MRI Magnetic Resonance Imaging.
RT Pituitary radiotherapy.

Introduction

Cushing syndrome (CS) is a clinical disorder caused by prolonged glucocorticoid (cortisol) exposure. CS can be divided into adrenocorticotrophic (ACTH)-dependent or ACTH-independent etiological categories (**Table 1**). ACTH-dependent CS can be secondary to a corticotroph pituitary adenoma secreting ACTH (Cushing disease; CD) or ectopic ACTH secretion. ACTH-independent is usually secondary to primary adrenal disease resulting in excessive cortisol secretion or to exposure to exogenous glucocorticoid administration (Magiakou and Chrousos, 2002). CS is very rare in childhood and adolescence; the incidence is approximately 10% of CS in the adult population which is reported as between 0.7 and 2.4 new cases/million/year (Newell-Price *et al.*, 2006; Lindholm *et al.*, 2001; Etxabe and Vazquez, 1994; Ambrosi *et al.*, 1990).

If pediatric CS is suspected it is extremely important to rapidly establish the diagnosis and the etiology using a formal investigation protocol. Once diagnosed, the primary aim should be the normalization of serum cortisol to minimize the adverse effects of prolonged hypercortisolaemia. Once remission is achieved, posttreatment management should focus on the optimization of growth, pubertal development, bone mineral density and body composition.

In this article, we will review the epidemiology, pathogenesis, diagnosis and management of children with pediatric CD. The recommendations are based on published data and our experience from the management of >70 cases of pediatric CS (53 cases of CD) during the last 35 years. The focus of this chapter will be on CD as this represents the commonest cause of CS in the pediatric age range.

Epidemiology

The most common cause of CS in all ages is iatrogenic, secondary to exogenous glucocorticoid administration such as inhaled, oral, parenteral or topical corticosteroids. Therefore, if CS is suspected, it is fundamental to take a thorough medication history to exclude this (Newell-Price *et al.*, 2006). Cushing disease (CD), caused by an ACTH-secreting pituitary adenoma is responsible for 75%–85% cases of endogenous pediatric CS patients compared with 49%–71% of adult cases (Magiakou *et al.*, 1994c; Magiakou and Chrousos, 2002; Weber *et al.*, 1995). In a series of 150 children with pituitary adenomas, 54.8% and 29.4% of the prepubertal children (0–11 years old) and adolescents aged 12 to 17 years had corticotroph adenomas (Kunwar and Wilson, 1999). Therefore,

Table 1 Classification of pediatric Cushing syndrome

ACTH-independent

1. Exogenous glucocorticoid administration (tablets, nose drops, inhalers, nasal spray, skin cream)
2. Adrenocortical tumor (adenoma or carcinoma)
3. Primary adrenocortical hyperplasia
   a. Primary pigmented nodular adrenocortical disease (PPNAD)
   b. Macronodular adrenal hyperplasia (AIMAH)
   c. McCune–Albright syndrome

ACTH-dependant

1. Cushing disease (ACTH-secreting pituitary adenoma)
2. Ectopic ACTH syndrome

in preadolescents, CD is the most common pituitary adenoma. In a review of 182 published pediatric CD cases, the median age at presentation was 14.1 years (Storr *et al.*, 2007). In our pediatric CD cohort, the median age was slightly lower, 12.3 years (Storr *et al.*, 2011). In adults, CD occurs more frequently in females with a ratio of 9:1 (females: males) (Magiakou and Chrousos, 2002). There was a striking male predominance (10:1) in our prepubertal CD patients which becomes an equal gender distribution during the pubertal age range (Storr *et al.*, 2004). Consistent with this, another study found that the female-to-male ratio was significantly different between patients who had surgery before the age of 15 years (0.8:1) and patients who had surgery after that age (3.7:1) (Lonser *et al.*, 2013) In contrast, a review from the NIH found an equal distribution of males to females in 102 pediatric patients with CD (53% vs. 47%; $n = 102$). There was also an equal gender distribution in prepubertal and pubertal patients (Libuit *et al.*, 2015).

Pathogenesis

CD is caused by ACTH-secreting pituitary corticotroph adenomas. These are usually microadenomas which in children are often extremely small—75% are less than 5 mm diameter (Lonser *et al.*, 2013). Macroadenomas (>1 cm in maximal diameter) are infrequent in children, occurring in approximately 4%–9% pediatric CD cases (Storr *et al.*, 2011; Lonser *et al.*, 2013) compared to ~10% of adult-onset CD (Feng *et al.*, 2017).

Molecular Pathogenesis

The molecular pathogenesis of CD is not fully understood. A number of hereditary disorders have been associated with corticotroph adenomas but these remain a very rare cause of CD. Multiple Endocrine Neoplasia Type 1 (MEN1) is an autosomal dominant disorder characterized by endocrine tumors including anterior pituitary adenomas. However, MEN-1 associated ACTH-secreting adenomas have been identified in only three cases (Rix *et al.*, 2004). Two of these went on to be diagnosed with hyperparathyroidism and one had a monozygotic twin subsequently diagnosed with hyperparathyroidism (Rix *et al.*, 2004). Pituitary macroadenomas are also recognized as an early manifestation of MEN1 (Stratakis *et al.*, 2000). However, no identifiable genetic cause was identified in eight patients with sporadic corticotroph macroadenomas (Cuny *et al.*, 2013). CD has recently been described one 21-year-old male patient with MEN2B and it was hypothesized that the RET oncogene may play a role in pituitary tumorigenesis (Kasturi *et al.*, 2017).

Corticotroph adenomas have also been identified in familial isolated pituitary adenoma (FIPA), McCune Albright Syndrome and Carney complex (Reincke *et al.*, 2015). Whole exome sequencing of 10 corticotroph adenomas revealed somatic missense mutations in the gene encoding ubiquitin-specific protease 8 (*USP8*) in four tumors (Reincke *et al.*, 2015). Mutations in the aryl hydrocarbon receptor-interacting protein (*AIP*) gene are associated with FIPA and most often present with pituitary macroadenomas. However, only one child with an ACTH secreting microadenoma out of 74 (1.4%) with CD was found to have an *AIP* mutation (Stratakis *et al.*, 2010). Therefore, a genetic cause of CD is extremely rare in sporadic cases. However, those with a positive family history or large adenomas should be referred for genetic counseling and testing (Storr and Savage, 2015; Cuny *et al.*, 2013).

Clinical Features

The main features of CD in childhood and adolescence are weight gain, growth arrest and typical Cushingoid facial features i.e., a plethoric, round face. **Table 2** shows the classical features of CD and the frequency in which they occur in children compared with adults (Storr *et al.*, 2011). It is important to recognize the features of CD early to allow timely diagnosis and management and to minimize the development of comorbidities. A subtle or subclinical presentation is unusual in children and although periodic CD exists, this is very rare in young patients. The onset of CD is usually gradual and may span many years which can lead to an unacceptable delay in diagnosis and initiation of definitive treatment.

The mean length of symptoms before diagnosis in our cohort of 43 pediatric CD patients was 2.5 ± 1.7 years (range 0.3–6.6 years) (Storr *et al.*, 2011). Although growth failure i.e., poor growth velocity is recognized in all children, not all have short stature (height SDS ≤ −2) (Storr and Savage, 2015). Whilst most pediatric CD patients in our cohort had a reduced height (<0.0 SDS), BMI SDS was >1.5 (Storr *et al.*, 2007). This reduction in height associated with elevated BMI/weight gain, is a key clinical feature of hypercortisolaemia in children. The presence of growth failure can also effectively differentiate children with simple obesity (mean height SDS 1.18 ($n = 41$) from those with Cushing's disease (mean height SDS −1.88 ($n = 25$), respectively (Greening *et al.*, 2006). In addition to growth retardation, many children have a delayed bone age. A retrospective review of our cohort revealed 15/17 (88%) children with CD, median age 12.1 years (range 5.8–17.4) presented with a mean bone age delay of 2 years (range −0.5–4.1) (Peters *et al.*, 2007).

Abnormal virilisation in combination with delayed puberty is also common in prepubertal children with CD. This is a result of high adrenal androgens combined with gonadotrophin deficiency. The latter is a consequence of the hypercortisolaemia suppressing gonadotrophin production (Dupuis *et al.*, 2007).

Table 2 Clinical features at diagnosis of pediatric Cushing disease ($n = 52$)

Major symptoms	*Patients (n)*	*% of total*
Facial changes	52	100
Weight gain	51	98
Weight loss	1	2
Pre-pubertal virilisation	21/24	88
Fatigue	33	63
Emotional lability/depression	30	58
Hirsutism	33	63
Headaches	26	50
Striae	25	48
Hypertension	24	45
Acne	22	42

In summary, the four key features suggestive of CD in children are: a change in facial appearance; weight gain; a history of growth failure +/− short stature and the presence of abnormal virilisation in prepubertal patients (Storr and Savage, 2015).

Diagnosis

Due to the rarity and complexity of pediatric CD, it is recommended that pediatric endocrinologists investigate suspected cases with the support of adult endocrinologists who are more experienced in the management of Cushing's syndrome.

Biochemical Evaluation

Before embarking on biochemical evaluation to confirm a diagnosis of Cushing syndrome, it is important to exclude exogenous CS secondary to oral, nasal or topical glucocorticoid treatments as this is much more common than endogenous Cushing's syndrome. A consensus statement recommends only investigating children with obesity and associated slowing of their growth (Nieman *et al.*, 2008). However, as this disorder often has an insidious onset, it is also important to have a low threshold for investigations and early referral to a tertiary centre if childhood CS is suspected.

The algorithm for investigations in children should be based on that performed in adults (Newell-Price *et al.*, 1999; Storr *et al.*, 2007; Guaraldi *et al.*, 2014). A suggested investigation protocol for suspected pediatric Cushing syndrome is shown in **Table 3** (Storr *et al.*, 2007; Guaraldi *et al.*, 2014). The protocol of investigations consists initially of confirmation or exclusion of hypercortisolaemia (Cushing syndrome) followed by investigations to determine the etiology.

Confirmation or Exclusion of Hypercortisolaemia

Key biochemical features of hypercortisolaemia are increased 24 h urinary-free cortisol (UFC) excretion, loss of serum cortisol circadian rhythm with detectable cortisol at midnight and failure of suppression of cortisol during the low-dose dexamethasone suppression test.

UFC measurements in children have a reported sensitivity of 88% and specificity of 90% (Batista *et al.*, 2007a) suggesting this is not an ideal screening test for childhood CS alone. In contrast, we recently showed that this test is a reliable and practical investigation with high diagnostic accuracy for pediatric CS (Shapiro *et al.*, 2016). As increased UFC excretion may not be a consistent finding in pediatric patients with CS, we recommend at least two serial measurements to definitively rule out the diagnosis (Batista *et al.*, 2007a). Additionally, further diagnostic testing may be required if the UFC is normal but there is a high clinical suspicion of CS (Shapiro *et al.*, 2016). If there is doubt about the interpretation of the UFC values, we recommend hospitalization for the measurement of serum cortisol to assess circadian rhythm.

The suggested minimum sampling times for serum cortisol are 0900 h, 1800 h and midnight (when the child is asleep) (Storr and Savage, 2015). A loss of circadian rhythm is suggestive of CS and a sleeping midnight sleeping cortisol ≥ 121 nmol/L (4.4.µg/dL) has a very high sensitivity and specificity of 99% and 100%, respectively (Batista *et al.*, 2007a). All our patients with pediatric CS of multiple etiologies had sleeping midnight cortisol levels of > 50 nmol/L, confirming that this is a key diagnostic marker for CS in children (Storr and Savage, 2016).

Late night salivary cortisol is a less invasive alternative to serum cortisol and avoids stressful venepuncture in children. Evaluation of this investigation in 11 children with CD yielded a sensitivity and specificity of 95.2% and 100%, respectively (Martinelli *et al.*, 1999). However normative ranges have not been characterized for different aged children. Following the assessment of midnight cortisol, a low-dose dexamethasone suppression test (LDDST) should be performed. The established regime for adults and children ≥ 40 kg is 0.5 mg dexamethasone every 6 h (0300, 0900, 1500 and 2100 h) for 48 h. In children

Table 3 Scheme of investigation for patients with suspected Cushing syndrome

Confirmation or exclusion of Cushing syndrome
1. Urinary free cortisol excretion (24 h urine collection) daily for at least 2 days
2. Serum cortisol circadian rhythm study (09.00, 18.00 h, midnight [sleeping])
3. Low-dose dexamethosone suppression test (LDDST)
a. Dose 0.5 mg 6 hourly (09.00, 15.00, 21.00, 03.00 h) for 48 h
b. Dose for patients weighing <40 kgs; 30 μg/kg/day
c. Serum cortisol measured at 0 and 48 h
Definition of etiology of Cushing syndrome
1. Plasma ACTH (09.00 h)
2. CRH test (1.0 μg/kg IV)
3. Analysis of change in serum cortisol during LDDST
4. Adrenal or pituitary MRI scan
5. Bilateral inferior petrosal sinus sampling for ACTH (with CRH)

<40 kg, 30micrograms/kg/day dexamethasone should be given as per NIH-recommendations (Magiakou *et al.*, 1994c). Serum cortisol is measured at times 0 and 48 h i.e., 6 h after last dose and is suppressed (<50 nmol/L) in normal subjects (Magiakou *et al.*, 1994c).

Confirmation of CD

Following confirmation of CS, the priority is to establish the etiology. A 0900 h plasma ACTH level will be normal or high in ACTH-dependent CS and is always low and usually undetectable in ACTH-independent CD (due to suppression of the HPA axis). An ACTH of ≥29 pg/mL has a sensitivity % and specificity of 70% and 100%, respectively for CD (Batista *et al.*, 2007a). A corticotrophin-releasing hormone (CRH) test, using human sequence CRH (1 microgram/kg i.v.) is also recommended to confirm the diagnosis of CD in children. Serum cortisol is measured after 15, 30, 60, 90 and 120 min (Batista *et al.*, 2009) and a rise of >20% is suggestive of central ACTH production i.e., CD. A sensitivity of 74% for the CRH test has been reported (Batista *et al.*, 2007a).

Other groups report high sensitivity and specificity (97.5% and 100%, respectively) of the high dose dexamethasone suppression test (HDDST) in the confirmation of CD (Batista *et al.*, 2007b). Our decision to stop performing HDDST follows the finding of serum cortisol suppression during L- and HDDST in pediatric patients with CD (Dias *et al.*, 2006). In 24 patients, the mean baseline serum cortisol values of 590.7 ± 168.8 nmol/L (21.4 ± 4.7 μg/dL) decreased to 337.4 ± 104.0 nmol/L (12.2 ± 3.8 μg/dL) at 48 h during LDDST ($P < 0.05$; mean decrease, 45.1%) with 66% decreasing by >30%. This cortisol suppression during LDDST correlated with that during HDDST ($r = 0.45$, $P < 0.05$). Consequently, the decrease of cortisol during the LDDST strongly supports the diagnosis of CD and negates the need for a HDDST.

Radiological Imaging

MRI has superseded previous techniques for pituitary visualization. Pituitary adenomas are generally hypointense compared to the adjacent gland and take up contrast less avidly and in a more delayed fashion, and therefore fail to enhance with gadolinium (Newell-Price *et al.*, 1998). The detection rate of pituitary adenomas by MR scanning is much lower in children compared to adults, which in our adult cohort is approximately 76% of cases (Storr *et al.*, 2011). On pituitary postcontrast MR scanning, 63% and 55% of the corticotroph adenomas were identified in two large pediatric series (Batista *et al.*, 2007a; Batista *et al.*, 2009). This relatively poor visualization rate in children could be explained by the limited spatial resolution of MRI, i.e., small lesions within a small pituitary gland are less conspicuous. Therefore, pituitary MRI imaging alone cannot be relied upon to predict the adenoma position or to confirm the diagnosis of pediatric CD.

Bilateral Simultaneous Inferior Petrosal Sinus Sampling

Due to the low visualization rate of MRI scanning, we recommend bilateral simultaneous inferior petrosal sinus sampling (BSIPSS) to confirm the diagnosis of CD prior to transsphenoidal sinus surgery (TSS) (Storr and Savage, 2016). In children, ectopic ACTH secretion is extremely rare and so the aims of BIPSS is to confirm central ACTH secretion before embarking on pituitary surgery and to contribute to the localization of the microadenoma by demonstrating lateral or midline ACTH secretion.

BSIPSS was first established in adults at the NIH to enable distinction between CD and ectopic ACTH syndrome and also to provide a method of identifying a lateral versus central source of ACTH secretion within the pituitary (Oldfield *et al.*, 1991) It has

now become routine in adult practice unless the pituitary MRI unequivocally shows a lesion and all other investigations suggest central ACTH-dependent CD.

BIPSS is a highly specialized technique and in our centre, is performed by the same radiologist who regularly studies adult patients. In the majority of cases, general anesthesia (GA) is not required so that potential alteration of ACTH secretion is avoided. However, in very young children GA may be necessary. A pre-CRH inferior petrosal sinus/peripheral (IPS/P) ratio of ≥ 2.0 or post CRH IPS/P ratio of ≥ 3.0 is diagnostic of central ACTH- dependent CD with a sensitivity of 95% and specificity of 100% (Oldfield *et al.*, 1991). Lateralization of ACTH secretion is confirmed by an inter-petrosal sinus gradient IPSG ≥ 1.4.

The first pediatric data were reported in the large NIH series where the predictive value of lateralisation was 75%–80% (Magiakou and Chrousos, 2002). A subsequent study found the concordance of ACTH localization during BSIPSS and the adenoma position to be only 58% however exclusion of midline and bilateral lesions increased the positive predictive value to 70% (Batista *et al.*, 2006).

To date, we have successfully undertaken BSIPSS in 40 children without complications. The reported results suggest that ACTH sampling gives a better prediction of the site of the microadenoma than pituitary MR imaging (Magiakou and Chrousos, 2002; Storr *et al.*, 2011; Magiakou *et al.*, 1994c).

Treatment

CD in childhood leads to significant comorbidity and early diagnosis and definitive treatment is essential to effectively manage the symptoms and achieve an acceptable adult height, pubertal development and normal body composition.

Pediatric and Adult Cooperation

CD is extremely rare in children and even experienced pediatric endocrine centers will see relatively few cases during a 20-year period. Consequently, pediatric endocrinologists may not acquire the expertise to manage these complex patients. It is therefore essential that there is collaboration with a specialized adult endocrinology centre with experience in treating CD. The combined experience of a pediatric endocrinologist with expertise in pediatric CD, pituitary surgery and pituitary radiotherapy is optimal for the patient (Storr and Savage, 2015).

Pituitary Surgery: Selective Microadenomectomy

Transsphenoidal surgery (TSS) is the first line treatment for children and adults with CD. This procedure is established as safe and effective in children (Massoud *et al.*, 1997; Knappe and Ludecke, 1996; Kanter *et al.*, 2005; Joshi *et al.*, 2005). The aim of TSS is to selectively remove the adenoma tissue, maximizing the potential for normal pituitary tissue to remain in situ. The small size of ACTH-secreting adenomas and the pituitary fossa in children in association with absent aeration of the sphenoid bone in young patients adds to the technical difficulty of TSS. A pituitary surgeon with experience of transsphenoidal surgery in children will generally achieve a higher rate of cure.

The outcome of TSS depends on the definition of postoperative "cure" or remission. An undetectable postoperative 09.00 h cortisol of <50 nmol/L (Storr *et al.*, 2011) or <28 nmol/L (Lonser *et al.*, 2013) is considered "remission." This evidence of successful surgery is supplemented by immunohistochemical confirmation of an ACTH-producing adenoma.

In the two pediatric series where "cure" was defined as an undetectable postoperative serum cortisol "cure" rates were 100% and 69%, respectively (Storr *et al.*, 2011). Follow-up data suggest that recurrence rates of CD in these patients were very low (Storr *et al.*, 2011; Yordanova *et al.*, 2016; Batista *et al.*, 2009). Other pediatric series report surgical "cure" rates of between 50% and 78% (Leinung *et al.*, 1995; Devoe *et al.*, 1997; Linglart and Visot, 2002; De Oliveira *et al.*, 2010; Dyer *et al.*, 1994). Few report rates $>90\%$ (Magiakou *et al.*, 1994c; Lonser *et al.*, 2013; Fahlbusch *et al.*, 1994; Styne *et al.*, 1984).

Initial postoperative remission in children was associated with the identification of an adenoma at surgery and long-term remission correlated with younger age, smaller adenoma and morning serum cortisol of <1 μg/dL (28 nmol/L) after surgery (Lonser *et al.*, 2013). Lasting remission in children is observed in those patients with younger age, smaller tumor size and absence of cavernous sinus or dural invasion (Lonser *et al.*, 2013). However, recurrence of CD in adults has been reported up to 15 years after apparent surgical cure, even in individuals who had very low or undetectable postoperative cortisol levels (Alexandraki *et al.*, 2013). In our series of 21 pediatric CD patients where long-term follow-up data was available, clinical and biochemical recurrence of hypercortisolemia was seen in 2 patients (10%) at 2 and 6 years following TSS (Yordanova *et al.*, 2016). Therefore, lifelong follow-up for children treated for CD is essential.

Endoscopic Pituitary Surgery

More recently, the less invasive technique of endonasal endoscopic transsphenoidal pituitary surgery (ETES) has been used in some centers. In adult CD patients ETES has shown equivalent rates of complete tumor resection and is now established as the

standard approach (Goudakos *et al.*, 2011; Deklotz *et al.*, 2012). It has been associated with a shorter hospital stays, reduced bleeding, pain perception, anterior pituitary deficiencies and surgical complication rates (Storr *et al.*, 2014; Massimi *et al.*, 2011; Chivukula *et al.*, 2013). Early experience in pediatric CD showed excellent outcomes although the numbers are currently limited (Storr *et al.*, 2014).

Pituitary Radiotherapy

A proportion of pediatric patients who undergo TSS for CD do not achieve postoperative cure or remission. The options for second-line therapy are repeat TSS, pituitary radiotherapy (RT), long-term medical therapy to control hypercortisolaemia and bilateral adrenalectomy (Acharya *et al.*, 2010; Storr *et al.*, 2003a; Stratakis, 2012) In our centre, if there is persistent hypercortisolaemia or failure of remission within 2–4 weeks of TSS, then external pituitary radiotherapy (RT) is offered. Pituitary RT is now known to be safe and effective in children with CD with a more rapid mode of action than in adult patients (Storr and Savage, 2015; Storr *et al.*, 2003a). Stereotactic radiotherapy and gamma knife approaches are now available and utilized in adult CD, however experience is limited, particularly in children.

In our centre, a total dose of 45 Gy in 25 fractions over ~35 days is delivered. The effectiveness and rapid onset of this therapy was confirmed in three small series. In the first, series, a 12 out of 15 patients were cured within 18 months of radiotherapy and 10 of these were cured within 9 months of treatment (Jennings *et al.*, 1977). In our own series, 7 children were treated and all were cured with a mean interval from RT to cure of 0.94 years (range 0.25–2.86) (Storr *et al.*, 2003b). In the third series, eight subjects were treated and four were cured in 9–18 months after RT (Acharya *et al.*, 2010). In a further series, 8 children were treated with stereotactic external RT using 60 Co gamma radiation. Seven of the eight subjects were cured during the first year after completion of therapy (Thoren *et al.*, 1986).

Careful monitoring of pituitary function is required postpituitary RT. Growth hormone (GH) deficiency was present in 83% of pediatric CD patients post-RT at a mean interval of 1 year (range 0.11–2.54). However, on retesting at an interval of 9.3 years (range 7.6–11.3), 75% of patients, GH secretion recovered (Chan *et al.*, 2007). GH deficiency and hypogonadism were also documented in seven children successfully treated with higher doses of 50–70 Gy (Acharya *et al.*, 2010). In another series of eight children, two developed hypothyroidism and all GH deficiency (Thoren *et al.*, 1986).

Medical Therapy and Bilateral Adrenalectomy

Definitive treatments such as surgery and/or radiotherapy, rather than long-term medical therapies are currently recommended for the management of pediatric CD. Medical therapies can be used to urgently lower cortisol levels in very sick patients, to normalize the hypercortisolemia in preparation for surgery or whilst awaiting the effects of radiotherapy. Adrenal steroidogenesis inhibitors such as metyrapone and ketoconazole are well tolerated and can be highly effective at reducing cortisol levels either alone or in combination (Biller *et al.*, 2008). Intravenous administration of etomidate has successfully controlled hypercortisolaemia in children with CD who were either too unwell for TSS or presented with acute unmanageable symptoms such as respiratory failure or severe psychosis (Greening *et al.*, 2005; Chan *et al.*, 2011; Storr and Savage, 2015).

Historically, the recommended treatment for CD was bilateral adrenalectomy (BA). However this can lead to the development Nelson's syndrome; a triad of excessive ACTH, pigmentation and an enlarging corticotroph adenoma (Hopwood and Kenny, 1977; McArthur *et al.*, 1979). Although Nelson's syndrome is rare, it is a potentially life-threatening complication and children are more at risk than adults (Barber *et al.*, 2010). In our centre three patients were treated with BA, 1 historically and 2 for life-threatening CD. Therefore, bilateral adrenalectomy remains a therapeutic option for CD in life-threatening situations or where TSS is not possible or available.

Postremission Growth and Development and Pituitary Function

Growth failure and short stature is almost always seen at diagnosis in pediatric patients with CD (Magiakou and Chrousos, 2002; Lebrethon *et al.*, 2000). The excessive production of adrenal androgens can also accelerate bone age and further compromise growth (Hayles *et al.*, 1966). Poor postremission catch-up growth has been reported in childhood CD (Magiakou *et al.*, 1994a, b). This has been attributed to continuing GH deficiency, occurring either from TSS, pituitary RT or the long-standing effects of chronic hypercortisolaemia on pituitary and growth plate physiology (Lebrethon *et al.*, 2000).

In the absence of catch-up growth, we recommend that GH deficiency is investigated at 3 to 6 months after TSS or completion of RT. If required, GH therapy should be initiated without delay and GnRH analogue therapy may be added to delay puberty and epiphyseal closure. Results demonstrate that this regime usually enables adequate catch-up growth and adult height within range of target height for the majority of patients (Davies *et al.*, 2005). Combined treatment with GH and aromatase inhibitors may also be a therapeutic alternative in pubertal patients (Boronat *et al.*, 2012).

Normal body composition is more difficult to achieve. Many patients remain obese and BMI SDS was elevated ($P < 0.01$) at a mean interval of 4.1 years after diagnosis in 14 patients (Davies *et al.*, 2005). A long-term follow-up study showed that the total body fat and the

ratio of visceral to subcutaneous fat remained abnormally high in the majority of pediatric CD patients studied 7 years after cure (Leong *et al.*, 2007). The implications of chronic excess visceral fat in terms of risk for adult metabolic syndrome deserve future study. Bone mineral density (BMD) was closer to normal together with some patients having normal BMD at diagnosis (Scommegna *et al.*, 2005).

Pituitary function should be closely monitored following TSS and pituitary RT. A summary of reported long-term pituitary deficiencies following first-line TSS in children with CD is shown in **Table 4**. Our recent study of 21 pediatric CD patients revealed short-term growth hormone deficiency (GHD) in 14 (81%) patients (11 following TSS and 3 after RT) and 4 (44% of tested) had long-term GHD. Gonadotropin deficiency caused impaired pubertal development in 9 (43%) patients; 4 requiring sex steroid replacement postpuberty. Four (19%) patients had multiple pituitary hormone deficiencies, 3 after TSS and 1 post-RT (Yordanova *et al.*, 2016).

Pituitary function was analyzed in six patients after receiving RT and although GH deficiency occurred frequently initially, some recovery occurred in adult life (Chan *et al.*, 2007). Gonadotrophin secretion was generally preserved with normal or early puberty; the latter being a well-recognized complication of cranial radiotherapy (Nicholl *et al.*, 1993). TSH and ACTH deficiency was minimal (Chan *et al.*, 2007). It is important to note that the risk of hypopituitarism may continue to increase in the years after radiation.

Brain atrophy, cognitive impairment and psychopathology, most commonly depression, have been reported in adults with hypercortisolaemia (Dorn *et al.*, 1997). A study in children with CD, found significant cerebral atrophy at diagnosis, however, there was no difference in IQ scores between patients and controls. This study reported an almost complete reversal of the cerebral atrophy as has been observed in association with hypercortisolaemia-induced severe psychosis (Chan *et al.*, 2011). Surprisingly, this was associated with a significant decline in cognitive output 1 year after TSS (Merke *et al.*, 2005). In contrast, adult studies showed reversible cognitive decline and loss of brain function with normalization of cortisol levels (Merke *et al.*, 2005; McEwen, 2002). In our series, 5/21 patients (24%) had long-term psychiatric comorbidities which included cognitive dysfunction, depression and mood disturbance (Yordanova *et al.*, 2016).

A recent review found children with CD have impaired quality of life which did not resolve within 1 year of treatment (Keil *et al.*, 2009). There is little data on the effects of hypercortisolaemia on long-term neurocognitive function in children and cognitive functioning following RT has yet to be studied.

Table 4 Reported cure rates and long-term pituitary function following first-line transsphenoidal surgery (TSS) in childhood CD

Series	*No. CD patients*	*Age (yrs)*	*No. of first-line TSS*	*Outcome*	*Long-term pituitary deficiencies*
Lonser *et al.*, (NIH, Bethesda, USA)	200	4.0–19.0	173/200 (87%)	189/200 (95%) cured[a]	10/200 (5%) DI Incomplete data
Storr *et al.* (2011) (Barts Health, London)	41 (1 macro-adenoma)	5.7–17.8	36/41 (88%)	24/35 (69%) cured[a] (macroadenoma not cured)	11/24 (46%) GH 2/24 (8%) DI 2/24 (8%) Hypopit
De Oliveira *et al.* (2010) (São Paulo, Brazil)	15	6.0–18.0	15	9/15 (60%) cured[a]	1/9 (11%) Hypopit 1/9 (11%) GH 1/9 (11%) DI
Acharya *et al.* (2010) (Mumbai, India)	48	9.0–19.0	48	27/48 (56%) cured[a]	Not published
Kanter *et al.* (2005) (Virginia, USA)	33	5.0–19.0	33	76% cured[a]	1/33 (3%) ACTH 1/33 (3%) DI Incomplete data
Massoud *et al.* (1997) (Great Ormond Street Hospital, London)	12	8.7–16.3	12	9/12 (75%) (clinical and biochemical remission)	7/9 (78%) GH 4/9 (44%) ACTH 4/9 (44%) GT 3/9 (33%) TSH 1/9 (11%) DI
Leinung *et al.* (1995) (Rochester, Minnesota, USA)	22 (1 macro-adenoma)	10.1–18.9	22	10/22 (45%) cured[a] (macroadenoma not cured)	1/22 (5%) TSH Incomplete data
Magiakou *et al.* (1994c) (NIH, Bethesda, USA)	50	Mean	14.4 ± 4	37/50 (74%)	35/37 (95%) cured[a] 6/37 (16%) TSH 3/37 (8%) DI 3/37 (8%) GH 1/37 (3%) GT
Dyer *et al.* (1994) (Suresnes, France)	36	≤ 16.0	33/36 (92%) (23 selective, 8 subtotal)	23/33 (69%) (hypocortisolaemia or "physiological" cure)	1/33 (3%) DI 1/33 (3%) Hypopit Incomplete data

[a]"Cure" defined as undetectable serum cortisol in the immediate postoperative period (<50 nmol/L). *CD*, Cushing's disease; *No.*, number; yrs., years; *GH*, growth hormone; *DI*, cranial diabetes insipidus; hypopit, pan hypopituitarism; *ACTH*, adrenocorticotropic hormone, *GT*, gonadotropins, *TSH*, thyroid stimulating hormone.

Summary and Future Perspectives

Pediatric CD is rare and close liaison with adult endocrinologists who regularly manage CD is recommended. Pediatric CD should be suspected in children who present with weight gain in association with short stature or reduced height velocity. A careful detailed history and a formal investigation protocol requiring hospitalization is important to make a secure diagnosis. The choice and interpretation of tests should be discussed with an adult specialist with experience of CD. Referral should be considered to a centre combining pediatric and adult endocrinology, BIPSS, TSS and pituitary RT. A specialized multidisciplinary approach to define the optimal therapeutic strategy is essential. Additionally, choosing a neurosurgeon experienced in TSS in children is likely to significantly improve the chance of effective and curative therapy. The less invasive technique of endonasal endoscopic transsphenoidal pituitary surgery provides an alternative to conventional transsphenoidal microscopic surgery in managing pediatric CD. Posttreatment management may pose difficulties in optimizing growth, body composition and puberty. Life-long surveillance is required to monitor for potential complications and relapse of CD.

Further studies are required to assess in detail the impact on long-term cognitive impairment and psychopathology following remission of childhood CD. Additionally, further studies are warranted to identify novel genetic defects associated with pituitary corticotroph cell tumourigenesis and to assess the efficacy of new medical therapies and surgical approaches.

Genetic Control of Fetal Sex Development

Rajini Sreenivasan, Brittany Croft, and Andrew Sinclair, Murdoch Children's Research Institute, Melbourne, VIC, Australia

Nomenclature

Gene symbol	Gene name
AMH	Anti-Müllerian hormone
AR	Androgen receptor
CBX2	Chromobox homolog 2
CTNNB1	Catenin (cadherin-associated protein), beta 1
CYP19A1	Cytochrome P450, family 19, subfamily A, polypeptide 1
DAX1	Nuclear receptor subfamily 0, group B, member 1 (*NR0B1*)
DHH	Desert hedgehog
DMRT1	Doublesex and mab-3 related transcription factor 1
EMX2	Empty spiracles homeobox 2
FGF9	Fibroblast growth factor 9
FGFR2	Fibroblast growth factor receptor 2
FOG2	Zinc finger protein, multitype 2 (*ZFPM2*)
FOXL2	Forkhead box L2
GADD45γ	Growth arrest and DNA-damage-inducible, gamma
GATA4	GATA binding protein 4
IGF1R	Insulin-like growth factor 1 receptor
LHX9	LIM homeobox 9
MAMLD1	Mastermind-like domain containing 1
MAP3K1	Mitogen-activated protein kinase kinase kinase 1, E3 ubiquitin protein ligase
MAP3K4	Mitogen-activated protein kinase kinase kinase 4
NR5A1 (SF1)	Nuclear receptor subfamily 5, group A, member 1
PGD2	Prostaglandin D2
PTGDS	Prostaglandin D2 synthase
RSPO1	R-spondin 1
SOX3	SRY (sex determining region Y)-box 3
SOX9	SRY (sex determining region Y)-box 9
SRY	Sex determining region Y
WNT4	Wingless-related MMTV integration site 4
WT1	Wilms tumor 1

Glossary

Gonadal dysgenesis A number of genetic conditions involving abnormal development of the gonads, resulting in underdeveloped and dysfunctional gonads (streak gonads).

Granulosa cells Cells that supply nutrients to the developing oocyte in the ovary and have a function analogous to that of the Sertoli cells in the testis.

Leydig cells Testosterone-producing cells located adjacent to the seminiferous tubules in the testis.

Sertoli cells Somatic supporting cells in the seminiferous tubules of the testes to which spermatids attach until they form spermatozoa.

Steroidogenesis The biological synthesis of steroid hormones (e.g., estrogen, progesterone, testosterone, cortisol, and aldosterone) from cholesterol.

Testis cords Specialized tubular structures that enclose and protect germ cells from external signals, support their development into mature spermatogonia, and eventually channel them into the male reproductive tract.

Theca cells Endocrine cells associated with ovarian follicles that produce the androgen substrate required for ovarian estrogen biosynthesis.

Sex Determination

The gonads are reproductive organs that function to produce gametes and sex hormones. In addition, they have a unique bipotential ability to differentiate into two distinct organs: the testis in males and ovary in females (reviewed in Brennan and Capel, 2004; Eggers *et al.*, 2014; Ohnesorg *et al.*, 2014). As a result of this unique feature, gene mutations that disrupt gonad development not only lead to defects in gonadal formation or function, but can also result in sex reversal.

Sex determination refers to the mechanism that determines the fate of the fetal bipotential gonad, and whether it develops into a testis or ovary (**Fig. 1**). In most mammals, sex is determined by chromosomal constitution, with males and females bearing XY and XX sex chromosomes, respectively. At around 4 weeks in humans or embryonic day 10 (E10) in mice, Steroidogenic factor 1 (SF-1, encoded by the *NR5A1* gene) and Wilms tumor associated gene 1 (*WT1*) are expressed in the genital ridge of both sexes, specifying the formation of the bipotential gonad. The bipotential gonad develops through thickening and proliferation of the coelomic epithelium along the mesonephros, giving rise to the somatic cells of the gonad (Karl and Capel, 1998). The primordial germ cells (PGCs) are specified in the epiblast prior to gonad formation; they then proliferate and migrate to the genital ridge via the hindgut, and eventually populate the gonads around E9.5–E11.5 in the mouse (McLaren, 2003).

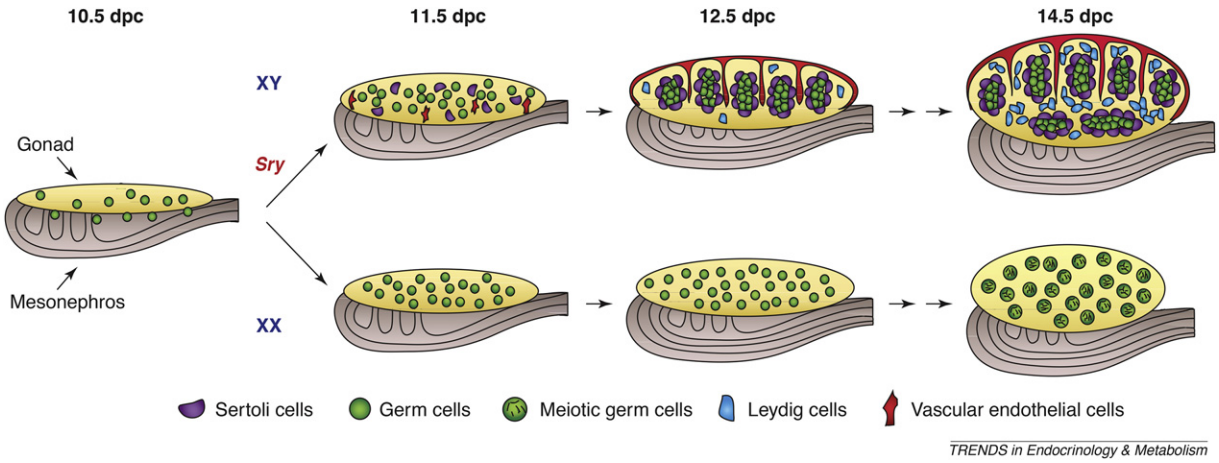

Fig. 1 Early gonad development in the mouse. A thickening of the coelomic epithelium of the mesonephros (*gray*) around E10 allows development of the bipotential gonad (*yellow*). Primordial germ cells (*green*) migrate from the hindgut into the genital ridge and populate the gonads between E9.5 and E11.5. Expression of *Sry* in XY gonads peaking at E11.5, and its downstream activation of *Sox9*, triggers testis differentiation, marked by differentiation and migration of Sertoli cells (*purple*) to enclose germ cells and form testis cords, as well as the formation of male-specific vasculature (*red*). The steroidogenic Leydig cells (*blue*) in the testicular interstitium begin to differentiate around E12.5. In contrast, during ovarian development, regulated by *Rspo1* and *Wnt4*, no apparent morphological changes are observed until the entry of germ cells into meiosis between E13.5 and E14.5. Modified from Ross, A. J. and Capel, B. (2005). Signaling at the crossroads of gonad development. *Trends in Endocrinology and Metabolism*, **16**(1), 19–25.

In the future male, expression of the Y-linked Sex-determining Region on the Y (*SRY*) gene, at 6 weeks in human or E10.5 in mice in pre-Sertoli cells, marks the initiation of male sex determination (Sinclair *et al.*, 1990; Koopman *et al.*, 1991). SRY, together with SF-1 (*NR5A1*), triggers the activation of *SRY*-related HMG box 9 (*SOX9*), thereby initiating a genetic cascade that drives the formation of the testis (**Fig. 1**). In mice, the expression of *Sry* and *Sox9* enables the proliferation of coelomic epithelial cells (Schmahl *et al.*, 2000), the differentiation of Sertoli cells, and their encapsulation of germ cells to form testis cords between E11.2 and E12.5 (Ross and Capel, 2005). In parallel, male-specific vasculature develops from vascular endothelial cells that migrate from the mesonephros into the gonad (Brennan *et al.*, 2002). The steroidogenic fetal Leydig cells then differentiate within the interstitial spaces between testis cords from E12.5 to E13.5 (**Fig. 1**).

In contrast, in the future female, few morphological changes are visible in the early XX gonad (**Fig. 1**). The entry of germ cells into prophase of meiosis between E13.5 and E14.5 in the mouse marks the first apparent feature of ovarian development (Menke *et al.*, 2003). Other events, such as differentiation of the somatic granulosa cells and development of the primordial follicles, occur just prior to birth (Ross and Capel, 2005). Ovarian development in mice is regulated by the expression of R-spondin 1 (*Rspo1*), which activates Wingless-related MMTV integration site 4 (*Wnt4*) signaling (Tomizuka *et al.*, 2008). In addition, Forkhead box L2 gene (*Foxl2*) is a transcriptional regulator required for granulosa cell function. Both Wnt signaling and *Foxl2* repress testicular development. For example, overexpression of β-catenin (*Ctnnb1*), a Wnt signaling component, inhibits the male pathway (Maatouk *et al.*, 2008). It has also been shown that *Foxl2* actively prevents transdifferentiation of the ovary into a testis (Uhlenhaut *et al.*, 2009).

These antagonistic interactions between the male and female pathways are exemplified by sex reversal phenotypes resulting from the gain or loss of function of the above-mentioned genes. For example, loss of *Sox9* in mice causes XY sex reversal, leading to the formation of ovaries (Barrionuevo *et al.*, 2006). Activation of β-catenin in XY gonads also leads to XY sex reversal (Maatouk *et al.*, 2008). In addition, a double knockout of *Foxl2* and *Wnt4* leads to complete XX sex reversal, resulting in the development of testes (Ottolenghi *et al.*, 2007) (**Fig. 1**).

Sex Differentiation

Sex differentiation refers to the progressive acquisition of male or female characteristics in the genital tract and external genitalia. Once sex is determined, subsequent gene expression in the Leydig cells gives rise to testosterone production, which results in the male sexual phenotype. Before sex differentiation has occurred, both male and female reproductive ducts are present in the developing embryo. Through the action of testosterone, the male-specific Wolffian duct develops into the epididymis, vas deferens, and seminal vesicles. Anti-Müllerian hormone (AMH) synthesized in Sertoli cells causes regression of the female-specific Müllerian duct (see **Fig. 2**) (Kobayashi and Behringer, 2003).

Similarly in the female, subsequent estrogen synthesis from the theca cells leads to the female sexual phenotype. Additionally, the lack of testosterone and AMH facilitates regression of the Wolffian duct and allows development of the Müllerian duct into the fallopian tubes (oviducts), uterus, and upper vagina (see **Fig. 2**) (Matzuk and Lamb, 2008).

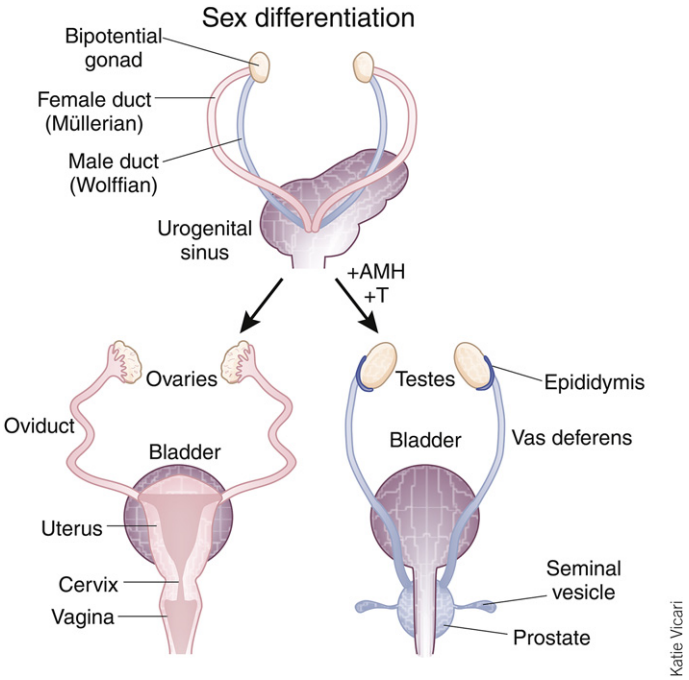

Fig. 2 Overview of human sex differentiation. Testosterone and anti-Müllerian hormone (AMH) secreted by the testis enable regression of the Müllerian duct and development of the Wolffian duct into the epididymis, vas deferens and seminal vesicles. The absence of testosterone (T) and AMH in the female allows regression of the Wolffian duct and development of the Müllerian duct into the uterus, oviducts and upper vagina (Matzuk and Lamb, 2008).

The external genitalia remain undifferentiated in human for up to 9 weeks. Subsequently, the genital tubercle differentiates into the penis in males (under the stimulation of dihydrotestosterone) and clitoris in females, while the labioscrotal swellings develop into the scrotum in males and the labia and vagina in females (Rey and Josso, 2009) (**Fig. 2**).

Disorders of Sex Development

Sex determination and differentiation are tightly regulated by genetic pathways involving several transcription factors and signaling molecules. Disruption of these pathways can cause congenital conditions known as disorders of sex development (DSDs) in which chromosomal, gonadal, or anatomic sex is atypical (Hughes *et al.*, 2006). DSDs occur when the phenotypic sex is inconsistent with the genotypic sex, or when sex determination and differentiation are incomplete or mixed (Matzuk and Lamb, 2008). Perturbations during sex determination can lead to defects in early gonad formation, while disruptions of sex differentiation may affect development of the internal and/or external genitalia and other secondary sexual characteristics.

DSDs can be categorized into three broad groups: (a) Sex Chromosome DSD (e.g., 45,X Turner syndrome and 47,XXY Klinefelter syndrome); (b) 46,XY DSD, which includes disorders of testicular development (e.g., complete/partial gonadal dysgenesis, gonadal regression, and ovotesticular DSD), disorders of androgen synthesis or action, and nonclassified forms such as hypospadias; and (c) 46,XX DSD, which includes disorders of ovarian development (e.g., ovotesticular DSD, testicular DSD, and gonadal dysgenesis) and disorders of androgen excess (Lee *et al.*, 2006; Mendonca *et al.*, 2009).

Clinical phenotypes observed in 46,XY DSD patients include testicular dysgenesis, ovotestes (gonads containing both testicular and ovarian tissue), anorchia (absence of testes due to embryonic testicular regression), cryptorchidism (undescended testes), female or ambiguous external genitalia, micropenis, hypospadias (abnormally positioned urethra), chordee (abnormal downward curvature of the penis), and gynecomastia (breast enlargement). In 46,XX DSD patients, clinical phenotypes such as testis or ovotestis development, primary ovarian insufficiency, Müllerian aplasia, utero-vaginal atresia, clitoromegaly (enlarged clitoris), ambiguous or male external genitalia, and lack of breast development may manifest.

DSDs are currently the most common congenital birth defect, with 1 in 150 boys presenting with hypospadias, 1 in 4500 live births with ambiguous genitalia, and 1 in 20,000 births with gonadal dysgenesis (complete sex reversal; Nassar *et al.*, 2007; Thyen *et al.*, 2006). Patients and their families are often traumatized by the uncertainty of gender, and the accompanying psychosexual consequences and possible surgical interventions. DSD patients are most likely to be infertile, and some are at an increased risk of gonadal cancer.

DSDs are a major pediatric concern and are often misdiagnosed and poorly prognosed due to the lack of an accurate diagnosis. Current approaches to diagnosis involve anatomical, imaging, and endocrine analysis. There is a great need for an accurate genetic

diagnosis of DSDs; this would enable clinicians, patients, and their families to make informed decisions with regard to clinical management and treatment options, thereby improving outcomes for patients.

Genetic Regulation of Fetal Sex Development

Gonad development involves a complex genetic cascade in which several factors either promote or repress each other in order to allow an initial bipotential gonad to differentiate into a testis or ovary (**Fig. 3**). Factors involved in establishment of the bipotential gonad include WT1, LHX9, EMX2, SF-1, GATA4, and its cofactor FOG2. Factors that regulate male sex determination and differentiation include SRY, SOX9, SF-1, IGF1R, WT1, AMH, GATA4/FOG2, PTGDS/PGD2, FGF9/FGFR2, DMRT1, DHH, CBX2, GADD45γ, MAP3K1, and MAP3K4. Ovarian development is controlled by several factors including RSPO1, CTNNB1, WNT4, FOXL2, DAX1, BMP2, and FST. Mutations in most of these genes are known to cause DSDs (reviewed in Eggers *et al.*, 2014; Ono and Harley, 2013; Sreenivasan and Harley, 2013). Despite this knowledge, around 60% of 46,XY DSDs still remain unexplained genetically, highlighting the fact that additional factors critical for gonadal development have yet to be discovered (**Fig. 3**).

Molecular Basis of Disorders of Sex Development (DSD)

Genetic Mutations

Genomic analysis of DSD patients has led to the identification of a number of gene mutations associated with these conditions. Together with gain-of-function and loss-of-function studies in mouse models, the roles of these genes in the control of gonadal development and endocrine function have been defined. Genes that have been implicated in 46,XY and 46,XX DSDs are described below.

AMH *(Anti-Müllerian hormone)*

AMH encodes a glycoprotein secreted by Sertoli cells of the developing testis. It functions as a signaling molecule required for the regression of the Müllerian ducts in male embryos which would otherwise differentiate into the uterus and fallopian tubes. *AMH* is also required for Leydig cell differentiation and function and follicular development in adult females. Homozygous *Amh* knockout XY mice develop female reproductive organs and are often sterile. In XX homozygous knockout mice, premature depletion of primordial follicles occurs. 46,XY DSD patients with *AMH* mutations have normal testes, male ducts, and external genitalia but develop persistent Müllerian duct syndrome (PMDS), type I (Knebelmann *et al.*, 1991).

AMHR2 *(Anti-Müllerian hormone type II receptor)*

The *AMHR* gene encodes a serine-threonine kinase transmembrane receptor to which AMH binds. *AMHR2* mutations result in similar phenotypes to those of *AMH* mutations. Homozygous knockout XY mice have a normal male reproductive tract, but also have a uterus and oviducts. While *Amhr2* knockout XY mice are able to produce functional sperm, most males are infertile as sperm transfer is blocked by the female reproductive organs. Persistent Müllerian duct syndrome (PMDS), type II resulting from *AMHR2* mutations has been shown to be inherited in an autosomal recessive fashion (Imbeaud *et al.*, 1994).

ARX *(Aristaless related homeobox)*

ARX encodes a transcription factor that regulates brain development, neuronal migration, and Leydig cell development. Lack of *ARX* in XY mice causes abnormal neuron development and disrupted Leydig cell differentiation. Human ARX mutations may result in testicular dysgenesis and ambiguous genitalia. Other associated conditions include X-linked lissencephaly with ambiguous genitalia, epilepsy, Proud syndrome (agenesis of the corpus callosum with abnormal genitalia and intellectual disability), and Partington X-linked mental retardation syndrome (Kitamura *et al.*, 2002; Kato *et al.*, 2004).

ATRX *(Alpha thalassemia/mental retardation syndrome X-linked)*

ATRX is a DNA helicase involved in chromatin remodeling that plays a role in testicular differentiation, α-globin regulation, and brain development. *ATRX* deficiency in XY mice causes apoptosis of proliferating Sertoli cells and impaired spermatogenesis (Bagheri-Fam *et al.*, 2011). Human *ATRX* mutations cause X-linked α-thalassemia/mental retardation syndrome and mental retardation-hypotonic facies syndrome. DSD phenotypes include testicular dysgenesis, cryptorchidism, micropenis, hypospadias, and either female, ambiguous, or male external genitalia (McPherson *et al.*, 1995).

CBX2 *(Chromobox homolog 2;* M33*)*

CBX2 encodes a polycomb protein that represses gene transcription during development by chromatin remodeling and histone modifications. *CBX2* regulates *NR5A1*, *SRY*, and *SOX9* transcription. Mice lacking *Cbx2* exhibit XY gonadal sex reversal (Katoh-Fukui *et al.*, 1998). *CBX2* mutations are autosomal recessive, resulting in 46,XY DSD with ovaries containing oocytes and normal internal and external female genitalia (Biason-Lauber *et al.*, 2009).

