in sporadic and familial cases of congenital hypothyroidism with TD. The phenotype of the patients ranges from mild hypothyroidism to severe hypoplasia of the thyroid. As in the case of TTF-1, all affected individuals are heterozygous from the mutated allele, and in the familial cases transmission is autosomal dominant with incomplete penetrance and variable expressivity (Ramos *et al.*, 2014). This dominant effect of *PAX8* mutations could be due to a gene dose

requirement (haploinsufficiency). In these patients, the single functioning allele is not able to produce a sufficient amount of Pax8 to support the normal development of the gland.

FOXE1

Homozygous missense mutations in the *FOXE1* gene have been described in cases affected with Bamfort syndrome. This syndrome is characterized by cleft palate, bilateral choanal atresia, spiky hair, and congenital hypothyroidism with TD. All patients show athyreosis, whereas in mice the absence of Foxe1 causes either athyreosis or defects in thyroid migration. All the reported FOXE1 mutations occurred within the forkhead domain (FHD) and led to either partial or complete loss of the DNA-binding ability and of the transcriptional activity of the mutated protein.

TSHR

Mutations in the *TSHR* gene have been identified in patients affected by congenital hypothyroidism with thyroid hypoplasia and compensatory increased TSH secretion. The disease is inherited as an autosomal recessive trait, and the phenotype ranges from asymptomatic hyperthyrotropinemia to congenital hypothyroidism with severe hypoplasia of the thyroid. The different penetrance of the phenotype is likely due to the residual mutant receptor activity (Grasberger and Refetoff, 2017). Nonfunctional mutations in the two alleles produce severe hypothyroidism (uncompensated TSH resistance), while mutations in at least one allele with residual receptor function produce either mild hypothyroidism (partial compensation) or isolated hyperthyrotropinemia (full compensation).

Nkx2.5/Csx

Nkx2.5/Csx, located at 5q34, is a member of the NKx2 family. During early embryonic development of the mouse, Nkx2.5 is expressed in the progenitors of the myocardial cells, in the pharyngeal endoderm and in the developing thyroid (from E8.5 to E11.5). A smaller sized thyroid bud was detected in Nkx2.5 null embryos, suggesting that Nkx2.5 is required during organogenesis of the thyroid. Mutations in NKX2.5 gene have been detected in patients with congenital heart disease (CHD) and patients with either thyroid ectopy or athyreosis. However, pedigree and functional data suggested that NKX2.5 mutations were not a major contributor in the pathogenesis of thyroid dysgenesis, though their role as a genetic modifier cannot be excluded (van Engelen *et al.*, 2012).

GLIS3

GLIS3 biallelic mutations have been reported in consanguineous familial cases with variable manifestations of neonatal diabetes, CH, polycystic kidneys, glaucoma, hepatic fibrosis and exocrine pancreatic deficiency (Senée *et al.*, 2006). Most cases have a thyroid gland in situ; athyreosis is described only in one case (Dimitri *et al.*, 2011).

JAG1

Jagged ligands, expressed on the cell surface, interact with Notch receptors on adjacent cells, resulting in receptor cleavage and translocation to the cell nucleus. The disruption of the Notch signal leads to thyroid dysgenesis in zebrafish, suggesting an essential role of Notch pathway in thyroid development (Porazzi *et al.*, 2012). Heterozygous jagged 1 protein (JAG1) mutations have been reported in Alagille syndrome type 1 (ALGS1) which is characterized by variable involvement of liver, heart, skeleton, eye and facial defects. de Filippis *et al.* (2016) described 2 ALGS1 patients with thyroid hypoplasia and four CHTD patients (one with thyroid ectopy, one with a normal gland in situ and two with thyroid hypoplasia) with heterozygous JAG1 mutations. jag1a/b morphant zebrafish showed variable defects of thyroid development, indicating that JAG1 can contribute to the pathogenesis of thyroid dysgenesis.

BOREALIN

Homozygous mutations of CDCA8/BOREALIN were found in 2 consanguineous cases and monoallelic mutations in 2 sporadic cases of CHTD (Carre *et al.*, 2017). Borealin is expressed in thyrocytes and is a major component of the Chromosomal Passenger Complex (CPC), implicated in chromosome segregation and cytokinesis.

NTN1

Deletion in Netrin-1 gene (NTN1) was reported in one patient with congenital heart (VSD) and thyroid ectopy (Opitz *et al.*, 2015) and in 1 case of sporadic thyroid ectopy (Dr. Michel Polak, personal communication). Functional studies in zebrafish revealed that thyroid migration is disturbed in ntn1a morphant due to lack of proper guidance exerted by dysplastic pharyngeal vessels.

Conclusion

Although early in development TTF-1, Foxe1, Pax8, and Hhex are expressed in the thyroid primordium, none of them is essential for the initial steps of thyroid morphogenesis. Recent studies have identified fibroblast growth factors (Fgfs) and bone morphogenetic proteins (Bmps) as key players of an evolutionarily conserved mechanism for thyroid specification. However, additional factors required for thyroid anlage specification are still to be identified. It is possible that the identification of the genes controlling TTF-1, Foxe1, Pax8, and Hhex expression can give us information on how thyroid precursor cells begin their differentiation. Mutations in genes involved during the initial steps of thyroid morphogenesis could be responsible for thyroid agenesis (i.e., absence of the formation of a thyroid anlage). TTF-1, Foxe1, Pax8, and Hhex are transcription factors whose role is to control the expression of target genes that ultimately actuate a specific developmental program. The identification of these genes is still a matter of study. A number of cases of congenital hypothyroidism with TD could be due to mutations in genes that are targets of the transcription factors TTF-1, Foxe1, Pax8, and Hhex. Nevertheless, causal mutations have been found in a minority of CH cases, mainly to orthotopic hypoplasia, whereas the commonest developmental anomaly, thyroid ectopy, remains unexplained, indicating the involvement of still unidentified genes or alternative mechanisms. In this context, more recent studies describe new genes or pathway (e.g., GLIS3, JAG1) involved in thyroid development that may provide new clues for understanding the CH pathogenesis. The existence of alternative mechanisms for CH pathogenesis is also supported by the elevated frequency of discordance for CH phenotype between monozygotic twins. This latter finding suggests the involvement of non-Mendelian mechanisms, including post zygotic somatic mutations, environmental or epigenetic factors, that might predispose to or protect from the full expression of a CH genetic background. Interestingly a recent systematic NGS analysis performed in a large CH population reveals a frequent oligogenic origin of CH (de Filippis *et al.*, 2017). This data, consistent with a previously proposed animal model of a multifactorial pathogenesis of CH (Amendola *et al.*, 2005), may constitute a suitable explanation for the variable expressivity and penetrance of genetic defects previously reported in several CH familial settings.

Glossary

Chaperones Proteins that assist the noncovalent folding or unfolding and the assembly or disassembly of other macromolecular structures.

Circadian rhythm Physiological activity that occurs approximately every 24 h, or the rhythm of such activity.

Deiodinase Enzymes containing selenium, in the form of the amino acid selenocysteine, and important in the activation and deactivation of thyroid hormones.

Glycoprotein hormones Family of glycosylated, cysteine-rich proteins consisting of an alpha and beta subunit.

G-proteins Family of proteins involved in transmitting signals from a variety of different stimuli outside a cell into the inside of the cell.

Hypothalamus Region of the diencephalon at the base of the brain in which specialized nerve cells originate and produce neuropeptides that regulate the secretion of hormones from the pituitary gland.

N-glycosylation The addition of sugar chains at the amide nitrogen on the side chain of asparagine.

O-glycosylation The addition of sugar chains on the hydroxyl oxygen on the side chain of hydroxylysine, hydroxyproline, serine, or threonine.

Pituitary Small gland, the hypophysis cerebri, connected to the base of the brain by a stalk and located in a depression in the sphenoid bone (the sella turcica).

Thyroglobulin Large glycoprotein that is synthesized in the thyroid gland and is the substrate for thyroid hormone formation.

Thyroxine (T4) 3,5,30,50-Tetraiodothyronine, the major hormonal product of the thyroid gland, formed by the coupling of two diiodotyrosine residues within the thyroglobulin molecule.

Triiodothyronine (T3) Active form of thyroid hormone produced in the thyroid gland by the coupling of a monoiodotyrosine and a diiodotyrosine residue in thyroglobulin, and in other organs by the deiodination of a 30'iodine atom from thyroxine.

Thyroid gland activity is the result of a dynamic regulating network that include the hypothalamic thyrotropin-releasing hormone (TRH), the pituitary glycoprotein hormone thyroid-stimulating hormone (TSH), and the circulating thyroid hormones with their feedback effects at the hypothalamic and pituitary levels. The first findings of a possible relationship between the pituitary and the thyroid was described more than 150 years ago from Niepce but only in the middle of the last century it was possible to isolate the first thyrotropin-releasing factor from porcine hypothalamus (Schally *et al.*, 1966) and to establish the primary structure of the TSH (McKenzie, 1960; Liao and Pierce, 1971; Fiddes and Goodman, 1979).

TRH

Structure

TRH is the most important endogenous stimulator of the HPT axis (**Fig. 1**). It is a small pyroGlu-His-Pro-NH2 tripeptide derived from a larger precursor which is posttranslationally cleaved by prohormone convertases (PC1/3, PC2), carboxypeptidase E, pyroglutamyl cyclase, and peptidylglycine α-hydroxylating monooxygenase.

Synthesis and Secretion

The human preprohormone *TRH* gene mapped on chromosome 3. TRH is synthesized and released from specific hypothalamic neurons within the paraventricular nucleus and then transported into the median evidence via axons of specialized nerve. It is then released, by membrane depolarization through Ca^{2+}-dependent exocytosis, into the hypophyseal portal blood system thus reaching the anterior pituitary gland where it stimulates the thyrotropes through the interaction with its specific receptor, the TRH receptor. The TRH has a very short half-life that ranges from 2 to 6 min, since it is rapidly inactivated by proline endopeptidase, pyroglutamyl peptidase I (PPI), and the membrane-bound PPII, which hydrolyze active TRH in the hypothalamus and pituitary (Iversen, 1991).

Regulation

The regulation of the TRH neuron activity is under the control of multiple factors (e.g., leptin, NPY, environment), that act either directly or indirectly, although the thyroid hormones are surely its most potent negative regulators. Indeed, thyroid hormones

 doi:10.1016/B978-0-12-801238-3.65239-X

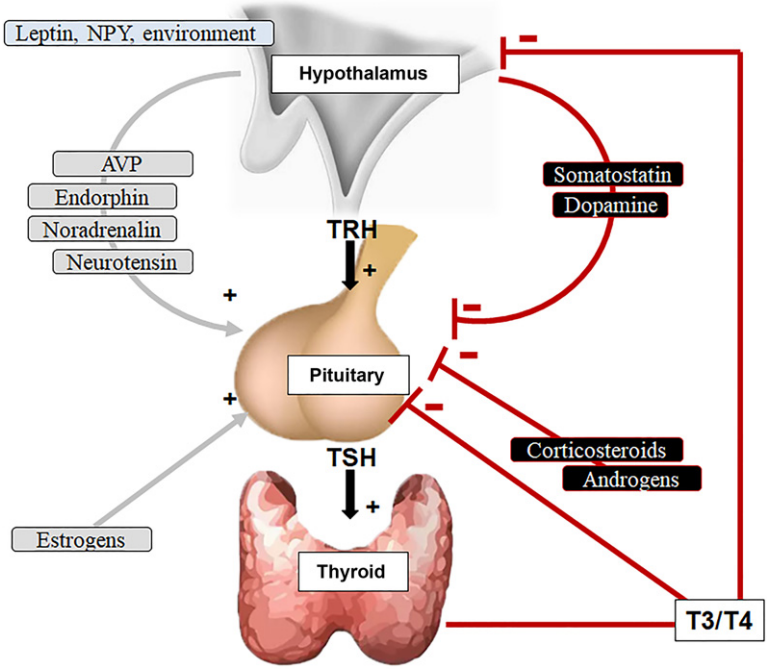

Fig. 1 Schematic representation of the hypothalamus–pituitary–thyroid axis.

interact with their specific nuclear receptors on TRH neurons to reduce TRH synthesis and secretion. Moreover, other factors, such as somatostatin, dopamine, glucocorticoids, adrenergic agents regulate the pituitary TSH response to TRH, but it is difficult to distinguish between hypothalamic and pituitary effects.

TRH Receptor

TRH receptor belongs to the family of the seven-transmembrane domain G protein coupled receptors. It is mainly expressed in the anterior pituitary, in neuroendocrine brain regions, in the autonomic nervous system, and in the brainstem. Upon TRH binding it mediates its signaling by the recruitment of the Gq protein thus leading to the stimulation of the phospholipase C. This will induce the intracellular accumulation of inositol 1,4,5-triphosphate (IP3) and 1,2-diacylglycerol (DAG) and thus the increase of intracellular Ca^{2+} concentrations and phosphokinase C activation (Engel and Gershengorn, 2007). TRH receptor expression on the thyrotropes is regulated by thyroid hormones but not by TRH (Chiamolera and Wondisford, 2009).

TRH Action on the Pituitary Gland

TRH induces secretion and synthesis of pituitary TSH. TRH injection in humans causes up to a 22-fold increase in TSH within half an hour. Continuous intravenous TRH infusion over 4 h results in a biphasic TSH surge, being the first peak the early release of preformed TSH, and the second peak the release of newly synthesized TSH. TRH has also been proven to affect the bioactivity of TSH by acting on its glycosylation pattern. Moreover, TRH is also known to stimulate pituitary prolactin secretion and may induce hyperprolactinemia in some hypothyroid patients. PRL levels are reduced by 40% in TRH-null mice, such as in the patients with a complete resistance to TRH (Collu *et al.*, 1997; Bonomi *et al.*, 2009). Although TRH is dispensable for pregnancy and lactation (Bonomi *et al.*, 2009), it is needed for lactotroph function, principally during lactation in mice.

TSH

Structure

TSH is a member of the glycoprotein hormones family together with the luteinizing hormone (LH) and follicle stimulating hormone (FSH), originated from the pituitary, and CG which has a placental origin. As demonstrated by the available crystal structure of the CG and FSH (Lapthorn *et al.*, 1994; Fan and Hendrickson, 2005), glycoprotein hormones are heterodimers characterized by a common alpha subunit (92 amino acids) and a specific beta subunit (TSH: 118 aa, FSH: 111 aa, LH: 121 aa, and

CG: 145 aa). Each subunit belongs to the "cysteine-knot growth factors" superfamily since it is characterized by six cysteines linked by disulfide bridges (Grossmann *et al.*, 1997). These latter stabilize the structure of each subunit that can be displayed in a "Y" shape, formed by three loops: loop 1 and 3 are parallel to one end of the subunit, and loop 2 extends at the other end. The heterodimer is than formed by the two subunits that are hinged head to tail and substantially back to back forming a protein slightly curved with loops alpha 1, alpha 3, and beta 2 at one end and loops beta 1, beta 3, and alpha 2 at the other end. The beta subunit of glycoprotein hormones in then characterized by a long C-terminal end after loop 3, that will make the so called "determinant loop." This is a short loop in the center of the dimer, between cysteines 10 and 12, that encloses the alpha subunit as a safety belt and it was indeed called "seat-belt" (Shupnik *et al.*, 1989; Magner, 1990; Lapthorn *et al.*, 1994). The glycoprotein hormones are characterized by various N-glycosylation sites and indeed the carbohydrate residues constitute around 20% and 10% respectively of the alpha and beta subunit molecular weights. A supplementary O-glycosylation site is also placed on the free alpha subunit (Shupnik *et al.*, 1989, 1994; Magner, 1990, 1994).

Synthesis and Secretion

TSH is synthesized in the adenohypophysis by the thyrotropes, which represent approximately 5% of the pituitary endocrine cells and are sited in the anterior median part of the gland. TSH biosynthesis results from several stages inside the rough endoplasmic reticulum and the proximal and distal Golgi (Magner, 1990, 1994; Cohen and Wondisford, 2013) where specific enzymes act modifying the posttranslational subunit precursors and adding the carbohydrate chains. The signal peptide allows the translocation of both alpha and beta precursors across the membrane of the rough endoplasmic reticulum where the cleavage of the signal peptide and the glycosylation of some asparagine residues take place. These precursors, which are rich in mannose, are preassembled in the rough endoplasmic reticulum in conjunction with a dolichol phosphate carrier and then moved to the glycosylation sites. The glycosylation process plays a key role in allowing the correct folding of the two subunits in forming the heterodimer. Glycoprotein are maintained in the rough endoplasmic reticulum until the end of the process by chaperone molecules, and then, heterodimers move to the following compartment for the posttranslational modifications leading to the formation of complex oligosaccharide chains. O-glycosylation of alpha subunit excess takes place in the proximal Golgi compartment, while sialylation and sulfation processes of the oligosaccharide complex in the Golgi distal compartment. TSH heterodimers, thus, enter the secretion pathway and are transported into small secretory granules. The pituitary content of immunoreactive TSH is about 80–200 mIU. TSH and the free subunits are released by exocytosis in a pulsatile manner with an average of 13 pulses/24 h. The daily production of TSH is 75–150 mIU with a circadian rhythm characterized by a nocturnal rise with a peak after numbness and a nadir in midafternoon. TSH is water-soluble and thus circulates as a free molecule in the circulatory torrent. It acts interacting with a specific receptor, the TSH receptor expressed on the membrane of the thyroid cells, and it is subjected to renal and hepatic metabolism with a clearance of about 40–60 mL/min. TSH half-life ($t/2$) is about 50–80 min, although its $t/2$ is modified according to the presence of hypo- or hyperthyroidism, being respectively augmented or reduced, or to the degree of glycosylation.

Regulation

TSH synthesis and secretion is regulated by several factors. TRH represents the most important stimulating factor, while the circulating thyroid hormones act as negative regulators through the feedback mechanism at the hypothalamic–pituitary level (**Fig. 1**) (Hollenberg, 2013). TRH binds to the TRH receptor expressed on the membrane of the pituitary thyrotropes inducing the intracellular pathways of the IP3 and DAG. This stimulates the glycosylation of the alpha and beta subunits and finally the secretion by exocytosis of TSH by increasing the cytosolic free Ca^{2+}. Nevertheless, a prolonged stimulation of the TRH receptor by its ligand is demonstrated to cause a "downregulation" phenomenon with the internalization of the receptors. On the contrary, thyroid hormones act both on the hypothalamus and pituitary with a negative feedback mechanism. Triiodothyronine (T3), decreases the TRH synthesis from the hypothalamus both inhibiting the gene-expression of the TRH precursor (prepro-TRH) and increasing the TRH degradation by specific enzymatic activities. Moreover, T3 is able to inhibit the TSH secretion and then the synthesis at the pituitary level through the interaction with the T3 nuclear receptors at this level.

Other factors are then involved in the complex regulation of the TSH synthesis and release, and thus, in turn, of the hypothalamus–pituitary–thyroid axis. This is the case of somatostatin and dopamine, two hypothalamic factors able to inhibit TSH secretion. Somatostatin was demonstrated to decrease TSH basal level and its response to TRH stimulation, and its long acting analogs are proved to be effective in treating the TSH-secreting pituitary adenomas (Beck-Peccoz *et al.*, 1996). Dopamine effect on TSH secretion is instead more complex and it is exercised both at the median eminence and pituitary level. TSH inhibition due to dopamine is more evident in females and in hypothyroidism. Moreover, the use of dopamine agonist in the treatment of pituitary adenomas secreting PRL and/or GH has not been proven to induce a simultaneous condition of central hypothyroidism with low TSH, since in this case the thyroid hormones negative feedback mechanism is prevailing. On the contrary, the infusion of high doses of dopamine for a prolonged period may cause central hypothyroidism. Contrary to dopamine, adrenergic substances seem to be able to induce the release of TSH from the human pituitary, although their role remains uncertain. Finally, high doses of corticosteroids, such as in the Cushing syndrome, stress conditions, anorexia nervosa, psychiatric disorders, and non-thyroidal illnesses, has been proven to decrease basal and TRH-stimulated TSH secretion. Sex hormones seems also to influence TSH response to TRH stimulation, being the estrogens able to increase and the androgens able to inhibit this stimulated secretion.

TSH Receptor

TSH receptor, which belongs to the superfamily of the G protein coupled receptors (Parmentier *et al.*, 1989), is placed on the basolateral membrane of thyrocytes (about 1000 receptors per cell) and mediates all TSH actions on the thyroid gland besides being the target for different autoimmune thyroid diseases (Parmentier *et al.*, 1989; Grossmann *et al.*, 1997). It is encoded by a specific 10 exons gene that maps on chromosome 14. TSH receptor extracellular domain is encoded by the first nine exons, while the last exon codes for the other two domains, the transmembrane and the intracellular ones. It is a 744 amino acids glycoprotein characterized by an N-terminal ECD with leucine-rich repeats and 6 N-glycosylation sites, and a C-terminal portion comprising a 7 spanning transmembrane domain and an intracellular tail. There is a 70% homology to the C-terminal portion and 40% to the N-terminal part between the three glycoprotein hormone receptors, the TSH and LH–FSH receptors. A crystal structure of the TSH receptor in complex with a human monoclonal stimulant antibody was published in 2007 (Sanders *et al.*, 2007), as well as a bioinformatic model of TSH receptor complexed with its natural ligand (Krause *et al.*, 2012). The interaction of the TSH with the extracellular domain of the TSH receptor and the consequent modifications of the transmembrane domain, leads to the recruitment of the G-proteins and the following activation of the downstream intracellular pathways, the cyclic adenosine monophosphate (cAMP) and the Ca-IP3 pathways (Sanders *et al.*, 2007; Krause *et al.*, 2012). The intracellular cAMP elevation activates cAMP-dependent protein kinase, which promotes the phosphorylation of cytosolic proteins, leading to some specific response of the thyroid cells. The elevation of IP3 induces and increase in the cytosolic Ca^{2+} which, in turns, is responsible for the cellular effects, while diacylglycerol activates a protein kinase that is responsible for specific biological effects that are still poorly understood.

TSH Action on the Thyroid Gland

TSH acts almost exclusively on thyrocytes, where it controls, through different mechanism and kinetics, cells activity (thyroid hormones synthesis and secretion) and their general metabolism (mitotic activity, carbohydrate, lipid, and protein) (Sanders *et al.*, 2007; Krause *et al.*, 2012). Indeed, TSH, via the cAMP pathways, enhances the thyroglobulin gene-expression thus stimulating the synthesis of this protein which is essential for the biosynthesis of the thyroid hormones. Furthermore, another cAMP mediated effect of TSH is represented by the stimulation also of the expression of the Na^{+}–I^{-} symporter which allow the active transport of the iodide inside the thyrocytes. Moreover, TSH stimulates the iodination of thyroglobulin and the synthesis of thyroid hormones by increasing the generation of H_2O_2, substrate of the thyroid peroxidase, by the action of specific enzymes, the so called "dual oxidase." This latter effect is mediated via the IP3/DAG intracellular pathways. In addition, TSH, via cAMP, fosters the thyroglobulin endocytosis and thyroid hormones secretion by thyroglobulin hydrolysis. In addition, TSH exerts other effect on the thyrocytes including the activation of the pentose pathway by increasing the production of H_2O_2 and the stimulation of the cell growth and proliferation (Kimura *et al.*, 2001).

Thyroid-Stimulating Hormone (TSH; Thyroptopin)☆

Leonidas H Duntas, University of Athens, Athens, Greece

Historical Aspects

In 1916, Bennett M. Allen at Kansas University and Philip E. Smith at Cornell and Berkeley, California, working independently, observed that thyroid follicles from thyroidectomized tadpoles contained less colloid and that the tadpoles consequently grew far more slowly (Magner, 2014; Allen, 1916; Smith, 1916). These findings substantially validated the theory of a pituitary factor that stimulates the thyroid gland. In the late 1950s, the introduction of improved ion exchange chromatography resulted in the elucidation of the primary structure of thyroid-stimulating hormone (TSH), or thyrotropin, as a glycoprotein, composed of two peptide chains, which is secreted from the thyrotrophic cells that are basophilic and constitute approximately 5% of all anterior pituitary cells (Pelletier *et al.*, 1978).

Structure and Metabolism

The α (alpha) subunit with a 92-amino acid sequence, which is virtually identical to that of human chorionic gonadotropin (hCG), luteinizing hormone (LH), and follicle-stimulating hormone (FSH), forms the effector region that stimulates adenylate cyclase (involved in the generation of cAMP). In contrast, the β (beta) subunit (TSHB) containing a 118-amino acid sequence is unique to TSH and therefore determines its receptor specificity (Porcellini *et al.*, 2003).

TSH is released in a pulsatile manner, resulting in both circadian and ultradian rhythms of its serum concentrations: the latter should be borne in mind when interpreting clinical laboratory findings (Brabant *et al.*, 1990).

TSH, which is excreted via the kidneys, has a half-life of about an hour in healthy individuals and is likely to be dependent on the degree of glycosylation, since de-glycosylated TSH is more rapidly degraded. This mechanism is regulated by the hypothalamic thyrotropin-releasing hormone (TRH), which regulates the glycosylation process of TSH, a fact that explains the observed accelerated metabolism of TSH in hyperthyroidism and its retarded metabolism in hypothyroidism (Ridgway *et al.*, 1974).

Regulation and Physiology

TRH is the main regulator of TSH. The stimulated effect on pituitary TSH is mediated via the nucleus paraventricularis and nucleus dorsomedialis, both of which contain a high number of TRH positive cells: these, together with the very high number of TRH content in the projection areas of the eminentia mediana, release TRH into the thyrotrophic area of the pituitary as well as into the neurohypophysis and the extrahypothalamic central nervous system. The effect of TRH on TSH is mediated via a calcium-dependent process, in vitro studies having shown that interaction of TRH with its specific pituitary receptors rapidly results in activation of phosphatoinositol metabolism, the latter acting as a "second messenger" system (Weintraub *et al.*, 1985). This leads to release of calcium from the intracellular storage space, accompanied by a quick inflow from the extracellular space and an increase in intracellular calcium activity, which mediates the release of TSH (Brenner-Gati and Gershengorn, 1986).

Somatostatin, another peptide generated and secreted by the hypothalamus, has an opposite effect by decreasing or inhibiting the release of TSH. There are also other as yet undetermined factors that may have a stimulating action on TSH, such as catecholamines through their interaction with the TRH, presumably histamine, via stimulation of TRH, and vitamin D (1,25 (OH) D3), via its interaction with intracellular calcium (D'Emden and Wark, 1987).

TSH stimulates the thyroid gland to synthesize and secrete thyroxine (T4) and triiodothyronine (T3) which, depending on their concentration in the blood, regulate the pituitary release of TSH. Feedback loops, from which most control mechanisms originate, are especially important in the endocrine system, with negative feedback being the more frequent. One example of a negative feedback circuit occurs in the case that T3 and T4 concentrations are low, whereby the secretion of TSH is increased; in contrast, when T3 and T4 concentrations are high TSH secretion is decreased (Estrada *et al.*, 2014). TH additionally exerts a negative effect at hypothalamic levels (**Fig. 1**). The negative effects on TSH synthesis are mediated via attenuation of hypothalamic stimulation by reducing the number of TRH receptors in the pituitary as well as by a direct action mediated via nuclear receptors suppressing the generation of the TSH subunits.

☆*Change History:* February 2018. Leonidas Duntas updated the text and references to the entire article.

This article is an update of D. Aled Rees, Maurice F. Scanlon, TSH (Thyroid-Stimulating Hormone; Thyrotropin), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 615–619.

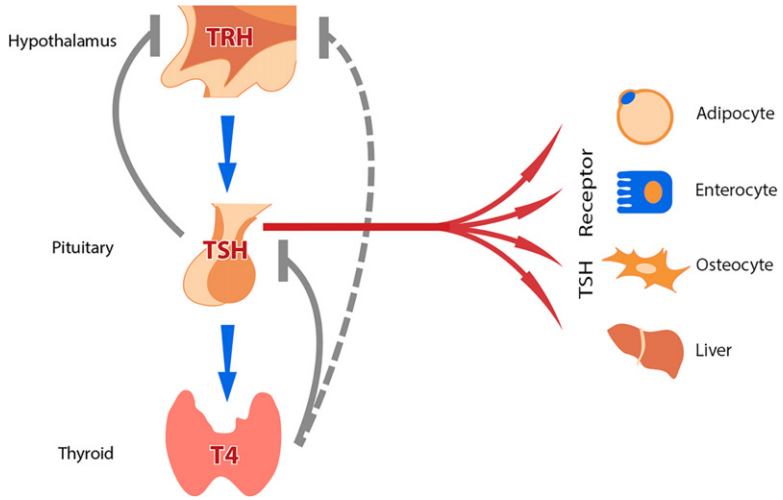

Fig. 1 TRH is released from the hypothalamus and activates the pituitary synthesis and secretion of TSH, which in turn stimulates the thyroid to secrete thyroid hormones (TH). In a paradigm of a negative feedback mechanism, TSH inhibits TRH secretion, while TH inhibits TSH and potentiates the inhibitory action of TSH to TRH release. TSH exerts various effects on a variety of organs in the periphery via stimulation of its receptor.

Stimulation of the G protein-coupled TSH receptor, which is found mainly in thyroid follicular cells, increases T3 and T4 production and secretion (Parmentier *et al.*, 1989). The TSH receptor consists of a seven-transmembrane (serpentine) domain with a large 400 amino acid extracellular NH2 domain, which is thought to exert an inhibitory action (Dumont *et al.*, 2000). This occurs via a cascade leading to thyroid hormone synthesis and secretion in the following manner: (1) upregulation of the sodium-iodide symporter (NIS) activity at the basolateral membrane of follicular cells, this elevating intracellular concentrations of iodine (iodine trapping); (2) iodination of the precursor protein thyroglobulin (Tg) in the follicular lumen, iodination of the tyrosyl residues of Tg precede TH biosynthesis, the latter depending on the interaction of iodide, TG, hydrogen peroxide (H_2O_2), and thyroid peroxidase (TPO) at the apical plasma membrane of thyrocytes: this results in thyroid hormone biosynthesis coming under the tonic control of TSH; (3) stimulation of the conjugation of iodinated tyrosine residues, this resulting in the formation of T4 and T3 which remain attached to the thyroglobulin protein; (4) increased endocytosis of the iodinated thyroglobulin protein across the apical membrane back into the follicular cell; (5) stimulation of proteolysis of iodinated thyroglobulin to form free T4 and T3; (6) secretion of T4 and T3 across the basolateral membrane of follicular cells to enter the circulation (Carvalho and Dupuy, 2017).

Pars Tuberalis TSH

It was recently shown in animals that breed seasonally that a long-day stimulation of the pituitary gland may induce TSH secretion from the pars tuberalis (PT), which locally activates thyroid hormone within the hypothalamus: this subsequently stimulates gonadotropin-releasing hormone followed by gonadotropin secretion, leading to gonadal growth (Nakayama and Yoshimura, 2018).

Diagnosis and Reference Levels

Measurement of TSH concentrations is an important component of the thyroid function test when an excess (hyperthyroidism) or deficiency (hypothyroidism) of thyroid hormones is suspected. The sensitivity of the TSH assay has been considerably improved over the last two decades, rendering it today's most reliable screening test for thyroid dysfunction. However, the interpretation of the results should additionally take into consideration both TSH and FT4 concentrations, while T3 measurements may be necessary in only a minority of cases. For the monitoring of hypothyroid patients on thyroxine, measurement of TSH alone is usually sufficient. An increase in TSH above the reference levels indicates under-replacement or poor compliance, whereas a significant reduction in TSH suggests over-treatment. A low or low-normal TSH value in the differential diagnosis may also be an indicator of pituitary disease.

In 2002, the National Academy of Clinical Biochemistry (NACB) recommended age-related reference limits for children, these usually being higher than in adults, starting from about 1.3 to 19 mIU/L for normal-term infants at birth, dropping to 0.6–10 mIU/L at 10 weeks old, to 0.4–7.0 mIU/L at 14 months and gradually declining during childhood and puberty till reaching adult levels, 0.4–4.0 mIU/L (Baloch *et al.*, 2002). Importantly, as TSH levels increase, FT3/FT4 ratios also rise until age 40, then

continuously decline with increasing age, thus reflecting a diminishment in T4 to T3 conversion rate which most likely forms part of the aging process (Strich *et al.*, 2016).

The reference interval for TSH varies significantly by age, sex, hour of day, and ethnicity, though it is unaffected by time of year. While females have significantly higher TSH than males, the magnitude of these differences did not exceed 0.1 mIU/L or 0.1 ng/dL, respectively. Although the 2.5% TSH reference interval remains constant through the day and age ranges, the upper limit (97.5%) of the TSH reference interval increases from 6.45 to 7.55 mIU/L with age, mainly due to a progressive increase in the amplitude of the nocturnal TSH surge (Ehrenkranz *et al.*, 2015).

The TSH threshold for initiating treatment is still not well defined due to the lack of large randomized controlled trials. However, it has been widely accepted that treatment of subclinical hypothyroidism should be started at TSH $\geq$ 10 mIU/L and subclinical hyperthyroidism at TSH $<$ 0.1 mIU/L. Recommendations on screening are controversial, though most guidelines advocate that thyroid function should be checked in patients at risk for hypothyroidism, those over 60 and those with known cardiovascular disease and heart failure (Floriani *et al.*, 2018).

Challenges in the Interpretation of TSH Results

Heterophilic antibodies (HA—including human anti-mouse antibodies (HAMA) and rheumatoid factor (RF)) may interfere with TSH measurement, causing a higher or, rarely, lower TSH result as compared to the actual true TSH level (Mongolu *et al.*, 2016). HA may occur in up to 4.4% of samples tested, generating a discrepancy between TSH and free T4 values and, most importantly, between laboratory values and patients' conditions. Macro-TSH-endogenous antibodies bind to TSH reducing its activity, while TSH-isomers-natural variations of the TSH molecule, with lower activity, exert a lesser effect, the pituitary gland being thus forced to produce more TSH to overcome this deficiency (Hattori *et al.*, 2016).

These factors must be kept in mind so as to avoid skewed results.

Extrathyroidal Effects of TSH

TSH receptors are found in various cells, while experimental data have revealed an important role of TSH in a range of extra-thyroidal organs and systems (Fröhlich and Wahl, 2016). Two outstanding examples are the observations that TSH supported T-cell development in the thymus and improved natural killer cell activity (Provinciali *et al.*, 1992) and that thymocytes responded in a time-dependent manner upon stimulation with TSH, with application at 0900 h inducing proliferation but application at 1800 h having no effect. The latter underlines the importance of circadian changes in TSH levels and TSH receptor expression (Winczyk and Pawlikowski, 2000). Below an update on the physiology of TSH receptor in enterocytes, osteocytes, and adipocytes.

TSH and Enterocytes

Exogenous application of TSH can induce intraepithelial lymphocyte development in the intestinal epithelium, though not in athymic mice. Furthermore, TSH regulates the activity of the intraepithelial immune system, while the pattern of TSH-immunoreactive cells in the mucosa is changed from the upper and lower parts of the intestinal crypts to the stained cells in the apical region of the villi on infection with rotavirus (Wang and Klein, 1995; Fröhlich and Wahl, 2016). It is of note that TSH in the small intestine is specifically localized to regions below the crypt-villus units. Upon investigation, these disclosed, on the one hand, high-level TSH staining in the lower crypts in the absence of IL-7 staining and, on the other hand, TSH and IL-7 co-staining in the upper crypt regions. In rotavirus-infected mice, a notable difference was observed between TSH staining pattern in infected and in noninfected animals. Interestingly, 2 and 3 days postinfection TSH expression was high in and close to the apical villi where virus infection was most severe (Scofield *et al.*, 2005). It is thus probable that TSH exerts immunomodulatory activity on inflammation of the intestine.

TSH and Osteocytes

Both hyperthyroidism and hypothyroidism interfere with inhibitors of Wnt signaling, dickkopf-1 (DKK1), and sclerostin and have been associated with bone loss and osteoporosis (Tsourdi *et al.*, 2015). Osteoclasts, originating from multipotent progenitors in bone marrow, differentiate to osteoclast precursors, fusing and becoming mature (multinucleated) osteoclasts, a process primarily mediated by the receptor activator of nuclear factor kappa B (RANK) binding to its cellular receptor. The sensitivity of osteoclasts to TSH is regulated by estrogen, a lack of which results in the bone loss seen in postmenopausal women—and particularly those under TSH suppression with L-T4 (Martini *et al.*, 2008; Fröhlich and Wahl, 2016). Both estrogen binding to estrogen receptor alpha and TSH binding to TSH receptors inhibit RANKL signaling, leading to bone degradation. Estrogen acts by increasing osteoprotegerin, which binds RANKL and prevents it from binding to RANK, while TSH receptor activation, by antagonizing RANKL signaling and inhibiting RANKL-induced osteoclast formation and stimulation of osteoblast differentiation, increases bone mass.

TSH and Adipocytes

While the effect of subclinical hypothyroidism on lipid profiles is not as yet clarified, overt hypothyroidism is known to be associated with increased lipid profiles, this relationship being strongly influenced by gender and age as well as by degree of thyroid failure (Alamdari *et al.*, 2015). The TSH receptor (TSHR) is present in both white adipose tissue and brown adipose tissue (BAT) and is increased during brown adipocyte differentiation. Moreover, TSH increases basal and T3-stimulated uncoupling protein-1 (UCP1) and DIO2 expression as well as DIO2 activity and lipolysis (Martinez-deMena *et al.*, 2015).

TSH interacts with insulin on differentiated human adipocytes modulating their respective intracellular signaling. TSHR is upregulated by insulin and low-TSH, whereas it is downregulated by high TSH and T3. Given that TSH inhibits insulin-stimulated Akt phosphorylation in adipocytes, while insulin reduces the ability of TSH to activate PKC and stimulate lipolysis (Felske *et al.*, 2015), it is evident that TSH is involved in lipolysis and maintenance of thermogenesis. Moreover, TSH may stimulate cholesterol biosynthesis, this hypothesis recently being supported by the observation of a bidirectional relationship between TSH-β (TSHB) and total- and LDL-cholesterol (LDL-c) in adipose tissue (Moreno-Navarrete *et al.*, 2017). Of particular note, interventional reduction of cholesterol leads to decreased TSHB mRNA, while, conversely, excess cholesterol upregulates TSHB mRNA in human adipocytes. This underscores the significance of TSH as a paracrine factor and modulator in cholesterol metabolism. In this line of evidence, TSH was recently positively associated with hepatic PCSK9 expression (Gong *et al.*, 2017). In subclinical hypothyroid patients with higher serum TSH levels, significantly higher serum PCSK9 levels, along with increased LDL-c concentrations, were reported as compared with those of matched euthyroid persons. The above results point to a regulating role of TSH in hepatic PCSK9 expression, which further aggravates the state of dyslipidemia.

TSH Function and Secretion☆

Susan R Rose and Janet S Chuang, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States

Introduction

Thyrotropin (thyroid-stimulating hormone (TSH)), produced in the anterior pituitary gland, is released into the systemic circulation, and acts on the thyroid gland to produce secretion of thyroxine (T4) and triiodothyronine (T3). T4 and T3 are carried in the circulation in association with binding proteins. Their free hormones (free T4 (FT4) and free T3 (FT3)) enter peripheral cells and interact with genes in the cell nucleus. FT4 and FT3 regulate protein synthesis that affects metabolic processes of the body (e.g., growth, energy, intestinal motility, cardiac output and pulse rate, hair growth, body temperature). TSH synthesis is regulated by feedback of FT4 and FT3 on both pituitary TSH-producing cells and hypothalamic cells producing TSH-releasing hormone (TRH). This negative feedback system is the major regulator of hypothalamic-pituitary-thyroid (HPT) axis especially in conditions where primary thyroid dysfunction is present. However, it is becoming increasingly evident that control of the HPT axis is much more complex than previously thought. For example, changes in circadian rhythm, food intake, and environmental temperature result in predictable changes of thyroid hormone that seem to override classic negative feedback regulation (Costa-e-Sousa and Hollenberg, 2012). Much work is still needed to elucidate these relevant neuroendocrine pathways.

Genetics and Embryology of Pituitary Development

The anterior pituitary originates from an invagination of oral ectoderm by the 4th or 5th week of gestation (Rathke's pouch), which migrates to meet the posterior pituitary (an extension of neural ectoderm of the floor of the forebrain near the hypothalamus). The vascular connection between the hypothalamus and pituitary (portal circulation) begins to develop by 7 weeks of gestation and is established by 20 weeks (Kronenberg and Williams, 2008). Functional development of the anterior pituitary is determined by a cascade of transcription factors under complex temporal regulation, resulting in commitment of differentiated cell types including thyrotrophs or TSH secreting cells between 12 and 24 weeks gestation (Scully and Rosenfeld, 2002). Mutations affecting transcription factors involved early in pituitary development (HESX1, SOX2, SOX3, OTX2, LHX3, LHX4) may present as syndromic hypopituitarism with craniofacial abnormalities such as septo-optic dysplasia and holoprosencephaly (Parks *et al.*, 1999). Defects in transcription factors expressed later in pituitary development will manifest with varying combinations of pituitary hormone deficiencies. Defects in PROP1 and POU1F1 (PIT1) can all result in TSH deficiency (Mehta and Dattani, 2008).

Thyroid Function in the Fetus and Infant

Fetal Thyroid Physiology

The fetal HPT axis functions for the most part independently from that of the mother. The maternal delivery of TSH to the fetus via transplacental passage is negligible. In contrast there is transfer of maternal T4 and T3 to fetal blood, and this is essential for normal early fetal neurogenesis (Haddow *et al.*, 1999; Patel *et al.*, 2011). During the first 8–16 weeks of gestation, the human fetal thyroid synthesizes only minute amounts of T4 and T3. TRH has been found in fetal whole-brain extracts by 30 days and in the hypothalamus by 9 weeks of gestation. TSH can be detected in fetal blood by 10–12 weeks. As a result of maturation of the HPT axis, fetal hypothalamic expression of TRH and production of TSH and T4 progressively rise from mid gestation to peak during the month prior to term. TSH then remains higher than maternal levels possibly reflecting a higher set point for feedback (Kratzsch and Pulzer, 2008). T3 levels in fetal blood remain low until 26–30 weeks of gestation, a consequence of high levels of type III deiodinase activity (which converts T4 to inactive reverse T3) in peripheral fetal and placental tissues (Patel *et al.*, 2011).

☆*Change History*: November 2017. Susan R. Rose made updates to text from section "Depressed TSH" through "Thyroid Replacement and Adrenal Function" using track changes, as well as going over whole document. Added in text citations and removed outdated references. Updated reference list. Reviewed "Further Reading" to reduce to limit of 15. Janet S. Chuang made updates to body of text from section "Introduction" to "Depressed TSH" as per track changes, added in text citations and updated reference list.

This article is an update of Susan R Rose, TSH Function and Secretion, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 620–626.

 doi:10.1016/B978-0-12-801238-3.04110-6

Neonatal Thyroid Physiology

At delivery, the sudden cool temperature stimulates a dramatic rise in plasma TSH during the first hour of life. The levels of TSH rise to a peak of more than 50 mU L^{-1} at 30 min of age, stimulating a rise in serum total and free T4 (FT4) and T3 (FT3). In full-term infants with normal thyroid function, TSH levels are generally below 20 mU L^{-1} at 24 h of age and are 1.3–16.0 mU L^{-1} by 4 days of age. By 6 weeks of age, TSH concentrations approximate those of adults. In full-term infants, serum T4 and FT4 concentrations fall gradually during the subsequent 4–6 weeks, and serum T3 levels rise gradually after the neonatal period to achieve mature levels by 2–12 weeks of age. By 6 months of age, the levels of T4 and FT4 remain slightly higher than those of older children and adults, and the circadian pattern of TSH secretion begins to appear. These observations suggest that hypothalamic–pituitary regulation of TSH secretion matures gradually from 6 weeks to 6 months of postnatal age.

Thyroid Function After Premature Birth

In preterm infants, the neonatal rise of TSH and the rise in T4, FT4, and FT3 are blunted. By 4 days of age, TSH levels have declined to 0.8–6.9 mU L^{-1}. T4 and FT4 levels in preterm infants exceeding 30–32 weeks gestation increase progressively over the ensuing 4–8 weeks to values comparable to those of term infants. In contrast, levels of T4 and FT4 in very low-birthweight infants (less than 30 weeks or less than 1200–1500 g) decline progressively after day 1, reaching a nadir at 1–2 weeks of age. This drop appears to be the result of many factors, including nutritional problems, alterations in thyroid binding globulin, immaturity of HPT axis, immaturity of the thyroid gland itself, and increased tissue utilization of T4 (LaFranchi, 1999). This relative hypothyroxinemia is most profound in those infants born most prematurely.

TSH Structure and Glycosylation

TRH has been shown to be necessary for TSH synthesis, posttranslational glycosylation, and secretion of a fully bioactive TSH molecule from the pituitary. TSH is composed of an α-subunit (identical to that of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and human chorionic gonadotropin (hCG)) and a unique β-subunit. For TSH to act, both the α- and β-subunits interact with the G protein-coupled TSH receptor. Both subunits undergo posttranslational glycosylation in response to TRH. The glycosylation patterns influence the bioactivity of the TSH molecule (Persani, 1998). There are two oligosaccharide chains on the α-subunit and one on the β-subunit. Highly sialylated chains (as in recombinant TSH) have decreased bioactivity, decreased hepatic clearance, and longer half-life. Conditions with altered TSH glycosylation resulting in abnormal bioactivity are listed in the following table (Rose, 2000):

Conditions of decreased TSH bioactivity	Mixed hypothyroidism (central hypothyroidism with elevated TSH)
	Primary hypothyroidism
	Nonthyroidal illness
Conditions of increased TSH bioactivity	Resistance to thyroid hormone
	TSH-secreting pituitary adenomas

The TSH β-subunit gene was cloned in 1988, allowing research leading to production of recombinant TSH. Key domains of the β-subunit allowing ligand receptor interaction were identified, potentially permitting engineering of TSH molecules with increased bioactivity (Weintraub and Szkudlinski, 1999).

Regulation of TSH Synthesis and Release

TSH-Releasing Hormone (TRH)

Like GH, TSH is synthesized in anterior pituitary cells in response to a releasing hormone. TRH is secreted from the hypothalamus and transported to the pituitary via the venous portal system. Dopamine and somatostatin (both of which inhibit TSH release) are also transported from the hypothalamus (Rose, 2000). The TRH (G protein-coupled) receptor has been identified on pituitary cells and also in the central and peripheral nervous systems.

Circadian Variation in TSH Concentration

In persons of all ages after infancy (6 months), TSH secretion normally occurs in a circadian pattern with lower concentrations in the afternoon, a nocturnal surge beginning after 1900 h, and higher concentrations between 2200 and 0400 h. Peak TSH levels between 2200 and 0400 h are followed by a gradual decline between 0400 and 1000 h to nadir TSH values. Small frequent pulses occur as an overlay on this overall "sin wave"-shaped circadian pattern. Thus, at least one-third of the trophic influence of TSH on

the thyroid gland occurs during the hours of sleep. Central hypothyroidism (FT4 in the lowest third of the normal range) can be confirmed in children older than 1 year by the am to pm TSH ratio or the TSH surge test (Rose, 2010).

Despite the clear description of the daily pattern of TSH variation in the literature, the neuroendocrine influences that result in this circadian pattern have not yet been fully characterized. Factors regulating the timing and amplitude of the TSH surge may include an endogenous surge in hypothalamic TRH secretion at night, timing of onset of sleep, psychiatric disturbance, and/or altered pituitary sensitivity to endogenous TRH. Substances that appear to influence pituitary sensitivity to TRH include α-adrenergic stimuli, somatostatin, endogenous opiates, dopamine, cortisol, leptin, and GH concentrations.

TSH Function at the Receptor

TSH Receptor Binding

TSH is secreted from the pituitary into the blood, stimulating synthesis and release of T4 and T3 from the thyroid gland as well as influencing uptake of iodine. Both subunits of TSH interact with the G protein-coupled cell membrane receptor to generate the second messenger, cyclic AMP (cAMP), within the cell. The TSH receptor has an extracellular glycosylated portion and an intracellular portion with a cytoplasmic "tail" involved in G protein coupling and signal transduction. Both portions undergo posttranslational processing, influencing receptor-binding affinity of TSH. Mature complex glycosylation of the extracellular portion is required for TSH binding; if there are only mannose-type sugars, TSH binds with only low affinity (Persani *et al.*, 1998; Rose, 2000).

Results of TSH Receptor Binding

TSH receptor binding leads to increased synthesis of iodothyronines and to their storage in thyroid colloid in association with thyroglobulin. TSH receptor binding also leads to increased release of fully formed T4 and small amounts of T3 from the colloid. Plasma T4 and T3 circulate in the serum bound to thyroid-binding globulin and albumin, with only small amounts that are "free" or unbound. FT4 undergoes intracellular deiodination to FT3, which interacts with DNA to influence cellular mRNA and protein synthesis. Both T4 and T3 provide negative feedback at the hypothalamus and pituitary to modulate TRH and TSH secretion.

TSH Receptor Mutations

A TSH receptor mutation database has been established to allow easy access to the many identified TSH receptor mutations and their clinical consequences (Trulzsch *et al.*, 1999; Kronenberg and Williams, 2008; Paschke, 2013). Inactivating mutation can present as TSH resistance or in rare cases congenital hypothyroidism with eutopic thyroid. To date, over 50 loss-of-function mutations have been identified in humans. Nearly 100 gain-of-function mutations have been documented. Activating mutations of the TSH receptor in focal tissue may result in hyperfunctioning thyroid nodules/carcinoma or multinodular goiter. Expression of these mutations in all thyroid cells can result in thyrotoxicosis presenting during the neonatal period (and persisting beyond 6 months of age), late infancy, childhood, or adulthood (Trulzsch *et al.*, 1999; Kronenberg and Williams, 2008; Paschke, 2013).

Elevated TSH Secretion

Primary Hypothyroidism

Congenital hypothyroidism

Primary hypothyroidism (reduced function of the thyroid gland itself with low FT4 and high TSH) is the most common form of hypothyroidism both in the general population and in cancer survivors. There is now universal screening for congenital primary hypothyroidism in the United States. American newborn screening programs measure either TSH (with secondary T4 assay) or total T4 by radioimmunoassay (with secondary TSH) in blood spot samples obtained after 24 h of age. Hypothyroxinemia is defined as a total T4 value below 90% of the samples screened on that day. Measurement of TSH in hypothyroxinemic infants identifies those with primary hypothyroidism. TSH values often exceed 50–100 mU L^{-1} in infants with thyroid agenesis and other forms of permanent primary hypothyroidism. TSH levels exceeding 16–20 mU L^{-1} between 24 and 96 h of age, or 5.0–7.7 mU L^{-1} between 1 and 12 months of age, may reflect primary thyroid dysfunction (LaFranchi, 2011; American Academy *et al.*, 2006). Rarely, congenital primary hypothyroidism results from a genetic defect (Knobel and Medeiros-Neto, 2003; Nicholas *et al.*, 2016; Lof *et al.*, 2016).

Hypothyroidism in preterm infants

It should be recognized that very low-birthweight infants are at an eightfold increased risk for the development of transient primary hypothyroidism with low T4 levels and marked elevations in TSH (LaFranchi, 1999; Rapaport *et al.*, 2001). Transient primary hypothyroidism in preterm infants may, in some cases, be induced by transdermal absorption of iodine antiseptics. On the other hand, in iodine-deficient geographic regions, transient hypothyroidism is more likely related to insufficient iodine intake. Transient primary hypothyroidism may be accompanied by a delayed rise in TSH that is not detected until several weeks after birth (American Academy *et al.*, 2006). The prevalence of permanent congenital primary hypothyroidism in preterm infants is comparable to that in term infants. There is concern that permanent congenital primary hypothyroidism may be masked in premature infants due to drug administration that suppresses TSH, hypothalamic–pituitary immaturity, and other effects of neonatal illness. Many centers now rescreen at-risk infants as they approach discharge but it is unclear if the rescreening tests are just detecting a transient problem versus true permanent hypothyroidism (Leger *et al.*, 2014).

Acquired primary hypothyroidism

Primary hypothyroidism may be acquired after infancy and may represent a late presentation of thyroid dysgenesis or dyshormonogenesis. Most commonly, acquired primary hypothyroidism is due to thyroid autoimmunity associated with thyroid peroxidase antibodies (as in Hashimoto's thyroiditis). In acquired primary hypothyroidism, TSH may be as elevated as 1800 mU L^{-1}. The frequency of primary hypothyroidism is increased in chromosome abnormality syndromes such as Turner, Klinefelter, and Down syndromes. Most patients with mildly elevated TSH concentrations have been considered to have mild or "compensated" hypothyroidism. However, mild primary hypothyroidism has potential clinical importance, given that children with mild TSH elevation and T4 levels within normal limits typically grow less well than do other children. In addition to slow growth, mild hypothyroidism causes fatigue, dry skin, constipation, increased sleep requirement, and cold intolerance. Thyroid replacement therapy in mild hypothyroidism improves growth velocity, lipid profile, and energy level (Rose, 1995).

Primary hypothyroidism after cancer

Primary hypothyroidism (with TSH elevation) is most likely to occur in patients who have received mantle irradiation for Hodgkin's disease, craniospinal radiation for medulloblastoma, or total body irradiation prior to bone marrow transplantation. Primary hypothyroidism is rarely isolated in cancer survivors, who may also have GH deficiency, adrenocorticotropic hormone (ACTH) deficiency, and/or pubertal disorders (Sklar, 1997; Yeung *et al.*, 1998).

Thyroid Hormone Resistance and TSH-Secreting Adenoma

In thyroid hormone resistance and TSH-secreting adenoma, TSH is measurable (inappropriately) in the presence of elevated T4 and elevated FT4. In resistance, this biochemical picture is associated with few or no symptoms of hyperthyroidism. Patients may have goiter but may be euthyroid or even hypothyroid. In contrast, in TSH-secreting adenomas, patients are clinically hyperthyroid. Pituitary TSH-secreting adenomas are uncommon in general and are particularly rare in the pediatric age group.

Depressed TSH Secretion

Hyperthyroidism

Low serum TSH concentration is an appropriate response to excessive thyroid hormone levels resulting from either endogenous or exogenous source. Graves' hyperthyroidism is a result of antibodies to the TSH receptor, binding in a manner that activates the intracellular G protein signaling pathway as if TSH were binding at the receptor. A hypersecreting thyroid nodule (making thyroid hormone independent of TSH stimulation) will also suppress the TSH concentration. Hyperthyroidism in McCune–Albright syndrome is an example of a chronically activated G protein pathway.

Central Hypothyroidism

Reduced TSH surge

A blunted or absent nocturnal TSH surge is a characteristic of central hypothyroidism, suggesting a loss of the normal circadian variation in TRH (and thus a reduction in total TSH release) and loss of one-third to one-half of the daily trophic stimulus to the thyroid gland. In central hypothyroidism, FT4 is low or in the lowest third of the normal range, with a normal daytime TSH. Measurement of the nocturnal TSH surge has improved sensitivity for detection of central hypothyroidism compared with the TRH test. Central hypothyroidism (FT4 in the lowest third of the normal range) can be confirmed by the am to pm TSH ratio or the TSH surge test (Rose, 2010).

Low-normal T4 and FT4

Many patients with central hypothyroidism maintain normal daytime TSH concentrations and iodothyronine concentrations that are just below the normal range or in the lowest third of the normal range. These patients remain clinically puzzling and, therefore, are often not treated with thyroid replacement medication. Failure to recognize and treat central hypothyroidism can result in poor growth in children and in a less than optimal state of health in children and adults. Subtle hypothyroidism may be associated with depression and mild hyperlipidemia.

A cause of short stature

In children referred to endocrinology for evaluation of apparent idiopathic short stature, approximately 13% had isolated central hypothyroidism (a blunted TSH surge associated with low or low-normal FT4 in the absence of any other pituitary hormone disturbance). The incidence was 33% of children with height shorter than -2 SD who had an FT4 in the lowest third of the normal range. Growth velocity significantly improved in children during treatment with levothyroxine compared with that in children who had a normal TSH surge and who were otherwise clinically similar (Rose, 1995). Children with known hypopituitarism also show blunting of the nocturnal TSH surge. Familial central hypothyroidism has been recognized to be caused by an IGSF1 gene mutation or altered TSH beta subunits (Garcia *et al.*, 2017; Tenenbaum-Rakover *et al.*, 2016; Nicholas *et al.*, 2017).

Thyroid function after head injury

Disturbances in thyroid function are commonly observed in head-injured patients, including low T3 and low T4, usually with a normal level of TSH (Reifschneider *et al.*, 2015; Giuliano *et al.*, 2016). Reverse T3 is often elevated. Thyroid axis injury may still be quite difficult to identify in newly injured patients because of the prolonged half-life of T4 (7 days).

Central hypothyroidism after cancer

Central hypothyroidism is recognized in as many as 65% of patients after brain tumor or nasopharyngeal tumor, in more than 35% after bone marrow transplant, and in as many as 15% after leukemia, suggesting that central hypothyroidism (hypothalamic–pituitary–thyroid dysregulation) may be quite common in cancer survivors (Rose, 2001; Rose *et al.*, 2016). In contrast, primary hypothyroidism occurs most commonly after total body radiation or radiation to the nasopharynx, neck, or spine (Oudin *et al.*, 2016). Central and mixed hypothyroidism both occur in patients after radiation to the head and include brain tumors, nasopharyngeal tumors, and total body radiation (Rose, 2001). Chemotherapy alone can cause primary or central hypothyroidism, but the frequency of this occurrence is much less than that after radiotherapy.

Central hypothyroidism in adults

Central hypothyroidism can be quite difficult to recognize in adults where slowed growth rate is not available as a sign. Symptoms of hypothyroidism (e.g., asthenia, edema, drowsiness, adynamia, skin dryness) may be of gradual onset and be unrecognized until therapy is begun and the patient feels better (Razvi *et al.*, 2016).

Mixed Hypothyroidism

Mixed hypothyroidism consists of central hypothyroidism with TSH elevation. It has been described in survivors of childhood cancer and in women with Sheehan syndrome (postpartum pituitary necrosis). With reduced TRH from the hypothalamus, TSH may be abnormally glycosylated and of lower biological activity (Persani, 1998; Persani *et al.*, 1998). Thus, mild elevation of serum TSH concentrations (5–14 mU L^{-1}) may be seen in central hypothyroidism; the differentiation from primary hypothyroidism can be made by documentation of a blunted or absent TSH surge. In Sheehan syndrome patients, elevated 24-h TSH was observed with blunting of the TSH surge, suggesting dysregulated release of biologically inactive TSH.

Diagnosis of Hypothyroidism

Individual Set Point for TSH and FT4

FT4 is currently the best measure of thyroid status along with serum TSH. FT4 remains fairly stable in an individual over the years at an optimal "set point" for thyroid function (Andersen *et al.*, 2003). If FT4 production from an injured thyroid gland declines (as in mild primary hypothyroidism), the intact pituitary secretes more TSH. Thus, in primary hypothyroidism, a serum sample for TSH at 0800 h is the best test (Rose, 2010; Fitzgerald and Bean, 2016).

Monitoring

Yearly measurements of TSH and FT4 and growth surveillance are recommended in children at risk for hypothyroidism, such as in girls with Turner syndrome, children with Down syndrome, and childhood cancer survivors. Earlier diagnosis of mild hypothyroidism will allow earlier intervention to improve growth velocity and quality of life. In a healthy person with slow

growth or other symptoms of hypothyroidism, criteria for starting thyroid hormone therapy without further diagnostic testing include (1) TSH above 4 mU L^{-1} at 0800 or 0900 h or above 3 mU L^{-1} between 1000 and 2000 h (regardless of the FT4 value) and (2) FT4 at or below the lower limits of the normal range for the assay (regardless of the TSH value). If FT4 is in the upper two-thirds of the normal range and TSH does not meet the preceding criteria, no thyroid therapy is needed, and thyroid status and growth (in children) should be reviewed in 1 year in patients at risk. If FT4 is in the lowest one-third of the normal range without TSH elevation, the AM-PM TSH ratio should be measured (Rose, 2010). The combination of history of head injury or cranial or total body radiation, slow growth rate, normal weight gain, no intercurrent illness, delayed bone maturation, and declining FT4 or FT4 below the lower limits of normal or TSH above the upper limits of normal should be diagnostic of hypothyroidism.

Therapy for Hypothyroidism

Starting Thyroid Hormone Therapy

Thyroid hormone doses at initiation of therapy are much higher in infants (10–12 μg kg^{-1} BW day^{-1}) and toddlers (5–8 μg kg^{-1} BW day^{-1}) than in children (3 μg kg^{-1} BW day^{-1}) and adolescents or adults (1.25–1.50 μg kg^{-1} BW day^{-1}). These doses approximate 100 μg per meter squared per day.

Typical initial thyroid replacement dose in healthy young people with TSH of less than 30 mU L^{-1} and without risk of cardiac decompensation is 3 μg levothyroxine per kilogram body weight given daily in the morning (Khandelwal and Tandon, 2012). If TSH is more elevated or if there are concerns about medical stability, starting with one-quarter of this dose and increasing by a quarter dose each month can permit more gradual physiological and psychological adjustments to the new metabolic state. In general, because levothyroxine has a long half-life of about 6 days, it is useful to measure thyroid levels only after 4 weeks.

Thyroid Dose Adjustment

Thyroid dose should then be adjusted as follows: In primary hypothyroidism, TSH is the most useful test to monitor during therapy. The target should be a TSH of 0.5–1.5 mU L^{-1}, without symptoms of overreplacement. In central or mixed hypothyroidism, therapy with levothyroxine rapidly suppresses TSH before resolution of clinical symptoms, so TSH is not useful to measure. The recommendation is to monitor FT4 during therapy, adjusting the dose to achieve FT4 just above the middle of the normal range and without symptoms of hypo- or hyperthyroidism (Khandelwal and Tandon, 2012).

Thyroid Replacement and Adrenal Function

Because thyroid therapy can result in improved metabolic clearance of many substances such as cortisol, thyroid hormone replacement can result in clinical decompensation of patients with unrecognized adrenal insufficiency. In patients at risk, it is necessary to evaluate for primary adrenal insufficiency and/or hypothalamic ACTH deficiency and to provide such patients with hydrocortisone prior to initiating thyroid therapy.

TSH (Thyrotropin) Receptor☆

Yuji Nagayama, Nagasaki University, Nagasaki, Japan

Glossary

G protein-coupled receptor The largest superfamily of cell surface receptors that couple to heterotrimeric G (GTP-binding) proteins and mediate cellular responses to a diverse array of signaling molecules, including peptides, glycoprotein hormones, neurotransmitters, phospholipids, and odorants, as well as photons. A common structural feature is the presence of seven transmembrane-spanning segments connected by alternating intra- and extracellular loops, with the N terminus located on the extracellular side and the C terminus located on the intracellular side of the membrane.

Graves' disease An organ-specific autoimmune thyroid disease, characterized by the presence of stimulating antithyrotropin receptor autoantibodies in patients' sera that mimic the action of thyrotropin, thereby overstimulating the thyroid gland and causing goiter and hyperthyroidism.

Leucine-rich repeats (LLRs) A motif comprising 20 to 30 aa tandemly repeated sequences found in numerous proteins of diverse origins and with varied functions, forming amphipathic β-sheet structures and likely mediating specific protein–protein interactions. The consensus sequence proposed for the TSH receptor is xLxxTxxLTxLPxxAFxxLxxLxxL, where x is any amino acid. Ribonuclease A inhibitor was the first protein with LLRs to have its three-dimensional structure solved.

Introduction

TSH receptor (TSHR) is the primary molecule regulating both differentiated function and growth of thyroid follicular cells. On binding of TSH, TSHR transduces signals through G_s–cyclic AMP (cAMP) and G_q–phospholipase C cascades. The former regulates iodide uptake and expression of thyroid-specific proteins, such as thyroid peroxidase, thyroglobulin, and the sodium–iodide symporter, and the latter regulates iodide efflux and H_2O_2 production. TSHR involves three thyroid pathologies: autoimmune thyroid disease, oncogenesis, and congenital thyroid dysfunction. TSHR is one of the main autoantigens in autoimmune thyroid disease; autoantibodies against TSHR stimulate thyroid cells in Graves' disease patients [thyroid stimulating antibodies (TSAb)] or block TSH action in some patients with hypothyroidism (TSH-blocking antibodies (TBAb)). Ectopic expression of TSHR may play a role in the pathogenesis of extrathyroidal manifestations of Graves' disease (ophthalmopathy and pretibial myxoedema). Gain- and loss-of function mutations of the receptor cause hyperfunctioning adenoma/non-autoimmune congenital hyperthyroidism and congenital hypothyroidism, respectively.

Structure and Function of TSH Receptor

The TSHR protein consists of 764 amino acids (aa) (including a 21 aa signal peptide) and is structurally and functionally divided into two domains: the large N-terminal extracellular domain (ECD) (aa 1-~415), a unique feature of GPHR subfamily and the transmembrane domain (TMD), a characteristic of the GPCR superfamily. From its N-terminus, the TSHR ECD comprises a cysteine-rich sequence called cysteine-box 1 (C-b1) (aa ~24-~41), leucine-rich domain (LRD) containing eleven leucine rich repeats (LRR) (aa ~35-~280) and the hinge region containing the C-b2, C-b3 and C-peptide (aa ~281-~415). The TMD contains seven transmembrane helixes connected with extracellular and intracellular loops, and ends with the C-terminal tail (see Fig. 1A).

TSHR undergoes a variety of posttranslational modifications. The nascent TSHR (~95 kDa) first transforms to the precursor protein attached to mannose-type oligosaccharides on six N-linked glycosylation sites (NxS/T) (~100 kDa) in the endoplasmic reticulum and then to the mature protein with complex oligosaccharides (~120 kDa) in the Golgi apparatus, which is thereafter expressed on the cell surface. Thus, TSHR is heavily glycosylated and contains an ~25 kDa glycan, which corresponds to 40% of the molecular mass of the A-subunit (see below).

TSHR undergoes intramolecular cleavage into two subunits: the TSH-binding A-subunit and the transmembrane B-subunit. This cleavage apparently occurs at multiple sites in the hinge region of the mature receptor on or near the cell surface, presumably by a membrane-associated matrix metalloproteinase, resulting in the removal of a peptide corresponding to an approximately 50 aa insertion (aa 317–366, called C peptide). Although these two subunits are still linked by disulfide bridges at this point, their reductions by a cell surface enzyme, possibly protein disulfide isomerase, releases the A-subunit, a phenomenon called "receptor shedding" (see Fig. 1B and C). The B subunit remains embedded in the plasma membrane. Cleavage does not affect the receptor

☆*Change History:* July 2016. Y Nagayama updated Abstract, Text, Further Reading and Figure 1, and added Figure 2.
This article is an update of Yuji Nagayama, TSH Receptor (Thyrotropin Receptor), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 632–635.

 doi:10.1016/B978-0-12-801238-3.96039-2

function in terms of high TSH-binding and TSH-mediated signal transduction. However, it is generally thought that the free A-subunit is more immunogenic than the single-chain receptor or two-subunit receptor, and may be the main autoantigen in Graves' disease.

There are 11 cysteines in the ECD, clustering in three distinct regions; C-b-1, 2 and 3. There are two disulfide bridges in the C-b1 between C24 and C29, and C31 and C41, and three in the C-b2/3 between C283 and C398, C284 and C408, and C301 and C390 (Fig. 1).

Other posttranslational modifications include (1) sulfation of Y385, which is required for high-affinity binding for TSH, but not TSAb; (2) palmitoylation of C699 in the C-terminal cytoplasmic tail of the receptor, which positively controls the rate of intracellular trafficking of the receptor; and (3) the formation of oligomers, which rapidly dissociate into monomers upon TSH binding.

The crystal structures of TSHR aa 1–260 complexed with TSAb monoclonal (M22) or TBAb monoclonal (K1-70) were resolved, from which, together with that of FSH-FSHR ECD complex, the detailed structure of TSHR ECD bound to TSH, TSAb and TBAb were determined. As shown in Fig. 2, the amino acid residues on the receptor involved in binding for all the ligands widely distributes over the concave of the LRD, and, in case of TSH and TSAb, further extend to C-b1 and the hinge region. Thus, the ligand binding site(s) on the receptor are conformational and consists of multiple, discontinuous amino acid sequences. As mentioned above, Y385 binds to TSH, but not antibodies. Finally the binding sites for TSH, TSAb and TBAb are substantially overlapping.

TSH Receptor Gene

The TSHR gene consists of 10 exons and 9 introns and spans > 60 kb on human chromosome 14q. Exons 1–9 encode most of the ECD, with each exon corresponding to a LRR, and exon 10 encodes part of the ECD and the TMD. These findings indicate that the TSHR gene is derived from the integration of multiple genes, each encoding a LRR into a prototypic intronless G protein-coupled receptor gene. The full-length TSHR cDNA is approximately 4 kb long and contains a single open reading frame of 2292 bp.

Multiple TSHR mRNAs are detected in the thyroid tissue; there are major transcripts of ~4 kb and several other minor transcripts. The former correspond to the full-length receptors with distinct 3′-untranslated regions and the latter correspond to alternatively spliced, truncated receptors lacking the TMD.

The promoter region of the TSHR has characteristics typical of those of housekeeping genes with multiple transcription start sites. TSH induces a transient increase and subsequent down-regulation of TSHR expression under in vitro culture conditions, whereas TSHR mRNA levels are relatively stable in vivo. The minimal sequence required for thyroid-specific expression and negative regulation by TSH is located at −195 to −39 bp of the 5′-flanking region.

TSHR is also expressed in the extrathyroidal tissues such as fat tissues and retro-orbital fibroblasts, which may be relevant for extrathyroidal manifestations of Graves' disease.

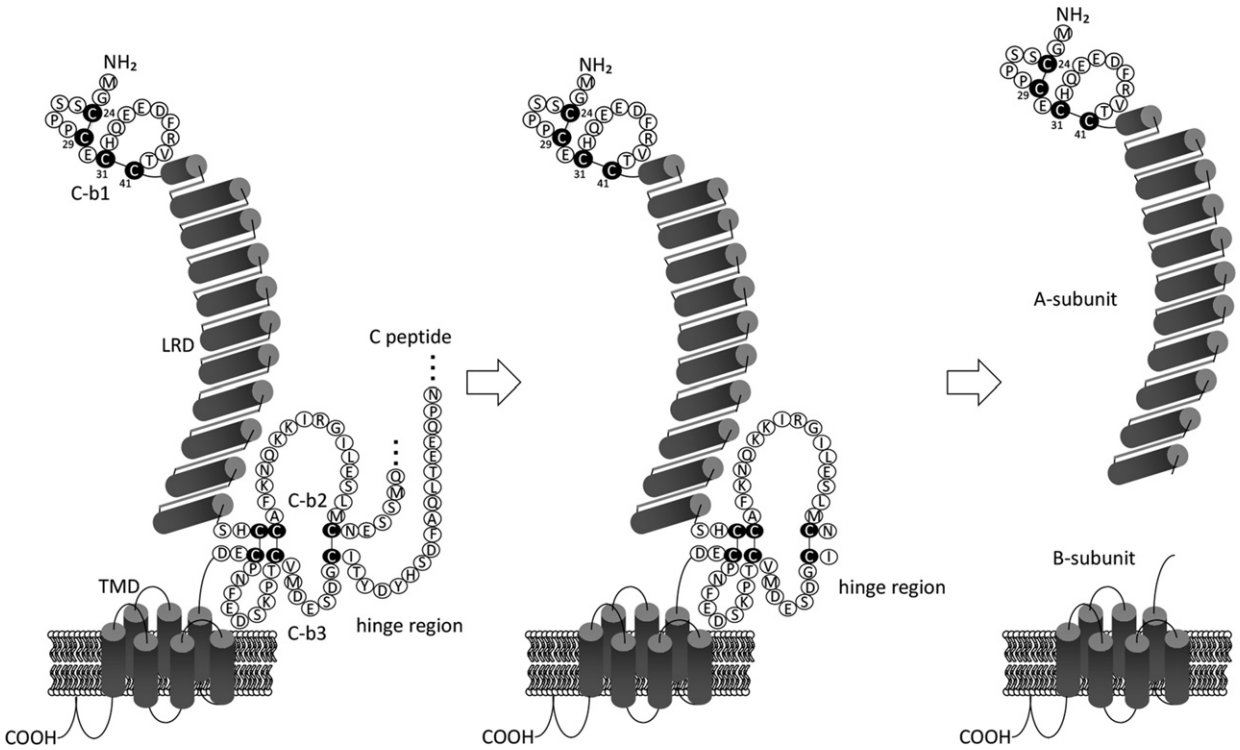

Fig. 1 Schematic representations of TSH holoreceptor (A), two-subunit receptor (B) and separated two-subunits (C).