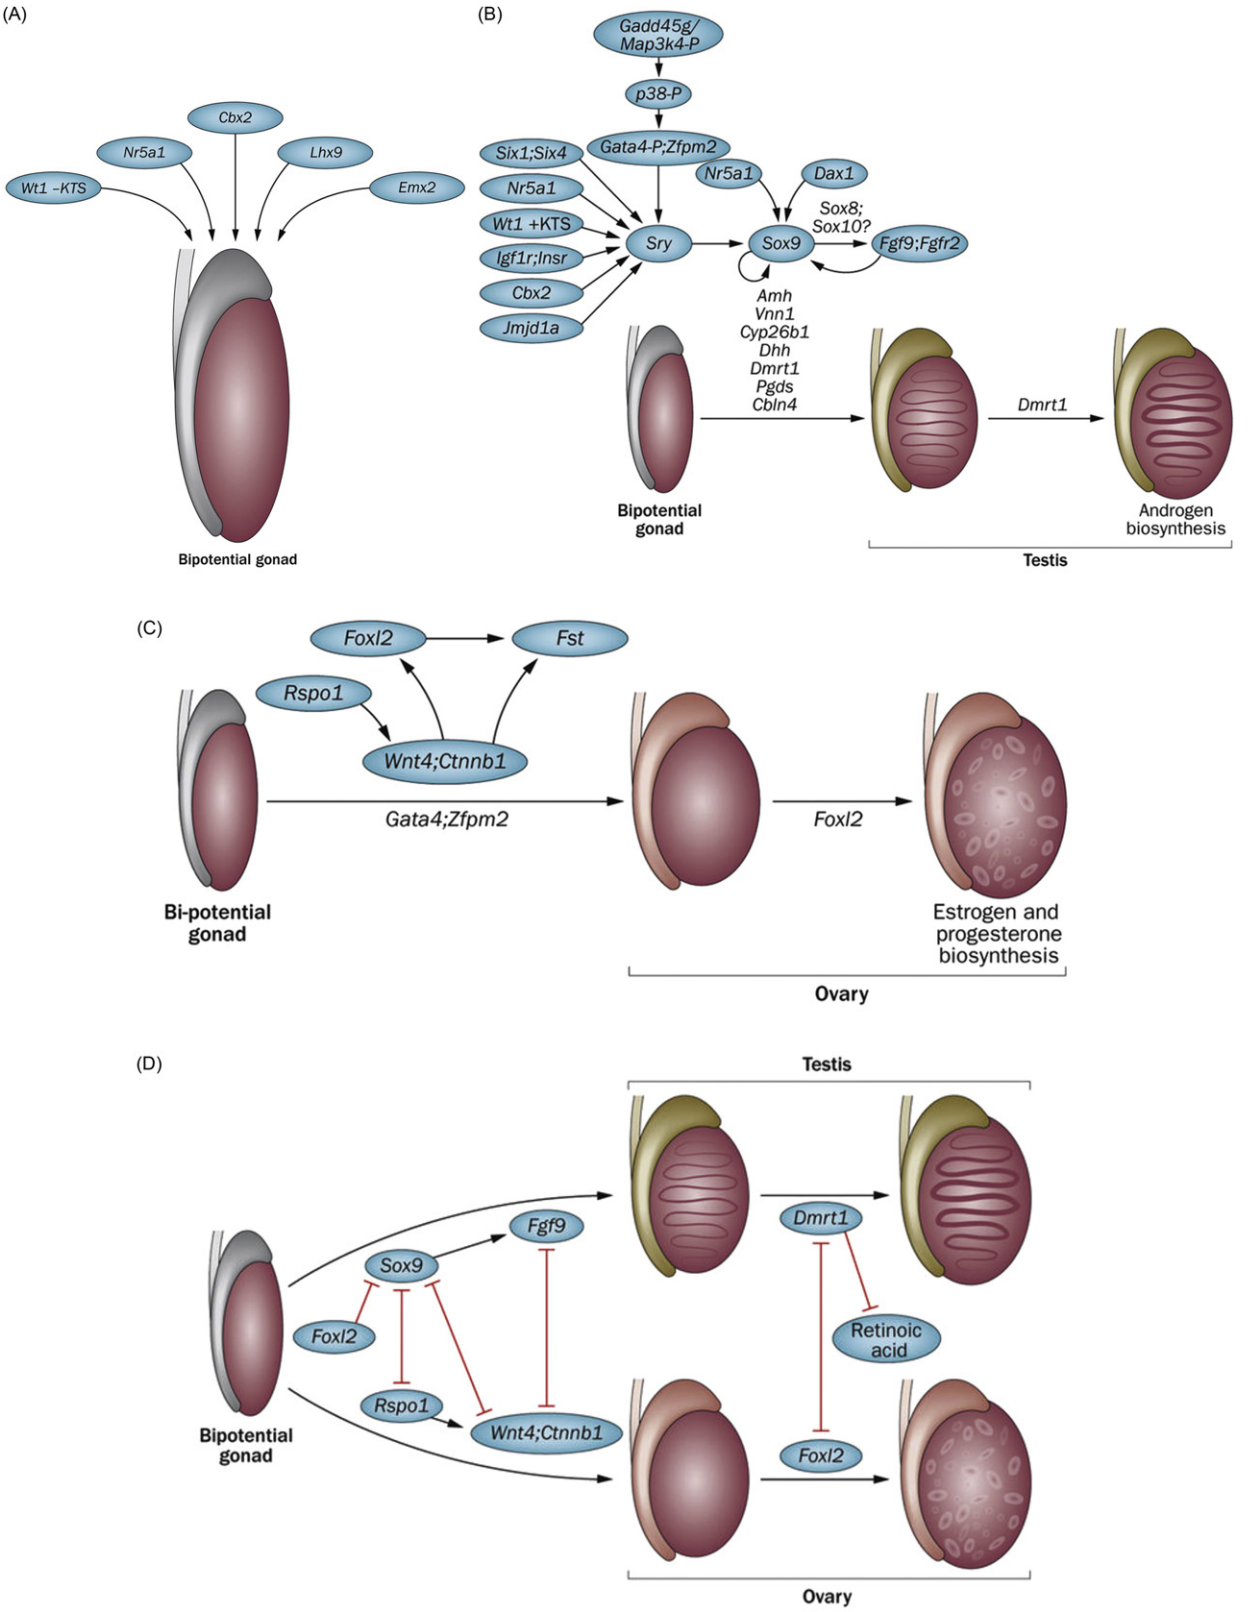

Fig. 3 Genetic regulation of mouse embryonic gonad development. (A) Genes involved in development of the bipotential gonad; (B) Genetic regulation of testis development and differentiation; (C) Genetic regulation of ovarian development and differentiation; (D) Antagonistic interactions between genes that regulate testicular and ovarian development enable repression of the pathway of the opposite sex, thereby preventing sex reversal (Eggers *et al.*, 2014).

CYP19A1 *(Cytochrome P450, family 19, subfamily a, polypeptide 1; aromatase)*

CYP19A1 encodes a cytochrome P450 enzyme that synthesizes estrogen from androgens (Harada, 1992). Autosomal recessive 46,XX DSD with mutations in *CYP19A1* have been reported where patients develop aromatase deficiency and present with hypoplastic ovaries, ambiguous external genitalia, androgenization during pregnancy, and lack of breast development (Ito *et al.*, 1993; Akcurin *et al.*, 2016). 46,XY DSD patients with *CYP19A1* gain-of-function mutations develop aromatase excess syndrome (AEXS), an autosomal dominant disorder resulting from excess estrogen production. Patients with AEXS may develop gynecomastia and mild hypogonadotropic hypogonadism (Shozu *et al.*, 2003).

DAX1 *(DSS-AHC critical region on the X chromosome 1, gene 1;* NR0B1*)*

DAX1 encodes a nuclear receptor required for testis, ovary, adrenal, and gonadotroph differentiation (Niakan and McCabe, 2005). In XY mice, *Dax1* duplications cause male-to-female sex reversal and gonadal dysgenesis. Human *DAX1* duplications result in X-linked recessive, dosage-sensitive male-to-female sex reversal by antagonizing *SOX9* expression, leading to 46,XY testicular dysgenesis, ovarian development, and female or ambiguous external genitalia (McCabe, 1996). Associated phenotypes include adrenal hypoplasia congenita (AHC) with hypogonadotropic hypogonadism.

DHH *(Desert hedgehog)*

DHH is a signaling molecule required for differentiation of Schwann cells as well as the testis (Bitgood *et al.*, 1996). In mice, *Dhh* regulates differentiation of Leydig cells and peritubular myoid cells to enable normal development of the testis cords (Clark *et al.*, 2000). *Dhh* knockout mice develop testes with abnormal peritubular tissue and severely restricted spermatogenesis. *Dhh* has also been implicated in germ cell proliferation and differentiation. Mutations in *DHH* are autosomal recessive and may lead to 46,XY partial gonadal dysgenesis with minifascicular neuropathy (Umehara *et al.*, 2000). Isolated 46,XY gonadal dysgenesis, persistent Müllerian ducts, and female external genitalia may also occur (Canto *et al.*, 2004).

DMRT1 *(Doublesex and mab-3 related transcription factor 1)*

DMRT1 encodes a highly conserved transcription factor essential for male sex determination and testicular differentiation (Raymond *et al.*, 1998). In XY mice lacking *Dmrt1*, postnatal testis development is severely impaired with an apparent loss of Sertoli cells and germ cells. *Dmrt1* prevents the transdifferentiation of male-specific Sertoli cells into female-specific granulosa cells by antagonizing the female sex determining factor *Foxl2* in the postnatal testis (Matson *et al.*, 2011). Hence, postnatal overexpression of *Dmrt1* in XX mice results in transdifferentiation of granulosa cells into Sertoli cells. In 46,XY patients, *DMRT1* deletions result in male-to-female sex reversal (Muroya *et al.*, 2000). Phenotypes include complete gonadal dysgenesis, presence of Müllerian structures, female or ambiguous external genitalia, and cryptorchidism.

FOXL2 *(Forkhead box L2)*

FOXL2 encodes a forkhead transcription factor essential for ovarian folliculogenesis and granulosa cell development. In mice, *FOXL2* antagonizes *SOX9* and *DMRT1* to prevent testicular differentiation in adult females (Matson *et al.*, 2011; Uhlenhaut *et al.*, 2009). As a result, *Foxl2* ablation in adult XX mice leads to transdifferentiation of ovaries to testes. While *FOXL2* is not strictly a causative gene for DSDs, mutations in it cause autosomal dominant blepharophimosis, ptosis and epicanthus inversus syndrome (BPES), characterized by eyelid malformation and female infertility caused by primary ovarian insufficiency (POI; Crisponi *et al.*, 2001).

GATA4 *(GATA-binding protein 4)*

GATA4 encodes a transcription factor required for myocardial differentiation and function as well as for testicular development. GATA4 activates *SRY* expression together with its cofactor *ZFPM2* (*FOG2*) (Tevosian *et al.*, 2002) and also activates *AMH* transcription (Tremblay and Viger, 1999; Watanabe *et al.*, 2000). Testis development is severely impaired in XY mice bearing a *Gata4* knockin with a targeted mutation that abolishes the interaction of *GATA4* with its *FOG* cofactors. Human mutations in *GATA4* result in autosomal dominant 46,XY DSD (testicular dysgenesis and female or ambiguous external genitalia) and congenital heart disease (Lourenco *et al.*, 2011).

HHAT *(Hedgehog acyltransferase)*

HHAT encodes a membrane bound acyltransferase that functions in the Hedgehog signaling pathway. In XY mice, *Hhat* is required for proper testis cord formation and differentiation of fetal Leydig cells. Homozygous *Hhat* knockout mice develop testicular dysgenesis, apolar Sertoli cells, fewer fetal Leydig cells, hypogonadism, and female external genitalia. Human mutations in *HHAT* result in autosomal recessive 46,XY DSD with partial or complete gonadal dysgenesis and chondrodysplasia (Callier *et al.*, 2014).

MAMLD1 *(Mastermind-like domain containing 1;* CXORF6*)*

MAMLD1 is transactivated by SF-1 to regulate fetal Leydig cell function and enhance testosterone production. Human mutations in *MAMLD1* result in X-linked hypospadias 2 (HYSP2) and myotubular myopathy. Hence, *MAMLD1* is essential for the normal development of male genitalia (Fukami *et al.*, 2006). However, while *Mamld1*-deficient mice display significantly reduced expression of multiple genes in fetal Leydig cells, both genital and reproductive development are unaffected (Miyado *et al.*, 2012).

MAP3K1 *(Mitogen-activated kinase 1)*

MAP3K1 functions as a serine-threonine kinase within the JNK and ERK kinase signaling pathways and the NF-kappa-B pathway. *MAP3K1* mutations may cause autosomal dominant complete and partial 46,XY gonadal dysgenesis with persistent Müllerian ducts (Pearlman *et al.*, 2010). Female/male/ambiguous external genitalia, hypospadias, and chordee have also been observed. While XY mice lacking *Map3k1* do not show male-to-female sex reversal (Warr *et al.*, 2011), loss of another MAP kinase *Map3k4* in mice of a sensitized background results in embryonic gonadal XY sex reversal due to reduced *Sry* transcription (Bogani *et al.*, 2009).

RSPO1 *(R-spondin family, member 1)*

RSPO1 encodes a secreted signaling molecule that regulates *WNT4* expression and is essential for female sex determination. *RSPO1* promotes ovarian development by upregulating the canonical WNT/β-catenin signaling pathway to antagonize testis formation. Homozygous XX *Rspo1* knockout mice show partial sex reversal with masculinized ovaries containing a coelomic blood vessel, fetal oocyte depletion, and ectopic testosterone production (Chassot *et al.*, 2008). Human mutations in *RSPO1* lead to the autosomal recessively inherited disorder palmoplantar hyperkeratosis with squamous cell carcinoma of the skin and 46,XX female-to-male sex reversal (Parma *et al.*, 2006). DSD phenotypes include testicular structures, the absence of Müllerian ducts, and masculinized or ambiguous internal and external genitalia.

SF-1 *(Steroidogenic factor 1;* NR5A1; AD4BP*)*

SF-1 is a nuclear receptor encoded by the *NR5A1* gene with crucial roles in steroidogenesis and sex determination, enabling proper development of the adrenal glands, gonads, and gonadotrophs. SF-1 regulates Sertoli cell-expressing genes such as *SOX9* and *AMH*. Gonads and adrenal glands are absent in XY and XX mice that lack *Nr5a1*. *NR5A1* mutations can be autosomal dominant or recessive, and are associated with adrenal hypoplasia congenita (AHC; primary adrenal insufficiency), gonadotrophin deficiency, and both 46,XY and XX DSD. 46,XY patients present with testicular dysgenesis, spermatogenic failure, hypospadias, and female or ambiguous external genitalia. In 46,XX DSD, primary ovarian insufficiency (POI) and testicular or ovotesticular DSD may occur (reviewed in Ferraz-de-Souza *et al.*, 2011).

SOX3 *(*SRY*-related HMG box gene 3)*

SOX3 is an X-linked transcription factor involved in the development of the pituitary and central nervous system; it does not normally play a role in sex development. However, *SOX3* has a sequence almost identical to the Y-linked *SRY* gene and, as a consequence, can substitute for its function. This was demonstrated when ectopic expression of *Sox3* was induced in the developing gonads of transgenic XX mice. This resulted in complete female-to-male sex reversal because *Sox3* was able to function and drive testis development in the absence of *Sry*. Similarly, in humans, rearrangements affecting *SOX3* regulatory regions can cause it to be ectopically expressed in the developing testis and substitute for *SRY*. This resulted in 46,XX female-to-male sex reversal, where patients develop small testes with abnormal spermatogenesis and normal male external genitalia (Sutton *et al.*, 2011). Other conditions associated with *SOX3* mutations include X-linked mental retardation with isolated growth hormone deficiency and panhypopituitarism.

SOX9 *(*SRY*-related HMG box gene 9)*

SOX9 encodes a transcription factor essential for normal testicular differentiation and development of the skeleton and other organs. It regulates several genes in the sex determining pathway, including *AMH*, *FGF9*, *PTGDS*, and *ETV5*, and also maintains its own expression. XY mice lacking *Sox9* show complete male-to-female sex reversal, while XX mice with ectopic expression of *Sox9* show female-to-male sex reversal. In humans, mutations within and around *SOX9* cause CD/SRA (*c*ampomelic *d*ysplasia, *a*utosomal *s*ex *r*eversal), a dominant condition characterized by skeletal abnormalities and sex reversal in 75% of patients (Foster *et al.*, 1994; Wagner *et al.*, 1994). Deletions in regulatory regions upstream of *SOX9* may result in isolated 46,XY DSD with phenotypes such as dysgenetic testes, ovotestes, and female or ambiguous external genitalia. Duplications/triplications in *SOX9* or its regulatory region can result in 46,XX sex reversal with testicular DSD, absent Müllerian ducts, and male or ambiguous external genitalia (Benko *et al.*, 2011).

SOX10 *(*SRY*-related HMG box gene 10)*

SOX10 encodes a transcription factor that is closely related to *SOX9* and is involved in neural crest and glial development. *Sox10* overexpression in XX mice leads to female-to-male sex reversal (Polanco *et al.*, 2010). In humans, *SOX10* duplication in a 46,XX DSD patient led to an almost complete masculinization of the external genitalia (Seeherunvong *et al.*, 2004).

SRY *(Sex-determining region Y)*

The *SRY* gene, located on the Y chromosome, encodes a transcription factor that initiates the genetic regulation of testicular differentiation (Sinclair *et al.*, 1990; Koopman *et al.*, 1991). It is required for the activation of *SOX9* expression, resulting in Sertoli cell differentiation from somatic precursor cells of the bipotential embryonic gonad. XY mice lacking *Sry* exhibit testicular dysgenesis and persistent Müllerian ducts, while XX mice with *Sry* translocations show complete sex reversal. Both 46,XY and 46,XX DSD can result from mutations in *SRY*. In 46,XY individuals, mutations in *SRY* result in Swyer syndrome with phenotypes such as testicular dysgenesis, ovotestis, and female or ambiguous external genitalia, while 46,XX DSD patients with *SRY* translocations show female-to-male sex reversal with male or ambiguous genitalia (reviewed in Goodfellow and Lovell-Badge, 1993).

TSPYL1 *(Testis-specific Y-encoded-like protein 1)*

TSPYL1 is a gene of unknown function that may be involved in chromatin remodeling. Human mutations in *TSPYL1* lead to autosomal recessive sudden infant death with dysgenesis of the testes syndrome (SIDDT; Puffenberger *et al.*, 2004). Reproductive phenotypes include fetal testicular dysgenesis, intra-abdominal and dysplastic testes, ambiguous external genitalia, partial development of the penile shaft, and reduced fetal testosterone levels.

WNT4 *(Wingless-related MMTV integration site 4)*

WNT4 is a signaling molecule that regulates ovarian development and antagonizes testis formation. *Wnt4* knockout in XY mice causes abnormal vasculature and function, while XX knockout mice show partial sex reversal with masculinized features such as ovaries with a coelomic blood vessel, absent Müllerian ducts, presence of Wolffian ducts, and ectopic testosterone synthesis (Vainio *et al.*, 1999). *WNT4* duplication in humans is associated with 46,XY testicular dysgenesis and ambiguous external genitalia (Jordan *et al.*, 2001). *WNT4* mutations may result in Mayer-Rokitansky-Kuster-Hauser syndrome, where 46,XX patients present with utero-vaginal atresia. Müllerian aplasia and hyperandrogenism may also occur (Biason-Lauber et al., 2004, 2007; Philibert *et al.*, 2008). *WNT4* mutations may also cause the autosomal recessive SERKAL syndrome (46,XX *s*ex *r*eversal with dysgenesis of *k*idneys, *a*drenals, and *l*ungs, Mandel *et al.*, 2008).

WT1 *(Wilms tumor associated gene 1)*

The *WT1* gene encodes a transcription factor essential for the development of the urogenital ridge (Wagner *et al.*, 2003). XY and XX mice deficient in *Wt1* lack gonads and a urogenital tract. *Wt1* induces the expression of *Sry*, and also synergizes with *Nr5a1* to activate *Amh* expression (Kreidberg *et al.*, 1993; Hammes *et al.*, 2001). Mutations in *WT1* are autosomal dominant and can result in Frasier syndrome, where 46,XY patients present with testicular dysgenesis and female or ambiguous external genitalia with an increased risk of gonadal tumor. Associated phenotypes include Wilms tumor, type 1 (a kidney tumor), WAGR syndrome (*W*ilms tumor, *a*niridia (absence of the iris), *g*enitourinary anomalies and mental *r*etardation), and Denys-Drash syndrome (Barbaux *et al.*, 1997; Haber *et al.*, 1990; Hastie, 1992; Park *et al.*, 1993; Schumacher *et al.*, 1998).

ZFPM2 *(Zinc finger protein, FOG family member 2;* FOG2*)*

ZFPM2 encodes a zinc finger cofactor of GATA4. *Zfpm2* deficiency in XY mice leads to reduced *Sry* expression and male-to-female sex reversal (Manuylov *et al.*, 2011). Human mutations in *ZFPM2* cause complete or partial gonadal dysgenesis in 46,XY individuals (Bashamboo *et al.*, 2014).

Androgen-related genes implicated in DSDs

Genes that encode components of the steroidogenic pathway have also been implicated in DSDs. These DSD mutations are all autosomal recessively inherited. Patients with such mutations usually have normal gonadal development, but exhibit perturbations in external genitalia development due to abnormal androgen synthesis or action. Androgen-related genes that have been implicated in DSDs are listed in **Table 1**.

Alterations Affecting Noncoding Regulatory Regions of DSD Genes

As discussed earlier in this article, much of what is known about the genetic cause of DSD comes from examining changes in the coding regions of genes. However, there is an ever-growing number of genes that are affected by noncoding variation.

Noncoding variation is broadly defined as mutations, deletions, insertions, and rearrangements in regions of the genome not directly required for protein coding. This can include promoters and introns as well as regions far up or downstream of the gene itself (Baetens *et al.*, 2016). Variations in these noncoding regions often influence the regulation of genes, altering where, when, or how much a particular gene is expressed (Shlyueva *et al.*, 2014). This is an important factor when studying the genetic causes of DSD, as inappropriate expression of a male determining gene in an XX environment or vice versa can cause sex reversal. In this section, we shall discuss how alterations to noncoding regulatory regions can cause DSD.

SRY

SRY, the master sex determining gene, is most commonly translocated from the short arm of the Y chromosome onto the X, causing male-to-female 46,XX ovotesticular DSD. Mutations in the coding region of the gene are also responsible for a significant proportion of 46,XY DSD cases. However, there is only one known case of a mutation upstream of *SRY* in the promoter. This 3 bp deletion removes an important transcription factor binding site, preventing transcriptional activation of *SRY* in the developing gonad (Assumpcao *et al.*, 2005). This, in turn, caused 46,XY complete gonadal dysgenesis in the patient and was inherited from the father, who carried the mutation and had severe hypospadias as a child.

SOX9

SOX9 expression in the testis is regulated by a complex and undefined number of regulatory elements within a region 2 Mb upstream of the promoter. Multiple cases of copy number variations (CNVs) upstream of *SOX9* have been identified in both 46,XY and 46,XX DSD. Duplications ~500 kb upstream of *SOX9* in 46,XX individuals lead to female-to-male sex reversal, whereas

Table 1 Androgen-related genes implicated in DSDs

Gene symbol	*Gene name*	*Phenotypes*
46,XX DSD due to androgen excess		
HSD3B2	Hydroxy-delta-5-steroid dehydrogenase, 3 beta- and steroid delta-isomerase 2	CAH, primary adrenal failure, hyperandrogenism, clitoromegaly
CYP21A2	Cytochrome P450, family 21, subfamily A, polypeptide 2	CAH, hyperandrogenism, male/ambiguous external genitalia
CYP11B1	Cytochrome P450, family 11, subfamily B, polypeptide 1	CAH, glucocorticoid-remediable aldosteronism, ambiguous external genitalia
POR	P450 (cytochrome) oxidoreductase	CAH, Antley–Bixler syndrome with disordered steroidogenesis, ambiguous external genitalia
GCCR (NR3C1)	Glucocorticoid receptor	Cortisol resistance, ambiguous external genitalia
HSD3B2	Hydroxy-delta-5-steroid dehydrogenase, 3 beta- and steroid delta-isomerase 2	CAH, primary adrenal failure, partial androgenization, ambiguous external genitalia, hypospadias
LHCGR	Luteinizing hormone/choriogonadotropin receptor	Leydig cell hypoplasia, hypergonadotropic hypogonadism, female/ambiguous external genitalia, micropenis
DHCR7	7-dehydrocholesterol reductase	Smith–Lemli–Opitz syndrome, female/ambiguous external genitalia
STAR	Steroidogenic acute regulatory protein	Lipoid adrenal hyperplasia (primary adrenal failure), pubertal failure, female external genitalia
CYP11A1	Cytochrome P450, family 11, subfamily A, polypeptide 1	Congenital adrenal insufficiency with partial/complete 46,XY sex reversal, pubertal failure, female or ambiguous external genitalia
CYP17A1	Cytochrome P450, family 17, subfamily A, polypeptide 1	CAH, hypertension, micropenis, female/ambiguous external genitalia
POR	P450 (cytochrome) oxidoreductase	CAH, Antley–Bixler syndrome with disordered steroidogenesis, male/ambiguous external genitalia
HSD17B3	Hydroxysteroid (17-beta) dehydrogenase 3	Undermasculinisation, gynecomastia, female/ambiguous external genitalia
SRD5A2	Steroid-5-alpha-reductase, alpha polypeptide 2	Partial androgenization at puberty, micropenis, ambiguous external genitalia, hypospadias
CYB5A	Cytochrome b5 type A, microsomal	Methemoglobinemia, type IV, female external genitalia
AKR1C2	Aldo-keto reductase family 1, member C2	Obesity, hyperphagia, and developmental delay, testes lacking spermatogonia, uterus-like structure, cryptorchidism, female/ambiguous genitalia
AR (NR3C4)	Androgen receptor	Complete/partial androgen insensitivity syndrome (AIS), gynecomastia, blind vagina, micropenis, abdominal/inguinal testes, X-linked hypospadias 1 (HYSP1), female/ambiguous genitalia, Kennedy disease

CAH, congenital adrenal hyperplasia

deletions in this region can result in 46,XY male-to-female sex reversal. The overlap of the patients' CNVs has defined two separate regulatory regions RevSex (24 kb, Ohnesorg *et al.*, 2017) and XYSR (34.5 kb, Kim *et al.*, 2015). It is theorized that these regions of the genome contain testis-specific enhancers necessary to drive *SOX9* expression in the testis. A loss of one or both of these regions in an XY individual results in a loss of *SOX9* expression and sex reversal (Kim *et al.*, 2015), whereas a duplication of the RevSex region in an XX individual could increase *SOX9* expression driving testis development (Benko *et al.*, 2011; Cox *et al.*, 2011; Hyon *et al.*, 2015; Vetro *et al.*, 2011; Xiao *et al.*, 2013).

SOX3

There have been cases of CNVs upstream and downstream of *SOX3* causing inappropriate ectopic expression of the gene in the developing testis, which causes sex reversal in 46,XX patients (Sutton *et al.*, 2011). *SOX3* shares a lineage with SRY, and they have almost identical DNA sequences. Although *SOX3* has no normal role in gonad development, it is proposed that abnormal ectopic expression of *SOX3* in the embryonic gonad is sufficient to substitute for SRY and drive testis development in an XX environment.

GATA4

A 35 kb deletion downstream of GATA4 was identified in a 46,XY patient with gonadal dysgenesis, including the *NEIL2* gene (White *et al.*, 2011). This downstream deletion contains a potential regulatory element within the intron of NEIL2, a gene with no

known or plausible function in sex differentiation (Ohnesorg *et al.*, 2016). *GATA4* regulation is also affected by deletions directly upstream of the gene causing 46,XY DSD (Harrison *et al.*, 2014).

NR0B1 (DAX1)

NR0B1 is sensitive to copy number changes, and many patients have been identified with duplications (46,XY DSD) and deletions (46,XX DSD) of the gene causing DSD (Barbaro *et al.*, 2007, 2008; Ledig *et al.*, 2010; Rojek *et al.*, 2016; White *et al.*, 2011). The regulatory region of NR0B1 is also sensitive to changes in copy number, as one case of a deletion 11–268 kb upstream of the coding region has been found to be associated with 46,XY sex reversal (Smyk *et al.*, 2007). A 60 kb inversion of the regulatory region, 4 kb upstream of the gene was discovered in one patient with adrenal hypoplasia and hypogonadotropic hypogonadism (Skinningsrud *et al.*, 2009). The inversion relocated the binding site of SF1 within the regulatory region, altering *NR0B1* expression.

DMRT1

Alterations in gene copy number resulting in a loss of DMRT1 have been detected in many cases of 46,XY gonadal dysgenesis (Barbaro *et al.*, 2009; Ledig et al., 2010, 2012; Tannour-Louet *et al.*, 2010). However, there is one patient with a deletion upstream of *DMRT1* resulting in the loss of the DMRT1 regulatory region (Barbaro *et al.*, 2009; Calvari *et al.*, 2000).

AR

Multiple noncoding variations have been identified associated with *AR* in human DSD cases. One such mutation was identified in the 5′ untranslated region of the *AR* gene introducing a new upstream start codon. This caused the expression of a short upstream open reading frame, which reduces the translation of the actual *AR* gene (Hornig *et al.*, 2016). Another noncoding variant has been detected in two sisters with 46,XY androgen insensitivity syndrome (AIS). This variant, located in intron 6 of the *AR* gene, created a de novo 5′ splice site and exonic splicing enhancer motif, causing two different spliced transcripts, leading to a premature stop codon within the transcript (Känsäkoski *et al.*, 2016).

New Technologies in DSD Research

Genomic technologies have come a long way in the last few decades, ever since the human genome was sequenced. The advent of massively parallel sequencing (MPS) has created multiple avenues for genomic research. Up until recently, the process of detecting single gene variation was laborious and expensive, as techniques such as Sanger sequencing can only target one specific region. The sheer number of genes that are associated with DSD also made it difficult to know which gene to screen. This section will focus on the new and emerging technologies being used to discover novel variants associated with DSD.

CNV Analysis

The majority of DSD research traditionally focuses on single nucleotide polymorphisms (SNPs) and small insertions and deletions (INDELs) in the coding regions of genes. However, as we have discussed in this article, a significant proportion of DSDs can be attributed to changes in copy number of genes as well as their regulatory regions. Specialist technologies are required to detect duplications or deletions greater than 1 kb (Redon *et al.*, 2006).

Historically, the only CNVs that could be detected were large-scale chromosomal rearrangement, above 10 Mb, using fluorescent in situ hybridization (FISH). FISH is still commonly used today to detect a patient's karyotype and presence of the Y chromosome. However, as FISH is limited in resolution and the technique can be cumbersome, many researchers are moving towards sequencing-based methods to detect karyotype and changes in copy number.

There are a number of technologies available to detect much smaller CNVs, such as those less than 1 kb. The two most popular technologies are CNV arrays and multiplex ligation-dependent probe amplification (MLPA). The two array technologies for detecting small CNVs are SNP arrays and comparative genomic hybridization (CGH) arrays. SNP arrays use fluorescent probes targeted to common SNPs. A higher intensity of SNP fluorescence indicates a duplication, and a lower intensity a deletion of the region (Nowak *et al.*, 2009). CGH arrays use tagged oligonucleotide probes to specific regions so that the copy number can be determined by changes in the probe number of the test sample compared to a control sample (Bashamboo *et al.*, 2010). These arrays can be customized to target certain regions of interest with higher probe density; the probes can also be evenly spaced across the entire genome to assay overall CNV.

By contrast, MLPAs are more targeted, cheaper, and quicker to use if screening a few key loci at a time. MLPA is a PCR-based method that can interrogate up to 40 genomic loci (Schouten *et al.*, 2002). These probes can be custom designed to allow for detection of CNVs at a number of locations, both coding and noncoding. MLPA is primarily used to screen for common CNVs associated with particular groups of patients (Sellner and Taylor, 2004). Arrays and MLPAs are often used sequentially. MLPAs are commonly used to confirm the results obtained from arrays and fine map CNVs, as probes can be designed to cluster around known breakpoints (Kim *et al.*, 2015; Ohnesorg *et al.*, 2017; White *et al.*, 2011, 2012).

Massively Parallel Sequencing Technologies

MPS, previously known as next generation sequencing, includes methods such as whole exome, whole genome, and custom targeted gene sequencing panels. MPS uses a parallel sequencing method where short oligonucleotide adapters are bound to the genomic fragments (100–300 bp). These fragments are then amplified using PCR and bound to a sequencing plate which can be read (Van Dijk *et al.*, 2014). The short reads are reassembled and aligned to the reference genome before variant analysis is conducted.

Until recently, targeted gene panels had been the norm when examining large DSD patient cohorts (Eggers *et al.*, 2016). Targeted panels have the benefit of being tailored to the disease of interest, allowing researchers to examine known causative genes and research candidates. Overall, a targeted approach reduces the bioinformatic load and prevents incidental findings, making it easier for researchers to find causative variants (Croft *et al.*, 2016). When large patient cohorts are being examined, targeted panels are considerably cheaper than other sequencing methods. However, as the number of genes associated with disorders such as DSD grows, targeted panels can be limited.

Whole exome sequencing (WES) analyzes the protein coding regions of the genome. The exome is less than 2% of the total genome, yet it contains around 85% of known disease-causing variants (Choi *et al.*, 2009; Van Dijk *et al.*, 2014). WES has a distinct advantage over targeted gene panels, as the data generated can be used to examine diagnostic and candidate genes as well as novel genes yet to be associated with DSD. WES is increasingly the method of choice for screening patient cohorts, although researchers often focus their analysis on a candidate list similar to targeted sequencing.

Whole genome sequencing examines the entire genome: coding and noncoding regions, such as promoters, enhancers, and introns. All these regions can be assayed and examined for potentially damaging variants. With the help of advanced bioinformatic techniques, WGS can also be used to detect CNVs. WGS generates the greatest amount of data of any technique, making it a challenge to store and analyze these data. As with WES, it can be difficult to filter out causative variants, requiring the data to be refined with candidate lists of coding and noncoding regions to focus the analysis. Currently, WGS remains the most expensive option for examining patient data, and only two small studies using WGS have been conducted on DSD patients (De Sousa *et al.*, 2016; Haines *et al.*, 2015). However, as the price continues to drop, WGS will become the only test necessary to capture the genetic variation in a patient. Sequence data from those patients who did not receive an initial diagnosis can be re-analyzed in subsequent years, as our knowledge of the genetics underlying DSD grows.

Hormonal Control of Fetal Sex Development

Nadine Hornig, Alexandra Kulle, and Paul-Martin Holterhus, Christian-Albrechts University of Kiel (CAU), Kiel, Germany; and University Hospital of Schleswig-Holstein (UKSH), Kiel, Germany

Nomenclature

AR	Androgen receptor
AMH	Anti-Müllerian hormone
APOD	Apolipoprotein D
AIS	Androgen insensitivity syndrome
DSD	Disorders of sex development
HOXA13	Homeobox gene A13
PMDS	Persistent Müllerian duct syndrome
RWDD1	RWD domain containing 1
TGFß	Transforming growth factor beta

In contrast to gonadal development in the early embryo, which is determined by the sex chromosomes and by the subsequent coordinated expression of sex specific genes in the gonadal anlagen, the sexually dimorphic anatomic differentiation of male and female internal and external genitalia after the 7th week of gestation is under hormonal control (Wilson *et al.*, 1981). The presence of the testes and their hormones, testosterone produced in the Leydig cells (Wilson *et al.*, 1981) and Anti-Müllerian Hormone (AMH) produced in the Sertoli cells (Lee and Donahoe, 1993), are crucial for the development of the male internal and external genitalia. In contrast, the absence of the testes and the consequent lack of these two hormones in the embryo result in the development of female internal and external genitalia.

Hormonal Control of Sex Development by Anti-Müllerian Hormone (AMH)

Anti-Müllerian Hormone (AMH) is synthesized and secreted by the Sertoli cells within the fetal testes. It is a transforming growth factor beta (TGFß) family member peptide and signals specifically through the Anti-Müllerian Hormone type II receptor (Josso et al., 1993, 2006). AMH expression is regulated in the early embryo by SRY HMG box related gene 9 (SOX9) at the very onset of testicular differentiation from the bipotent gonadal anlagen, by steroidogenic factor-1 (SF-1), by Wilms' tumor 1 (WT1) and by GATA zinc finger transcription factors (Rey *et al.*, 2003) (**Fig. 1**). In the male fetus, AMH actively represses the development of the paired Müllerian ducts, thus inhibiting the development of the upper part of the vagina, the uterus and the fallopian tubes (Rey and Picard, 1998). Animal studies in rats have shown that AMH targets the Müllerian ducts in the fetus through the Müllerian duct mesenchyme which is the sole initial site of AMH type II receptor expression. This in turn affects the mesenchymal–epithelial interaction in the male, resulting in apoptosis of the intraductal epithelium (Roberts *et al.*, 1999). Animal data on mice have further suggested that the WNT pathway is involved in AMH-mediated Müllerian duct regression since inactivation of β-catenin can block this process (Kobayashi *et al.*, 2011). The absence of high Anti-Müllerian hormone concentrations during regular female genital differentiation consequently results in normal differentiation of the Müllerian ducts and hence leads to the development of the female internal genitalia (Rey and Picard, 1998) (**Fig. 1**). The key role of AMH in sex-specific hormonal control of Müllerian duct development is supported by the persistent Müllerian duct syndrome (PMDS) in otherwise normally virilized 46,XY males due to inactivating mutations in either the AMH-gene or in the AMH type II receptor gene (Picard *et al.*, 2017). Further clinical evidence for the role of AMH in Müllerian duct regression comes from patients with 46,XY disorders of sex development (DSD) due to gonadal dysgenesis (Josso *et al.*, 2013). They typically have low AMH due to impaired Sertoli cell development in the dysgenic testes. Consequently, Müllerian ducts have developed partially or completely in affected individuals. In contrast, 46,XY DSDs with a high degree of testicular differentiation and intact Sertoli cells, for example, androgen insensitivity syndrome and 5alpha reductase type II deficiency, have normal-for-male AMH levels, and in consequence Müllerian ducts have typically undergone regression (Josso *et al.*, 2013). An understanding of the role of AMH in hormonal control of sex development is therefore important for clinical differential diagnosis in DSDs.

The Role of Androgen in the Hormonal Control of Fetal Sex Development

Virilization of the internal and external genitalia in the male occurs between the 8th and 12th week of gestation and is mediated by testosterone secreted by the fetal testes (Siiteri and Wilson, 1974; Wilson *et al.*, 1981; Goto *et al.*, 2006). In response to adequately high levels of testosterone, the distal parts of the paired Wolffian ducts will develop into epididymis, ductus deferens and Glandulae vesiculares, while the distal orifices of the Wolffian ducts ending in the urogenital sinus will form the later pars prostatica and pars membranosa of the urethra. The genital tubercle and the urethral folds of the initially bipotent external genitalia will form the glans penis and the corpus spongiosum (**Fig. 2**). Midline fusion of the labioscrotal swellings results in the corpus cavernosum and the scrotum. The latter process is completed at the end of the 12th week of gestation.

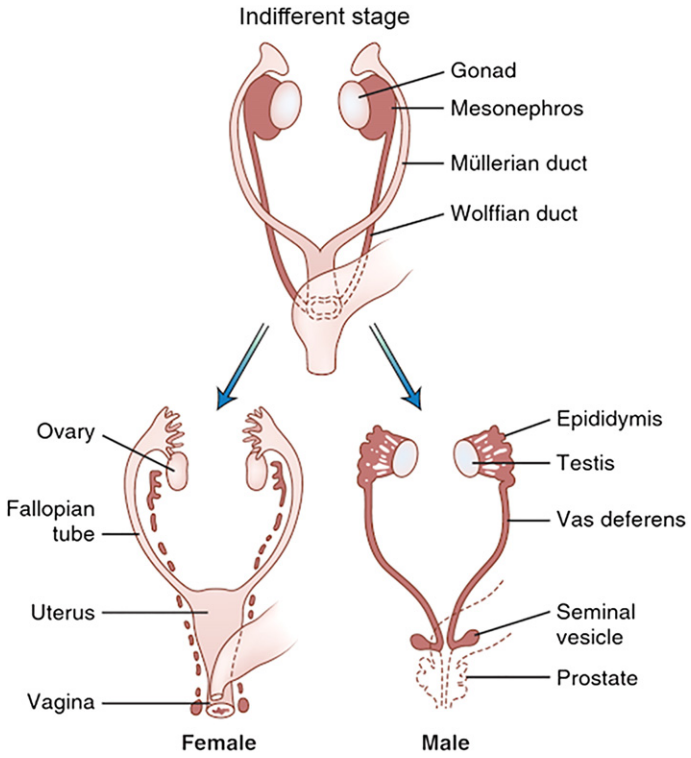

Fig. 1 Embryonic differentiation of female and male genital ducts from Wolffian and Müllerian primordial tissue before descent of the testes into the scrotum. In females, Müllerian structures persist to form the fallopian tubes, uterus, and upper portion of the vagina. The lower portion of the vagina and urethra are derived from the urogenital sinus. In males, Wolffian structures develop into the epididymides, vasa deferentia, and seminal vesicles, whereas the prostate and prostatic urethra are derived from the urogenital sinus. In some cases, a small Müllerian remnant can persist in males as a testicular appendage. Adapted from Acherman, J.C. and Hughes, I.A., (2016). Pediatric disorders of sex development, In: Melmed, S., Polonsky, K.S., Larsen, P.R., (eds.). *Williams Textbook of Endocrinology*, (13th edn.), ISBN 978-0-323-29,738-7, Philadelphia, PA: Elsevier.

The absence of high levels of testosterone in the female during this critical time window leads to regression of the Wolffian ducts. The urethral folds will form the later labiae minorae, and the labioscrotal swellings differentiate to become the labiae majorae. The genital tubercle develops into the female clitoris (Wilson *et al.*, 1981). There is evidence for estrogen receptor expression in the fetal urogenital sinus, the vagina (Taguchi *et al.*, 1986) and the uterus of female human fetuses (Glatstein and Yeh, 1995). However, ovarian biosynthesis of estradiol is believed to not be biologically relevant in the fetus but rather during puberty to promote breast development, growth and maturation of the uterus and the Fallopian tubes, as well as female body proportions.

Testicular descent completes fetal male genital differentiation. A transabdominal phase between the 8th and 15th week of gestation involves regression of the cranial ligament and enlargement of the caudal genito-inguinal ligament (gubernaculum) (Hutson and Hasthorpe, 2005). The subsequent inguinoscrotal phase occurs between the 25th and 35th week of gestation and is characterized by the migration of the gubernaculum from the groin to the scrotum (Hutson and Hasthorpe, 2005). Testicular descent is strictly androgen dependent although the Leydig cell factor insulin-like peptide 3 (INSL3) and its receptor RXFP2 are also involved (Zimmermann *et al.*, 1999; Feng *et al.*, 2009).

Steroid formation in the human fetal testes is initiated between the 8th and 11th week of gestation and peaks between the 11th and 14th week (Tapanainen *et al.*, 1981). It occurs in the Leydig cells and is thought to be almost entirely dependent on hCG/LH signaling via the LHCGR (luteinizing hormone receptor/human chorionic gonadotrophin receptor), which is a seven transmembrane G-protein-coupled receptor on the cell surface (Themmen *et al.*, 1998). While LH is low or even unmeasurable before the 12th week of gestation in the male fetus, hCG is already present at this time and peaks between the 11th and 14th week. Despite the rise of LH between the 14th and 20th week, hCG still remains the dominant detectable gonadotrophin at this time, indicating that it is the primary initial stimulus for early human testosterone biosynthesis (Clements *et al.*, 1976). In contrast, during the second half of pregnancy, fetal pituitary LH takes control over testicular testosterone biosynthesis (Winter *et al.*, 1977). Human fetal testicular tissue is able to bind hCG specifically in order to subsequently stimulate testosterone formation in vitro between the 14th and 19th week of gestation (Huhtaniemi *et al.*, 1977). Before the 15th week of gestation specific high affinity binding sites for hCG are low compared to the maximum reached between the 15th and 20th week, after which they decline (Molsberry *et al.*, 1982). There appears to be a discrepancy between the relatively late time point of the presence of relevant hCG-concentrations and hCG-binding in these classic experimental studies and the fact that the anatomic genital virilisation process has already been completed in the 12th week of gestation (Wilson *et al.*, 1981; Goto *et al.*, 2006). Interestingly, Del Valle

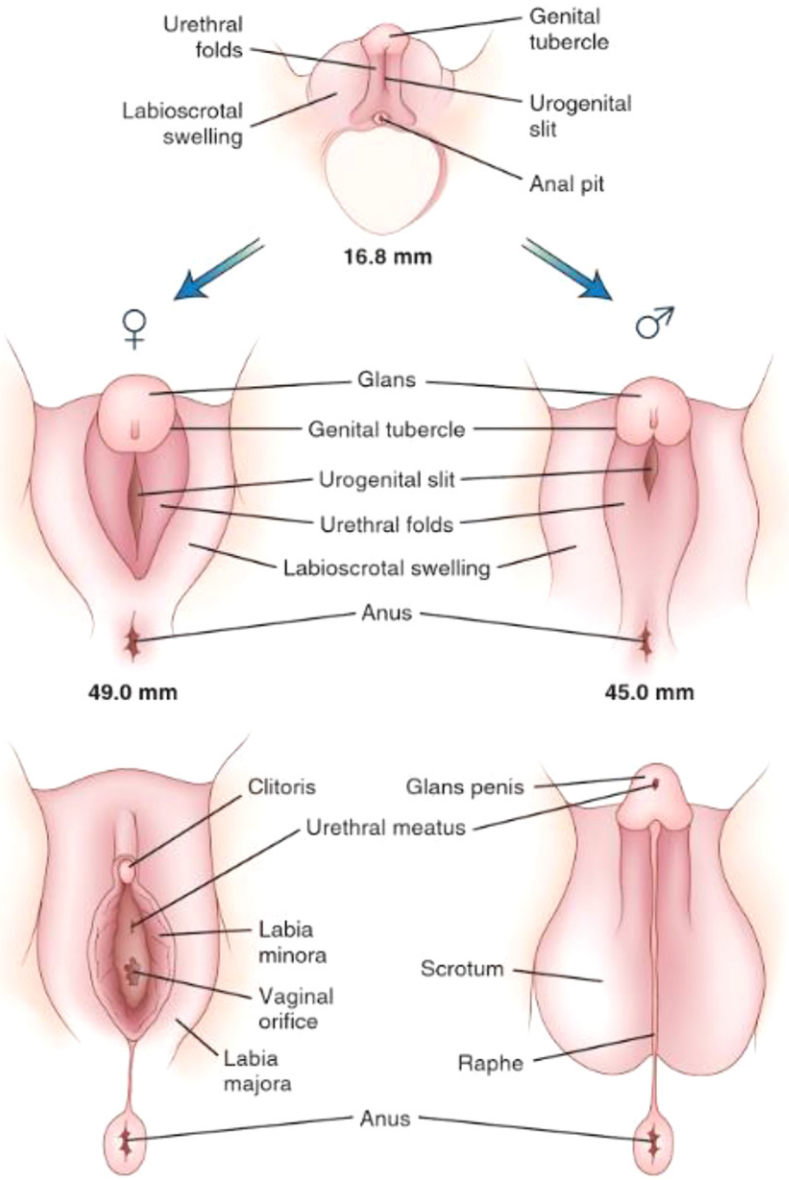

Fig. 2 Differentiation of male and female external genitalia. Adapted from Acherman, J.C. and Hughes, I.A., (2016). Pediatric disorders of sex development, In: Melmed, S., Polonsky, K.S., Larsen, P.R., (eds.). *Williams Textbook of Endocrinology*, (13th edn.), ISBN 978-0-323-29,738-7, Philadelphia, PA: Elsevier.

and co-workers have recently compiled a comprehensive genomic atlas of human adrenal and gonadal development which is a valuable scientific resource for understanding human genital differentiation (Del Valle *et al.*, 2017). They found that LHCGR mRNA already increases markedly in the 8th week of gestation in the human fetal testis, reaching peak levels at about the 9th week of gestation (Del Valle *et al.*, 2017) (**Fig. 3**). This molecular study therefore documents the very early presence of the LHCGR in the fetal Leydig cells and supports the role of the hCG-LHCGR signaling cascade in the control of fetal testosterone formation. Further downstream within the Leydig cells, steroid biosynthesis via the LHCGR involves the intracellular second messenger cyclic adenosine 3′,5′-monophosphate (cAMP), which then stimulates expression of two important cytochrome P450 steroid biosynthesis enzymes, P450 side chain cleavage and 17alpha hydroxylase/17,20 lyase (Payne, 1990). Del Valle found in their genomic atlas that mRNA expression levels of STaR (steroidogenic acute regulating protein), CYP11A1 (P450 side chain cleavage), HSD3B2 (3ß hydroxysteroid dehydrogenase, type II), CYP17A1 (17alpha hydroxylase/17,20 lyase) and HSD17B3 (17ß hydroxysteroid dehydrogenase type III) rise in parallel with LHCGR mRNA during the 8th week of gestation (Del Valle *et al.*, 2017). Therefore, the complete classic steroid biosynthesis pathway from cholesterol down to testosterone is reflected in the enzymatic mRNA-expression pattern detectable in the early testis after the 7th week of gestation. The biological relevance of all of these different steps for the normal formation of gonadal testosterone, and consequently for normal genital differentiation in the male human fetus, is underlined in individuals with disorders of sex development (DSD) with inactivating mutations in the coding

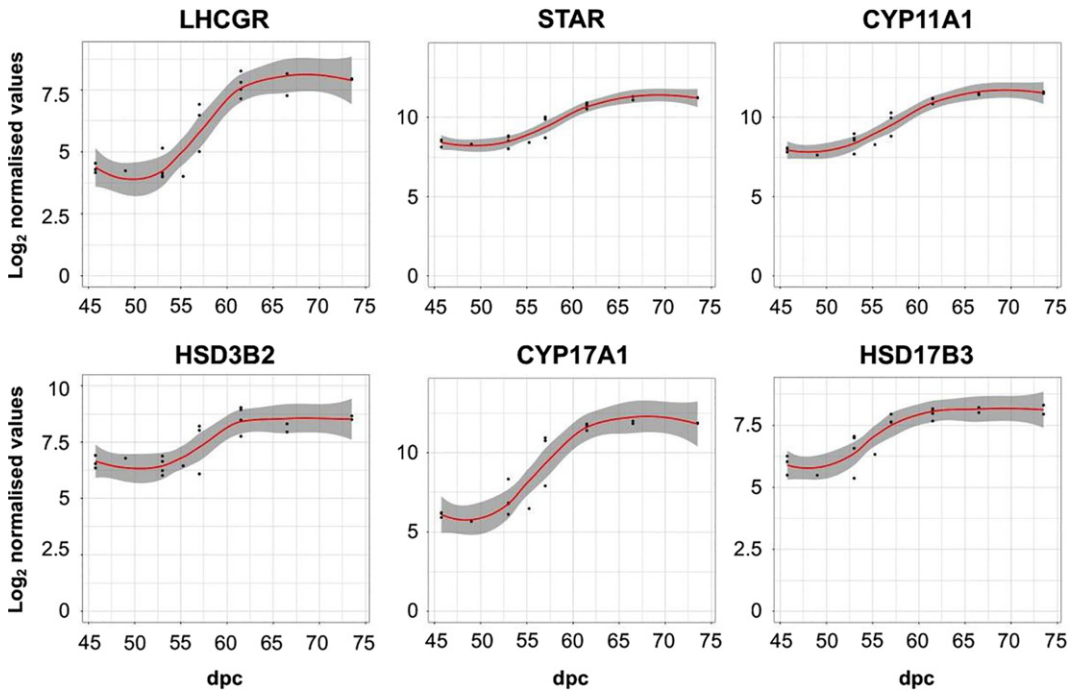

Fig. 3 Gene expression of key steroid biosynthesis genes during early testicular development (Figure from Del Valle, I., Buonocore, F., Duncan, A.J., et al., (2017). A genomic atlas of human adrenal and gonad development. *Wellcome Open Research* **2**, 25). The scatter plots show changes in gene expression patterns for known testicular steroidogenic genes, LHCGR, STAR, CYP11A1, HSD3B2, CYP17A1, and HSD17B3 (normalized gene expression values for testis samples between approximately 46 and 74 dpc).

genes. The latter can all result in deficient to absent genital virilisation, for example, in Leydig cell hypoplasia (Kremer *et al.*, 1995), STaR deficiency (Lin *et al.*, 1995), P450scc deficiency (Hiort *et al.*, 2005), 3ß-hydroxysteroid dehydrogenase type II deficiency (Rheaume *et al.*, 1992), 17alpha/17,20 lyase deficiency (Kagimoto *et al.*, 1989) and 17ß hydroxysteroid dehydrogenase type III deficiency (Geissler *et al.*, 1994).

Anatomic genital virilisation also requires proper peripheral conversion of testosterone to the more active metabolite dihydrotestosterone (Keller *et al.*, 1996) through steroid 5alpha reductase. Two different isoenzymes exist for the 5alpha-reductase, type I and type II, of which the type 2 enzyme is pivotal for fetal sexual development and is expressed in the fetal genital skin, the fetal male accessory sex glands and the prostate (Thigpen *et al.*, 1993). Deletion of the SRD5A2 gene encoding 5alpha-reductase type 2 or inactivating mutations in this gene cause 5alpha reductase type II deficiency characterized by a virilisation deficit in the external genitalia. This underlines the fact that testosterone alone is not sufficient for achieving the normal male genital phenotype but that dihydrotestosterone is also needed (Andersson *et al.*, 1991; Wilson *et al.*, 1993).

There is some data suggesting that the classical gonadal androgen biosynthesis pathway might not on its own be sufficient for ensuring normal male or female sexual differentiation. Some years ago an alternative biochemical pathway to dihydrotestosterone, known as the backdoor pathway, was discovered (Auchus, 2004). AKR1C2 (aldo-keto reductase family 1 member C2) is one of the enzymes which is involved in this alternative pathway but not in the classic pathway. Partially inactivating mutations of the AKR1C2 gene have been described in four individuals with a mild to moderate virilisation deficit at birth (Flück *et al.*, 2011), suggesting that in certain situations the classic biosynthesis pathway to dihydrotestosterone is not the exclusive player in regular masculinization of the male fetal genital tract. In female development, some experimental evidence shows that the low-androgen environment necessary for female internal and external genital differentiation needs to be protected by early adrenal cortisol biosynthesis limiting inadequately early adrenal androgen formation via negative feedback to the anterior pituitary corticotrophs (Goto *et al.*, 2006). These two examples show the increasing complexity of our understanding of hormonal control and modulation of fetal sex development but they also offer new opportunities for a comprehensive understanding of the biochemical mechanisms of disorders of sex development.