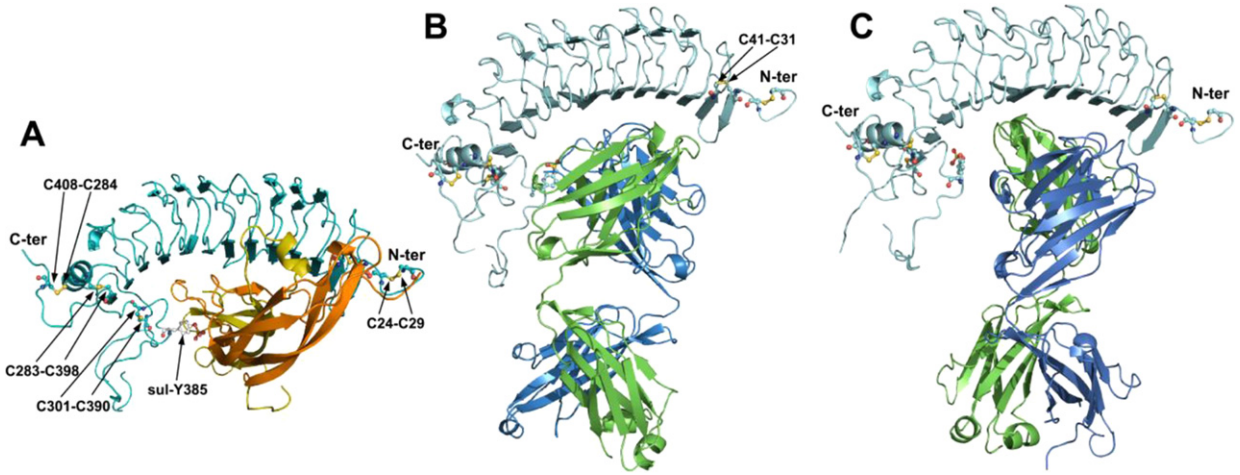

Figure 2 Comparative models of (A) the TSH-TSHR ECD complex (conformational arrangements show a final stage in the proposed activation mechanism when sulphated Tyr 385 is bound to the hormone; see Figure 10D), (B) the M22-TSHR ECD complex and (C) the K1-70-TSHR ECD complex. The TSHR ECD is shown in cyan, the hormone α subunit is shown in olive and β subunit in orange. Antibody light chains are shown in green and heavy chains in blue. The N- and C-termini of the TSHR ECD, disulphide bonded cysteines and the TSHR sulphated Tyr385 are marked. Reproduced, with permission of the copyright holder RSR Ltd, from Figure 9 of Furmaniak *et al.* (Horm Metab Res.47,735-752,2015).

Autoimmunity

As mentioned above, the TSHR autoantibodies act as agonists in patients with Graves' disease (TSAb) or as antagonists in some patients with autoimmune hypothyroidism (TBAb). To detect these antibodies, two assays have become available. One is a bioassay for TSAb that measures agonist-mediated cAMP production using thyroid cells of various species or mammalian cells stably expressing recombinant TSHR. The other is competition of antibodies for ^{125}I-, chemiluminescence- or biotin-labeled TSH (or M22) binding to TSHR [TSH-binding inhibiting antibody (TBIAb)]. Although the TBIAb assay has long used porcine thyroid membrane as an antigen, a highly sensitive TBIAb assay with recombinant human TSHR has become commercially available. However, this assay cannot discriminate between stimulating and blocking antibodies.

TSHR autoantibodies can be experimentally elicited by traditional immunization approaches using the soluble TSHR protein with classical adjuvants, which, however, are usually without noticeable TSAb activities. In contrast, immunization of mice with syngeneic cells co-expressing TSHR and major histocompatibility complex class II antigen or genetic immunization with plasmid- or adenovirus-encoded human TSHR can effectively induce TSAb and Graves'-like hyperthyroidism. Since Graves' disease is an antibody-mediated disease, it has long been believed that the T helper 2 cell (Th2)-based immune response is predominant in Graves' disease. However, studies with these animal models challenge this concept, suggesting that the Th1 immune response may be more critical than previously anticipated or that the Th1/Th2 paradigm may be too simplistic to explain the pathogenesis of Graves' disease. Th17, a newly identified immune response, unlikely participates in the pathogenesis in animal models.

Development of Graves' disease is controlled by both genetic and environmental factors. The TSHR gene is one of the candidates for polygenic, inherited predisposing gene of Graves' disease. The TSHR gene polymorphisms conferring susceptibility are located in the intron 1, regulating relative expression levels of alternatively spliced form of the receptor (similar to the A-subunit) in the thyroid and of the holoreceptor in the thymus.

Naturally Occurring Mutations

Numerous mutations in the TSHR gene causing loss- or gain-of-function have been identified. Constitutively activating mutations were found in hyperfunctioning thyroid adenomas and autosomal-dominant congenital non-autoimmune hyperthyroidism. Most of the mutations are point mutations, resulting in a single amino acid substitution, and are localized in the TMD. TSHR is "noisy," that is, it displays significant constitutive activity even in the absence of agonist. Unliganded ECD likely constrains the receptor activity. In contrast, loss-of-function mutations in congenital hypothyroidism associated with resistance to TSH can be found in any region of the receptor. Furthermore, a unique mutation (K183R), which increases the sensitivity to human CG and causes a type of familial gestational hyperthyroidism, has also been identified.

T3	3,3′,5-Triiodo-L-Thyronine
rT3	3,3′, 5′-Triiodo-L-Thyronine (reverse T3)
3,5-T2	3,5-Diiodo-L-Thyronine
3-T1AM	3-Iodo-thyronamine
TR	T3 Receptor
TRH	Thyrotropin releasing hormone
Triac	3,3′,5-Triiodothyro-acetic acid
TRPM8	Transient receptor potential cation channel subfamily M member 8
TSH	Thyrotropin, thyroid stimulating hormone
TTR	Transthyretin

Glossary

Conjugation The 4′-OH group of THM that carry iodine substituents at the phenolic ring is rather acidic and is conjugated by sulfotransferases or glucuronyltransferases. These reactions generate THM with higher solubility than those of the native highly hydrophobic iodothyronines. Conjugated THM enter the bile excretion pathway and may undergo enterohepatic circulation. Sulfation of THM occurs in the fetus and may contribute to the generation of a more soluble reservoir form of thyroid hormones. Sulfatases cleave the 4′-*O*-sulfate ester of THM and liberate the free thyroid hormone.

Deiodination The iodinated thyroid hormones thyroxine (T_4) and 3,3′,5-triiodothyronine (T_3) and their THM undergo several steps of enzymatic reductive deiodination either at the 5′ (phenolic ring or outer ring) or 5 position (tyrosyl ring or inner ring), leading to the release of iodide and the formation of hormonally active T_3 from T_4 or inactive metabolites such as reverse T_3 (3,3′,5′-triiodothyronine), 3,3′-T_2, or monoiodinated metabolites. Also, 4′-O-sulfated THM including thyronamines can be deiodinated. The action of deiodinases as "gatekeepers" to nuclear action of the active thyroid hormone T_3 is essential for the proper coordinated development of vertebrate organisms.

Euthyroid sick syndrome or low T_3 syndrome A clinically relevant constellation in the course of a critical illness, with rapid decrease in serum concentrations of T_3, increased serum reverse T_3, and unaltered or decreased production rate of T_4 while thyrotropin (TSH) remains normal or even decreases. Persistence of this syndrome and decreased T_4 concentrations are associated with an increased mortality. In critically ill patients, mean nocturnal TSH secretion and the number of TSH surges are markedly reduced. This syndrome develops by a combination of interference of proinflammatory cytokines in the negative feedback regulation at several levels, disturbance of hypothalamic stimulation of the thyroid and growth hormone axes, and poor tissue perfusion resulting in decreased expression of 5′-deiodinases (DIO1, DIO2) and increased expression of 5-deiodinase (DIO3) activity.

Iodothyronines Iodinated derivatives of the thyroid hormones T_4 and T_3 that are formed by sequential deiodination of T_4 and T_3 or that are sulfated or glucuronidated metabolites. Apart from T_3, the other iodothyronines, including T_4, do not bind to the nuclear T_3 receptor in vivo and therefore are not thyromimetically active. 3,5-T2 also exerts thyromimetic activity probably via mitochondrial mechanism of action and at high concentrations via T_3 receptors.

Thyroid hormone The thyroid produces and secretes T_4 and T_3, which are iodinated derivatives of the amino acid tyrosine. T_4 is considered as prohormone that acts primarily after 5′-deiodination to T_3, the active thyroid hormone. Some rapid T_4 effects may be exerted via binding and activation of $\alpha v\beta 3$ integrin receptors at the plasma membrane. Thyroid hormones regulate the development, differentiation, growth, energy, and structural metabolism of higher vertebrates, including humans. Thyroid hormones act in a permissive way in close cooperation with other hormonal, neuronal, and nutritive signals. Deficiency of iodine or thyroid hormones during pregnancy leads to severe impairment of the development of the central nervous

☆*Change History*: February 2018. Josef Köhrle has updated the chapter. New information especially on recent developments of pre-receptor control of T3 ligand availability for T3 receptors, which is controlled by thyroid hormone transmembrane transporters and deiodinase isoenzymes, was added and recent findings on the role of thyroid hormone metabolites such as thyronamines and thyroacetic acids and their receptors and mechanism of action was included.

This article is an update of Josef Köhrle, Thyroid Hormone Metabolism, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 480–489.

 doi:10.1016/B978-0-12-801238-3.99455-8

system (cretinism) and impairment of many metabolic functions in the adult organism.

Thyroid hormone metabolites This term comprises the classical thyroid hormones T_4 and T_3, their deiodinated metabolites and their recently re-discovered decarboxylated metabolites, the thyronamines 3-iodo-thyronamine and the iodine-free thyronamine as well as the oxidized metabolites of the latter two compounds, i.e., 3-iodo-thyroacetic acid and thyroacetic acid, all of which show various pharmacological actions distinct from those of the classical thyroid hormones T_3 and T_4.

Introduction

The roles of the essential trace element iodine and of the thyroid gland for development and normal function of vertebrate organisms, especially in humans, have been known for a long time (Hoefig *et al.*, 2016), but it was not until 1915 that the iodine containing prohormone thyroxine (T_4) was isolated by Edward C. Kendall. Charles R. Harington and George Barger performed the correct structure analysis and chemical synthesis of T_4 in 1927. In 1952 Jack Gross and Rosalind Pitt-Rivers concomitantly with the French team Jean Roche, Serge Lissitzky, and Raymond Michel identified the bioactive TH 3,3′,5-triiodothyronine (T_3), the "real TH" (**Fig. 1**). Various enzymes metabolizing the amino acid-derived TH have been characterized during the past 65 years. These enzymes generate a complex pattern and network of T_4-derived iodinated metabolites (THM), some of which have specific biological functions that differ from those of the bioactive TH T_3. T_3 exerts its influence mainly by modulation of action of the ligand-dependent transcription factors, the nuclear T_3 receptor forms (TRα and TRβ) (Tata, 1999). In addition to this key mechanism of action, several other biological effects of T_4, T_3 and THM derived therefrom have been reported. However, these effects are less well characterized (e.g., activation of plasma membrane associated integrin receptor $\alpha v\beta 3$, several intracellular kinase cascades [e.g., Pi3K] modulation of the organization of the cytoskeleton, or direct influence of THM on mitochondrial function). Some of these rapid effects also involve ligand binding to TR, but do not require DNA binding and transcription modulation of the TR-THM complexes. Iodothyronines comprise iodinated metabolites of the prohormone T_4 that have an intact diphenylether structure which is generated by coupling of two iodinated tyrosines residues of thyroglobulin during biosynthesis of TH in the thyroid gland. The sole source of T_4 in humans and higher animals are the angiofollicular units of the thyroid gland, whereas the other THM are formed intracellularly in various organs and tissues (Bianco *et al.*, 2002; Köhrle, 2000). T_4 is a highly hydrophobic, lipid-soluble compound that circulates in the blood bound to three main distribution proteins: thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin. T_4 and THM are excreted mainly via the bile and the feces. Iodide liberated

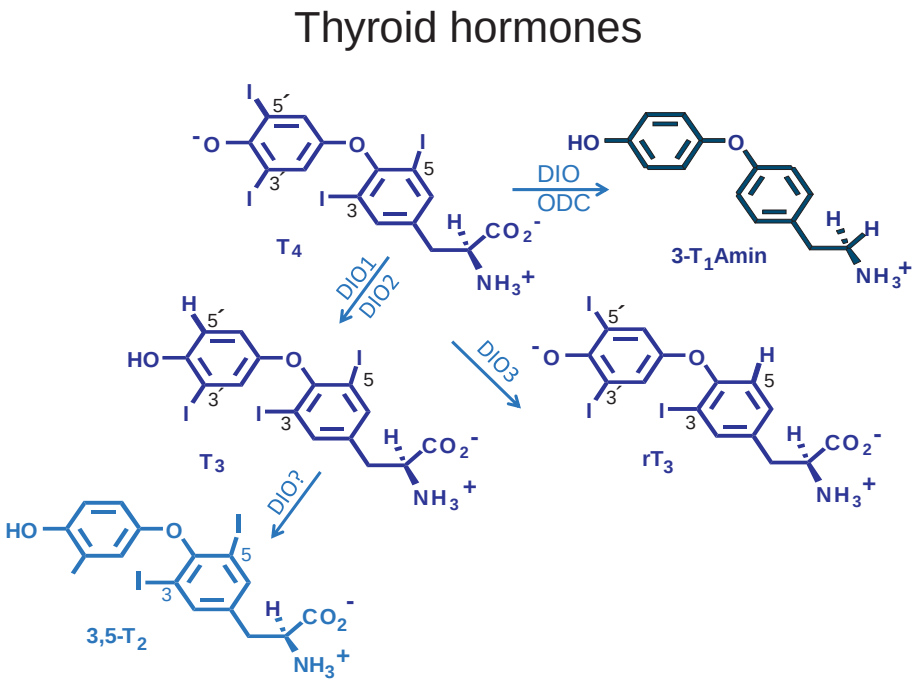

Fig. 1 Enzymatic deiodination of the prohormone T_4 to the thyromimetically active T_3 by the selenoenzymes type 1 or type 2 5′-deiodinase and inactivation of T_4 to rT_3 by type 3 5-deiodinase (DIO). 3,5-T_2 is a further thyromimetic TH metabolite, probably generated by DIO activity. 3-T_1AM represents a novel TH metabolite mainly antagonistic to T3 action. 5′-D, 5′-deiodination (phenolic or outer-ring deiodination); 5-D, 5-deiodination (tyrosyl- or inner-ring deiodination). Numbers indicate substituent positions (*n′*) at the phenolic (outer) ring or (*n*) at the tyrosyl (inner) ring.

from the THM by enzymatic deiodination, together with a fraction of nutritional iodide uptake, is excreted into the urine. Urinary iodide concentrations provide a valuable indicator of the iodine supply of the organism.

T_4 and THM are derivatives of the amino acid tyrosine and carry several ionic charges in solution. Therefore, efflux of T_4 and T_3 from the thyrocytes and uptake of THM into target cells require transport processes across cellular membranes such as facilitated, active or passive carrier-mediated transport, which is catalyzed by several specific proteins such as members of the monocarboxylate transporter (MCT8. MCT10), organic anion transporter (OATP1c1) or L-type amino acid transporter (LAT1, LAT2) families, which are not yet fully characterized with respect to their relevance and functional characteristics (Hennemannn *et al.*, 2001; Wirth *et al.*, 2014). Mutations of the *MCT8* gene cause a severe X-linked neuromuscular developmental disorder, the Allan–Herndon–Dudley syndrome (Groeneweg *et al.*, 2017). Tissue- and development-specific expression of these TH transmembrane transporters contributes to the bioavailability of THM in cells and organs and provides a first level of control for metabolism of THM by intracellular enzymes that depend on substrate availability (Köhrle, 2007). No enzymes metabolizing THM in the blood or in the interstitial space have been identified. The free THM concentrations in serum and interstitial space are very low in the picomolar range due to the binding of T_4 and T_3 by the high-affinity distribution proteins TBG, TTR, and albumin. With exception of 3-T1AM that has high affinity to apolipoprotein B100, the other THM exhibit lower affinity for these binding proteins than T_4 and T_3 and thus might be more available to metabolic transformations.

Enzymatic Deiodination of Thyroid Hormone Metabolites

Sequential Reductive Monodeiodination Both Activates and Inactivates Thyroid Hormone Metabolites

Reductive deiodination of the prohormone T_4 generates iodothyronine metabolites with different biological function (**Fig. 1**) (Dentice *et al.*, 2013). Deiodination at the 5′-position of the phenolic (outer) ring of T_4 produces the thyromimetically active hormone T_3. Deiodination at the 5-position of the tyrosyl ring (inner ring) generates reverse-T_3 (rT_3), a metabolite devoid of thyromimetic action at the nuclear T_3 receptors but with the potential to act as a competitor to T_4 in the 5′-deiodination reaction. rT_3 circulates in the serum of normal persons in concentrations similar to those of T_3. DIO enzymes are expressed in a development-, tissue-, and cell-specific manner and are regulated by different factors (Köhrle, 2002). All three DIO enzymes belong to the class of selenocysteine-containing proteins and are encoded by three different genes. With few exceptions, selenium availability is not a limiting factor in humans for the expression of the three DIO selenoenzymes, which rank very high in tissue-specific selenium supply among the selenoproteins. However, in vitro and animal studies indicate selenium-dependent regulation of the three DIO enzymes. Only during severe selenium deficiency, under protein-free diets due to metabolic diseases (phenylketonuria), long-term total parenteral nutrition, or malabsorption syndromes selenium deficiency may impair expression of deiodinase enzymes and T_3 formation in children and adults. All three DIO isoenzymes are obligatory intracellular integral membrane proteins with their active sites oriented toward the cytosol. Evidence has been presented that inactivation of the DIO enzymes, especially DIO2, occurs by the ubiquitin-associated proteasome protein degradation system (Bianco *et al.*, 2002). Reductive deiodination of THM by DIO isoenzymes requires reduced cellular cosubstrates such as thioredoxins or glutathione, while reduced dithiols (DTT or DTE) are used as cosubstrates for in vitro activity measurements (Köhrle, 2002).

Two 5′-Deiodinases Are Involved in Activating Thyroid Hormone Metabolism

5′-Deiodination at the phenolic ring is catalyzed by two enzymes, the type 1 and the type 2 5′-deiodinase (DIO1 and DIO2, respectively), which differ in various aspects as indicated in **Table 1** (Köhrle, 2000; Bianco *et al.*, 2002). DIO1 is less selective in substrate specificity than DIO2, which preferentially deiodinates T_4 with a low-nanomolar Michaelis–Menten constant (K_m) for this substrate. DIO2 produces T_3 mainly for the local supply in tissues expressing this enzyme, which renders these tissues independent from circulating T_3. DIO2 does not contribute significantly to circulating plasma T_3, which is mainly provided by DIO1 action on T_4 in liver, kidney, and thyroid tissues expressing high DIO1 activity in normal healthy subjects. The extent to which thyroid DIO1 activity contributes to T_3 secreted by the thyroid gland, which also produces T_3 apart from T_4 during TH synthesis especially under conditions of iodine deficiency and in Graves' autoimmune thyroid disease, is unclear. In the latter constellation, DIO2 activity also adds to thyroid T_3 production from T_4 because DIO2 expression in Graves' disease is stimulated by TSH receptor-stimulating autoantibodies, similar to TSH stimulation of DIO2 in autonomous adenoma. Thyroid stimulation by TSH or TSH receptor-stimulating autoantibodies also enhances the ratio of T3 versus T4 formation in thyroglobulin. DIO1 also contributes to the inactivation of T_4 by deiodination at the tyrosyl ring, generating rT_3 and degrading T_3 to 3,3′-T_2. Especially, sulfated iodothyronines are good substrates of DIO1 (Visser *et al.*, 1998).

Type 3 5-Deiodinase Inactivates Thyroid Hormones

The third deiodinase, 5-deiodinase (DIO3), removes iodine from the 5 position of the tyrosyl ring (inner-ring deiodination) (**Fig. 1**). DIO3 is responsible for the majority of rT_3 formation and T_3 degradation and is considered the main TH-inactivating enzyme (Dentice *et al.*, 2013; Bianco *et al.*, 2002). Expression of DIO3 occurs in several tissues and cells that do not respond to TH action, especially in fetal tissues, undifferentiated progenitor and tumor cells. Thus, DIO3 can be considered as one of the

Table 1 Properties of the Deiodinase Enzymes

	Type 1 5′-deiodinase DIO1	*Type 2 5′-deiodinase DIO2*	*Type 3 5-deiodinase DIO3*
Function and substrate preference	Systemic > local T_3 production; degradation of rT_3 and sulfated T4, T3 and other THM; rT3 > T4S > T3S > T4, T3	Local > systemic T_3 production; T4 > T3	Inactivation of T_4 and T_3; T3 > T4
Expression	Liver, kidney, thyroid, pituitary; at low levels in heart and many other tissues; loss of expression in tumors; higher expression in hyperthyroidism	Pituitary, brain, brown adipose tissue, skin, placenta; thymus, pineal; glial cells, tanycytes; higher expression in hypothyroidism; overexpression in mesothelioma cell line	Placenta, uterus, brain, fetal tissues; many other tissues, except normal adult pituitary and adult healthy liver, thyroid, kidney; re-expression in pathological organs (liver, pituitary); overexpression in hemangioma, activated macrophages, neutrophils and several solid tumors
Subcellular location	Endoplasmatic reticulum in liver; inner plasma membrane in kidney and thyroid	Inner plasma membrane; p29 subunit associated with F-actin respectively perinuclear vesicles	Endoplasmatic reticulum
Human gene location	1p32–p33	14q24.3	14q32
Enzyme stimulation or induction	T_3, retinoids; TSH and cAMP in thyroid only; testosterone in liver; selenium; carbohydrate	cAMP; FGF; β-adrenergic agonists; nicotine; phorbolesters via PKC; ANP and CNP via cGMP in glial cells	T_3, FGF, EGF; selenium
Inhibition	PTU, iodoacetate, aurothioglucose, genistein, F21388, iopanoate, xanthohumol, dexamethasone	T_4, rT_3; iopanoate, xanthohumol, F21388	Iopanoate, xanthohumol

Abbreviations used: ANP, atrial natriuretic peptide; CNP, C-type natriuretic peptide; DTE, dithioerythreitol; DTT, dithiothreitol; EGF, epidermal growth factor; F21388, 5′-deiodinase inhibitor; FGF, fibroblast growth factor; PKC, protein kinase C; PTU, 6-*n*-Propyl-2-thiouracil; THM, thyroid hormone metabolites.

components of a relay of "gatekeepers" of TH action that prevent cellular T_3 action from occurring at an inappropriate time, location, or concentration (Köhrle, 2000). Because DIO3 can act on both T_4 (forming rT_3) and T_3 (forming 3,3′-T_2), it can perform the gatekeeping function in cell types that are exposed to T_4 and/or T_3 and thus might act independently of the expression pattern of cell type-specific TH transporters, restricting the uptake of these TH. On the other hand, the development-, tissue-, and cell-specific expression pattern of the two 5′-deiodinase enzymes provides a system of systemic or local production of the thyromimetically active nuclear receptor ligand T_3. Expression of the DIO isoenzymes in hypothalamic TRH neurons and the thyrotrope cells of the anterior pituitary controls the local production and concentrations of T_3, which suppresses gene expression and secretion of TRH and TSH, respectively (Gereben *et al.*, 2015). Therefore, DIO isoenzymes play a key role in negative feedback regulation of TRH and TSH by circulating TH concentrations. Recently, a delicate antidromic balance of coordinated expression of DIO2 and DIO3 isozymes has been reported during commitment, differentiation and proliferation of various progenitor cells and tumor stem cells (Dentice *et al.*, 2013). While proliferation seems to require high levels of DIO3 activity resulting in low local T3 concentration, cellular differentiation is characterized by high DIO2 activity and enhanced local T3 production delivering the thyromimetic ligand T3 for binding to T3 receptors, which may function as tumor suppressor genes.

Intracellular Targeting and Compartmentalization of Active and Inactive Iodothyronines

Because all three DIO isoenzymes are located inside the cell with active sites exposed toward the cytosol (**Fig. 2**), their action also depends on the availability of the main substrate T_4, which reaches the cytosol via cell-type-specific T_4 carriers such as MCT8. T_3 entering the cells via the same or distinct TH transmembrane transporters may therefore bypass the control exerted by the intracellular DIO network and gain direct access to the intracellular T_3 receptors. T_3 formed by the high activity of 5′-DI in liver, kidney, or thyroid might not be targeted to the nuclear T_3 receptor of the same cells but rather channeled toward efflux and export

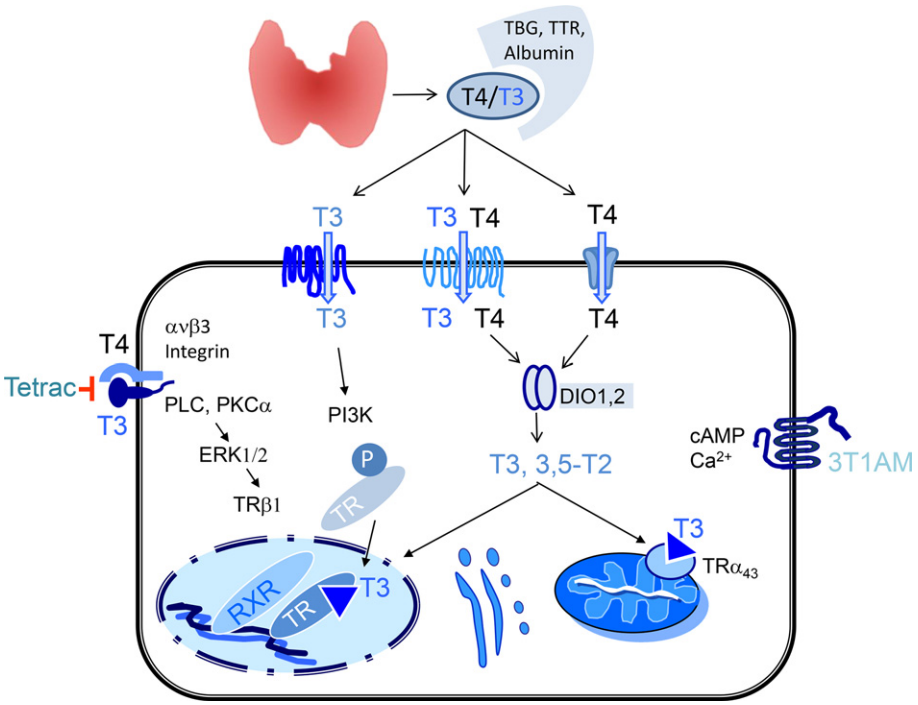

Fig. 2 Schematic representation of TH synthesis by the thyroid; transport and distribution by the serum-binding proteins, thyroxine-binding protein (TBG) and transthyretin (TTR); cellular uptake by thyroid hormone transporters such as MCT8, OATP1, LAT2; intracellular activation of the prohormone T_4 to the thyromimetically active hormone $T_3$by Dio; binding of T_3 to nuclear, cytosolic or mitochondrial T_3 receptors; and modulation of transcription of T_3-regulated genes. T_4 and T_3 activate and Tetrac inhibits the integrin receptor $\alpha v\beta 3$; TH also activate cytosolic kinase cascades; $3T_1AM$ activates plasma membrane signaling via TAAR, ADRA2 or TRPM8; RXR, retinoic acid receptor; TR, T_3 receptor.

into circulation via TH transmembrane transporters and thus reach (other) target cells only after its transient circulation in the blood pool of TH.

Iodothyronine Deiodinases Participate in the Control of Cell-Type-Specific Production and Action of Thyroid Hormone

It has long been known that TH action, mainly exerted by the thyromimetically active T_3, and to some extent also by 3,5-T_2, depends on the cellular expression pattern of T_3 receptors, which mediate TH action on gene expression (Tata, 1999). The cloning of several isoforms of (nuclear) TH receptors, encoded by two different genes (TR-α and TR-β), which occur in different splice forms that bind either both ligand and DNA (TR-α_1, TR-β_1, TR-β_2, and several variants) or only hormone-responsive elements of DNA (TR-α_2), added to the complexity of the regulation of TH action. This complexity has become even more complicated by the demonstration that in many instances the cellular location of the T_3 receptor differs from that of T_3 formation by the DIO1 or DIO2 enzymes. Two examples are the distinct location of Dio2-forming T_3 and the T_3 receptor-mediating T_3 action in the development of the inner ear hair cells and cochlea or the retina development of the eye. Whereas T_3 receptors are located in the sensory epithelium of the inner ear, the Dio2 enzyme producing the active ligand T_3 is located in the surrounding connective tissue cells in a development-dependent manner. This implies that T_3 produced from T_4 must be released from the connective tissue stromal cells and taken up by the sensory epithelial cells. Therefore, defects in both the time-dependent and the spatial organization of this network of ligand availability might lead to disturbed hearing function, known to be affected by fetal or congenital hypothyroidism. During retina development of the eye, a close correlation between the expression of T_3 receptors, Dio2 and Dio3 is reported. Local overexpression of Dio3, removing the active ligand T_3, disturbs the development of the eye. Coordinated temporal compartmentalization of the T_3 receptors, the ligand-activating Dio2, and the ligand-inactivating Dio2 also occurs at the implantation site of the embryo in the uteroplacental unit and the fetal epithelium. Again, the expression patterns of the three Dio isoenzymes appear strictly associated with different cell types in a time- and space-dependent manner, thus allowing for strictly controlled ligand availability to the developing fetus. In the latter case, especially the temporal expression pattern of the T_3- and T_4-inactivating enzyme Dio3, is essential for the control of TH transfer from the maternal to the fetal compartment because it is well-known that excessive exposure of the fetal tissues and the fetal brain to TH leads to irreversible brain damage such as occurs in uncontrolled maternal hyperthyroidism during pregnancy. Comparable antidromic developmental and cell-type specific patterns of expression of TH transmembrane transporters (e.g., MCT8, MCT10 and OATP1c1), DIO isozymes and TR forms have been

reported and studied during fetal and neonatal brain development (Wirth *et al.*, 2014). Recent evidence—especially established during molecular analysis of defects underlying the Allan–Herndon–Dudley syndrome caused by MCT8 mutations—indicates that prereceptor control of local availability of the thyromimetically active ligand T3, which is binding and modulating TR function, is a key mechanism for adequate brain development. While endothelial cells express TH transmembrane transporters and deliver TH to brain cells, astrocytes and tanycytes are the main cell types expressing Dio2, generating the active ligand T3 for neurons, which are devoid of Dio2 but express TR and Dio3 inactivating this hormonal signal. Further detailed analysis is required to map the temporal and spatial expression patterns of TH transmembrane transporters on brain cells during development and in the adult differentiated brain.

Amphibian Metamorphosis Is a Paradigm of Spatial and Temporal Control of Thyroid Hormone Expression

Similar patterns of spatial and temporal control of the concentration of active ligand T_3 have been demonstrated for the developmental program of expression of T_3 receptors, DIO enzymes and TH transmembrane transporters during amphibian metamorphosis that is under fundamental control by TH (Tata, 1999). Although the thyroid gland provides the prohormone T_4 and a small amount of circulating T_3 (which might be needed to prime the metamorphic events), the local production and removal of the active ligand T_3 are under the control of the TH transmembrane transporter and DIO network, which is expressed in a cell-type-specific manner. Disruption of these organized networks of control of ligand availability for T_3 receptors might occur during various diseases, affecting either the cellular organization of tissues and or the expression of the three DIO enzymes.

Aberrant and Inappropriate Expression of Deiodinases

The concept of the pre-receptor control of availability of the thyromimetically active ligand T_3 by appropriate expression of TH transmembrane transporters and DIO isoenzymes (Köhrle, 2000; Köhrle, 2007) has gained support by the identification of several pathological constellations in which aberrant or inappropriate expression of DIO isoenzymes has been observed. The first example is the overexpression of DIO3 in some infantile hemangiomas leading to extremely severe hypothyroidism that in some cases cannot be treated with excessive doses of administered T_4—a syndrome called "consumptive hypothyroidism." The opposite constellation is found for some mesothelioma tumors, in which overexpression of DIO2 leads to elevated T_3 production. For DIO1, less clear-cut alterations of expression have been described in humans. Remarkably low DIO1 expression has been reported for several solid tumors, in part associated with altered expression of TR forms or even TR mutants, while DIO1 re-expression in these tumor cells prevents their proliferation and migration in vitro.

However, several animal experimental models with altered expression or regulation of Dio1 activity have been described. Decreased (hepatic) expression of Dio1 leads to constellations characterized by normal to elevated serum T_4, decreased or normal serum T_3, and elevated rT_3. The latter parameter might be the leading sign of decreased expression of Dio1 because rT_3 is almost exclusively degraded by this Dio enzyme, whereas its production occurs via Dio3 and, to a minor extent, Dio1. Therefore, the ratio of serum T_3/rT_3 might be the most sensitive parameter of altered Dio1 activity. Recent studies in various animal models, mimicking the nonthyroidal illness, low T3 syndrome, also revealed evidence for de novo expression of Dio3 under such conditions in activated monocytes and neutrophils or parenchymal tissues such as liver (van der Spek *et al.*, 2017). Thus, both elevated Dio3 and/or impaired Dio1 activity might contribute to decreased T_3 and elevated rT_3 concentrations in blood.

Several polymorphisms have been reported in the *DIO* genes gene in association with altered plasma TH concentrations and THM ratios. In combination with a further polymorphism of the TSH receptor gene, clear-cut alterations of the setpoint of the pituitary feedback control of TH secretion and homeostasis are apparent (Peeters *et al.*, 2003a). A polymorphism in the *DIO2* gene leading to an amino acid exchange in the enzyme has been found to be associated with obesity in diabetic patients and linked to neurodegenerative disorders.

Low T_3 Syndrome or Euthyroid Sick Syndrome

A long-standing clinically relevant conundrum is the low T_3 syndrome or the euthyroid sick syndrome, characterized by low serum concentrations of T_3, elevated rT_3, and normal, elevated, or, in later stages, decreased serum T_4 without appropriate compensatory elevation of serum TSH concentrations (de Vries *et al.*, 2015). This peculiar hormone constellation has initially been explained by decreased hepatic T_3 formation by Dio1, normal or decreased TH synthesis, and lack of pituitary stimulation of TSH secretion (**Table 2**). Many facets of regulation of thyroid hormone homeostasis contribute to this syndrome, which is observed during carbohydrate starvation, acute and chronic illness, after surgical intervention, trauma, infection, sepsis, or after administration of certain drugs that inhibit (hepatic) DIO1 activity. In addition to decreased hepatic and, in some cases, impaired renal and thyroidal DIO1 activity, the remarkable interruption of the normal negative feedback of TH at the hypothalamic and pituitary level is a hallmark of this syndrome. Experiments using various animal models, including knockout mice models, suggest that elevated concentrations of proinflammatory cytokines (interleukins-1 and -6, tumor necrosis factor-α, and interferon-γ) under these conditions contribute to the inhibition of Dio1 activity while concomitant hypoxia and altered cellular redox state may elevate Dio3

Table 2 Pathogenesis of low serum concentrations of T_3 and T_4 in the euthyroid sick syndrome of nonthyroidal illness

Low T_3/T_4 state
Decreased hepatic Type I 5′-deiodinase activity
Increased Type III 5-deiodinase activity
Decreased concentrations of serum thyroid hormone-binding proteins
Increased circulating inhibitors of binding of T_3 to serum proteins
Decreased tissue uptake of T_3 by peripheral tissues
Decreased TRH, TSH and thyroid hormone secretion
Hypercortisolism
Elevated proinflammatory cytokines (IL-1, IL-6, and TNF-α)
Interference of drugs with serum binding, tissue uptake, and 5′-deiodination (dopamine, glucocorticoids, propranolol, uremic compounds)

Abbreviations used: IL, interleukin; TRH, thyrotropin releasing hormone; TSH, thyroid-stimulating hormone; TNF-α, tumor necrosis factor-α.

activity and thus contribute to the interruption of the negative feedback of TH at the central level (Papanicolaou, 2000). In addition, both TH binding in serum and cellular uptake appear to be changed under these circumstances. If recovery or causal treatment of the underlying disease are not possible, this condition may worsen because T_4 production decreases ("low T_4 syndrome"), a condition with a bad prognosis and high mortality rate. Attempted treatment or substitution with TH (T_4 or T_3) were unsuccessful and even worsened the situation by generating a negative nitrogen balance or an even more pronounced catabolic constellation.

Support for this concept was provided in a clinical study on intensive care patients. A systematic analysis of the activities of the three DIO isoenzymes in biopsies of postmortem tissues (liver and skeletal muscle) and the corresponding serum concentrations of TH, together with other routine clinical chemistry parameters, revealed a re-expression of hepatic DIO3 in critically ill patients, which is similar to the pattern in fetal human liver (Peeters *et al.*, 2003b). This finding may explain the rapid decrease in circulating T_3 and the increase in rT_3 in combination with decreased hepatic DIO1 activity. Lowest DIO1 and highest DIO3 activities were observed in patients who died from cardiovascular complications, suggesting that poor tissue perfusion alters the normal expression levels of these two DIO enzymes. No significant expression of DIO2 activity was found in both kidney and muscle. In addition, successful disruption of this vicious cycle of the euthyroid sick syndrome has been demonstrated in intensive care patients who received a combined stimulation by the hypothalamic releasing hormones TRH and growth hormone-releasing peptide, whereas administration of either component alone was not successful in restoring the growth hormone (GH)—TH axes in severe illness (Van den Berghe *et al.*, 1999). Pulsatile secretion of the pituitary hormones GH, TSH, and prolactin was reamplified by this combination of releasing factors, which also substantially increased circulating concentrations of insulin-like growth factor-1, T_4, and T_3 while avoiding an increase in rT_3. Apparently, such interference at the hypothalamic level of regulation enabled this metabolic improvement and the restoration of normal feedback loops. Whether this treatment regimen can be used for all variants of the euthyroid sick syndrome remains to be established. Independent support for this hypothesis derives from observations in children and adult patients treated with GH. This regimen led to decreased T_4 and rT_3 and increased serum T_3 concentrations independent of alterations in TSH and suggests stimulation of hepatic DIO1 activity by GH. This interpretation is supported by several studies of animal models indicating increased hepatic Dio1 expression and activity after GH treatment. No data are available on a GH-dependent decrease in hepatic DIO3, which is normally not expressed in rodent liver. Whether concomitant tissue-specific downregulation of DIO2 expression, as described for skeletal muscle, is additionally involved in adaptation mechanisms required for the cellular decrease in T3 concentration observed in the euthyroid sick syndrome remains to be studied.