Androgens induce their sex differentiating effects in the fetal genital target tissues via the intracellular androgen receptor which is a ligand-activated nuclear transcription factor of androgen-regulated target genes (Brinkmann *et al.*, 1989). The androgen receptor shares its characteristic modular structure of three distinct functional domains with other members of the nuclear receptor family. A comparatively large first exon encodes the N-terminal transactivation domain. Exons 2 and 3 encode the first and second zinc finger important for DNA binding of the receptor. This is connected by a short hinge region to the C-terminal ligand (androgen) binding domain encoded by exons 4–8 (Brinkmann *et al.*, 1989; Werner and Holterhus, 2014). Androgen binding induces structural changes to the androgen receptor, recruitment of co-regulators, translocation into the nucleus, dimerization, chromatin remodeling, binding to specific androgen-response DNA-elements eventually leading to transcription and translation of

androgen responsive target genes (Werner and Holterhus, 2014). As described above for the Müllerian ducts, AMH and the mesenchymal AMH type II receptor (Roberts *et al.*, 1999), mesenchymal–epithelial interactions also play a crucial role in transducing morphogenetic androgen effects via the androgen receptor during genital virilization in the fetus (Cunha *et al.*, 1981; Cunha, 2008). Based on an impressive series of tissue recombination experiments on mouse urogenital sinus and prostate development, Cunha and coworkers documented that only the urogenital mesenchyme exhibits nuclear androgen binding sites in the early embryo. The mesenchyme is the primary target and mediator of morphogenetic effects of androgens on the epithelium, inducing subsequent specific patterns of morphogenesis, cytodifferentiation and biochemical properties. Thereafter, the epithelium begins to express the androgen receptor following a coordinated temporal sequence (Cooke *et al.*, 1991). The pivotal role of the urogenital sinus mesenchyme is further confirmed by experimental tissue recombinants composed of androgen receptor positive rat urogenital sinus mesenchyme associated with bladder epithelium from androgen insensitive mice in which the mesenchyme still induces epithelial morphogenesis in response to androgen (Sugimura *et al.*, 1986). Accordingly, immunohistochemical detection of the androgen receptor in human embryos is restricted to the mesenchyme of the urogenital sinus at 8 weeks of gestation while it appears subsequently in the epithelium only after 9 weeks of gestation (Sajjad *et al.*, 2004). The central role of the androgen receptor in human sexual differentiation is confirmed by patients who have inactivating mutations of the X-chromosomal androgen receptor gene leading to the androgen insensitivity syndrome (Lubahn *et al.*, 1989; Patterson *et al.*, 1994). Androgen insensitivity syndrome is characterized by a wide spectrum of virilization defects in 46,XY individuals, ranging from completely female external genitalia through ambiguous phenotypes to only minimal forms (Patterson *et al.*, 1994).

While the function of the androgen receptor as a transcriptional regulator of androgen responsive target genes is quite well understood in vitro at the molecular level (Simental *et al.*, 1991; Jenster *et al.*, 1991; Werner and Holterhus, 2014), almost nothing is known about the mesenchymal transcriptional androgen response programs important for initiation of the sexual differentiation process in the human fetus. Global gene expression studies using cDNA microarrays on cultured human prostate cancer cells have impressively shown the comprehensiveness of global changes of the transcriptome through androgen (DePrimo *et al.*, 2002). More recently, Nash and co-workers have identified 7534 androgen receptor binding sites in the genome of primary embryonic prostate fibroblasts derived from 12 to 16 week old human embryos through ChIPseq (Chromatin Immuno-Precipitation DNA-Sequencing) (Nash *et al.*, 2017). While subsets of identified transcripts reflected genes expressed in vivo and regulated by androgens when compared with published expression datasets, actual androgen regulation of transcription has not been experimentally investigated in these cells (Nash *et al.*, 2017).

Due to the central initial role of the urogenital mesenchyme rather than the epithelium in the fetus, and since the external genital origin enables biopsies, cultured genital skin fibroblasts have become an important experimental model in research into human sexual differentiation. They bind androgen specifically (Kaufman *et al.*, 1976), express the androgen receptor at the protein level (Holterhus *et al.*, 1997) and convert testosterone to the more active dihydrotestosterone (Pinsky *et al.*, 1978). Stillman and coworkers were the first to show that genital skin fibroblasts are functionally androgen responsive, since the activity of aromatase in these cells is induced by androgen which is reduced or absent in patients with androgen insensitivity syndrome (Stillman *et al.*, 1991). Nitsche and coworkers used a differential display RT-PCR strategy and reported 54 androgen regulated cDNAs, of which two had some similarities to L-plastin and testican respectively (Nitsche *et al.*, 1996). Using a genome-wide scale cDNA microarray approach, as described above for prostate cancer cells (DePrimo *et al.*, 2002), we previously found only three significant and reproducible androgen regulated transcripts, of which apolipoprotein D was most strongly androgen regulated (Appari *et al.*, 2009). Accordingly, patients with inactivating androgen receptor gene mutations did not show androgen regulation of apolipoprotein D transcription (Appari *et al.*, 2009; Hornig *et al.*, 2016). Apolipoprotein D plays a role as a male pheromone transporter (Zeng *et al.*, 1996) and in controlling cell proliferation (Simard *et al.*, 1991). However, due to the postnatal origin of these cells, direct conclusions regarding their influence on fetal sexual differentiation are limited. Interestingly, several patients with a complete or partial virilization defect and clinical characteristics of androgen insensitivity syndrome have significantly reduced or even absent induction of apolipoprotein D expression by dihydrotestosterone in genital skin fibroblasts despite the absence of inactivating androgen receptor gene mutations (androgen insensitivity syndrome type II, AIS type II) (Hornig *et al.*, 2016). This suggests the existence of currently unknown molecular components which are relevant for the transduction of normal morphogenetic effects caused by androgen via the androgen receptor in the human embryo. One possible mechanism may be the expression of androgen receptor co-regulators in the sensitive time window between the 8th and 12th week of gestation. A potential example in the mouse genital tubercle may be RWD domain containing 1 (RWDD1), which was identified in this tissue a few years ago (Grötsch *et al.*, 2012). RWDD1 is expressed during embryonic days E15, E16, and E17. It interacts with the androgen receptor at the molecular level and enhances androgen receptor-dependent transactivation (Grötsch *et al.*, 2012). Another mechanism may be the expression context of developmental genes in the embryonic genital anlagen, which may crosstalk with the androgen pathway via modification of androgen receptor expression levels. The homeobox A13 (HOXA13) gene may provide some insight. HOXA13 mutations can cause genitourinary tract malformations in mice and humans, and specifically hypospadias in boys with hand foot genital syndrome (Morgan *et al.*, 2003; Mortlock and Innis, 1997). In mice, knockout of hoxa13 leads not only to reduced expression of Fgf8 and Bmp7 in the urethral plate epithelium but it also markedly reduces androgen receptor abundance. This links the developmental gene program of the genital tubercle with the mechanisms of hormonal control of fetal sex development via the androgen receptor (Morgan *et al.*, 2003). Unfortunately, there is currently no comparable data on gene expression in relation to androgen action in the human fetal genital mesenchyme.

Programming Androgen Actions

Our classical understanding of androgen action via the androgen receptor in endocrinology is short-term change of gene transcription as documented by reporter gene assays (Jenster *et al.*, 1991) or in genome-scale gene transcription studies on androgen responsive cells (DePrimo *et al.*, 2002; Appari *et al.*, 2009). In addition, from a developmental perspective, androgens are also able to implement long-term stable (irreversible) functional and structural changes of phenotypic traits, which may be summarized as programming androgen actions, during sensitive ontogenetic time windows (Werner and Holterhus, 2014). On the one hand, androgen induced irreversible changes of genital cytodifferentiation and anatomy in the male, for example, the irreversible fusion of the genital midline, indicate that ontogenetic programming is already evident during fetal life between the 8th and 12th week of gestation (Cunha *et al.*, 1981; Cunha, 2008; Wilson *et al.*, 1981). On the other hand, early embryonic androgen actions also appear to program post-natal sex-specific reproductive phenotypic traits, for example, anogenital distance, penile growth, testicular size, Sertoli cell number and Leydig cell function, giving rise to the definition of a "male programming window, MPW" in the fetus (Welsh *et al.*, 2008; Scott *et al.*, 2008; van den Driesche *et al.*, 2012). The concept of androgen programming per se is not very recent and there appear to be more time windows for other traits, for example, the neonatal period in which androgen was shown to program post-natal traits in rat liver biochemistry more than 40 years ago (Gustafsson and Stenberg, 1974a,b). Moreover, prenatal androgen programming of post-natal traits is not restricted to male fetal development. There is data supporting the fact that in utero exposure of female animals to androgen has long-lasting consequences for post-natal ovarian function (e.g., early follicle development) and on metabolic traits (Abbott *et al.*, 2006; Franks, 2012). In essence, androgen programming in the female may be an important link to understanding the pathogenesis of ovarian-metabolic diseases such as polycystic ovarian syndrome (Cardoso *et al.*, 2015; Ramaswamy *et al.*, 2016).

In genome-scale microarray-based gene transcription studies on cultured genital skin fibroblasts we have previously found that sex-specific differentiation of the human external genitalia is accompanied by global differences of gene transcription programs unmasking androgen programing at the molecular level (Holterhus *et al.*, 2003; Holterhus *et al.*, 2007). In particular, we could identify a signature of 612 transcripts differing between embryologically homologous, labio-scrotal swellings derived 46,XY scrotal fibroblasts and 46,XY labia majora fibroblast from patients with complete androgen insensitivity syndrome. As discussed above, the post-natal origin of the cells limits assignment to a specific fetal time window. However, computerized hierarchical clustering based on this 612-gene signature distinguished individuals with different phenotypic degrees of partial androgen insensitivity syndrome, mostly according to the extent of anatomic external genital virilisation (Holterhus *et al.*, 2007). In essence, the cells had memorized the degree of virilisation of the genitalia they were originally biopsied from, reflecting the degree of fetal androgen action and supporting the hypothesis that these programs had indeed originated, at least in part, from the anatomic masculinization window between the 8th and 12th week of gestation (Holterhus *et al.*, 2007).

Using a similar genome-scale microarray approach involving male controls and patients with defined disorders of sex development, androgen programming can also be shown outside the genitalia in peripheral blood mononuclear cells (Holterhus *et al.*, 2009). In 334 mice Yang and coworkers demonstrated the enormous extent of global sex-specific gene transcription in liver, adipose tissue, muscle and brain involving up to approximately 70% of the active transcriptome (Yang *et al.*, 2006). Based on the points discussed here, it is likely that fetal androgen programming contributes to these findings and may have relevance in medicine beyond genital development, since it may contribute to the sexual dimorphism found in various extra-genital sex-specific traits in health and disease, for example, incidence rates and response to treatment. The underlying mechanisms of molecular androgen programming are not yet well investigated. Epigenetic modification of genomic DNA, for example, methylation at CpG sites in the gene promoters, is assumed to play a central role in long term control of gene transcription and consequently in maintaining tissue specificity, integrity and function. Accordingly, different healthy human cell types and tissues are characterized by specific large-scale differences in their gene methylation signatures (Eckhardt *et al.*, 2006). In a recent study using the same genital skin fibroblast model as for the transcriptome studies (Holterhus *et al.*, 2007), we could document the existence of androgen programmed gene methylation signatures (Ammerpohl *et al.*, 2013). The molecular pathways showing how androgen is able to implement these specific epigenetic changes during the male androgen programming windows remain to be discovered.

Introduction

Embryology Review (Domenice *et al.*, 2017)

Sex development involves precise spatio-temporal orchestration of multiple factors. Sex determination is governed by the sex chromosomes. In the presence of the SRY gene, typically located on the short arm of the Y chromosome, the undifferentiated gonad is directed to develop into a testis. In the absence of the SRY gene, ovary specific transcription factors initiate and maintain ovarian differentiation.

Phenotypic sex development can be considered as a two-step process: (see **Fig. 1**).

1. Testis or ovary formation from the primitive gonad (sexual determination); and
2. Internal and external genitalia differentiation largely directed by factors secreted by the fetal testis (sexual differentiation).

Mesonephric (Wolffian) and paramesonephric (Müllerian) ducts are both present in male and female fetuses. The Wolffian ducts originate in the intermediate mesoderm and grow caudally to end in the cloaca during the 5th embryonic week. Also, during the 5th embryonic week, the Müllerian ducts arise as invaginations of the coelomic epithelium.

Anti-Müllerian hormone (AMH), also known as Müllerian inhibitory hormone (MIH), is secreted by the testicular Sertoli cells and acts through its receptor on the Müllerian ducts to cause their regression. Testosterone is secreted by the testicular Leydig cells and acts via the androgen receptor in the Wolffian ducts to induce the formation of epididymis, deferent ducts, and seminal vesicles.

The external genitalia of the fetus derive from mesenchyme cells located in the cloaca. The initial development of the external genitalia is influenced by factors modulating the interactions between the epithelial and mesenchymal tissues. Genes from the *BMP*, *FGF*, and *HOX* families are involved in genital tubercle formation. Under androgen stimulation in the male fetus, the urethral folds, genital tubercle and genital swellings give rise to corpus spongiosum and primitive urethra, phallus, and scrotal swellings respectively. This process is mediated by testosterone and dihydrotestosterone (DHT), which acts on the androgen receptor of the prostate and external genitalia leading to its masculinization. In androgen target cells such as the prostate, testosterone is converted by 5α-reductase to DHT, which has a higher affinity for the androgen receptor. After testis determination, hormones produced by the male gonad induce the differentiation of internal and external genitalia acting on their specific cognate receptors. The up regulation of AMH gene in the fetal Sertoli cells is induced by *SOX9*. Subsequently, *NR5A1/SF1*, *WT1*, and *GATA4* synergize to increase AMH transcription while the AMH promoter may be stabilized by the *SOX-HSP7-WT1* complex. Differentiation of fetal Leydig cells is influenced by Sertoli cell factors including desert hedge-hog (*DHH*) and platelet-derived growth factor A (*PDGFα*); other factors involved in Leydig cell differentiation include Aristaless-related homeobox (*ARX*), *MAMLD*1, *GATA4*, *DAX1*, and *NR5A1*. *NR5A1* regulates gonadal steroidogenesis. The Leydig cells also produce *INSL3*, which along with testosterone is responsible for the transabdominal phase of testicular descent during fetal weeks 10–15. The inguinoscrotal phase, occurring between 27 and 35 weeks, is largely mediated by androgen action.

In the absence of the *SRY* gene such as female fetuses with a 46,XX chromosomal complement, *RSPO1* and *WNT4* are expressed to stabilize cytoplasmic *β*-catenin. Both *WNT4* and *β*-catenin suppress the *SOX9*/*FGF9* positive feedback loop, allowing ovarian differentiation to proceed. Most evidence indicates that ovarian differentiation occurs independently in several lineages including supporting cells and germ cells. In females, ovaries do not produce AMH during fetal development; hence, development and maintenance of the Müllerian duct structures occur. Furthermore, because the fetal ovaries do not secrete significant amounts of androgens, the Wolffian ducts become atrophic. In the absence of either testosterone secretion or 5α-reductase activity, bipotential external genital structures develop along female lines. Specifically, in the absence of androgens the labioscrotal and urethral folds form the labia majora and minora, respectively. The genital tubercle develops into a clitoris and the urogenital sinus gives rise to the urethral opening and anterior portion of the vagina. The posterior portion of the vagina develops from the Müllerian ducts in the absence of AMH (Ahmed *et al.*, 2013; Ostrer, 2014).

Disorders of sex development (DSDs) are defined as congenital conditions within which the development of chromosomal, gonadal, and anatomic sex is atypical. The broad term DSD, adopted at the Consensus Conference (Lee *et al.*, 2006), has been generally accepted by many medical professionals but not universally by some patient and support groups. Positive aspects about having a term providing for scientific accuracy within a biological and medical context include: (1) bona fide genetic disorders

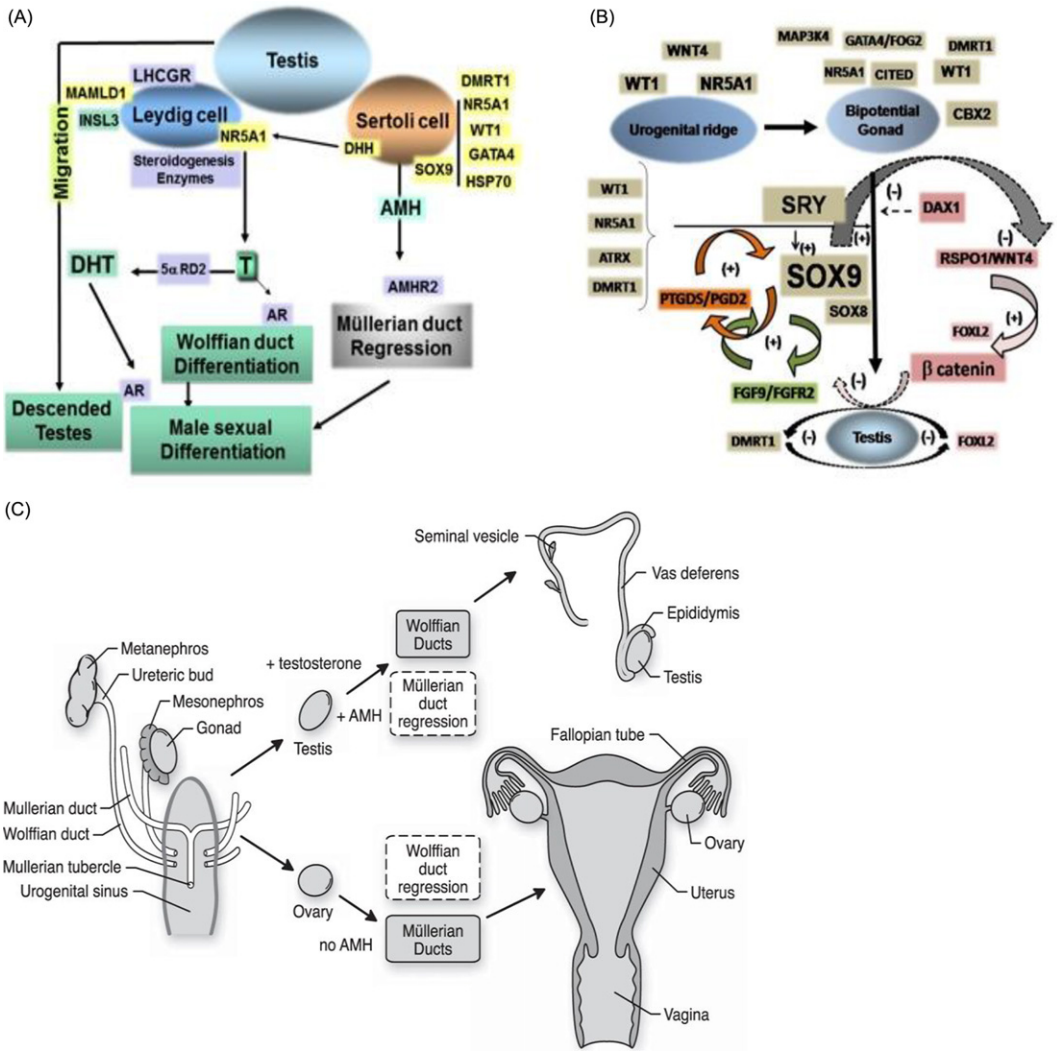

Fig. 1 (A) Summary of the molecular events in sex determination indicating the genes in which molecular defects can cause gonadal disorders. (B) Summary of the molecular events in sex differentiation indicating the genes in which molecular defects cause 46,XY DSD in humans. (C) Development of internal genitalia from common genital structures. Ordinarily, the *SRY* gene on the Y chromosome would trigger testes and subsequent male internal genital development from production of the hormones, T and anti-Mullerian hormone (AMH). In 46,XX testicular DSD, testis determination can be triggered by *SRY* or *SOX9* translocation, *SOX3* or *SOX9* duplication, or *RSPO1* loss of function. In 46,XY gonadal dysgenesis, testis development does not occur or is incomplete, and internal female genitalia will develop. This will be triggered by *SRY*, *NR5A1*, *DHH*, or testis-determining gene loss of function mutations, *DAX1* or *WNT4* duplication, or *MAP3K1* gain of function mutations. Disorders of sex development (DSDs): An update. *The Journal of Clinical Endocrinology and Metabolism* 99(5), 1503–1509.

facilitate access to healthcare and insurance; (2) an umbrella classification helps to generate comprehensive and integrated models of care; and (3) it provides a framework for knowledge accumulation and research funding. At the same time, this terminology avoids confusion by distinguishing these genetic conditions from individual variation in gender identity and sexual orientation (Barthold, 2011; Hughes *et al.*, 2007).

Negative connotations of DSD perceived by some advocacy organizations include the stigma of "disorder" and perceived implications that "sex" involves sexual behavior. The term DSD is not felt to be applicable to all individuals included, such as males with congenital adrenal hyperplasia (CAH), resulting in participant refusal regarding research under this heading. Some people consider "intersex" to be a better term than DSD, especially for infants requiring male or female assignment, some substitute the word "disorders" by "differences," whilst still others call for an alternative nomenclature (Fisher *et al.*, 2016; Gillam *et al.*, 2010; Pasterski *et al.*, 2010; Wiesemann *et al.*, 2010).

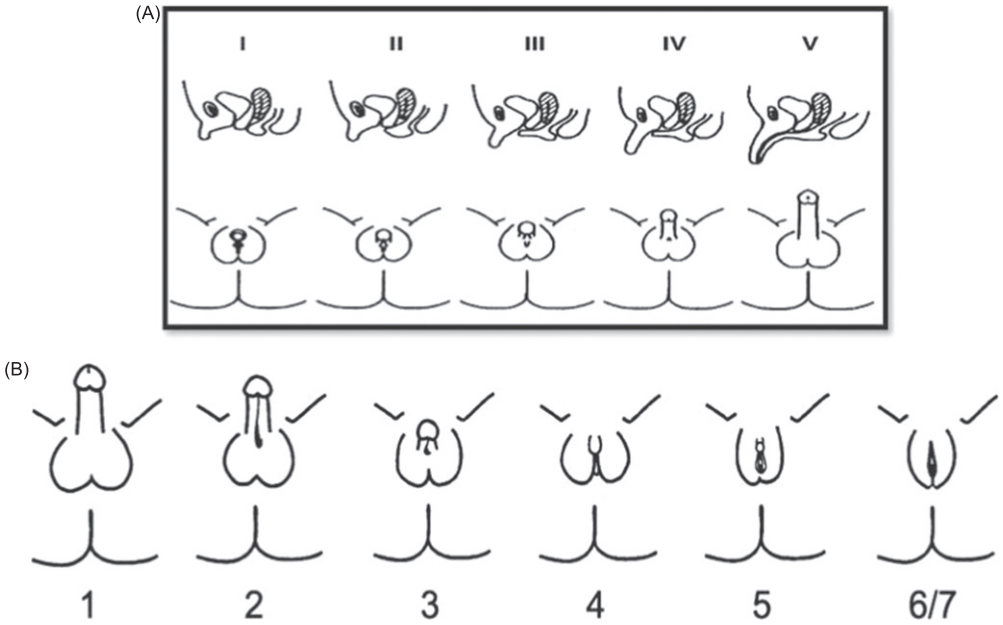

Fig. 2 Prader stages of virilization in females (A) and Quigley stages of lack of virilization in males (B).

Prader stages show progressive virilization from stage 1 to 5 while Quigley grade 2 is isolated hypospadias or micropenis with lesser virilization extending to stage 5 with grade 1 and 6 being normal male and female genital phenotypes (see **Fig. 2**).

Classification

Disorders of sex differentiation (DSD) are congenital conditions with atypical development of one or more of the following: chromosomal, gonadal and genital sex. This broad category, created during the 2005 Intersex Consensus conference, was proposed to replace previously used terms including the term intersex, ambiguous genitalia, and the hermaphroditism categories (Houk *et al.*, 2006; Houk and Lee, 2008). While these latter categories were based upon anatomic definitions, they carried connotations regarding gender and sexual behavior. DSDs incorporated the former categories of female pseudohermaphroditism (46,XX individuals with virilization of external genitalia), 46,XY DSD; male pseudohermaphroditism (46,XY individuals with incomplete masculinization of external and internal genitalia), and sex chromosome DSD (to include all disorders of gonadal development with variations in the sex chromosome number or structure) (Hughes *et al.*, 2006a,b).

Major categories of DSDs are: (Lee *et al.*, 2006)

1. 46,XX DSDs include all situations in which the karyotype is 46,XX, ovaries are present and the external genitalia are masculinized, essentially the former female psuedohermaphrodite category. The most common diagnosis within this category is 21-hydroxylase deficiency congenital adrenal hyperplasia, the most frequent DSD presenting with ambiguous genitalia. However, once this diagnosis is made, there is no reason to use this DSD category. Because the cause is androgen excess, the internal genitalia are expected to be female.
2. 46,XY DSDs include 46XY males with incomplete masculinization of external genitalia, basically the former male pseudohermaphrodite category. This category includes both isolated unilateral and bilateral cryptorchidism and hypospadias, which are associated with other reproductive system developmental problems. They show presence of testes, at least during fetal development. Nonhormone disorders such as peno-scrotal transposition have been included under this classification.
3. Sex chromosome DSDs include categories in which abnormal gonadal development related to an abnormality of the sex chromosomes X or Y. This new category includes former categories of true hermaphrodite (46,XX/46,XY chimeric, ovotesticular DSD ovotesticular DSD), mixed gonadal dysgenesis (in which extent of gonadal dysgenesis differs between the 2 gonads) and other types of asymmetric gonadal differentiation in which karyotype is 45,X/46,XY. This includes two major categories of gonadal maldevelopment: Turner syndrome and Klinefelter syndrome and their variants. It should be noted that since ovotesticular DSD may be associated with not only 46,XX/46,XY, but also 46,XX and 46,XY, that this diagnosis may be found under all three of these major classifications.
4. Another broad DSD definition to include 46,XY individual having appropriate internal and external genital differentiation, such as congenital adrenal hyperplasia; 21-hydroxylase deficiency.

Minor categories of DSD to describe rare conditions such as XY female, XX sex reversal and XY sex reversal, the terms 46, XX testicular DSD, and 46, XY complete gonadal dysgenesis was suggested.

Table 1 Classification of DSD guided by genetic differences

46, XX DSD	*46, XY DSD*	*Sex chromosome DSD*
- Ovotesticular DSD	- Complete gonadal dysgenesis	45,X mos 45,X/46,XX
- Testicular DSD	- Partial gonadal dysgenesis	45,X/46, XY (MGD, ovotesticular DSD)
- Gonadal dysgenesis	- Gonadal regression	46,X, i(Xq) 46,X,del (Xp)
	- Ovotesticular DSD	46,XX/46,XY (chimeric/ ovotesticular DSD) 47, XXY (Klinefelter syndrome/ variants) 46,XX (Yp translocation) 46,X,del(X)t(X;Y) (XX SRY+ male)
Disorders of androgen excess	Disorders of androgen synthesis	
- CAH (mutations in CYP21A2, CYP11B1, POR, HSD3B2)	- CAH (mutations in StAR, CYP11A1, HSD3B2, POR, CYP17A1)	
- Aromatase deficiency	- Isolated defects in androgen biosynthesis (mutations in CY5B, HSD17B3, SRD5A2)	
- Maternal luteoma	- LH receptor defects (LHR mutations); Leydig cell hypoplasia, aplasia	
- Exogenous exposures, iatrogenic		
	Disorders of androgen action	Other chromosomal rearrangements
	- Complete and partial androgen insensitivity syndrome (Mutations in androgen receptor gene)	
Unclassified conditions	Unclassified conditions	
- Cloacal exstrophy	- Persistent Müllerian duct syndrome (mutations in AMH and AMHR)	
- Vaginal atresia	- Hypospadias, unknown etiology	
- Mullerian, renal, cervicothoracic somite abnormalities	- Epispadias	
- Other complex syndromes	- Other complex syndromes	

Lee, P. A., Houk, C. P., Ahmed, S. F., Hughes, I. A. and International Consensus Conference on Intersex organized by the Lawson Wilkins Pediatric Endocrine Society and the European Society for Paediatric Endocrinology. (2006). Consensus statement on management of intersex disorders. International Consensus Conference on Intersex. Pediatrics 118 (2), e488–e500.

The categories of this classification 46,XX; 46,XY, and sex chromosome DSD are listed in **Table 1**, noting that in addition unclassified conditions are listed that may be part of complex syndromes. **Table 2** further subdivides these major categorizes into nondysgenetic, dysgenetic, and malformative, including genes mutated, illustrating the complexity of diagnoses and findings which may occur under the broad definition of DSD (Hutson *et al.*, 2014).

Disorders included in the classification of 46,XX DSD include disorders associated with fetal androgen excess such as virilizing congenital adrenal hyperplasia and maternal hyperandrogenemia. Other disorders included in this category include vagina atresia/ agenesis and congenital anomalies of the female genitourinary tract such as the Rokitansky–Mayer–Küster–Hauser (RMKH) syndrome, Bardet–Biedl syndrome, Kaufman–McKusick syndrome, Fraser syndrome, and Winters syndrome.

Classifications of 46,XY DSD include disorders of testicular development (complete and partial gonadal dysgenesis), disorders of androgen action (complete and partial androgen insensitivity), disorders of AMH/AMH receptor, androgen biosynthesis defect, severe hypospadias, penoscrotal transposition, and bladder exstrophy.

Classifications of sex chromosome DSD include the following: 45,X (Turner syndrome and variants); 47,XXY (Klinefelter syndrome and variants); 45,X/46,XY (mixed gonadal dysgenesis, ovotesticular DSD); and 46,XX/46,XY (chimeric, ovotesticular DSD). In addition, the term 46,XX testicular DSD has replaced the rare XX male category. The term 46,XY complete gonadal dysgenesis has replaced the XY sex reversal category (Ahmed *et al.*, 2013).

The framework provided by the current DSD classification system provides a logical and cogent approach for use during the initial diagnostic assessment of the patient. Once a specific diagnosis is confirmed, the patient can be described by the specific diagnosis. Nevertheless, despite the advancement in the molecular genetics of disorders of sex development, a specific diagnosis cannot be identified for some patients; these patients are best classified under a general term until a specific molecular etiology has been identified (Lee *et al.*, 2016).

In spite of the attempts to be mindful and respectful, this newer classification has been criticized for stigmatizing and unnecessarily "medicalizing" those with intersex traits. Nonetheless, this classification scheme provides the framework to guide the initial diagnostic evaluation of individual patients. This is particularly relevant for infants with external genitalia so ambiguous that it is necessary to determine sex of rearing. With increasing knowledge accrues of the molecular basis of disorders of sex differentiation/development, greater clarity will occur (Lee *et al.*, 2016; Yatsenko and Witchel, 2017).

Table 2 Classification of DSD guided by karyotype

Category	*Gene*	*Pathogenic type*	*Etiology with examples/associations*
46,XX DSD		*Nondysgenetic DSD*	*Excessive adrenal androgen synthesis*
			Congenital adrenal hyperplasia (CAH)
	CYP21A2		- 21α-Hydroxylase deficiency
	CYP11B1		- 11β-Hydroxylase deficiency
	CYP19A1		Aromatase deficiency
			Androgen secreting tumors during pregnancy
			Luteomas, thecomas
			Theca lutein cysts of the ovaries
			Androgenic drugs during pregnancy
			Norethindrone, danazol, ethisterone, norethynodrel, medroxyprogesterone
		XX gonadal dysgenesis	
	BMP15		Ovarian dysgenesis
	DCAF17		Woodhouse–Sakati syndrome, ovarian dysgenesis
	FIGLA		Ovarian insufficiency
	FOXL2		Ovarian dysgenesis and blepharophimosis
	FSHB		Ovarian insufficiency
	FSHR		Ovarian insufficiency
	MCM8		Ovarian insufficiency
	MCM9		Ovarian insufficiency
	MKKS		McKusick–Kaufman syndrome
	NOBOX		Ovarian insufficiency
	PSMC3IP		Ovarian insufficiency
	SOHLH1		Ovarian insufficiency
	WNT4		Congenital absence of upper vagina and uterus, may be associated with MURCs syndrome (Müllerian and renal aplasia, cervicothoracic somite dysplasia)
		Malformative disorders	
			Urogenital sinus anomalies
			Cloacal exstrophy
46,XY DSD		*Nondysgenetic DSD*	*Disorders of androgen synthesis*
	STAR		Lipoid CAH
	CYP11A1		Cholesterol desmolase deficiency; adrenal insufficiency, sex reversal
	CYP17A1		P450c17 deficiency; undervirilization, hypertension
	POR		P450 oxidoreductase deficiency; Antley–Bixler syndrome
	HSD3B2		3β-Hydroxysteroid dehydrogenase (HSD) type 2 deficiency
	HSD17B3		17 β-HSD type 3 deficiency
	SRD5A2		5α reductase deficiency and other DHT synthesis defects
	AKR1C2 and AKR1C4		Testicular dysgenesis; 3α-hydroxysteroid dehydrogenase deficiency
	MAMLD1		Mastermind-like domain with 1 gene; micropenis, bifid scrotum
	MAP3K1		Gonadal dysgenesis
	CBX2		Gonadal dysgenesis, ovotesticular disorder
	DHH		Desert hedgehog (DHH)-testicular dysgenesis with minifascicular neuropathy
	DMRT1 and DMRT2		Testicular dysgenesis and mental retardation
	GATA4		Testicular anomalies with or without congenital heart disease
	NROB1 (DAX1)		Gonadal dysgenesis, sex reversal
	SOX8		Gonadal dysgenesis
	SRY		Swyer syndrome/gonadal dysgenesis
	WWOX		Gonadal dysgenesis
	ZFPM2		Gonadal dysgenesis
	WT1		Denys–Drash syndrome-associated with Wilms tumor
	WT1		Frasier syndrome-associated with gonadoblastoma
			Disorders of androgen action
	AR (NR3C4)		Complete AIS (CAIS) and partial AIS (PAIS)
	LHCGR		Leydig cell hypoplasia
			Disorders of AMH synthesis or action
	AMH		Persistent Müllerian duct syndrome

Table 2 Continued

Category	*Gene*	*Pathogenic type*	*Etiology with examples/associations*
	AMHR2		Persistent Mullerian duct syndrome
		DSD with additional congenital anomalies	
	NR5A1		Steroidogenic factor 1 deficiency, testicular dysgenesis + adrenal insufficiency
	WT1		Denys–Drash syndrome; Frasier syndrome; Meacham syndrome
	DMRT1		Testicular dysgenesis and mental retardation
	ATRX		Alpha-thalassemia mental retardation syndrome
	ARX		Hydranencephaly and abnormal genitalia
	CDKN1C		*IMAGe syndrome*
	DHCR7		Smith–Lemli–Opitz syndrome
	HHAT		Chondrodysplasia
	KAT6B		Genitopatellar syndrome
	SOX9		Gonadal dysgenesis and campomelic dysplasia
	CHD7		CHARGE syndrome
	HOXA13		Hand-foot-genital syndrome
	ROR2		Tyrosine-protein kinase transmembrane receptor Robinow syndrome
	RSPO1		Sex reversal, palmoplantar keratosis
	GL13		Pallister–Hall syndrome
	SPECC1L		Cytospin A protein
	PITX2		Paired-like homeodomain transcription Factor 2 Hypospadias and cryptorchidism Bladder exstrophy
	MKKS		McKusick–Kaufman syndrome centrosome-shuttling protein type II; chaperonin family Vas deferens absence - With cystic fibrosis

Presentation

Many aspects of care for children with disorders of sex development (DSD), defined as a misalignment between chromosomal, gonadal, and phenotypic sex, have fundamentally changed recently—particularly regarding gender assignment. However, uneasiness persists about the management of children with DSD because of reported poor outcomes (Houk and Lee, 2010). The three components of sexual psychosexual development—gender identity, gender role, and sexual orientation—may not always be typically concordant and aligned in individuals with DSD. However, in those with DSD, the primary goal is for gender identity to be consistent with gender assignment. In other words, an overarching goal of DSD management is to avoid a gender assignment that increases the risk of gender dysphoria (Sandberg *et al.*, 2017). In the past, similar discomfort led to the overly simplistic and dogmatic management approach, particularly gender assignment, whereby sexually ambiguous infants were assigned a gender based on a prescriptive set of rules. These rules involved potential for fertility and traditional sexual activity given possible surgical genital repair. For example, a 46,XY patient judged to have an inadequate penis was assigned female, whereas a virilized 46,XX patient with ovaries and a uterus was assigned female, independent of the degree of external genital virilization. To address the poor outcomes associated with the previous medical management paradigms, recent emphasis has been placed on the use of principles, cultural background, and parental input to help make clinical decisions in DSD infants—particularly those with uncertain outcomes regarding adult gender identity and quality of life variables (Ahmed *et al.*, 2011; Houk and Lee, 2010; Indyk, 2017).

If the appearance of the external genitalia is sufficiently ambiguous to render gender assignment impossible or the phenotype is not consistent with prenatal genetic tests, then de facto, extensive investigation is required. However, the recognized extent of genital ambiguity may depend on the expertise of the observer, and prior to presentation to a clinical expert, the label of ambiguous genitalia is often assigned to newborns where the most appropriate sex of rearing is not immediately clear to those present at the child's birth (Mendonca, 2014).

The birth prevalence of genital anomalies may be as high as one in 300 births but the birth prevalence of complex anomalies of true genital ambiguity on expert examination may be as low as one in 5000 births (Ahmed *et al.*, 2011).

When evaluating these infants, the clinical features of the external genitalia that require examination include the symmetry of the external genitalia, presence of gonads in the labioscrotal folds, the fusion of the labioscrotal folds, the size of the phallus and the site of the urinary meatus on the phallus, although the real site of the urinary meatus may, sometimes, only become clear on surgical exploration. These external features can be individually scored to provide an aggregate score, referred to as the external masculinization score (EMS). Infants with suspected DSD who require further clinical evaluation and need to be considered for

investigation by a specialist should include those with isolated perineal hypospadias, isolated micropenis, isolated clitoromegaly, any form of familial hypospadias and those who have a combination of genital anomalies with an EMS of <11. This will avoid unnecessary detailed investigations into boys with isolated glanular or mid-shaft hypospadias and boys with an unilateral inguinal testis. However, investigations are generally indicated with the co-existence of a systemic metabolic disorder, associated malformations or dysmorphic features, a family history of consanguinity, stillbirths, multiple miscarriages, fertility problems, genital abnormalities, hernias, delayed puberty, genital surgery, unexplained deaths, and the need for steroid replacement.

The external genital appearance may be similar for a masculinized female newborn and an undervirilized male newborn, although the former is symmetrical and the latter may be asymmetrical. The presence or absence of palpable gonad(s) is a key finding. If gonads are not palpated beneath the genital folds or in the inguinal area, 46,XX DSD is most likely. When one or two gonads are palpated, 46,XY DSD or gonadal DSD (ovotesticular DSD or mixed gonadal dysgenesis) is likely.

Adolescents (Ahmed *et al.*, 2016)

The initial assessment in an affected adolescent should be aimed at establishing a relationship with the patient and starting the process of diagnosis. An appropriate hospital setting is very important for the sensitive management of complex conditions with full access to the necessary medical, nursing and psychological care. Whilst the explanation of the diagnosis to the patient and the family is critical, this needs to be performed sensitively and carefully and expert psychological input is essential. There are three common DSD presentations in adolescents: (1) a girl with primary amenorrhoea (with or without breast development); (2) a girl who virilizes at puberty; or (3) a boy with pubertal delay (see **Table 3**).

The appearance of clitoromegaly and hirsutism at puberty in the presence of primary amenorrhoea is a classical presentation of two 46,XY DSDs: 17β-hydroxysteroid dehydrogenase type 3 (17bHSD3) deficiency and 5α-reductase type 2 deficiency. It is less typical of partial androgen insensitivity syndrome (PAIS) that is usually associated with ambiguous genitalia at birth. In all these conditions, Müllerian structures will not be detectable. Also, in partial gonadal dysgenesis and ovotesticular DSD, the mild clitoromegaly that may have been present at birth may have been overlooked but becomes a more prominent feature at adolescence. The differential diagnosis would also include CAH and androgen secreting tumors of the ovary or adrenal gland; in all these cases, Müllerian duct derived structures are present.

Although the most common cause of delayed puberty is constitutional delay, all boys with delayed puberty who are over the age of 14 years should be assessed. Overweight boys need careful examination so that a buried penis is not mistaken for micropenis. Rarely, PAIS, a disorder of testosterone biosynthesis or mild forms of testicular dysgenesis, can present in this age group, especially if there is a history of hypospadias repair or orchidopexy.

In adolescents with an existing DSD, transferring to adult services is an opportunity to review the diagnosis, discuss hormone replacement therapies, potential for fertility, and consider further investigations.

Discussion

When a newborn presents with ambiguous genitalia, it is crucial to exclude life-threatening disorders such as adrenal insufficiency (Bangalore Krishna *et al.*, 2017). The extent of internal and external differentiation should be assessed in a

Table 3 Common features of DSD presenting at puberty

Delayed puberty	*Primary amenorrhea*
1. Gonadal dysgenesis - 46 XX pure gonadal dysgenesis - 46 XY pure gonadal dysgenesis - 46 XX sex reversal 2. Mixed gonadal dysgenesis 3. Ovotesticular DSDs 4. LH receptor defects (Leydig cell dysgenesis) 5. 17 hydroxylase deficiency	1. Complete androgen insensitivity 2. Mayer–Rokitansky–Kuster–Hauser syndrome *Failure of attempted sexual intercourse* 1. Mayer–Rokitansky–Kuster–Hauser syndrome 2. 17-β hydroxysteroid dehydrogenase deficiency 3. 17 hydroxylase deficiency
46XX with virilization (acne, hirsutism, amenorrhea, clitoromegaly) 1. Congenital adrenal hyperplasia, nonclassic forms *46XY subjects raised female with subsequent virilization* 1. 17-β hydroxysteroid dehydrogenase deficiency 2. 5-alpha reductase deficiency	*With cyclic hematuria in a phenotypic male* 1. 21 hydroxylase deficiency 2. timely manner. And, if possible, a specific etiology can be identified, so that, together with the parents, an appropriate gender assignment can be made. Parents need to be provided information regarding reproductive system differentiation so they can understand how ambiguity may occur (Indyk, 2017). While typically the karyotypes of 46,XX and 46,XY indicate female and male respectively, it should be pointed out that this is not necessarily an indication that female gender assignment is the most appropriate for all with 46,XX and likewise for 46,XY and male gender assignment. One can share the concept that specific genes direct reproductive system development. Changes in these genes alter the function of the genes and the proteins encoded by these genes. Parents should be provided with new information as it becomes available. Together with the team of experts, the parents will participate in the decision-making regarding gender assignment. The parents need to understand that a gender assignment will be made, with their input, as soon as possible, while in the meantime they need to consider whether to delay the birth announcement and with whom to share information about their child's condition. Full disclosure and education should provide the parents with a perspective that their child, with careful ongoing care, can be expected to have a good quality of life.

Part of the initial interview with the parents should include seeing and examining their infant's genitalia, with careful demonstration of the ambiguous features, while discussing the common origin of female and male structures. The decision for gender assignment, based upon the anatomy and anticipated functional abilities of the reproductive system, should primarily be based upon the most probable future gender identity (although this cannot be predicted) (Sandberg *et al.*, 2012). When data do not suggest one assignment over the other, family perspectives including cultural and religious factors are of key importance. It must be considered that androgen exposure to the developing fetal brain impacts aspects of sexual identity, most clearly gender role behavior as manifest by childhood play preferences, but less clearly effects upon both gender identity and sexual orientation. This may apply to the 46,XX DSD patient with excessive androgen exposure during fetal life, as well as to the poorly virilized 46,XY DSD whose CNS was exposed to normal male levels of androgen during fetal life, or who has sufficient androgen insensitivity so prenatal androgen exposure had diminished impact. Available data indicate that most XX females with virilizing 21-hydroxylase deficiency identify as heterosexual females and most XY females with CAIS identify as females. Hence, while extent of fetal androgen exposure must be considered, this still represents an unknown factor in the development of a gender identity with the future possibility of a gender identity that differs from the sex of rearing (Lee *et al.*, 2012). The topics of biological sex, sex of rearing, and gender identity should be discussed with the parents (Wilson *et al.*, 2012).

In cases of 46,XX DSD, the newborn with ambiguous genitalia is usually assigned female (Kim and Kim, 2012). The rationale for this is that the ovaries and uterus have the potential for normal function so with appropriate medical therapy and surgical construction, fertility and sexual function can be expected. An exception to this assignment should however be considered when external genital development is completely male, except of an empty scrotum. Such individuals raised as males have gender identity and sexual orientation typical for most males, require less surgery and function socially and sexual as males, albeit with infertility (Mieszczak *et al.*, 2009).

For 46,XY DSD, the trend is toward male assignment even when penis and testicular development is subnormal, particularly if there is evidence of prenatal androgen secretion. Assignment as female is currently considered a drastic step, based upon outcome data including gender development contrary to assignment and self-reassignment of gender. Exceptions to this are those with testicular agenesis, complete androgen insensitivity, LH receptor defects and individuals who have no evidence of exposure or responsiveness to androgen. In these instances, sex of rearing needs to be carefully considered with the parents. Those with partial androgen insensitivity must be carefully assessed; those with evidence of androgen responsiveness are generally assigned male, while those with no evidence of responsiveness postnatal, female.

In cases of gonadal DSD, gender assignment should be based on several criteria. A defect in 5α-reductase is an indication for male sex for rearing because pubertal virilization will lead to penile development (although it will be subnormal), normal pubic hair development, and the acquisition of male sexual identity. In contrast, very rarely with inborn errors of testosterone biosynthesis, if male reconstructive surgery appears to be highly unlikely, female assignment may be a consideration, if results suggest that fetal testosterone secretion was markedly subnormal. When a vagina and uterus are present, female assignment may be considered depending upon evidence of testicular testosterone secretion and extent of masculinization and likelihood of successful vaginoplasty.

In cases of complete androgen insensitivity, female assignment is appropriate; with partial androgen insensitivity, male assignment is currently done except in those instances failing to demonstrate responsiveness to exogenous testosterone stimulation. Confirmation of a described mutation in the androgen receptor gene may be helpful for management depending upon variability described for the specific mutation. Only a positive response is potentially helpful, lack of identification of a described (a negative screen) is not helpful.

In patients with ovotesticular disorder, female assignment may be considered with evidence of potential ovarian and uterine function, while substantial external genital development and the presence of testicular function is the basis for consideration of a male assignment (Houk and Lee, 2010).

No area of pediatric endocrinology engenders more controversy than the management of DSD conditions affecting reproductive development. With some variations, guidance from clinicians and ethicists has focused on principles and processes aimed at fostering the over-all well-being of the child and future adult by: (1) minimizing physical and psychosocial risk; (2) preserving

potential for fertility; (3) upholding the individual's rights to participate in decisions that will affect them now or later; (4) leaving options open for the future by avoiding irreversible treatments that are not medically necessary until the individual has the capacity to consent; (5) providing psychosocial support and peer support; (6) supporting the individual's healthy sexual and gender identity development; (7) using a shared decision-making approach that respects the individual's and parents' wishes and beliefs; (8) respecting the family and parent–child relationships, and (9) providing patients with full medical information appropriate for age, developmental stage and cognitive abilities (Lee *et al.*, 2016). While each of these principles is important, striking the appropriate balance among them becomes challenging in the clinical setting. For example, respecting parents' wishes for early genital surgery may impinge on the child's right to participate in decision making and may reduce the child's options for the future (Nabhan and Lee, 2007).

Androgen Biosynthetic Defects: 17β-Hydroxysteroid Dehydrogenadse Type 3 and 5α-Reductase Type 2 Deficiencies

Nathalia L Gomes*, **Rafael L Batista***, **and Berenice B Mendonca,** University of São Paulo, São Paulo, Brazil

Introduction

Androgens play an important role in the process of sex differentiation. During the embryological development of 46,XY individuals, the testosterone secreted by the testicular Leydig cells acts on the androgen receptor in the Wolffian ducts inducing the formation of epididymis, deferent ducts, and seminal vesicles (Jost *et al.*, 1973). Testosterone is further converted to dihydrotestosterone (DHT), which acts on the androgen receptor of the external genitalia and prostate leading to its masculinization (Jost *et al.*, 1973). Disturbance in androgen production can lead to a 46,XY child with a disorder of sex development (DSD) (Hughes *et al.*, 2006; Lee, 2006).

In 46,XY DSD patients, testosterone (T) biosynthesis defects due to enzyme deficiency accounts for a considerable number of patients. The phenotypes are variable, ranging from normal female external genitalia to various degrees of undermasculinization of male external genitalia (Hughes *et al.*, 2006; Lee, 2006).

The most common enzymatic defect in testosterone biosynthesis is the 17β-hydroxysteroid dehydrogenase type 3 (17β-HSD3), also known as 17-β-keto reductase deficiency. It is characterized by isolated impairment of testosterone production not affecting glucocorticoid and mineralocorticoid adrenal secretion. This disorder consists of a defect in the last step of steroidogenesis when androstenedione (Δ4) is converted into testosterone (T) and estrone into estradiol. There are five steroid 17β-HSD enzymes that catalyze this reaction (Andersson *et al.*, 1996) and 46,XY DSD results from impairment of 17β-HSD type 3 (17β-HSD3) isoenzyme activity (Geissler *et al.*, 1994; Saez *et al.*, 1971) which is expressed exclusively in the testes (Geissler *et al.*, 1994). Defects in *SRD5A2* gene, which codifies 5α-reductase type 2 enzyme (5α-RD2), decrease the conversion of testosterone into DHT. There are two 5α-RD isoenzymes, but only the type 2 has high expression in genital skin early in gestation and in adulthood, as well as in prostate, epididymis, and seminal vesicle (Silver *et al.*, 1994).

Both 17β-HSD3 and 5α-RD2 deficiencies are caused by homozygous or compound heterozygous mutations in the *HSD17B3* and *SRD5A2* genes, respectively. Hormonal diagnosis is highly used, despite some discrepancies (Khattab *et al.*, 2015; Lee *et al.*, 2007; Perry *et al.*, 2011), being the molecular analysis the diagnostic tool of choice. The molecular genetic testing not only confirms the diagnosis, but also provides the orientation for genetic counseling.

In both androgen synthesis defects, most patients have severe undervirilization of the external genitalia at birth leading to a female sex assignment in most of the patients (Mendonca *et al.*, 2016, 2017). However, the extreme undervirilization during embryogenesis is opposed to the observed at puberty. At this age, a strong virilization is observed, including muscle mass development, deepen voice, and penile length. In addition, there is a high frequency of gender change in these individuals at adulthood, especially in patients who have not undergone gonadectomy at puberty (Furtado *et al.*, 2012). Considering the psychosexual development and the high level of gender change (from female to male), it is preferable to assign those patients as males (Mendonca *et al.*, 2016, 2017).

Our aim is to review and discuss these two rare disorders regarding their clinical, hormonal, and patients' long term outcomes, highlighting their similarity and main differences between them (**Table 1**).

Epidemiology

Similar to other autosomal recessive disorders, 17β-HSD3 deficiency has an increased frequency in highly inbreed areas. Most cases of 17β-HSD3 deficiency have been reported in Europe, Asia, Australia, and South America, but there are only 12 reports in the United States until now (Mains *et al.*, 2008; Chuang *et al.*, 2013; Boehmer *et al.*, 1999). The incidence is quite variable around the world, ranging from 1:147,000 newborns in Netherlands (Rosler, 2006) to 1: 100–300 in the Gaza Strip Arab population (Rosler *et al.*, 1996). Thus, ethnic origin as well as the report of consanguinity should be considered when diagnosing this disorder.

Allelic variants in the *SRD5A2* gene have been described in several countries, including Brazil, Mexico, Egypt, China, Korea, Pakistan, Portugal, Italy, India, Turkey, Austria, Dominican Republic, and recently in Bulgaria (Mendonca *et al.*, 1996, 2016; Imperato-McGinley *et al.*, 1974; Ko *et al.*, 2010; Adiyaman *et al.*, 2006). Extensive haplotype analysis has not been done in these allelic variants to confirm a possible genetic common background, but their prevalence in restricted regions suggests a possible founder effect (Mendonca *et al.*, 2016).

Clinical Features

In both conditions, the external genitalia appearance at birth is typically female or strongly undervirilized (Lee *et al.*, 2007; Rosler, 2006; Mendonca *et al.*, 2000), leading to female social sex assignment in most of the cases (Andersson *et al.*, 1996; Lee *et al.*, 2007; Rosler, 2006; Cohen-Kettenis, 2005; Rosler and Kohn, 1983).

*Both authors contributed equally to this article.

Table 1 Phenotype of 46,XY subjects with 17β-HSD type 3 and 5α-RD type 2 deficiencies

Parameters	*17β-HSD type 3*	*5α-RD type 2*
Gene/location	*HSD17B3*; 9q22.32	*SRD5A2;* 2p.23.1
Molecular defects	*Missense* allelic variants; exonic deletion, duplication, intronic splice site mutations	Essentially *missense* allelic variants; small deletions, splice site, stop codons, small indels, gross deletions
Inheritance pattern	Autosomal recessive	Autosomal recessive
External genitalia	Severe undervirilization of the external genitalia at birth	Severe undervirilization of the external genitalia at birth
Müllerian duct derivatives	Absent	Absent
Wolffian duct derivatives	Present	Present, small prostate
Testes	Usually located in the groin area or in labioescrotal folds	Usually at inguinal area
Puberty	Virilization at puberty; gynecomastia is observed in ∼30%	Virilization at puberty; gynecomastia is uncommon
Hormonal diagnosis	T/Δ4 ratio below <0.8	T:DHT >8.5 Low specificity; molecular diagnosis is necessary
Psychosexual aspects	Most patients are assigned as female social sex; gender dysphoria and gender change is observed in 39%–64%	Most are raised in the female social sex. Gender change to male social sex is observed in 48%–77%
Treatment	*Females*: surgical feminization of external genitalia, gonadectomy, replacement with estrogens at 11–12 years old vaginal dilatation *Males*: repair of cryptorchidism and hypospadias; testosterone replacement when necessary	*Females*: surgical feminization of external genitalia, gonadectomy followed by estrogen replacement starting at 11–12 years old; vaginal dilatation before sexual activity *Male social sex*: high T or DHT treatment for 6 months to increase penile length. Orthophaloplasty, scrotumplasty, vaginal pouch resection and hypospadias correction
General outcomes	Infertility; female or male gender identity	Infertility is usual but fertility is possible using assisted reproduction techniques

In 17β-HSD3 and 5α-reductase 2 deficiencies, the phenotype is sufficiently variable to cause problems in accurate diagnosis, particularly in distinguishing it from partial androgen insensitivity syndrome (PAIS) and from others enzymatic defects affecting testosterone synthesis (Rosler, 2006; Bertelloni *et al.*, 2006).

At infancy, patients with 17β-HSD3 and 5α-RD2 deficiencies seek for medical attention due to an inguinal hernia or clitoromegaly and at puberty due to amenorrhea and virilization (Andersson *et al.*, 1996; Lee *et al.*, 2007; Mains *et al.*, 2008; Rosler *et al.*, 1992, 1996; Mendonca *et al.*, 2000). The degree of virilization varies from increased body hair, deepening of the voice, development of male body habitus, and clitoris enlargement (reaching as much as 5–8 cm in length) (Lee *et al.*, 2007; Rosler, 2006; Mendonca *et al.*, 2000; Rosler *et al.*, 1992). At surgery, gonads are usually located in the groin area or in labioescrotal folds. Wolffian derivatives including the epididymides, vas deferens, seminal vesicles, and ejaculatory ducts are present (Andersson *et al.*, 1996; Lee *et al.*, 2007; Mendonca *et al.*, 2000), suggesting that a low amount of T is enough to develop male internal genitalia or that T is produced in peripheral tissues by alternative 17β-HSD isoenzymes or by 5α-RD type 1.

In 17β-HSD3 deficiency, there are some hypotheses to explain the paradoxal failure of intrauterine virilization followed by virilization at puberty. The aromatization of Δ4 by the placenta might prevent its extragonadal conversion to T in the fetus (Saez *et al.*, 1971). At puberty, the conversion of androstenedione (Δ4) to testosterone (T) by other 17β-HSD isoenzymes, presumably 17β-HSD5, should contribute to the observed virilization. The AKR1C3 (17β-HSD5) is expressed not only in extra-gonadal tissues, but also in genital skin fibroblast (Werner *et al.*, 2012) and its levels increase with aging in scrotal skin fibroblasts, while 17β-HSD3 mRNA expression is noted to be higher in the younger age groups (Hoppe *et al.*, 2006). Since the testes of patients with 17β-HSD3 deficiency also express AKR1C3, it is possible that Leydig cells of these patients may be a significant source of T synthesis in the presence of high Δ4 levels at puberty, indicating that this enzyme should play a large role in the virilization of these patients at puberty. Another possibility is a residual 17β-HSD3 function capable of maintain testosterone secretion in the presence of elevated LH and androstenedione levels (Andersson and Moghrabi, 1997).

Mild gynecomastia (Tanner II–III) is present in less than 30% of the adult patients, as previously reviewed (Mendonca *et al.*, 2017), probably due to peripheral conversion of Δ4 to estrogens (Moghrabi and Andersson, 1998).

In 5α-reductase 2 deficiency, affected individuals also present atypical external genitalia, ranging from a typical female external genitalia to a undervirilized male external genitalia (Imperato-McGinley, 2002). However, hypospadias, penile urethra, and micropenis have been described in individuals with allelic variants in the *5SAR2* gene. Internal genitalia (including vasa deferentia, seminal vesicles, epididymis, and ejaculatory ducts) are usually normal, but prostate is hypoplastic. The testes are located at inguinal area in most cases, suggesting that dihydrotestosterone has a role in the testes descent (Mendonca *et al.*, 1996). At puberty,

virilization is observed in individuals who kept the gonads, including voice deepening and muscle development, but gynecomastia is very rare, a feature which is helpful to clinical diagnosis after puberty.

Hormonal Diagnosis

17β-HSD3 deficiency can be reliably diagnosed by endocrine evaluation in most of the patients. The endocrine hallmarks of 17β-HSD3 deficiency are increased concentrations of Δ4 and reduced levels of T, leading to a low T/Δ4 ratio. It is considered that a T/Δ4 ratio below <0.8 is suggestive of 17β-HSD3 deficiency, based on a previous study in which all but 1 of the 18 index patients with 17β-HSD3 deficiency had a low T/Δ4 ratio (0.4 ± 0.2), measured by radioimmunoassay, after hCG stimulation (Boehmer *et al.*, 1999). No patients with AIS (androgen insensitive syndrome) or normal control had a T/Δ4 ratio <0.8 after hCG stimulation test.

However, there are known diagnostic pitfalls in hormonal analysis, as a low T/Δ4 ratio may also be found in other causes of 46, XY DSD (Faisal Ahmed *et al.*, 2000) and some proven molecular 17β-HSD3 deficiency patients had a normal T/Δ4 ratio (Khattab *et al.*, 2015; Lee *et al.*, 2007). The median post-hCG T/Δ4 ratio was significantly lower in a group of dysgenetic 46,XY DSD (9 of 16 patients had a T/Δ4 < 0.8) and 4 of 84 patients diagnosed as AIS (1 with the complete androgen sensitivity form and 3 with the partial form) had a T/Δ4 ratio also less than 0.8 (Faisal Ahmed *et al.*, 2000). Two of the 14 cases of 17β-HSD3 deficiency reported from the UK database had a T/Δ4 ratio >0.8 (Lee *et al.*, 2007). In addition, 67% of 17β-HSD3 deficiency patients of a national cooperative study from the Netherlands were misdiagnosed as AIS (Boehmer *et al.*, 1999).

All previous reported patients had hormonal evaluation performed by immunoassays. However, steroids with lower concentration such as androstenedione should be measured by a very specific assay such as high-performance liquid chromatography and tandem mass spectrometry to determine the T/Δ4 ratio correctly. But even in this ideal scenario, the hormonal diagnosis can fail. Two patients with atypical genitalia, who were assigned in the female social sex, were evaluated at 5 months and 9.2 year of age, respectively (Khattab *et al.*, 2015). After the hCG stimulation test, there was a clear elevation of serum testosterone with a small increase of the androstenedione levels (both measured by HPLC tandem mass spectrometry) resulting in a high T/Δ4 ratio (2.47 and 2.27, respectively). Both patients have deleterious molecular defects in *HSD17B3* gene. One possible explanation for the normal T/Δ4 ratio in these children with normal T/A ratio is the individual and temporal variability in the *HSD17B* isoenzymes activity (Khattab *et al.*, 2015).

In 5α-RD 2 deficiency the presence of an elevate testosterone and a low dihydrotestosterone suggests the 5α-RD2 deficiency diagnosis (Mendonca *et al.*, 2016; Inacio *et al.*, 2011). T/DHT ratio is helpful to diagnosis, but a pubertal level of testosterone is necessary to estimate this ratio. The T/DHT cut-off is not unequivocal but a ratio of >8.5 has been proposed as a cut-off for identifying 5α-RD 2 deficiency but with low specificity. During childhood, hCG stimulation test is necessary to obtain a pubertal level of testosterone (>100 ng/dL). Further, DHT measurement by immunoassay is not reliable considering the very low peripheral concentration of this hormone and the high cross-reaction with testosterone (Mendonca *et al.*, 2016). An alternative for 5α-reductase 2 deficiency diagnosis is the measurement of the 5α to 5β-reduced steroids in urine by chromatography–mass spectrometry (GC–MS). This technique is helpful, especially because it can be used in prepubertal and in individuals which had undergone to bilateral orquiectomy, but it still not easily available.

These difficulties for an unequivocal diagnosis using hormonal methods indicates that molecular diagnosis is preferable mainly in newborns.

Molecular Diagnosis

Both 17β-HSD3 and 5α-RD type 2 deficiencies are autosomal recessive disorders, and molecular defects can be emerged in homozygous or compound heterozygous states.

Up to now, almost 37 mutations in the *HSD17B3* gene have been reported. These include missense, nonsense, exonic deletion, duplication and intronic splice site mutations. Although mutations have been described throughout the *HSD17B3*, a mutation cluster region was identified in the exon 9. Outside exon 9, the most frequent site of mutation in *HSD17B3 gene* is the R80 in exon 3, which has been found in Palestinian, Brazilian, and Turkish families (McKeever *et al.*, 2002; Andonova *et al.*, 2017).

In the *5ARD2* gene, 90 different allelic variants related with 5α-RD type 2 deficiency have been described. The majority are *missense* mutation ($n = 60$), but small deletions, indels, splice site mutations, stop codons, and gross deletions were also described (Mendonca *et al.*, 2016). The *5ARD2* gene is composed by 5 exons and the allelic variants are concentrated especially at exons 1 and 4 (Thigpen *et al.*, 1992). Of the 254 aminoacids in the 5α-RD type 2 enzyme, mutations were found in a total of 67. Possible putative founder effect include p.Q6X and p.R227 in Asia and p.Q126R in Brazil. Usually, homozygous defects are more frequent than compound heterozygous and there is only one case of uniparental disomy reported (Chávez *et al.*, 2000).

Germ Cell Tumor Risk

The Consensus of Disorder of Sex Development reported a high risk (28%) of tumor development in patients with 17β-HSD3 deficiency (Lee, 2006). However, this high frequency for 17β-HSD3 deficiency was based on the gonadal tissue analysis of only

seven patients with 17β-HSD3 deficiency (Hughes *et al.*, 2006). In a recent review (Mendonca *et al.*, 2017), this prevalence was estimated in 5% taking the data of all the 40 reports of histological analysis of testicular tissue stained with hematoxylin-eosin of patients with 17β-HSD3 deficiency (Lee *et al.*, 2007; Chuang *et al.*, 2013; Cools *et al.*, 2005, 2006; Mendonca *et al.*, 2000; Wunsch *et al.*, 2012; Costa *et al.*, 2014; Telles de Sousa Castro *et al.*, 2012). The maintenance of the testes in patients with 17β-HSD3 deficiency and male social sex seems to be safe, except when the testes cannot be positioned into the scrotum.

In patients with 5-α reductase type 2 enzyme deficiency, the gonadal tumor risk is not clearly known, but is estimated to be so rare as described in complete androgen insensitivity syndrome (Kathrins and Kolon, 2016; Huang *et al.*, 2017).

Psychosexual Aspects

The most dramatic psychosexual outcome in 46,XY DSD is observed in patients with 17β-HSD3 and 5α-RD2 deficiencies. There is a high rate of gender change (from female to male) in both conditions: 39%–64% and 50%–63%, respectively (Furtado *et al.*, 2012; Cohen-Kettenis, 2010). It is probably due to prenatal androgen exposure, which is related with male psychosexual development, regardless of the karyotype and the external genitalia appearance (Berenbaum and Beltz, 2011; Hines, 2011).

In a recent review, we found that 61% of adult patients with 46,XY DSD due to 17β-HSD3 deficiency who were reared as female and not undergone gonadectomy during childhood, kept the female social sex and 19 of them (39%) changed to male social sex (Mendonca *et al.*, 2017). In the other hand, all patients that had undergone gonadectomy during childhood, kept the female social sex in adulthood (Bertelloni et al., 2009a,b).

Besides hormonal and physical factors, ethnical and cultural ones also play an important role in choosing male social sex. As an example, in Arabic families, it is preferable to be a sterile man to a sterile woman (Rosler, 2006; Rosler *et al.*, 1996; Rosler and Kohn, 1983). In one of those consanguineous families, who carried the mutation p.R80H in *HSD17B3* gene in the Gaza territory (Rosler, 2006; Rosler *et al.*, 1996; Rosler and Kohn, 1983), the spontaneous adoption of male identity of seven patients after puberty led some parents to request an early alteration of registration of their affected children during childhood (Rosler, 2006). In this family, the subjects who adopted the male social sex showed a much better adaptation to the new conditions than before the sex change (Rosler, 2006).

In 5α-RD type 2 deficiency, the prevalence of gender change is 48%–60% of the individuals at adulthood (Mendonca *et al.*, 2016). Correlation between the type of allelic variant and functional effects was not established (Costa *et al.*, 2012). At present, it is possible to conclude that gender change from female to male in 5α-RD2 enzyme deficiency individuals diagnosed at adulthood is common, but it is not a rule.

In both conditions affected individuals should be assigned as male considering the spontaneous puberty and the high frequency of female to male gender change. If assigned in female social sex, early gonadectomy should be performed to avoid virilization (Mendonca *et al.*, 2009; Mendonca, 2014).

Fertility

There are some 46,XY 17β-HSD3 deficiency patients reared as males and no report of preserved fertility (Andersson *et al.*, 1996; Lee *et al.*, 2007; Rosler, 2006; Cohen-Kettenis, 2005; Rosler and Kohn, 1983). There is one case report of an adult 17β-HSD3 deficiency patient whose biopsy of the testes at the age of 26 revealed absence of spermatogenesis, proving that he was sterile, despite the fact of having undergone relatively early orchidopexy (the left testis was brought down at the age of 2.5 years and the right testis at the age of 4) (Dumić *et al.*, 1985). There is no phenotype in 46,XX patients and fertility is preserved (Rosler *et al.*, 1996).

In 5α-RD type 2 deficiency there are some semen abnormalities including high viscosity, reduced volume, and reduced sperm account (Costa *et al.*, 2012; Russell and Wilson, 1994). In the germ cell analysis, there is a lack of primary spermatocytes. For most affected individuals, spontaneous fertility is not possible, but assisted reproduction techniques are helpful (Guercio and Rey, 2014). In vitro fertilization, intracytoplasmic sperm injection, and uterine insemination were used with success (Katz *et al.*, 1997; Matsubara *et al.*, 2010). In 46,XX *5ARD2* allelic variants carriers individuals, fertility and phenotype are normal.

Conclusion

46,XY DSD due to 17β-HSD3 deficiency and 5α-RD2 are autosomal recessive disorders that can be clinically indistinguishable due to the severe undervirilization of the external genitalia at birth followed by virilization at puberty. These diagnoses should be considered in front of females with inguinal hernias or mild clitoromegaly in infancy or early childhood as well as with amenorrhea and virilization at puberty. Most affected individuals are assigned and reared as females with high percentage of gender change to male social sex. In most patients the correct diagnosis can be achieved by a low T/A ratio (<0.8) for 17β-HSD3 deficiency and T/DHT ratio >8.5 for 5-α reductase type 2 deficiency. However, only molecular diagnosis is able to unequivocally confirm the diagnosis in both conditions.

Maintenance of the testes in patients with male social sex is safe and recommended, except when the testes cannot be positioned inside the scrotum. Fertility is difficult but it is possible and had been described in rare reports of 5α-RD type 2 patients.

Androgen Insensitivity Syndrome (AIS): Complete AIS (CAIS)

Jarmo Jääskeläinen, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland

AIS and the Role of Androgens in Sex Development

Androgen insensitivity syndrome (AIS) is caused by target tissue resistance to androgen action. The AIS patient has 46,XY karyotype and gonads that are differentiated into testes. The testes are capable of producing testosterone which is further metabolized into dihydrotestosterone. However, as the receptor is deficient, androgens are not capable to turn on or off the activity of androgen-responsive genes and to induce the development of male sexual characteristics. The clinical manifestations of androgen insensitivity syndrome vary from external genitalia that are completely female to degrees of partial masculinization. These syndromes are the most common identifiable cause of male undermasculinization, representing approximately half of all 46,XY patients with a disorder of sex development (DSD; Thyen *et al.*, 2006). Complete AIS (CAIS) if the extreme of the wide phenotypic spectrum seen in AIS.

After development of the testis from the bipotential gonad, the events of male sex differentiation involve two pathways, one inhibitory and one stimulatory (**Fig. 1**). The inhibitory pathway is to represses the development of the Müllerian ducts (fallopian tubes, uterus, and upper third of the vagina). This process occurs between 6 and 8 weeks' gestation and is mediated by anti-Müllerian hormone (Josso *et al.*, 1991). The stimulatory events of male sex differentiation require high levels of androgens and a functional androgen receptor. Testosterone is critical in stabilizing the Wolffian duct system to prevent its involution and to induce differentiation into the epididymides, vasa deferentia, and seminal vesicles. Stabilization of the Wolffian ducts occurs between 9 and 13 weeks' gestation, when testosterone is secreted from the testes mostly under the control of placental chorionic gonadotropin. Dihydrotestosterone (DHT) is not involved in this process, as the 5α-reductase enzyme which converts testosterone into DHT is not yet expressed in these tissues (Wilson *et al.*, 1993). On the contrary, 5α-reductase is expressed already at this stage of development in the prostate, prostatic urethra, and external genital primordia, and their development is DHT dependent (Imperato-McGinley *et al.*, 1992).

Testicular descent occurs in two morphologically distinct phases which are under different hormonal control from the testis (Hutson *et al.*, 2015). During the first phase, insulin-like hormone 3 (INSL3) from the Leydig cells anchors the testis near the future inguinal canal by stimulating the gubernaculum to swell (Hutson *et al.*, 2015). In the second, inguinoscrotal phase, the gubernaculum bulges out of the inguinal region to create the future inguinal ring and then migrates to the scrotum enabling the intraperitoneal testis to leave the abdomen while still remaining inside an extension of the peritoneum. The final event is closure of the proximal processus vaginalis in the human, thereby preventing inguinal hernia and/or hydrocele (Hutson *et al.*, 2015). Androgens control the inguinoscrotal phase, but the exact mechanism is not clear. Previously, it was assumed that androgens act directly on the gubernaculum, but AR does not appear in the gubernaculum during the critical inguinoscrotal phase of testicular descent (Nation *et al.*, 2011).

The Androgen Receptor

The androgen receptor (AR) is a well-defined transcriptional regulatory factor that belongs to the steroid/nuclear receptor superfamily (Evans, 1988). Four of these receptors, the androgen receptor, glucocorticoid receptor, mineralocorticoid receptor, and

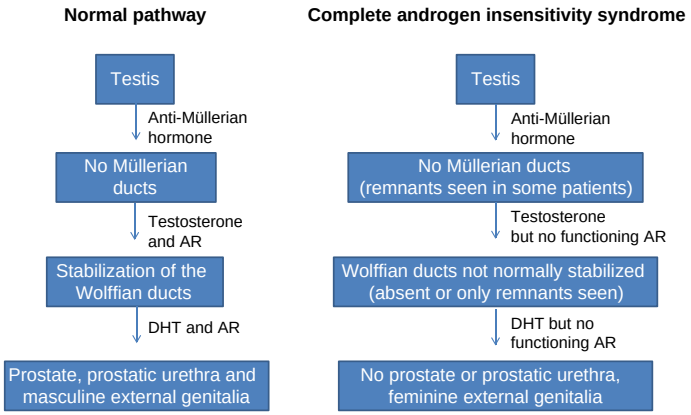

Fig. 1 Differences in sexual differentiation in normal 46,XY male and in 46,XY female with complete androgen insensitivity syndrome (CAIS). https://link.springer.com/referenceworkentry/10.1007/978-3-319-29456-8_26-1.

progesterone receptor, are closely related and even have an ability to activate gene transcription via the same hormone response element. AR interacts directly with its target genes as a hormone-receptor complex and regulates their transcription.

The human *AR* complementary DNA was cloned in 1988 (Chang *et al.*, 1988; Lubahn *et al.*, 1988), and in the same year the first *AR* gene mutation associated with CAIS was reported (Brown *et al.*, 1988). The human *AR* gene is located on chromosome Xq11–12 (**Fig. 2**). The *AR* gene is about 90 kb long, but only about 2750 nucleotides code for an AR protein of 919 amino acid residues. The AR protein migrates during SDS-PAGE as 110 and 112 kDa proteins, the latter representing the phosphorylated form of the AR protein (Brown *et al.*, 1989; Chang *et al.*, 1988; Lubahn *et al.*, 1988). The gene is divided into eight exons, and the first exon includes two homopolymeric amino acid, polyglutamine and polyglycine, repeats which are polymorphic in length (Andrew *et al.*, 1997; Lumbroso *et al.*, 1999).

Like all nuclear receptors, the AR protein consists of four major functional domains: a variable N-terminal transactivation domain (NTD, encoded by exon 1), a highly conserved DNA-binding domain (DBD, encoded by exons 2 and 3), hinge region or bipartite nuclear localization signal (encoded by exons 3 and 4), and a conserved C-terminal ligand-binding domain (LBD, encoded by exons 4 to 8; **Fig. 2**). In addition to their principal functions, these major domains embody subsidiary functions affecting receptor dimerization, nuclear localization, and transcriptional regulation (Brinkmann, 2001). After binding of an androgen molecule to the LBD, AR rapidly translocates to the nucleus, where it directly interacts with DNA as a homodimer, at androgen response elements (ARE) found in the regulatory regions of target genes (**Fig. 3**). This complex can thenceforth recruit coactivators through the ligand-dependent transactivation function (AF-2) located in the LBD and hence control transcription of specific genes. Through this mechanism, androgens such as testosterone and DHT regulate a wide range of physiological androgenic and anabolic responses, most notably male sexual differentiation and maturation including the development, growth, and maintenance of the normal prostate. The ligand structure itself determines the number of interactions it can make with the AR LBD. For example, a potent synthetic androgen tetrahydrogestrinone establishes more van der Waals contacts with the receptor than the natural ligands testosterone and DHT, whereas the geometry of the atoms forming electrostatic interactions at both extremities of the steroid nucleus seems mainly responsible for the higher affinity and androgenic potency measured experimentally for DHT over testosterone (Pereira de Jésus-Tran *et al.*, 2006).

In the AR N-terminal domain there are motifs that form the interface for the interaction of NTD with the LBD. These motifs interact with different regions of the LBD to stabilize the hormone-receptor complex (He *et al.*, 2000). There also seems to be a putative interface between the AR, DBD, and LBD. Some LBD mutations which decrease DNA binding leave ligand binding unaffected, as well as some DBD-residing mutations which lower the ligand binding do not affect the DNA-binding affinity. Therefore, it has been proposed that certain AR residues are involved in allosteric communications between the AR-DBD and AR-LBD (Helsen *et al.*, 2012).

Androgen receptor is expressed in various human tissues, and AR defects have been recognized also in conditions other than AIS, such as the X-linked motor neuron disorder known as Kennedy's disease and prostate cancer.

Androgen Receptor Gene Mutations in AIS

The rates of detected mutations in AIS have varied depending on phenotype, family history, and screening method. In the Cambridge cohort, an *AR* mutation was found in 83% of the cases with CAIS (Ahmed *et al.*, 2000a). In a small Brazilian study on 32 AIS patients from 20 families, the strict selection criteria, which included also family history suggestive of X-linked inheritance in prepubertal subjects and the presence of gynecomastia in postpubertal subjects, resulted in the identification of mutations in

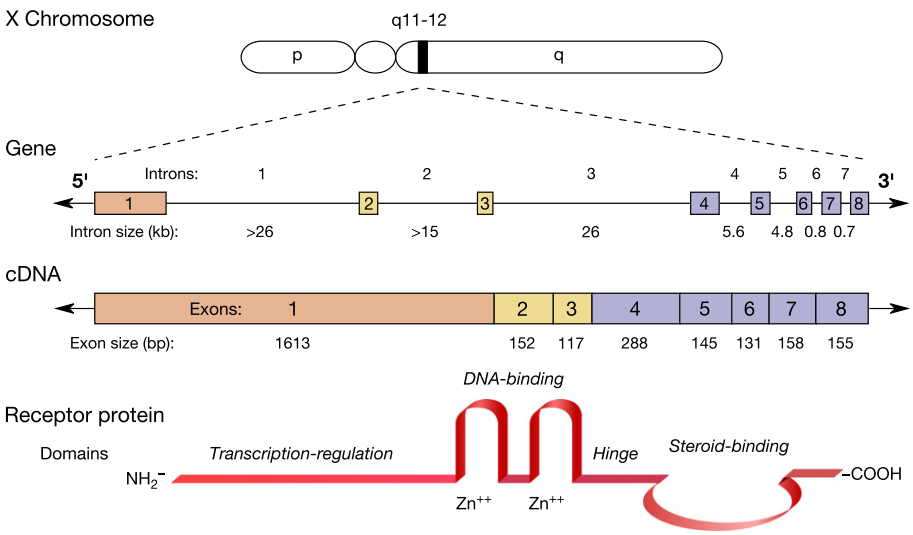

Fig. 2 Location and structure of the human androgen receptor: The *AR* gene is located on the long arm of the X chromosome. The eight exons are separated by introns of various lengths. The AR protein has several functional domains. Quigley, C. A., De Bellis, A., Marschke, K. B. et al. (1995). Androgen receptor defects: Historical, clinical, and molecular perspectives. *Endocrine Reviews* 16, 271–321.

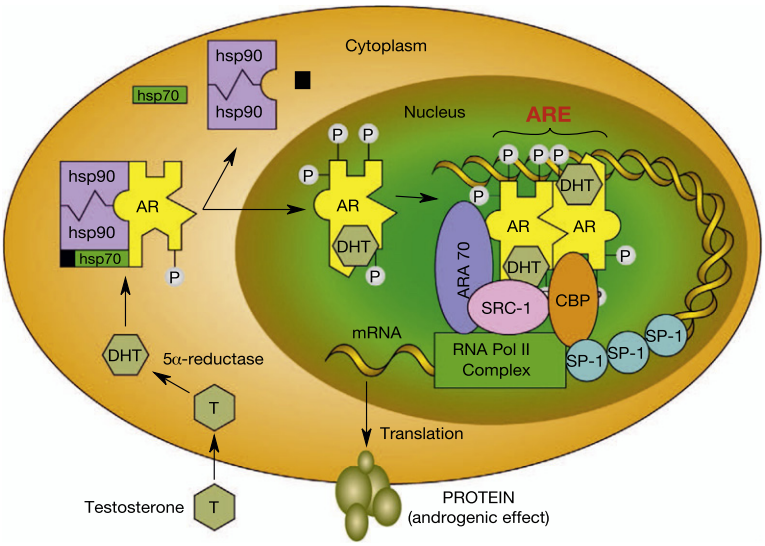

Fig. 3 Ligand-dependent activation of the androgen receptor. Androgens enter the cell and bind to the AR. Upon ligand binding, the AR undergoes conformational changes and the translocates to the nucleus where dimerization and DNA binding to regulatory androgen response elements occurs. AR (androgen receptor); DHT (dihydrotestosterone); CBP (CREB-binding protein); ARE (androgen response element); hsp (heat shock protein); SRC-1 (steroid receptor coactivator 1). Figure by Jonathan Marcus, based on an original drawing in: Meehan, K. L. and Sadar, M. D. (2003). Androgens and androgen receptor in prostate and ovarian malignancies. *Frontiers in Bioscience* 8, d780–d800.

100% of subjects with CAIS (Melo *et al.*, 2003). All in all, in CAIS the likelihood of finding a disease-causing mutation is significantly higher than in PAIS or MAIS.

More than 550 single-nucleotide variants in *AR* have been found to cause AIS (the androgen receptor mutations database, last updated in 2012; Gottlieb *et al.*, 2012). Almost two thirds are missense mutations (Jääskeläinen, 2012). About a quarter are nonsense point mutations, small deletions, or insertions leading to a premature stop codon. Intron splice site mutations and large deletions spanning several exons cover less than 10% of all the reported mutations. Most detected mutations have been identified in patients with CAIS (Jääskeläinen, 2012).

More than half of all *AR* mutations are located in the LBD, and a majority of these are missense mutations (Gottlieb *et al.*, 2012). These mutations include the amino acid residues that line the AR ligand-binding pocket. Other clusters are located at the activation function 2, a regulatory surface cleft termed binding function 3, and a region that tethers the C-terminal tail of the receptor (Estébanez-Perpiñá *et al.*, 2007; Tahiri *et al.*, 2001). The mechanisms by which the LBD mutants disrupt AR signaling are not only diminished ligand binding but include also disturbed interaction with the cofactors, transactivation domain, or DNA-binding domain (Ghali *et al.*, 2003; Helsen *et al.*, 2012; Jääskeläinen *et al.*, 2006; Thompson *et al.*, 2001).

The proportion of detected and reported mutations in the N-terminal transactivation domain (encoded by exon 1) has constantly increased, and the past very low detection rates most likely reflect challenges in sequencing this GC-rich exon. In a recent report on patients with CAIS, the mutation rate in exon 1 was already 27% (Philibert *et al.*, 2010). Most exon 1 mutations lead to a premature stop codon (associated with CAIS) and less than a third are missense mutations, mostly associated with PAIS or MAIS (Jääskeläinen, 2012).

About 15% of all detected AR mutations lie within the DBD encoded by exons 2 and 3, and only a few mutations in AR hinge region (codons 628–669, between DBD and LBD) have been reported (Jääskeläinen, 2012).

AIS is inherited in a recessive X-linked manner. Thus, the proband is likely hemizygous for the *AR* mutation and the mother of the proband is a heterozygous carrier. When the mother has more than one affected child but the pathogenic *AR* variant cannot be found in her leukocyte DNA, she most likely has germline mosaicism. Further, all *AR* gene mutations are not inherited: 30% of all detected mutations are de novo mutations, and there is evidence that every third de novo mutation may have occurred at a postzygotic stage leading to a somatic mutation (Hiort *et al.*, 1998).

The phenotype may vary with identical genotypes. The androgen receptor mutations database includes about 50 cases where an identical AR mutation is associated with significant phenotypic diversity. Identical mutations have been associated with different PAIS phenotypes even in the same kindred, and siblings with the same AR mutation have been assigned a different sex of rearing (Batch *et al.*, 1993). Phenotypic variability may be due to somatic mosaicism (Holterhus *et al.*, 1997) or to variable expression of other genes necessary for androgen biosynthesis and metabolism (such as 5α-reductase) (Boehmer *et al.*, 2001).

AR Polymorphisms and Androgen Insensitivity

There are two polymorphic trinucleotide repeat segments in the AR NH2-terminal domain of the receptor, $(CAG)_n$ encoding a polyglutamine and $(GGN)_n$ encoding a polyglycine repeat segment, respectively (Lubahn *et al.*, 1988; Chang *et al.*, 1988). The

length of CAG repeats varies from nine to 36 in normal population (Andrew *et al.*, 1997). When this region is ≥38 repeats in length, it may lead to reduced virilization, defective spermatogenesis, and spinal bulbar muscular atrophy (SBMA), known also as Kennedy's disease (La Spada *et al.*, 1991).

Downstream of the CAG_n repeat polymorphism is located the GGN repeat region, represented by $(GGT)_3GGG(GGT)_2(GGC)_n$ with n varying from 10 to 35. In AIS, these two polymorphisms may modulate the phenotypic expression of a given AR mutant in affected individuals (Werner *et al.*, 2006; Rajender *et al.*, 2008). Furthermore, AR CAG repeat length may contribute to the causation of androgen-related genital abnormalities with multifactorial etiology, including hypospadias (Huang *et al.*, 2015; Lim *et al.*, 2001). When within the normal length range, neither $(CAG)_n$ nor $(GGN)_n$ are single causative factors for AIS, but they have been associated with male infertility or serum testosterone concentrations. In 1994, Chamberlain et al. reported that AR function is reduced in vitro by increasing the length of CAG repeat. However, this association may be nonlinear: median CAG lengths (22–23 repeats) have resulted in higher AR-mediated transcription than longer and shorter repeats (Nenonen *et al.*, 2011).

AR Mutation Negative AIS

No other genetically proven mechanism than the mutated *AR* has been shown for AIS. Theoretically such a mechanism could be a coactivator defect. Two sisters who were resistant to several steroids, including androgens, have been reported (New *et al.*, 2001). Also, one subject with CAIS has been reported, in whom the transmission of the activation signal from the AF1 region was disrupted but no mutation was found in the AR gene suggesting that a coactivator interacting with this region was lacking in this patient (Adachi *et al.*, 2000). However, no proven molecular defect in any coactivator has been found in any AIS patient. Next generation multigene panel sequencing should therefore be considered for an AIS patient with no detected mutation in the *AR*.

Studying Androgen Receptor Function In Vitro

The effect of the identified mutation on androgen receptor-dependent transactivation is the most used AR functional assay. The AR expressing plasmid (either normal or mutated) is transfected into a mammalian cell line (which itself does not express AR) together with a hormone response element in construct with a suitable reporter vector. The transfected cells are then incubated with the ligand, and thereafter the reporter activity is assayed.

Another functional assay is studying interaction between the AR amino- and carboxylterminal domains (N/C interaction assay based on reporter gene activation in a mammalian two-hybrid assay; He *et al.*, 2000). Missense mutations found in the AR-LBD that reveal near-normal androgen-binding kinetics may display disrupted N/C-interaction, and the decreased N/C-interaction has been shown to mirror the degree of AIS (Jääskeläinen *et al.*, 2006).

Missense mutations in the DBD may lead to a complete disruption of AR binding to AREs associated with CAIS or only to an altered affinity and selectivity of AR–androgen response element interactions associated with PAIS or MAIS. The reduced or absent DNA binding can be demonstrated by electrophoretic mobility-shift assays (EMSAs) or by fluorescence recovery following photobleaching (FRAP) experiments, comparing cells transfected with green fluorescent protein-tagged mutant and wild-type AR (Farla *et al.*, 2004).

Studies of androgen binding in cultured genital skin fibroblasts have been utilized for the diagnosis of AIS for many years and elucidated the cause of AIS at the cellular level in many cases. A 2–3 mm genital skin biopsy intended for androgen receptor studies can be taken under local anesthetic from the labia which contains preferential expression of androgen receptor. Alternatively, skin from the prepuce or labioscrotal folds can be obtained at the time of surgery. After culturing an adequate number of cells, which takes a minimum of 6–8 weeks, the cells are incubated with a radiolabelled androgen (like DHT or mibolerone) in the presence or absence of an excess of the nonradiolabeled ligand. Several parameters (maximal ligand-binding capacity, ligand dissociation constant, thermolability) can then be measured (Griffin *et al.*, 1976).

Prevalence of Complete Androgen Insensitivity Syndrome

AIS is the most common specific cause for 46,XY undermasculinization, but the estimates of its prevalence have varied widely. Jagiello and Atwell estimated the prevalence of complete CAIS as 1:62,400 males based on the prevalence of inguinal hernia in phenotypic females (Jagiello and Atwell, 1962). Later, a group in Denmark reported a higher prevalence for AIS, 1:20,400 males, calculated from the number of primarily diagnosed cases with the disorder (Bangsbøll *et al.*, 1992). In a Dutch study, which included only cases with a proven molecular diagnosis of AIS, the incidence was 1:99,000 males (Boehmer *et al.*, 2001).

Clinical Presentation of CAIS

In CAIS, there are no visible clinical signs of androgen action and the subjects are born with normal female external genitalia, though the clitoris, labia minora, and labia majora may be underdeveloped. If prenatal examinations are performed, CAIS can be

suspected already prenatally, when the karyotype (46,XY) of the fetus does not match with the female phenotypic sex. The birth size of CAIS patients is on average the same as that of healthy male infants, suggesting that factors on the Y chromosome rather than exposure to prenatal androgens explain the sex dimorphism (Miles *et al.*, 2010). After birth, most subjects (up to 76%) are diagnosed early when inguinal hernias or inguinal or labial swellings in an apparently female infant are discovered to contain testes (Viner *et al.*, 1997). All in all, inguinal hernias have been reported to be present in 90% of patients with CAIS, and in most cases these are bilateral (Viner *et al.*, 1997). Estimates of the incidence of AIS in female infants with hernias have ranged from 1% to 2%, suggesting that any girl with an inguinal hernia should have a karyotype performed or CAIS otherwise excluded (Jagiello and Atwell, 1962; Pergament *et al.*, 1973). Girls with CAIS have a shorter vaginal length than healthy girls, and in ultrasonography no ovaries, fallopian tubes, or uterus can be seen (Hurme *et al.*, 2009). In some patients, however, rudimentary segments of the Müllerian ducts are present (Nichols *et al.*, 2009). Wolffian duct differentiation is testosterone dependent, and these patients should lack vasa deferentia, epididymides, seminal vesicles, and ejaculatory ducts. However, some phenotypic CAIS patients have Wolffian ducts, explained by minor residual activity of the mutant AR which is capable of responding to high local testosterone concentrations during early development (Hannema *et al.*, 2004). The testes can be located anywhere along the pathway from the lower abdomen to the scrotum. Many subjects with CAIS are not suspected of having the diagnosis until the onset of puberty, when breast development is normal, but pubic and axillary hair development is not, and menarche, initially considered late, never occurs. Some affected individuals develop normal female sexual hair at puberty, and even more CAIS patients have some fine, silky pubic hair (Tanner 2), developing under the influence of factors other than AR action (Boehmer *et al.*, 2001; Wisniewski *et al.*, 2000). If not diagnosed by this time, CAIS can first present after puberty as a gonadal tumor (Manuel *et al.*, 1976). The physical appearance is generally feminine, and affected individuals have mostly a feminine body image and sexual orientation (Wisniewski *et al.*, 2000). However, some recent reports indicate that less feminine gender roles and "not exclusively androphile sexual orientation" are more common in CAIS than previously thought (Brunner *et al.*, 2016). Adult height is between healthy males and females (Varrela *et al.*, 1984; Zachmann *et al.*, 1986). The enlarged adult stature in the syndrome is thought to be mainly due to the effect of the growth-controlling region on the long arm of the Y chromosome, but genome-wide association studies have identified several other loci that affect adult height (Lango Allen *et al.*, 2010).

Diagnosis of CAIS

Resistance to androgens, testosterone and its 5α-reduced product dihydrotestosterone (DHT) is diagnosed when circulating concentrations of serum hormones are normal or high but there is little or no clinical effect. The diagnosis of AIS is based on clinical findings, endocrine evaluation, and family history. The diagnostic criteria for AIS include:

1. 46,XY karyotype.
2. Presence of testes with histology showing testicular differentiation.
3. Normal testosterone production and metabolism.
4. Absence of Müllerian ducts (fallopian tubes, uterus, upper part of vagina; remnants may be present).
5. Normal female external genitalia (inguinal hernia and labial swellings containing testes may be present).
6. Spontaneous feminization (but no menses) at puberty before gonadectomy with no virilization despite normal or high male levels of testosterone.
7. Strict criteria for CAIS include also an identified mutation in the *AR* gene (Mongan *et al.*, 2015; Viner *et al.*, 1997; Zachmann *et al.*, 1986).

A complete diagnostic evaluation thus includes karyotype analysis, pelvic ultrasonography, basal (and potentially human chorionic gonadotropin (hCG) stimulated) serum testosterone, DHT, and androstenedione, as well as basal (and potentially gonadotropin releasing-hormone (GnRH) stimulated) serum luteinizing (LH) and follicle-stimulating hormone (FSH) concentrations. Nowadays, mutational analysis either by Sanger sequencing or next generation sequencing multigene panels is the best tool to confirm the diagnosis. In the case where no *AR* mutation is detected, a gonadal biopsy is valuable in the differential diagnosis; gonads of a patient with AIS usually show normal testicular differentiation, unlike the situation in gonadal dysgenesis. Also, genital skin fibroblast culture is useful when mutational analysis remains negative. Fibroblasts can be used to identify genomic mutations that disrupt normal RNA splicing, to quantify androgen binding, AR expression, and expression of androgen-dependent gene expression patterns (Holterhus *et al.*, 2007).

Differential Diagnosis of CAIS

In most cases CAIS is a relatively clear entity, and it only rarely leads to diagnostic problems if the initial diagnostic investigations are adequate. However, the differential diagnosis for CAIS includes several conditions leading to impaired androgen production and metabolism. Defects in steroid biosynthesis and metabolism can cause male undermasculinization. In 17β-hydroxysteroid dehydrogenase type 3 deficiency, the final step in testosterone biosynthesis (from androstenedione to testosterone) is impaired, but the ratio of testosterone to androstenedione is not always discriminative, and the phenotype of these children might be

indistinguishable from those with AIS (Lee *et al.*, 2007). During puberty, people with this condition develop some secondary sex characteristics, such as increased muscle mass, deepening of the voice, and development of male pattern body hair.

In 5α-reductase deficiency the peripheral conversion of testosterone to DHT is impaired but the ratio of DHT to testosterone is variable in this condition (Hiort *et al.*, 1996). At puberty, also these patients may present with virilization.

Finally, most 46,XY individuals with *NR5A1* loss-of-function mutations have evidence for gonadal dysgenesis, but some infants with heterozygous *NR5A1* mutations present with normal testosterone and DHT levels at infancy, and thus AIS may remain as a differential diagnosis (Coutant *et al.*, 2007).

Androgen biosynthesis is deficient in three other rare conditions: 3β-hydroxysteroid dehydrogenase, P450c17 (17α-hydroxylase), and steroidogenic acute regulatory protein (StAR) deficiencies, which may also be associated with deficient cortisol biosynthesis (Lin *et al.*, 1995; Rhéaume *et al.*, 1991; Yanase *et al.*, 1991). Leydig cell hypoplasia due to inactivating LH receptor mutations and congenital gonadotropin deficiency are other rare specific causes for deficient testosterone production (Kremer *et al.*, 1995). If gonadal histology is not available, disorders of gonadal differentiation must also be included in the differential diagnostics (Werner *et al.*, 2010).

Endocrine Profile in AIS

In a 46,XY individual with AIS, testicular differentiation occurs normally, and immature germ cells are present in the testes at birth and during childhood. However, in the absence of functional AR, there is a progressive decline of germ cell numbers with increasing age, and in adulthood, no germ cells are present in the testes of affected adults with severe AIS (Hannema *et al.*, 2006).

Generally, children and postpubertal (nongonadectomized) patients with AIS have normal or high basal and hCG-stimulated serum testosterone and DHT, as well as high LH concentrations (Ahmed *et al.*, 1999). Unlike in gonadal dysgenesis, serum FSH concentrations are generally normal (Melo *et al.*, 2003). However, at infancy basal testosterone and both basal- and GnRH-induced serum LH concentrations can be markedly low in infancy, and retained testosterone biosynthesis can only be detected by monitoring the testosterone response to hCG (Bouvattier *et al.*, 2002).

Estrogen production mainly by the testes, and to a lesser extent by aromatization of androstenedione and testosterone in peripheral tissues, is increased in individuals with AIS to about twice that of normal males due to increased LH stimulation of Leydig cells. Plasma or urinary levels of estrogens are at the upper limit of normal or elevated compared with those in normal males. SHBG levels are comparable to those in normal females reflecting peripheral androgen resistance (Tremblay *et al.*, 1972; Quigley *et al.*, 1995) whereas serum anti-Müllerian hormone and inhibin B levels are within or above the normal male reference range, suggesting uninhibited Sertoli cell function (Hellmann *et al.*, 2012).

Treatment

Though management of DSD, including androgen insensitivity syndrome, is nowadays largely discussed and debated, decision on female sex of rearing is normally not an issue in CAIS. The diagnostic and management procedures should be performed by a multidisciplinary team including key members from endocrinology (pediatric or adult), urology, gynecology, and psychology. Additional members of the team may include specialists in clinical genetics, medical ethics, and social services (Hiort *et al.*, 2014; Hughes *et al.*, 2012).

The initial management is focused on counseling and gender assignment. After this, management addresses discussing functional issues like timing of gonadectomy to prevent tumor formation in testes, hormone replacement or supplementation at the appropriate time in life, and psychological support for the patient and family.

Gonadectomy and the Risk of Gonadal Neoplasia in AIS

The risk of gonadal neoplasia (most commonly type II germ cell tumors, including seminoma) is increased in AIS, but the malignancy rates vary in different studies (Cools *et al.*, 2006). The traditional consensus is that the testes should be removed at some stage in the case of female sex of rearing. The main controversy has been the timing of gonadectomy. Currently, the accepted practice is to leave the testes in place until after puberty has been completed (Hughes *et al.*, 2006; Patel *et al.*, 2016). There are strong arguments supporting this practice. First, it is not possible to obtained a true informed consent from a children. Secondly, true gonadal neoplasia is very rare until after puberty (Manuel *et al.*, 1976). Though carcinoma in situ and gonadoblastoma have been detected at variable rates in adolescent CAIS females, the youngest case with seminoma was a 14-year-old girl (Hurt *et al.*, 1989). Thirdly, if gonads are not removed, spontaneous development of female secondary characteristics at puberty occurs satisfactorily. Furthermore, prepubertal low serum concentrations of estrogens may be important for higher central nervous system centers involved in the development of sexual identity and for bone mineralization (Collaer and Hines, 1995; Soule *et al.*, 1995).

The estimates of overall risk of gonadal malignancies in AIS have varied from 5.5% to 14% (Cools *et al.*, 2006; Deans *et al.*, 2012; Cools *et al.*, 2017). The risk of neoplasia seems to increase by age (Manuel *et al.*, 1976). However, some patients want to defer gonadectomy further, and an increasing number of women want to retain their gonads indefinitely (Deans *et al.*, 2012). The

retained gonads can be followed by magnetic resonance (MR) imaging (Nakhal *et al.*, 2013) or by ultrasonography (Patel *et al.*, 2016). MR imaging is accurate in the detection of testicular changes, including paratesticular cysts and Sertoli cell adenomas (which are usually benign). However, neither technique can depict premalignant changes like carcinoma in situ; therefore, most experts still recommend gonadectomy after puberty (Nakhal *et al.*, 2013). If gonads are not visualized, laparoscopic gonadopexy, and gonadal biopsy have also been suggested (Patel *et al.*, 2016). Neoplastic lesions of carcinoma in situ (CIS) and gonadoblastoma express consistently octamer-binding transcription factor (OCT 3/4). If OCT 3/4 is positive, gonadectomy is recommended (Patel *et al.*, 2016).

Treatment of the External Genitalia and Vagina

In CAIS, the external genitalia are unambiguously female and no early surgery is necessary. The vagina is short in this condition, but surgical vaginal elongation is not indicated in most cases. Vaginal elongation can either be achieved digitally or by using dilators, and when this is done, most women are capable of normal intercourse (Boehmer *et al.*, 2001). When a vaginoplasty procedure is required, the laparoscopic Vecchietti procedure is becoming more widely available and appears to be a suitable surgical option based on a recent detailed review of the literature (Mongan *et al.*, 2015).

Hormone Replacement, Fertility, and Bone Mineral Density

Clearly, in the absence of a uterus, a female patient with CAIS, is destined to be infertile. If gonads are remained in place, estrogen treatment at puberty is usually not indicated as the feminization occurs spontaneously due to excess testosterone being aromatized. If gonads are removed before the onset of puberty, pubertal induction with either transdermal natural estrogen or starting with ethinylestradiol is indicated (Mongan *et al.*, 2015). Progesterone substitution is not needed in the absence of uterus. Some adult women with CAIS prefer to take supplementary testosterone after gonadectomy, because they report an improvement in wellbeing. This is not a standard therapy, and the mechanism of this therapy in the absence of functional AR is not clear. Apart from aromatization, nongenomic effects of androgens or their potential effects as neurosteroids have been suggested (Mongan *et al.*, 2015).

The role of androgens in skeletal maturation and bone mineralization is not as clear as that of estrogens. All published reports show that adult CAIS patients have bone mineral densities (BMD) somewhat lower than healthy female subjects (Bertelloni *et al.*, 1998; King *et al.*, 2017; Marcus *et al.*, 2000; Muñoz-Torres *et al.*, 1995; Sobel *et al.*, 2006; Soule *et al.*, 1995). Bone mineral densities are lower than in healthy female subjects already before gonadectomy, and when adequately substituted with estrogens, the patients show moderate deficits in BMD, averaging close to -1 SDS from normative means. The severe (BMD < -2 SDS) osteopenia in some females may reflect a component of inadequate estrogen replacement rather than androgen lack alone (Marcus *et al.*, 2000). All in all, it seems that androgens have a role in bone mineralization independent from estrogens.

Androgen Insensitivity: Partial AIS

Rieko Tadokoro-Cuccaro and Ieuan A Hughes, University of Cambridge, Cambridge, United Kingdom

Introduction

Androgen insensitivity syndrome (AIS) is classified as a disorder of hormone action due to reduced or absent function of the androgen receptor (AR) protein encoded by the *AR* gene. In contrast to the subcategory of complete AIS characterized by no *AR* activity, partial AIS (PAIS) retains some ability to respond to androgens. Thus, affected individuals show some degree of virilization. The phenotypes of PAIS can vary widely, even though patients within a family can carry the same mutation. Consequently, management needs to be tailored to each affected individual.

Clinical Features

Individuals with PAIS present with varying degrees of virilization in contrast to females with CAIS. Typically, there is ambiguous genitalia at birth, with a spectrum ranging from predominantly female genitalia (clitoromegaly, scrotalized labia majora) to predominantly male genitalia (micropenis, hypospadias, bifid scrotum). The testes are undescended in about 50%. Development of secondary male characteristics may occur spontaneously at puberty, although many require treatment with exogenous androgens for complete pubertal development. Individuals with a mild form of AIS (MAIS) present with gynecomastia at adolescence or male factor infertility in adulthood. There may be a history in childhood surgical correction for mild hypospadias or undescended testis. In PAIS, Müllerian tracts (Fallopian tubes, uterus, and cervix) are usually absent and the gonads are differentiated as testes with normal or high levels of androgen production.

Table 1 summarizes the phenotype of the external genitalia in patients with PAIS from the Cambridge DSD database. Clinical features at the time of presentation were analyzed by sex of rearing (male $n = 49$, female $n = 13$).

Etiology

PAIS as a sub-category of AIS is caused by a mutation in the *AR* gene located on the X chromosome long arm. However, similar phenotypic features of PAIS can also arise from several other conditions associated with a 46,XY karyotype as summarized in **Table 2**. It is noteworthy that in partial gonadal dysgenesis due to *NR5A1* mutation, the gonads usually differentiate as testes which are able to produce testosterone (Coutant *et al.*, 2007; Domenice *et al.*, 2016). A phenotype consistent with PAIS may also occur in low birth weight infants but rarely is an *AR* gene mutation identified (Lek *et al.*, 2014).

Table 1 Features of external genital phenotype in PAIS assigned female versus male

	Raised female n = *13*	*Raised male* n = *49*
Scrotum/labia	Bifid (46%) Fused (8%) Unknown (46%)	Bifid (57%) Fused (24%) Unknown (18%)
Meatus	Perineal (54%) Unknown (46%)	Perineal (59%) Penile (6%) Glandular (18%) Unknown (16%)
Penis/clitoris	Normal for females (8%) Clitoromegaly (62%) Unknown (31%)	Micropenis (63%) Normal for males (24%) Unknown (12%)
Rt gonad	Intra-abdominal/non-palpable (8%) Inguinal (46%) Scrotal (38%) Unknown (8%)	Intra-abdominal (10%) Inguinal (20%) Scrotal (61%) Unknown (8%)
Lt gonad	Intra-abdominal/non-palpable (15%) Inguinal (46%) Labioscrotal (31%) Unknown (8%)	Intra-abdominal (12%) Inguinal (12%) Labioscrotal (67%) Unknown (8%)

 doi:10.1016/B978-0-12-801238-3.65166-8

Table 2 Differential diagnosis of PAIS

Partial gonadal dysgenesis
May have gene mutation *NR5A1, SRY, WT1*
Steroid biosynthetic defects
17,20-Lyase deficiency, p450 oxidoreductase deficiency, 17-β-hydroxysteroid dehydrogenase deficiency, type 3, 5α-reductase deficiency
Syndromes
Klinefelter syndrome, Smith–Lemli–Opitz syndrome, Frasier syndrome
Idiopathic
Others
Leydig cell hypoplasia due to inactivating LH receptor mutations

Diagnosis

The biochemical features consistent with PAIS comprise a normal or increased concentration of testosterone, either basally or following stimulation of the Leydig cells with human chorionic gonadotrophin (hCG). A normal increment in dihydrotestosterone (DHT) also generally excludes 5 alpha-reductase deficiency although the definitive test for this enzyme deficiency is analysis of a urinary steroid profile. The basal level of LH may be slightly elevated; the serum AMH level is normal and consistent with the presence of normally developed testes.

In contrast with CAIS, in only about 30% of individuals with a PAIS-consistent phenotype is a mutation in the *AR* coding region identified. Invariably the mutation is a single amino acid substitutions (missense mutation).

Molecular Studies

The AR is a member of the steroid/nuclear receptor superfamily, which shares a similar structural composition; N-terminal domain, DNA binding domain, hinge, and ligand binding domain. The AR resides in the cytoplasm in the cell in complex with heat shock proteins and co-chaperones. In the presence of androgens (dihydrotestosterone and testosterone), conformational changes occur including the release of heat shock proteins and closing the binding pocket. The AR then translocates to the nucleus where homodimerization occurs and transcription activity is initiated. In these multiple steps, interaction with a number of co-activators also regulates AR activity (Jaaskelainen, 2012). A defect in any of these steps may affect normal male development.