Tissue-Specific Expression Patterns of Deiodinase Enzymes and Homeostasis of Net T_3 Formation

The observations of hepatic re-expression of Dio3 and decreased activity of Dio1 in severe illness suggest that the developmental pattern of expression of deiodinases can be reverted under certain conditions or that an alteration of the cellular composition of a given tissue results in marked alterations in the net balance of homeostasis of T_3 formation. Decreased expression of DIO1 without evidence of a concomitant increase in DIO3 expression is also found in tumors of the thyroid, kidney, prostate, and testis. In pituitary adenoma, decreased expression of DIO1 is associated with elevated DIO3 activity, whereas the normal pituitary shows only low levels of this enzyme. Depending on the type of pituitary tumor, DIO2 expression is increased or reduced. Treatment of human cell lines derived from tumors expressing deiodinase activity with agents modulating chromatin methylation or histone acetylation or administration of retinoic acid, an agent known to induce cell differentiation, leads to re-expression of DIO1 activity, even in cell lines that have lost DIO1 expression. These observations indicate that several regulatory factors involved in development and differentiation exert marked influence on the production and homeostasis of T_3, which is essential for maintenance of the differentiated state and the metabolic function of various cell types, especially epithelial cells. Therefore, adequate production of thyromimetically active T_3 seems to be a key parameter of the normal cell and functional tissue, which is under a

complex network of control by potent factors involved in development, proliferation, differentiation, and maintenance of function of a vertebrate organism.

Metabolism of Thyroid Hormones at the Amino Acid Side Chain

TH and iodothyronines derived therefrom have an alanine amino acid side chain that can undergo oxidative decarboxylation and deamination, as found for other amino acids. Only limited in vivo experimental evidence is available on enzymatic decarboxylation of iodothyronines by ornithine decarboxylase to yield metabolites with an amine side chain, such as 3-Iodothronamine (T1AM) (Hoefig *et al.*, 2016). 3T1AM circulates in human blood in nanomolar concentrations and shows high-affinity binding to apolipoprotein B100. T1AM exerts a number of pharmacological effects via cell membrane G-protein coupled receptors, members of the family of trace amine- associated receptors (TAAR), adrenergic receptors (ADRA2) and the transient receptor potential cation channel subfamily M member 8 (TRPM8). Among those T1AM actions are some opposed to those of T3 (e.g. on cardiac function). T1AM administration affects memory, learning, behavior and pain sensation, decreases insulin and increases glucagon secretion, and high doses were reported to reversibly decrease body temperature by several degrees. Thyronamines are inactivated by enzymatic oxidation via inhibitor-sensitive monoamine oxidases. The oxidized product of T1AM, i.e. 3-iodothyroacetic acid, also shows some central effects at high concentrations.

Oxidative decarboxylation of T_4 and T_3 generates relevant circulating concentrations of both tetraiodothyro-acetic acid (Tetrac) and the corresponding triiodothyro-acetic acid (Triac), both of which can be measured in human serum. The enzymes catalyzing these reactions have not been characterized in detail and it is not clear whether thyronamine formation is an obligatory intermediary step in their formation. However, the metabolites Tetrac and Triac are of clinical relevance because Tetrac is a good substrate for the 5′-deiodinases and a ligand for the $\alpha v\beta 3$ integrin receptor while Triac is a potent ligand for nuclear T_3 receptors. Whether endogenous Triac reaches the nuclear T_3 receptor target in vivo and modulates the expression of T_3-regulated genes in humans is unclear. Triac has a short biological half-life compared to that of T_3 and is used in pharmacological doses for treatment of TH resistance and amelioration of the Allan–Herndon–Dudley syndrome. Triac efficiently suppresses elevated TSH but does not lead to hyperthyroid conditions in heart, liver, and other organs due to its rapid degradation and lack of accumulation in tissues.

Conjugation of Thyroid Hormones by Glucuronidases and Sulfotransferases

Glucuronidation

Multiple UDP-glucuronyltransferases appear to be involved in the glucuronidation of TH. The 4′-OH group of iodothyronines is rather acidic, depending on the iodine substitution pattern of the phenolic ring, and Tetrac and Triac are better substrates for glucuronidation than their parent compounds T_4 and T_3. Glucuronidated iodothyronines, which do not bind TR, show increased solubility in water and are rapidly excreted via the bile, but they may also undergo enterohepatic circulation. Drugs and agents interfering with UDP-glucuronyltransferases might therefore affect TH metabolism and elimination as indicated by findings on the effects of several halogenated aromatic compounds (PCB and dioxins) acting as endocrine disruptors in animal models (Gutleb *et al.*, 2016). Compounds that increase T_4 glucuronidation decrease serum concentrations of T_4 (e.g., phenobarbital and several halogenated aromatic compounds).

Sulfation

The second important pathway of TH conjugation of the phenolic 4′-hydroxyl group is catalyzed by sulfotransferases, which belong to a large superfamily of enzymes with tissue- and development-specific expression patterns. Sulfation accelerates the deiodination of different iodothyronines by Dio1 and initiates irreversible hormone degradation (Visser *et al.*, 1998). T_3 sulfate found during pregnancy in fetal and maternal circulation might function as a reservoir from which active T_3 is recovered by tissue sulfatase activity. T_2 sulfate, also found in fetal circulation, might represent an elimination form of excess TH secreted toward the maternal circulation when fetal type I deiodinase activity is still low. Significant sulfotransferase activity has been found in fetal tissues. Relevant sulfatase activities that might liberate T_3 from circulating T_3-sulfate have been observed in (maternal) placenta and liver during pregnancy as well as in other tissues. Changes in sulfation metabolism of TH have also been observed in adaptation to selenium deficiency and during fasting. Furthermore, several endocrine disruptors and drugs alter sulfation-related metabolism of TH and interfere with enterohepatic recycling of THM.

Drugs Interfering With Thyroid Hormone Metabolism

Several drugs and pharmaceuticals interfere with TH metabolism, especially their deiodination and conjugation reactions. Many phenolic aromatic, mono- or polycyclic agents compete with THM binding and deiodination by DIO isoenzymes. With few exceptions, these agents specifically interfere with one or more of the DIO enzymes. Several drugs routinely used in clinics interfere

with DIO1. Most efficient inhibition is observed for some iodinated oral cholecystographic X-ray contrast agents (ipodate or iopanoic acid), the antiarrhythmic drug amiodarone and its metabolites, the synthetic glucocorticoid dexamethasone, some antiphlogistic and antiinflammatory agents, and the large group of plant secondary phenolic metabolites (flavonoids, isoflavonoids, aurones, and chalcones). The latter compounds are contained in significant amounts in daily consumed plant-derived food, but it is unclear whether their consumption contributes to goitrogenesis under conditions of inadequate iodide supply. Many of these DIO-inhibiting compounds lead to a constellation of serum TH reminiscent of the low T_3 syndrome: normal or elevated T_4, low T_3, elevated rT_3, and normal TSH. The main effect of these compounds is inhibition of DIO1. Some agents are potent inhibitors of all three deiodinases (e.g., iopanoic acid, xanthohumol). No selective or isoenzyme-specific inhibitors of 5′-DII and 5-DIII are known. The antithyroid drug 6-*n*-propyl-2-thiouracil (PTU) and the isoflavone genistein are selective inhibitors of DIO1 in most species. However, the clinical use of PTU as an antithyroid drug is based mainly on its inhibition of TH synthesis catalyzed by the thyroperoxidase and less so via inhibition of DIO1 activity. The compound aurothioglucose is a potent inhibitor of DIO1 but also inhibits the other deiodinases at higher concentrations due to the presence of a selenocysteine residue in the active sites of all three DIO isoenzymes. The synthetic flavonoid F21388, derived from natural compounds, is a potent inhibitor of DIO1 and DIO2 and has been shown to modify transplacental TH transfer and TH transport to the fetal brain. The development of isoenzyme-specific inhibitors may provide the possibility for tissue- and cell-specific interference of TH action in a manner similar to that documented for the steroid field, for which selective inhibitors of steroid activation (e.g., aromatase inhibitors) and inactivation are already in clinical use.

Sodium/Iodide Symporter (NIS)☆

Nancy Carrasco and Rachel R Kaspari, Yale School of Medicine, New Haven, CT, United States

The thyroid hormones (T_3 and T_4) play a key role in prenatal and early development, and have often been called master regulators of intermediary metabolism throughout life—for good reason, given the myriad effects they have in virtually all tissues. Their impact on human health cannot be overstated. Of all metabolic diseases, thyroid maladies are second in frequency only to diabetes. Iodine, an environmentally scarce element, is an essential constituent of the thyroid hormones, which are the only iodine-containing hormones in vertebrates. Humans' only source of iodide (I^-) is their diet, and the first step in the biosynthesis of the thyroid hormones is the active transport of I^- into the thyroid follicular cells (Carrasco, 1993; Ravera *et al.*, 2017). This step is mediated by the sodium/iodide symporter (NIS), a key plasma membrane transport protein located at the basolateral surface of these cells (Portulano *et al.*, 2014). Although NIS was only identified at the molecular level in 1996, when the cDNA encoding it was first isolated (Dai *et al.*, 1996), the ability of the thyroid to actively take up I^- has been a mainstay of the clinical management of thyroid disease since 1946 (Seidlin *et al.*, 1946). The treatment for thyroid cancer based on administering radioiodide post-thyroidectomy, the most effective internal radiation cancer therapy devised to date, depends on the ability of most thyroid cancer cells to express functional NIS, which ensures that the administered radioiodide is selectively accumulated via NIS in these cells only, destroying them but sparing non-NIS-expressing cells (Ho *et al.*, 2013).

NIS relies on the sodium (Na^+) electrochemical gradient, maintained by the sodium/potassium ATPase, to drive the active transport of I^- into the cell. By coupling the inward transport of Na^+ down its electrochemical gradient to the translocation of I^- against its electrochemical gradient across the basolateral plasma membrane, NIS avidly concentrates I^- in the thyroid at concentrations over 40 times those inside thyroid cells (Ravera *et al.*, 2017). The K_m of NIS for I^- transport is 10–30 μM, and its K_m for Na^+ is 40–60 mM (Portulano *et al.*, 2014). In rats, NIS is a 618 amino acid protein (Dai *et al.*, 1996), whereas in humans, it is slightly larger, with 643 amino acids (Smanik *et al.*, 1996, 1997). The experimentally tested secondary structure model for NIS shows a hydrophobic protein with 13 transmembrane segments (TMSs), an extracellular amino terminus, and an intracellular carboxy terminus (Levy *et al.*, 1997, 1998a,b). Although NIS is N-glycosylated at three positions, N-glycosylation is not essential for I^- transport or for trafficking NIS to the plasma membrane (Li *et al.*, 2013). NIS is a phosphoprotein, and most phosphorylation occurs on its carboxy terminus (Riedel *et al.*, 2001). The carboxy terminus is also important for NIS trafficking and for its localization at the basolateral plasma membrane (Dohan *et al.*, 2007) (**Fig. 1**).

NIS has turned out to be a fascinating molecule and has yielded many surprises. Among them are these: it transports substrates with rather different geometries [e.g., I^- (spherical), perchlorate (ClO_4^-) and perrhenate (ReO_4^-) (both pyramidal), and thiocyanate (SCN^-) (planar)] (Eskandari *et al.*, 1997); it transports different substrates with different stoichiometries (Dohan *et al.*, 2007; Paroder-Belenitsky *et al.*, 2011) [I^-, chlorate (ClO_3^-), and SCN^- electrogenically ($2Na^+$/anion), but ReO_4^- and the environmental pollutant ClO_4^- electroneutrally ($1Na^+$/anion)]; and it has a very long half-life (over 5 days) (Riedel *et al.*, 2001). Moreover, although NIS was previously thought to be a thyroid-specific protein, it is now known to be expressed in various extrathyroidal tissues, including salivary glands, stomach, choroid plexus, lactating (but not non-lactating) breast, placenta, small intestine, and kidney (Tazebay *et al.*, 2000; Mitchell *et al.*, 2001; Spitzweg *et al.*, 2001; Morgenstern *et al.*, 2005; Di Cosmo *et al.*, 2006; Portulano *et al.*, 2014; Riesco-Eizaguirre *et al.*, 2014; Marti-Climent *et al.*, 2015). That NIS is expressed in the lactating breast is particularly significant, because it supplies I^- to the nursing newborn through the milk (Dohan *et al.*, 2003). Strikingly, NIS is also endogenously expressed in some breast cancers, both in primary tumors (Tazebay *et al.*, 2000) and in metastases (Wapnir *et al.*, 2003, 2004), suggesting that radioiodide ($^{131}I^-$) could potentially be used to treat breast cancer similarly to how it is used to treat thyroid cancer. In addition, NIS has also been experimentally expressed exogenously by gene transfer in cancers that do not express it endogenously to render them susceptible to radioiodide treatment (Portulano *et al.*, 2014; Ravera *et al.*, 2017).

Considering that NIS plays a key role in clinical medicine, particularly in the treatment of thyroid disease, and that its use is being extended beyond thyroid disease by carrying out gene transfer studies, it is imperative to understand how NIS works at the molecular level. A longstanding question in the field has been how NIS can transport I^- so efficiently when serum I^- concentrations are submicromolar and the K_M of NIS for I^- is 10–30 μM. Using statistical thermodynamics, it has been shown that NIS has a low intrinsic affinity for I^- (K_d = 224 μM), which increases 10-fold (K_d = 22.4 μM) when the symporter has two Na^+ ions bound to it. Therefore, at physiological Na^+ concentrations, ~79% of NIS molecules are occupied by two Na^+ ions, enabling them to bind and translocate I^- extremely efficiently (Nicola *et al.*, 2014). Furthermore, the mechanism by which NIS binds and releases its substrates has begun to be elucidated. To that end, specific amino acid positions that are crucial for NIS function have been identified. Some of these positions were ascertained to be critical when mutations at these positions were found in patients with congenital I^- transport defect (ITD) (Levy *et al.*, 1998c; Dohan *et al.*, 2002; De La Vieja *et al.*, 2004; De la Vieja *et al.*, 2005, 2007; Li *et al.*, 2013; Paroder *et al.*, 2013; Nicola *et al.*, 2015). ITDs are characterized by extremely low or no I^-

☆*Change History*: February 2018. Authors Carrasco and Kaspari updated everything with respect to the 2004 chapter.

This article is an update of Armin E. Heufelder and Werner Joba, Sodium Iodide Symporter, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 283–287.

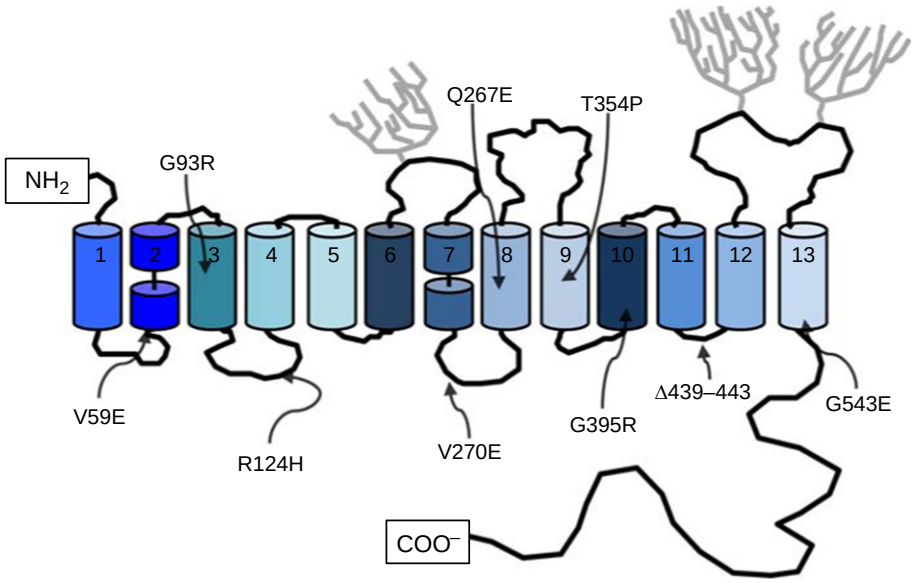

Fig. 1 Experimentally tested NIS secondary structure model. TMSs are shown as cylinders labeled 1 through 13; *black lines* connecting the cylinders represent extracellular and intracellular segments; and trees represent N-linked glycosylation at sites N225, 489, and 502. The single-letter amino acid code is used to label NIS amino acid substitutions identified in patients with ITD and experimentally investigated by determining the effects of several amino acid substitutions at the relevant positions. Δ indicates a deletion. From Ravera, S., Reyna-Neyra, A., Ferrandino, G., Amzel, L. M. and Carrasco, N. (2017). The sodium/iodide symporter (NIS): Molecular physiology and preclinical and clinical applications. *Annual Review of Physiology* **79**, 261–289.

accumulation in the thyroid and a low saliva-to-plasma I^- ratio. If not treated early in life, ITD can lead to hypothyroidism, goiter, and impaired physical and intellectual development. By determining the molecular requirements at these positions and combining these findings with data from molecular dynamics simulations using a NIS homology model (Paroder-Belenitsky *et al.*, 2011; Ferrandino *et al.*, 2016), it is becoming clearer that the two Na^+ ions bind cooperatively—that is, the binding of the first Na^+ increases the affinity of NIS for the second one and for I^-. In addition, the second Na^+ is coordinated by more residues than previously thought (Ferrandino *et al.*, 2016). The fully loaded complex (NIS, 2 Na^+ ions, and I^-) is translocated into the interior of the cell, where all three substrates are released, and the unloaded symporter returns to its original conformation facing the extracellular milieu to begin the cycle anew (Nicola *et al.*, 2014).

In the last two decades, NIS has become central in the use and optimization of gene transfer studies, because it can be used as both a reporter and a therapeutic gene (see Ravera *et al.*, 2017 and Portulano *et al.*, 2014 for detailed discussion). In addition, surprising data on the intricate metabolic crosstalk that takes place between several organs, including the thyroid, liver, pancreas, and adipose tissue, have been obtained in the recently generated NIS knockout (KO) mice (Ferrandino *et al.*, 2017a). Studies using this drug-free mouse model of hypothyroidism have also yielded compelling evidence that, at extremely high serum I^- concentrations, I^- can enter the thyroid via passive routes, as previously suspected, compensating for the absence of functional NIS molecules in patients with ITD. Indeed, when NIS KO mice were fed a standard chow diet, they exhibited reduced serum levels of T_4 but, surprisingly, their serum levels of T_3 and thyroid stimulating hormone (TSH) were similar to those of wild-type (WT) mice. Given that the chow diet supplies approximately 6 μg I^- per gram of food, which is 40 times the recommended daily amount of I^- for mice (National Research Council (U.S.). Subcommittee on Laboratory Animal Nutrition, 1995), these findings indicate that some I^- enters the thyroid passively via non-NIS routes (Ferrandino *et al.*, 2017a). In contrast, when NIS KO mice are fed a diet supplying the recommended minimum daily amount of dietary I^- for rodents [minimum I^- diet (MID); 0.15 μg per gram of food], they show markedly lower serum T_4 and T_3 and drastically greater serum TSH levels than WT mice, as expected.

It has been proposed that hypothyroidism-induced non-alcoholic fatty liver disease (NAFLD) is due to reduced thyroid hormone signaling in the liver, which reduces fatty acid utilization and results in triglyceride accumulation (Liu *et al.*, 2007; Mullur *et al.*, 2014). Several drug-free models of hypothyroidism were used to better define the mechanisms underlying hypothyroidism-induced NAFLD (Ferrandino *et al.*, 2017b). WT mice placed on a low I^- diet (LID) supplying one-tenth the daily recommended amount of I^- for rodents (0.01 μg per gram of food) become mildly hypothyroid, as shown by lower serum T_3 and T_4 and greater serum TSH than euthyroid mice (WT mice on a chow diet). These mildly hypothyroid mice had a higher fat mass and lower lean mass than, and overall similar body weight to euthyroid mice. Mildly hypothyroid mice readily developed NAFLD, even though hepatic genes known to be downregulated in hypothyroidism (Dozin *et al.*, 1986; Jump, 1989; Zavacki *et al.*, 2005; Visser *et al.*, 2016) were found to be expressed at similar or greater levels in these than in euthyroid mice. Expression of β-oxidation genes was similar between mildly hypothyroid and euthyroid mice, and mitochondria from LID mice oxidized ^{14}C-palmitate and generated CO_2 and acid-soluble metabolites at the same rate as mitochondria from euthyroid mice, suggesting that lipid utilization does not

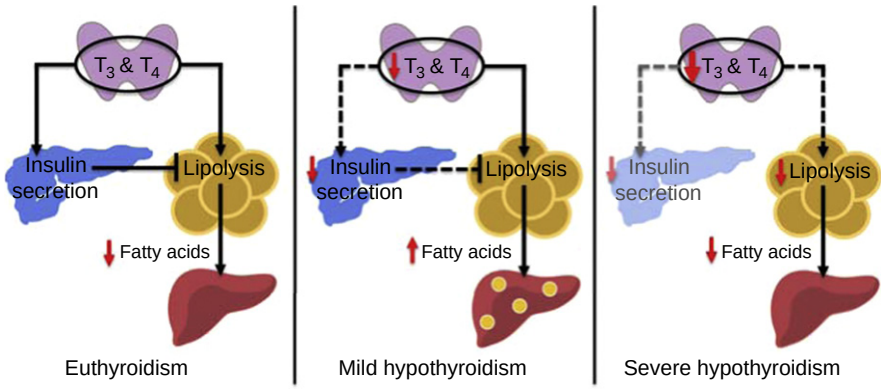

Fig. 2 Overview of the mechanisms that are involved in the development of hypothyroidism-induced NAFLD in mild hypothyroidism and those that protect against NAFLD in severe hypothyroidism. In euthyroidism (left panel), insulin is secreted in response to a meal, which inhibits lipolysis in the adipose tissue, and prevents NAFLD. In mild hypothyroidism (middle panel), insulin secretion is impaired; as a result, lipolysis is not suppressed, fatty acids are accumulated as triglycerides in the liver, and NAFLD develops. In severe hypothyroidism (right panel), adrenergic stimulation of lipolysis is constitutively suppressed, which protects against the development of NAFLD. Adapted from Ferrandino, G., Kaspari, R. R., Spadaro, O., Reyna-Neyra, A., Perry, R. J., Cardone, R., Kibbey, R. G., Shulman, G. I., Dixit, V. D. and Carrasco, N. (2017). Pathogenesis of hypothyroidism-induced NAFLD is driven by intra- and extrahepatic mechanisms. *Proceedings of the National Academy of Sciences of the United States of America* **114**(43), E9172–E9180.

contribute to the development of hypothyroidism-induced NAFLD. Mildly hypothyroid islets had impaired insulin secretion mostly during the second phase of insulin release. The impaired insulin secretion in mildly hypothyroid mice prevents the suppression of lipolysis caused by insulin in fed conditions, leading to increased fatty acid delivery to the liver, where triglyceride accumulation thus occurs. Mildly hypothyroid mice also have increased levels of the key lipolysis enzyme hormone sensitive lipase phosphorylated on activating positions in their visceral adipose tissue under fed conditions. Furthermore, insulin infusion during a euglycemic–hyperinsulinemic clamp study suppressed glycerol and palmitate turnover in euthyroid mice, but failed to suppress turnover in mildly hypothyroid mice, suggesting that insulin action in the adipose tissue is impaired in these mice.

Adrenergic stimulation of lipolysis was not impaired in mildly hypothyroid conditions, but it was in conditions of severe hypothyroidism (NIS KO mice on a LID). Consistent with the impairment of lipolysis, severely hypothyroid mice showed significantly lower fasting serum glycerol and fatty acid levels than mildly hypothyroid mice, along with reduced activating phosphorylations of hormone sensitive lipase in their visceral adipose tissue. Strikingly, severely hypothyroid mice are protected against development of NAFLD, even though they exhibit reduced expression of hepatic genes previously shown to be down-regulated in hypothyroidism (Dozin *et al.*, 1986; Jump, 1989; Zavacki *et al.*, 2005; Visser *et al.*, 2016). These results suggest that hypothyroidism-induced NAFLD is not due to reduced thyroid hormone signaling in the liver, as previously surmised, but rather to unsuppressed lipolysis, which occurs in mildly hypothyroid but not in severely hypothyroid conditions (Ferrandino *et al.*, 2017b) (**Fig. 2**).

Thyroid Peroxidase☆

Salvatore Benvenga, University of Messina, Messina, Italy and General Hospital "G. Martino" of Messina, Messina, Italy
Roberto Vita, University of Messina, Messina, Italy

Glossary

Immune tolerance Unresponsiveness of the immune system to antigens that potentially can elicit an immune response. Tolerance to self-antigens is accomplished via central and peripheral mechanisms.

Gene mutation Alteration in DNA structure resulting from substitution, insertion or deletion of nucleotides.

Gene polymorphism Allele variant in a population with a frequency $\geq 1\%$.

Heme Iron containing prostethic group covalently bound to TPO that is essential for its enzymatic activity.

Genetics of Thyroid Peroxidase

Thyroid peroxidase (**Fig. 1**), also called thyroperoxidase (TPO) is a 100 kDa, glycosylated heme-protein bound to the apical membrane of the thyroid follicular cell.

TPO belongs to the same family of human peroxidases, together with lactoperoxidase, myeloperoxidase and eosinophil peroxidase, with which TPO shares 48%, 47% and 47% sequence homology, respectively (Godlewska *et al.*, 2017; Le *et al.*, 2015).

The *TPO gene* has been mapped at 2p13. It comprises 17 exons, spanning more than 150 kb of DNA. Two different TPO cDNAs, hTPO-1 (3048 bp) and hTPO-2 (2877 bp) were isolated in 1987 from a human thyroid cDNA library (Kimura *et al.*, 1987). Compared to hTPO-1, hTPO-2 has a 171 bp deletion that results in a 57 amino acid shorter protein, and is produced by alternative splicing of the primary *TPO gene* transcript (Kimura *et al.*, 1987). Particularly, a proximal histidine is linked to the iron center of the enzyme and is located in the 171 bp sequence that is deleted in hTPO-2. Since this sequence is critical for heme binding, and therefore for enzymatic activity, hTPO-2 was later proved not to have peroxidase activity. Compared to hTPO-1, hTPO-2 is also broken down more rapidly and is not capable to reach the cell surface. The *hTPO-1 gene* encodes for a 933 amino acid protein, which consists of a large extracellular region (called ectodomain, and containing a myeloperoxidase-like domain, a complement controlled protein-like domain, and an epidermal growth factor-like domain), a short transmembrane region, and a cytoplasmic tail (Godlewska et al., 2017; Libert *et al.*, 1987) (**Fig. 2**).

A fully active isoform devoid of the EGF-like domain, called isoform4, was also described (Ferrand *et al.*, 2003). Worthy of note, the 510–567 region contained in the extracellular domain, is homologous to the heme-binding region of the bovine cytochrome C oxidase polypeptide 1, which is encoded by the mitochondrial genome. Based on this observation, some authors have hypothesized that a mitochondrial gene module contributed to the evolution of the *TPO gene* (Libert *et al.*, 1987).

Thyroid Peroxidase Mutations and Variants

It is intuitive supposing that mutations of the *TPO gene* result in partially or totally deficient iodide organification and, consequently, in hypothyroidism. A number of studies have screened patients with either congenital or acquired hypothyroidism for TPO mutations in different countries (Bakker *et al.*, 2000; Nascimento *et al.*, 2003; Wu *et al.*, 2002). Thyroid dyshormonogenesis accounts for 10%–15% of all cases of congenital hypothyroidism, and results from disruption at any stage of iodide organification due to mutations of TPO, thyroglobulin (Tg), H_2O_2-producing system, or administration of TPO inhibitors. So far, more than 80 mutations in the *TPO gene* have been identified, resulting in variable impairment of TPO bioactivity (Belforte *et al.*, 2012). Defective TPO activity has a prevalence of 1 in 40,000 newborns. TPO gene mutations have mostly autosomal recessive inheritance, and are associated with qualitative or quantitative defects in TPO activity (Baş *et al.*, 2014; Ris-Stalpers and Bikker, 2010). In a recent study, Cangul *et al.* have identified 21 TPO mutations in 28 patients with thyroid dyshormonogenesis in a Turkish consanguineous community (Cangul *et al.*, 2013). Furthermore, two missense mutations in the *TPO gene*, Glu799Lys and Arg648Gln, have been reported in an inbred Amish population (Pannain *et al.*, 1999). Most TPO mutations, such as Arg412His substitution or the nonsense mutation at Glu596, are associated with intellectual disability and goiter due to compensatory hyperplasia (Mittal *et al.*, 2016). Moreover, an iodide organification defect that resulted from the expression of a mutant TPO

☆*Change History*: December 2017. Salvatore Benvenga and Roberto Vita have re-written this chapter in all its parts.

This chapter is an update of Francesco Boi and Stefano Mariotti, Thyroid Peroxidase, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 530–533.

Fig. 1 Predicted tertiary structure of the human thyroid peroxidase 1 (devoid of the heme group) retrieved by using the free web portal Phyre2 available at http://www.sbg.bio.ic.ac.uk/phyre2 (Kelley et al., 2015).

(Arg693Trp) paternal allele associated with the lack of maternal allele transcript was reported in three siblings of an Italian family (Fugazzola *et al.*, 2003).

Recent researches have revealed that single nucleotide polymorphisms (SNP) of the *TPO gene* associate with autoimmune hypothyroidism, as TPO variants are recognized as nonself antigens by the immune system. Indeed, the prevalence of TPOAb is as high as 80% in subjects with hypothyroidism (Fatourechi, 2009). Recently, the substitution of asparagine with threonine at position 217 and/or the substitution of threonine with proline at position 725, were reported to increase chances of developing subclinical hypothyroidism by 1.5–5.6-fold in Iranian and Indian populations (Khoshi *et al.*, 2017; Balmiki *et al.*, 2014). Conversely, the Asp666Asp polymorphism was found to be protective for hypothyroidism (Balmiki *et al.*, 2014).

In two large genome-wide association studies carried out in Caucasian and Asian populations, the authors reported different loci associated with TPO positivity. Interestingly, two of those (rs11675434 and rs2071403) are in linkage disequilibrium and are located near the *TPO gene* (Medici *et al.*, 2014; Kwak *et al.*, 2014). The polmorpishm rs11675434 has been associated with Graves' ophthalmopathy, especially in males and in patients whose onset occurs $\geq$45 years (Kuś *et al.*, 2017), but not with Graves' disease itself (Kuś *et al.*, 2017). The involvement of the TPO antigen in the pathogenesis of Graves' ophthalmopathy is confirmed by the expression of TPO and related mRNA in the orbital tissue of such patients (Kuś *et al.*, 2017). However, in contrast with anti-TSH

receptor antibodies, the role of TPOAb has to be understood, since some studies have concluded that higher serum levels of TPOAb are associated with decreased risk of Graves' ophthalmopathy (Lantz *et al.*, 2014).

Thyroid Peroxidase Activity

TPO is synthetized in polyribosomes and undergoes glycosylation in the Golgi apparatus. Upon packaging into vesicles, TPO reaches the apical membrane. TSH stimulates all these steps (Kuliawat *et al.*, 2005). Different glycosylation patterns of TPO account for its heterogeneity using immunoblotting (Gardas *et al.*, 1997). Other posttranslational modifications contributing to the formation of the mature protein are proteolytic trimming (cleavage of the N-terminal 1–108 residue), iron-protoporphyrin IX (heme) covalent binding, and dimerization at level of the extracellular domain (Le *et al.*, 2015). Despite previous crystallographic studies, the structural interpretation of these data remains obscure, so that an experimentally determined structure is still lacking. In this regard, the dimeric myeloperoxidase has been used as a reliable template for TPO (Baker *et al.*, 1994). Interestingly, both in TPO and in myeloperoxidase dimerization occurs at the same site (Cys296), where a disulfide bond links together the two monomers. Recently, Le *et al.* have proposed two models for spatial orientation of TPO: whereas in the *trans* model the cavity containing the heme group faces the follicular lumen, in the *cis* one the prosthetic group faces the apical membrane (Le *et al.*, 2015).

The heme group is essential for enzymatic activity of TPO, namely oxidation of inorganic iodide (I^-), and coupling of iodotyrosine residues on Tg. Particularly, TPO acts as a H_2O_2 donor and oxidizes I^- to I^+, an unstable ion that is capable to bind to Tg (Kopp, 2013). Controversy exists on whether or not iodination of Tg occurs via the production of a TPO-bound iodinated intermediate (Kessler *et al.*, 2008).

TSH stimulates all the steps of thyroid hormones biosynthesis, including TPO production and targeting to the apical membrane of the thyrocyte. In this regard, a number of transcription factors, such as the thyroid transcription factors-1 and 2, and the paired box gene 8 may have a key role in TPO expression (Gerard *et al.*, 1988).

Autoimmunity Against Thyroid Peroxidase

Experimentally, thyroiditis can be induced in mice by injecting purified thyroid antigens from other species, like porcine TPO or TPO peptides or recombinant TPO ectodomain (Ng and Kung, 2006). For instance, transgenic H2-k mice expressing T cell receptor for human TPO, when exposed to the TPO 536-547 peptide develop severe thyroiditis and hypothyroidism (Quaratino *et al.*, 2004). More recently, alternative approaches such as injections of fibroblasts coexpressing TPO and MHC class II, expression of TPO using plasmids or viral vectors or transgenic mice (TAZ10) expressing a human T-cell receptor specific for TPO but lacking other functional T cells and B cells, have been also used (Flynn *et al.*, 2004; Quaratino *et al.*, 2004; McLachlan and Rapoport, 2014).

TPO is a major thyroid antigen together with Tg and the TSH receptor. TPO has been isolated and identified only in the 80s as the "thyroid microsomal antigen," previously reported as a target of the autoimmune process in Hashimoto's thyroiditis (Czarnocka *et al.*, 1985; Libert *et al.*, 1987). However, similarly to TgAb, TPOAb are found also in patients with Graves' disease, underlining that both Hashimoto's thyroiditis and Graves' disease are characterized in their initial stage by a common breakdown of self-tolerance and TPOAb production even before overt thyroid disease (Marcocci *et al.*, 1982; McLachlan and Rapoport, 2014). In this regard, up to 10% of euthyroid subjects can be found positive for TPOAb, and are at risk of developing an autoimmune thyroid disease, as demonstrated by precociously altered ultrasound echogenicity (Acar *et al.*, 2013).

Tg has higher immunogenicity compared to TPO and the TSH receptor, as Tg is more abundant in thyroid and is larger. However, glycosylation of Tg is similar to TPO, 12% and 10%, respectively, but lower than TSH receptor A-subunit (40%) (Chazenbalk *et al.*, 2005). In addition, efficacy of the immune response after immunization with the membrane-bound TPO is greater compared to the soluble Tg or TSH receptor A-subunit (McLachlan and Rapoport, 2014). Since there are patients that produce both TgAb and TPOAb, bispecific "TgPO" antibodies have been postulated. These antibodies might discriminate patients with autoimmune hypothyroidism (with a prevalence as high as 35%–41%) from antibody-positive euthyroid individuals and from patients with nonautimmune hypothyroidism (Estienne *et al.*, 1999). Alternatively, certain patients produce concomitantly TPOAb and TgAb because TPO and Tg share cross-reactive epitopes, such as residue 119–126 of TPO and 2763–2770 of Tg (McLachlan and Rapoport, 2014).

A number of investigations have demonstrated two immunodominant regions within the TPO molecule, called immunodominant region A and B (Ruf and Carayon, 2006; Czarnocka *et al.*, 1997). Approximately 25% of TPOAb of patients with autoimmune thyroid disorders bind to the immunodominnat region A, while 50% of them bind to the immunodominant region B (Jastrzebska-Bohaterewicz and Gardas, 2004). In tridimensional models, the immunodominant region A consists in epitopes scattered across the TPO molecule, and including the complement controlled protein-like domain and the myeloperoxidase domain. In contrast, the immunodominant region B clusters close to the dimer interface at the myeloperoxidase-like domain (Le *et al.*, 2015). It is likely that the interaction of TPO with autoantibodies leads to conformational changes consisting in dissociation of dimers into monomers in order to access to immunodominant region B epitopes (Baker *et al.*, 1994; Le *et al.*, 2015). These data are confirmed by other studies according to which T cells and autoantibodies interact with TPO epitopes

downstream of amino acid 109, namely beyond the cleaved N-terminal region (McLachlan and Rapoport, 2007). Interestingly, even if the heme group is pivotal for the enzymatic activity, it is not involved in TPO autoantibody recognition (McLachlan and Rapoport, 2014). Even though in vitro TPOAb show complement-dependent and antibody-dependent cytolysis activity, in vivo the apical membrane-bound enzyme is not accessible to TPOAb, thus it has been proposed that TPO would interact with autoantibodies either after conformational changes upon micropinocytosis of colloid droplets, or after transcytosis from the basolateral membrane via the Fc receptor (Rebuffat *et al.*, 2010; Estienne *et al.*, 2002). Interestingly, TSH specifically stimulates the expression of the autoantibody binding domains of the TPO molecule in vitro (Rasmussen *et al.*, 1999).