When an *AR* mutation is identified in PAIS and particularly if it is novel, it is important, to demonstrate pathogenicity and the results are relevant for genetic counseling. Classical functional assays include transactivation assays with reporter genes and androgen binding assays with analysis of dissociation kinetics. These require cell culture facilities. Alternatively, now that the 3-D structures of the DNA binding and ligand binding domains have been established, it is possible to study the impact of the mutation using in silico 3-D structure analysis, or online bioinformatics tools including http://www.bioinf.org.uk/saap/, FATHMM, PolyPhen2, and SIFT. An example of the results of an androgen receptor functional in vitro assay for a mutant AR and its structural analysis is shown in **Fig. 1**. The degree of virilisation varies according to the type of substitution at codon 582 with a milder form of PAIS manifest in the subject with the 582L substitution. Even so, the phenotype can vary between individuals with the same *AR* mutation so much so that there are examples where siblings with same *AR* mutation have a different sex of rearing (Boehmer *et al.*, 2001) The variation in phenotype in these situations may be attributable to quantitative differences in androgen concentrations during the male fetal programming window, somatic mutation status, or other genetic background (Quigley *et al.*, 2004; Jaaskelainen, 2012).

In the majority of individuals with a PAIS-like phenotype and in whom mutation has not been found in the *AR* coding region, the cause is unkown. However, the recent application of exome sequencing techniques has identified deleterious molecular changes outside the *AR* coding region as a pathogenic explanation for a PAIS phenotype. One profound example was reported in several generations of a large family with PAIS where an X-linkage studies clearly indicated association with an AR defect yet no mutation was found in the *AR* coding region (Ahmad *et al.*, 2017). Subsequently, exome sequencing identified an intronic variant between exon 1 and exon 2 of the *AR* canonical transcript which was predicted to cause an alternatively spliced AR transcript and presumably resulting in nonsense-mediated decay.

Management

The management of disorders (differences) of sex development (DSD) requires a multidisciplinary team of specialists comprised of an endocrinologist, pediatric urologist (surgeon), gynecologist, geneticist, and a psychologist who preferentially should act as an early contact with families (Brain *et al.*, 2010). PAIS is a common cause of XY DSD and poses multiple challenges in management, not least in reaching agreement on the appropriate sex assignment after birth. There will be multiple facts for the families to assimilate and subsequent steps to take; establishing a diagnosis or not/accepting diagnosis, reaching a decision on sex assignment,

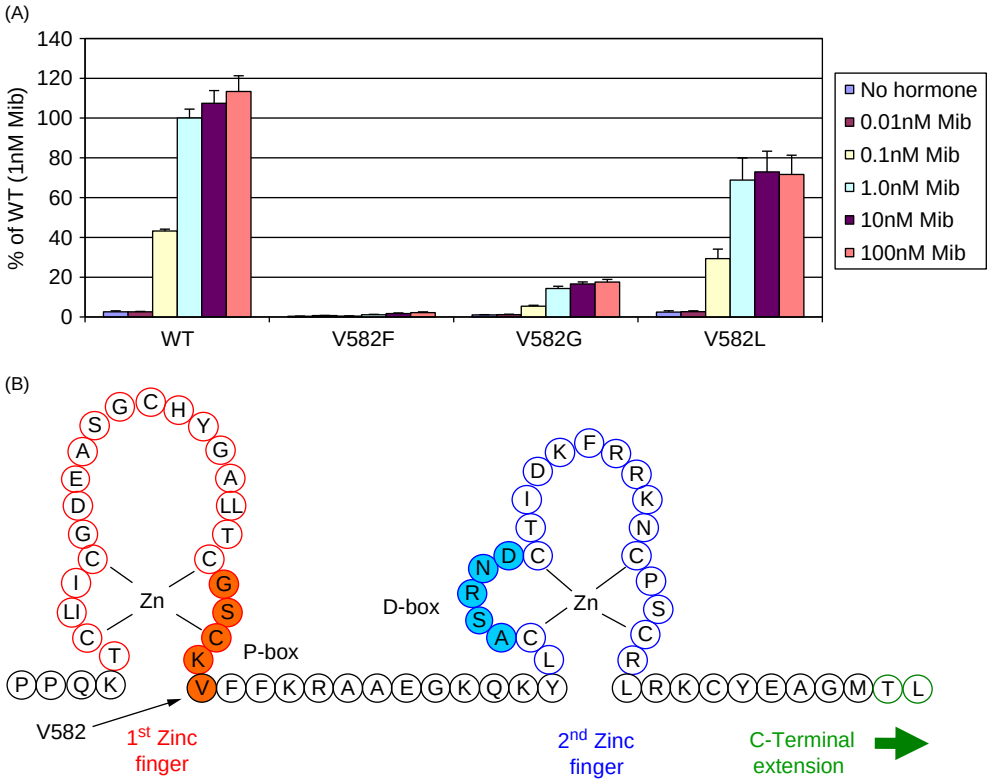

Fig. 1 (A) The effects of substitution of a valine (V) at codon 582 in the DNA binding domain with phenylalanine (F), glycine (G), and leucine (L) are shown in a transactivation assay with the synthetic androgen mibolerone. Responsiveness of the reporter gene is related to a complete or partial androgen insensitivity syndrome phenotype. (B) The linear stretch of amino acids comprising the DNA-binding domain is also shown. Mib = mibolerone. CAIS = complete androgen insensitivity syndrome. PAIS = partial androgen insensitivity syndrome. From Hughes, I.A., Davies, J. D., Bunch, T.I., Pasterski, V., Mastroyannopoulou, K. and MacDougall, J. (2012). Androgen insensitivity syndrome. *Lancet* 380, 1419–1428.

planning as a consequence any surgical treatment, hormone replacement therapy, age-appropriate disclosure and transitioning to young adult care. Generally in DSD, sex assignment is an amalgam complexed with the karyotype, development of the external and internal genitalia, the nature and function of the gonads, coupled with the overarching views of the family and their cultural background. The response of the external genitalia to a short course of androgens (given systemically or topically) may be taken in to consideration (Hughes *et al.*, 2012). In the case of PAIS, intuitively it would be expected that resistance to androgen would, a priori, bias decisions towards female sex assignment. However, the majority are now raised as male (Hughes *et al.*, 2012; Kolesinska *et al.*, 2014). The external masculinisation score (EMS) is a validated tool to evaluate the degree of under-masculinisation, the normal male having a composite score of 12 and a normal female newborn a score of 1 (Ahmed *et al.*, 2000). A study using the international DSD database (I-DSD Registry https://www.i-dsd.org/) reported that the EMS of PAIS individuals raised male was significantly higher than those who were raised as female (Kolesinska *et al.*, 2014).

Individuals with PAIS raised as male are likely to require two or more surgical procedures to repair hypospadias in the early years of childhood and occasionally, several more in later life. Orchidopexy is also often needed for testis maldescent. Pubertal development can be spontaneous but the use of exogenous androgens is common practice to complete full puberty. In a pubertal outcome study, intramuscular or topical androgen treatment was required in about half the patients with PAIS (Lucas-Herald *et al.*, 2016). The requirement for androgen supplementation was less frequent in patients with PAIS-like phenotype but in whom an *AR* mutation was not found. Gynecomastia is a frequent problem in PAIS males occurring almost universally in the presence of an *AR* mutation. The mechanism is excess conversion to estrogens from increased androgen levels (Hellmann *et al.*, 2012). Treatment with tamoxifen, an estrogen receptor blocker, was effective in suppressing gynecomastia in two siblings with PAIS (Saito *et al.*, 2014). Aromatase enzyme inhibitors may be another option to try before deciding on a surgical solution, though there is not enough evidence that it is effective in individuals with DSD. Invariably, reduction mammoplasty is often needed to solve the problem.

Infants with PAIS raised as female may require in due course feminizing genital reconstruction (clitoroplasty, labioplasty, vaginoplasty). The timing and extent of such surgery in all categories of DSD is the subject of considerable debate amongst health care professionals and patient advocacy groups. Early genitoplasty has been common practice based on the premise that this enabled the family to accept the child's assigned gender more readily and would improve subsequent psychological outcome. (Guarino *et al.*, 2013). Now, delaying decisions about surgery should be considered to enable more involvement on the part of the

patient in decision making, particularly when irreversible surgery such as gonadectomy takes place. Indeed, a moratorium on any surgery taking place before the age of consent is advocated by some (Diamond and Beh, 2008). Early vaginoplasty may result in high rates of introital stenosis and a requirement for repeat reconstructive surgery in adolescence before tampon use or sexual intercourse (Guarino *et al.*, 2013). Individuals raised female should preferably have gonadectomy before puberty in order to avoid further virilization. Thereafter, estrogen replacement therapy is required to induce breast development and a regimen continued as would be the case in females with CAIS who have the testes removed.

Long Term Outcome

Only limited information is available about long-term outcomes in PAIS. In one outcome study of 15 males with PAIS (age range 16–38 years), penile length ranged from 3 to 5 cm (average 4.6 cm) and severe gynecomastia was present in 87% (Bouvattier *et al.*, 2006). Scores for sexual function were significantly reduced in all areas analyzed, including noncommunication, nonsensuality, infrequency, avoidance, impotence and dissatisfaction with sexual performance. Outcome is worse in PAIS with a confirmed *AR* mutation compared with other forms of XY DSD where androgen production is also normal and there is no *AR* mutation (Lucas-Herald *et al.*, 2016). The same study reported a difference in prevalence of micropenis, undescended testis, hypospadias and the need for reconstructive surgery, despite both groups having a similar EMS. The difference was attributable to the degree of androgen resistance in target tissues of males with an *AR* mutation. Gynecomastia is universal in PAIS.

Height is increased in PAIS, although the series of 14 males in this study also included those with MAIS (Hellmann *et al.*, 2012). Four men with MAIS were fertile. The risk for gonadal malignancy in CAIS has been analyzed in large numbers and is low, particularly before puberty. In contrast, information about this risk is sparse in PAIS despite those raised male retaining their testes in to adulthood. However, recent analysis of relatively small numbers of AIS patients indicated that the risk of germ cell neoplasia in situ (GCNIS), a pre-malignant stage of gonadal tumor, was no greater in PAIS than in CAIS (Cools and Looijenga, 2017). It must be emphasized that longer term outcome studies incorporating older adult males with PAIS are needed to determine the effects of partial androgen resistance not only on sexual function and quality of life, but morbidity associated with cardiovascular and bone disease.

Nomenclature

ALK	Activin-like kinase
AMH	Anti-Müllerian hormone
AMHR2	AMH receptor type 2
AP2	Activating enhancer-binding protein 2
BMP	Bone morphogenetic protein
DSD	Disorders of sex development
FSH	Follicle-stimulating hormone
GATA4	GATA-binding, protein 4
GNAS1	Guanine nucleotide-binding protein, alpha-stimulating activity, polypeptide 1
GnRH	Gonadotropin releasing hormone
hCG	Human chorionic gonadotropin
LH	Luteinizing hormone
LH–CG-R	Luteinizing hormone/chorionic gonadotropin receptor
NFκB	Nuclear factor kappa-B
PMDS	Persistent Müllerian duct syndrome
PCSK5	Proprotein convertase, subtilisin/kexin-type, 5
PRR13	Proline-rich, protein 13
SP1	Specificity protein 1
SOX8	SRY-related HMG-box, gene 8
SOX9	SRY-related HMG-box, gene 9
SF1	Steroidogenic factor 1
TGFβ	Transforming growth factor beta
WT1	Wilms tumor, gene 1

Glossary

Disorders of sex development (DSD) Congenital conditions in which the development of chromosomal, gonadal or genital sex is atypical.

Müllerian ducts Ducts existing in both the XY and the XX embryo in the early stages of development, regressing due to AMH action in the male fetus, and giving rise to the Fallopian tubes, the uterus and the upper part of the vagina in the female due to the lack of AMH at that stage.

Precocious puberty Establishment of pubertal clinical features (in the male, testicular volume attaining 4 mL) before the age of 9 years.

Primary hypogonadism In the male, insufficiency of testicular function, due to a disorder affecting primarily the testis. In adult endocrinology, it is usually called hypergonadotropic hypogonadism.

Secondary or central hypogonadism In the male, insufficiency of testicular function, due to a disorder affecting primarily the pituitary or the hypothalamus. In adult endocrinology, it is usually called hypogonadotropic hypogonadism.

Testotoxicosis or gonadotropin-independent precocious puberty Early development of pubertal features in the testis, owing to an activating mutation of the LH receptor leading to a constitutively high testosterone production by Leydig cells in the absence of pituitary LH elevation.

Introduction

Anti-Müllerian hormone (AMH), also called Müllerian inhibiting substance (MIS), is a protein first identified by its ability to cause regression of the Müllerian ducts in the male fetus. In the female fetus, the Müllerian ducts develop into the uterus, vagina, and fallopian tubes. The classical experiments of Alfred Jost demonstrated that testosterone alone is not sufficient to bring about normal male development, and that a separate factor is necessary for Müllerian duct regression (Jost, 1953). That factor, AMH, was eventually purified from bovine testis through its ability to cause regression of rat Müllerian ducts in vitro (Picard and Josso, 1984), allowing the isolation of the bovine and human AMH genes (Cate *et al.*, 1986; Picard *et al.*, 1986). The genes in turn provided the primary amino acid sequence for AMH, showing that it was a member of the transforming growth factor (TGF)-β family of growth and differentiation factors (Cate *et al.*, 1986; Pepinsky *et al.*, 1988). Subsequently, the identification of the specific receptor for AMH, AMHR2 (Baarends *et al.*, 1994; di Clemente *et al.*, 1994b), and genetic perturbation experiments of AMH and AMHR2 expression in mice (Behringer *et al.*, 1990; Mishina *et al.*, 1996) led to elucidation of the AMH signaling pathway and the discovery of new biological roles for AMH in reproductive development.

AMH Expression and Regulation

AMH is expressed essentially by Sertoli cells of the testes and granulosa cells of the ovary, as indicated by the observation of undetectable serum AMH in gonadectomized (Grinspon *et al.*, 2012; Lee *et al.*, 1997; Long *et al.*, 2000) or congenitally agonadal patients (Grinspon *et al.*, 2012; Hagen *et al.*, 2010; Lee *et al.*, 1997). However, the ontogeny and levels of expression of AMH differ considerably between male and female gonads. In the testis, AMH expression arises as soon as Sertoli cells differentiate in the 8th week of fetal life (Josso *et al.*, 1993) and persists at high levels until the onset of puberty, when it decreases progressively to adult levels (Rey *et al.*, 1996) (**Fig. 1**). In the ovary, AMH expression begins with the appearance of primary follicles, at approximately 23 weeks of fetal life (Kuiri-Hanninen *et al.*, 2011); secondary and small antral follicles (<9 mm) express the highest levels of AMH, whereas granulosa cells of large antral follicles show a heterogeneous pattern of expression (Rey *et al.*, 2000).

The onset of AMH expression in Sertoli cells is driven by SOX9, independently of gonadotropin stimulation, and further upregulated by SF1, GATA4, and WT1 (reviewed in Edelsztein *et al.*, 2016). Later on, FSH increases testicular AMH output by stimulating Sertoli cell proliferation and upregulating AMH expression, in response to increased expression of trans-activating

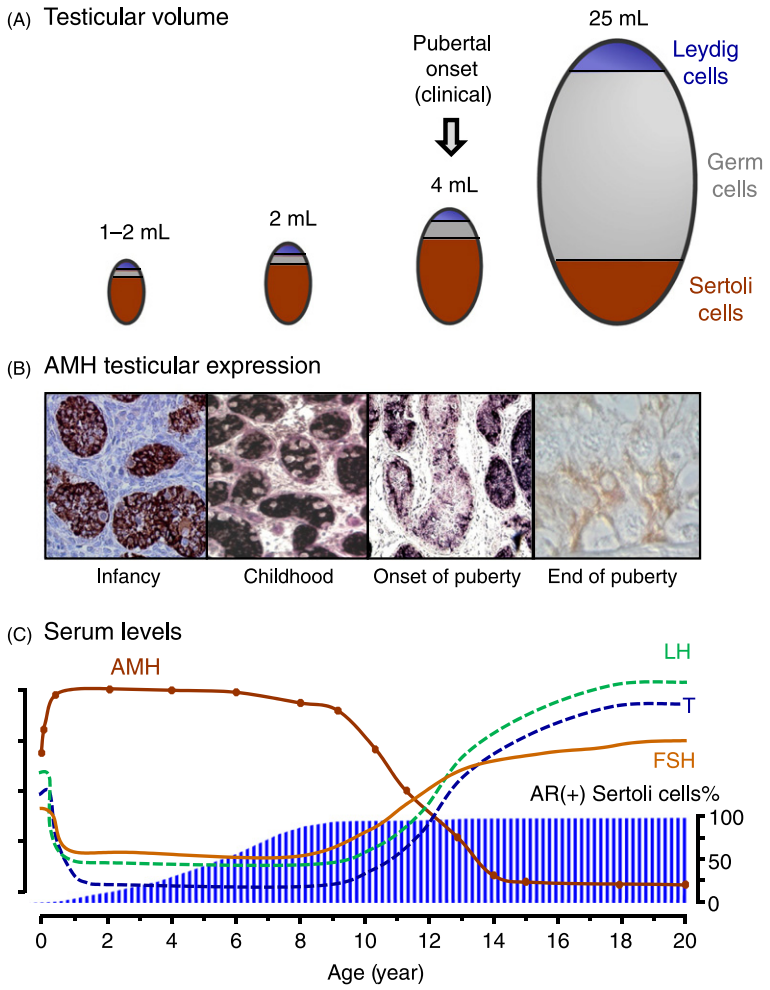

Fig. 1 Ontogeny of AMH expression in postnatal life in relationship with testicular volume and other reproductive hormones. (A) Testicular volume, as measured by Prader's orchidometer shows almost no variation during infancy and childhood; most of testicular tissue is represented by Sertoli cells. Clinically, pubertal onset is defined by testicular volume attaining 4 mL. During pubertal development, testicular volume increases due to the establishment of pubertal and adult spermatogenesis, and germ cell number determines testicular size. (B) AMH expression as revealed by immunohistochemistry. In infancy and childhood, all Sertoli cells express high levels of AMH. At the onset of puberty, AMH expression declines progressively in seminiferous tubules showing pubertal spermatogenesis. By the end of puberty, AMH expression is very low in all Sertoli cells. (C) Schematic serum levels of AMH, testosterone (T) and gonadotropins (FSH and LH) from birth through adulthood (*left axis*) and percentage of Sertoli cells expressing the androgen receptor (AR, *right axis*). Reprinted with permission from: Rey, R.A., et al. (2009). Ontogeny of the androgen receptor expression in the fetal and postnatal testis: its relevance on Sertoli cell maturation and the onset of adult spermatogenesis. *Microscopy Research and Technique* **72**, 787–795, © 2009 Wiley-Liss Inc., and Edelsztein, N.Y., *et al.* (2016). factors SOX9, SF1, AP2, and NFκB (Lasala *et al.*, 2011; Lukas-Croisier *et al.*, 2003). At puberty, testosterone concentration increases within the testis and provokes a dramatic decrease in AMH expression, a typical feature of Sertoli cell maturation (Al-Attar *et al.*, 1997; Rey *et al.*, 1993) concurrent with the androgen-induced onset of pubertal spermatogenesis (reviewed in Rey, 2014) (**Fig. 1**). Interestingly, AMH is not downregulated by androgens in the fetal and neonatal testis because Sertoli cells do not express the androgen receptor before the first year of postnatal life (Chemes *et al.*, 2008) (**Fig. 1**). In the ovary, SOX9 is not expressed, and SOX8 secreted by the oocyte functions as the initial activating factor for AMH (Salmon *et al.*, 2005). Gonadotropins and steroids also regulate AMH in the ovary: FSH stimulates AMH transcription (Taieb *et al.*, 2011) and estradiol has differential effects according to which estrogen receptor is involved (Grynberg *et al.*, 2012).

Molecular Biology of AMH and AMHR2

The human *AMH* gene contains five exons, maps to chromosome 19 p13.3 (Cohen-Haguenauer *et al.*, 1987), and is situated between the genes for splicing factor 3a and junctional sarcoplasmic reticulum protein 1, which are <400 bp away. It encodes for a protein of 560 amino acids containing a 24 amino acid signal sequence. Analyses of the bovine testicular and human recombinant proteins have shown that AMH is synthesized as a homodimeric precursor, containing an N-terminal pro-region and a smaller C-terminal mature domain, which shares homology with members of the TGFβ family (Pepinsky *et al.*, 1988) and has binding sites for AMHR2. A molecular model of the C-terminal domain (**Fig. 2**) reveals a cysteine knot motif that is characteristic of all TGFβ family members. The precursor undergoes a cleavage at monobasic sites between the two domains that is required for binding to AMHR2, but the pro-region and C-terminal homodimers remain associated in a noncovalent complex (Pepinsky *et al.*, 1988). Although only $\sim$5% of secreted AMH is cleaved at these sites, proteolytic processing can be driven to completion in vitro using plasmin (Pepinsky *et al.*, 1988). Nachtigal and Ingraham (1996) have proposed that kex2/subtilisin-like endoprotease PCSK5 may be responsible for cleavage in vivo. While cleavage is necessary for AMH binding to AMHR2, only a fraction of the cleaved endogenous AMH measured in body fluids is competent for binding AMHR2: 56% in follicular fluid, 11% in male serum, and 0% in female serum (Pierre *et al.*, 2016). Thus, levels of cleaved AMH in body fluids do not necessarily inform about the levels of bioactive AMH and suggest that, after cleavage, AMH can undergo further structural changes or interactions that prevent binding to AMHR2.

The *AMHR2* gene contains 11 exons, maps to chromosome 12q13 (Imbeaud *et al.*, 1995a), and is situated between two transcription regulators, SP1 and PRR13. It encodes for a 573 amino acid membrane protein containing a signal sequence, an N-terminal extracellular domain that binds AMH, a single transmembrane domain, and an intracellular domain with serine/threonine kinase activity. The signal sequence has been shown to be defective, indicating that AMHR2 uses its transmembrane domain for insertion and orientation in the membrane, a characteristic of type III membrane proteins (Belville *et al.*, 2009). A molecular model of the extracellular domain (**Fig. 3**A) reveals a three-finger toxin fold and four disulfide bridges found in other TGFβ type II receptors, while a model of the intracellular domain (**Fig. 3**B) reveals the general fold of a two-domain kinase, with an N-lobe consisting mainly of a five stranded B-sheet and a C-lobe that is mainly α-helical. Analyses of AMHR2 biosynthesis have

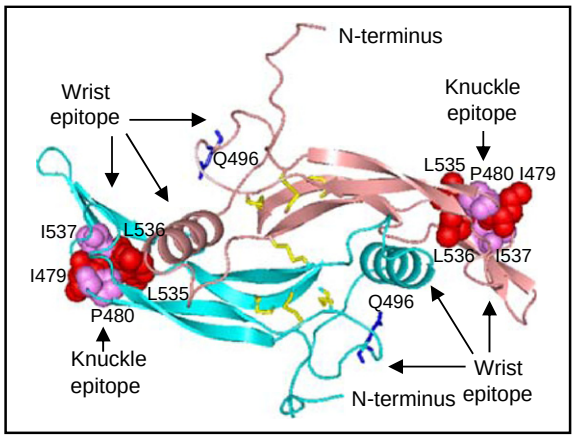

Fig. 2 Molecular model of C-terminal AMH. A three-dimensional model of the C-terminal dimer was generated by comparative modeling using human BMP9 (Brown *et al.*, 2005) as a template. The wrist epitope, the putative binding site for the type I receptor, is composed of the prehelix loop and α-helix of one monomer together with the concave side of the fingers of the second monomer (Sebald *et al.*, 2004). A mutation in the prehelix loop of AMH, Q496H, causes persistent Müllerian duct syndrome (Belville *et al.*, 2004). Residues in the knuckle epitope of AMH, the putative binding site for AMHR2, are similar to those present in BMP7 and activin at the interface with ActR2B (Greenwald *et al.*, 2003, Thompson *et al.*, 2003). Disulfide bonds (*yellow*) and Q496 residues (*blue*) are shown as sticks; residues in the knuckle epitopes are shown as spheres. Modified, with permission from Belville, C., *et al.* (2004). Mutations of the anti-Müllerian hormone gene in patients with persistent Müllerian duct syndrome: biosynthesis, secretion, and processing of the abnormal proteins and analysis using a three-dimensional model. *Molecular Endocrinology* 18, 708–721. © 2004 The Endocrine Society.

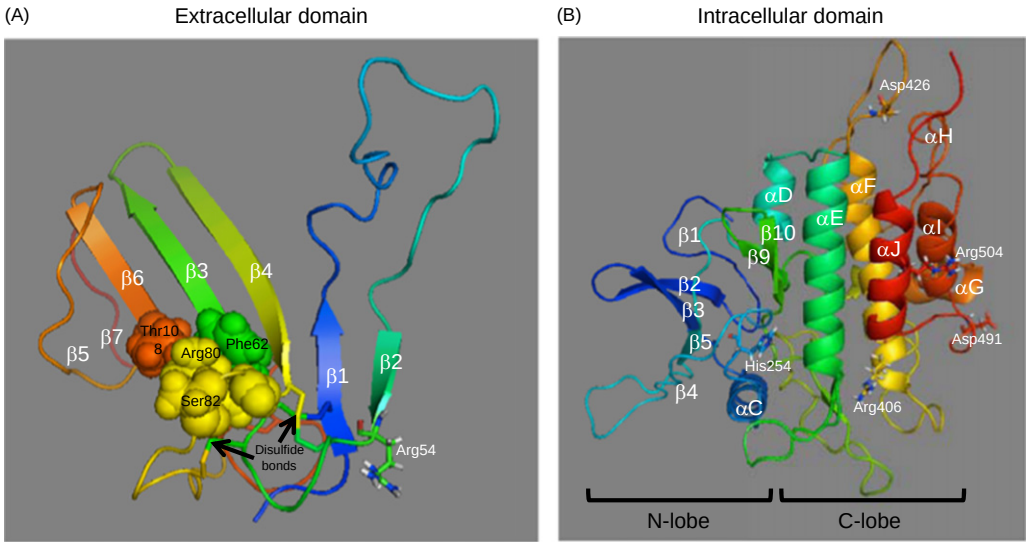

Fig. 3 Molecular models of AMHR2 extracellular and intracellular domains. (A) The extracellular domain exhibits the general three-finger toxin fold of type II receptors and displays five disulfide bridges, four of which are conserved in the other three receptors. Based on how the activin type II receptor interacts with BMP2, AMH may bind to an interface on the extracellular domain composed of residues Phe62, Arg80, Ser82, and Thr108, which are shown as spheres. (B) The intracellular domain exhibits the general fold of a two-domain kinase, with an N-lobe consisting mainly of a five-stranded β-sheet and a C-lobe, which is mainly α-helical. Residues affected by PMDS mutations (Arg54, His254, Arg406, Asp426, Asp491, and Arg504) are shown as sticks. Mutations of Arg54, Arg406, Asp426, Asp491, and Arg504 are described in Belville et al. (2009); the His254 mutation in Abduljabbar et al. (2012). Reprinted with permission from: Josso, N. *et al.* (2013). The persistent Müllerian duct syndrome. In: New, M.I., Parsa, A., Yuen, T.T., O'Malley, B.W., Hammer, G.D., eds. *Genetic steroid disorders*. New York, NY: © Elsevier 2013.

identified a number of mechanisms implicated in its constitutive negative regulation, including cleavage of the extracellular domain and promiscuous disulfide bond mediated homo-oligomerization, both of which lead to intracellular retention (Hirschhorn *et al.*, 2015).

The AMH Signaling Pathway

Like other members of the TGFβ family, AMH signals by assembling a transmembrane serine/threonine kinase receptor complex of type I and type II components, resulting in the phosphorylation and activation of type I receptor kinase by the constitutively active kinase domain of the type II receptor. The activated type I receptor then phosphorylates the cytoplasmic Smad proteins 1, 5, or 8, which interact with Smad 4 and migrate into the nucleus, where, in concert with other transcription factors, they modulate the transcription of target genes (Gouédard *et al.*, 2000; Massagué *et al.*, 2005). AMHR2, the type II receptor, and AMH, are mutually specific, while ALKs 2, 3, and 6 serve as type I receptors for both AMH and members of the bone morphogenetic protein (BMP) family (Baarends *et al.*, 1994; di Clemente *et al.*, 1994b). A model is shown in **Fig. 4**.

Unlike other TGFβ ligands, where the noncovalent complexes are latent and cannot bind their type II receptors, the AMH noncovalent complex can bind to AMHR2, which induces dissociation of the pro-region (di Clemente *et al.*, 2010). A similar mechanism has been proposed for the BMP7 noncovalent complex (Sengle *et al.*, 2008). The X-ray structures for two TGFβ ligand complexes have provided insights into how a latent complex (TGFβ1) differs from a non-latent complex (BMP9). The latent TGFβ complex is in a cross-armed conformation in which the growth factor (i.e., C-terminal domain) conformation is "tensed" (Shi *et al.*, 2011), while the non-latent BMP9 complex is in an open-armed conformation in which the growth factor conformation is "relaxed" (Mi *et al.*, 2015). This suggests that the AMH noncovalent complex may be in an open-armed conformation.

Biological Roles of AMH

In causing regression of the Müllerian duct in the male fetus, AMH acts via a paracrine mechanism, since it is the surrounding mesenchymal cells that express AMHR2. Apoptosis and epithelial to mesenchymal transformation (Allard *et al.*, 2000), epithelial cell migration (Austin, 1995), and proteolysis (Roberts *et al.*, 2002) have important roles in regression. Perturbation of AMH expression in mice revealed a role for AMH in the adult male. Strong overexpression of AMH in transgenic mice led to incomplete fetal virilization and decreased serum testosterone in the adult (Behringer *et al.*, 1990), whereas AMH-deficient mice exhibited Leydig cell hyperplasia (Mishina *et al.*, 1996). These effects are due to AMH blocking the differentiation of Leydig cell precursors and decreasing the expression of steroidogenic enzymes (Lee *et al.*, 1999; Racine *et al.*, 1998).

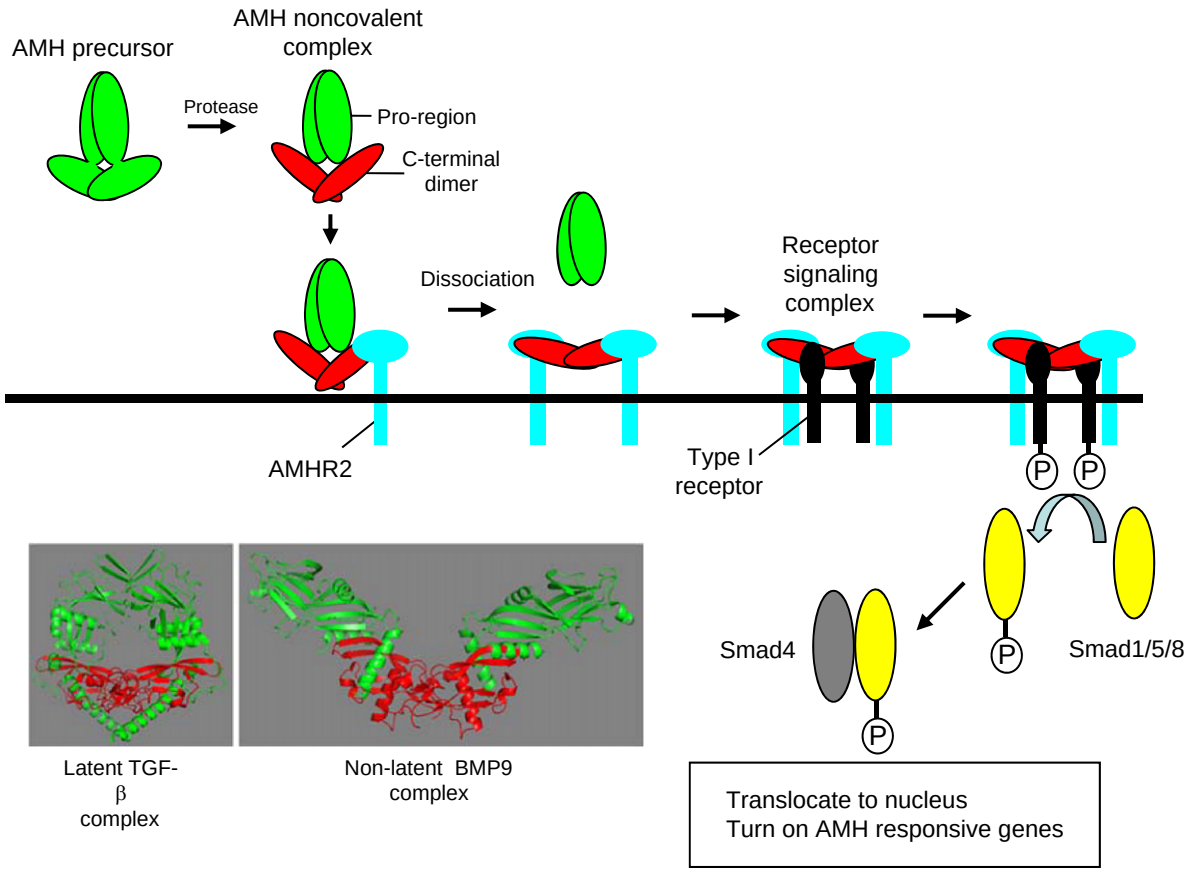

Fig. 4 Model showing processing of AMH and assembly of the AMH receptor signaling complex. The AMH precursor must be cleaved to bind AMHR2. After binding, the proregion domain dissociates from the mature domain. The inset shows structures for the latent TGFβ noncovalent complex and the non-latent BMP9 noncovalent complex. Pro regions are shown in green and mature C-terminal domains are shown in *red*. Modified with permission from: Pierre, A., *et al.* (2016). Most cleaved anti-Müllerian hormone binds its receptor in human follicular fluid but little is competent in serum. *The Journal of Clinical Endocrinology and Metabolism* **101**, 4618–4627 © 2016 The Endocrine Society.

In females, the role of AMH has been predominantly elucidated in rodents, where it has an inhibitory effect on primordial follicle recruitment and on the responsiveness of growing follicles to FSH (Durlinger *et al.*, 1999, 2001). In particular, AMH has been shown to repress aromatase expression in immature rat and porcine granulosa cells (di Clemente *et al.*, 1994a) and human granulosa-lutein cells (Pellatt *et al.*, 2011). Thus, AMH may act as a follicular gatekeeper, ensuring that small antral follicles produce little estrogen prior to selection (Sacchi *et al.*, 2016).

An intriguing activity of AMH has been its ability to induce gonadal sex reversal in female fetuses such as the bovine freemartin, where the female fetus is exposed to the AMH produced by her male twin (Vigier *et al.*, 1984) and in female mice overexpressing human AMH (Behringer *et al.*, 1990). This effect can be reproduced in vitro with rat fetal ovaries and purified AMH (Vigier *et al.*, 1989). However, because male AMH-deficient mice exhibit normal testicular development, it can be concluded that AMH does not play an obligatory role in mammalian testis determination. In the last few years, the role of AMH has been investigated in a number of species of fish and eels. Although these species do not have Müllerian ducts, AMH is expressed—some species carry a duplicated copy of the AMH gene (Hattori *et al.*, 2012; Rondeau *et al.*, 2016)—in the Sertoli cells, where it regulates germ cell proliferation (Miura *et al.*, 2002; Morinaga *et al.*, 2007), and also acts as a testis-determining factor (Kamiya *et al.*, 2012). Thus, while mammalian AMH can still modulate gonadal differentiation when it is expressed inappropriately, it no longer performs this function during normal development.

A few endocrine roles have been proposed in the nervous and cardiovascular systems (reviewed in McLennan and Pankhurst, 2015). Adult motor neurons express AMH and its receptors, suggesting that it may act as a survival factor (Wang *et al.*, 2005). It has been proposed that AMH is responsible for the male bias in the size of the cerebellum with males having more Purkinje cells than females (Wittmann and McLennan, 2011). This is supported by the fact that AMH deficient male mice have a cerebellum size and Purkinje cell number similar to those observed in females. Identification of AMH receptivity in both pituitary and GnRH neurons has also led to the intriguing idea that AMH participates in the hypothalamic–pituitary control of reproduction. Indeed, combining in vivo and in vitro experiments, AMH was shown to increase GnRH neuron firing and GnRH-dependent LH pulsatility in the adult (Cimino *et al.*, 2016), and to specifically regulate FSH and not LH in females before puberty (Garrel *et al.*, 2016).

AMH is a Marker of Gonadal Function in Boys

In the last 15 years, the use of AMH as a marker has gained success in the field of reproductive endocrinology, as a marker of the ovarian follicle reserve in adult women with infertility (reviewed in Dewailly *et al.*, 2014). However, assays for AMH measurement were initially developed to assess testicular function in males during infancy and childhood (Baker *et al.*, 1990, Hudson *et al.*, 1990, Josso *et al.*, 1990), a period where basal gonadotropin and androgen levels are little informative (reviewed in Valeri *et al.*, 2013).

Anorchidism and Monorchidism

In boys with nonpalpable gonads, serum AMH determination without the need for a stimulation test is useful to distinguish between anorchidism and bilateral cryptorchidism with testes in abdominal position (**Fig. 5**). Indeed, undetectable AMH has a better predictive value for the diagnosis of anorchidism than low testosterone post-hCG, and detectable AMH is more informative than the increase of testosterone after an hCG test in boys with intra-abdominal testes (Lee *et al.*, 1997).

In boys with monorchidism, while Leydig cell function is largely compensated, lower AMH indicates that Sertoli cell proliferation and function is insufficient to compensate for the function of the absent testis (Grinspon *et al.*, 2016a).

Hypogonadism

In the prepubertal male, Sertoli cell hormones are the best biomarkers to diagnose an impaired testicular function, that is, hypogonadism (Rey *et al.*, 2013). Because very low or undetectable levels of gonadotropins and testosterone are usually found in

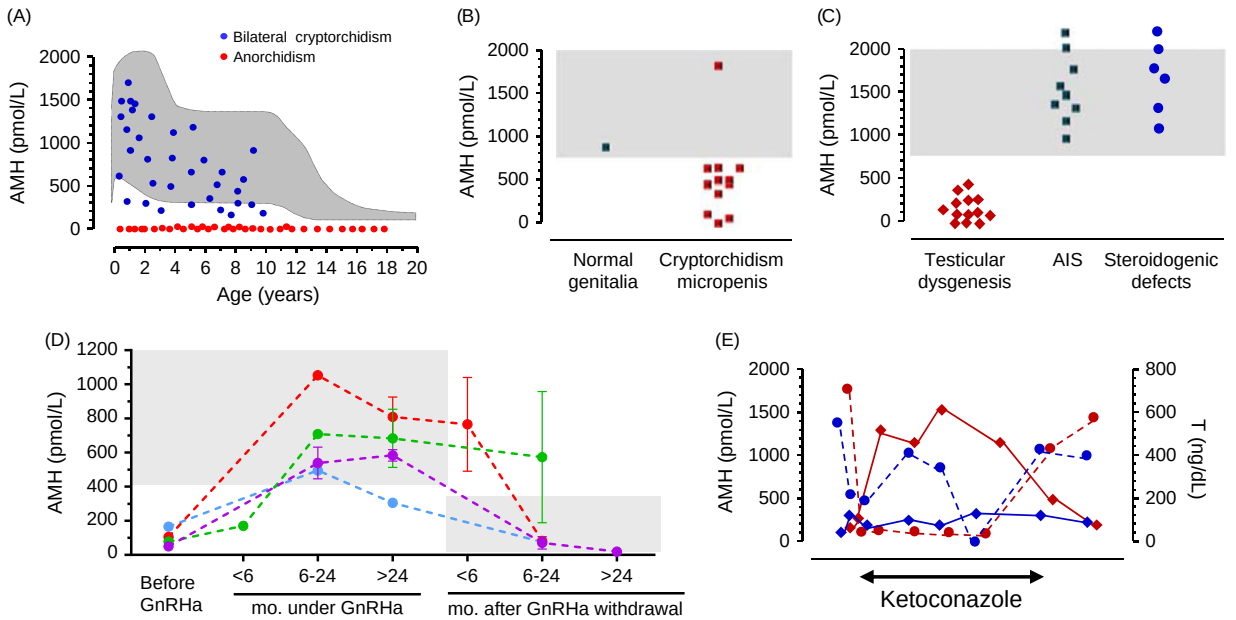

Fig. 5 Utility of serum AMH in boys with disorders of the gonadal axis. (A) AMH is undetectable in boys with anorchidism, but clearly detectable in boys with bilateral cryptorchidism (data from Grinspon, R. P., Ropelato, M. G., Bedecarrás, P., et al. (2012). Gonadotrophin secretion pattern in anorchid boys from birth to pubertal age: Pathophysiological aspects and diagnostic usefulness. *Clinical Endocrinology*, **76**, 698–705). (B) AMH is low in most newborns with multiple pituitary hormone deficiency and micropenis/cryptorchidism reflecting hypogonadotropic hypogonadism, but normal in the newborn with normal genitalia (data from Braslavsky, D., Grinspon, R. P., Ballerini, M. G., *et al.* (2015). Hypogonadotropic hypogonadism in infants with congenital hypopituitarism: A challenge to diagnose at an early stage. *Hormone Research in Paediatrics*, **84**, 289–297). (C) AMH is low in patients with DSD due to gonadal dysgenesis but normal/high in those with androgen synthesis defects or androgen insensitivity syndrome (AIS, data from (Rey, R. A., Belville, C., Nihoul-Fékété, C., *et al.* (1999). Evaluation of gonadal function in 107 intersex patients by means of serum antimüllerian hormone measurement. *Journal of Clinical Endocrinology and Metabolism*, **84**, 627–631). (D) In boys with central precocious puberty, serum AMH is low at the time of diagnosis reflecting increased intratesticular testosterone. Efficacious treatment with GnRH analogues curtails testosterone production and results in AMH elevation to normal prepubertal levels. When treatment is discontinued, testosterone increases and AMH declines again (data from Grinspon, R. P., Andreone, L., Bedecarrás, P., *et al.* (2013). Male central precocious puberty: Serum profile of anti-mullerian hormone and inhibin B before, during, and after treatment with GnRH Analogue. *International Journal of Endocrinology*, **2013**, 823064). (E) In boys with testostoxicosis, serum AMH is useful to monitor ketoconazole treatment adherence: in one patient (*red lines*), testosterone production (*circles*) was inhibited and AMH (*diamonds*) increased to prepubertal levels, whereas in the other case (*blue lines*) adherence to treatment was discontinuous, and AMH never increased to prepubertal levels (data from Rey, R., Lordereau-Richard, I., Carel, J. C., *et al.* (1993). Anti-müllerian hormone and testosterone serum levels are inversely related during normal and precocious pubertal development. *Journal of Clinical Endocrinology and Metabolism*, **77**, 1220–1226).

the normal boy, their determination is not useful for the diagnosis of secondary (central or "hypogonadotropic") hypogonadism. Also, since gonadotropins are within the normal range in approximately 30%–60% of anorchid boys (Grinspon *et al.*, 2012), their elevation cannot always be used as a marker of primary (or "hypergonadotropic") hypogonadism in pediatric patients. In contrast, low serum AMH allows a diagnosis of impaired testicular function, both in the case of primary hypogonadism, such as testicular regression (Imbeaud *et al.*, 1995b) and Klinefelter (Bastida *et al.*, 2007) syndromes or after chemotherapy (Cuny *et al.*, 2011; Laporte *et al.*, 2011), as well as of secondary hypogonadism due to hypothalamic or pituitary dysfunction (Bougnères *et al.*, 2008; Braslavsky *et al.*, 2015) (**Fig. 5**). In boys with absence of pubertal development by the age of 14 years, low AMH is found in patients with secondary (or "hypogonadotropic") hypogonadism (Young *et al.*, 1999) whereas normal serum AMH is suggestive of a constitutional delay of puberty (Coutant *et al.*, 2010).

Precocious Puberty

As previously described, the increase in testosterone concentration normally occurring within the testis during the early stages of pubertal development induces Sertoli cell maturation and a downregulation of AMH expression. A decrease in serum AMH is also observed in boys with precocious puberty due either to an early activation of hypothalamic GnRH secretion resulting in central precocious puberty (**Fig. 5**) or to the existence of an hCG-secreting tumor. Likewise, serum AMH is below the prepubertal range in boys with precocious development due to androgen-secreting Leydig cell tumors or to activating mutations of the LH–CG receptor responsible for gonadotropin-independent precocious puberty, also known as testotoxicosis (**Fig. 5**). In these patients, serum AMH monitoring is useful to assess the efficacy of and compliance to treatment (Rey *et al.*, 1993). Conversely, AMH does not decrease in precociously virilized patients due to an extra-testicular origin of androgens, like congenital adrenal hyperplasia, adrenal tumors or exogenous testosterone administration. Interestingly, AMH also remains in the normal prepubertal range in boys with central precocious puberty or with testotoxicosis before the age of 1 year, even if intratesticular testosterone levels are elevated (Grinspon *et al.*, 2013). This is probably explained by the lack of expression of the androgen receptor in Sertoli cells in the first year of life (Chemes *et al.*, 2008).

Macro-Orchidism

Because testes attaining a volume of 4 mL are the main clinical hallmark of the initiation of puberty in males, the diagnosis of precocious puberty should always be ruled out in boys with enlarged testes. Stable prepubertal AMH levels rule out precocious pubertal development in monorchid boys of prepubertal age with compensatory macro-orchidism of the remaining testis (as described above) or in patients with syndromic prepubertal macro-orchidism, like X fragile syndrome. Other rare conditions in which the increase in testis volume justifies ruling out precocious pubertal development are Peutz–Jeghers syndrome and particular forms of McCune–Albright syndrome mosaicism characterized by a Sertoli cell-limited existence of the somatic activating mutation in the *GNAS1* gene-encoding for the Gsα protein involved in the FSH receptor transduction pathway- in the testis. In both cases, AMH levels remain high indicating that the increase in testicular volume does not reflect an increase of intratesticular testosterone and the onset of pubertal spermatogenesis (Rey *et al.*, 2006; Venara *et al.*, 2001).

Disorders of Sex Development (DSD)

In patients with ambiguous or female external genitalia who carry a Y chromosome, low or undetectable serum AMH levels are indicative of gonadal dysgenesis, whereas normal or elevated AMH indicates normal Sertoli cell function and tips the diagnosis towards an isolated Leydig cell dysfunction (**Fig. 5**), like Leydig cell aplasia/hypoplasia or steroidogenic enzyme defects, or to androgen insensitivity (reviewed in Josso *et al.*, 2012). AMH is also within the normal range in newborns with non-endocrine malformative syndromes affecting genital development, for example, isolated hypospadias (Rey *et al.*, 2005) or bladder exstrophy (Grinspon and Rey, 2014), indicating that testicular function is preserved.

Conversely, in virilized XX newborns the finding of serum AMH above the female range is suggestive of the existence of testicular tissue, thus making a differential diagnosis between patients with aromatase deficiency who lack testicular tissue and those with ovotesticular or testicular DSD in whom the circulating levels of AMH are usually commensurate with the amount of testicular tissue present (Grinspon *et al.*, 2016b; Rey and Grinspon, 2011).

A particular form of DSD, due to deficiency of AMH production or resistance to AMH resulting in the persistence of Müllerian ducts in boys, is dealt with in detail below.

The Persistent Müllerian Duct Syndrome (PMDS)

Defects in the synthesis or action of AMH impair the regression of male fetal Müllerian ducts, giving rise to the Persistent Müllerian Duct Syndrome (PMDS), characterized by the persistence of uterus and tubes in otherwise normal 46,XY males. In approximately 90% of cases, the syndrome is due to mutations in the genes coding for AMH or its type II receptor, AMHR2. It is considered a rare condition but its reported incidence is increasing, perhaps due to a rise in awareness of medical providers. PMDS is usually discovered at surgery or laparoscopy motivated by uni or bilateral cryptorchidism with or without inguinal hernia. It is an

inherited disease, transmitted as an autosomal recessive trait, in accordance with the autosomal location of the *AMH* (Cohen-Haguenauer *et al.*, 1987) and *AMHR2* (Imbeaud *et al.*, 1995a) genes. The rate of consanguinity is high, 40% and 33% in *AMH* and A*MHR2* mutations respectively.

Anatomical Features

There is no significant difference in the anatomy of patients with either *AMH* or *AMHR2* mutations. Testes are tightly tethered to the Fallopian tubes; their position depends upon the degree of mobility of the Müllerian derivatives (**Fig. 6**). In 50% of cases, the uterus and tubes are in the pelvis, firmly maintained by the broad ligament. Both testes are in an ovarian position and cannot be palpated. Alternatively, part of the uterus can be dragged into the inguinal canal by a descending testis. This results in an inguinal hernia containing the uterus and the ipsilateral Fallopian tube and testis. The contralateral testis either remains in an ovarian position or follows the uterus into the inguinal hernia, resulting in transverse testicular ectopia. This otherwise rare condition is present in approximately 25% cases of PMDS. Abnormalities of the male excretory ducts are common.

Complications

Adult patients are often diagnosed because of malignant degeneration of testes or Müllerian derivatives. The risk of testicular cancer in PMDS has recently been estimated at 33% (Picard *et al.*, 2017), higher than is expected for neglected cryptorchidism. Seminomas are the most frequent tumors but many other histological types have been described. Malignant degeneration of Müllerian derivatives is possible but rarer (Farikullah *et al.*, 2012).

Infertility is the most frequent complication of PMDS; only 10%–20% of patients have fathered children. In these cases, at least one testis was in a scrotal position and excretory ducts were intact. As discussed below, the vas is embedded in the uterine wall and easily damaged if hysterectomy is attempted. Furthermore, orchidopexy of abdominal testes is technically difficult and may lead to testicular demise. Not surprisingly, PMDS patients had not been diagnosed l*et a*lone operated at the time their children were conceived.

Endocrine Investigations

AMH serum levels differ widely according to genotype. Very low serum AMH concentration is characteristic of AMH mutations. However low AMH concentration in newborns or in boys undergoing puberty is physiological (Grinspon *et al.*, 2011), and should not be interpreted as a sign of AMH mutation. In insufficiently virilized patients with retained Müllerian ducts, low AMH values reflect testicular dysgenesis, not PMDS. In those with a mutation of the AMH type II receptor, AMH levels are normal but not particularly high. Normal AMH values are also found in subjects with "idiopathic" PMDS in whom neither *AMH* nor *AMHR2* mutations have been detected.

Treatment

Treatment aims at the prevention of the two main complications of PMDS, infertility and cancer. It consists in correction of cryptorchidism. Hysterectomy is usually required for several reasons. Müllerian derivatives may cause discomfort or undergo

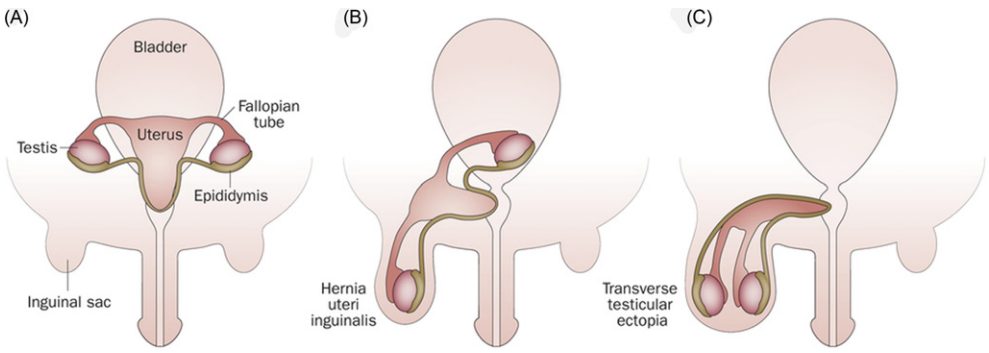

Fig. 6 The three main clinical presentations of persistent Müllerian duct syndrome. (A) Bilateral cryptorchidism: the testes are in the pelvis, in the position of normal ovaries. This presentation is found in approximately 55% of cases with mutations in the AMH pathway and in 86% of idiopathic cases. (B) Unilateral cryptorchidism: one testis is in an inguinal hernia along with its attached tube and uterus. This presentation is known as "*hernia uteri inguinalis*" and occurs in approximately 20% of cases with mutations of the AMH pathway and in 14% of idiopathic cases. (C) Transverse testicular ectopia: both testes and part of the Müllerian organs have herniated into a single processus vaginalis. This presentation is very evocative of PMDS and is seen in approximately 25% of cases with AMH or AMHRII mutations but never in idiopathic cases ($P < 0.001$). Reproduced with permission from: Hutson, J.M., et al. (2014). Malformation syndromes associated with disorders of sexual development, *Nature Reviews. Endocrinology* **10**, 476–487. © 2014 Macmillan Publishers Limited.

malignant degeneration. They also block the descent of abdominal testes. However, the surgeon should bear in mind that the excretory ducts are in close apposition or even enclosed in the uterine wall and careful dissection is required to avoid harming them. If this occurs, testicular sperm extraction followed by intracytoplasmic sperm injection may be successful. Placement of the testes in the scrotum should hopefully prevent malignant degeneration but this is not always the case. Two patients in whom cryptorchidism had been corrected earlier developed testicular cancer (Manassero *et al.*, 2004, Melman *et al.*, 1981).

Molecular Studies

Mutations of the *AMH* or *AMHR2* genes are responsible for 90% of PMDS cases. The rest have no identified molecular cause and are presently labeled idiopathic. A total of 64 different pathogenic *AMH* alleles of various types have been described in a total of 80 families. There is no hotspot: mutations are distributed along the whole length of the gene. Exon 4 is very rarely involved and exons 1 and 2 are proportionally the most affected. In exon 5, the bases coding the biologically active C-terminus of the AMH protein are hit at nearly three times the rate of the others. Belville *et al.* (2004) have studied the biosynthesis and secretion of seven mutant AMH proteins and shown that amino acid changes have significant effects upon protein stability and folding. Recurrent mutations and those of particular interest are shown in **Fig. 7**A.