The first step in the development of autoimmune diseases is the breakdown of immune tolerance, namely the initiation of the response against self-antigens. Disruption of immune tolerance has been hypothesized to occur both at central and peripheral levels (McLachlan and Rapoport, 2014). The autoimmune regulator (AIRE) gene greatly influences the thymic expression of thyroid antigens, which is pivotal in central tolerance to thyroid antigens, including TPO. This is confirmed by the high prevalence of TPOAb and autoimmune hypothyroidism in patients with autoimmune polyglandular syndrome type 1 who carry mutations in the AIRE gene (Perniola *et al.*, 2008). At a peripheral level, regulatory CD4+ CD25+ Foxp3+ T cells (Treg) are essential in maintaining immune tolerance. Indeed, mice depleted of Treg lymphocytes develop thyroiditis (McLachlan *et al.*, 2007).

Autoimmune thyroid diseases are supposed to develop when one or more environmental triggers hit genetically predisposed individuals (Benvenga and Guarneri, 2016; Burek and Talor, 2009). Concerning environmental factors, for the purpose of the present chapter we will herewith address only infectious microorganisms, disregarding the role of other factors, such as radiation and iodine, for which we refer to specific entries of this *Encyclopedia*.

According to the molecular mimicry hypothesis, antigens of certain microorganisms may share epitopes with thyroid autoantigens, eliciting an immune response directed against both these microorganisms and thyroid. For instance, antibodies directed to *Yersinia Enterocolitica* lipoprotein and its outer membrane proteins cross react with the TSH receptor, stimulating it, thus triggering Graves' disease in predisposed individuals. Also, the outer membrane proteins of *Y. Enterocolitica* contain cross-reactive T cell epitopes and have mitogenic effect on B cells (Wang *et al.*, 2010; Guarneri *et al.*, 2011). Finally, germline gene precursors of TSH receptor antibodies have been reported to contain binding sites for *Y. Enterocolitica* proteins (Hargreaves *et al.*, 2013). Other investigations demonstrated a similar trigger role also for Coxsackie virus B and other enteroviruses for Graves' disease and Hashimoto's thyroiditis, respectively. In this regard, hepatitis C virus has been recently reported in autoimmune and nonautoimmune hypothyroid patients (Kraemer *et al.*, 1998; Di Domenicantonio *et al.*, 2014). Overall, bacterial (*Y. Enterocolitica*, *Borrelia Burogdorferi*, *Helicobacter Pylori*, *Rickettsia Prowazeki*), viral (enteroviruses, cytomegalovirus), fungal (Candida), and protozoan (*Toxoplasma gondii*) triggers may break down immune tolerance either via molecular mimicry or T cell cross-reactive epitopes (Benvenga and Guarneri, 2016). Alternatively, recently published bioinformatics data have highlighted the role of peptides from microorganisms, such as *Y. Enterocolitica*, *B. Burgdorferi*, and *Clostridium Botulinum* that are capable, similarly to thyroid autoantigens, to bind certain HLA-DR motifs. Consistency between in silico prediction of cross-reactivity and experimental results confirms the above-mentioned data (Benvenga and Guarneri, 2016).

Thyroid Peroxidase in Cancer

A number of studies have highlighted the relation between thyroid autoimmunity and breast cancer. Indeed, women with hyperthyroidism are more prone to develop breast cancer, in contrast with women with hypothyroidism (Søgaard *et al.*, 2016). In early investigations carried out in the 90s, it stood out that the prevalence of TPOAb and other thyroid autoantibodies was higher in women with breast cancer (Rasmusson *et al.*, 1987; Giani *et al.*, 1996; Smyth *et al.*, 1998). Based on these findings, a protective role of TPOAb has been postulated, so that TPOAb positivity can favorably influence prognosis of these patients (Giustarini *et al.*, 2006). Other studies did not corroborate these data (Jiskra *et al.*, 2007). It has been hypothesized that one or more shared antigens between breast cancer and thyroid cells are capable to induce an immune response. Common candidate antigens are the sodium/iodide symporter (NIS), expressed both in thyroid and in breast, or cross-reactive epitopes in TPO and lactoperoxidase, the former being expressed in thyrocytes, whereas the latter in breast cells (Muller *et al.*, 2014). However, the role of thyroid autoimmunity in the development of breast cancer is not fully understood. In vivo experiments have shown that T3 can stimulate the estrogen receptor in breast-cancer derived cell lines, enhancing their proliferation (Hall *et al.*, 2008).

Only recently hTPO-1 isoform and TPO mRNA were found in breast carcinoma samples, and also in the peritumoral tissue (Muller *et al.*, 2014) In this regard, Godlewska *et al.* have demonstrated that TPO expression is four-fold higher in normal breast compared with breast cancer (Godlewska *et al.*, 2017). TPO expressed in breast cancer is immunogenically similar to thyroid TPO, since it is recognized by monoclonal antibodies directed to the immunodominant regions A and B. In addition, TPO mRNA expression inversely correlates with tumor progression, namely the less differentiated the cancer, the lower TPO mRNA expressed, so that compared to well-differentiated and moderately differentiated tumors, in poorly differentiated tumors TPO mRNA expression is 2.3 and 1.6-fold lower, respectively (Godlewska *et al.*, 2017).

TPO and its spliced forms are detected also in thyroid cancer regardless of histotype and stage, although their expression is lower compared with normal thyroid tissue (Di Cristofaro *et al.*, 2006). Studies on three-dimensional structure of TPO isoforms revealed that it might differ compared to the structure of full-length TPO, and this difference may impact on their immunogenicity (Godlewska *et al.*, 2017). Certain TPO variants have been associated with the risk of developing thyroid cancer. In a case control-study carried out in two European populations, two polymorphisms (rs2048722 and rs732609) showed a negative or positive association with differentiated thyroid cancer in the Italian population and in the Spanish one, respectively (Cipollini *et al.*, 2013).

Thyroglobulin☆

Marina Muzza and Laura Fugazzola, University of Milan, Milan, Italy and IRCCS Italian Auxological Institute, Milan, Italy

Glossary

DNA A nucleic acid that constitutes the genetic material of all cellular organisms and the DNA viruses.

Epithelial cells Cells that form the barrier between an organism and its external environment.

RNA A linear, usually single-stranded polymer of ribonucleotides found in all living cells.

Transcription The formation of a nucleic acid molecule using a template of another molecule, particularly the synthesis of an RNA molecule using a DNA template.

The follicular structures of the thyroid gland are composed of a single layer of epithelial cells encompassing a lumen that is filled with the most abundant thyroidal protein: thyroglobulin (Tg), Tg functions as a scaffold protein for thyroid hormone synthesis and as a storage protein for thyroid hormone and iodine, several other proteins, such as thyroid peroxidase and thyroid oxidase, are involved in thyroid hormone synthesis, On stimulation of the thyroid by thyrotropin, several processes, including Tg synthesis, are up-regulated in the thyrocytes, favoring thyroid hormone synthesis.

The Thyroglobulin Gene

The thyroglobulin (Tg) gene, mapped to human chromosome 8q24.2–q24.3, covers at least 300 kb of genomic DNA. The coding sequence is divided over 48 exons separated by intronic sequences varying in size up to 64 kb (Mendive *et al.*, 2001). The complete gene sequence is available on GenBank (accession number NT 008150).

Thyroglobulin Expression, Synthesis, and Maturation

Initial transcription of the Tg gene is regulated by the transcription factors TTF1 (NKX-2.1), TTF2 (FKHL15), and PAX8. The 8.7-kb Tg mRNA is the most highly expressed transcript in normal thyrocytes, with an expression level of 2.7%. The open reading frame of Tg consists of 8307 bp. Because of the use of alternative polyadenylation cleavage sites, there is variation in the size of the 3′ untranslated region. Furthermore, polymerase chain reaction (PCR) showed that 11 alternatively spliced Tg mRNA variants occur. The most abundant and largest Tg mRNA encodes a protein of 2768 amino acid residues, including the signal peptide. After translation of the mRNA, the posttranscriptional route of Tg starts with the signal peptide directing the uptake in the endoplasmic reticulum (ER) where the first carbohydrate molecules are attached and Tg obtains its tertiary and quaternary structure. At least seven molecular chaperones are known to guide this process to ensure correct folding. Tg that "passes" the ER quality control is directed to the Golgi apparatus where glycosylation proceeds and is subsequently transported to the follicular lumen. If the alternative spliced mRNAs are translated, it is possible that these Tg molecules are considered to be "misfolded" by the ER quality control and never reach the follicular lumen. On the other hand, these alternatively spliced transcripts may result in a population of Tg-like proteins that could down-regulate thyroid hormone production because the configuration of the protein is less optimal for thyroxine formation. Moreover, alternatively spliced Tg molecules might have a lower degree of iodination and could be involved in the recently proposed feedback function of Tg when poorly iodinated follicular Tg suppresses the transcription of thyroid-specific transcription factors TTF1, TTF2, and PAX8 (Van de Graaf *et al.*, 2001).

Functional Domains of Thyroglobulin

The normal Tg protein product is a homodimer containing 10% carbohydrates, with a molecular weight of 660,000. The protein shows several characteristic sequences, and specific functions are attributed to some of these (summarized in **Table 1**) (Targovnik *et al.*, 2017).Glycosylation is a key event in Tg maturation. Approximately three-quarters of the potential glycosylation sites in Tg are occupied. Human Tg contains different types of carbohydrate units. Common are the "polymannose" units consisting of mannose and *N*-acetylglucosamine and the "complex" unit that has a core of three mannose residues with several chains of *N*-

☆*Change History*: March 2018. Marina Muzza and Laura Fugazzola updated the sections "Thyroglobulin Expression" and "Synthesis, and Maturation and Thyroglobulin Synthesis Defects", added an item in "Further Reading" section.

This article is an update of Jan J.M. de Vijlder, Simone A.R. van de Graaf and Carrie Ris-Stalpers, Thyroglobulin, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 366–368.

Table 1 Summary of thyroglobulin characteristic sequences

Thyroglobulin (amino acid residue nr)	*Characteristics*
−19	5′ amino acid
−19 ↔ −1	Signal peptide
1	5′ amino acid after signal peptide cleavage
59, 93, 181, 467, 479, 512, 731, 799, 930, 1203, 1332, 1348, 1699, 1757, 1852, 1896, 2105, 2233, 2274, 2565	Glycosylation sites
5, 1291, 2554, 2747	Iodothyronine acceptor sites
130, 847, 1448	Iodothyronine donor sites
	Domains with cysteine-rich repeated sequences
12 ↔ 1191, 1492 ↔ 1546	Type 1
1437 ↔ 1484	Type 2
1584 ↔ 2168	Type 3
2192 ↔ 2716	Acetylcholine esterase homologous domain
1440 ↔ 1443, 1454 ↔ 1457, 1471 ↔ 1474	Thioredoxin boxes
789 ↔ 1173	Heparin-binding domain
2749	3′ amino acid

acetylglucosamine, galactose, and fucose or sialic acid extending from it. Both types of carbohydrate complexes are linked to peptide through an asparagine-*N*-acetylglucosamine bond. Moreover, human thyroglobulin (hTg) contains two additional carbohydrate units linked to the peptide chain through the hydroxyl group of serine or threonine.

Tg contains several tyrosine residues that are preferentially iodinated. By coupling of two iodotyrosine residues, one functioning as a donor residue and the other as acceptor residue, thyroxine is generated at the acceptor site. The selectivity of tyrosine residues that become iodinated appears to be strongly dependent on the stereo-specific structure of the molecule. The main product is thyroxine and in much lesser quantities, 3,5,3′-triiodothyronine (I3) and 3,3′5′ triiodothyronine (reverse I3) are formed.

The N-terminal and the central part of the monomer includes three types of repetitive motifs comprising cysteine-rich repeat domains covalently bound by disulfide bonds (11 type 1, 3 type 2, and 5 type 3).

The function of the 11 type 1 cysteine-rich repeats in the molecule, which is described in bovine and human Tg, is not clear. It has been shown that these repeats are protein modules that can act as pH-dependent binders and reversible inhibitors of the proteases implicated in Tg degradation and thyroxine release.

ACHE-like domain is required for protein dimerization and consequently plays a critical structural and functional role in the TG protein, that is essential for intracellular transport of TG to the site of its hormonogenesis.

Three conserved thioredoxin boxes have been identified in mammalian Tg, and studies on a bovine Tg fragment revealed a role for these boxes in self-assisted disulfide-bond formation leading to the intramolecular cross-linking of luminal Tg.

In rat Tg, the heparin-binding domain is proposed to bind to megalin that participates in the endocytosis of Tg–T4 complexes from the follicular lumen.

Thyroglobulin Synthesis Defects

The Tg synthesis defect has been studied extensively in three animal species. In Afrikander cattle, a homozygous nonsense mutation in exon 9 results in truncated Tg protein of 75 kDa due to the conversion of arginine 697 to a premature stop codon. In this case, an alternatively spliced mRNA lacking exon 9 sequence also is present, encoding a Tg protein of 250 kDa. In Dutch goats, a homozygous nonsense mutation in exon 8 changes tyrosine 296 to a stop and results in a truncated Tg protein of 40 kDa, causing hypothyroidism with goiter. Administration of extra iodine to homozygous mutant Dutch goats restores euthyroidism, but goiter persists. Furthermore, in a mouse model (cog/cog mouse), congenital goiter is linked to the Tg locus and is caused by the transition of leucine 2366 in the Tg protein to proline. This defect results in an ER storage disease.

Patients with this autosomal-recessive condition display a wide range of thyroid dysfunction, ranging from severe hypothyroidism to euthyroidism, congenital goiter or goiter appearing shortly after birth and elevated thyroidal radioiodine uptake. The plasma Tg concentration is usually low, especially in relation to the thyroid-stimulating hormone (TSH) concentration, and intravenous injection of TSH does not increase the plasma Tg concentration. Patients classified in the category "Tg synthesis defects" often have abnormal circulating iodoproteins, mainly iodinated albumin, and excrete iodopeptides of low molecular weight in the urine.

To date, one hundred seventeen deleterious mutations in the human TG gene have.

been identified: 19 splice site mutations, 23 nonsense mutations, 57 missense mutations,13 deletions and 4 single nucleotide insertions or duplication. Mutations of TG gene have been also associated with endemic and nonendemic simple goiter. The p.

C1058R and p.C1977S mutations are the most frequently identified TG mutations in Japanese population, whereas the frequent mutation p.R277* is found in Caucasian populations.

Nucleotide substitutions or deletion in acceptor or donor splice sites can cause exon skipping in the TG gene resulting in an altered ability to transfer an iodophenoxyl group from the donor site to the acceptor iodotyrosine.

The 23 nonsense mutations generate truncated proteins missing functional domain and could represent targets for nonsense mediated mRNA decay (NMD) pathway, a RNA surveillance mechanism that degrades mRNAs containing premature terminated codons.

Sixteen missense mutations involved Cys residue and may eliminate disulfide bonds and alter the normal conformational structure of the TG, possibly preventing the interaction of hormonogenic acceptor and donor sites. Finally, nine missense mutations were reported in the ACHE homology domain: functional analyses indicate that these mutations may result in retention of the TG protein inside the ER and degradation via the proteasome system, as already observed in the cog/cog congenital goiter mouse (Targovnik *et al.*, 2011).

Serum Thyroid Hormone-Binding Proteins

Luigi Bartalena and Eliana Piantanida, University of Insubria, Varese, Italy

Glossary

Free thyroid hormone The fraction of thyroxine (0.03%) and triiodothyronine (0.3%) not bound to thyroid hormone-binding proteins and metabolically active at the tissue level.

Thyroxine-binding globulin The major thyroid hormone-binding protein; it binds two-thirds to three-fourths of thyroid hormone in serum.

Thyroxine-binding globulin deficiency and excess Conditions characterized by a deficiency or excess, respectively, of the major thyroid hormone-binding protein; both thyroxine-binding globulin deficiency and thyroxine-binding globulin excess can be either acquired or inherited (X-linked).

Transthyretin A protein involved in the transport of both thyroid hormones and retinol-binding protein, thus being involved also in vitamin A transport.

Introduction

Thyroid hormones, thyroxine (T_4), and triiodothyronine (T_3), are reversibly bound in the bloodstream to a set of carrier proteins (thyroid hormone-binding proteins) mostly of liver origin (Bartalena, 1990). Major thyroid hormone-binding proteins include thyroxine-binding globulin, transthyretin, and albumin. These three proteins account for the binding of most thyroid hormone (95%) (Bartalena and Robbins, 1993). Minor thyroid hormone-binding proteins include lipoproteins (about 5% binding) and, under certain circumstances, immunoglobulins (both IgM and IgG) (**Table 1**). (Benvenga, 2013; Benvenga and Robbins, 1993). The interaction of thyroid hormone-binding proteins with thyroid hormones is such that most T_4 (99.97%) and T_3 (99.7%) are bound, and only a minute fraction of thyroid hormone is unbound or free. The latter, however, is metabolically active at the tissue level, thus accounting for thyroid status. Acute variations in thyroid hormone synthesis and secretion are followed by changes in the proportion of bound hormone, which allow maintenance of the normal free thyroid hormone concentration (Bartalena, 1990). Thus, thyroid hormone-binding proteins exert a buffering action that protects the body against acute variations in thyroid hormone production. Furthermore, thyroid hormone-binding proteins form an important extrathyroidal pool of thyroid hormone and may facilitate its uniform cellular distribution. Thyroid hormone-binding proteins may also help to avoid iodine urinary loss by conferring macromolecule properties to the small thyroid hormone molecules. Finally, thyroxine-binding globulin, like corticosteroid-binding globulin, may be involved in targeting the amount of delivered hormone by its site-specific, enzymatic cleavage (Benvenga, 2013). In this regard, release of thyroid hormone from thyroxine-binding globulinat the infected/inflamed tissue site might provide a relevant amount of iodide and iodine for a significant bactericidal/antiinflammatory action.

Molecular and Physicochemical Properties of Thyroid Hormone-Binding Proteins

Thyroxine Binding Globulin

Thyroxine-binding globulin is a 54-kDa single-polypeptide chain glycoprotein synthesized by the liver. The single-copy gene encoding for human thyroxine-binding globulin, located on the long arm of the X chromosome (Xq22.2), consists of five exons spanning 5.5 kilobase pairs. The mature protein is composed of 395 amino acids. The amino acid sequence of human thyroxine-binding globulinhas revealed a high degree of homology with other members of the serine protease inhibitors (SERPIN) family, including corticosteroid-binding globulin, α_1-antitrypsin, and α_1-antichymotrypsin.

Thyroxine-binding globulin contains approximately 20% of carbohydrates by weight organized in four asparagine-linked oligosaccharide chains with an average of 10 sialic acid residues. Carbohydrates affect the half-life of thyroxine-binding globulin in serum since deglycosylation is associated with a rapid clearance of the protein by the liver. In addition, deglycosylation slightly reduces thyroxine-binding globulin immunoreactivity, T_4-binding activity, and stability. Thyroxine-binding globulinhas only one binding site for thyroid hormones, and binds T_4 with a higher affinity than T_3. Because of its very high affinity for thyroid hormones, thyroxine-binding globulin, although present in serum at a much lower concentration than transthyretin or albumin, binds approximately 65% of T_4 and 75% of T_3 (**Table 1**).

Thyroxine-binding globulin concentration in normal adult human serum ranges from 12 to 20 mg/L (**Table 2**), with a maximal T_4-binding capacity of 0.14–0.25 mg T_4/L. Thyroxine-binding globulin is detectable in the 12-week-old fetus; concentrations in newborns are higher than in adults, decline until mid adulthood, and increase in the elderly.

Site of synthesis	Liver	Liver Choroid Plexus Retina Pancreas	Liver

TBG: Thyroxine-Binding Globulin; *TTR*: Transthyretin.

Transthyretin

Transthyretin is a 56-kDa nonglycosylated protein composed of four identical 127-amino acid subunits, (**Table 2**). Transthyretin has two identical thyroid hormone binding sites, but normally only one of them is occupied. The normal serum transthyretin concentration is 250 mg/L (**Table 2**), corresponding to maximal binding capacity of 2 mg T_4/L. Transthyretin binds approximately 10% of T_4 and 10% of T_3. In addition, transthyretin also binds retinol-binding protein, thereby being involved in vitamin A transport. Transthyretin is mostly of liver origin, but it is also synthesized in pancreatic islet cells, retina, and epithelial cells of choroid plexus in both rats and humans. Transthyretin synthesized in the choroid plexus may be important for brain development by maintaining the appropriate T_4 concentration in the central nervous system and favoring its uniform distribution in different areas of the central nervous system (Bartalena, 1990).

The single-copy transthyretin gene is located on chromosome 18 and composed of four exons spanning 7.3 kilobase pairs. The 5′-flanking region has a highly homologous DNA sequence across species, suggesting its crucial role in the regulation of transthyretin gene expression.

Albumin

Albumin is a 66-kDa nonglycosylated protein composed of 585 amino acids (**Table 2**). It has a relatively strong binding site for thyroid hormone and several additional sites with much lower affinity. Its serum concentration is very high (40 g/L), and the percentage of thyroid hormone bound to albumin is about 20% of T_4 and 10% of T_3.

The single-copy albumin gene is located on the long arm of chromosome 4, linked to vitamin D-binding α_2-globulin, whereas in mice the gene is located on chromosome 5, close to the α-fetoprotein gene. There is 90% homology between the human albumin gene and the corresponding gene in rodents. Most automated methods, however, are liable to unpredictable and variable artefacts, which clinicians should be aware of.

Lipoproteins

Lipoproteins are complex molecules composed of a protein moiety (apolipoprotein) and a lipid (both polar and nonpolar) moiety. They bind approximately 3% of T_4 and 6% of T_3. High-density lipoproteins are the major lipoprotein plasma carriers of thyroid hormones through a specific interaction with their apolipoproteins (A-I, A-II, A-IV, C-I, C-II, C-III, and E). These

apolipoproteins have a single thyroid hormone binding site encoded by exon 3 (exon 2 for apolipoprotein A-IV) of the respective gene. The thyroid hormone binding site on apolipoproteins is distinct from the apolipoprotein portion that binds to cell lipoprotein receptors. The physiological role of thyroid hormone binding to lipoproteins is unsettled, but lipoproteins may facilitate enterohepatic circulation, transplacental passage, and central nervous system distribution of thyroid hormones, and they may be involved in thyroid hormone delivery to target tissues with cell surface receptors for apolipoproteins (Benvenga, 2013).

Variations in Thyroid Hormone-Binding Proteins

Acquired Variations

Thyroxine binding globulin

Many drugs and pathophysiologic conditions (**Table 3**) cause changes in the serum TBG concentration, through variations in either thyroxine-binding globulin synthesis or metabolic clearance rate. Hyperthyroidism and hypothyroidism cause a slight decrease and increase, respectively, in serum thyroxine-binding globulin levels by affecting liver synthesis of the protein. Pregnancy and estrogen therapy cause an increase in serum thyroxine-binding globulin concentrations likely due to the longer half-life of thyroxine-binding globulin in the circulation because of estrogen-induced increased sialylation of the protein. Serum thyroxine-binding globulin values are also increased in patients with acute or chronic hepatitis and in a significant proportion of cases of hepatocarcinoma. Whereas in hepatitis the increase in thyroxine-binding globulin is probably the consequence of thyroxine-binding globulin release from damaged liver cells, in hepatocarcinoma the underlying mechanism may be increased liver synthesis of thyroxine-binding globulin. Patients with nephrotic syndrome have a reduced thyroxine-binding globulin concentration due to massive renal protein loss. Losses of TBG through peritoneal membrane are likely to account for the decrease in the thyroxine-binding globulin concentration observed in patients with chronic renal failure undergoing regular peritoneal dialysis. Serum thyroxine-binding globulin (but not corticosteroid-binding globulin) levels are increased in AIDS patients, possibly due to associated hepatitis or to a specific enhancement of thyroxine-binding globulin hepatic synthesis. Patients with diabetic ketoacidosis often have decreased serum thyroxine-binding globulin levels, which might be related to the lack of stimulation of liver protein synthesis by insulin. Starvation or extreme protein-calorie malnutrition cause a decrease in serum thyroxine-binding globulin concentration likely related to decreased hepatic synthesis of the protein. These effects, as well the decrease in thyroxine-binding globulin that occurs in severe terminal illness, may be mediated by inhibition of thyroxine-binding globulin synthesis caused by interleukin-6. Minor variations in serum thyroxine-binding globulin concentration have been reported in several other pathophysiologic conditions (**Table 3**).

Table 3 Acquired serum thyroxine-binding globulin (TBG) variations

Condition/drug	*Serum TBG concentration*
Hypothyroidism	Increased
Pregnancy	Increased
Acute and chronic hepatitis	Increased
Hepatocellular carcinoma	Increased
AIDS	Increased
Oat Cell Carcinoma	Increased
Estrogens	Increased
Perphenazine	Increased
5-Fluorouracil	Increased
Heroin, Methadone	Increased
Clofibrate	Increased
Mitotane	Increased
Hyperthyroidism	Decreased
Nephrotic syndrome	Decreased
Chronic renal failure	Decreased
Diabetic ketoacidosis	Decreased
Starvation	Decreased
Cushing syndrome	Decreased
Acromegaly	Decreased
Androgens	Decreased
Anabolic steroids	Decreased
Glucocorticoids	Decreased
L-Asparaginase	Decreased
Interleukin-6	Decreased

Table 4 Acquired serum transthyretin (TTR) variations

Condition/drug	*Serum TTR concentration*
Insulinoma	Increased
Glucagonoma	Increased
Gastrointestinal carcinoids	Increased
Depression	Increased
Androgens	Increased
Anabolic Steroids	Increased
Glucocorticoids	Increased
Perphenazine	Increased
Parkinson's disease	Increased
Protein-calorie malnutrition	Decreased
Liver diseases	Decreased
Nephrotic syndrome	Decreased
Cystic fibrosis	Decreased
Estrogens	Decreased

In addition to estrogens, other drugs cause an increase in serum thyroxine-binding globulin concentration, including 5-fluorouracil, clofibrate, heroin, and methadone (**Table 3**). Conversely, administration of androgens, anabolic steroids, glucocorticoids, and L-asparaginase decreases serum thyroxine-binding globulin levels (**Table 3**) (Bartalena, 1990).

Transthyretin

The serum transthyretin concentration is often decreased in patients with severe nonthyroidal illness, particularly during protein-calorie malnutrition, nephrotic syndrome, liver diseases, and cystic fibrosis (**Table 4**). In such circumstances, serum transthyretin levels decrease, whereas TBG and albumin concentrations may remain normal. Both decreased liver synthesis of transthyretin (possibly mediated by interleukin-6) and its accelerated degradation contribute to these changes. Transthyretin may be increased in patients with pancreatic endocrine tumors (insulinomas or glucagonomas) or gastrointestinal carcinoids, probably due to transthyretin synthesis by the neoplasm. Transthyretin levels are increased in the central nervous system but not in the serum of patients with endogenous depression or with Parkinson's disease (after adrenal medullary autotransplantation). These changes probably reflect an increased transthyretin synthesis by the choroid plexus. Many drugs affect serum transthyretin concentration, and the effect is often the converse of that on thyroxine-binding globulin. Thus, estrogens decrease serum transthyretin concentration and androgens, anabolic steroids, and glucocorticoids increase serum transthyretin concentrations (**Table 4**). Although the underlying mechanisms are not completely understood, variations in transthyretin synthesis likely contribute to these changes (Benvenga, 2013).

Albumin

The albumin concentration is decreased in many acute and chronic nonthyroidal illnesses. These variations occur concomitantly and are always associated with the previously mentioned similar changes in serum TBG and TTR concentrations.

Inherited Variations

Thyroxine binding globulin

Familial forms of thyroxine-binding globulin deficiency and thyroxine-binding globulin excess, both inherited as X-linked traits, exist (Ferrara *et al.*, 2015). These defects involve the thyroxine-binding globulin gene rather than the rate of thyroxine-binding globulin disposal. Complete thyroxine-binding globulin deficiency, partial thyroxine-binding globulin deficiency, and thyroxine-binding globulin excess are distinguished according to serum thyroxine-binding globulin levels in hemizygous subjects. When TBG deficiency is complete, affected males have no detectable thyroxine-binding globulin in serum, whereas carrier females have half the normal serum thyroxine-binding globulin levels. In partial thyroxine-binding globulin deficiency, serum thyroxine-binding globulin, concentration in heterozygous females is usually higher than half the normal value. In the presence of excess thyroxine-binding globulin, the serum concentration of the protein is usually two- to fourfold higher than normal.

Complete thyroxine-binding globulin deficiency occurs in about 1 in 15,000 newborn males (Refetoff, 1990). 27 thyroxine-binding globulin variants have been associated with complete thyroxine-binding globulin deficiency. In most cases, a single nucleotide substitution, a frameshift due to nucleotide deletion, or multiple nucleotide deletions are the mechanisms leading to early termination of translation and truncation of the thyroxine-binding globulin molecule. Mutations may also occur outside the coding region of the thyroxine-binding globulin gene.

Partial thyroxine-binding globulin deficiency is more common and occurs in 1 in 4000 newborns. 18 different thyroxine-binding globulin variants, characterized by missense variations, cause variable degrees of decreases in the serum thyroxine-binding

globulin concentration. Some of these variants are unstable, have a reduced binding affinity for T_4 and T_3, or show an abnormal migration pattern on isoelectric focusing. In 5% of families studied in Refetoff's laboratory in Chicago, the thyroxine-binding globulin deficiency was not due to mutations in the thyroxine-binding globulin gene, but rather in a liver-specific enhancer, whose activity was reduced.

Inherited thyroxine-binding globulin, excess is rare and occurs in about 1 in 25,000–30,000 newborns. The pathophysiological basis of thyroxine-binding globulin excess has been shown to be thyroxine-binding globulin gene amplification (duplication and triplication), whereas no mutations in the coding and promoting regions have been detected.

Transthyretin

Many transthyretin variants characterized by single amino acid substitutions have been described, mostly in patients with familial amyloidotic polyneuropathy, amyloidotic cardiomyopathy, or senile systemic amyloidosis (Pappa *et al.*, 2015). Some of these transthyretin variants have a reduced binding affinity for thyroid hormone. A different transthyretin variant characterized by an increased affinity for T_4 is responsible for a pattern of euthyroid hyperthyroxinemia (i.e., transthyretin-associated hyperthyroxinemia).

Albumin

A well-characterized inherited albumin variation transmitted as an autosomal dominant trait is familial dysalbuminemic hyperthyroxinemia, which is characterized by the presence in serum of an albumin variant with increased affinity for thyroid hormones. In many cases, the albumin variant has increased affinity for T_4 only; in other instances, an increased affinity for T_3 and/or reverse T_3 is also present. Three different single nucleotide substitutions have been identified as the molecular basis for the increased albumin affinity for thyroid hormone.

The inherited absence of albumin (analbuminemia) and the polymorphism called bisalbuminemia have negligible effects on thyroid hormone transport because the decrease in albumin levels is partially compensated for by a slight increase in TBG and TTR levels.

Effects of Variations in Thyroid Hormone-Binding Proteins on Thyroid Function Tests

Variations in thyroid hormone-binding protein concentrations or affinity profoundly affect serum total thyroid hormone concentrations. This is particularly true for thyroxine-binding globulin because it has a major role in thyroid hormone binding. Accordingly, a decrease or an increase in the serum thyroxine-binding globulin concentration lead to a decrease or an increase, respectively, in serum total thyroid hormone levels. Although the latter changes are similar to those found in hypothyroidism and hyperthyroidism, respectively, they do not reflect thyroid hypofunction or hyperfunction because they are not associated with variations in the metabolically active, free (unbound) thyroid hormone fraction. Similar considerations are tenable for Familial Dysalbuminemic hyperthyroxinemia and transthyretin-associated hyperthyroxinemia. Therefore, thyroxine-binding globulin excess, familial dysalbuminemic hyperthyroxinemia, and transthyretin-associated hyperthyroxinemia are among the most important causes of euthyroid hyperthyroxinemia. The latter may be independent of thyroid hormone-binding protein variations and caused by drugs (e.g., amiodarone, propranolol, iodinated contrast agents, and L-thyroxine), resistance to thyroid hormones, or the acute phase of some psychiatric disorders (**Table 5**).

Thus, should serum total thyroid hormone measurement provide results that are in contrast with the clinical picture, a thyroid hormone-binding proteins abnormality should be suspected and searched for. The correct definition of thyroid status requires measurement of serum free thyroid hormones and thyrotropin concentrations. This approach is particularly useful when thyroid hormone-binding proteins (e.g., thyroxine-binding globulin excess or familial dysalbuminemic hyperthyroxinemia) coexist with thyroid disorders, such as Graves' disease or Hashimoto's thyroiditis. In these circumstances, serum total thyroid hormone levels may be normal in hypothyroid patients, whereas the increased levels of hyperthyroid patients may not easily be distinguished from the increased concentrations due to thyroid hormone-binding protein abnormalities.

Table 5 Causes of euthyroid hyperthyroxinemia

Thyroxine-binding globulin excess
Transthyretin-associated hyperthyroxinemia
Familial dysalbuminemic hyperthyroxinemia
Amiodarone
Propranolol
Iodinated contrast agents
L-thyroxine therapy
Resistance to thyroid hormone
Acute phase of psychiatric disorders

Because serum free thyroid hormone determination is crucial for the assessment of thyroid status and to avoid inappropriate treatment for hyperthyroidism or hypothyroidism, it is essential to select methods for free thyroid hormone measurement that are not affected by the abnormal thyroid hormone-binding protein concentration or affinity. The two-step methods in which free hormone is first separated from protein-bound hormone by dialysis, ultrafiltration, column adsorption chromatography, or immunoadsorption provide the most reliable results. In fact, in the second step (immunoassay) the tracer is not in contact with thyroid hormone-binding proteins, thus preventing interaction between the two and consequent artifactual results.

Conclusions

Thyroid hormone-binding proteins exert functions that are important for thyroid physiology. They provide a buffering action, preventing abrupt changes in serum thyroid hormone levels; function as a storage system for thyroid hormones; they are involved in targeted delivery of thyroid hormone at the tissue level, thus facilitating thyroid hormone cellular distribution. TBG is the major thyroid hormone-binding protein in serum since it binds approximately two-thirds to three-fourths of T_4 and T_3. Both inherited and acquired variations of the major thyroid hormone-binding proteins (thyroxine-binding globulin, transthyretin, and albumin) have been demonstrated. These variations do not modify thyroid status but do affect the results of serum total thyroid hormone measurement and may lead to incorrect diagnosis and inappropriate treatment for hyperthyroidism or hypothyroidism. Thus, for a correct definition of thyroid status, determination of free T_4 and T_3 by assays that are not influenced by thyroid hormone-binding proteins is required.

Glossary

Cofactor (corepressor or coactivator) Ancillary molecule that binds to the nuclear receptor and dictates the negative or positive response to the receptor. Basically a corepressor binds to an unliganded receptor and is released upon binding of the ligand, which allows for the binding of the coactivator. The cofactors interact with the transcription machinery.

Dimerization Association of two molecules of the receptor. This can be an homodimerization (two molecules of the thyroid hormone receptor) or an heterodimerization (one molecule of thyroid hormone receptor and one molecule of retinoic acid receptor).

Transcription machinery All the molecular complex assembled on the regulatory region of the genes.

Dominant negative effect Disturbance of the functioning of the normal receptor (wild-type receptor) by a mutant receptor or an inactive isoform.

The thyroid hormones exert their biological effects essentially through a classical pathway grounded by nuclear receptors (Cheng *et al.*, 2010; Sap *et al.*, 1986), the so-called thyroid hormones receptors (TRs). There is also growing evidence of a nonclassical pathway involving membrane receptors (Davis *et al.*, 2016). The biological effects of the two pathways are also named genomic effects, a regulation of the expression of target genes on the one hand, and nongenomic effects, usually more rapid effects, on the other hand. The present article will concentrate on the classical pathway.

Mechanisms of Action of Thyroid Hormones on Their Nuclear Receptors

The nuclear thyroid hormone receptors (TRs) belong to the superfamily of nuclear receptors (Cheng *et al.*, 2010), as well as steroid receptors, vitamin D receptor, and retinoic acid receptors.

They bind to specific regions of the genes that they regulate, the hormone responsive elements (made of two half sites), here the TRE for thyroid hormone responsive elements (**Fig. 1**), and influence positively or negatively the transcription of the genes, that is the production of the messenger RNA. This regulation of the gene transcription is mediated by an interaction between the TR and either coactivators or corepressors, and then with histone acetylase/deacetylase system. The TR is thus a piece of the transcription machinery, similarly to other nuclear receptors (Cheng *et al.*, 2010; Vella and Hollenberg, 2017).

However, the TR behaves differently with other steroid receptors in that it is already localized in the nucleus of the cells and bound to the TREs in absence of the ligand. This unliganded TRE-bound state already participates to the regulation of transcription of the target gene: repression if the gene is positively regulated by thyroid hormones, or activation if it is a negatively regulated gene. Surprisingly, owing to the tremendous amount of studies on the field, the mechanism of negative regulation by thyroid hormones, that is, the regulation of TSH, is still poorly understood (Vella and Hollenberg, 2017).

In addition, the TR can bind as monomer, as homodimer and can heterodimerize with the retinoic acid receptor RXR (Cheng *et al.*, 2010; Williams *et al.*, 1991; Yen, 2001). The binding as monomer, homodimer or heterodimer is probably dictated by the spatial organization of the TREs, as well as the liganded/unliganded state.

The DNA binding of the TR, as well as the interaction with dimerization partners and cofactors should be viewed as a dynamic, permanently changing process, rather than a static combination, although the latter is a helpful model to describe the transcription machinery.

The Thyroid Hormone Receptor Protein Structure

Like the other nuclear receptors, the TRs are modular structures built of several domains (Cheng *et al.*, 2010; Yen, 2001), (**Fig. 2**).

The DNA binding domain, the C domain, includes two zing fingers responsible for the contact and the specificity of binding to TREs. Each zinc finger contains four cysteines coordinated by a zinc anion. Two regions, the P and D boxes, also participate in the specificity of recognition of the DNA sequence and of the spacing between the two half sites of the TRE.

☆*Change History:* March 2018. Claire Briet, Frederic Illouz and Patrice Rodien participated to the *de novo* writing of this chapter. Figure 1 is a new one. Figure 2 is the simplified version of previous figure 2.

 doi:10.1016/B978-0-12-801238-3.96026-4

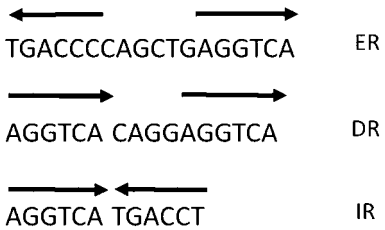

Fig. 1 Thyroid hormone responsive elements (TRE). The two half sites AGGTCA are shown in different orientations. *ER*: Everted repeat, *DR*: Direct repeat with four nucleotide space, *IR*: Inverted repeat or palindrome.

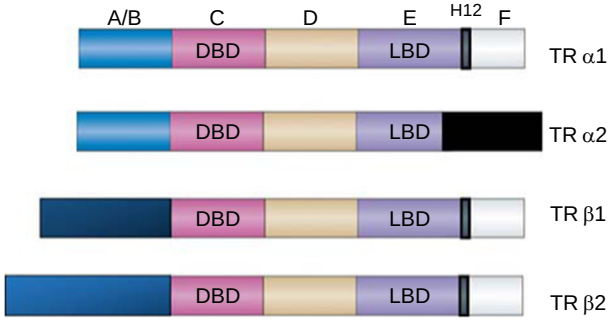

Fig. 2 Structure of the four main isoforms of thyroid hormone receptors with domains A–F indicated. *DBD*: DNA binding domain, *LBD*: ligand binding domain, *H12* Helix 12.

The ligand binding domain, also named the E/F domain, is made of several alpha helixes, delimitating the ligand pocket. The twelfths and last helix can adopt different positions depending on the presence or absence of the ligand. In brief, it moves from a mobile and remote position in absence of ligand to a closer and fixed position and closes the ligand pocket, as the lid of a mouse trap. In addition, by contacting the other parts of the ligand binding domain, it masks the anchoring sites for the corepressors which can no longer bind to the receptor, and contributes to the delineation of the anchoring surface for the coactivators. Again the opening/closing of the binding pocket as well as the blockade/liberation of the anchoring sites for cofactors have to be envied as dynamic processes with specific configurations favored rather than frozen by the binding to DNA, ligand and cofactors. The ligand binding domain also includes some regions involved in the homo or heterodimerization.

It is largely accepted that the active ligand of the TRs is triiodothyronine (T3) and that T4 is essentially a prohormone. More recently, it was shown that T4 can also activate the TRα in some conditions. This may depend on the cellular context (Schroeder *et al.*, 2014).

The D domain, also called the hinge region, between the DNA binding domain and the ligand binding domain, is involved in the biding of corepressors, whereas the A/C domain is involved in the binding of coactivators.

Much information has been obtained with the study of truncated or chimeric forms of the TRs which has allowed to identify different regions spread along the linear representation of the protein and preferentially interacting with DNA, ligand, cofactors, dimerization partners. This makes it hard to understand how the receptor functions. Only the three dimensional structure, in models and cristalls, can reconcile all the data by packing remote distant regions together, and building the functional domains.

Several Isoforms With Different Tissue Distributions

There are two genes in human, encoding the TRs. The α gene (THRA), c-erbA-α is located on chromosome 17 and the β gene (THRB) c-erbA-β on chromosome 3. From both genes are several isoforms produced: TRα1 and 2 and TRβ 1,2 and TRβ3 (at least in rodents) (Williams, 2000). The different isoforms are produced by alternate splicing and different transcription starting sites. Also an additional gene is present on the c-erbA-α locus on the reverse direction, coding for rev-erb α and β, involved in the circadian rythms and metabolic regulations (Kojetin and Burris, 2014).

The TRα1, β1, and β2 are *bona fida* receptors for thyroid hormones, whereas TRα2 has a truncated ligand binding domain and does not transmit the thyroid hormones signal. Truncated forms of TRα and TRβ, lacking the DNA binding domain, but able to bind the hormone have also been described (Chassande *et al.*, 1997).

The role of TRα2 and the truncated forms is still mysterious. TRα2 has been shown to be able to inhibit the function of the other TRs, in vitro, when dimerization with them. However, the physiological role of such a dominant negative effect in vivo, is not known so far. Similarly, the truncated forms, unable to bind DNA, may be able to regulate the activity of full length receptors (Chassande *et al.*, 1997).

The different TRs have preferential, not exclusive, organ and tissue distribution which leads to the concept of α or β regulation in different organs (Cheng *et al.*, 2010).

For example, the hypothalamus and pituitary gland functions are mainly regulated by the TRβ receptors especially the TRβ2. The liver mainly expresses the β1 receptor, whereas the heart can be seen as an α organ, as well as the brain. This is, however, an oversimplification, as TRα1 is also active in the liver, some genes in the heart are also regulated by the TRβ, though less importantly than TRα, and, the heart rhythm is largely dependent on TRα. The bone development appears mainly dependent on TRα, but TRβ is also involved. Finally it was shown that the high TSH observed in TRβ KO mice, as expected, was further increased by the double knock out TRα and TRβ (Gauthier *et al.*, 1999, 2001; Macchia *et al.*, 2001). This illustrates the redundancy, overlap and possible rescue between the different isoforms.

The preferential regulation by TRα or TRβ of different genes is thus the result of the relative expression of the isoforms in the organ, and as nicely shown in the liver, of the nonhomogenous expression of both the target genes and the TR isoforms in the same organ (Zandieh Doulabi *et al.*, 2002). In addition, the availability of the different coactivators and corepressors will modulate the effect of thyroid hormones differently in different cells.

Targeting Specific Isoforms for Specific Effects

Some biological effects of thyroid hormones, may be sought out in therapeutic. Among them, the capacity to lower blood cholesterol which is dependent on TRβ1 is a pharmaceutical goal. However, the α effects such as the heart and bone response to thyroid hormones, limit their potential use in metabolic disease. Targeting exclusively the TRβ, leaving the TRα unaffected, with specific agonist is thus an interesting approach for metabolic disorder. TRβ agonists have been largely investigated, with success in animal models. There are less data in human models and some concerns on potential liver and cartilage toxicity have emerged (Delitala *et al.*, 2017; Ladenson *et al.*, 2010; Sjouke *et al.*, 2014). However, it should be kept in mind that the isoform specificity of these agonists is far from perfect. Indeed some agonists do only display a preferential binding and activation of TRβ rather than an exclusive one, with a very small difference in affinity for both α and β receptors (Borngraeber *et al.*, 2003). Due to the high homology of TRα and TRβ ligand binding domains, it is indeed quite surprising that it was possible to design specific agonists (Wagner *et al.*, 2001). Also, as mentioned above, it appears that T4, can be a ligand for TRα, depending on the type of coactivator interacting with the receptor (Schroeder *et al.*, 2014). The organ specificity agonists also relays on tissue diffusion of the agonist (Takahashi and Izuchi, 2016; Trost *et al.*, 2000).

In addition, if targeting the TRβ to lower cholesterol in order to prevent or treat metabolic disorders appears efficient, it was shown that the fat deposition in arteries, leading to atheroma, is dependent on TRα (Billon *et al.*, 2014).

Along with the design of isoform specific agonists, the design of specific antagonists may be of value (Baxter *et al.*, 2002). For example, antagonizing the TRα, may be of help in treating heart rhythm disorders, or osteoporosis. In fact, desethylamiodarone, the active metabolite of amiodarone, has been shown to be an antagonist of TRα and TRβ (van Beeren *et al.*, 1996). This may participate in its antiarrhythmic action.

Human Rare Diseases of Thyroid Hormone Receptors

The resistance to thyroid hormone (RTH) syndrome has been of great value to understand the mechanisms of action of TRβ (Dumitrescu and Refetoff, 2013). Indeed the heterozygous state of loss of function mutations in patients affected by the syndrome, in agreement with the autosomal dominant transmission, leads to the concept of dominant negative effect, explained by the homo or heterodimerization of the TRs.

The more recent description of first cases of patients harboring TRα mutations will undoubtly lead to a better comprehension of the distinct roles of TRα and TRβ. Interestingly, in the majority of cases with mutations affecting both TRα1 and TRα2, the phenotype was not different from the one in patients harboring a mutation affecting exclusively TRα1 (Moran and Chatterjee, 2015).

Thyroid Hormone Action☆

Yui Watanabe and Roy E Weiss, University of Miami Miller School of Medicine, Miami, FL, United States

Glossary

ATPase Any enzyme that converts energy-rich ATP to ADP to catalyze a process.

Coactivator Class of proteins that can bind to regulatory transcription factors. The intrinsic histone-modifying activity of coactivators leads to activation of transcription.

Corepressor Class of ubiquitous proteins that can form a physical link between regulatory transcription factors and enzymes that modify histone proteins so that transcription is repressed.

Deiodinase Group of three enzymes that catalyze the removal of an iodine atom from iodothyronines. Iodothyronines may contain up to four iodine atoms. The principal actions are conversion of T_4 to T_3 by deiodinase type I and type II and conversion of T_4 and T_3 to reverse T_3 and T_2 by deiodinase type III.

Histone protein Highly abundant nuclear protein. In sets of four, it forms scaffolds around which DNA is wound.

Hormone response element Short, specific nucleotide sequence in the promoter of a gene that is recognized by the DNA-binding part of a hormone-dependent transcription factor. Examples are thyroid hormone response elements and estrogen response elements, which confer thyroid hormone and estrogen responsiveness, respectively, to the promoter.

Promoter Sequence of DNA that precedes the transcribed part of a gene and to which RNA polymerase binds to begin transcription. A promoter may be several thousand nucleotides long and contains multiple binding sites for transcription factors.

RNA polymerase Enzyme that catalyzes the synthesis of an RNA molecule on a DNA template. The DNA sequence of a gene is thus transcribed into messenger RNA, which is subsequently translated into protein.

Transcription factor Any protein that is required to initiate or regulate transcription. There are general factors and gene-specific ones, such as DNA-binding hormone receptors.

Introduction

The two forms of thyroid hormone found in the circulation are T_4 (3,5,3′,5′-tetraiodothyronine or thyroxine) and T_3 (3,5,3′-triiodothyronine). Although T_3 is the biologically most active form, T_4 may elicit specific effects and in this article the singular form "thyroid hormone" is used to include both. Perhaps the best known examples indicating the wide range of effects of thyroid hormone are the induction and progression of metamorphosis in amphibians and the marked stimulation of the overall metabolic rate in mammals. Although critical fluctuations in circulating thyroid hormone levels occur during development and differentiation in most species, hormone levels are remarkably constant throughout life with a reproducible circadian fluctuation in most mammals and humans. Depending on the underlying mechanism, some effects of thyroid hormone are quite rapid, whereas most take hours, reflecting both the genomic and nongenomic pathways of thyroid hormone action.

Perhaps not surprising, the mechanisms by which thyroid hormone exerts its myriad effects are complex and certainly not completely understood. A large number of processes are directly affected by thyroid hormone, but the full physiological effect is often the result of additional, secondary effects. As appears to be the case for various steroid hormones, nonnuclear actions may contribute to the full spectrum of direct effects of thyroid hormone, but evidence for this is relatively sparse. In contrast, following the seminal work of Tata and Oppenheimer in the 1960s and 1970s it was generally accepted by the early 1980s that regulation of gene expression, mediated by nuclear thyroid hormone receptors (TRs), is the principal mechanism of action of the hormone. The independent discoveries of multiple T_3-binding nuclear receptors in 1986 opened the way to a detailed analysis of transcriptional regulation as the molecular basis of thyroid hormone action. This mode of action proves to be particularly complex, and together with an increasing amount of information on the role of local thyroid hormone metabolism in different tissues, it is becoming clear that thyroid hormone action can be modulated at the level of individual tissues throughout life.

☆*Change History*: January 2018. Evolution of Thyroid Hormone Action

Information on the origins and earliest effects of thyroid hormone has increased our understanding of the effects in higher organisms. A brief overview of the evolutionary development of thyroid hormone action and its major effects is therefore given, followed by a description of the mechanisms of action and the tissue-specific effects of thyroid hormone in mammals, including man.

Synthesis of Thyroid Hormone in Invertebrates

Spontaneous iodination of tyrosine residues in proteins occurs in the iodine-rich marine environment. Subsequent coupling of two iodinated tyrosines and digestion of proteins may release iodothyronines, including T_4 and T_3, and these thyroid hormones are indeed found in significant amounts in marine invertebrates. At least in some species of jellyfish, organification of iodine to form T_4 actually appears to play a role in the timing of the asexual reproductive cycle in a process called strobilation, which may be likened to metamorphosis in amphibians. T_4 production is therefore an ancient biochemical process with possibly a physiological role in the most primitive invertebrates, predating the evolution of specialized thyroid cells. Such cells are found in the immediate precursors of vertebrates, the protochordates (sea squirts). These cells actively form T_4-containing proteins but are not yet organized in the typical thyroid follicle structure. Furthermore, release and subsequent absorption of T_4 appear to be dependent on digestion of the secreted proteins in the gut.

Synthesis of Thyroid Hormone in Vertebrates

Follicular thyroid cells, in which thyroid cells enclose a follicular lumen containing iodinated proteins (thyroglobulin), are found in the most primitive living vertebrates, the sea lampreys. At this point in evolution, thyroid cells have acquired a protein-digesting enzyme that allows the release of T_4, and in adult lampreys the gland has become endocrine. Interestingly, during the larval stage of this organism, which lasts up to 5 years and constitutes the better part of its life, the thyroid cells are still nonfollicular and T_4 secretion is exocrine followed by absorption. Upon metamorphosis, these epithelial cells form thyroid follicles and secreted T_4 is then directly absorbed by the vascular system. Therefore, the development of the lamprey seems to recapitulate the evolutionary acquisition of the endocrine thyroid gland.

All vertebrates contain follicular thyroid cells, although the localization and organization into a discrete gland vary greatly, from scattered follicles in the subpharyngeal area in lampreys to follicles located mostly in the kidneys in fish, a disk-shaped gland next to the heart in turtles, two widely separated globules on either side of the trachea in birds, and a bilobed gland connected by an isthmus straddling the trachea in lizards, as is also the typical structure of the thyroid gland in all mammals. Despite these differences, the circulating levels of free T_3 and T_4 are within one order of magnitude throughout the vertebrate lineage, with the exception of some species of fish.

Modes of Action and Effects of Thyroid Hormone in Invertebrates

The presence of T_4 or T_3, particularly in marine organisms, is not proof of a physiological function given the spontaneous generation of iodothyronines under certain conditions. Nevertheless, iodothyronines appear to have effects in invertebrates as mentioned previously, although direct evidence for these effects is limited. A stronger case for a physiological role for thyroid hormone in primitive organisms is perhaps made by the presence of the specialized T_4-producing cells in lampreys. This has interesting implications for the primordial mode of action of thyroid hormone. Phylogenetic analysis of the large family of DNA-binding nuclear receptors, of which the TRs are members, shows that the common ancestral proteins were DNA-binding factors without ligand-binding properties. The capacity to selectively bind hormones and other regulatory compounds evolved relatively late. In the case of the thyroid receptors, it appears to have occurred during the development of the vertebrate lineage. The earliest effects of thyroid hormone must then be assumed to be extranuclear, and this mode of action may still be relevant in higher organisms.

Modes of Action and Effects of Thyroid Hormone in Vertebrates

Development of the large diversity of effects in vertebrates is linked to the adaptive progression of tissue distribution of the T_3 receptors (TRs) and mutations within the receptors allowing interactions with other DNA-binding proteins or accessory factors. Genes may have developed thyroid hormone responsiveness by acquiring the specific sequence in their promoter region that is required for binding of TRs. In contrast, the part of the receptor that recognizes this six-base pair sequence is highly conserved in this family of receptors and therefore not a factor in the diversification of T_3 action. Further development of (variable) tissue

responsiveness is probably also linked to the evolving expression patterns of the thyroid hormone-metabolizing deiodinases, which are present throughout the vertebrate lineage.

Growth and Development

The receptor-mediated effects of thyroid hormone on growth and development are evident in all vertebrates. The most striking of these is the transition of the larval amphibian from an aquatic vegetarian organism to a terrestrial carnivore. This experiment can be done with a salamander by simply adding T_4 to the aquarium water. The ensuing metamorphosis leads to radical changes in the appearance of the animal, including replacement of the fin-like tail and appendages with legs and claws and a round tail; replacement of a smooth skin with a thicker keratinized skin; the loss of gills and acquisition of lungs; development of eyelids; complete restructuring of the mouth, tongue, and intestinal tract to allow a mostly carnivorous diet; and numerous biochemical changes to accommodate a different respiratory and metabolic physiology. The increase in thyroid activity and thyroid hormone levels at metamorphic climax in amphibians triggers and sustains the process. Cells in all tissues undergoing metamorphic changes express TRs, and thyroid hormone induces or represses the expression of many genes. In addition, responsiveness of tissues is actually increased by T_3-dependent stimulation of the expression of TRs, as is the case in the restructuring of the tail. A surge in thyroid hormone levels is similarly critical in early growth and differentiation in fish, reptiles, and birds. All these effects have their counterparts in the fetal and perinatal development in mammals, particularly with respect to brain development. In humans, the critical involvement of thyroid hormone is illustrated by the striking and mostly irreversible effects of congenital hypothyroidism on growth, metabolism, reproduction, and mental development (cretinism). The surge in T_3 and T_4 levels reaches its peak in humans during the first 2 months after birth, coinciding with the phase of maximal cortical growth. This growth spurt starts during the third trimester when fetal thyroid activity increases and the dependence on maternal thyroid hormone wanes. However, thyroid hormone is required for central nervous system development beginning in the 10th week of fetal life, coinciding with the appearance of TRs in neuronal tissue. Relatively low levels of thyroid hormone are essential throughout intrauterine development to ensure proper timing and progression of the various phases of brain development. Studies in rats show that T_4 levels are critical because neurons preferentially take up this iodothyronine and then convert it to T_3. Monocarboxylate transporter 8 (MCT8) is a specific transporter of thyroid hormone and involved in thyroid hormone transport in the brain. Individuals with *MCT8* mutations have severe mental and neurological impairment. Studies of 3,5-diiodothyropropionic acid (DITPA), a thyroid hormone receptor agonist, have shown that it is dependent on MCT8 and is a potential therapy for the patients with *MCT8* mutations (Di Cosmo *et al.*, 2009).

Metabolism

The basal metabolic rate (BMR), which is the sum of all energy-consuming processes of an individual when completely at rest, is reduced in humans by 40% in hypothyroidism, whereas it is increased by 50% in hyperthyroidism. Thyroid hormone has essentially the same stimulatory effect on metabolism and concomitant O_2 consumption in other mammals and birds. It was previously thought that this effect played a crucial role in the evolutionary development of endothermy since metabolism in cold-blooded animals appeared unresponsive to thyroid hormone. However, this effect proved dependent on body temperature and the BMR of fish, amphibians, and reptiles is similarly responsive to T_3, albeit the extent of the effect is somewhat less than in mammals. Thyroid hormone does not appear to play a major role in thermoregulation in warm-blooded animals, and the effect on energy turnover, and hence heat production, is considered to be a second-order phenomenon.

The T_3-dependent stimulation of the BMR is the sum of increased energy consumption and substrate metabolism. The major energy-consuming processes in all tissues at rest are maintenance of the mitochondrial proton (H^+) gradient; maintenance of the gradients of calcium (Ca^{2+}), sodium (Na^+), and potassium (K^+) over various cellular membranes; and synthesis of DNA, RNA, and proteins. The effect on the BMR is not primarily the result of the stimulation of a single process, as has long been maintained for the effect of thyroid hormone on the sodium–potassium pump (Na^+–K^+-ATPase). Cellular ion homeostasis is nevertheless an important aspect of the effect of thyroid hormone on the BMR. This homeostasis involves the energy-dependent transport of Ca^{2+}, Na^+, and K^+ ions against gradients across the plasma membrane, as well as across intracellular membrane systems in the case of Ca^{2+}, to maintain their critical cytosolic concentrations. These processes account for a considerable part of the metabolic rate in mammals due to the passive and facilitated leak of ions through membranes. The expression and activity of the major ion-pumping ATPases are stimulated by thyroid hormone, as are the passive-leak characteristics of membranes. The proliferation of some intracellular membranes is also increased by thyroid hormone, and together these effects result in increased ion fluxes and ATP consumption. Proliferation of mitochondria as well as their capacity for oxidative phosphorylation are also stimulated by thyroid hormone, ensuring sufficient ATP production to meet the greater demand due to increased ion cycling and other processes.

To fuel the extra ATP turnover, thyroid hormone increases the rate of glucose production by the liver and increases the availability of the necessary substrates—amino acids, glycerol, and free fatty acids from proteins and fat. Thyroid hormone stimulates the breakdown of protein and fat, but at the same time it stimulates the synthesis of these compounds. This cycling of substrates, which consumes a considerable amount of energy, appears futile, but it allows for the regulated liberation of the substrates mentioned previously.

Which Iodothyronines Are Active in Mammals?

T_4 and T_3

The thyroid produces mainly T_4, whereas 80% of circulating T_3 results from peripheral enzymatic deiodination of T_4, predominantly in the liver. The protein-bound and free plasma levels of T_4 in all species that have been studied are substantially higher than those of T_3. In humans, the difference is approximately 40-fold for total hormone and 5-fold for free hormone. Nevertheless, as noted previously, T_3 is considered to be the active form of thyroid hormone in mammals. Although T_4 can affect the expression of thyroid hormone-responsive genes, the affinity of the thyroid hormone receptors for T_4 is considerably lower compared to that for T_3. In some thyroid hormone effects, such as the effect on neurons and the downregulation of pituitary thyroid-stimulating hormone (TSH or thyrotropin) production, T_3 cannot substitute for T_4 and T_4 appears to be the active form. In the latter case, as in neurons, the genes encoding the TSH-α and TSH-β subunits are indeed responsive to T_3, but the pituitary cellular T_3 content is determined by T_4 uptake and subsequent deiodination rather than by the plasma T_3 levels.

Other Iodothyronines

Progressive deiodination of T_4 and T_3 by the three known deiodinases gives rise to a number of different triiodothyronines and diiodothyronines. Of these, reverse T_3 (3,3′,5′-triiodothyronine) and 3,5-T_2 (3,5-diiodothyronine) have also been shown to elicit T_3-like effects. Because the affinity of the TRs for these compounds is negligible and the effects do not require de novo protein synthesis, the mechanism of action must be extranuclear. In the case of stimulation of mitochondrial activity by 3,5-T_2, it was indeed shown to involve a direct interaction of this iodothyronine with mitochondrial enzymes.

Enzymatic removal of the amino group (deamination) of T_4 and T_3 gives 3,5,3′,5′-tetraiodothyroacetic acid (Tetrac), 3,5,3′-triiodothyroacetic acid (Triac), and 3,5-diiodothyropropionic acid (DITPA), respectively. Tetrac can be deiodinated to Triac, and Triac has an even higher affinity for TRs than T_3. When administered at concentrations comparable to those of T_4 and T_3, these compounds show T_3-like effects. These thyroid hormone analogs have the potential to rescue thyroid hormone signaling (Groeneweg *et al.*, 2017a,b; Ferrara *et al.*, 2015).

Although it cannot be ruled out that in certain circumstances cellular concentrations of these metabolites may reach levels high enough to elicit significant effects, they are generally considered to be of little or no physiological relevance based on the known low plasma concentrations.

Mechanisms of Thyroid Hormone Action

In the following sections, the mechanisms of the primary actions of thyroid hormone are presented (i.e., those mediated by T_3 receptors and those that may involve direct interaction with a target). Additional actions may include effects on the stability of specific proteins or the messenger RNAs (mRNAs) encoding these proteins. However, there are few examples, and the mechanism is not understood. **Fig. 1** summarizes the modes of action that are discussed here. The first step in thyroid hormone action is actually transport of the thyroid hormone (T_3 or T_4) into the cell. We have learned much in the last several years about the classes of transporters responsible for intracellular thyroid hormone transport. Specifically the proton linked monocarboxylate transporter family, organic anion transporter family, L-type amino acid transporters, and Na^+-taurocholate co-transporting polypeptide have all been identified as thyroid hormone transporters across the blood–brain barrier and the intestinal wall (Groeneweg *et al.*, 2017c;

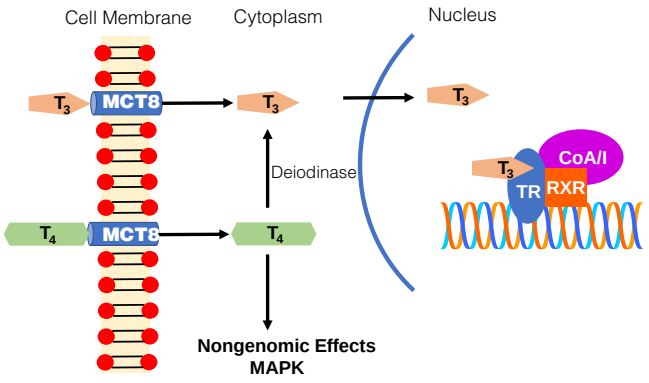

Fig. 1 Modes of action of thyroid hormone. T4 and T3 are actively taken up by the cell by specific transporters (MCT8). Deiodinases can convert T4 to T3 in the cytoplasm. T3 is translocated to the intranuclear milleu whereupon it binds to a complex of up to 40 proteins, one of which is a typical thyroid hormone receptor (TR). Once TH binds TR there is a release of the co-represors and retinoic acid x receptor (RXR) and recruitment of a coactivator. There is also a nongenomic pathway of TH action mediated by MAP-kinase (MAPK).

Brent, 2012). We do not have any information about the mechanism of transport of the thyroid hormone from the cytoplasm into the nucleus.

Extranuclear Action

Stimulation by T_4 and T_3 of the activity of the plasma membrane Ca^{2+}-pump (Ca^{2+}-ATPase) in red blood cells, which do not have a nucleus, is the best documented example of an extranuclear thyroid hormone effect. The in vitro effects correlate with increased activity of this enzyme in erythrocytes taken from hyperthyroid patients and decreased activity in those from hypothyroid patients. In vitro and in vivo studies also show that T_3 and T_4 stimulate glucose uptake in a variety of tissues, increase heart rate, and induce vasodilation, with effects appearing within minutes. Similarly, in various cultured cell types, the addition of physiological amounts of T_3 or T_4 almost instantly stimulates Ca^{2+} influx or the activity of proteins involved in cellular signaling processes. These effects, however, are transient and it is not clear whether they are relevant under normal conditions. The molecular mechanism underlying the mostly membrane-associated rapid effects is also unclear. There is evidence of a direct interaction of T_3 or T_4 with membrane-bound proteins, thereby altering their properties. Based on a large body of data, an alternative hypothesis proposes that T_3 and T_4 affect membrane properties in a less specific way by becoming part of it. The physicochemical properties of the molecules are such that the lipophilic, iodinated phenolic part inserts readily in the outer leaflet of the lipid bilayer, whereas the hydrophilic amino and carboxyl groups prevent the molecule from crossing the membrane (it is for this reason that specific thyroid hormone transporters are required for cellular uptake). This partitioning in the membrane at normal levels of T_3 and T_4 reduces its fluidity, and this will affect the activity of membrane-associated enzymes.

Such a mechanism may also account for the immediate effects of T_3 and T_4 on many mitochondrial membrane-bound enzymes, although this is a matter of debate. Irrespectively, the number of mitochondria, mitochondrial membrane density, and mitochondrial activity generally increase with increasing thyroid activity. This may in part be a secondary response to greater ATP demand. However, the presence of high-affinity thyroid hormone-binding proteins in the inner mitochondrial membrane in hormone-responsive tissues, but not in refractory tissues such as testis and spleen, suggests a unique pathway of thyroid hormone action in mitochondria. These proteins are known to be truncated forms of the TR-α protein, known as p43 and p28, and indeed act as T_3-dependent transcription factors of genes encoded in the mitochondrial genome. As with T_3, specific binding sites for T_2 were identified in the inner membrane of rat liver mitochondria, however, the mechanism of T_2 action on mitochondria is poorly understood (Davis *et al.*, 2016). Apart from this relatively rapid receptor-mediated action, several nuclear-encoded mitochondrial enzymes are regulated via nuclear TRs.

Changes in thyroid status also lead to alterations in the lipid composition and properties of membranes, most notably affecting the saturation of fatty-acyl chains of the phospholipids. Such changes have also been shown to affect membrane-associated enzymes. These lipid alterations are thought to be related to the effects of thyroid hormone on the expression of lipid desaturases. Any subsequent effects on membrane-associated processes are therefore secondary to a nuclear-mediated action of the hormone.

Receptor-Mediated Nuclear Action

There are two known genes for thyroid hormone receptors (i.e., TR-α and TR-β). Multiple receptor isoforms and related proteins are expressed through alternative splicing of mRNAs. Of these, TR-α_1, TR-β_1, TR-β_2, and TR-β_3 are bona fide TRs in that they bind T_3 and confer transcriptional regulation of target genes. Other forms, such as TR-α_2 (DNA binding but not hormone binding) and the ΔTR-α/ΔTR-β forms (hormone binding but not DNA binding), can act as dominant negative factors interfering with TR action. These factors may increase the capacity for tissue-specific fine-tuning of thyroid hormone effects. Some in vivo data support such a role, but the precise physiological relevance in different tissues is unknown.

Studies of receptor-knockout mice lacking either functional TR-α or TR-β receptors indicate a large degree of redundancy between both isoforms. The molecular mechanism of transcription regulation is considered identical for the TR-α and TR-β isoforms, which is supported by in vitro analyses. Some isoform-specific effects are observed in knockout mice as well as in cases of TR-β mutations in humans, including cardiac pacemaking (TR-α_1), development of hearing (TR-β_1), and thyroid hormone feedback regulation (TR-β_2). These dependencies reflect tissue-restricted expression of TRs rather than gene-specific regulatory mechanisms.

Regulation of Gene Transcription

Transcription of a gene's DNA into mRNA requires recruitment of the RNA polymerase complex to general transcription factors that are already bound to the promoter region of the DNA, immediately upstream of the coding sequence. The rate of expression of a gene is basically determined by the ease with which these complexes are formed. Promoter activity and transcription rate are therefore terms that describe the frequency with which transcription of a gene is initiated following assembly of the complex. Gene transcription is primarily modulated by factors that either facilitate and stabilize the assembly of the transcription machinery or disrupt it. The RNA polymerase complex that transcribes the gene is exceptionally large, containing more than 100 different proteins. In contrast, nuclear DNA in its compact form is not readily accessible for such large complexes. Every 200-base pair stretch of DNA is wrapped around a disk-shaped histone protein complex forming a string of so-called nucleosomes that compact the DNA further by combining with other proteins. The resulting chromatin structure, however, is dynamic and can be made accessible to large DNA-binding complexes by modification of the histone proteins. Addition of acetyl groups to histones relaxes

the chromatin structure, whereas deacetylation closes it. Two classes of enzymes are responsible for this reversible chemical modification: histone acetyl transferases (HATs) and histone deacetylases (HDACs). These proteins are key factors in the regulation of gene expression because they can be recruited by transcription factors, including nuclear hormone receptors.

Thyroid Hormone Response Elements

The TRs belong to the large family of ligand-dependent transcription factors, which includes receptors for steroid hormones, retinoic acid and related retinoids, and vitamin D. Specific DNA sequences (response elements) are required in the promoters of genes to allow binding of these receptors, making the gene hormone responsive. Receptors in this family recognize the six-base pair element AGGTCA and interaction of two receptors (dimerization) is typically required for functional activity. The DNA motif to which each receptor binds is consequently referred to as a half-site, and the spacing and orientation of the half-sites determine receptor specificity of the response element. In the case of TRs, the optimal arrangement of half-sites in a thyroid hormone response element (TRE) is either a direct repeat spaced by four base pairs, a palindrome, or an everted repeat with a six-base pair gap (**Fig. 2**).

Deviations from the optimal half-site sequence and, to a lesser extent, from the optimal spacing between them are common in naturally occurring TREs. This variation is responsible for large differences between TREs in TR-binding affinity and stimulation of promoter activity. The relaxed constraints placed on TRE structures are evident in **Fig. 3**, which shows several natural TREs. TREs often consist of three or four half-sites allowing for binding of additional TRs, which further increases promoter activation. In addition, a promoter may contain several TREs contributing to the overall T_3 responsiveness.

TRs readily form heterodimers on TREs with the retinoid X receptor (RXR) with greater binding affinity than that of TR homodimers. Transcription activation by T_3 is also higher, requiring no ligand for RXR. RXRs are also considered the natural partner for TRs in vivo because of the ubiquitous presence of these proteins.

Interactions between different hormone receptors within the family are possible given their similar structure and DNA-binding properties. Some studies support this, showing, for instance, that estrogen receptors can interfere with TR action on T_3-responsive promoters, whereas TRs can bind to and block estrogen response elements in vitro. Moreover, it was shown that T3 decreased expression of estrogen receptors in testis of gold fish (Marlatt *et al.*, 2012). This so-called crosstalk may be relevant in tissues in which both hormone signaling routes are active, such as the hypothalamus in this example, but in vivo data in the hypothalamus

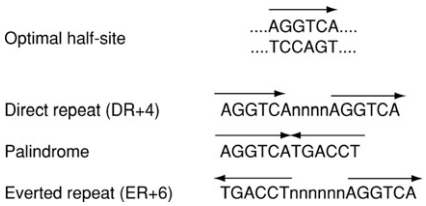

Fig. 2 The optimal half-site for TR binding is depicted as in double-stranded DNA. Only the top strand of DNA is depicted in the three TREs that confer high T_3 responsiveness to a promoter. The *arrows* indicate the orientation of half-sites in a TRE, and "n" can be G, A, T, or C. The hexamer sequence and optimal half-site arrangements are derived from studies of synthetic TREs.

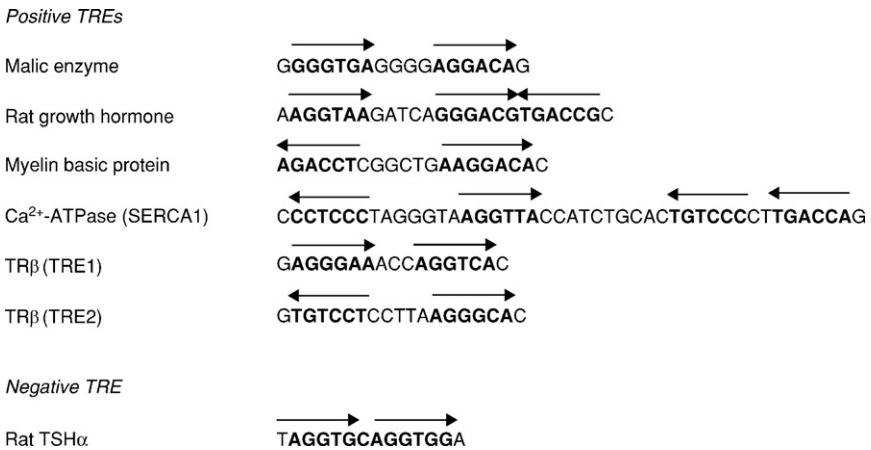

Fig. 3 A selection of natural TREs illustrating the variation in half-site sequence and spacing between half-sites. All indicated half-sites are functional in these TREs and the invariable central two Gs (Cs) are essential for TR binding. TREs from the rat growth hormone gene and the Ca^{2+}-ATPase gene from rat skeletal muscle are examples of composite response elements. Both TREs from the human TR-β promoter contribute to the T_3 responsiveness of this gene. The TRE from the rat TSH-α gene is an example of a half-site structure conferring a negative T_3 response.

are lacking. Also, crosstalk between TRs and peroxisome proliferator-activated receptor (PPAR) which plays a key role in lipid metabolism, carcinogenesis, and cardiovascular diseases was identified. In vitro and in vivo studies indicated that TR-β_1 repressed the transcriptional activity of PPARg via binding to PPAR response element (Araki *et al.*, 2005).