Mutations of the *AMHR2* gene, totaling 58 different alleles, have been identified in 75 families. A 27-bp deletion in exon 10, encoding the kinase domain, has been detected in 30 patients, mostly Northern Europeans. The deletion can be recognized by PCR which should be performed as a first line investigation when an *AMHR2* mutation is suspected. Recurrent mutations and those of particular interest are shown in **Fig. 7**B. Receptor molecules with truncating mutations upstream of the transmembrane domain are not secreted, unless the AMHR2 signal sequence is replaced by that of the TGFβ receptor type II, indicating that the AMHR2 signal sequence is defective (Belville *et al.*, 2009).

Idiopathic PMDS occurs in approximately 10% of patients. No mutations of either the *AMH* or the *AMHR2* genes can be detected. Mutations in the distal promoter or in the central part of introns might have been overlooked, however idiopathic PMDS

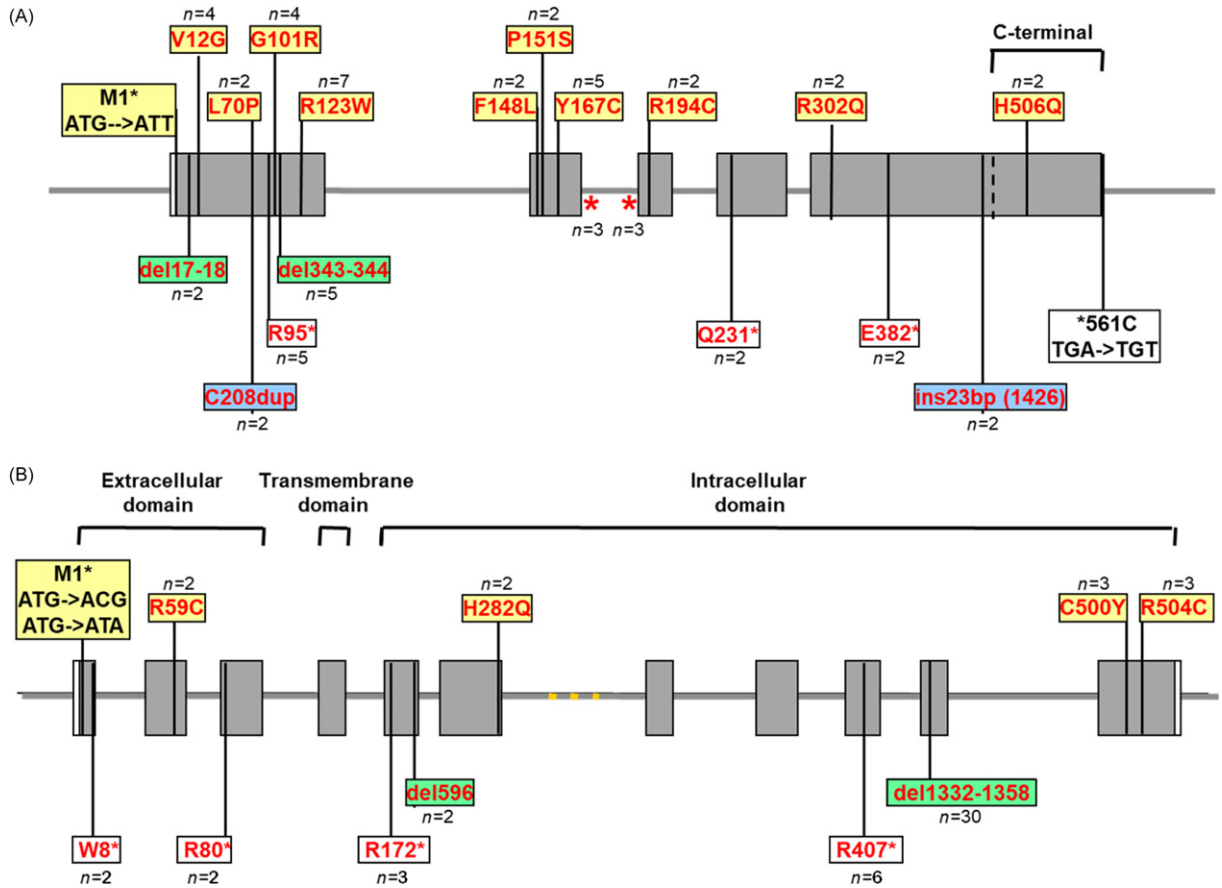

Fig. 7 Recurrent mutations (*red print*) and mutations of the ATG initiating and TGA terminating codon (*black print*) detected in the *AMH* gene (A) and the *AMHR2* gene (B). *n*: Number of affected families. Type of mutation: missense, yellow box; nonsense, white box; deletion, green box; insertion, blue box; splicing mutation, star. Reproduced with permission from: Picard, J.Y. et al. (2017). possibly represents a separate entity. Associated malformations are frequent, and the characteristic transverse testicular ectopia is not observed. The rate of consanguinity is only 10%, much lower than the 30%–40% frequency observed for *AMH* and *AMHR2* mutations.

Hypospadiac Genital Tubercle (GT)

Maguelonne Pons, Daniela-Brindusa Gorduza, and Pierre Mouriquand, Mère-Enfant Hospital – Claude-Bernard University, Lyon, France

Introduction

Hypospadias is a congenital malformation of the genital tubercle (GT), which has been known and described since antiquity but only understood and treated from the 19th century onwards. It was indeed not until the 1980s that modern management of hypospadias was developed, with new procedures and a better approach of its management.

The hypospadiac GT is the consequence of a development arrest of the tissues forming its ventral aspect (Mettauer, 1842) which occurs during the "masculinization window" (6–16 weeks of gestation) (Welsh *et al.*, 2008). This is characterized by an ectopic meatus on the ventral side of the penis or the scrotum, an asymmetrical foreskin and a possible penile curvature. The causes of this common congenital malformation, which affects one in 140–330 newborn boys in Europe (Springer *et al.*, 2016; van Rooij *et al.*, 2013), are essentially unknown and probably multifactorial. Hypospadias incidence seems to be increasing according to various epidemiological studies, although this remains a controversial issue (Main *et al.*, 2010; Yiee and Baskin, 2010).

Although it may appear straightforward to identify a hypospadiac penis, its clinical management still varies greatly from one center to another. There continues to be no clear consensus on the assessment of severity of this anomaly, on the possible treatments or on their evaluation (Castagnetti and El-Ghoneimi, 2010; Snodgrass *et al.*, 2011).

Anatomical and biological evaluations of hypospadias have changed over the past decades. Criteria of evaluation of hypospadias have changed in terms of anatomical description and biological screening. A better understanding of the embryology, etiological, and epidemiological aspects of the development anomalies of the GT has led to a more adjusted biological and surgical approach. Assessment of the hypospadiac GT is a crucial step to explore the causes and plan surgery which, in some cases, can be preceded by hormonal stimulation. Surgical treatment aims at achieving a normal-looking penis, with a slit-shaped meatus sitting on the apex of the glans, without penile curvature, thus allowing normal micturations in a standing position and a future normal sexual function. The place of preoperative biological screening, preoperative hormonal stimulation, the choice of urethroplasty, and the follow-up are the essential issues of this chapter. Evaluation of outcome is a critical point as there are no current consensual protocols, and long-term results are often lacking as well as psychological evaluation.

Epidemiology

The incidence of hypospadias varies from 0.3% to 0.7% in live male births (Paulozzi *et al.*, 1997). There is approximately 1 hypospadias for every 250 male births. The incidence is higher if there is a family history of hypospadias (1 in 100 to 1 in 80 male births) (Gearhart *et al.*, 2009). The incidence varies with ethnicity, as illustrated by a population-based study from the state of Washington which showed hypospadias was more prevalent in male infants born to Caucasian mothers compared with male infants of black (OR 0.67, 95% CI 0.51–0.89) and Hispanic mothers (OR 0.46, 95% CI 0.37–0.58) (Springer *et al.*, 2016).

In the last 15 years, the incidence of hypospadias in Western countries seems to have increased (Loane *et al.*, 2011). In Denmark, the incidence was measured at 0.24% and 0.52% in 1977 and 2005, respectively. A recent publication (Nordenvall *et al.*, 2014) confirmed an augmentation of incidence of hypospadias in Sweden (4.5 per 1000 live-born boys until 1990, 8 per 1000 boys from 1990 to 2009). In the United States, data from two birth defects surveillance systems demonstrated a doubling of hypospadias rates (0.2%–0.4%) from 1970 to 1993 (Canon *et al.*, 2012; Paulozzi *et al.*, 1997). In Western Australia, the rate increased from 0.28% in 1980 to 0.43% in 2000.

Although these trends may reflect improved surveillance and detection, it is unlikely that these measures can account for the entire increase in the different geographical locations. These findings suggest that temporal changes may be due to other risk factors, especially greater exposure to environmental factors (disruptors) or drugs that may disrupt the androgenic stimulation required for the development of the male external genitalia.

There are other publications that contested this fact: Fisch *et al.* (2009) retrospectively reviewed the total prevalence of hypospadias in New York State from 1992 to 2005, and showed that there was no statistical change in hypospadias rates in New York State over this time period. A larger study of 29 national registries (4 million births per year worldwide) confirmed the stability of the incidence of hypospadias in most cases except two registers (Scandinavia and Japan), especially during the period 1970–1998.

Definition and Understanding of the Anatomy of Hypospadias

Defining the anatomy of hypospadias is an essential step for the management of this congenital anomaly.

Three anatomical features are classically described (**Fig. 1**):

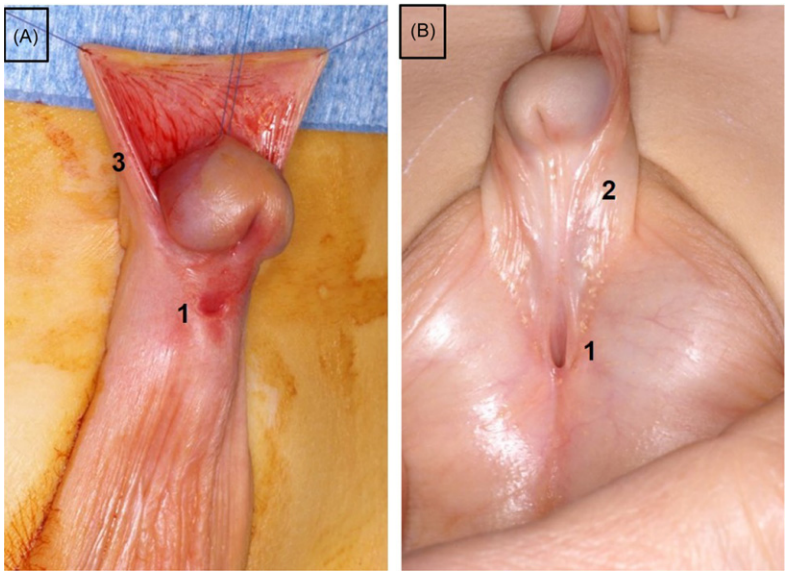

Fig. 1 Definition of hypospadias: (1) ectopic urethral meatus, (2) ventral curvature of the penis, (3) deficient ventral foreskin with a marked excess of skin on the dorsal aspect of the GT. (A) A midshaft hypospadias and (B) a proximal (scrotal) hypospadias.

- an ectopic urethral meatus opening which may be located at any point from the glans to the base of the penis and even on the perineum;
- a ventral curvature of the penis of variable magnitude; and
- a deficient ventral foreskin with a marked excess of skin on the dorsal aspect of the GT (hooded foreskin).

The curvature and the hooded foreskin are not constant. A hypospadiac meatus may be found under a normally formed prepuce. An isolated curvature may occur without an ectopic urethral opening, but it is often associated with a hypoplastic urethra, not surrounded by spongiosum ("missed hypospadias").

From the tip to the base of the ventrum of the hypospadiac GT, one can identify several anatomical features (**Fig. 2**):

1. The glans is open ventrally.
2. A segment of urethral tube of variable length is missing and is replaced by a urethral plate extending from the ectopic meatus towards the glans cap, lying on the ventrum of the two corpora cavernosa. Looking more carefully at this strip of tissues sitting between the ectopic meatus and the glans, a tongue of urethral mucosa (shiny tissue) followed distally by skin is often identified during the surgical procedure. This demonstrates the arrest of growth of the urethral bud at the origin of the hypospadias condition.
3. Then comes the ectopic meatus and behind it a segment of hypoplastic circular urethra, not surrounded by any corpus spongiosum (CS). A thin layer of skin is often stuck tightly on the underdeveloped urethra.
4. The division of the CS is always proximal to the ectopic meatus (and sometimes several centimeters behind the ectopic meatus) in two pillars that extend laterally up to the glans cap in a fan-shaped position. This division of the CS is often outlined on the ventral skin by a small cutaneous ridge.
5. Proximal to the division of the CS, all of the structures forming the ventral aspect of the penis are normal.
6. The frenular artery is constantly missing.
7. The dorsum of the GT is normal.
8. Associated anomalies are common: undescended testes and/or micropenis (<25 mm dorsal length/<15 mm width before 1 year of age), which may reflect the testicular failure to produce enough androgens during gestation (see later); presence of mullerian remnants (utricular cavity), which may reflect the testicular failure to produce enough anti mullerian hormone (AMH); scrotal transposition; and other non-genital anomalies such as the midline syndrome which may involve the heart, the palate, or even midline brain defects.

Classification of Hypospadias

Many classifications of hypospadias have been published, mainly based on the position of the ectopic meatus (Vidal *et al.*, 2010), which is an insufficient criterion to define the severity of hypospadias. Several other aspects of the anomaly visible at the time of surgery should be looked for before deciding the most appropriate technique of reconstruction, including:

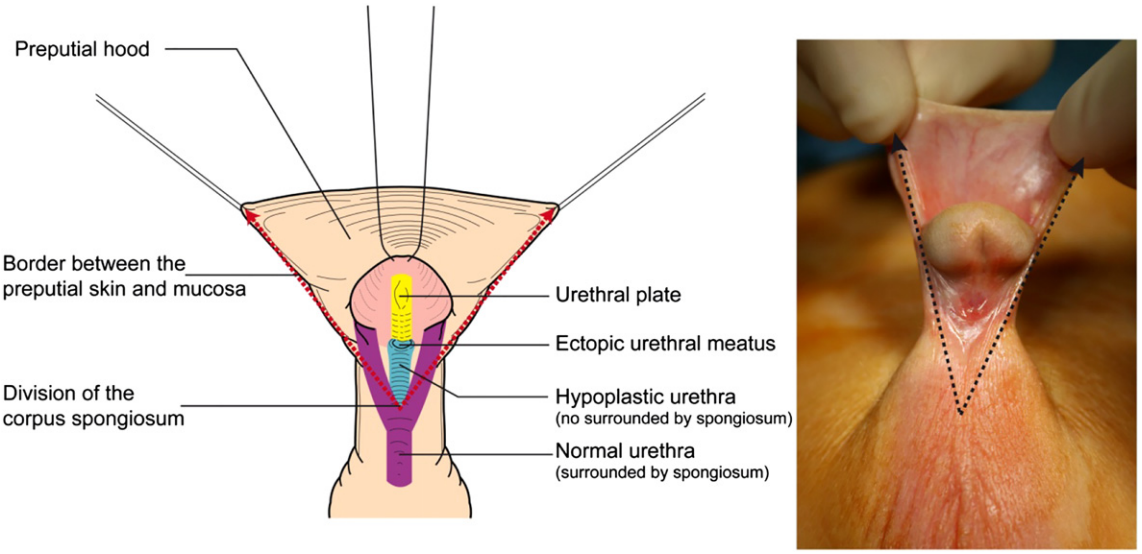

Fig. 2 From the tip to the base of the penis: the ventral aspect of the glans is wide opened. The urethral plate extends from the apex of the glans down to the ectopic meatus. Behind the ectopic meatus sits a segment of hypoplastic urethra not surrounded by any spongiosum. The division of the corpus spongiosum marks the proximal limit of the malformation. It defines a triangular defect whose summit is the division of the corpus spongiosum, whose base is the glanular cap and whose sides are represented by the two lateral pillars of atretic spongiosum.

- level of division of the CS;
- degree of hypoplasia of the tissues forming the ventral aspect of the penis;
- quality of the urethral plate;
- size of the penis (which is often arguable);
- size of the glans;
- availability of the preputial skin;
- ano-scrotal distance or ano-penile distance, which may reflect the degree of prenatal androgen exposure.

The level of division of the CS is a more accurate criterion to define the severity of hypospadias (Gearhart *et al.*, 2009), as it shows where the GT development arrest occurred (**Fig. 3**). It therefore seems logical to define the degree of severity of hypospadias according to the level of division of the CS, which will help the surgeon to choose the optimal technique of reconstruction:

1. Hypospadias with a distal division of the CS associated with little or no curvature.
2. Hypospadias with a proximal division of the CS frequently associated with a ventral curvature.
3. Cripple hypospadias, or "hypospadias with previous failed surgery": this occurs in patients who have already undergone several procedures that failed, leaving behind scarred tissues, an abnormal meatus, urethral strictures, urethral dehiscence, fistulas, residual curvature, poor cosmetic results, and/or a psychological impact of various severity.

Classifications of hypospadias should therefore be revisited not only with the anatomical criteria mentioned above, but also in the "biological context" of the hypospadiac patient.

Embryology

The GT and genitalia are formed during the masculinization window (6–16 WG) during which a flare of human chorionic gonadotrophin (HCG) coming from the placenta will stimulate the production of the fetal testicles testosterone. The urethra is the result of a double process: centrifugal growth of the urogenital sinus under the GT and centrifugal tubularization of the urethral plate. The GT becomes the phallus in the male and the clitoris in the female.

Four main actors (Snodgrass *et al.*, 2011) intervene in the construction of the tubercle genital in the male fetus:

1. the child himself with his genes, his gonads and their hormonal production, the central hormonal control, and the target tissues with their receptors and protein platform;
2. the placenta, which is the main hormonal machinery especially during the first part of the gestation, playing an essential role during the masculinization window;
3. the mother, who is the system of reference and whose hormonal status and concomitant diseases could affect the growth of the GT; and
4. the mother's environment during the masculinization window, which may contain some hormonal disruptors or promoters which could interact with the child's formation.

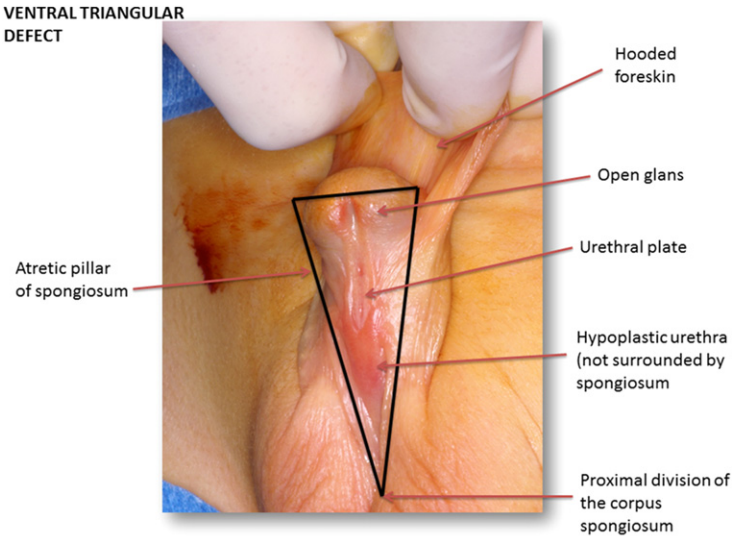

Fig. 3 Hypospadias with a proximal division of corpus spongiosum. The severity of hypospadias can be assessed once the division of the corpus spongiosum and the degree of ventral hypoplasia are identified—the ventral triangular defect.

Hypospadias is a result of this faulty process. Beyond 16 WG, the linear growth of the GT continues beyond the prenatal flare of testosterone, implying that other growth factors might be involved. The tissular proteins are also likely to play important roles in the construction of the GT. Tissues sitting on the ventral surface of the hypospadiac GT do not have the same protein platform as those of the GT dorsum or control group (Morera *et al.*, 2004). The balance between structural proteins and enzymes is altered, and could explain some healing complications commonly reported after hypospadias surgery.

Preoperative Management

Endocrine Screening of the Hypospadiac GT/Investigations

Hypospadias with a labeled biological or genetic context may not have the same predictive outcome as those with no identified etiology, although very few patients have an abnormal biological screening. There is no consensus on the endocrine and genetic screening for the hypospadiac GT. A full biological assessment with karyotype, sequencing of various genes including those involved in the tissular androgen receptors, testosterone, and its precursors, AMH, inhibin B are required for some in case of severe hypospadias or hypospadias associated with other genital anomalies (undescended testes; persistent mullerian structures) (Snodgrass *et al.*, 2011).

Two periods are particularly informative (Gorduza *et al.*, 2010; Vidal *et al.*, 2010) to explore the endocrine function of gonads:

- During the first day of life, the child hormonal machinery is still under the influence of the placental activity.
- During the minipuberty, which extends between day 15 and day 90 of life, there is a flare of hormonal secretions coming from the testicles under the influence of central gonadotrope hormones (testosterone and its precursors for the Leydig cells; AMH and inhibin B for the Sertoli cells). FSH and LH are indicators of the activity of the hypothalamic–pituitary–gonadal axis during "minipuberty." Beyond 6 months of life, plasma AMH remains high (Josso *et al.*, 2006), but androgens can only be measured after stimulation (HCG or recombinant) because of the physiological rest of Leydig cells activity in the prepubertal boy. There is no consensus between centers about HCG and androgenic stimulation protocols and their interpretation.

Pre-Operative Hormonal Stimulation

Preoperative androgen stimulation is commonly used prior to hypospadias reconstruction primarily for small penises (<2–2.5 SD), small glans width, narrow urethral plate, severe proximal hypospadias, or in redo surgery with the aim of increasing the size of the penis and boosting the healing process by increasing the penile blood supply (Malik and Liu, 2014; Netto *et al.*, 2013). Multiple stimulating protocols have been described using either systemic testosterone, local dihydro-testosterone, or HCG (Kaya *et al.*, 2008; Nerli *et al.*, 2009). Here again, no consensus has been found on penile stimulation. More recent studies have pointed out the potential negative effects of androgen stimulation on the healing process after hypospadias surgery. Hence some authors recommend a 3–6-month gap between the stimulation and the surgical procedure (Gilliver *et al.*, 2007; Gorduza *et al.*, 2011; Snodgrass *et al.*, 2011).

Surgery

There is a common temptation to try to universalize one technique for most forms of hypospadias. Several attempts were made in the past and all failed to convince the hypospadiologists. Each surgeon has his or her own convictions, to varying degrees (Snodgrass *et al.*, 2011). The multiplicity of techniques clearly demonstrates that none of them is fully satisfactory. The main current debate splits the surgeons who are keen to use solely ventral tissues to repair the missing urethra and those who use dorsal tissues or other tissues, claiming that ventral tissues alone cannot grow satisfactorily.

Although most hypospadias to date have been surgically treated, those with a distal division of the CS may not need surgery and this non-surgical option needs to be given to the parents.

Objectives of Hypospadias Surgery

From the anatomical description, it is clear that surgery entails three main steps (Gearhart *et al.*, 2009):

1. Degloving the GT down to the base to identify the level of division of the CS which is the main criteria to define hypospadias severity, that is, the degree of hypoplasia of the ventral tissues and consequently the degree of ventral curvature. The evaluation of a persistent curvature after full dissection is necessary to evaluate the need to straighten the GT.
2. Choosing the adequate technique of urethroplasty, which is dependent on the quality of the urethral plate, the availability of preputial tissue, the length of urethra to be reconstructed, the size of the glans, and the depth of the glans groove.
3. Covering the straightened GT with a redistribution of the penile skin.

Surgical Techniques

We shall only mention techniques that are commonly used in most departments of pediatric urology. Three surgical steps characterize most surgical techniques.

First, degloving the penis and a deep dissection of the glans wings represent the first step of this surgery, straighten the penis in most cases, and correct the common ventral glans tilt. In some cases (proximal hypospadias), the residual curvature demonstrated by an erection test is due to asymmetrical corpora cavernosa. It requires a dorsal corporeoplasty or a ventral plasty of the corpora using a patch of tissue (scrotal vaginal tissue).

Second, once the GT has been fully dissected, the length of urethra to be reconstructed can be evaluated. The technique chosen depends on the size and quality of the urethral plate.

If the urethral plate is wide and healthy, some will choose to tubularize it following the Thiersch–Duplay technique (Duplay, 1880).

If it is too narrow to be tubularized, the Snodgrass open urethrotomy (Snodgrass and Lorenzo, 2002) is a popular option, or additional tissue can be laid on the urethral plate using a rectangle of pediculized preputial mucosa (onlay urethroplasty), or a flap of ventral penile skin (Mathieu procedure) (Mathieu, 1932).

If the segment of urethra to replace is short (<1.5 cm), and if the distal urethra is not hypoplastic, a complete mobilization of the whole penile urethra may be adequate to bridge the defect. This technique (Beck-Koff) has the advantage of avoiding the use of non-urethral tissue (Koff, 1981; Thiry *et al.*, 2014).

If the urethral plate is not preservable, a tube needs to be made to replace the missing urethra using either a pediculized rectangle of preputial mucosa (Asopa-Duckett technique) or buccal mucosa (Duckett, 1981).

In major hypovirilization of the GT, the Koyanagi procedure (Koyanagi *et al.*, 1983) mobilizing the tissues of the ventral and lateral aspects and dorsal prepuce with the blood supply is a reliable option to reconstruct the missing urethra. Two-stage procedures (Bracka-Cloutier procedure) are an alternative for long urethroplasties using either preputial mucosa or buccal mucosa (Bracka, 1995).

Third, once the urethra is repaired, the ventral radius of the penis needs to be reconstructed. This includes:

- meatoplasty aiming at creating a slit-shaped meatus;
- glanuloplasty by stitching together the two glans wings over the reconstructed urethra to refashion the ventral aspect of the glans;
- creation of a mucosal collar around the glans;
- coverage of the reconstructed urethra (spongioplasty) using the lateral pillars of spongiosum, or a dorsal or scrotal layer of well vascularized tissue, or the pedicle of the onlay flap itself. The coverage with well vascularized tissues of the neourethra is meant to reduce the risk of fistulae;
- skin cover with a redistribution of the skin shaft bringing the excess dorsal skin to the ventrum.

Some prefer to reconstruct the foreskin; others favor circumcision.

General anesthetic is the rule often associated with caudal or penile anesthesia (Tosetti *et al.*, 2013).

Time of Surgery

The patient's age at surgery for primary hypospadias repair is usually between 6 and 24 months. In 1996, the American Academy of Pediatrics recommended performing this surgery after 6 months of age with particular reference to the risks, benefits, and psychological effects of surgery and anesthesia (Manzoni *et al.*, 2004). After 18 months, the child is more mobile and less cooperative. One study showed no difference concerning psychological effects and quality of life among boys having surgery repair before or after 18 months of age (Weber *et al.*, 2009).

Post-Surgical Evaluation and Follow-Up

Evaluation of outcome is another critical step in this management, and includes functional and cosmetic results through adolescence until adulthood. One essential characteristic of pediatric urology/surgery is that reconstructions are performed on growing organs (Gorduza *et al.*, 2010; Snodgrass *et al.*, 2011).

Cosmetic, functional, and psychological results are subjective and evaluated in various ways which are hardly comparable from one publication to another (Mouriquand *et al.*, 2011). Patients' own evaluations often differ greatly with those of the surgeon, especially regarding the cosmetic appearance (Örtqvist *et al.*, 2015). Functional evaluation includes the quality of the urine stream through the reconstructed urethra which is subjectively assessed by the patient, the parents, and the surgeon: direction and strength of the stream, spraying stream, straining micturations, pain, and duration of micturation give some clues on the urethral flow but remain subjective. Interpretation of urine flow studies is questionable, as most patients who received urethral surgery have long-lasting dyssynergic voiding, and because the urodynamic profile of the reconstructed urethra is abnormal even without significant urethral stricture. This explains why most urine flow studies after hypospadias surgery have a flat profile. This is due to the material used for reconstruction, which does not have the same urodynamic profile as the native urethra (Olsen *et al.*, 2011).

On the long-term sexual outcome, there is a paucity of publications. It seems that straightforward hypospadias repairs do not have serious late consequences on sexual life, contrary to multi-operated patients who are more affected by the psychological consequences of multiple complications (Jones *et al.*, 2009; Kiss *et al.*, 2011; Rynja *et al.*, 2011). Aulagne et al. (2010) and Wang et al. (2010) noted that early surgery was preferable in terms of psychological outcome.

Fertility in hypospadias patients is rarely affected in isolated distal hypospadias, but can become significant when hypospadias is part of an endocrine or genetic disorder, or associated with other genital disorders (e.g., undescended testes, persistent mullerian structures, hypoplastic testes with a poor sperm count) (Asklund *et al.*, 2010) or in proximal hypospadias when the ejaculation process may be disturbed by anatomical factors (urethral dysmotility, persisting penile curvature, anejaculation) (Jiao *et al.*, 2011). Fertility is also influenced by psychosocial factors and body esteem (Vandendriessche *et al.*, 2010).

We would recommend evaluating the cosmetic and functional outcome (mostly how the child passes water) 2 months and then 1 year after surgery, and at puberty. When redo surgery is needed, we would advise waiting at least 6 months after the first procedure before considering surgery again.

Different types of complications include the following:

1. Cosmetic complications are common and mostly represented by irregular scars and ventral excess of skin.
2. Healing complications are mostly represented by fistulae (4%–28%) and dehiscence of the reconstructed urethra, proximal stenosis at the junction between the native and the reconstructed urethra (6%–12%), and distal stenosis through the glans or meatal stenosis (0%–14%) (Cimador *et al.*, 2013).

Fistulae are the most common complication and incidence varies according to surgical technique. They usually appear within a few months of surgery and can be related to an insufficient blood supply of the skin flaps used for reconstruction, a distal stenosis, or infection. Fistulae are often located at the level of the corona and commonly found in a lateral position. The orifice on the penile surface is always smaller than the defect found inside on the urethral wall.

Stenosis usually happens later and may also reflect a poor blood supply or inadequate material for reconstruction. Late stenosis may be a consequence of the poor growth of the tissues used for urethroplasty. Ventral dysplastic tissues located beyond the division of the CS appear not to have the same growth potential as the rest of the GT.

Fistulae and stenosis are commonly associated.

3. Urine flow disorders are also common. They can either be related to the material used for urethroplasty (mostly skin) which does not have the same properties as normal urethral tissue and/or be related to an inadequate urethroplasty. The urodynamic profile of the reconstructed urethra explains the abnormal urine flow studies with flat curves commonly found after hypospadias surgery; incidence varies according to surgical technique (Scarpa *et al.*, 2010), even in non-stenotic urethroplasties. Ballooning of the neourethra (urethrocele) (4%–12%) is due to insufficient backing of the reconstructed urethra and often triggered by the high urethral flow pressures created by the trans-glanular segment of the reconstruction (Cimador *et al.*, 2013).
4. The reconstructed urethra can get very dilated proximal to the glans crossing, creating a pouch which does not empty well and which causes urine dribbling after micturation, pain, and urinary tract infections.
5. Persistent penile curvature and secondary penile deformities (9%–32%) are related either to unrecognized curvature at the time of primary surgery or insufficient growth of the reconstructed urethra due to immature tissues or scarred tissues. Literature is very poor regarding long-term outcomes of early corporeoplasty (Cimador *et al.*, 2013).

6. Association with a mullerian remnant (utricular pouch) is common with severe hypospadias where the gonads have failed to produce enough AMH to erase the mullerian ducts. Most utricular pouches are asymptomatic, but some may cause dysuria and urinary tract infections. In these situations, a laparoscopic removal of the utricular pouch should be discussed. However, this procedure carries the risk of damaging the vas deferens which are often included in the walls of the utricular cavity.
7. Ejaculation dysfunction is also identified in young adults with a history of severe hypospadias. The nature of the neourethral tissues or the presence of a utricular pouch can alter the ejaculation process and subsequently the patient's fertility.
8. Sexual and psychological disorders mostly related to repeated hypospadias surgery are also poorly documented.
9. Unevaluated complications: glans sensitivity is not reported after hypospadias surgery, although it is likely to be affected.

Parents should be warned that late inadequacy of the reconstructed urethra may occur.

Conclusion

Hypospadias remains a challenge, as many unknown factors are found at each step of its management. There is no minor hypospadias, and identifying the level of division of the CS is the essential initial step to define the severity of a hypospadias. It is difficult to compare techniques and outcomes, as there are no objective parameters and no consensus among hypospadiologists. The key message is that pediatric urologists and pediatric surgeons are operating on growing organs and tissues, and the challenge is to choose a technique of reconstruction that will grow at the same pace as the patient. Some hopes are raised with bioengineering to find a more physiological material for urethroplasty. Long-term follow-up is crucial as pediatric urologists are operating on growing organs, but none of the criteria used to assess hypospadias repair is fully satisfactory. The cosmetic results are subjective and quite variable between parents and doctors. The functional outcome in terms of urine flow is mainly based on the patient's (parents') impression. The psychological long-term effects of penile surgery are poorly reported, although current literature seems to show an adequate psychosexual development after hypospadias surgery in most cases.

Undescended Testes☆

Ritzén E Martin, Karolinska Institute, Stockholm, Sweden

Glossary

Cryptorchidism A testis that is not correctly descended in the scrotum, although it is located in the normal pathway, contrary to an ectopic testis.

Ectopic testis The testis is found outside the normal path of decent from the abdomen to the scrotum.

Orchidopexy Surgical transfer of a testis from a supras-crotal position to the scrotum.

Spermatogenesis The complete sequence of events of cell division and cell maturation that leads from spermatogonia to fully developed spermatozoa.

Spermatogonia Stem cells of spermatogenesis and the earliest stages of germ cell maturation, in the absence of which no sperm can be produced. Spermatogonia are present in the normal testis throughout childhood and adulthood.

Testicular descent The normal transposition of the testis during fetal or the first six postnatal months of life from the lower abdomen, through the inguinal canal, to the scrotum.

Undescended testes Synonymous with nondescended testes, cryptorchidism, retained testes, and retentio testis.

Introduction

With very few exceptions, the testicles of mammals are located in a sac on the outside of the body cavity, exposed to potential trauma rather than protected inside the pelvis or abdomen. From a developmental perspective, this seems to be a risk factor for securing fertility, which should be an absolutely vital strategy for survival of a species. Thus, this location must offer other developmental benefits. The most obvious is the lower temperature in the scrotum than in the abdomen (2°C or 3°C, depending on the species). In fact, it has been shown that this seemingly minor difference in temperature is crucial for completion of spermatogenesis; in most mammals, failure of the testes to descend from the abdominal cavity to the scrotum leads to infertility. On the other hand, this does not mean that spermatogenesis occurs in all testes that are brought into the scrotum; the non-descent can be secondary to an abnormal development of the testis that might impair spermatogenesis. Another possible benefit of the low scrotal temperature may relate to the incidence of mutations of the genome. A reduced temperature in the testis, the organ with the highest cell proliferation in the male body, will reduce the incidence of mutations that will be transmitted to offspring to a level that is optimal for long-term development (mutations with positive effects are beneficial) but not so high that it compromises fertility or that the occurrence of malformations is at an unacceptable level for the development of the species.

Nomenclature and Differential Diagnosis

One conventional definition is that normal testicular descent has occurred when the location of the testis is below the border between scrotal and abdominal skin in a resting, standing position. However, this "resting" state may not be present during examination in the clinic—the cremasteric reflex will retract the testes when the examiner's hand approaches. A practical way to circumvent this is to pull the testis down gently, hold it for approximately 30 s until the cremasteric reflex has been exhausted, and then release it. The position of the released testis approximates the resting position. If a testis is in a supra-scrotal position at the start of the examination but after manipulation remains in the scrotum, it is called a retractile testis. This condition is thought not to need any further attention. For clinical studies, a more exact location of the testes than "scrotal," "sub-inguinal," or "inguinal" should be used, preferably by measuring the distance in millimeters between the testis and a defined point (e.g., the pubic tubercle or the external inguinal orifice).

The term cryptorchidism is often used to describe the condition of undescended testes. This term implies that the testes are "hidden," that they can neither be seen nor palpated. Since in clinical practice even inguinal or sub-inguinal (pre-scrotal) palpable testes should be considered undescended, the term cryptorchidism is not always correct. "Non-descended" and "retained" (Latin: *retentio testis*) are synonyms of undescended testes that are sometimes used (**Fig. 1**).

In approximately 10%–20%, both testes are found above the scrotum. Even after successful treatment, the prospect for future fertility is worse (approximately 65%) in bilateral than unilateral cryptorchidism (approximately 90%) (Lee, 2005). Untreated bilateral cryptorchidism in adulthood is not compatible with fertility.

☆*Change History*: December, 2017. Ritzén E Martin updated the text and added new figure.

This chapter is an update of E. Martin Ritzén, Undescended Testes, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 651–655.

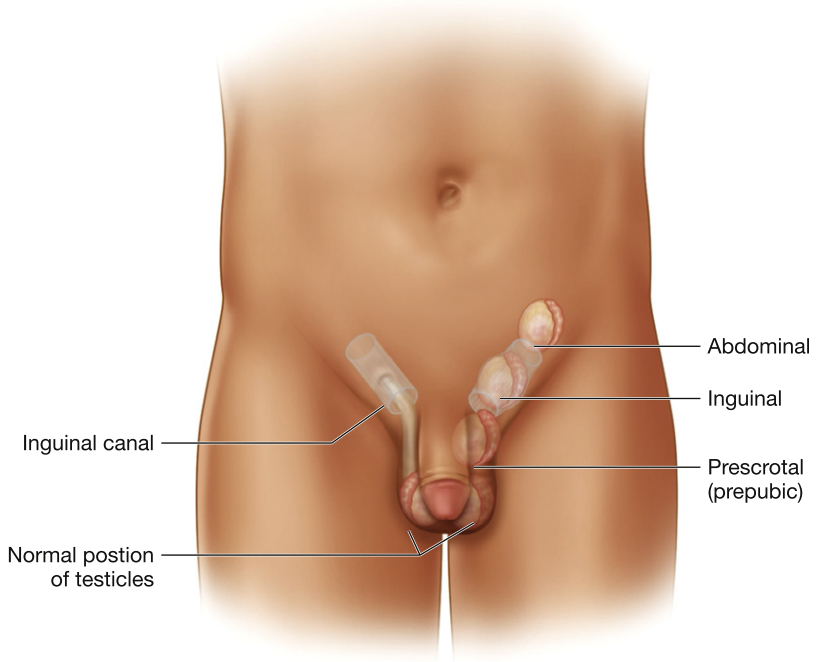

Fig. 1 A schematic drawing of the various locations where a testis can be found along its natural path of descent from the abdomen through the inguinal canal to the scrotum.

If no testis is palpable, it is important to consider a possible disorder of sex development (DSD), especially if combined with hypospadias of any degree. Such patients should be referred to a DSD team immediately after birth, since the new born might be a virilized girl with congenital adrenal hyperplasia; a possibly life-threatening condition.

If both testes undergo atrophy after that male sex differentiation is completed, the boy is born with normal male sex organs but will need testosterone substitution at puberty.

The term ectopic testis has been coined to describe a position of the testis that is outside the normal path of the testis during descent. Only during surgery can the true differentiation between a low inguinal and an ectopic testis be made.

It is difficult to distinguish bilaterally retained abdominal testicles from testicular atrophy. The differentiation between the two may be aided by a human chorionic gonadotropin (hCG) stimulation test. Significantly increased testosterone levels indicate the presence of testicles. Measurement of inhibin B in serum is valuable since in boys this hormone is only produced in Sertoli cells.

Acquired Cryptorchidism

Acquired cryptorchidism is a term that is used in cases when a testis at some stage (most often during the first 6 months of age) has been found in the scrotum, but later in a supra-scrotal or inguinal position. This is found to be the case in about one of five testes that are undescended at birth, but descend during the first 3–6 months (Kollin *et al.*, 2013). Thus, this group of boys should be followed at annual examinations and treated if found to be ascended. Such examinations can be done by the parents, after proper instructions. Secondary ascensus may explain why many studies find about 1% undescended testes at age 6 months, but up to 3% of all boys are eventually operated for cryptorchidism.

Incidence of Cryptorchidism

The classical epidemiological studies by Scorer (1956) in England are often cited. Using his quite strict definitions, 2.7% of boys with a birth weight of >2.5 kg had undescended testes at birth, but testicular descent proceeded during the first postnatal months so that at age 3 months only 0.9% were considered to have incompletely descended testes. In premature infants, the incidence was much higher (21% if <2.5 kg), reflecting the late normal descent in utero. When Scorer's study was repeated 20 years later using the same methodology, the incidence at birth and at 3 months was 3.4% and 1.4%, respectively, suggesting a negative trend in fetal testicular development during this period. This has been paralleled by a similar increase in the incidence of testicular cancer, suggesting a possible common environmental cause of testicular maldevelopment.

The term "testicular dysgenesis syndrome" has been coined to describe a common cause for cryptorchidism, hypospadias, testicular cancer and future impaired spermatogenesis (Skakkebaek *et al.*, 2001). Early on, exposure of mother and fetus to environmental estrogenic compounds was suspected to impair testicular function, but later many other such "endocrine disruptors" have been identified. A recent meta-analysis (Bonde *et al.*, 2017) of publications that examine a possible link between individual endocrine disruptors and testicular dysgenesis in boys failed to show convincing evidence to prove such a relation, although animal experiments have proven that prenatal exposure to compounds such as phthalates and bisphenol A definitely can cause impaired testicular function. The authors of the meta-analysis conclude that "the current epidemiological evidence is compatible with a small increased risk of male reproductive disorders following prenatal and postnatal exposure to some persistent environmental chemicals classified as endocrine disruptors but the evidence is limited." The possibility of a "cocktail effect" of many simultaneous exposures to endocrine disruptors is difficult to study and can presently not be excluded.

Mechanisms of Testicular Descent

The translocation of the fetal testicles from the lower abdominal wall to their final destination in the scrotum is lead through the inguinal canal by the gubernaculum, one end of which is anchored in the epididymal tail and the other in what is to become the bottom of the scrotum. Initially, the gubernaculum fills the canal, and through successive shortening and swelling of its intra- and extracanalicular parts it is believed to aid the testis through the canal. The precise hormonal regulation of this series of events is incompletely known. In addition to non-hormonal homeobox genes, some endocrine factors have been suggested to have a crucial role in one or several of the events leading to testicular descent.

Undescended testicles are often found in boys with hypogonadotropic hypogonadism or androgen insensitivity. Thus, deficiency of androgenic hormones is important for the final passage through the inguinal canal. Patients with persistent Müllerian duct syndrome due to a loss of function of anti-Müllerian hormone or its receptor also have retained testicles. Therefore, this hormone has been suggested to be a key factor for testicular descent. However, since in this syndrome the testes are closely linked to the uterus and fallopian tubes, this may in itself hinder descent. It has been found that in mice the newly described *Insl3* gene is important for gubernacular development and testicular descent from its proximal abdominal position to the internal opening of the inguinal canal. No human disease has yet been ascribed to this factor.

Abnormal Functions of Undescended Testicles

Spermatogenesis

Numerous animal experiments have proven that spermatogenesis is blocked at a pre-meiotic stage if the testes are retained in or moved into the abdomen at any time after birth. This spermatogenic arrest is reversed if the testes are transferred to the scrotum or even if they are cooled in an abdominal position with a cooling device. These experiments prove that a temperature $<37^{\circ}C$ is needed to complete spermatogenesis. In man, the difference between abdominal and scrotal temperature is $2^{\circ}C$ or $3^{\circ}C$. Germ cells, including spermatogonia and spermatocytes, seem to be the most temperature-sensitive cells, but impaired Sertoli cell function at $37^{\circ}C$ may also be of importance.

On the other hand, not all undescended testicles will attain normal spermatogenesis if they are transferred to the scrotum by surgery or by hormonal treatment. As many as 40% of successfully treated men with primary bilaterally undescended testicles are reported to have grossly subnormal sperm quality (Lee, 2005). Although the treatment itself may be harmful to the testis, this suggests that a number of undescended testicles have other deficiencies in spermatogenesis that are unrelated to their abdominal or inguinal position. However, it is not possible to distinguish the testes with primary defects in spermatogenesis from those that will normalize when put in a scrotal position.

Steroidogenesis

Animal experiments have demonstrated that even if the testes are translocated to the abdomen, normal blood levels of testosterone can be maintained. However, there is a subtle difference: The Leydig cells are enlarged and have a lower sensitivity to stimulation by Lutropin (synonyms: luteinizing hormone, LH, interstitial cell-stimulating hormone) or *h*uman *C*horionic *G*onadotropin (hCG). It is not known whether this is due to a primary effect of temperature on the Leydig cells or if it is secondary to damage to the seminiferous tubules, causing an abnormal paracrine hormonal milieu.

In man, normal testosterone levels in blood are generally seen even when the testicles are undescended. Thus, a stimulation test with hCG can be used to differentiate between bilaterally nonpalpable retained testicles and the complete absence of testes (testicular atrophy). It is important to remember that even a small testis that has a poor prognosis with regard to spermatogenesis should only be removed if the other testis is present and functioning. This small testis may mean the difference between life long testosterone replacement and no need for medication.

Malignancies

It is frequently cited that undescended testicles often develop malignancies and therefore should either be placed into the scrotum or removed. The basis for this assumption lies in the finding of an overrepresentation of undescended testicles (with or without successful treatment) in cohorts of patients with testicular cancer. Five to ten percent of men with testicular tumors have a history of undescended testes. However, the true incidence of testicular cancer in a group of men with undescended testes has not been well documented. In a Swedish retrospective study (Pinczowski *et al.*, 1991) all 3000 boys with undescended testes from a defined geographical area underwent orchidopexy. These patients, as well as 30,000 boys operated on for inguinal hernia, were searched for in the Swedish Cancer Registry when they were adults. In the previously cryptorchid cohort, four cases of testicular cancer occurred versus 0.54 expected, yielding a relative risk of 7.4 (95% confidence interval, 2.0–19.0). The hernia controls had no increased risk. The most prevalent testicular cancer was seminoma, which has a good prognosis following modern treatment. Thus, the absolute risk (4/3000) does not motivate special follow-up of patients operated for cryptorchidism. However, it is recommended that an undescended testis should be brought into a palpable position so that tumor formation can be detected at an early stage, even in cases in which there is little hope of spermatogenesis. Since testosterone production might be maintained even in a small and soft testicle, it should not be removed unless the contralateral testis is normal.

Treatment

There is much controversy regarding the methods of treatment of undescended testicles, despite the numerous articles that have been published. The major controversies relate to the method (hormonal or surgical) and the most suitable age of treatment.

Hormonal Treatment

Based on the common finding of undescended testicles in boys with hypogonadotropic hypogonadism or androgen insensitivity, stimulation of the testes through administration of hCG or gonadotropic-releasing hormone (GnRH) has been advocated as the logical treatment. Direct systemic administration of testosterone has the drawback of treating the whole body as much as the testis and its surroundings and in a few trials has not been shown to be very effective.

Human chorionic gonadotropin

In many countries, injection of hCG for 3–5 weeks is the recommended treatment of undescended testicles. The following is a typical treatment regimen: injection of 500 IU hCG intramuscularly twice weekly for 5 weeks for boys younger than 6 years and doubling the dose for older boys. In uncontrolled studies, this treatment is reported to result in testicular descent in approximately 50% of patients; the non-responders are referred for surgery. However, meta-analyses of randomized controlled studies indicates that the success rate is only 19%, compared to 5% for placebo groups.

The short-term side effects of hCG treatment include pain of injections, increased frequency of erections, and sometimes development of pubic hair. Animal experiments and some clinical observations have raised concern regarding possible long-term adverse effects of hCG on the testis. Thus, impaired spermatogenesis has been noted in dogs treated with hCG at the time of puberty. In rats, injection of hCG or LH causes an acute inflammatory response in the testicular interstitium, with increased intratesticular pressure, extravasation of leukocytes, and signs of edema. A similar histological picture has been reported in testicular biopsies taken within a few days after completed unsuccessful hCG treatment. Furthermore, it has been shown that the number of apoptotic spermatogonia is markedly increased following a course of hCG treatment when compared to the degree of apoptosis in biopsies taken from boys operated on without prior hCG treatment. In a small study, a positive correlation was found between the number of apoptotic spermatogonia within 1 month after treatment in childhood and the follitropin (follicle-stimulating hormone, FSH) levels as adults, approximately 20 years later. Testicular volume in adulthood was negatively correlated with the initial degree of spermatogonial apoptosis, suggesting an impaired spermatogenesis secondary to the post-hCG apoptosis (Dunkel *et al.*, 1997). In conclusion: hCG treatment is not very effective and there are concerns about its safety.

Gonadotropin-releasing hormone

When this hormone became available as a therapeutic modality, several publications reported good results on undescended testicles. However, later controlled studies were unable to repeat these results, and it has been concluded that GnRH treatment is most successful in boys with retractile or high scrotal testes. If results of the professional examination during the neonatal period are available, such information is of great help for predicting whether hormonal treatment (hCG or GnRH) will be effective: only boys who had palpable testes at birth will respond to hormonal treatment. Also, success is rare if the testicle is not palpable at the time of later examination. The mechanism of action seems to be through increased release of pituitary gonadotropins that stimulate secretion of testosterone in a mode similar to hCG but with a more moderate stimulation of Leydig cell testosterone production. Thus, it can be considered similar to a mild hCG treatment. No side effects of GnRH treatment of undescended testes have been reported.

Surgery (Orchidopexy)

Open surgery is the most direct way of transferring an abdominal or inguinal testis into the scrotum. This method has been used for a very long time. The major complications are surgical: in addition to the small risk of general anesthesia, the blood supply to the testis might be damaged during surgery. A high incidence of testicular atrophy after surgical orchidopexy has been reported from departments in which "scrotal and inguinal surgery" (including orchidopexy and hernia repair) is considered to be an activity for surgeons in training. In skilled hands, this complication should be rare if the testis is not situated very high in the abdomen. Surgery has the added advantage that it provides opportunities for direct observation of the testis and, in selected cases, biopsy for microscopical investigations.

Comparison Between Hormonal and Surgical Treatment

The main advantages of hormonal treatment are that it is inexpensive and that hospitalization and the trauma of anesthesia and surgery are avoided (when successful). This method also provides an opportunity to test the capacity of the non-palpable testicles to produce testosterone if blood samples are taken at the end of hormone administration.

The major reason for treating undescended testicles is to save future fertility. Unfortunately, there are no published studies in which patients have been randomized to surgical or hormonal treatment and followed up into adulthood. Therefore, a scientifically based conclusion regarding the advantages of the two approaches in terms of future fertility cannot be made. The possible adverse effects of hCG on future spermatogenesis and the poor efficacy of hCG or GnRH argue against this as the first-line therapy; instead, a primary surgical approach is favored, provided that a skilled surgeon is available.

Age at Which Undescended Testicles Should be Treated

Again, the scientific foundations for recommendations are weak. The single classical report by the Swiss pathologist Hedinger (1979) is generally referred to as an argument for early treatment. He compared sections from undescended and normally descended testicles of boys who had died suddenly. The number of spermatogonia per seminiferous tubular cross section was determined. He noted that in normally descended testicles, there was a steady decline in the number of spermatogonia from birth until one or two years of age, followed by a slow increase that continued until puberty. In the undescended testes, the initial decline was similar, but the normal increase in spermatogonia after age 2 years did not occur.

The Hedinger study seems to show that undescended testes should be brought into the scrotum before the age of 2 years. It is assumed that spermatogenesis will be improved after successful treatment. Repeat follow-up biopsies have been studied in only two publications: one showed improved spermatogenesis, one did not. It is not known whether the catch-up of spermatogenesis is more complete after early rather than after later treatment. Nevertheless, treatment before age two has become the standard of treatment in many countries. If this approach is followed, initial surgery is to be preferred rather than hormonal treatment since the latter seems to be even less effective at ages younger than 4 years.

Final recommendations about the most suitable age for treatment of undescended testes must await results of controlled, randomized studies of treatment at various ages. The final outcome to be evaluated in such studies should be spermatogenesis and fertility in adulthood. This requires very long-term prospective studies. Careful measurements of testicular size during the first years after treatment may to some extent predict spermatogenesis and should be performed in future studies.

Conclusions

The condition of undescended testicles is the most common inborn developmental abnormality in boys, affecting approximately 1% of the entire male population. The cause may be hormonal deficiencies or, in most cases, unknown. Untreated, undescended testicles always have severely impaired spermatogenesis, but testosterone production is generally acceptable. The risk of malignancy in undescended testicles is increased. If the testes are moved into the scrotum, future spermatogenesis will be improved but not to the full extent. The risk of malignancies is reduced by orchidopexy before puberty. Both the choice of treatment (hormonal or surgical) and the most appropriate age of treatment (1–4 years) are controversial. However, based on current knowledge, skilled surgery at an early age, rather than hormonal treatment, seems to be advisable.

Abbreviations

ArKO	Aromatase knockout
BMD	Bone mineral density
CRE	cAMP response element
CREB	cAMP response element binding protein
CYP19A1	Aromatase gene
DHEAS	Dehydroepiandrosterone sulfate
E2	Estrogen
ERT	Estrogen replacement therapy
GH/IGF1 axis	Somatotropic axis
GnRH	Gonadotropin releasing hormone
ND	Not determined
SF1	Steroidogenic factor 1
WT	Wild type

Glossary

Acanthosis nigricans Skin pigmentation disorder in which dark thick poorly defined areas of velvety texture appear especially in the neck, armpit, and body folds. Related to hyperinsulinism.
Aromatization The last step in estrogen synthesis. The reaction includes three hydroxylations of the 19 methyl group of the androgen molecule with the simultaneous elimination of the methyl group that results in the formation of a benzene ring.
Astenospermia Less than 50% of motile spermatozoa.
Azoospermia Absence of spermatozoa in the ejaculate.
Congenital adrenal hyperplasia Group of steroidogenic disorders that impair cortisol biosynthesis.
Disorders of sexual development Congenital conditions in which chromosomal, gonadal, or anatomical sex is atypical.
GnRH pulse generation Hypothalamic neuronal network that control the pulsatile secretion of gonadotropins.
Hypospadias Disorder of the anterior urethral and penile development in which the urethral opening is ectopically located on the ventral aspect of the penis.
Osteopenia A skeletal condition characterized by a decreased bone mineral density when compared with the reference standard (between -1 and -2.5 SD).
Osteoporosis A skeletal condition characterized by a decreased bone mineral density when compared with the reference standard (under -2.5 SD).
Polycystic ovary syndrome Disorder characterized by hyperandrogenism, ovulatory dysfunction, and polycystic ovarian morphology.
Teratospermia Less than 30% of morphologically normal spermatozoa.

Several molecular CYP19A1 gene alterations associated with cytochrome P450 aromatase (cP450arom) deficiency have been described in both females and males. This has contributed considerably to the understanding of cP450arom activity in different tissues, influencing sexual differentiation, patterns of gonadotropin secretion by the hypothalamic–pituitary axis, reproductive capacity, lipid metabolism, insulin sensitivity, and skeletal maturation and growth. Studies of aromatase deficiency in humans were complemented with studies in mouse knockout models that demonstrated the role of estrogens in several tissues. In this article, molecular studies, the clinical phenotypic variations throughout life in both sexes, gonadal function, fertility, and gender identity are addressed.

Characteristics of cP450arom

cP450arom is the enzyme that catalyzes the synthesis of estrogens from androgens. Therefore, the activity of this enzyme complex affects both androgen metabolism and estrogen synthesis. The biological importance of the aromatase complex is related not only to its role in the synthesis of estrogens, but also to its potential influence on the balance of the androgen–estrogen ratio in different tissues. In the 1980s, the human aromatase protein was purified from placental microsome and the aromatase activity was demonstrated by conversion of androstenedione to estrone (Pasanen and Pelkonen, 1981; Mendelson *et al.*, 1985; Kellis and Vickery, 1987; Osawa *et al.*, 1987; Hall *et al.*, 1987). The aromatase

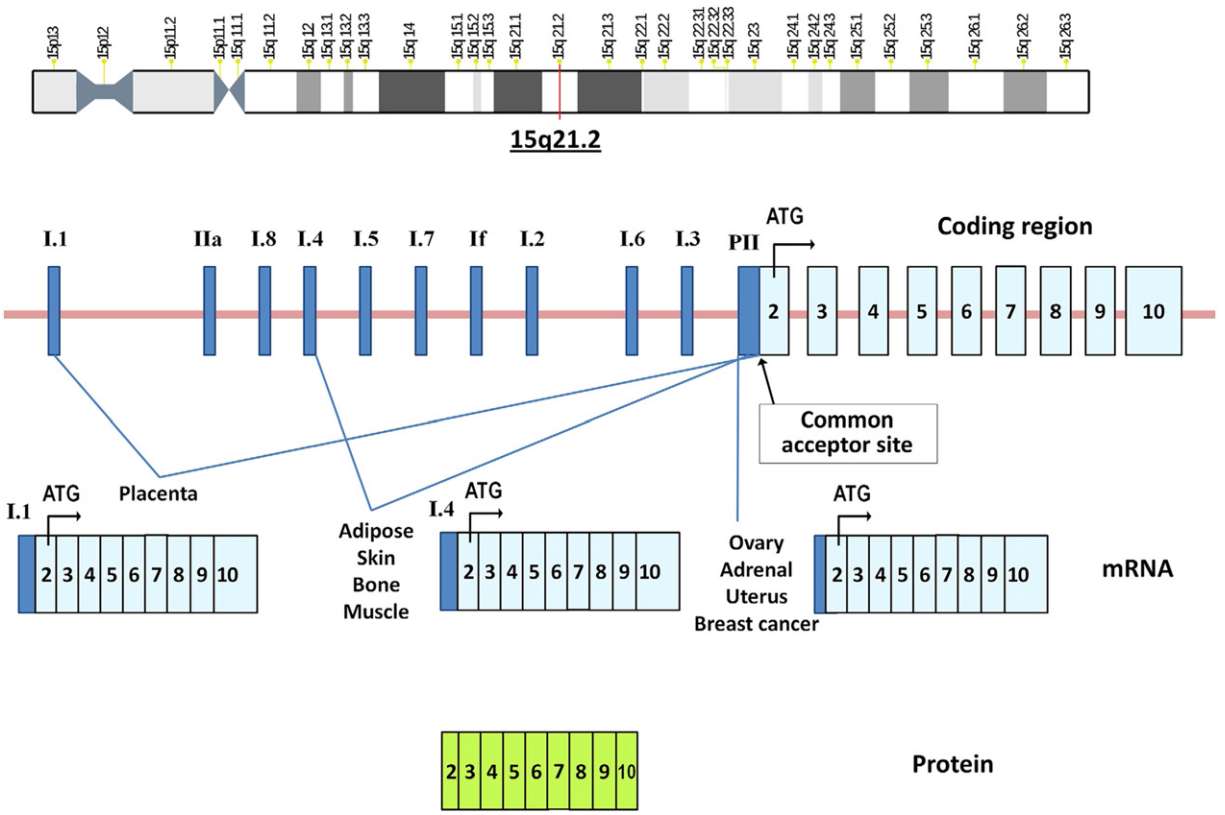

Fig. 1 Representation of the CYP19A1 splicing mechanism.

complex is expressed in the endoplasmic reticulum of cells and consists of two components: cP450arom and a ubiquitous flavoprotein, NADPH-cytochrome P450 reductase. Although androstenedione and testosterone are the most common and the most physiologically important substrates, 16OH-dehydroepiandrosterone sulfate (DHEAS) arising from fetal liver hydroxylation of fetal adrenal DHEAS is an important substrate for placental estriol synthesis during pregnancy, in both humans and higher primates (Belgorosky and Rivarola, 2004). In humans, cP450arom appears to be the product of a single gene—CYP19A1—located on chromosome 15q21.1. The size of the aromatase gene is larger than 123 kb; however, the protein-coding sequence is contained within 9 exons (2 – 10) spanning approximately 35 kb of DNA (Means *et al.*, 1989). Several promoters are found within a 90-kb region upstream of the coding region associated with multiple first exons that are involved in tissue-specific expression. These exons, which are not translated, generate alternative splicing in such a fashion that the coding region, and hence the protein sequence, is conserved in every tissue (**Fig. 1**).

The three-dimensional crystal structure of human aromatase was identified with purified aromatase protein extracted from placental microsome (Ghosh *et al.*, 2009). The human aromatase consists of a heme group and a polypeptide chain of 503 amino-acid residues and exhibits high substrate specificity in catalyzing the synthesis of estrogens from androgen precursors. The most highly conserved region consists essentially of a four-helix bundle, two sheets, and the heme-binding region (Graham-Lorence *et al.*, 1995).

cP450arom is expressed in a number of tissues, including the syncytiotrophoblast layer of the placenta, gonads, adipose tissue, bone, brain (including the hypothalamus, hippocampus, and amygdala), coronary arteries, and various fetal tissues, such as liver, skin, intestine, testis, and ovary (Graham-Lorence *et al.*, 1995). CYP19A1 gene expression is subjected to multifactor regulation by a diverse group of hormones and factors that differ markedly between tissues. Thus, a strict control over tissue-specific expression is necessary for proper regulation of estrogen synthesis during fetal development, as well as during postnatal life.

The human placenta (syncytiotrophoblast layer) is capable of aromatizing large amounts of androgen precursors produced by the fetal and maternal adrenal glands into estrogens. At term, approximately equal amounts of estrogens are produced from circulating maternal DHEAS and fetal DHEAS. The rate of estrogen production and the level of circulating estrogens increase markedly during pregnancy. Following fertilization, concentrations of 17β-estradiol increase gradually to a range of 6–30 ng/mL at term (Tal *et al.*, 2000). This enzyme protects the fetus from virilization even in the presence of large amounts of aromatizable androgens. One of the clinical signs of aromatase deficiency may manifest during pregnancy, as a pregnant mother of an aromatase-deficient fetus becomes virilized (see later).

Reported Human Mutations

Since aromatase deficiency was first described by Shozu *et al.* (1991), 37 cases (26 females and 11 males) have been published (PubMed indexed). These cases are listed in **Tables 1** and **2**.

Several deleterious mutations in the coding region of the CYP19A1 gene were reported in aromatase deficient patients, comprising point mutations, deletions, insertions, splice site mutations, as well as a placental promoter I.1 variation that reduced gene transcription.

Tables 1 and **2** describe the molecular defects, in-vitro aromatase activity of mutants, and clinical phenotype in female and male aromatase-deficient subjects, respectively. Variations in phenotype are compared with in-vitro functional derangements of mutants. Data reported suggest some genotype–phenotype correlation as lower cP450arom activity was associated with a more severe phenotype. However, phenotype is also dependent on sex and age.

Pregnancy, the Fetus, and Newborns

The active human placental aromatization of androgens protects the fetus against the virilizing action of fetal androgens. In congenital aromatase deficiency, the overload of androgens may cause signs of maternal virilization (acne, deep voice, clitoris enlargement) during pregnancy, and this might alert obstetricians to the possibility of this diagnosis. After delivery these symptoms usually disappear gradually (Shozu *et al.*, 1991; Morishima *et al.*, 1995; Mullis *et al.*, 1997; Ludwig *et al.*, 1998; Deladoëy *et al.*, 1999; Herrmann *et al.*, 2002; Belgorosky *et al.*, 2003; Lin *et al.*, 2007; Hauri-Hohl *et al.*, 2011; Verma *et al.*, 2012; Ludwikowski *et al.*, 2013; Marino *et al.*, 2015; Akçurin *et al.*, 2016; Zhu *et al.*, 2016; Miedlich *et al.*, 2016). Nevertheless, this finding is not always present, since about 1% of normal placental aromatase activity seems enough to prevent virilization of the mother. Therefore, CYP19A1 mutations that retained partial activity did not lead to maternal virilization during pregnancy (Mullis *et al.*, 1997; Grumbach and Auchus, 1999). Patient data suggest that estrogen synthesis in the blastocyst, fetus, and placenta is not essential either for normal embryonic and fetal development and survival or in the physiology of the pregnant woman (Conte *et al.*, 1994; Morishima *et al.*, 1995). Onset of labor has been described as spontaneous (Shozu *et al.*, 1991; Mullis *et al.*, 1997; Deladoëy *et al.*, 1999; Belgorosky *et al.*, 2003) and newborns were born full term with adequate weight for gestational age (Shozu *et al.*, 1991; Conte *et al.*, 1994; Morishima *et al.*, 1995; Mullis *et al.*, 1997; Deladoëy *et al.*, 1999; Belgorosky *et al.*, 2003; Bouchoucha *et al.*, 2014; Zhu *et al.*, 2016).

In the female fetus, placental aromatization of androgens is particularly important to avoid an effect of androgens on the differentiation of the external genitalia. In a newborn with 46,XX ambiguous genitalia, aromatase deficiency should be considered among other entities after ruling out the diagnosis of congenital adrenal hyperplasia (CAH) because of its high incidence. Moreover, before the definitive diagnosis of aromatase deficiency was made, some patients were assumed to have CAH and treated as such (Verma *et al.*, 2012; Saraco *et al.*, 2015).

In most female cases of aromatase deficiency described in the literature, ambiguous genitalia, with various degrees of masculinization of the external genitalia, were reported. As expected, in all these cases, gonads were nonpalpable and differentiation of the female internal genitalia was not affected. Milder genital manifestations, such as clitoral hypertrophy or partial fusion of the labia, have been described in four females (Lin *et al.*, 2007; Hauri-Hohl *et al.*, 2011; Marino *et al.*, 2015; Akçurin *et al.*, 2016). The discordant presentation of mild androgenization with the complete lack of enzyme activity described by Lin is difficult to explain and it is a matter of speculation. Hauri-Hohl *et al.* (2011) described a newborn with transient mild hypertrophy of the clitoris having a loss-of-function missense mutation in CYP19A1 combined with the first-described variant of the placenta promoter with a significant reduction in function. This phenotype might represent a placenta-specific, prenatally limited component of aromatase deficiency occurring in utero only.

Even though aromatase deficiency manifests during fetal life in both sexes, external genitalia in 46,XY newborns remain normal and there are no symptoms of aromatase deficiency during infancy and childhood in most boys (Deladoëy *et al.*, 1999). In only one boy reported by Bouchoucha *et al.* (2014) the presence of glandular hypospadias and bilateral cryptorchidism with inguinal testes was described; however, causality between the *CYP19A1* mutation and the genital anomaly in this patient remains elusive.

An endocrinological profile has been described in some female cases with aromatase deficiency during the first month of postnatal life. Low estrogen levels along with high androgen levels were found in the cord serum and serum androgen levels returned rapidly to normal after delivery in some cases (Shozu *et al.*, 1991; Deladoëy *et al.*, 1999). Extremely high serum LH and FSH levels resulting in high serum androgen levels were reported in two aromatase-deficient newborn girls (Belgorosky *et al.*, 2003; Akçurin *et al.*, 2016). This abnormal serum gonadotropin pattern might reflect a central change in the activity of the gonadotropin releasing hormone (GnRH) pulse generator and/or an effect at the pituitary level, presumably induced by increased androgens and aromatase deficiency during fetal and neonatal life. Bouchoucha *et al.* (2014) described a female newborn who presented with elevated serum testosterone and androstenedione levels at birth that normalized thereafter. Normal serum testosterone levels were reported in an affected girl of 3 days (Conte *et al.*, 1994). No data exist on gonadotropin levels during the newborn period in affected boys. Very high serum-free testosterone and androstenedione levels at 2 weeks of postnatal life followed by a decrease to the normal range during the first month of life was reported in only one affected newborn boy (Deladoëy *et al.*, 1999). At 4 weeks after birth, the estradiol levels were low; the androstenedione level was decreasing toward the normal level for age and sex, whereas the free testosterone level had already dropped to within the normal range.

Table 1 Molecular defects of the *CYP19* gene, in vitro aromatase activity of mutants, and clinical phenotype in published female deficient subjects

Report	*Gene mutations*	*Description*	*Aromatase activity*	*Phenotype*
Shozu et al. (1991), Harada *et al.* (1992)	c.[743 + 2T > C]; [743 + 2T > C]	IVS6 + 2T > C Mutation at consensus 5′splice site (5′ss) in intron 6 which results in the use of a cryptic site downstream and in the in-frame incorporation of 87 nucleotides. Then, a protein with additional highly hydrophobic 29 amino acids will be generated	Less than 0.3% of wild type (WT) control. The extra amino acids might induce conformational changes and reduction of activity	Ambiguous genitalia at birth
Ito *et al.* (1993), Conte *et al.* (1994)	c.[1303C > T]; [1310G > A]	p.Arg435Cys: Arg435 is highly conserved within the heme-binding region among cP450s p.Cys437Tyr: The cysteine 437 is the critical cysteine in the heme-binding domain and is the most conserved residue in all cP450 proteins	p.Arg435Cys mutant protein showed approximately 1.1% of WT activity p.Cys437Tyr mutant protein was inactive	Ambiguous genitalia at birth Delayed bone age Absent puberty and pubertal growth spurt. Ovarian cyst and virilizing signs at puberty
Morishima *et al.* (1995)	c.[1123C > T]; [1123C > T]	p.Arg375Cys	0.2% of WT activity Protein modeling studies suggest that the affected region may affect the substrate access channel to the membrane	Ambiguous genitalia at birth Absent puberty and pubertal growth spurt According bone age Ovarian cyst and virilizing signs at puberty
Mullis *et al.* (1997), Janner *et al.* (2012), Burckhardt *et al.* (2015)	c.[1224delC]; [296 + 1G > A]	p.Lys409AsnfsTer36: A base pair deletion (C) in codon 408 (exon 9). A frameshift occurs resulting in a nonsense codon IVS3 + 1G > A: G > A change at the canonical donor splice site in intron 3. The splice site is ignored, and a stop codon arises 3 bp downstream. No active transcript was found	ND. However, no aromatase activity is expected	Ambiguous genitalia at birth Ovarian cysts during infancy and childhood Low BMD at 3.5 years of age Follow-up from 3.5 to 15 years under ERT. Normalization of growth and bone maturation with different threshold for estradiol action on FSH regulation
Ludwig *et al.* (1998)	c.[1108G > A]; [1108G > A]	p.Val370Met	ND	Ambiguous genitalia at birth Lipid abnormalities early in life
Belgorosky *et al.* (2003), Pepe *et al.* (2007), Guercio *et al.* (2009)	c.[1236delA]; [628G > A]	p.Glu412AspfsTer33: a bp deletion (A) in glu 412 (exon 9) causing a frame-shift generating a stop codon 98 bp downstream. Then, a truncated protein with an altered heme-binding domain might be generated c.628G > A: G to A at the consensus donor splice site in exon 5–intron 5 junction causing in-frame exon 5 skipping	The peptide expressed from p. Glu412AspfsTer33 is expected to be completely inactive as the frame shift altered the highly conserved heme-binding domain The protein without amino acids 151–209 encoded by exon 5 does not have aromatase activity As the –E5 mRNA might be expressed as a splice variant in normal tissues, some + E5 transcripts from the c.628G > A allele might explain the partial Aromatase deficiency phenotype (Lin *et al.*, 2007; Pepe *et al.*, 2007)	Ambiguous genitalia at birth Delayed bone age during childhood Ovarian cysts from infancy to puberty Spontaneous breast development at 7.7 years Virilizing signs at puberty Normal BMD during follow-up Insulin resistance since 7.2 years of age and Type 2 diabetes during follow-up
Lin *et al.* (2007)		p.Arg435Cys

			metabolizing androstenedione was reduced to 19%. Modeling of the structure of the novel p.Arg192His variant of the CYP19A1 protein revealed a crucial role of the arginine 192 residue in substrate binding as well as catalysis	
Chen *et al.* (2015)	c.[384A>G]; [1494T>C]	p.Tyr81Cys; p.Leu451Pro Both the Tyr81 and Leu451 residues were highly conserved in vertebrate aromatase orthologs, and were also conserved in human aromatase paralogs	Three-dimensional modeling predicted that the p.Tyr81Cys and p.Leu451Pro mutations would probably result in loss of aromatase function In-cell aromatase activity assay: p. Tyr81Cys mutant was found to have 14.3% wild-type activity, whereas the p. Leu451Pro mutant was found to have 3.1% wild-type activity p.Tyr81Cys mutant showed lower Vmax, higher Km, and lower catalytic efficiency p.Leu451Pro mutant had lower Vmax, Km and catalytic efficiency	Continuous linear growth, delayed bone maturation, tall stature, eunuchoid body proportions, genu valgum Normal libido Normal testicular volume Normal spermogram Increased serum basal FSH, with normal LH and testosterone levels Overweight, acanthosis nigricans, dyslipidemia and severe steatohepatitis Impaired glucose tolerance and hyperinsulinemia Osteopenia
Miedlich *et al.* (2016)	c.[628G>A]; [628G>A]	Previously reported (Pepe *et al.*, 2007)		Continuous linear growth, delayed bone maturation, unfused growth plate, arachnodactyly Normal libido Normal testicular volume Normal serum FSH and LH levels with upper normal basal testosterone Low BMI. Normal OGTT Osteoporosis

ND, not determined; *BMI*, body mass index; *OGTT*, oral glucose tolerance test.

Follow-Up

In almost all cases of aromatase deficiency the clinical phenotype was reported only once, when initial diagnosis was made. Only a few reports describe longitudinal clinical and biochemical findings of the affected subjects of both sexes (Conte *et al.*, 1994; Bilezikian *et al.*, 1998; Bouillon *et al.*, 2004; Guercio *et al.*, 2009; Verma *et al.*, 2012; Janner *et al.*, 2012; Burckhardt *et al.*, 2015; Marino *et al.*, 2015; Saraco *et al.*, 2015). Fortunately, a growing number of reports has broadened the spectra of phenotypes and genetic mutations underlying this rare disorder and increased the knowledge on aromatase physiology.

The clinical phenotype of aromatase deficiency includes changes in the hypothalamic–pituitary–gonadal axis, ovarian cyst formation, alterations of growth, skeletal maturation, and bone homeostasis, as well as changes in insulin sensitivity and lipid profile. As previously mentioned, the phenotype depends on sex and age, and may vary according to the level of enzyme activity.

Hypothalamic–Pituitary–Gonadal Axis

Biochemical findings in aromatase-deficient patients have further clarified the role of estrogens on the sex steroid-gonadotropin feedback system in humans. Aromatase and estrogen receptor alpha are predominantly expressed in the pituitary (Scully *et al.*, 1997; Shughrue *et al.*, 1998) and the hypothalamus.

In patients with aromatase deficiency, the elevated levels of androgens fail to suppress gonadotropins into the normal range in the absence of estrogen supporting the primary role of estrogen in the feedback mechanism of gonadotropin secretion within the hypothalamic–pituitary–gonadal axis in both males and females (Conte *et al.*, 1994; Morishima *et al.*, 1995; Ludwig *et al.*, 1998; Belgorosky *et al.*, 2003; Lin *et al.*, 2007; Guercio *et al.*, 2009; Verma *et al.*, 2012; Janner *et al.*, 2012; Bouchoucha *et al.*, 2014; Marino *et al.*, 2015; Zhu *et al.*, 2016; Morishima *et al.*, 1995; Carani *et al.*, 1997; Herrmann *et al.*, 2002; Maffei *et al.*, 2004, 2007; Lanfranco *et al.*, 2008; Baykan *et al.*, 2013).

In girls with aromatase deficiency, during infancy and childhood the hypothalamic–pituitary–gonadal axis showed persistently high basal and stimulated serum FSH levels (Conte *et al.*, 1994; Mullis *et al.*, 1997; Ludwig *et al.*, 1998; Belgorosky *et al.*, 2003; Lin *et al.*, 2007; Verma *et al.*, 2012; Ludwikowski *et al.*, 2013; Bouchoucha *et al.*, 2014; Marino *et al.*, 2015; Akçurin *et al.*, 2016; Zhu *et al.*, 2016), suggesting that during infancy and childhood, minimal amounts of estrogens are required to restrain pituitary FSH in normal prepubertal females. Basal serum LH levels were quite variable, ranging from normal (Conte *et al.*, 1994; Mullis *et al.*, 1997; Belgorosky *et al.*, 2003; Lin *et al.*, 2007; Hauri-Hohl *et al.*, 2011; Verma *et al.*, 2012; Bouchoucha *et al.*, 2014; Akçurin *et al.*, 2016) to high (Ludwig *et al.*, 1998; Ludwikowski *et al.*, 2013; Marino *et al.*, 2015; Akçurin *et al.*, 2016). A serum LH hyper-response after LHRH stimulation was observed in two girls (Mullis *et al.*, 1997; Belgorosky *et al.*, 2003). Two patients showed initial high basal serum LH levels that normalized thereafter (Marino *et al.*, 2015; Zhu *et al.*, 2016). In two affected girls studied longitudinally (Belgorosky *et al.*, 2003; Janner *et al.*, 2012), different patterns of serum LH levels were found in response to GnRH during prepuberty. LH amplitude was reported to be normal by Janner *et al.* (2012) but high by Belgorosky *et al.* (2003). Belgorosky *et al.* also showed that in early prepuberty, along with normal serum androgen levels, peak serum LH response was 10 times lower than in late prepuberty. It has been known for many years that sex hormones of extragonadal origin (adrenal) or administrated exogenously produce not only the development of secondary sexual characteristics, but also an advance in the induction of the onset of GnRH-dependent puberty in boys and in girls. Therefore, in the study by Belgorosky *et al.*, it was speculated that the pubertal serum LH response to acute GnRH stimulation detected in this aromatase-deficient girl might be secondary to a prolonged effect of androgens on the central nervous system, which includes, among other effects, the maturation of the GH/IGF1 axis, resulting, in turn, in an irreversible maturation of the GnRH pulse generator. In the patient described by Hauri-Hohl *et al.* (2011), accordingly to the clinical phenotype, serum gonadotropin levels measured several times between the ages 4 and 10.5 were always normal. Interestingly, the patient presented with a placenta-specific, prenatally limited component of aromatase deficiency as mentioned earlier.

During puberty, basal and post-GnRH LH and FSH levels were elevated in almost all affected females (Conte *et al.*, 1994; Morishima *et al.*, 1995; Belgorosky *et al.*, 2003; Lin *et al.*, 2007; Guercio *et al.*, 2009; Janner *et al.*, 2012; Verma *et al.*, 2012; Gagliardi *et al.*, 2014; Marino *et al.*, 2015; Saraco *et al.*, 2015). Serum androgens (testosterone and androstenedione) levels were clearly high compared with normal values for age and stage of sexual development mirrored elevated LH levels, whereas serum estradiol levels were extremely low. However, normal serum gonadotropin and androgen levels were found at 10 years of age in an affected patient with a partial form of aromatase deficiency (Marino *et al.*, 2015). This hormonal pattern supports the concept of a primary role of estrogen in the negative feedback mechanism of gonadotropin secretion within the hypothalamic–pituitary–gonadal axis in females. Moreover, levels of serum gonadotropins and testosterone decreased after low-dose estrogen replacement in an aromatase-deficient man (Carani *et al.*, 1997). A different threshold for estradiol action in aromatase-deficient adolescents under estrogen therapy was reported by Guercio *et al.* (2009), Janner *et al.* (2012), Marino *et al.* (2015), and Saraco *et al.* (2015). Even though during late prepuberty and puberty, systemic estrogen administration was followed by clinical signs of estrogen response, such as normalization of growth and skeletal maturation, this was not able to normalize the pituitary–gonadal axis, particularly serum FSH levels and ovarian cysts. It was speculated that this atypical response may have been secondary to lower aromatase activity and poor local estrogen synthesis from androgen precursors in peripheral tissues not only at ovarian levels, but also at local hypothalamic–pituitary levels (Marino *et al.*, 2015; Saraco *et al.*,

2015). It seems unlikely that the lack of serum FSH level suppression was related to a low level of serum inhibin B since in an aromatase-deficient patient reported by Burckhardt *et al.* (2015), the upper normal serum inhibin B levels detected were unable to suppress serum FSH levels under low-dose E2 treatment.

In contrast to affected infant girls, hormonal studies in a 2-month-old boy reported by Deladoëy *et al.* (1999) revealed that basal and GnRH-stimulated FSH levels were normal despite low serum estrogen concentrations, suggesting that estrogens are not involved in the regulation of FSH secretion during infancy. Moreover, in this boy normal serum inhibin B levels for sex and age were found. Hence, it had been proposed that inhibin B might be a major contributor to the regulation of serum FSH secretion in normal infant males. The fact that in the affected boy, free testosterone and androstenedione levels were very high at 2 weeks of postnatal life, followed by a decrease to the normal range during the first month of life, suggests a role for cP450arom in fetal and newborn testicular function. Indeed, it has been described that cP450arom is highly expressed in fetal and neonatal human testes, compared with testes of individuals of older prepubertal ages (Berensztein *et al.*, 2006). This finding suggests that aromatase activity might play a role in modulating testosterone secretion: the high aromatase expression of human neonatal Leydig cells decreased at 2–4 months of age, while peak testosterone secretion occurred during the postnatal testicular activation period. A similar normal hormonal profile, compatible with normal testicular function and gonadotropin secretion, was reported in an affected prepubertal boy at 4 and 6 years of age (Bouchoucha *et al.*, 2014). Therefore, a gender-specific negative feedback mechanism could be suggested, at least during infancy and early childhood.

Data from early and midpubertal boys receiving estrogens or aromatase inhibitors suggest that once puberty starts, estrogens become involved in the negative feedback control of gonadotropin secretion (Kletter *et al.*, 1997; Wickman *et al.*, 2001).

Different studies have evaluated the role of estradiol in the control of gonadotropin secretion in males and have demonstrated that estrogens have a direct modulatory and inhibitory effect on the pituitary release and/or synthesis of LH and FSH (Finkelstein *et al.*, 1991). In adult men with aromatase deficiency slight increments of basal serum FSH were consistently found despite normal inhibin B levels (Morishima *et al.*, 1995; Carani *et al.*, 1997; Herrmann *et al.*, 2002; Maffei *et al.*, 2004, 2007; Lanfranco *et al.*, 2008; Baykan *et al.*, 2013; Chen *et al.*, 2015). Only two male patients with normal FSH levels together with increased basal testosterone levels were reported (Bouillon *et al.*, 2004; Miedlich *et al.*, 2016). It could be suggested that high serum testosterone might be responsible for a complete negative feedback on gonadotropins even in the absence of estradiol. However, in other affected individuals, basal serum FSH levels were increased even when testosterone was elevated above the reference values (Morishima *et al.*, 1995; Rochira *et al.*, 2006). We can also speculate that in the presence of high serum testosterone levels, minimal residual aromatase activity could already be enough for gonadotropin suppression (Miedlich *et al.*, 2016). Nonetheless, normal serum FSH levels were also found in an aromatase-deficient man with null mutations within the CYP19A1 gene (Bouillon *et al.*, 2004).

Basal serum LH levels are within the normal range in most affected aromatase-deficient men, and in only two cases mild increases in serum LH levels were reported (Morishima *et al.*, 1995; Baykan *et al.*, 2013). Nevertheless, when assessed by dynamic tests, increases in LH pulsatility and pulse amplitude were demonstrated in affected men (Rochira *et al.*, 2006; Hayes *et al.*, 2000).

Puberty

Classically, in complete aromatase deficiency at puberty, lack of estrogens results in hypergonadotropic hypogonadism with failure of spontaneous pubertal development and primary amenorrhea but excessive virilization (Conte *et al.*, 1994; Morishima *et al.*, 1995; Lin *et al.*, 2007; Gagliardi *et al.*, 2014). The pubertal spurt is absent and bone age delayed.

Since the first description of partial forms of aromatase deficiency by Lin *et al.* in 2007, variable or nonclassic phenotypes have been reported (Lin *et al.*, 2007; Pepe *et al.*, 2007; Verma *et al.*, 2012; Marino *et al.*, 2015; Saraco *et al.*, 2015), illustrating that phenotypic variability can occur in aromatase insufficiency in humans. Affected females showed spontaneous breast development that in some cases progressed to Tanner stage IV (Lin *et al.*, 2007; Marino *et al.*, 2015), but with primary amenorrhea. In almost all, these findings were accompanied by the presence of a pubertal size uterus, enlarged ovarian cysts, high basal serum gonadotropin and androgen (testosterone and androstenedione) levels, and virilizing signs. Hence, low levels of residual aromatase activity can be associated with breast development and estrogen biosynthesis, particularly when circulating androgenic substrate concentrations (androstenedione, testosterone) are elevated. Functional studies of reported cP450arom mutants showed variable residual aromatase activity that could explain the partial phenotype found (**Table 1**). Interestingly, two described mutations associated with splicing events resulted in transcript variants that were also found in normal human steroidogenic tissues, suggesting that a misbalance between normal and alternative-inactive splicing variants might explain the partial deficiency phenotype.

Detailed information on pubertal milestones in aromatase-deficient males is scarce; however, in most of them pubertal development was normal and persistent linear growth was observed after reaching Tanner stage 5 (Morishima *et al.*, 1995; Carani *et al.*, 1997; Bilezikian *et al.*, 1998; Bouillon *et al.*, 2004; Maffei *et al.*, 2004, 2007; Baykan *et al.*, 2013; Chen *et al.*, 2015; Miedlich *et al.*, 2016). The use of aromatase inhibitors to improve adult height in pubertal boys with idiopathic short stature was associated with an increase in serum gonadotropin levels and a consequent rise in testosterone concentrations, raising concerns about pubertal progression (Hero *et al.*, 2005). It could be speculated that affected boys may show an accelerated pubertal tempo consistent with supraphysiological levels of testosterone.

Gonadal Development

The expression of aromatase in the ovary plays an important role in the regulation of the reproductive cycle in females. Aromatase is also expressed in the male gonad; however, in contrast to its key role as an endocrine coordinator in females, in males, the paracrine effects of aromatase products are essential for normal spermatogenesis (Stocco, 2012).

Ovaries

In the ovaries, cP450arom is expressed in two different stages of differentiation of a unique cell, the granulosa cell: the preovulatory follicles and corpora lutea of ovulatory women. Aromatase expression in the granulosa cells of the ovary is regulated primarily by promoter II under the control of the gonadotropin FSH, whose action is mediated by cAMP. Transcriptionally, regulation is by a hexameric sequence binding SF-1 and an imperfect CRE binding CREB and other factors (Simpson *et al.*, 2002).

The well-timed and cell-specific expression of aromatase in the ovary is crucial for the autocrine regulation of folliculogenesis, the endocrine control of the female reproductive tract, and the coordination of gonadotropin secretion. Estrogen modulation of the structure and function of oviducts, the uterus, and the vagina are essential for oocyte survival, fertilization, and implantation (Stocco, 2012).

Multiple ovarian cysts have been described in human aromatase-deficient patients in infancy and childhood (Mullis *et al.*, 1997; Belgorosky *et al.*, 2009; Marino *et al.*, 2015) and particularly during puberty (Conte *et al.*, 1994; Morishima *et al.*, 1995; Lin *et al.*, 2007; Belgorosky *et al.*, 2009; Verma *et al.*, 2012; Janner *et al.*, 2012; Eklioglu *et al.*, 2014; Burckhardt *et al.*, 2015; Marino *et al.*, 2015; Saraco *et al.*, 2015), as well as in female aromatase knockout (ArKO) mice (Britt *et al.*, 2000). It was assumed that an amplification of FSH signaling that occurred in the presence of high intraovarian androgens could be involved in the development of ovarian follicular cysts already in infancy (Belgorosky *et al.*, 2009; Janner *et al.*, 2012). Accordingly, mutations in the FSHB subunit as well as mutations in the FSH receptor result in a phenotype of small ovaries containing only primordial follicles (Themmen and Huhtaniemi, 2000). It is remarkable that histopathological analysis was consistent with that of the polycystic ovary syndrome (Morishima *et al.*, 1995).

Despite the classical picture of bilateral polycystic ovaries described in the natural development from infancy to adulthood in these patients, the ovarian phenotype is not consistent in some affected females. In 2007, Lin *et al.* reported a pubertal female who had severe aromatase deficiency showed mild postnatal androgenization of the genitalia, moderate elevation of androgen levels at puberty, and small ovaries at adolescence. Functional studies indicated that aromatase activity was severely disrupted, but there was no explanation for her mild excess androgen production. Later, in 2014, Gagliardi *et al.* reported the natural history of aromatase deficiency in a female who was not treated until adulthood. At the age of 25 years, the patient showed the classical phenotype, but bilateral streak ovaries were found on laparoscopy and excised. Histological examination revealed atretic and primordial follicles, but no evidence of ovulation. Streak ovaries are consistent with the phenotype of the ArKO mouse followed through adulthood. An age-dependent phenotype was observed in the ArKO ovaries, with a progressive deterioration or degeneration of the ovaries (Britt *et al.*, 2000). The ovarian morphology of ArKO mice (Simpson *et al.*, 2002) showed an early block in follicular development at the antral stage with absent corpora lutea, followed by hemorrhagic cysts and subsequently, absent secondary and antral follicles and atresia of the primary follicles with increased collagen deposition. This model might explain the phenotype of this adult patient considering that the longer life span of the human may permit more complete follicular atresia and collagen deposition mimicking the classical streak ovaries seen in Turner's syndrome (Gagliardi *et al.*, 2014). Nevertheless, Akçurin *et al.* (2016) have recently described three related Turkish cousins with a severe form of aromatase deficiency secondary to a novel homozygous 568insC mutation. These girls presented with hypoplastic ovaries already in prepubertal years. No functional studies have been performed to understand this complex phenotype. Therefore, the mechanism involved in the ovarian phenotype and outcome is poorly understood.

Testes

In contrast to the restricted expression of aromatase in the ovary, the enzyme is widely expressed in the testis and accessory glands. The wide distribution of aromatase in the male gonads is essential to maintain the high levels of estradiol needed for normal spermiogenesis, sperm maturation, sperm motility, and possibly acrosomal reaction.

In ArKO mice, testicular histology and morphology showed age- and diet-related changes. From 4.5 months of life, dysmorphic seminiferous tubules and disrupted spermatogenesis become noticeable (Robertson *et al.*, 1999, 2002). At 1 year of age, ArKO mice consistently show reduced testicular volume, spermiogenesis failure, and Leydig cell hyperplasia, probably as a consequence of increased serum LH levels.

In aromatase-deficient adult males, testicular volume has been reported to be variable, ranging from macroorchidism (Morishima *et al.*, 1995) to normal (Bouillon *et al.*, 2004; Lanfranco *et al.*, 2008; Miedlich *et al.*, 2016) or even microorchidism (Carani *et al.*, 1997; Maffei *et al.*, 2004). Information on testicular histology and morphology is very scarce, with data from only two affected male adults. One of the patients had a history of bilateral cryptorchidism and surgery at the age of 6, making the interpretation of the findings even more difficult.

Fertility

Several factors may affect reproduction in women with aromatase deficiency, mostly in complete forms, including hypergonadotropic hypogonadism, hyperandrogenism, ovarian cysts, and surgical consequences of genital reconstruction of ambiguous genitalia. Although variable phenotypes have been described and some affected females have partial forms of aromatase deficiency with spontaneous breast development and uterine growth despite androgen excess and virilization (Lin *et al.*, 2007; Pepe *et al.*, 2007; Verma *et al.*, 2012; Marino *et al.*, 2015; Saraco *et al.*, 2015), disease course in adulthood and long-term consequences on fertility are unknown. Data on the long-term follow-up of these patients might clarify our understanding of the reproductive outcomes (Guercio *et al.*, 2015).

Fertility is uncertain in aromatase-deficient males, but may be impaired considering the role of estrogens in human testicular function, spermatogenesis, and fertility. In normospermic adult males, lower sperm concentration and reduced sperm motility were associated with aromatase polymorphisms that decrease enzyme activity (Lazaros *et al.*, 2011). Data on sperm analysis or testicular biopsies of adult aromatase-deficient men are scarce and inconsistent. Pre-existing conditions, such as cryptorchidism, further complicate the interpretation of the results. Total germ-cell depletion, focal hypospermatogenesis, low sperm counts, and decreased motility have been reported (Carani *et al.*, 1997; Herrmann *et al.*, 2002; Maffei *et al.*, 2004, 2007; Baykan *et al.*, 2013).

Gender Identity/Psychosexual Development

In mammals, sex differences in brain structure and function are programmed by exposure to testosterone during a critical period in perinatal development (Cooke *et al.*, 1998). In the female, fetal androgen action might have consequences on brain programming of future sexual identity and behavior (Bao and Swaab, 2011). However, changes in gender identity, sex role behavior, and gender dysphoria are unusual in 46,XX aromatase-deficient patients, although reported in detail in a few cases (Conte *et al.*, 1994; Morishima *et al.*, 1995; Sudeep *et al.*, 2013). Male gender identity, male gender role behavior, and gender dysphoria were reported in only one 46,XX subject raised as male (Lin *et al.*, 2007). Whether prenatal and postnatal androgen exposure coupled with relative estrogen insufficiency—a unique feature of aromatase insufficiency—is important, or whether social and cultural influences are predominant, remains unclear.

In the affected males, adult male cisgender identity, heterosexual orientation, and normal libido have been reported (Morishima *et al.*, 1995; Carani *et al.*, 1997; Herrmann *et al.*, 2002; Maffei *et al.*, 2007; Lanfranco *et al.*, 2008; Chen *et al.*, 2015). Only a modest decreased libido was reported in one subject without change after high-dose estrogen treatment (Morishima *et al.*, 1995; Bilezikian *et al.*, 1998).

Insulin Sensitivity and Lipid Profile

In adipose tissue, aromatase is expressed primarily in the stromal mesenchymal cells or preadipocytes where the majority of aromatase transcripts contain exon I.4 followed by exon I.3 and II (Simpson *et al.*, 2002). Estrogens regulate glucose homeostasis in the skeletal muscle and liver by modulating insulin production in pancreatic β-cells and regulating energy balance in the hypothalamus. In addition, an antilipogenic and pro-lipolytic effect acting directly on adipose tissue has been reported (Foryst-Ludwig and Kintscher, 2010).

Data obtained from ArKO mice of both sexes showed an adipose phenotype together with insulin resistance (IR), elevated serum lipid, and fatty liver, suggesting an association between aromatase deficiency and metabolic alterations (Jones *et al.*, 2000; Nemoto *et al.*, 2000; Takeda *et al.*, 2003).

IR, an abnormal lipid profile, as well as clinical features similar to the metabolic syndrome, have been well described in aromatase-deficient adult men. In these patients, estrogen therapy has been suggested to play an important role in lipid regulation, fatty acid homeostasis, and glucose metabolism (Morishima *et al.*, 1995; Carani *et al.*, 1997; Herrmann *et al.*, 2005; Maffei *et al.*, 2004, 2007; Lanfranco *et al.*, 2008; Baykan *et al.*, 2013; Chen *et al.*, 2015). Recently, however, an aromatase-deficient man harboring the c.628 G>A mutation without biochemical features of IR, dyslipidemia, or overweight/obesity has been reported. Although this mutation has been related to the metabolic phenotype in other affected subjects (Maffei *et al.*, 2004; Guercio *et al.*, 2009), the capacity of the specific mutation c.628 G>A to translate into expression of differentially functioning proteins (Pepe *et al.*, 2007) might explain the variable phenotypes.

In female aromatase-deficient patients, the relationship between carbohydrate metabolism, lipid profile, and estrogen deficiency has not been clearly defined. Lipid abnormalities were found in a Vietnamese affected girl of 18 months of age (Ludwig *et al.*, 1998) and in two adolescents reported by Lin *et al.* (2007). In one of the latter patients the metabolic profile normalized under estrogen therapy. IR and glucose intolerance but a normal lipid profile was reported in two affected females with partial forms of aromatase deficiency at 9 and 13.5 years of age (Belgorosky *et al.*, 2003; Guercio *et al.*, 2009; Verma *et al.*, 2012). Both presented spontaneous thelarche along with high serum FSH levels, clinical and biochemical hyperandrogenism, and ovarian cysts. In two other pubertal affected females with partial aromatase deficiency reported by Marino *et al.* (2015), normal glucose tolerance along with normal androgen levels was noticed. This finding might reflect that high androgen levels contribute to the development of IR in women as previously proposed (Peiris *et al.*, 1989). A more classic or prominent metabolic picture of

abdominal obesity, hepatic steatosis, dyslipemia, and IR was reported in a 25-year-old affected woman in whom estrogen treatment was delayed until adulthood. Since in ArKO mice models, metabolic abnormalities were age dependent, prolonged estrogen deficiency could be required in women to develop a full metabolic phenotype. Long-term studies would be necessary to draw more solid conclusions in this regard.

Even though metabolic abnormalities were resolved by estrogen treatment in ARKO mice (Takeda *et al.*, 2003), in humans, the effect of estrogen therapy on glucose homeostasis and IR is complex and controversial (Jones *et al.*, 2006). Failure to improve IR in some aromatase-deficient patients of both sexes was reported (Herrmann *et al.*, 2002; Maffei *et al.*, 2004; Guercio *et al.*, 2009; Verma *et al.*, 2012; Chen *et al.*, 2015). Moreover, the optimal dose and route of estrogen replacement therapy in such cases are still unclear due to the scarcity of the disease (Chen *et al.*, 2015).

Growth, Skeletal Maturation, and Bone Homeostasis

Androgens and estrogens are important for the maintenance of the skeleton in both sexes (Grumbach and Auchus, 1999; Simpson *et al.*, 2002). The important role of aromatase in bone physiology was clearly shown in ArKO mice (Oz *et al.*, 2000), in which reduced bone density and skeletal abnormalities were observed.

The male aromatase-deficient phenotype is characterized by tall stature with eunuchoid body proportions and continued linear growth into adulthood due to unfused epiphysis, genu valgum, and osteopenia/osteoporosis that remarkable improves with estrogen replacement treatment. This aspect has been addressed in detail in several reports (Bulun, 2014; Grumbach and Auchus, 1999; Bilezikian *et al.*, 1998; Bouillon *et al.*, 2004; Lanfranco *et al.*, 2008; Zirilli *et al.*, 2008; Rochira *et al.*, 2007, 2015).

In affected females bone age is delayed, particularly in late prepuberty, and absence of the growth spurt is observed. Estrogen therapy has been shown to induce a pubertal growth spurt and epiphyseal fusion (Belgorosky *et al.*, 2009; Janner *et al.*, 2012; Verma *et al.*, 2012; Marino *et al.*, 2015; Saraco *et al.*, 2015). Since aromatase-deficient women are treated earlier to induce pubertal development, it may be possible that these subjects, if untreated, will develop the same phenotype as that observed in the male counterpart. Concordantly with this, a nontreated 32-year-old Indian woman with tall stature, eunuchoidal proportions, osteopenia, and fractures was reported (Gagliardi *et al.*, 2014).

Data on the role of estrogens in bone mineralization during childhood are scarce. In the patient reported by Mullis *et al.* (1997), low bone mineral density (BMD) was found. Moreover, BMD improved after treatment with low-dose estrogens, suggesting that minimal quantities of estrogens are also required to preserve mineral bone acquisition in early childhood. Nevertheless, in the case reported by Belgorosky *et al.* (2003), BMD remained normal throughout the follow-up. The explanation could be that in this particular case, partial cP450arom deficiency was found, secondary to a mutation at the consensus donor splice site in the exon 5/intron 5 junction. Therefore, some expression of the cP450arom protein at the growth plate might be expected, which may have been enough to maintain normal mineral bone acquisition, at least during childhood.

Estrogen Replacement Therapy

The clinical consequences of estrogen deficiency in aromatase-deficient patients reinforce the importance of clinical management and estrogen replacement. Recently, this aspect has been carefully addressed by Bulun (2014) and Zhu *et al.* (2016). To date there is no consensus regarding the age of initiation and the dosage of estrogen to use to guide this indication. Thus, such treatment should be individualized at this time.

Conclusions

Patients with cP450arom deficiency represent a source of knowledge on estrogen physiology and pathology, in particular on the role of estrogens in bone maturation, gonadotropin modulation in both sexes, gonadal development and function, as well on glucose and lipid metabolism. Recently, data on new molecular mechanisms have expanded the clinical and biochemical phenotype of affected individuals. At this time, long-term studies are needed to establish a therapeutic strategy to prevent the devastating consequences of prolonged estrogen deficiency.

Introduction

In 1938, Henry Turner described a disorder in seven women which was characterized by absence of female sexual characteristics, increased skin folds in the region of the neck (pterygium colli), a wide angle between the upper and lower arm (cubitus valgus), and short stature. As early as 1930, however, Otto Ullrich had recognized the same disorder as being a specific entity. Before them, in 1768, the anatomist Morgagni already observed inadequately developed ovaries without oocytes in one female patient. Many years later, in 1955, Grumbach et al. described the inadequately developed ovaries as gonadal dysgenesis. After the development of techniques for demonstrating human chromosomes, Ford et al. reported that the cause of the disorder is the absence of one of the X chromosomes.

Definition and Incidence

Nowadays, the syndrome is commonly termed Turner syndrome (TS) and is caused by the complete or partial absence of one of the two X chromosomes in some or all cells of the female body. TS occurs in approximately 1/2000–1/2500 female births and is characterized by 3 main clinical features: (1) abnormal external appearance and abnormalities of certain internal organs; (2) malformation of the ovaries; and (3) short stature.

Genetics

Chromosome Changes

Investigations of the chromosomes are usually carried out by traditional karyotyping of cultured leucocytes. The chromosome change observed most often (in ~50%–60% of patients with TS) is the complete absence of an X chromosome: karyotype 45,X (Table 1 and Fig. 1). If an X chromosome is lost by faulty distribution during later cell divisions or loss of one of the X chromosomes after the formation of the fertilized ovum, then a mixture of cell lines with both normal and abnormal chromosome counts develop, described as a mosaic. This results in karyotypes such as 45,X/46,XX. In these cases, the signs of TS are often present as well, although the phenotype can be milder in case of a low-grade mosaicism (i.e., relatively low percentage of cells showing deviant or missing X chromosome).

TS may also be the result of partial X chromosome loss due to a structural aberration. Such an aberration might, for instance, be caused by transverse instead of longitudinal division of the chromosomes after DNA-replication cell division (leading to an isochromosome of the X chromosome long arm and loss of the short arm), by the major and minor deletions of either the long arm or the short arm of the X chromosome, or by the formation of a ring X chromosome.

Features of TS may also be seen in cases where, besides one of the cell lines mentioned, cells with material from the Y chromosome are present (e.g., karyotype 45,X/46,XY). The presence of Y chromosome material may cause the development of gonadoblastoma. Therefore, probing for Y chromosome material should be performed in any TS patient with evidence of virilization, or when a marker chromosome (a sex chromosomal fragment of unknown origin, i.e., X vs. Y) is found. This can be achieved by molecular studies or FISH (fluorescent in situ hybridization) using a Y centromeric or short arm probe (including the SRY-gene).

Low-grade mosaic TS can easily be missed with conventional karyotyping and analyzing 30 cells. Therefore, in cases of serious clinical suspicion of TS, standard karyotyping and/or FISH of a second tissue, for example, buccal cells or fibroblasts, should be performed. In addition, extended genetic testing of a second tissue should be considered in all patients with a full-blown monosomy 45X to elucidate the complete genotype and to rule out a potential 45,X/46,XY mosaicism.

☆*Change History*: December, 2017. Theo CJ Sas, JAEM van Alfen-van der Velden and Sabine MPF de Muinck Keizer-Schrama has added text and change Table 3 to a simpler form.

This chapter is an update of Theo C. J. Sas, Sabine M. P. F. de Muinck Keizer-Schrama, Turner Syndrome, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 642-650.

Table 1 Some typical chromosome changes and their relative frequency in patients with TS ($n = 649$)

Karyotype	*Number of patients*	*Percentage*
45,X	396	60.9
46,X,Xp-	6	0.9
46,X,Xq-	5	0.8
46,X,i(Xq)	38	5.9
45,X/46,XX	86	13.3
45,X/46,X,i(Xq)	41	6.3
45,X/46,X,r(X)	30	4.6
Complete mosaics and rare deviations (e.g., 46,X.r(X); 45,X/47,XXX; 45,X/46,XX/47,XXX; 45,X/46,X,Xp-)	42	6.5

Notes: 46,X,Xp- = short arm missing; 46,X,Xq- = long arm missing; 46,X,i(Xq) = isochromosome of two long arms; 46,X,r(X) = ring chromosome. Based on collective statistics from Ranke, Brook, Lenko, Prelz, Lippe.

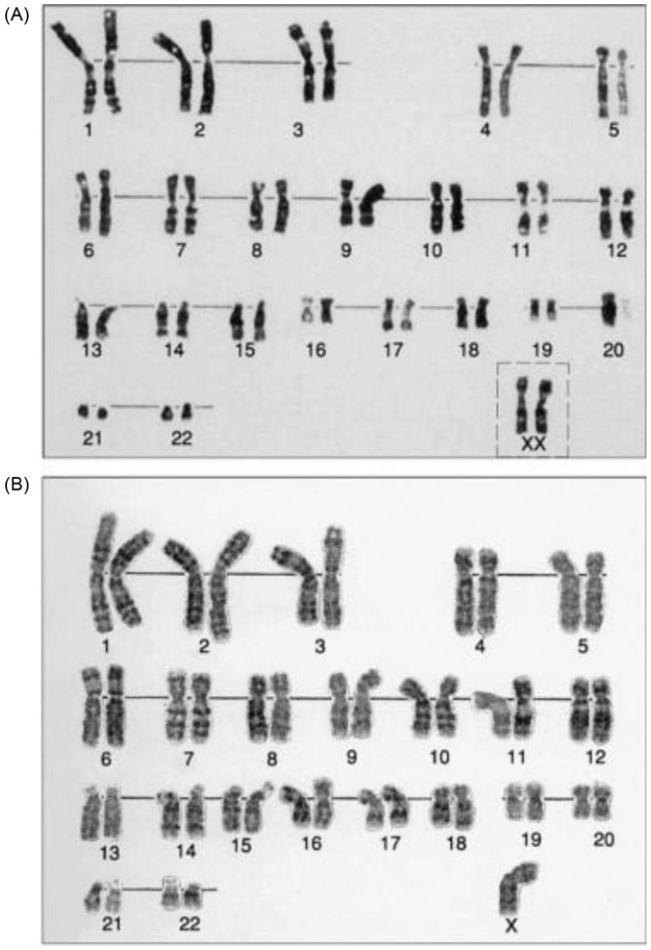

Fig. 1 (A) Normal karyotype and (B) karyotype of a girl with classic Turner syndrome. From Ranke, M.B. (1997). Turner syndrome: A clinical overview. Oxford: Oxford Clinical Communications.

In females with one X chromosome and a deletion distal to Xq24 on the other X chromosome, and in women over the age of 50 years with $<5\%$ 45,X mosaicism, the genetic situation is not considered as TS.