Stimulation of Gene Transcription by T_3

One aspect of TRs that is unique in the nuclear receptor family is the fact that TRs and TR–RXR heterodimers are bound to TREs in the unliganded state, whereas the other receptors require ligand for DNA binding. Furthermore, binding of unliganded TRs results in a substantial repression of basal promoter activity. Activation of transcription is induced by binding of T_3 to the TR. This not only relieves the repression but also further stimulates promoter activity. **Fig. 4** summarizes the current model of the in vivo molecular mechanism underlying this action of T_3. The essential classes of factors involved are depicted, but different proteins exist within each class, some of which show tissue-specific expression. Transcription is repressed in the absence of T_3 because the TR recruits a histone deacytelase to the promoter by means of a ubiquitous corepressor protein such as nuclear receptor corepressor (NCOR) and silencing mediator for retinoid and thyroid hormone receptor (SMRT) that serves as an adapter, having binding sites for both TR and the HDAC protein. Binding of T_3 induces a marked conformational change in the TR, which disrupts binding of the corepressor complex. Instead, binding of coactivator proteins such as steroid receptor coactivator 1 (SRC-1) is now possible. Several such proteins form a complex with histone acetylase activity. This in turn opens up the local chromatin structure, allowing the assembly of an active transcription complex. Additional direct interactions of the TRs with basal transcription factors appear to further facilitate this process. In vivo studies have shown that coactivator and corepressor are involved in TR sensitivity and transcriptional response to the hormone, for instance, lack of corepressor induces a higher percentage of the receptors which bind to T_3 and coactivators and results in increasing TR sensitivity (Astapova, 2016). This role of the corepressor has also been supported by a result that patients with TBL1X defect, which is part of the NCOR complex and plays a role in its interactions with chromatin, were considered to have increased TR sensitivity to thyroid hormone (Heinen *et al.*, 2016).

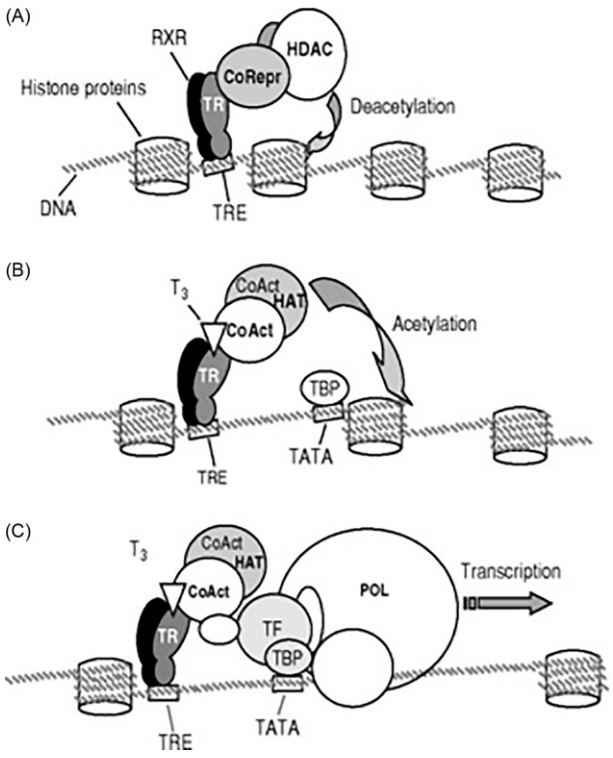

Fig. 4 Model of the T_3-dependent stimulation of transcription in a T_3-responsive gene. (A) Basal or repressed state in the absence of T_3. DNA is in its compacted form wound around histone proteins (nucleosomes) and bound to other ubiquitous proteins (not depicted). TR–RXR dimers are bound to the TRE. TR forms a complex with a protein with histone deacetylase activity (HDAC), which maintains the compact structure. The interaction is through a corepressor protein (CoRepr). (B) Activation. The corepressor complex is replaced by coactivator proteins (CoAct) upon binding of T_3 to its receptor. Histone acetylase activity (HAT) in the CoAct proteins opens up the nucleosome structure. The TATA box-binding protein (TBP) is a general transcription factor that binds to the DNA sequence TATA at the transcription initiation site. (C) Transcription. Following assembly of multiple general transcription factors (TF), which is stabilized by proteins that interact with the TR complex, the RNA polymerase complex (POL) is recruited to the promoter and transcription ensues.

Table 1 Genes known to be transcriptionally regulated by thyroid hormone[a]

	Gene function
Gene transcription stimulated by T_3	
BDNF	Brain-derived neurotropic factor. Stimulation of expression of this brain-specific regulatory factor may in part explain the critical role of thyroid hormone in brain development
Myelin basic protein	Major protein component of the insulating myelin sheaths surrounding axons
β_1-Adrenergic receptor	Stimulation of expression of this receptor accounts for the potentiating effect of thyroid hormone on the adrenergic responsiveness of many tissues, such as liver, fat, skeletal muscle, and heart
TR-β_1	Thyroid hormone receptor β_1. Stimulation of expression of this TR is particularly important for the timing of brain development
HCN2	Hyperpolarization-activated cyclic nucleotide-gated channel. Cardiac ion channel involved in pacemaker activity
MHC-α	Myosin heavy-chain α. One of the two ATPase proteins responsible for cardiac contraction. MHC-α imparts faster contraction at higher energy consumption than MHC-β. MHC-β is the predominant isoform in human heart
SERCA2a	Sarcoplasmic reticulum (SR) Ca^{2+}-ATPase. Ion pump that regulates intracellular calcium, playing a key role in the contraction–relaxation cycle of the heart. SERCA2a is also expressed in skeletal muscle
SERCA1	Isoform of SERCA2a but exclusively expressed in skeletal muscle. It can be expressed at much higher levels than SERCA2a and its activity may account for up to 50% of the total energy consumption of contracting muscle
GLUT4	Insulin-responsive glucose transporter. Responsible for insulin-stimulated uptake of glucose, particularly in skeletal and cardiac muscle and adipose tissue
PEPCK	Phospho-enol-pyruvate carboxy kinase is a key enzyme in gluconeogenesis in liver and skeletal muscle
Malic enzyme	Malic enzyme, or malate dehydrogenase, catalyzes the last oxidation step in the citric acid cycle in mitochondria
Cholesterol hydroxylase	Cholesterol 7α-hydroxylase is a key enzyme in the hepatic degradation of cholesterol into bile acids
Na^+/K^+-ATPase	Ubiquitous ion pump in the plasma membrane of cells responsible for maintaining the gradients of sodium and potassium between the extracellular and intracellular space
MyoD and myogenin	Two different transcription factors that drive the expression of many muscle-specific genes during the differentiation of skeletal muscle (myogenesis)
rGH	Rat growth hormone. The TRE in this pituitary gene was the first to be analyzed in detail. A similar TRE has not been identified in the human GH gene
Deiodinase type 1	This enzyme is responsible for the peripheral production of T_3 through deiodination of T_4. It is primarily expressed in liver and kidney
UCP1	Stimulation of expression of uncoupling protein 1 is responsible for the T_3-induced thermogenic response in brown adipose tissue. It uncouples mitochondrial respiration, thereby converting oxidative energy directly to heat
Gene transcription inhibited by T_3	
MHC-β	Myosin heavy-chain β. Slower and more energy-efficient isoform of the two myosin ATPases responsible for cardiac contraction. The hypothyroid rodent heart expresses almost exclusively MHC-β, which is nearly completely replaced by MHC-α in hyperthyroidism. This shift occurs to some extent in the hyperthyroid human heart
TSH-α and-β	Both anterior pituitary genes encoding the α- and β-subunits of thyroid-stimulating hormone (TSH or thyrotropin) are negatively regulated by thyroid hormone. This is part of the negative feedback loop regulating plasma thyroid hormone levels
TRH	Thyrotropin-releasing hormone, synthesized in the hypothalamus, is the principal positive regulator of TSH synthesis. Repression of transcription of this gene is another aspect of the feedback inhibition of thyroid hormone production

[a]One or more TREs have been identified in the promoters of these genes.

Inhibition of Gene Transcription by T_3

The mechanism of T_3-induced repression of transcription, such as in the case of the TSH-α, TSH-β, and thyrotropin-releasing hormone (TRH) genes, is not understood. Corepressors and coactivators appear to be equally involved in this mode of regulation but with exactly opposite effects compared to the positively regulated genes (i.e., unliganded TRs stimulate transcription, which is abolished after T3 binding). Although TRE-like binding sites or even single half-sites have been implicated in some downregulated promoters, a consensus negative TRE has not been defined.

Many genes are expected to be directly regulated by T_3 based on the responsiveness of expression under various conditions. The list of promoters that are shown to contain functional TREs is continuously growing. A selection of such genes are presented in Table 1 together with a short description of the function of each gene.

Effects of Thyroid Hormone on Target Tissues

The large number of different processes, factors, and mechanisms summarized in the previous sections provide an explanation for the variety of tissue-specific actions of thyroid hormone. The responsiveness of tissues with respect to transcription of specific genes is dependent on the mix of TRs and their numerous cofactors, the details of which are poorly understood. Furthermore, the rate of cellular T_3 and/or T_4 uptake and local activity of hormone-metabolizing deiodinases will determine a tissue's T_3 concentration. As noted previously, many of the physiological effects of altered thyroid hormone levels are secondary to a limited number of direct

actions of T_3, and a large-scale analysis of gene expression indicates that the current list of genes that are directly regulated by T_3 is far from complete.

The effects of thyroid hormone on some of the major responsive tissues, based on both clinical and animal experimental data, are described in the following sections. The emphasis is on the effects for which the primary targets of thyroid hormone are known.

Brain

The development of the central nervous system is severely impaired in the absence of sufficient levels of thyroid hormone. The incomplete maturation of the brain is evidenced by neurological defects and mental retardation in humans. The timing of connections between axons, dendrites, and their targets in the developing brain is critical for the formation of the neuronal network. Diminished axonal growth and reduced dendritic arborization are evident in cerebral cortex, hippocampus, and cerebellum and in the visual and auditory cortex of hypothyroid rats. The expression of many genes is dependent on T_3, but only a few have been shown to be directly regulated, such as myelin basic protein and brain-derived neurotropic factor. The action of T_3 on the other genes may in part be permissive, which means that T_3 is essential for the action of another factor. For example, the stimulation of expression of ornithine decarboxylase by growth hormone in the brain is absolutely dependent on thyroid hormone. This enzyme is essential in nucleic acid and protein synthesis, and thyroid hormone alone has no effect on its expression. Interestingly, in hypothyroidism all enzymes that are dependent on thyroid hormone eventually reach normal levels of expression. It therefore appears that the timing of thyroid action is critical, and that there is a transient period of hormone responsiveness during the development of the brain.

Bone

Development and growth of bone are critically dependent on thyroid hormone, as evidenced by the typical short stature of adults when neonatal hypothyroidism remains untreated. The cell types that are involved in bone formation (osteoblasts) and bone resorption (osteoclasts) are both stimulated by T_3, with effects on several critical enzymes. In hyperthyroid patients, increased bone formation and resorption result in a net loss of bone thickness and increase in porosity, leading to greater risk of fractures. Some studies have shown that TR-α1 is the predominant TR expressed in bone and that T_3 actions are anabolic during growth but catabolic in the adult skeleton via increased osteoclastic bone resorption (Williams and Bassett, 2017). However, little is known about the primary targets and mechanism of action of T_3 in bone cells, mainly because these cells are difficult to study in culture. Thyroid hormone is required for the effects of growth hormone on bone growth and development, which involve the production of insulin-like growth factor 1. Some of the effects of T_3 may therefore result from this permissive action of thyroid hormone. However, studies using TR knockout mice indicate that many of the effects of T_3 on bone metabolism are nuclear mediated and independent of growth hormone.

Heart

Cardiovascular effects are among the most prominent clinical manifestations of thyroid disease. The expression of key cardiac proteins is dependent on thyroid hormone, as evidenced by the profound changes in cardiac performance in the transition from hypothyroidism to hyperthyroidism. Thyroid hormone directly regulates the expression of genes involved in membrane depolarization, muscle contraction, Ca^{2+} handling, and adrenergic signaling (**Table 1**). These actions include positive and negative regulation of transcription. In addition, extranuclear effects on membrane ion fluxes contribute to the increase in heart rate and a reduction in vascular resistance. All these effects combine to increase the performance of the heart, with a concomitant increase in energy turnover. A key factor is the stimulation of the Ca^{2+}-pump of the sarcoplasmic reticulum, whereas its inhibitory protein phospholamban is reduced. The sarcoplasmic reticulum membrane system is the intracellular store for Ca^{2+} required for each contraction. The higher Ca^{2+}-pump activity increases the amount of Ca^{2+} that can be released from the sarcoplasmic reticulum as well as the speed with which it can be taken up again during relaxation. The result is an increased contractile capacity of the heart. Together with the increase in heart rate, the hemodynamic load placed on the heart increases with higher T_3 levels. Such mechanical load is a major independent stimulus for growth of the heart and responsible for the progressive cardiac hypertrophy seen with increasing thyroid hormone levels. The combined effects of T_3 on cardiac function and vascular resistance result in an increase in cardiac output adapted to the higher overall metabolic demand made by the organism.

Skeletal Muscle

The overall effect of thyroid hormone on skeletal muscle is similar to that described previously for the heart: that is, an increase in performance at the expense of a higher energy turnover. Stimulation of the rates of contraction and relaxation by thyroid hormone is a classic observation in thyroidology. Changes in expression of genes similar or identical to those in cardiac tissue underlie this effect, but multiple isoforms and cell-specific and innervation-dependent factors make for a less straightforward regulation by T_3. Generally, T_3 induces a shift in the expression of myosin-ATPase proteins, which determine the rate of contraction, from the slow myosin heavy-chain form (MHC I) to faster MHC II forms. MHC I is identical to MHC-β in heart and this gene is also negatively regulated in skeletal

muscle by T_3 at the promoter level. Direct regulation is not established for the multiple MHC II forms that are similar, but not identical, to cardiac MHC-α. As in heart, the relaxation rate is determined by the level of expression of the Ca^{2+}-pump of the sarcoplasmic reticulum. Muscle also expresses the SERCA2 form present in the heart, but T_3 preferentially stimulates the expression of a second isoform (SERCA1). This protein is virtually identical to the SERCA2 form, but the promoter of the SERCA1 gene is completely different, with different TREs allowing much higher expression of the protein compared to the SERCA2 form. Proliferation of the sarcoplasmic reticulum membrane is also stimulated by T_3. The expression of the fast MHC isoforms and the high Ca^{2+}-pump levels increase the energy cost of contraction two- or threefold in the transition from hypothyroidism to hyperthyroidism. The economy of force production is consequently reduced by T_3 since absolute force production is not affected by these changes.

The timing of expression of a series of fetal and adult MHC isoforms during development is dependent on thyroid hormone. Similar to brain, the adult expression patterns are ultimately obtained irrespective of the thyroid status. This is not the case for the SERCA1 gene, which is absolutely dependent on thyroid hormone. Effects of neonatal hypothyroidism on muscle development in rats are fully reversible by treatment with thyroid hormone.

Liver

Plasma levels of cholesterol, particularly low-density lipoprotein (LDL) cholesterol, are increased in hypothyroid patients. This is the result of decreased LDL cholesterol uptake by the liver (due to reduced LDL receptor numbers) and reduced hepatic metabolism of cholesterol. These effects can be reversed by treatment with thyroid hormone. The enzyme cholesterol 7α-hydroxylase is the rate-limiting step in the degradation of cholesterol into bile acids, and its expression is stimulated by T_3 at the promoter level. Whether the expression of LDL receptors is also directly stimulated by T_3 is not known. In vivo studies have shown that thyroid hormone reduces cholesterol in LDL receptor-knockout mice (Goldberg *et al.*, 2012). TRβ-selective thyroid hormone analogs were expected a role as lipid-lowering drugs. However, clinical trials of the first generation TRβ-agonists were discontinued because of adverse effects of thyroid hormones (Mondal and Mugesh, 2017).

T_3 stimulates the expression of a number of enzymes involved in lipogenesis, including malic enzyme, glucose-6-phosphate dehydrogenase, and fatty acid synthase. Malic enzyme is particularly responsive and the promoter of this gene contains a strong TRE. Interestingly, the same enzyme is expressed in brain, but it is unresponsive to T_3. In liver, several signal routes involved in energy metabolism, such as insulin signaling, converge on the promoter of this gene and interact with the T_3 signal. For instance, the stimulatory effect of T_3 on malic enzyme expression is increased 10-fold when a normal diet is replaced by a high-carbohydrate/fat-free (lipogenic) diet.

Synthesis of glucose (gluconeogenesis) from precursors such as amino acids and glycerol is an important liver function. T_3 stimulates the expression of key enzymes in this process, including pyruvate carboxylase, glucose-6-phosphatase, and phospho-enol-pyruvate carboxy kinase. A TRE has been identified in the promoter of the phospho-enol-pyruvate carboxy kinase gene.

In addition, T_3 stimulates the expression of the deiodinase type I gene, which converts T_4 to T_3. This enzyme is responsible for most of the circulating T_3 in the body and its promoter contains several TREs.

Adipose Tissue

Differentiation of preadipocyte cells into mature white adipose tissue is dependent on thyroid hormone, and the same key enzymes involved in lipid metabolism in liver are influenced by T_3 in fat tissue. High levels of T_3 shift the balance between fat synthesis and breakdown to net lipolysis, resulting in generalized fat mobilization and loss of body fat stores. Although brown adipose tissue is virtually absent in adults, as it is in most larger mammals, newborns have appreciable amounts of this type of fat tissue. It gets its color from the cytochromes in mitochondria, which are particularly abundant in these fat cells. In rodents, brown adipose tissue is the site of the thyroid hormone-dependent extra heat production in response to prolonged cold exposure. Circulating thyroid hormone levels do increase, but this is not essential for cold adaptation and the action of the hormone appears to be permissive. Surprisingly, however, the adipocytes greatly increase their T_3 content by increasing the expression of deiodinase type II. Like type I, this enzyme converts T_4 to T_3 and its expression is stimulated by the higher levels of circulating adrenergic hormones triggered by the cold stress. The increase in T_3 in the brown adipocyte in turn induces the transcription and expression of a protein called thermogenin or uncoupling protein 1, which uncouples respiration in mitochondria. This means that the energy produced by the numerous mitochondria in these cells is not stored in the form of ATP but rather directly released as heat. This mechanism is equally important in maintaining body temperature in newborns and it is an example of how thyroid hormone action may be regulated at the level of individual tissues.

Glossary

Dominant-negative effect (DNE) When mutant TRs interfere with functions of the wild-type TRs.

Resistance to thyroid hormone (RTH) A syndrome of reduced target tissue responsiveness to thyroid hormone, usually inherited in an autosomal dominant manner.

Retinoic acid receptor (RXR) Thyroid hormones form heterodimers with RXRs and bind to TRE.

Thyroid hormone receptor (TR) Nuclear receptor that mediates thyroid hormone transcription.

Thyroid response element (TRE) Specific DNA sequences located near the transcription start point of thyroid hormone-regulated genes.

Introduction

The syndromes of resistance to thyroid hormone (RTH) are generally characterized by reduced tissue responsiveness to thyroid hormone (TH) despite elevated circulating levels of free T_3 and/or T_4 (Refetoff et al., 1993). It is associated with an inappropriately normal or raised serum TSH characteristic of impaired thyrotroph sensitivity. The original clinical description of RTH was reported by Refetoff *et al.* (1967) in two subjects with deaf-mutism, delayed bone age, and stippled epiphyses. Despite these symptoms of hypothyroidism, serum levels of TH were high. Furthermore, administration of exogenous TH failed to produce the expected metabolic effects and failed to suppress thyrotropin-releasing hormone (TRH)-stimulated TSH. These observations lead to the diagnosis of RTH. Twenty years later, the molecular basis of the syndrome was found to be due to a mutation in the TH receptor β (THRB and *TRβ*) gene (Sakurai *et al.*, 1989; Usala *et al.*, 1990). To date, 186 different mutations in the *TRβ* gene, found in $>$ 3000 individuals in 500 families, have been described. As our knowledge of the different thyroid function phenotypes has evolved, it has become clear that RTH is part of a larger group of conditions known as impaired sensitivity to thyroid hormone (Refetoff *et al.*, 2014). Those with classic RTH due to TRβ mutations are known as RTH-beta. This is to distinguish them from a group of patients with mutations in the *TH receptor alpha* (*THRA* and *TRa*) gene RTH-alpha who have low serum T_4, borderline high T_3, and very low rT_3, with normal to elevated TSH concentrations (Espiard *et al.*, 2015; Moran *et al.*, 2013, 2014; Tinnikov *et al.*, 2002; Bochukova *et al.*, 2012; van Mullem *et al.*, 2012; Tylki-Szymanska *et al.*, 2015). A high ratio of free T3 to free T4 seems to be a common finding in the 14 cases of RTH-alpha described to date. Two other syndromes belonging to the group of impaired sensitivity to thyroid hormone include patients with gene mutations affecting TH metabolism, such as SBP2 (Di Cosmo *et al.*, 2009; Dumitrescu *et al.*, 2005) or transport via MCT8 (Dumitrescu *et al.*, 2004; Friesema *et al.*, 2004, 2010; Papadimitriou *et al.*, 2008). The latter is associated with severe psychomotor defects. Knowledge of the molecular mechanisms involved in mediation of TH action allows the recognition of the phenotypes caused by genetic defects in the involved pathways.

The inheritance pattern of RTH-beta is autosomal dominant in most cases. There is a small subgroup (about 10%) of patients with apparent RTH-beta phenotype (elevated T4, T3, and nonsupressed TSH) but without mutations in the *THRB* gene, and they are referred to as non-TR RTH. The molecular basis for their condition is unknown.

Although the initial description of RTH was associated with signs of hypothyroidism, the phenotype of RTH is variable, both between families and among family members with identical TH receptor (TR) mutations. The majority of the patients present with mild-to-moderate symptoms. This variability in clinical manifestation may be due in part to the severity of the hormonal resistance, the effectiveness of compensatory mechanisms, the presence of modulating genetic factors, and the effects of prior therapy.

Although the apparent insensitivity to TH may vary in severity, the common feature characteristics of the syndrome are goiter, growth delay, elevated serum levels of free T_3 and/or T_4, and normal or slightly increased TSH level that responds to TRH.

☆*Change History:* October 2017. GA de Carvalho, TM Fighera, and RE Weiss updated all sections and deleted Table 2, and further information has been included in the text.

This article is an update of Gisah Amaral de Carvalho and Roy E. Weiss, Resistance to Thyroid Hormone (RTH), in Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 208–216.

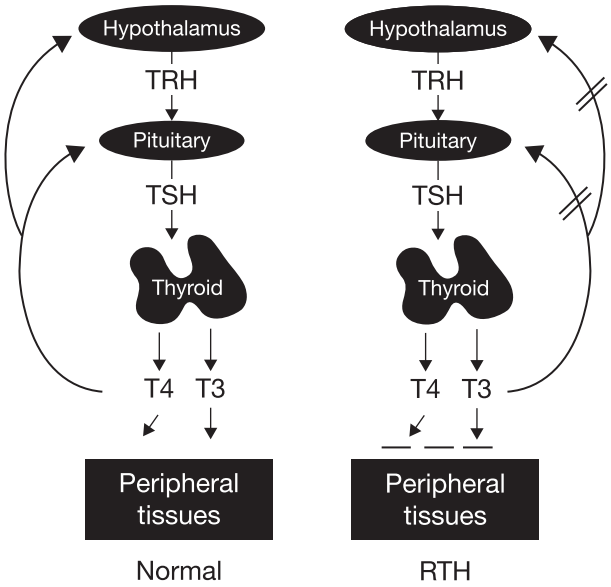

Fig. 1 Schematic representation of the hypothalamic–pituitary–thyroid axis. Under normal conditions, the hypothalamus secretes TRH that stimulates the pituitary to produce TSH that stimulates the thyroid to produce mainly T_4. T_4 is metabolized in the peripheral tissues to T_3 and, in turn, THs feedback in an inhibitory fashion on the hypothalamus and pituitary. Thyroid hormone action on pituitary and peripheral tissues occurs when T_3 binds to its receptor; in RTH-beta, the feedback is inhibited due to decreased sensitivity of the pituitary to TH, resulting in elevated TSH with increased T_4 secretion. The peripheral tissues also have decreased sensitivity to TH in RTH-beta.

Thyroid Physiology

Biological Effects of Thyroid Hormone

THs are known to induce metamorphosis in amphibians by mediating remodeling of specific tissues and organs. In humans, severe TH deprivation during intrauterine life and in the immediate postnatal period results in impaired neurogenesis and growth retardation. In adult life, hypothyroidism affects the function of many organs and results in alterations of thermogenesis and behavior.

Thyroid Hormone Regulation

Several mechanisms are responsible for modulating the supply of TH to tissues: (1) The hypothalamus–pituitary–thyroid axis controls TH synthesis and releases from the thyroid gland via stimulation by TSH, (2) the generation of T_3 from T_4 at the tissues via the action deiodinases may modulate tissue responsiveness to TH, and (3) autoregulation of expression of TR can also modulate the effect TH has on a tissue, for example. The more receptor, the greater the response; the less receptor, the less response for a given amount of hormone. TSH synthesis and secretion is stimulated by TRH, a tripeptide derived from the hypothalamus. TSH originating from pituitary gland in turn stimulates TH synthesis and secretion. Although T_4 is the predominant form of TH released from the gland and T_3 generated at the tissue level is the biologically active hormone, T_4 can also bind to the TR but with 100-fold less affinity. T_3, generated from the conversion of T_4 in the pituitary and hypothalamus by type II deiodinase, controls the synthesis and secretion of TSH and TRH through a negative feedback loop (**Fig. 1**). Finally, proper TH action requires an intact TH, its transport across cell membrane, hormone activation through intracellular metabolism, cytosolic processing, nuclear translocation, binding to the TRs, and interaction with coregulators or other postreceptor effects mediating the TH effect.

The signs, symptoms, and laboratory abnormalities observed in RTH are due to reduced peripheral tissue and pituitary responsiveness to TH, resulting in impaired negative feedback of T_3 on TSH/TRH and impaired peripheral tissue action of T_3.

Mechanisms of TH Action

TH was once thought to solely enter the cell by a process of concentration-dependent passive diffusion after dissociation from the serum hormone-binding proteins. However, several molecules have been identified as putative TH transmembrane transporters. TH action, for the most part, is mediated through specific TRs in the cell nucleus, although pathways of nongenomic action of TH have been described (Bassett *et al.*, 2003).

TRs are members of the nuclear hormone receptor superfamily together with retinoic acid receptors (RXRs), 9-*cis* retinoic acid receptors, vitamin D3 receptors, and peroxisome proliferator-activated receptors (Cheng *et al.*, 2010). TRs act as ligand-dependent transcription factors that increase or decrease the expression of target genes depending on whether the gene promoters contain, respectively, positively or negatively regulated TH-response elements.

There are two genes, *THRA* and *THRB*, located on chromosomes 17 and 3, respectively, which encode TRs. TRs are cellular homologues of the viral oncogene erb-A. Each gene generates at least two proteins by alternative splicing: TRα_1, TRα_2, TRβ_1, and TRβ_2.

The relative expression of two TR genes and the distribution of their products vary from tissue to tissue and during different stages of development. Furthermore, TH differentially regulates the expression of two TR genes and their isoforms.

The THRα and THRβ proteins are structurally alike, which suggests that they might have similar functions. However, the identification of patients with mutations in *THRA* and their significant different clinical presentation to that of patients with mutations in *THRβ* suggests that the THR isoforms have distinct physiological roles that extend beyond differences in tissue distribution (Refetoff and Dumitrescu, 2007). In patients with mutations in *THRA*, the HPT axis is not impaired as it is in patients with RTH-beta (Bochukova *et al.*, 2012). These clinical observations are supported by findings in which THRβ was identified as the receptor that modulates negative regulation of the HPT axis (Abel *et al.*, 2001; Gauthier *et al.*, 2001).

The α and β TR isoforms have a well-conserved DNA-binding domain (DBD or C domain) separate from the ligand (T_3)-binding domain (LBD or E domain) by a hinge domain (D domain). TRα_2, due to a carboxyl-terminal sequence difference, does not bind TH, and the molecule does not function as a TR (**Fig. 2**).

TRs homodimerize (TR/TR) or form heterodimers with RXRs (TR/RXR) and bind to specific DNA sequences termed TH-responsive elements (TREs), which are located near the transcription start point of TH-regulated genes.

On genes upregulated by TH, the unliganded TRs suppress basal gene transcription activity by interacting with a class of nuclear proteins known as corepressors such as the nuclear receptor corepressor (NcoR) and the silencing mediator for retinoid and TH receptor (SMRT). Conformational changes of TR, produced by T3 binding, enhance the occupation of TREs by TR/RXR heterodimers, release the corepressor complex, and recruit coactivators such as steroid receptor coactivator 1 (SRC-1), among others, all exhibiting histone acetyl transferase activity. The latter modifies the structure of the chromatin and, through loosening the nucleosome at the site of the promoter, activates gene transcription (**Fig. 3**). The mechanisms involved in the genes that are downregulated by TH, such as TSH, are less well understood but likely to involve the same classes of molecules on a different TREs that cause corepressors to become "activators" and coactivators to become "repressors."

Molecular Basis of RTH

Location of Mutations Associated with RTH

RTHβ Mutations

The precise incidence of RTH-beta is unknown. Because most neonatal screening programs are based on the determination of TSH only and RTH-beta is rarely identified by this means (Weiss *et al.*, 1990), a limited neonatal survey by measuring blood T_4

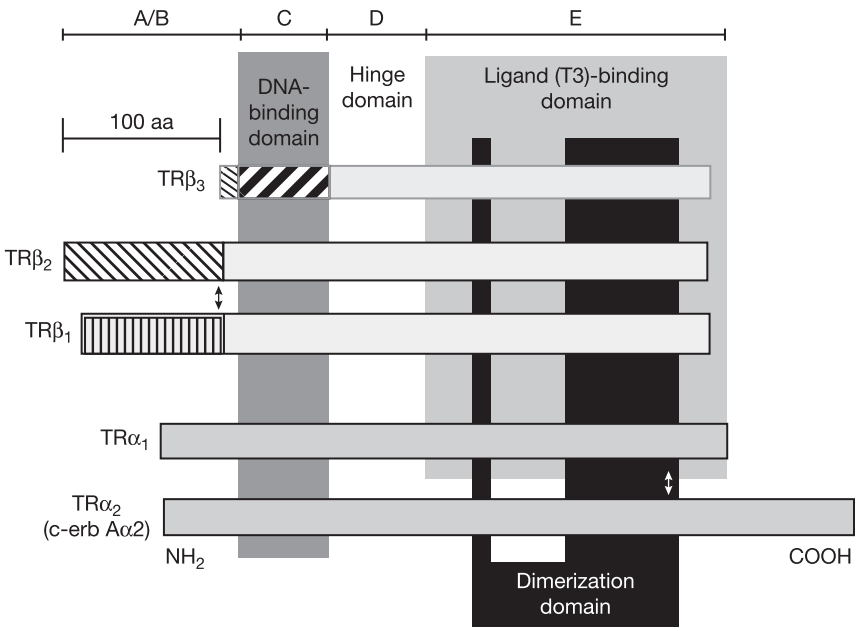

Fig. 2 Schematic representation of the principal TH receptor (TR) forms and their functional domains. Each of the two TR genes (THRA and THRB) expresses two major protein forms (1 and 2) by alternative splicing (*arrows*). The shading pattern of the bars corresponds to the degree of amino acid sequence similarity (identical, similar, or completely different). Differences are most marked in the amino termini (NH_2) of the TRs. The different carboxyl terminus (COOH) of the α2 completely abolishes T_3 binding, and this product is not considered to be a TR proper. The functional domains are also identified by a letter code and by the stippled backgrounds.

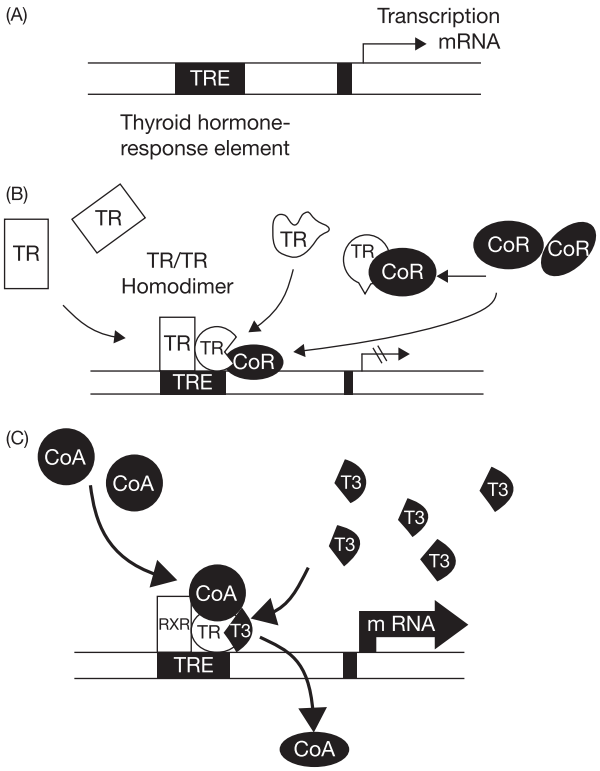

Fig. 3 Mechanism of TH action. Schematic representation of the elements involved in the mediation of TH action through the regulation of T_3-responsive genes expression (A). The unliganded TR homodimerizes with TR, associates with CoR (corepressor), and exerts the suppressive effect on genes positively regulated by TRE (B). Formation of a TR–T_3 complex resulting in disassociation of CoR, occupation of TRE by TR/RXR heterodimers, and recruitment of CoA (coactivator) to enhance transcription of genes positively regulated by TRE (C).

concentration suggested the occurrence of one case/40,000 live births (Lafranchi *et al.*, 2003; Tajima *et al.*, 2009) with equal frequency in both genders. Familial occurrence of RTH-beta has been documented in 75% of cases, while the incidence of sporadic cases is 21%. Inheritance is autosomal dominant. Transmission was clearly recessive in only one family (Refetoff *et al.*, 1967; Takeda *et al.*, 1992).

One hundred eighty-six different mutations in the *THRB* gene have been identified in subjects with RTH-beta belonging to 500 families. The majority (430 families) have a single nucleotide substitutions resulting in single amino acid replacements in 419 instances and stop codons in 11 others (**Table 1**). Deletions, insertions, and duplication were identified in 20 families. The majority of mutations have occurred in three "hot spots" located the LBD (exon 8–10) of TRβ (**Fig. 4**), and identical mutations have developed independently in different families (Weiss *et al.*, 1993).

The RTH index family had homozygous deletion of the *TR*β_1 allele, representing the only example of recessive inheritance of RTH. In all other cases, the inheritance pattern of RTH is autosomal dominant, involving a single nucleotide substitution or small deletions. All *THRB* gene mutations are located in the functionally relevant domain of T_3 binding and its adjacent hinge region. The mutant receptors cannot either bind TH or have reduced affinity. The result of this is that the corepressor is not released, and the gene is not activated. Other receptor mutants have been found that do bind T_3 but release the corepressor slower than normal or have a weaker interaction with the coactivator.

Ten to fifteen percent of families with RTH do not have mutations in the TRβ. These non-TR RTH subjects have a phenotype similar to those with TRβ mutations including baseline thyroid function tests and metabolic and TRH responsiveness to exogenously administered TH. Since non-TR RTH also has an autosomal dominant mode of inheritance, it is believed that other transcriptional cofactors involved TH action could be responsible for the hormone resistance. In support of this are studies of hypothalamic/pituitary/thyroid axis of knockout mice that lack the SRC-1 (coactivator) or the RXR and show that the absence of a cofactor can cause RTH. Further work is required to determine whether there are other forms of hormonal resistance in the non-TR RTH subjects in which the same cofactor may be responsible for mild but multiple hormone resistances.

Dominant Negative Effect

Mutant TRβs interfere with function of the wild-type TRs, a phenomenon termed dominant-negative effect (DNE). Mutant TRβ receptors are still able to bind to TRE and dimerize with normal TRs or RXRs, interfering with the function of the normal TRs. There is a strong correlation between the DNE measured *in vitro* and decreased release of transcriptional corepressor from TRs.

Table 1 Type of TRβ gene mutations

Type		*Number of occurrences at different sites*	*Number of families*	*Effect on TRβ*
Substitution	Single nucleotide	148	430	Single a.a. substitution; premature stop (C434X, K 443X, E445X, C446X, E449X)
	Dinucleotide	3	3	Single a.a. substitution (P453Y, P453 Y); premature stop (F451X)
Deletion	Single nucleotide	4	0	FrSh and stop (441X) of two a.a. extension
	Trinucleotide	5	6	Single a.a. deletion (T276D, T337D, M430D, G432D)
	Eight nucleotides FrSh normal stop at a.a. 461	1	1	
All coding sequences	1	1	Complete deletion	
Insertion	Single nucleotide	7	14	FrSh and two a.a. extension
	Trinucleotide	1	1	Single a.a. insertion (328S)
Duplication FrSh and two a.a. extension	Seven nucleotides	1	1	
Mutation at CpG dinucleotides		10	184[a]	42.8% of 430 families with single nucleotide substitutions and 46.1% of 191 similar families studied in the authors laboratory
De novo mutations b 43[b]	Total		[c]	20.6% of 209 families studied in the authors laboratory
	In CpGs	6	[c]	48.8% of the *de novo* mutations
No TRβ gene mutations		[d]	40[e]	14.0% of 243 families studied in the authors and in whom the TRHB gene was sequenced

[a]Not included are seven families in which the mutation did not follow the rule of G to A or C to T transition.
[b]Families with TRβ gene mutations excluding those with a single affected individual when both parents were not tested.
[c]Not counted as publications do not always include parental genotype.
[d]Nonapplicable.
[e]Total number of families underestimated because usually they are not reported.
a.a., amino acid; *FrSh*, frameshift

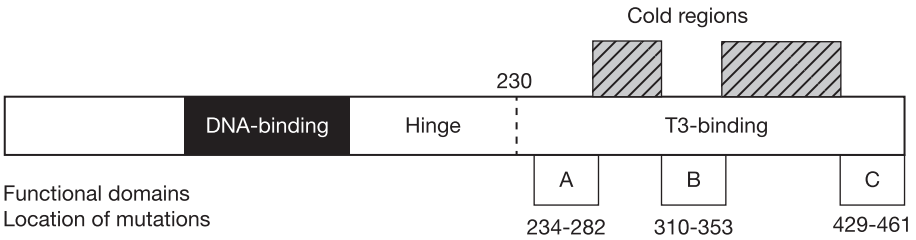

Fig. 4 Location of natural mutations in the TRβ gene associated with RTH-beta. Schematic representation of the TRβ and its functional domains for interaction with TREs (DNA binding) and with hormone (T_3 binding). The mutations that have been found in the TRβ cluster in three areas of the T_3-binding domain. The amino acid positions between which the mutations are found are indicated below the boxes (A, B, and C). Note the "cold regions" of 28 and 75 amino acids, devoid of mutations associated with RTH-beta.

For a DNE to occur, the TR mutant must bind to TRE, which may explain why no mutations have been identified in the DBD and why in the family with a deletion of all coding sequences of the TRβ gene the heterozygotes did not manifest the phenotype of RTH. Interestingly, one subject with homozygous deletion of TRβ Thr-337 (amino acid deletion) with dominantly inherited RTH pattern manifested the most severe form of RTH.

Subjects heterozygous for a *THRB* gene deletion are normal because the expression of a single TRβ allele is sufficient for normal function. RTH-beta manifests in homozygotes completely lacking the *THRB* gene and in heterozygotes that express a mutant THRB with DNE. The most severe form of RTH-beta, with extremely high TH levels and signs of both hypothyroidism and thyrotoxicosis, occurs in homozygous individuals expressing only mutant TRβs (Wu *et al.*, 2005; Yen *et al.*, 2006; Ferrara *et al.*, 2012). The more severe phenotypes in the subjects homozygous for mutant THRBs indicate a stronger DNE and support the notion that mutated THRB interferes with the function of THRA.

Pathophysiology

The lack of negative feedback of T_3 on TSH result in persistent TSH secretion and thyroid gland stimulation resulting in increased TH synthesis and secretion. The normal or slightly increased TSH usually responds by a further increase to the administration of TRH, distinguishing this from subjects with a TSH-secreting pituitary adenoma.

The serum TSH of RTH-beta patients is identical immunologically to the serum TSH of normal controls. It does not contain an excess of glycoprotein α-subunits (TSHα), typically found in the serum of patients with TSH-producing pituitary tumors. However, the TSH has an increased biological potency *in vitro*, perhaps explaining how normal TSH levels produce goiter and hypersecretion of TH by the thyroid gland. Another explanation but also unproved possibility to explain the goiter of RTH-beta subjects with normal serum TSH could be augmented thyrocyte sensitivity to TSH through increased density of TSH receptor units.

Various mechanisms can be postulated to show the tissue differences in TH resistance within the same subject and among individuals. The distribution of receptor isoforms varies from tissue to tissue (Lazar, 1993). This likely accounts for greater hormonal resistance in the liver as compared with the heart.

Several of the clinical features encountered in some patients with RTH-beta may be the manifestation of selective tissue deprivation of TH during early stages of development. The severity of symptoms is related to the relative expression of the mutant allele (and perhaps cofactors) in the particular tissue. For example, cardiac tissue predominantly expresses TRα. Most RTH-beta subjects present with tachycardia, because of their abnormal TRβ, they over produce TH, but since the heart has TRα, which is normal, tachycardia results.

Thyroid tissue obtained by biopsy or at surgery revealed various degrees of hyperplasia of the follicular epithelium, supporting the idea of structural heterogeneity of the follicles. Little can be said about the pathological findings in tissues other than the thyroid because of unavailability of autopsy data from patients with RTH-beta. Metachromasia in fibroblasts is present in patients with RTH-beta and in patients with myxedema due to TH deficiency, although treatment with the hormone failed to induce a disappearance of the metachromasia in fibroblasts from patients with RTH-beta.

Clinical Features

Clinical classification

The clinical presentation of RTH-beta is highly variable both between families and among members of the same family with identical TR mutations. The majority of individuals appear to be euthyroid, and therefore, they are asymptomatic. Some may manifest symptoms suggestive of TH deprivation such as growth retardation, impaired cognitive ability, and hypercholesterolemia, while others show signs of TH excess such as tachycardia, advanced bone age, or hyperactivity. Not uncommonly, individuals have symptoms of both TH deficiency and excess.

Subjects with RTH-beta that appear to be eumetabolic and maintain near-normal serum TSH concentrations have been classified as having generalized resistance to TH (GRTH). In such individuals, the defect seems to be compensated by the high endogenous levels of TH. In contrast, patients with equally high levels of TH appear to be hypermetabolic because they are restless and hyperactive or have a rapid heart rate. Such individuals have been classified as having selective pituitary resistance to TH (PRTH). Subdivision of RTH-beta into generalized RTH-beta (GRTH) and peripheral RTH-beta (PRTH) is an artifact arising from the subjective nature of symptoms and poor specificity of signs. Subjects harboring the same mutations, and even belonging to the same family, have been classified as having GRTH and PRTH. Furthermore, clinical studies have shown that the responses of peripheral tissues markers to TH action were equally attenuated. The classification of RTH-beta into GRTH and PRTH can therefore be viewed as opposite ends of the spectrum of a single disease.

Clinical findings

The phenotype of RTH-beta is variable, with most patients presenting with mild-to-moderate symptoms. In children, investigation leading to the diagnosis has been undertaken because of goiter, hyperactive behavior, learning disabilities, or developmental delay. Most adults seek medical attention because of goiter or rapid heart rate. RTH-beta has been diagnosed in infancy as a result of routine neonatal screening programs that measure both TSH and T_4 and to hormonal and DNA analyses performed in infants born to parents known to have RTH-beta. In adults, abnormalities found on routine thyroid testing, in the absence of clinical findings, have been responsible for the diagnosis of RTH-beta.

The majority of untreated subjects are eumetabolic at the expense of high levels of TH. The degree of this compensation for the tissue hyposensitivity to the TH is variable among individuals and in different tissues. As a consequence, clinical and laboratory evidence of TH deficiency and excess often coexists.

Many attempts have been made to demonstrate tissue hyposensitivity *in vitro*. The common finding of paradoxical responses to TH is difficult to explain. They are possibly due to (a) variable interaction of the mutant TR with the α and β isoforms of the normal TRs, (b) variable expression of the α and β TR genes in different tissues, and (c) differences in the regulation of expression of the TRα and TRβ genes by the hormone-activated TR, which in some tissues may be in opposite directions.

On physical examination, goiter is the most common abnormality, occurring in 66–95% of cases and almost always detected by ultrasonography. Gland enlargement is usually diffuse. Tachycardia occurs in up to 80–90% of subjects with RTH-beta and is caused by the excess of TH acting on the TRα gene and often brings the patient to the physician. Careful evaluation of subjects with RTH-beta has shown that one-half has learning disabilities, often associated with ADHD and, on the average, lower intellectual

quotients (IQ). However, frank mental retardation (IQ < 60) occurs in only 3% of the cases. RTH-beta can present with mild-to-moderate growth retardation and delayed bone maturation in 25% of the cases. Hearing defects have been detected in almost one-quarter of patients. Other features, such as frequent ear, nose, and throat infections; decreased bone mass; deafness; hypotonia; and seizures, have been recognized.

The course of the disease is as variable as its presentation. Some subjects have normal growth and development and lead a normal life. Others present variable degrees of mental and growth retardation. There is some evidence that the severity of resistance tends to improve as the subject gets older as determined by thyroid function tests. This has been shown in the TRβ knockout mouse model of RTH-beta (Weiss *et al.*, 2002) and is supported from some published studies in humans.

Diagnosis and Differential Diagnosis

Serum Levels of Thyroid Hormones and TSH

Elevation in the concentration of serum free T4 is a *sine qua non* requirement for the diagnosis of RTH-beta. It is often accompanied by high serum levels of T3 with nonsuppressed TSH.

In RTH-beta, serum T_3 and T_4 values range from just above to several folds the upper limit of normal. Reverse T_3 concentration is also high in these patients. The degree of T_3 and T_4 elevation is usually congruent, resulting in a normal T_3 to T_4 ratio. This contrasts with the disproportionate increase in serum T_3 concentration characteristic of autoimmune thyrotoxicosis. The concentration of serum thyroglobulin reflects the level of TSH-induced thyroid gland activity. The extrathyroidal conversion of T_4 to T_3 has been normal.

The fractional uptake of radioiodide by the thyroid gland is high. The iodide appears to be normally organified since no discharge of trapped iodide has been observed following the administration of perchlorate.

TRH Testing

A diagnostic feature of the syndrome is the presence of normal or slightly elevated serum TSH levels and preservation of its response to TRH despite elevated TH levels. The TSH response to TRH is either normal or exaggerated; the latter is more common in patients receiving antithyroid drug therapy or with history of prior surgery or radioiodide therapy. The bioactivity of secreted TSH is normal or increased, and the concentration of its free α-subunit is not disproportionately high. In contrast, the α-subunit to TSH ratio is elevated in TSH-secreting tumors.

Responses to the Administration of TH and Other Drugs

The administration of supraphysiological doses of TH suppresses TSH secretion resulting in the decrease and eventually the abolition of the TSH response to TRH. In subjects with RTH-beta, L-T4 given in doses of up to 1000 μg/day and L-T3 up to 400 μg/day may be necessary. Various responses of peripheral tissues to the administration of TH have been quantitated. Most notable are measurements of the BMR, pulse rate, reflex relaxation time, serum cholesterol, lipids, enzymes, SHBG, and urinary excretion of hydroxyproline, creatine, and carnitine. Either no significant changes were observed, or they were much reduced relative to the amount of TH given.

As expected, the administration of the TH analog, 3,5,3′-triiodo-L-thyroacetic acid (TRIAC), to patients with RTH-beta produced attenuated responses. A standardized diagnostic protocol, using short-term administration of incremental doses of L-T_3, is recommended. The three doses given in sequence to an adult are a replacement dose of 50 μg/day and two supraphysiological doses of 100 and 200 μg/day. The hormone is administered in a split dose every 12 h, and each incremental dose is given for 3 days. Doses are adjusted in children and in adults of unusual weight to achieve the same level of serum T_3.

Administration of glucocorticoids promptly reduced the TSH response to TRH and the serum T4 concentration (Refetoff *et al.*, 1993). The β-adrenergic blockers, propranolol and atenolol, produce a significant reduction in heart rate.

Family Studies

Once a diagnosis of RTH-beta is suspected, testing of thyroid function in siblings and parents can be helpful. Confirmation of the same phenotype in other related individuals make the diagnosis of RTH-beta more likely. TSH-secreting adenoma as such tumors has not been reported to be familial. Identification of an abnormal phenotype in an asymptomatic family member will allow for a correct diagnosis and may prevent unnecessary diagnostic testing and treatment. From a practical standpoint, a physician may find it difficult to arrange for thyroid testing on asymptomatic relatives; however, considering the cost of an MRI, documentation of an inherited disorder is more cost-effective.

Imaging Studies

Imaging studies are not necessary for the diagnosis of RTH-beta. While an MRI of the pituitary is oftentimes ordered to satisfy the physician that a TSH-secreting adenoma (TSHoma) is absent, it cannot be justified as routine in the workup for RTH-beta due to the fact that a small microadenoma may be missed by the MRI and 10% of normal individuals may have some abnormality that may not have any clinical significance.

Nevertheless, one condition that is most similar to RTH-beta in terms of thyroid function testing is a TSHoma and is often most confused with RTH-beta. In both conditions, the free TH levels can be elevated to the same degree, and the serum TSH will not be suppressed. While the TRH stimulation test and alpha subunit can be helpful, oftentimes, distinguishing between the two diagnoses can be challenging unless (1) there is a clear genetic diagnosis such as a mutation in the THRB or (2) there is familial evidence (see earlier) of the phenotype. However, it should be noted that there have been several case reports of patients with both RTH-beta and TSHomas occurring simultaneously (Ando *et al.*, 2001; Krysiak *et al.*, 2011; Teng *et al.*, 2015; Watanabe *et al.*, 1993).

Genetic Studies

The use of genetic testing in a family with RTH-beta for mutations in the *THRB* genes is no longer limited to research laboratories as Quest Diagnostics and others offer *THRB* gene sequencing for a definitive diagnosis. Once a mutation is identified, screening of other family members for the mutation can be more sensitive than screening for the phenotype due to the mild and variable nature of the RTH-beta phenotype. Confirmation of the mutation in a newborn may eliminate the need for treatment. Confirmation of the mutation in a fetus, at some point, may allow us to prescribe intrauterine treatment, if necessary.

Summary of Recommended Diagnostic Evaluation

1. Usual presentation—persistently high serum levels of TH with nonsuppressed TSH. Given the inherited nature of RTH-beta, normal thyroid tests are never seen in subjects who have not been treated.
2. Confirm the elevated serum levels of TH and exclude TH transport defect or antibody interference in the assays.
3. Measurement of thyroid function tests in other family members.
4. In sporadic cases, exclude the presence of a pituitary adenoma by measurement of α-subunit in serum.
5. Demonstrate a blunted TSH suppression and metabolic response to the administration of supraphysiological doses of TH.
6. Perform genetic studies when indicated.

Treatment

General Considerations

No specific treatment is available to fully correct the defect. Fortunately, in most cases of RTH-beta, the partial tissue resistance to TH appears to be adequately compensated by an increase in the endogenous supply of TH, and no treatment is necessary in these cases (Hassan and Koh, 2008).

In cases where previous erroneous diagnosis has occurred resulting in postsurgical or postradiation hypothyroidism, treatment with TH can be started. Serum TSH level can be used as a guideline for hormone dosage.

Some patients with RTH-beta present with peripheral tissues relatively more resistant than pituitary. Thus, compensation for the defect at the level of peripheral tissue is incomplete. In such instances, administration of supraphysiological doses of TH is indicated. Since the dose varies among affected subjects, it should be individually determined by assessing tissue responses.

Patients without prior antithyroid treatment but with more severe thyrotroph resistance and symptoms of thyrotoxicosis may also require therapy. Common symptoms are hyperactivity; tachycardia; and, less commonly, diarrhea. Usually, symptomatic treatment with a β-adrenergic-blocking agent would suffice. Local symptoms due to goiter size can be reduced by administration of a single high dose of L-thyroxine given every other day.

The exact criteria for treatment of RTH-beta in infancy have not been established. This is often an issue when the diagnosis is made at birth or in early infancy. In infants with elevated serum TSH levels, subclinical hypothyroidism may be more harmful than treatment with TH. Indications for treatment may include a TSH level above the upper limit of normal, retarded bone development, and failure to thrive. Treatment with L-T_3 may improve the symptoms of ADHD in a significant proportion of children that also have RTH-beta.

Although RTH-beta is a relatively rare condition, the physician should be aware that common diseases, such as autoimmune-mediated hypothyroidism and hyperthyroidism, can occur in subjects with RTH-beta. Concurrence of Graves' disease and RTH-beta would significantly alter the therapeutic and diagnostic approach to the care of these patients, but the overall goal would be to obtain clinical euthyroidism with a normal serum TSH.

Pharmacologic Therapy

TRIAC has been used successfully to decrease the serum TSH and TH levels, to reduce goiter size, and to alleviate some of the symptoms attributed to the effect of TH on peripheral tissues. However, the concomitant effects of TRIAC on markers that measure TH action on peripheral tissues, as well as on heart rate, are minimal probably because the decrease in TH levels is offset by the intrinsic specific thyromimetic effect of TRIAC (Radetti *et al.*, 1997). The ability of TRIAC to suppress TSH without an increase in the thyromimetic effect on peripheral tissues is due to properties of this TH analog: its higher affinity for the β, but not α TR as compared with T_3, and its more rapid degradation. The mechanism mediating a similar effect attributed to D-T_4 is less well understood.

Dopaminergic drugs and somatostatin analogs have had limited use because of side effects and low success rate in maintaining TSH suppression.

General guidelines for the treatment with TH, usually L-T_4, are (1) elevated serum TSH levels, (2) failure to thrive that cannot be explained on the basis of another illness or defect, (3) unexplained seizures, (4) developmental delay, and (5) history of growth or mental retardation in affected members of the family.

The future direction in the treatment of RTH-beta will be the use of "designer drugs" that have been designed to interact with a specific mutant TR. Such a TH analog would have a strong affinity for the mutant TR and could eliminate the DNE. The rarity of the syndrome combined with the fact that RTH-beta is not a life-threatening illness, the expense of the drug, and the necessary trials to obtain approval, even as an orphan drug, make the widespread availability of these drugs something for the future.

Management of Pregnancy and RTH-Beta

Little is known about the ideal management of a pregnant mother with RTH-beta. Different considerations may need to be made for whether the fetus also has RTH-beta. In such an instance, one may predict that an increase level of maternal TH is necessary for the early development of a similarly affected fetus but could be detrimental to an unaffected fetus. On the other hand, it is unknown whether a normal mother would be able to provide the appropriate amount of TH to an RTH-beta fetus (e.g., when the father is affected or a *de novo* mutation). A retrospective study of a large family the RTH-beta, due to THRB 243Q, demonstrated that pregnancy loss was increased by threefold in affected mothers, but not in couples with an affected father and unaffected mother (Anselmo *et al.*, 2004). Unaffected infants born to affected mothers had lower birth weights and suppressed serum TSH concentrations. Management of pregnancies in mothers with RTH who are carrying unaffected fetuses may warrant the use of antithyroid medication depending on the well-being of the fetus. In such mothers, free T4 should be maintained not higher than 20% above the upper limit of normal with the use of propylthiouracil. There is no basis for regular treatment of unaffected mothers carrying affected fetuses unless the fetus has a large goiter or is in distress. In such cases, treatment with intra-amniotic infusion of L-thyroxine could be considered. Further investigation is necessary for the evaluation of these important questions.

Management of Differentiated Thyroid Cancer and RTH-Beta

As more cases of RTH-beta are diagnosed, it is not unusual that there would be more cases of differentiated thyroid cancer found in RTH-beta patients. However, there is no direct evidence that RTH-beta is causative for thyroid cancer in humans. Mouse models with homozygous TRβ defects do have an increased incidence of differentiated thyroid cancer. The challenge in RTH-beta with thyroid cancer is the TH replacement following thyroidectomy. Such patients can require as much as 1 g of L-thyroxine daily to suppress the TSH.

TSH-Producing Adenomas and Resistance to Thyroid Hormones☆

P Beck-Peccoz, L Persani, and A Lania, University of Milan, Milan, Italy

Glossary

Hyperthyroidism Clinical condition characterized by excessive secretion of thyroid hormones in the presence of normal tissue response to thyroid hormone action.

Hypothalamic – pituitary – thyroid axis Axis composed of the hypothalamus (thyrotropin-releasing hormone [TRH] and other molecules produced in the brain), the pituitary (thyroid-stimulating hormone [TSH]), and the thyroid (thyroxine [T4] and triiodothyronine [T3]).

Pituitary tumors Neoplastic lesions of the pituitary; they are generally adenomas and rarely carcinomas, and they may be nonfunctioning or functioning with hypersecretion of prolactin (PRL), growth hormone (GH), adrenocorticotropic hormone (ACTH), gonadotropins, or thyroid-stimulating hormone (TSH).

Resistance to thyroid hormones An inherited disease characterized by a reduced responsiveness of target tissues to thyroid hormone action.

Introduction

Hyperthyroidism usually results from thyroid stimulation by anti-thyroid-stimulating hormone (TSH) receptor autoantibodies or toxic adenomas, most of them due to activating mutation of TSH receptor, and very rarely by TSH-producing adenomas (TSH-omas) or other causes of central hyperthyroidism such as pituitary resistance to thyroid hormone (RTH) action. However, during the past decades with the advent of ultrasensitive immunometric assays routinely performed as a firstline test of thyroid function, patients with central hyperthyroidism have been recognized with increasing frequency. Patients with central hyperthyroidism have normal or elevated circulating TSH levels in the presence of high thyroid hormone concentrations. The most frequent cause of central hyperthyroidism is a TSH-producing pituitary adenoma. However, a subset of patients with RTH may present with signs and symptoms of hyperthyroidism and may be confused with patients with TSH-omas. It is mandatory to distinguish RTH patients from those with TSH-omas because the treatment of the latter is completely different from that of RTH patients.

TSH-producing adenoma is a rare disorder, accounting for about 0.5–2% of all pituitary adenomas. The prevalence in the general population is 1–2 cases per million. However, this figure is probably underestimated because the number of reported cases of TSH-omas tripled during the past decade or so. The increased incidence of TSH-omas has been futher confirmed by recent data obtained from The Swedish Pituitary Registry, demonstrating an increased TSH-omas incidence over time (0.05 per 1 million per year in 1990–94 to 0.26 per 1 million per year in 2005–09), the national prevalence in 2010 being 2.8 per 1 million inhabitants. The increased number of reported cases of TSH-omas is due principally to the introduction of ultrasensitive immunometric assays for TSH as a firstline test for the evaluation of thyroid function. Indeed, many patients previously thought to be affected with Graves' disease were correctly diagnosed as patients with TSH-omas or, alternatively, with RTH based on the finding of measurable serum TSH levels in the presence of elevated thyroid hormone concentrations.

Pathology

All TSH-oma cases originate from pituitary thyrotropes, with the exception of two individuals who showed ectopic nasopharynx TSH-omas. Only one TSH-producing carcinoma has been reported in the literature. Most TSH-omas are macroadenomas, with microadenomas accounting for less than 15% of all reported cases. The occurrence of invasive macroadenomas is particularly high in patients with previous thyroid ablation by surgery or radioiodine. This aggressive transformation of the pituitary tumor resembles that occurring in Nelson syndrome after adrenalectomy for Cushing's disease.

By light microscopy, tumoral thyrotropes generally appear to be chromophobic, with atypical nuclei and mitoses, and so they are often mistakenly recognized as pituitary malignancy or metastasis from distant carcinomas. By electron microscopy, these tumors are monomorphous and characterized by a poorly developed Golgi apparatus and a low number of small secretory granules aligned mainly under the plasma membrane.

Approximately 75% of TSH-omas secrete TSH alone, which is often accompanied by an unbalanced hypersecretion of the α-subunit of glycoprotein hormones. Hypersecretion of growth hormone (GH) and/or prolactin (PRL), resulting in acromegaly and/or amenorrhea/galactorrhea syndrome, is present in approximately 25% of tumors, whereas the occurrence of mixed TSH/

 doi:10.1016/B978-0-12-801238-3.04206-9

gonadotropin adenomas is rare and no association with adrenocorticotropic hormone (ACTH) hypersecretion has been documented. This may be due to the fact that GH and PRL share with TSH the common transcription factor Pit-1.

As for most pituitary tumors, the pathogenesis of TSH-omas remains largely unknown. Screening studies for genetic abnormalities that may be responsible for tumor formation were generally negative. Anecdotal reports showed overexpression of the Pit-1 gene, absence of thyroid hormone receptor isoforms, and (recently) mutations in the beta isoform of the receptor leading to an altered feedback mechanism that is possibly responsible for the tumor formation. However, available data concern only a low number of tumors and are too preliminary to draw definite conclusions on transcriptional and/or expression abnormalities in TSH-omas.

Clinical Manifestations

TSH-omas may occur at any age, although most patients are in the third to sixth decade of life. Unlike the female predominance seen with other common thyroid disorders, TSH-omas occur with equal frequency in males and females. Patients with TSH-omas present with signs and symptoms of hyperthyroidism that are sometimes milder than expected on the basis of circulating thyroid hormone levels. Signs and symptoms of hyperthyroidism are frequently associated with those related to the mass effects of the pituitary adenoma. Visual field defects are present in approximately 40%, headache in 20% and partial or total hypopituitarism in 25% of patients (**Table 1**).

Most patients have a long history of thyroid dysfunction, often misdiagnosed as Graves' disease, and approximately one-third had inappropriate thyroidectomy or radioiodine thyroid ablation. In some acromegalic patients, signs and symptoms of hyperthyroidism may be clinically missed because those of acromegaly overshadow them. The presence of goiter, frequently uni- or multinodular ($\sim$90% of reported cases), is the rule. Also, in patients with previous thyroidectomy, thyroid residue may regrow as a consequence of TSH hyperstimulation. Progression toward functional autonomy or differentiated carcinomas seems to be infrequent. Bilateral exophthalmos occurred in a few patients who subsequently developed autoimmune thyroid disorders, whereas unilateral exophthalmos due to orbital invasion by pituitary tumor was reported in three patients with TSH-omas.

Diagnosis

Serum Thyroid Hormone and TSH Levels

Serum total and free thyroid hormone levels are definitely high in patients with TSH-omas, whereas TSH levels may be elevated or in the normal range (**Table 2**). In some patients with TSH-omas, the findings of normal TSH in the presence of high levels of free thyroxine (FT4) and free triiodothyronine (FT3) were demonstrated to be due to an increased biological activity of secreted TSH molecules.

Particular clinical situations and possible laboratory artifacts causing a biochemical profile similar to that characterizing central hyperthyroidism should be considered. Measuring free, instead of total, thyroid hormones may recognize most of the confusing conditions, including genetic alterations or drugs that may case quantitative/qualitative alterations of T4-binding globulin, albumin, or transthyretin leading to increases in thyroid hormone levels, particularly T4. Laboratory artifacts, such as those caused by circulating anti-T4 and/or anti-T3 autoantibodies that interfere in most immunometric assays, may cause falsely high levels of free thyroid hormones, whereas heterophilic antibodies directed against or cross-reacting with mouse immunoglobulin G (IgG), as well as anti-TSH autoantibodies in patients previously treated with bovine TSH or contaminated pituitary extracts, may lead to incorrect evaluation of the actual TSH concentrations.

Pituitary Glycoprotein Hormone α-Subunit

A helpful diagnostic tool for the diagnosis of TSH-omas is the determination of serum concentrations of the α-subunit, the subunit common to all pituitary glycoprotein hormones. Secretion of the α-subunit in these tumors is in excess not only of the TSH-β

Table 1 Clinical features of patients with TSH-omas

Feature	*Patients with TSH-omas (%)*
Goiter	91
Thyroid nodules	69
Severe thyrotoxicosis	30
Previous thyroidectomy	31
Menstrual disorders	33
Macroadenomas	84
Visual filed defects	40
Headache	20

Source Updated from data published through September 2013.

subunit but also of the intact TSH molecule, resulting in an α-subunit/TSH molar ratio generally higher than that recorded in controls matched for age and sex and with similar circulating levels of TSH, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) (Table 2).

Parameters of Peripheral Thyroid Hormone Action

Because patients with central hyperthyroidism may present with mild signs and symptoms of thyroid hormone overproduction, the measurements of several parameters of peripheral thyroid hormone action have been proposed to quantify the degree of hyperthyroidism. Some of these parameters, and in particular sex hormone-binding globulin (SHBG) and cross-linked carboxyterminal telopeptide of type I collagen (ICTP), have been used to differentiate hyperthyroid patients with TSH-omas from those with RTH (Table 2); patients with TSH-omas have levels of these indexes into the hyperthyroid range, whereas they are into the normal range in RTH patients.

Dynamic Testing

Several stimulatory and inhibitory tests are useful for the diagnosis of TSH-omas. Classically, the T3 suppression test has been used to assess the presence of a TSH-oma because complete inhibition of TSH secretion after T3 (80–100 μg per day for 8–10 days) has never been recorded in patients with TSH-omas (Table 2). It is worth noting that in patients with previous thyroid ablation, T3 suppression seems to be the most sensitive and specific test in assessing the presence of a TSH-oma. In approximately 93% of patients, TSH levels do not increase after TRH injection. The lack of TSH response to TRH may also be useful in unusual situations where TSH-omas coexist with primary hypothyroidism.

The majority of patients with TSH-omas maintain the sensitivity to native somatostatin or its analogues, and these tests may be predictive of the efficacy of long-term treatment in most patients.

Imaging Studies

When considering the diagnosis of a TSH-oma, full imaging studies, particularly nuclear magnetic resonance imaging (MRI) or high-resolution computed tomography (CT), are mandatory. Various degrees of suprasellar extension or sphenoidal sinus invasion are present in two-thirds of cases.

Differential Diagnosis

In a patient with signs and symptoms of hyperthyroidism, the presence of elevated thyroid hormone and detectable TSH levels rules out primary hyperthyroidism. When the existence of central hyperthyroidism is confirmed and the presence of methodological interferences is excluded, several diagnostic steps have to be carried out to differentiate a TSH-oma from RTH (Table 2). Indeed, the possible presence of neurological signs and symptoms (e.g., visual defects, headache) or clinical features of concomitant hypersecretion of other pituitary hormones points to the presence of a TSH-oma. Furthermore, the presence of alterations of pituitary content at MRI or CT scan strongly supports the diagnosis of a TSH-oma. Nevertheless, the differential diagnosis may be difficult when the pituitary adenoma is undetectable by MRO or CT scan or in the case of confusing lesions such as empty sella or pituitary incidentalomas. In these cases, elevated α-subunit concentrations or high α-subunit/TSH molar ratios and TSH

Table 2 Differential diagnosis between TSH-omas and RTH

Parameter	*TSH-omas*	*RTH*	P
Female/Male ratio	1.29	1.41	NS
Familial cases (percentages)	0[a]	86	<0.01
TSH (mU l^{-1})	2.9 ± 0.5	2.4 ± 0.4	NS
FT4 (pmol l^{-1})	39.8 ± 4.1	31.2 ± 2.3	NS
FT3 (pmol l^{-1})	13.9 ± 1.2	12.3 ± 1.0	NS
SHBG (nmol l^{-1})	121 ± 19	60 ± 5	<0.02
Lesions at CT or MRI (percentages)	98	7	<0.01
High α-subunit levels (percentages)	71	2	<0.01
High α-subunit/TSH m.r. (percentages)	82	2	<0.01
Absent or impaired TSH response to TRH test (percentages)	93	3	<0.01
Abnormal TSH response to T3 suppression test[b] (percentages)	100	100	NS

[a]Excluding the three families with Men-1 reported in the literature.

[b]Werner's test (80–100 μg T3 for 8–10 days). Quantitatively normal responses to T3 (i.e., complete inhibition of both basal and TRH-stimulated TSH levels) have never been recorded in either group of patients. Although abnormal in quantitative terms, TSH response to T3 suppression test was qualitatively normal in RTH patients.

Note. Only patients with intact thyroid were taken into account. Data are obtained from patients followed at our institute and are expressed as means ± SE.

unresponsiveness to TRH stimulation and/or to T3 suppression tests favors the presence of a TSH-oma. Moreover, in contrast to RTH patients, familial cases of TSH-omas have never been documented. Finally, an apparent association between TSH-oma and RTH was recently reported in a young Japanese woman, although genetic investigations of possible mutations in T3 receptor $\beta 1$ were not carried out. Nonetheless, the occurrence of TSH-omas in RTH patients is theoretically possible and, therefore, should be carefully considered.

Treatment and Follow-Up

Surgical resection is the recommended therapy for TSH-producing pituitary tumors. However, a radical removal of large adenomas, which still represent the majority of TSH-omas, is particularly difficult due to the local invasion of the tumor. Particular attention has to be paid to presurgical preparation of the patient. Antithyroid drugs or octreotide along with propranolol should be used to restore euthyroidism. If surgery is contraindicated or declined, as well as in the case of surgical failure, pituitary radiotherapy may be undertaken with the recommended dose of no less than 45 Gy fractionated at 2 Gy per day or 10–25 Gy in a single dose if a stereotactic gamma unit is available. The criteria of cure of patients operated and/or irradiated for TSH-omas have not been clearly established due to the rarity of the disease and the great heterogeneity of parameters used. In particular, clinical remission of hyperthyroidism with normalization of thyroid hormones, TSH, and α-subunit or α-subunit/TSH molar ratio, and with the disappearance of neurological symptoms, has been considered for the evaluation of the efficacy of surgery or radiotherapy in patients with TSH-omas. In our experience, undetectable TSH levels 1 week after surgery are likely to indicate complete adenomectomy provided that presurgical treatments were stopped at least 10 days before surgery. The most sensitive and specific test to document the complete removal of the adenoma remains the T3 suppression test. In fact, only patients in whom T3 administration completely inhibits basal and TRH-stimulated TSH secretion appear to be truly cured. No data on the recurrence rates of TSH-omas in patients judged to be cured after surgery or radiotherapy have been reported. Although earlier diagnosis has improved the surgical cure rate of TSH-omas, several patients require medical therapy to control the hyperthyroidism. Dopamine agonists, and particularly bromocriptine, have been employed in some TSH-omas with variable results, with positive effects being observed mainly in some patients with mixed PRL/TSH adenomas. Today, the medical treatment of TSH-omas rests on long-acting somatostatin analogues such as octreotide LAR and lanreotide SR. Treatment with these analogues leads to a reduction of TSH and α-subunit secretion in nearly all cases, with restoration of the euthyroid state in the majority of them.

Somatostatin analogs treatment induce the normalization of circulating thyroid hormone levels in more than 90% of patients and a significant decrease in goiter size in about 30% of cases. Somatostatin analog treatment induces a significant tumor mass shrinkage in about 40% of patients and vision improvement in about 70% of them.

Resistance to octreotide treatment has been documented in only 4% of cases.

According to recently published guidelines, somatostatin analogs treatment is indicated in patients not cured by surgery or to prepare patients to surgery, surgery remaining the therapy of choice for TSH-omas.

Thyroid Function Tests☆

ER Christ and Albert G Burger, University of Bern, Bern, Switzerland and University of Geneva, Geneva, Switzerland

Thyroid function tests are used for the diagnosis of all thyroid disorders, but are particularly important for the diagnosis of thyroid hormone deficiency (hypothyroidism) or excess (hyperthyroidism or thyrotoxicosis). Most frequently used are *in vitro* blood tests, but *in vivo* tests with radioisotopes can also provide information on thyroid function.

Pathophysiology

The thyroid is well known for its important stores of hormones, and the circulating thyroxine (T4) represents a large reservoir that is bound mainly to an interalpha glycoprotein, thyroxine-binding globulin (TBG), whereas other T4-binding proteins are transthyretin (prealbumin) and albumin. TBG has the highest affinity of these three proteins for T4. TBG's Ka value is $1 \times 1010\ M^{-1}$ compared with 7×10^{-7} and $7 \times 105\ M^{-1}$ for transthyretin and albumin, respectively.

The maximal binding capacity of TBG is about 250 nmol l^{-1} serum (20 μg/100 ml); and under most pathophysiological conditions, it is the limiting buffering system that determines the ratio of protein bound to the free T4. This ratio is extremely in favor of protein binding because the free fraction represents only 0.02% of the total serum T4.

There are three conditions for altering effective TBG concentrations.

The first condition is the inherited trait of x-linked absence (1:5000 births) or autosomal-linked increased TBG (1:25000) concentrations. In addition, many point mutations have been described, resulting in genetic variants, with perhaps the most striking one being found in Australia, where close to 30% of the aborigines present with a genetic variant due to direct consequence of the amino acid substitution and/or altered glycosylation of the protein. There is also a genetic variant where TBG concentrations are increased. This is due to gene duplication.

Second, serum TBG concentrations may vary as a function of glycosylation. A highly glycosylated TBG has a longer half-life. Estrogens increase glycosylation. Consequently, during pregnancy, TBG concentrations are very high. Androgens and glucocorticoids have the opposite effect. Obviously, TBG concentrations can also increase due to increased synthesis stimulated, for instance, by thyroid hormones and estrogens.