Table 2 Signs and physical features and their frequency in TS

Feature	*Frequency*[a]	*Feature*	*Frequency*[a]
Eyes	20%–39%	*Chest*	60%–79%
Ptosis		Scutiform thorax	
Epicanthus ("Mongol-fold")		Nipples apparently wide apart (not real, appearance results from scutiform thorax)	
Myopia			
Strabismus			
Nystagmus		Inverted nipples	
Ears	40%–59%	*Skeleton*	40%–59%
Deformed auricles		Wide angle of arm (cubitus valgus)	
Otitis media		Short metacarpal/metatarsal bones	
Impaired hearing		Scoliosis	
Mouth, jaw	60%–79%	*Heart vessels*	40%–50%
High arched palate (palatus arcuatus)		Stenosis of aortic isthmus	
		Bicuspid aortic valve	
Small lower jaw (micrognathia)		Aortic dilatation/aneurysm	
Defective dental development		Hypertension	
Skin, skin appendages	60%–79%	*Kidneys*	40%–59%
Lymphedema of hands and feet		Renal malformation (e.g., horseshoe kidney)	
Increased number of pigmented naevi			
		Renal aplasia	
Fingernail and toenail dysplasia		Changes in the renal pelvis and ureters	
Increased skin ridge patterns (dermatoglyphics)		Vessel abnormalities	
Neck	40%–59%	*Ovaries*	80%–100%
Short, thick neck		Gonadal dysgenesis	
Low nape of neck/hair-line			
Start of hair growth in nape of neck pointing upwards			
Pterygium colli			
		Growth	80%–100%
		Small-for-gestational age at birth	
		Growth retardation after birth	

Notes: Frequencies reported in the literature show some variation. Ranges are therefore given for frequency, rather than exact figures.
From Ranke, M.B. (1997). Turner syndrome: A clinical overview. Oxford: Oxford Clinical Communications.

Karyotype/Phenotype Correlation

The wide range of signs and features in TS (Table 2) suggest that a number of different X-located loci are responsible for the complete Turner phenotype. It is now widely accepted that hemizygosity of specific X–Y homologous genes which escape X inactivation (pseudo-autosomal) leads to haploinsufficiency, which in turn causes the characteristic Turner somatic features combined with the associated neurocognitive profile.

The important studies of the relationship between karyotype and phenotype in TS by Ferguson-Smith, published in 1965, first suggested that genes responsible for the TS phenotype could be assigned to specific regions of the X chromosome. With the further development of molecular techniques, it became possible to refine the short stature critical region to the extreme tip of the short arm of the X and Y chromosomes, the pseudo-autosomal region (PAR 1). Subsequently, the PAR 1 short stature gene SHOX (short stature homeobox) was identified, and haploinsufficiency of this gene appeared to be responsible for the disproportionate short stature of patients with TS. Other genetic studies showed that haploinsufficiency of one or more genes in Xp22.3 are associated with the TS neurocognitive profile and a "critical region" for normal ovarian function is assigned to Xq13–Xq26, excluding part of Xq22. However, despite the increasing knowledge of the function of specific X chromosomal genes in relation to the clinical features of TS, a well-defined phenotype-genotype relationship is still not available.

Clinical Features

General

In addition to the short stature and gonadal dysgenesis, there is a multiplicity of findings in patients with TS, occurring with varying frequencies (Table 2 and Fig. 2). The degree of severity of the abnormal appearance is usually most marked when there is a complete loss of an X chromosome (karyotype 45,X). A number of features listed in Table 2 are considered a part of a skeletal

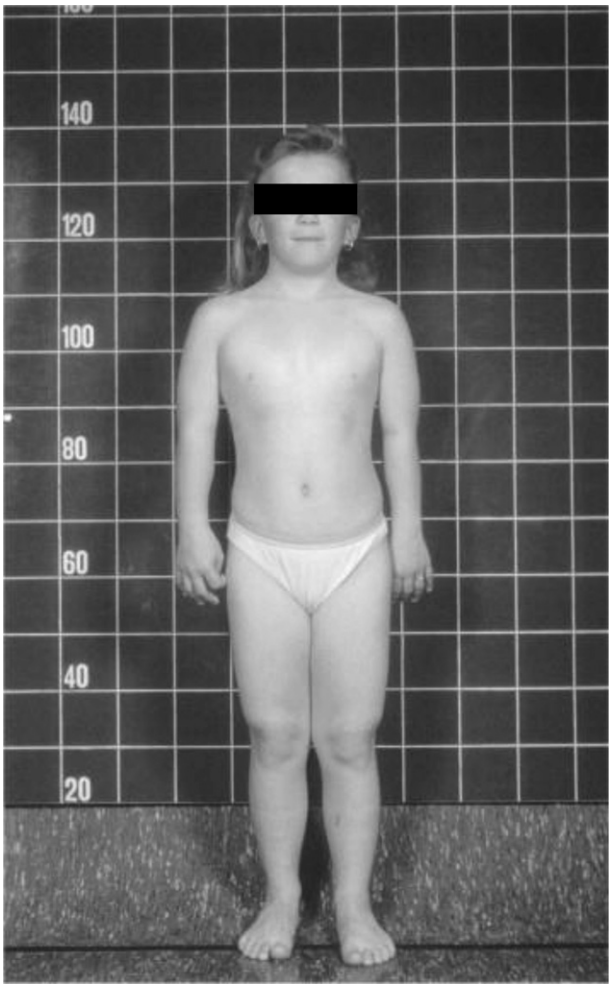

Fig. 2 Girl with Turner syndrome.

growth disturbance while other features can be explained by lymphatic obstruction or germ cell chromosomal defects. The growth failure and ovarian dysgenesis are the features with the highest frequency in TS.

Growth Failure

Growth is reduced in virtually all of the patients. Newborns with TS delivered at term are smaller than average girls, body length by approximately 3 cm, and the body weight by approximately 500 g. Postnatal growth rate appears to be in the normal range during the first 2–3 years of life. Thereafter, height velocity shows a gradual decrease compared with healthy girls, and in most girls, there is a lack of the pubertal growth spurt. Due to the delayed epiphyseal fusion, most untreated girls continue to grow until their late teens or beyond. The mean adult height of women with TS of white European origin ranges from approximately 142 to 147 cm in Northwestern Europe, which is approximately 20 cm smaller than the mean of the normal female population. **Fig. 3** shows the Dutch–Swedish–Danish reference values for height in TS which are based on data from a large multinational study. In 1997, haploinsufficiency of the so-called Short-stature homeobox-containing gene (SHOX) gene was identified as the main cause of short stature in TS. This state of SHOX haploinsufficiency not only appears to be the main cause of the disproportional short stature of women with TS, but is also believed to be the main cause of the relatively broad shoulders and pelvic width. However, other factors such as aneuploidy or chromosomal imbalance have also been suggested to contribute to short stature in TS.

Ovarian Dysgenesis

Since in TS the ovaries usually start to involute within 4 or 5 months of gestation, the majority of patients are infertile, have diminished ovarian estrogen and androgen production, and need estrogen therapy to induce pubertal maturation. However, there is wide variation in the loss of germ cells in girls with TS, such that 5%–10% retain sufficient ovarian function for puberty to commence spontaneously, though in most girls incompletely. The frequency of spontaneous puberty in mosaicism is significantly

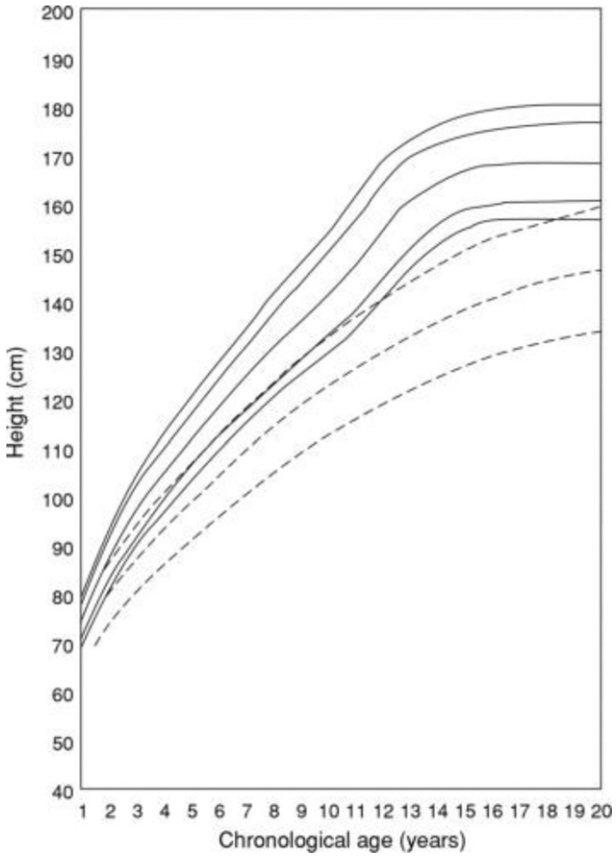

Fig. 3 Reference curve for healthy Dutch girls (3rd, 10th, 50th, 90th, and 97th percentiles, *solid lines*) and for untreated girls with Turner syndrome (North European references; 3rd, 50th, and 97th percentiles, *dotted lines*).

higher compared to the 45,X karyotype. Spontaneous menstrual bleeding occurs only in a few cases, and in most of these patients it persists for only a short period of time. Occasionally, spontaneous pregnancies have been reported.

Diagnosis

Prenatal

Most prenatally detected cases of TS are discovered incidentally during chorionic villous sampling or amniocentesis performed for unrelated reasons, the most common being advanced maternal age, which itself is not associated with an increased incidence of TS. Intra-uterine growth retardation is common in TS as well as polyhydramnion and certain ultrasound findings (e.g., increased nuchal translucency, coarctation of the aorta, renal abnormalities). Even when the prenatal diagnosis has been made by karyotype, chromosomes should be reevaluated postnatally.

Postnatal

Nowadays, TS is most frequently discovered during childhood; however, women are still diagnosed in adolescence and adulthood. The age at which the diagnosis is confirmed depends on the severity of the symptoms. The physical features are not always immediately obvious in every girl with TS, or might even be absent in some cases. Clinicians should always consider the diagnosis in any female patient with unexplained growth failure, pubertal delay, amenorrhea, or infertility.

Management in Childhood, Adolescence, and Adulthood

Recently, a clinical consensus guideline for the management of patient with TS has been published (Gravholt *et al.*, 2017). We give an overview of the most important aspects.

Table 3 Recommended estrogen replacement options for feminization in adolescent TS

Preparation	*Pubertal initiation dose*	*Adult dosing*
Transdermal E2	3–7 μg/day	25–100 μg/day
Micronized 17β oral E2 (E2)	0.25 mg/day	1–4 mg/day
Ethinylestradiol (EE)	2 μg/day	10–20 μg/day
Depot E2	0.2 mg/month	2 mg/month

Notes: Gradually increase E2 dose at 6–12 months interval over 2–3 years to adult dose. Begin cyclic progesterone after 2 years of estrogen or when breakthrough bleeding occurs.
Gravholt, C.H. *et al.* (2017). Clinical practice guidelines for the care of girls and women with Turner syndrome: Proceedings from the 2016 Cincinnati International Turner Syndrome Meeting, *European Journal of Endocrinology* **177**(*3*), G1–G70.

Short Stature

Although girls with TS are not GH deficient, treatment with biosynthetic recombinant human GH accelerates height velocity. To determine the effect of GH on adult height, the attained adult height is compared to the individually predicted adult height at the start of the GH treatment based on references for untreated girls with TS. In many countries, TS is an accepted indication for GH treatment, although controversy exists regarding the effects of GH treatment on adult height, since the mean increase in adult height varies between 0.2 and 16.0 cm in the different publications. For most girls a minimal gain in adult height of about 10 cm can be achieved when GH is started before the age of approximately 8 or 9 years (preferably from 6 years onwards) with a daily GH dose of about 0.045 mg kg^{-1} day^{-1} ($\sim$1.4 mg m^{-2} day^{-1}; $\sim$4 IU m^{-2}). A lower daily GH dose, as used in Europe for children with GH deficiency, does not seem to be enough to overcome the negative effect of the SHOX deficiency. An even higher GH dose, which is proven to be more effective, could be considered in extremely short girls or girls who are relatively old at diagnosis with a poor adult height prognosis. An alternative is the addition of the synthetic anabolic steroid oxandrolone (Ox) to the growth hormone therapy which increases the gain in adult height more than GH alone.

In general, in children who received GH treatment a small increase in the incidence of kyphoscoliosis, diabetes mellitus type 2, and benign intracranial hypertension is reported. Although supraphysiological GH dosages are given for several years in TS, no negative side effects of clinical importance of long-term GH treatment are found, besides a very slight increase in the incidence of edema in the first weeks of the treatment. GH has no adverse effects on glucose levels, but induced higher levels of insulin which decreased after discontinuation of GH. GH has no negative effect on heart morphology and function, blood pressure, aortic dilatation and stiffness, blood lipids, or bone density. During the relatively high-dose GH therapy, IGF-I levels increase to high normal levels but in some girls to levels above the $+2$ standard deviation (SD). Higher GH doses increase the IGF-I levels even more. It is unknown whether the higher IGF-I levels could have negative effects on health on the very long term. Consequently, most physicians will lower the dose of GH when the IGF-I levels are several times above the $+2$ SD. Long-term GH treatment seems to be safe, but continued observation into adulthood is required. If Ox dosages <0.06 mg kg^{-1} day^{-1} are used in addition to GH, side effects of Ox are mild. The most relevant safety concerns of treatment with Ox are virilization (including clitoromegaly and voice deepening) and a transient delay of breast development.

Gonadal Dysgenesis

Induction of Puberty

To induce puberty, continuous treatment with estrogens has to be given to girls with TS. Although 5%–10% retain sufficient ovarian function for puberty to start spontaneously, most girls show a progressive ovarian failure and need estrogen therapy for complete breast development and withdrawal bleeding. Administration of the natural estrogen 17β-estradiol is the treatment of choice for puberty induction. Micronized 17β-estradiol can be given either orally or, to avoid the first pass effect by the liver, transdermally. With transdermal (TD) patches or percutaneous gel, spontaneous pubertal hormonal changes are mimicked and normal pubertal development is achieved. Alternatively, oral ethinylestradiol can be used for puberty induction, when 17β-estradiol is not available. As oral ethinylestradiol is a synthetic estrogen that is not metabolized by the liver, it can be delivered at relatively low doses. However, synthetic estrogens have more pronounced effects on coagulation factors, lipid profiles, and blood pressure than natural estrogens. Other forms of estrogens are available as well. However, conjugated equine estrogen preparations (CEE, Premarin®) contain multiple estrogens, progestins, and androgens, some of which are not found in humans and are not justified for use in children. Similarly, for pubertal induction the oral contraceptive pill is best avoided, because the synthetic estrogen doses are too high and the typical synthetic progestin may interfere with optimal breast and uterine development. Furthermore, the oral contraceptive pill is conventionally taken with a pill-free week, resulting in 3 months of estrogen deficiency for each year of use.

In the absence of spontaneous puberty or stunted breast development, puberty induction is recommended from the age of 11–12 years to support psychosexual maturation and self-esteem. Although the appropriate starting dose has yet to be determined,

estrogen replacement is usually begun at 1/10–1/8 of the adult replacement dose and then increased gradually over a period of 2–4 years. To allow for normal breast and uterine development, it seems advisable to delay the addition of progestin at least 2 years after starting estrogen or until breakthrough bleeding occurs. Natural micronized progesterone and dydrogesterone or medoxyprogesterone are preferred to other progestagens because of their less negative effect on lipid metabolism and less androgenic effect. Based on these principles, suggested age-specific preparations and doses of estrogen substitution therapy in adolescence are listed in **Table 3**. This table is only a guideline, and individual tailoring of dose and timing will be required. Whether even earlier very low-dose estrogen administration from the age of 5 years onwards has beneficial effects on bone, cognition, and self-image in patients with Turner's syndrome remains to be proven and is not considered standard treatment.

Hormonal Replacement Therapy in Adulthood

To treat the short- and long-term consequences of estrogen deficiency in women with TS, continuation of hormonal replacement therapy (HRT) until the age of normal menopause is highly recommended. The available studies indicate that HRT has beneficial effects on bone density, risk of cardiovascular disease, and hyperinsulinism. In addition, HRT might have positive effects on general well-being, cognition, and psychosocial functioning. Natural estrogens are recommended either orally (2–4 mg 17β estradiol daily) or transdermally (50–200 μg 17β estradiol daily), combined with cyclic progestin. Since overweight and hypertension can be exacerbated by exogenous estrogen, particularly when administered by the oral rather than transdermal route, blood pressure should be checked at regular intervals.

Fertility

Ninety-five percent of women with TS are infertile. Abnormal germ cell development combined with accelerated oocyte loss result in a percentage of only 5%–10% of TS girls who will have oocytes remaining in their ovaries at pubertal age. Those with remaining follicles may develop ovulatory cycles and will have a short period of fertility prior to entering into a premature menopause. In general, outcomes of spontaneous pregnancy in TS women are poor, with miscarriage rates of 30%–45%, and structural and chromosomal abnormalities may affect 25% of live births.

In women with persisted ovarian function, cryopreservation of oocytes after ovarian hyperstimulation is a possible fertility preservation option. The availability of oocyte donation combined with in vitro fertilization now offers these women a realistic change of conceiving and delivering a healthy child. While recent case series indicate that implantation and pregnancy rates rival those obtained in non-TS women, women with TS may have higher rates of early pregnancy loss compared to other groups with premature ovarian insufficiency (early miscarriage 0%–80% vs. 8.7%), indicating reduced endometrial and uterine function.

Pregnancy is associated with maternal morbidity. Those with cardiovascular abnormalities may be at risk of aortic dissection, and pre-pregnancy screening for pre-exiting dilatation of the aortic root is therefore recommended. In addition to possibly increasing the rate of miscarriage, the hypoplastic uterus frequently observed in adult TS may be prone to rupture in late pregnancy. Furthermore, an increased risk of cephalo-pelvic disproportion at delivery exists. The mechanical and physiological stresses of pregnancy may be reduced by avoiding multiple pregnancy.

Other Medical Problems

Cardiovascular Disease

The most frequently observed major congenital cardiovascular abnormality in TS is the coarctatio aortae, which can be corrected by surgical intervention. Morphological abnormalities of the aortic valves, which are often found, are mostly not of clinical significance in childhood. The incidence of hypertension is higher in girls and adults with TS compared to healthy peers. The mechanisms leading to hypertension in these individuals are unknown and not clearly related to the cardiac or renal congenital abnormalities. Obesity, which is common in the adolescent and adult individuals, contributes to high blood pressure. Rupture of an aneurysm or dissection of the aorta in childhood has been rarely described and is associated with hypertension. However, even in the absence of predisposing factors as aortic valve abnormalities or hypertension, this life-threatening event occurs more frequently than in the normal population and can even occur at a younger age. Therefore, evaluation and follow-up of the cardiovascular dimensions using ultrasound in childhood and MRI in adulthood and monitoring blood pressure are required with adequate treatment when indicated. Particularly before and during pregnancy, repetitive MRIs of the aorta are required. In childhood as well as in adulthood, the measured aortic diameter has to be compared with the references and cut-off levels of girls or women with similar height (and weight or body surface).

The three times higher mortality in TS women is due to complications of structural abnormalities of the heart and aorta, as well as to the higher risk of ischemic heart disease and stroke. The chronic estrogen deficiency known to affect many adult women with TS is likely to be associated with increased cardiovascular morbidity, since it is becoming clear that estrogens confer cardioprotectivity not only by lowering harmful circulating lipids, but also through direct antioxidant effects, through the interaction of estrogens with smooth vascular muscles.

Fig. 4 Turner girl with pterygium colli (webbed neck).

Ocular Problems

The eyes often show slight changes in the position and form of the palpebral fissure or ptosis can be observed; this does not affect function. It is important that visual disorders and squinting should be diagnosed and treated as early as possible, to prevent further deterioration or permanent damage.

Ear and Hearing Problems

Ear malformations are frequently observed in patients with TS (**Table 2**) Furthermore, recurrent periods of otitis media are found in 50%–80% and complications are common, for example, cholesteatoma and tympanic membrane perforation. Conductive and sensorineural hearing loss is frequently observed in girls and women with TS, and correlates with the karyotype. Audiometric measurements often show a sensorineural dip in the midfrequencies. In young girls with TS this seldom leads to hearing impairment, but the dip broadens and the depth progresses over time, leading to social hearing problems later on. A high frequency hearing loss (presbyacusis) is also added to the dip at the age older than 35 years, leading to rapid hearing loss and social hearing problem at a younger age than in the normal population. About 26%–44% of adult women with TS have serious hearing loss requiring hearing aids. Frequent audiometric screening is important in girls and women with TS, since hearing loss negatively affects quality of life.

Skin and Neck

Swelling of the back of the hands and feet due to lymphedema is not exclusive to TS but is a striking feature, particularly in the newborn. In most girls the lymphedema shows a tendency to regress after birth. Some patients have an increased number of pigmented naevi, which are usually benign but often show a tendency to grow during puberty. Some clinical evidence has shown that, when GH is administered for short stature, the growth of melanocytic naevi is boosted without signs of malignant transformation. The patient's neck often appears short and thickset. In addition, a pterygium colli (webbed neck) can be found (**Fig. 4**), which can be corrected by surgery (favorable after a bilateral tissue-expander procedure). However, keloid scars develop more often than usual after surgical interventions.

Skeleton and Bone Mineral Density

Besides the "classic" cubitus valgus, occasionally Madelung's deformity of the wrist (the ulna projects beyond the level of the hand because the wrist is displaced towards the palm of the hand) or some other minor deformities of the hands and feet are found. In addition, girls and women with TS have relatively large hands and feet in relation to their height. Another skeleton problem is the higher risk of scoliosis in girls with TS than in the general population, particularly after 10 years of age. Consequently, if physical examination shows scoliosis, an orthopedic follow-up is required. Furthermore, girls with TS have a higher risk of congenital hip dysplasia. In addition, slipped capital femoral epiphysis is a rare complication of GH treatment. Consequently, every girl with TS with persistent pain in knee or hip needs referral to the orthopedic surgeon.

The risk of fractures in TS is higher than in the general population. This is partly due to the lower bone mineral density in TS as well as due to the higher risk of falling. Individuals with TS have an intrinsic defect in the cortical bone formation leading to higher risk of fractures of the long bones. When the estrogen deficiency is not treated sufficiently, the bone mineral content of the trabecular bone will be decreased, leading to a higher risk of (compression) fractures of the vertebra.

The interpretation of the two-dimensional dual energy X-ray absorptiometry (DEXA) measurement is more complex in individuals with short stature than in individuals with normal stature, leading more often to false lower values in TS. Consequently, a volumetric correction (bone mass per volume instead of bone mass per bone surface) has to be used. It is well known that treatment with estrogens is pivotal in order to avoid rapid bone mineral loss in adolescents and young adults. An adequate calcium and vitamin D intake as well as sufficient physical exercise are warranted as well.

Renal Disorders

Up to one-third of individuals with TS have structural renal malformations. Rotational abnormalities and double collecting systems are found most frequently. Although many of these abnormalities are without significant major renal complications, some may result in an increased risk of hypertension, urinary tract infections, or hydronephrosis. A renal ultrasound must be carried out at the time of diagnosis.

Autoimmunity: Thyroid Disease and Celiac Disease

Clinical and epidemiological evidence shows that the risk of autoimmune disease and especially thyroid disease is increased in TS. Up to 50% of women with TS have anti-thyroid antibodies and auto-immune thyroiditis is common: almost a quarter of the adult patients have hypothyroidism compared with 1%–2% of the general population. In addition, the incidence of celiac disease is higher in those with TS than in the general population. Consequently, thyroid hormone measurements and regular celiac antibody screening (or HLA DQ assessment) are required.

Glucose Metabolism and Insulin Sensitivity

Increased frequency of abnormal glucose tolerance, reduced insulin sensitivity, hyperinsulinemia, and inappropriately low insulin secretion are seen in TS. In a register study covering the entire population in Denmark, an increased relative risk of 4.38 was found. Not only type 2, but probably also type 1 diabetes is more prevalent in TS. Adiposity, which is seen in a large proportion of the adult Turner population sometimes combined with decreased physical fitness, is an important player in the development of type 2 diabetes.

Hepatic Function

Higher serum levels of hepatic enzymes such as alanine aminotransferase, gamma glutamyl transferase, and alkaline phosphatase have been found in adult TS women compared with controls. These elevated levels of some hepatic enzymes and proteins do not seem to be associated with overt hepatic disease. However, sometimes the elevated hepatic enzymes can be the first sign of celiac disease; therefore, a test for celiac disease should always be performed.

Cancer

The relative risk of most cancers is low in TS and comparable to that of the general population, with the exception of the colon and rectum. In two separate registers in Denmark, it was found that the relative risk of these cancers was 5–7 times that of the background population. In contrast, a British study on a national cohort of 3425 women with TS showed an increased risk of meningioma and childhood brain tumors, and possibly bladder cancer, melanoma, and corpus uteri cancer. However, the absolute risks are still small.

Since sex hormone substitution may lead to an increased risk of cancer of the breast and reproductive organs, concern have been raised about a possible increased risk in TS women on HRT. However, no increased risk in the two Danish registers has been found. Gonadoblastoma might develop in the ovaries of girls and women with TS with Y chromosome material. Therefore, in many countries it has become a standard procedure to determine Y chromosome material with fluorescent in situ hybridization (FISH) in a second tissue, for example, buccal mucosa, in girls with monosomy 45X. The risk of developing gonadoblastoma has previously been estimated as 25%–40%, although more recent data suggest a lower risk of only 7%–10%. Nevertheless, gonadectomy is still recommended in girls with TS with Y chromosomal material, to exclude malignancy with absolute certainty.

Cognitive and Psychosocial Abilities

No increase in the prevalence of mental retardation is associated with TS, except for these few patients with a ring X chromosome that fails to undergo X inactivation. Numerous studies have documented that girls with TS have a neurocognitive profile consisting of visuo-spatial information processing deficits in the context of relatively preserved verbal skills. In particular, persons with TS are impaired in the coding and transforming of visuo-spatial information. Compared to healthy controls, girls with TS are described as exhibiting difficulties with tasks of left/right discrimination, road map skills, mental rotation, line orientation, and integration of motor and visual/perceptual skills. It has been reported that girls with TS are vulnerable to specific behavioral problems, particularly hyperactivity and inattention, as well as learning disabilities.

In conjunction with behavioral problems, girls with TS often exhibit difficulties with social development and functioning. They have been described as showing delayed emotional maturity, difficulty understanding social cues, needing more structure to socialize, poor peer relations, shyness, and poor body image. Impairments in self-concept and self-esteem increase during adolescence, but interestingly improve with the initiation of estrogen replacement therapy. Abnormalities in cognitive and psychosocial abilities in persons with TS likely reflect underlying atypical brain development and function.

Girls with TS have a typically female pattern of development, with unambiguous female gender identification. Dating and initiation of sexual activities, however, may be somewhat delayed or infrequent. It is not clear whether this reflects some underlying genetic or hormonal influence on behavior or simply discomfort, because of the issues of short stature, physical anomalies, and infertility, with which women with TS have to cope.

Motor Performance

Girls with TS show substantially lower performance in gross and fine motor function tests, and motor milestones are achieved relatively late. Moreover, girls with TS frequently encounter problems in specific motor functioning, that is, oral-motor and visual-motor coordination, motor learning, and problems with accuracy and movement speed. Impaired motor ability can result in multiple practical problems that are age specific. Examples of these practical consequences include feeding difficulties (infancy), problems with writing, participation in sports (school age), and choice of study and employment (adolescence).

Klinefelter Syndrome

Shanlee M Davis, University of Colorado, Boulder, CO, United States
Judith L Ross, Thomas Jefferson University, Philadelphia, PA, United States

Glossary

Aneuploidy Abnormal number of chromosomes; in humans, fewer or >46 chromosomes.
Azoospermia Absence of motile sperm in the semen.
Epigenetic Heritable changes in gene activity and expression that are not due to changes in the DNA sequence.
Hypergonadotropic hypogonadism Poor function of the gonads (either testes or ovaries) resulting in insufficient sex steroid hormone production and elevated luteinizing hormone (LH) and follicle stimulating hormone (FSH) from the pituitary gland due to lack of negative feedback.
Microorchidism Small testes (testicles).
Noninvasive prenatal screening A method to screen for fetal chromosomal abnormalities through cell-free DNA in maternal blood.
Spermatogenesis The production of mature spermatozoa (sperm) occurring in the testis.
Spermatogonia Undifferentiated male germ cells in the testis that will undergo spermatogenesis.
Testicular sperm extraction (TESE) Surgical procedure to remove testicular tissue and extract viable sperm to be used in intracytoplasmic sperm injection (ICSI).
Virilization Development of masculine physical characteristics including penile growth, body hair, and deepening of the voice.

Introduction

Klinefelter syndrome (KS) was first described in 1942 by Dr. Harry Klinefelter, with clinical features of primary gonadal failure and tall stature in men (Klinefelter *et al.*, 1942). In 1959, Dr. Patricia Jacobs identified that this clinical phenotype was associated with an additional X chromosome, or karyotype 47,XXY (Jacobs and Strong, 1959). In the past 60 years basic science, translational, clinical, and epidemiological studies have greatly advanced our knowledge of both the endocrine and nonendocrine manifestations of KS, but the science particularly in the fields of genetics and reproductive endocrinology, continue to evolve our understanding of the pathophysiology and best management practices for KS.

There is some debate among parents and the professional community alike regarding terminology. The argument by some is that not all males with a 47,XXY karyotype have KS as they do not exhibit the features originally described in the syndrome, particularly in childhood, therefore should not be called KS. In addition, whether supernumerary aneuploidies including 48,XXYY, 48,XXXY, and 49,XXXXY are variants of KS or independent syndromes (Tartaglia *et al.*, 2011). For the purpose of this endocrine-focused chapter, we use KS to refer to any phenotypic male with an at least two X chromosomes and at least one normal Y chromosome, recognizing significant heterogeneity exists.

Clinical Overview

The additional X chromosome in males nearly universally results in abnormal testicular development, microorchidism, hypogonadism, and infertility (Davis *et al.*, 2015). Tall stature with longer extremities due to both genetic and hormonal factors is classically described but not ubiquitous. Many other conditions associated with KS include developmental delay, language-based learning disorders, mental health disorders, osteoporosis, diabetes, autoimmunity, and others (Davis *et al.*, 2016a). It is important to recognize that the presence and severity of any of these associated conditions are variable, resulting in a great deal of phenotypic heterogeneity.

Morbidity and mortality is higher in KS than reference male populations. Cohort studies from Europe have estimated the all-cause standardized mortality rate to be slightly higher than the general population, corresponding to approximately 2.1 years shorter lifespan (Bojesen and Gravholt, 2011). The risk of being admitted to the hospital is 70% higher in KS than the general population (Bojesen *et al.*, 2006a). The categories of causes for hospitalization and death that are greater in KS than the general population are numerous including diseases of the endocrine, nervous, respiratory, circulatory, digestive, and genitourinary systems.

Epidemiology

The estimated prevalence of KS is ~1 in 600 male births, making it the most common sex chromosomal aneuploidy (Coffee *et al.*, 2009; Nielsen and Wohlert, 1990; Herlihy *et al.*, 2011; Bojesen *et al.*, 2003). There is some evidence the prevalence may be increasing over time, although this needs to be confirmed (Morris *et al.*, 2008). Advanced maternal age is associated with an increased risk of chromosomal aneuploidies, however the relationship of parental age and 47,XXY is not as strong as with autosomal aneuploidies.

 doi:10.1016/B978-0-12-801238-3.66137-8

Diagnosis

A karyotype or chromosomal microarray will identify the extra X chromosome diagnostic of KS. This is typically performed on peripheral blood lymphocytes, however other tissue types including epithelial cells from a cheek swab or skin biopsy can also be used. Despite the high prevalence, historically only 25%–35% of males even in developed countries are ever correctly diagnosed (Abramsky and Chapple, 1997; Bojesen and Gravholt, 2011). This is not usually because they are not affected, but rather their symptoms are not recognized by clinicians. Earlier diagnosis allows for appropriate counseling, screenings, and interventions, and potentially better outcomes, but studies are needed to quantify this protective effect and identify best practices.

KS should be suspected and genetic testing should be obtained in any adolescent or adult male with microorchidism or hypergonadotropic hypogonadism. In infancy and childhood there are no pathognomonic features that lead to a diagnosis of KS, therefore a high degree of clinical acumen is needed to suspect this condition prepubertally. Noninvasive prenatal screening can detect KS and other sex chromosome aneuploidies in utero, and due to the test's relatively low-cost, low-risk, broad availability, and high reliability for autosomal aneuploidies, this is emerging as routine screening in prenatal care (Gregg *et al.*, 2016). Thus our KS patient population is being redefined, particularly in pediatrics, where the majority of patients will be identified through screening rather than by directed testing.

Genetics

The supernumerary X chromosome is typically a de novo nondisjunction error occurring during maternal or paternal gametogenesis. The supernumerary X chromosome can also be due to postzygotic errors in mitosis in the developing embryo. Rare cases of maternal trisomy X have been reported. However, KS is usually a random event and the chance of recurrence in subsequent pregnancies is low. Approximately half of the second X chromosome are paternal versus maternal in origin and there are conflicting results as to whether parental origin contributes to phenotypic variability.

Mosaicism is present in $\sim$7% of cases of KS and is associated with a more mild phenotype if a normal 46,XY cell line is present. In contrast, mosaicism with tetrasomy or pentasomy lines often have a more severe phenotype. Predicting phenotype based on the degree of mosaicism is difficult, however, as tests are typically only done in one tissue type (peripheral blood lymphocytes) and may or may not accurately reflect tissue-level mosaicism percentages.

The genetic mechanisms and pathophysiology of the clinical features of KS are multifactorial and remain poorly understood. When two or more X chromosomes are present (in males or females), the second X chromosome is largely silenced through a process of X-inactivation. Therefore, the majority of extra X genes are not expressed. Usually this occurs in a random fashion, however preferential inactivation of one X over another (skewed inactivation) has been reported in 10%–40% of males with KS and may correlate with phenotype (Iitsuka *et al.*, 2001). There are also genes that escape X-inactivation and these genes are expressed in duplicate (or triplicate in cases of trisomy). A classic example is the short-stature homeobox (SHOX) gene, a critical gene for linear growth located in the pseudoautosomal region of the X and Y chromosomes. In Turner syndrome (45,X), only one copy of the SHOX gene is expressed and short stature is a nearly universal feature of the condition. In KS and other sex chromosome trisomies (47,XXX and 47,XYY), a total of three copies are expressed and taller stature is a common feature of these conditions. All of the genes in the pseudoautosomal region and another 5%–15% of genes on the X chromosome escape X-inactivation and may therefore be expressed and potentially influence cellular and metabolic pathways (Berletch *et al.*, 2011).

Like all phenotypic variation in humans, polymorphisms in specific genes likely contribute to the variation seen in KS. The androgen receptor gene is particularly of interest due to its location on the X chromosome and the known hypogonadism. Longer CAG repeat lengths are associated with lower receptor activity, and in KS this has been associated with greater severity of the KS phenotype (taller stature, longer arm span, gynecomastia, and delayed puberty) (Zinn *et al.*, 2005; Chang *et al.*, 2015). Copy number variants are another reason for population variation and are reported to be more common on the X chromosomes of males with KS compared to control male or females (Rocca *et al.*, 2016).

Finally, an emerging area that needs additional attention is the role of the autosomes in the KS phenotype. The presence of an additional chromosome in both sex chromosome aneuploidy as well as trisomy 21 (Down syndrome) is associated with differential gene expression throughout the genome (Huang *et al.*, 2015; Zitzmann *et al.*, 2015; Do *et al.*, 2017). These epigenetic changes exponentially increase the complexity of the mechanisms involved in the phenotypic heterogeneity in KS.

Testicular Dysfunction

Testicular dysfunction is nearly universal in males with KS, although the molecular mechanisms underlying this are largely unknown. Microorchidism is essentially universal ($<$10 mL and usually $<$6 mL in adults), resulting in a discordance between the degree of virilization and testicular volume. The relative or absolute hypogonadism results in follicle stimulating hormone (FSH) and luteinizing hormone (LH) elevation. KS is the most common cause of hypergonadotropic hypogonadism in men.

Germ, Sertoli, and Leydig cell lines are all impaired in KS. **Fig. 1** reviews the hypothalamic pituitary gonadal axis in KS. Germ cells are noted to be fewer in number from a very early age and progressively decline particularly in puberty, with adult testes having no or rare pockets of spermatogonia (Davis *et al.*, 2015). Sertoli cell function is unequivocally poor as evidenced by lack of

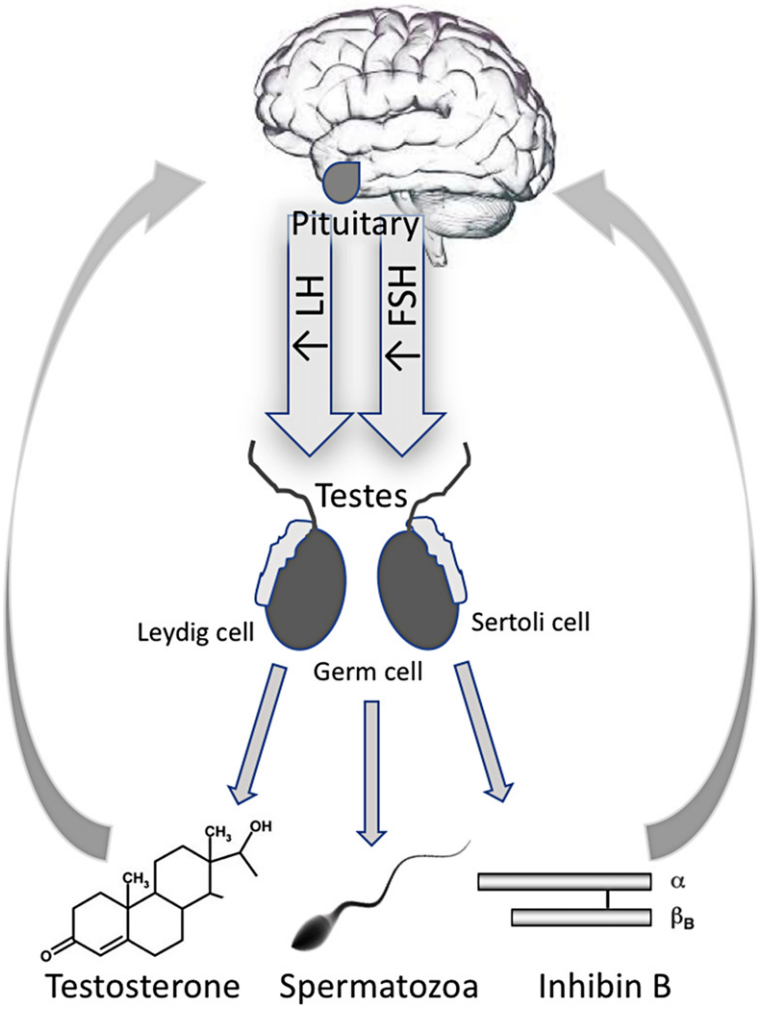

Fig. 1 The hypothalamic–pituitary–gonadal axis in KS. The extra X chromosome results in testicular dysfunction affecting germ cells > Sertoli cells > Leydig cells. Spermatogenesis and hormone production is impaired, which reduces negative feedback to the pituitary gland. The pituitary gland increases secretion of luteinizing hormone (LH) and follicle stimulating hormone (FSH) to stimulate the Leydig and Sertoli cells respectively.

the pubertal rise in inhibin B and low or undetectable levels in adulthood. Sertoli cell function may already be impaired in a subset of prepubertal boys with KS (Davis *et al.*, 2016b).

Testosterone Throughout the Lifespan

Leydig cell function in KS is more variable. Around 2–4 months of age, the hypothalamic–pituitary–gonadal axis is activated in males resulting in a testosterone surge known as "mini-puberty" (Rey, 2014). Mini-puberty does occur in infants with KS, however the few small studies that have been done have mixed conclusions as to whether testosterone is lower. The largest of these studies and the only one to use the gold-standard tandem mass spectroscopy reported testosterone was lower than average (Cabrol *et al.*, 2011). After mini-puberty but prior to true puberty, testicular testosterone production is normally minimal and whether testosterone deficiency is present prepubertally in KS remains an area of debate (Fennoy, 2011). Puberty starts normally in the majority of individuals with KS, however, LH rises about 2 years after pubertal onset on average. Testosterone initially rises appropriately in puberty but then plateaus or even declines (Bastida *et al.*, 2007). Based on these data, monitoring physical exam, gonadotropins, and testosterone throughout puberty is recommended. In adulthood, some men with KS will maintain serum testosterone concentrations within the low-normal adult range, however LH will be high and physical signs of hypogonadism, such as gynecomastia, can be present despite testosterone within the normal range (Davis *et al.*, 2015; Pacenza *et al.*, 2012).

Testosterone Replacement

There are not rigorously conducted studies to date evaluating the timing, formulation, or dosage of testosterone in KS. Therefore, there are a variety of approaches in when (and how) to initiate testosterone replacement (**Fig. 2**). In general, many pediatric

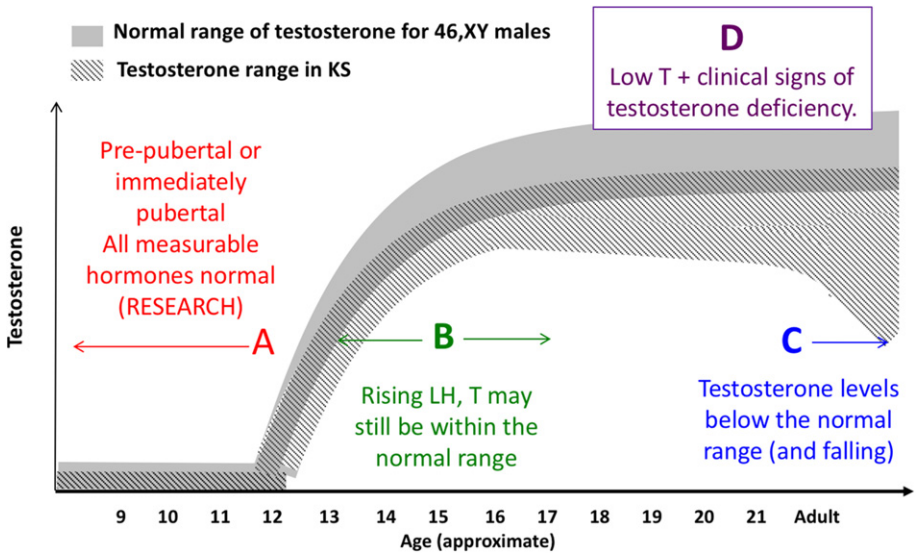

Fig. 2 Practice variations in testosterone initiation. Throughout the lifespan, serum testosterone concentrations in KS overlap with typical 46,XY males. There are no accepted standards for initiating testosterone replacement in KS. The most conservative is waiting until testosterone is low and there are clinical signs of testosterone deficiency (D). However, many symptoms of testosterone deficiency are subjective and/or are late-onset, therefore some will initiate treatment when testosterone is low but symptoms may not yet be present (C). Due to high luteinizing hormone (LH) and limitations of testosterone assays, a more proactive approach is testosterone supplementation before serum testosterone levels are overtly below the normal range (B). And finally, there is interest in using low-dose testosterone in prepubertal ages, but this is investigative (A).

endocrinologists in the United States will proactively consider testosterone treatment when LH is unequivocally above the normal range, much like treating compensated hypothyroidism when thyroid stimulating hormone is elevated. However, this is at odds with the Endocrine Society Clinical Practice Guideline that advises testosterone treatment should only be given for androgen deficiency syndromes, defined by unequivocally low testosterone (Bhasin *et al.*, 2010). Elevated LH, low testosterone, and clear symptoms of hypogonadism such as gynecomastia, stalled puberty, fatigue, and low libido is the most conservative approach, but there are concerns that this reactive rather than proactive approach may contribute to the higher risk of osteoporosis and metabolic syndrome, and negatively affect cognition and mental health. Due to the lack of evidence and variety of professional opinions, patients and parents have an especially important role in shared decision making regarding testosterone replacement in KS.

There are a variety of formulations available to provide exogenous testosterone. Injections, transdermal gel, transdermal patches, buccal tablets, and pellet implants are all FDA approved for male hypogonadism in adults with associated benefits and side effects for each formulation (Bhasin *et al.*, 2010). Any of these options are available to adult men with KS, however the long-acting formulations are not ideal for adolescents or adults with mild hypogonadism who may not need a full replacement dose (Rogol and Tartaglia, 2010). Low-dose intramuscular or subcutaneous injections or transdermal gel are best for testosterone initiation, particularly in adolescents (Rogol *et al.*, 2014). Monitoring for and managing side effects should follow the general guidelines for testosterone replacement (Bhasin *et al.*, 2010).

Fertility

Azoospermia is characteristic of KS, with $<10\%$ having any spermatozoa in ejaculate. Therefore, spontaneous pregnancies are very rare, and infertility has historically been emphasized as a key feature of the syndrome. However, advanced reproductive technology approaches, predominately testicular sperm extraction (TESE) followed by intracytoplasmic sperm injection (ICSI), has revolutionized the reproductive options in KS. In a meta-analysis that included 1248 men with KS, TESE success, defined as retrieval of mature sperm, was 44% (95% confidence interval 39%–48%) independent of age, hormone concentrations, and surgical method (Corona *et al.*, 2017). Pregnancy and live birth rate was 43% per ICSI cycle. Therefore, $\sim$16% of men with KS overall who sought reproductive assistance successfully fathered a child.

Given the natural history of progressive testicular fibrosis and worsening testicular function, it was hypothesized that earlier attempts would have higher success rates but a recent trial found no difference success between males 15–22 versus >23 years and was stopped early (Plotton *et al.*, 2015). Some studies have found younger age to be predictive of higher success with a statistical threshold around 35 years, however this was not confirmed on the meta-analysis. Invasive procedures in early adolescence (<15 years of age) are associated with poor sperm retrieval rates. Preservation of testicular tissue in pre- or postpubertal males with KS relies on the hope of technological advances to induce in vitro spermatogenesis and should be considered experimental (Franik *et al.*, 2016).

A practical approach to fertility in KS is to start with noninvasive methods (semen analysis) when the individual has reached sexual maturity. If spermatozoa are not identified, the patient should be counseled on the success rates and potential risks of

invasive procedures, specifically TESE. Interested patients should be referred to a male reproductive specialist with experience in TESE for KS patients. Specific attention should be given to the socioemotional maturity of the patient when discussing fertility options, particularly given the lack of data to support earlier intervention. The research would also suggest testosterone treatment should not be withheld in hypogonadal individuals for the purpose of future fertility.

Cardiometabolic and Bone Health

Adults with KS have a high prevalence of metabolic syndrome, type 2 diabetes, and osteoporosis (Salzano *et al.*, 2016). Adiposity is greater in KS for any given BMI, and these disorders of insulin resistance are correlated to visceral adiposity (Bojesen *et al.*, 2010, 2006b). Studies in pediatric populations have suggested the risk for cardiometabolic dysfunction is present early, with higher body fat and high prevalence of dyslipidemia (Davis *et al.*, 2016b; Bardsley *et al.*, 2011). Testosterone concentrations inversely correlate with bone density, adiposity, and insulin resistance in KS, however, testosterone treatment is not associated with better cardiometabolic outcomes in adults. Screening for these conditions, encouraging a healthy lifestyle, and optimizing testosterone replacement in KS is advised, but there is a lack of interventional trials in this area.

Nonendocrine Manifestations of KS

Nonendocrine manifestations associated with KS are variable but can impact the health and wellbeing of the individual as much or more than hypogonadism. Therefore, a holistic, multidisciplinary approach to care is highly recommended (Tartaglia *et al.*, 2015). **Table 1** has a list of nonendocrine medical and neuropsychological manifestations that are more prevalent in KS than in the general population. Clinicians caring for individuals with KS should be proactive in screening for and counseling about these risks.

Table 1 Conditions associated with KS

- Neurodevelopmental and psychological risks in KS
  - Speech and language disorders
    - Speech-language developmental delays
    - Receptive expressive language disorder
    - Apraxia/dyspraxia of speech
    - Pragmatic/social communication
    - Lower verbal IQ
  - Motor skills disorders
    - Gross or fine motor skills delay
    - Hypotonia
    - Motor coordination problems
    - Graphomotor deficits
  - Learning disabilities
    - Dyslexia
    - Other language-based learning disabilities
  - Attention deficit hyperactivity disorder
  - Sensory processing differences
  - Social differences
    - Autism spectrum disorders
    - Social cognitive deficits
    - Social-emotional immaturity
  - Adaptive functioning deficits
  - Executive functioning deficits
  - Emotional/psychological disorders
    - Anxiety
    - Depression
    - Mood disorders/bipolar disorder
    - Psychotic features/schizophrenia
- Medical risks in KS
  - Testicular dysfunction
    - Testosterone deficiency
    - Gynecomastia
    - Infertility
    - Cryptorchidism; hypospadias; micropenis
  - Cardiometabolic
    - Metabolic syndrome
    - Type 2 diabetes
    - Fatty liver disease
    - Dyslipidemia
  - Musculoskeletal
    - Osteoporosis
    - Scoliosis; kyphosis
    - Hypermobility
  - Vascular
    - Hypercoagulability
    - Varicose veins; venous stasis
  - Neurological
    - Seizures
    - Tremor
  - Congenital anomalies
  - Respiratory
    - Asthma, allergies
    - Recurrent respiratory infections
  - Gastrointestinal
    - Constipation
    - Gastroesophageal reflux
    - Intestinal vascular insufficiency
  - Autoimmunity
  - Malignancy
    - Breast cancer
    - Non-Hodgkin lymphoma
    - Extragonadal germ cell tumors
  - Eyes—strabismus
  - Dental
    - Enamel defects
    - Taurodontism
  - Nonspecific fatigue

Intellectual disability is rare in KS, however verbal cognition is a relative weakness in some males (Leggett *et al.*, 2010; Boone *et al.*, 2001). Language delays and language-based learning disabilities are present in ~75% (Bender *et al.*, 1983). It should also be noted that there are wide variations in cognitive ability, including academic strengths and weaknesses, with some individuals functioning in very superior ranges in both verbal and nonverbal areas. Executive and adaptive functioning is often more impaired than expected for cognitive abilities, therefore individuals often benefit from additional educational and occupational support. Neuropsychological evaluation can often be helpful to guide appropriate support as needed.

Summary

In summary, KS is a common but phenotypically heterogeneous genetic condition affecting males. Testicular development and function is impaired, often resulting in hypergonadotropic hypogonadism, but there are also neurodevelopmental, cardiometabolic, and other manifestations that present more variably. While historically this condition has been underdiagnosed, routine prenatal screening is quickly changing that landscape. Research is needed in basic, translational, clinical, and implementation sciences to advance the care and improve patient-centered outcomes for individuals with KS. With acknowledgement of our limited evidence-based research for best practices, a holistic approach to caring for the patient with KS throughout the lifespan is recommended.

45,X/46,XY Gonadal Dysgenesis, 46,XX/46,XY Chimerism (and Variants), and 46,XX Testicular and Ovotesticular DSD

Martine Cools, Ghent University Hospital, Ghent, Belgium

Nomenclature

DSD	differences/disorders of sex development
FISH	florescence in situ hybridization
EMS	external masculinization score
hCG	human chorion gonadotropin

45,X/46,XY Gonadal Dysgenesis

Etiology

45,X/46,XY gonadal dysgenesis (and variants) occurs with an estimated incidence of around 1.5/10,000 conceptions. Prefertilization causes include loss of the Y chromosome through meiotic nondisjunction or anaphase lag at the gamete level and, although occurring very rarely, paternal transmission of an abnormal Y chromosome with subsequent loss of Y (Chang et al., 1990). The majority of cases originates from postfertilization events, such as mitotic anaphase lag or interchromosomal rearrangements with final loss of a structurally abnormal Y chromosome (Hook and Warburton, 2014). It has been hypothesized that all live born 45,X individuals have some degree of mosaicism for a cryptic normal (XX or XY) cell line, for example, in the placenta, but data are not conclusive on this matter (Hook and Warburton, 2014).

Terminology

The condition associated with 45,X/46,XY gonadal dysgenesis is often referred to as "mixed gonadal dysgenesis" because affected individuals may have a streak gonad on one side and a testis on the other. In reality, gonadal histology in 45,X/46,XY individuals is far more complex (see below) and variable and can be appreciated only by detailed pathological description of the gonads, which in many cases is not available. The term should therefore be abandoned.

Although clinical features in 45,X/46,XY men may show some overlap with Turner syndrome, this term is reserved for females who have one intact X chromosome and complete or partial absence of the second sex chromosome in association with one or more clinical manifestations. Thus, this diagnosis is excluded in 45,X/46XY males (Gravholt *et al.*, 2017).

Diagnosis

A karyotype should be obtained in any girl with growth failure, with or without the typical features associated with Turner syndrome (Gravholt *et al.*, 2017), and with a low threshold in boys with short stature or a discrepancy between actual height and target height. If associated with a history of undescended testes and/or hypospadias, karyotyping is imperative. Florescence in situ hybridization (FISH) with X and Y centromere probes in at least 100–200 interphase cells from two different tissues (e.g., peripheral blood, buccal swab, skin fibroblasts) can identify low-grade mosaicism.

The presence of minor Turner stigmata, such as short 4th metacarpal/metatarsal or short stature in an individual with presumed 46,XY gonadal dysgenesis, should always prompt investigations to exclude 45,X/46,XY mosaicism (Cools and Kohler, 2017).

Clinical Presentation

Ninety-five percent of individuals who have a 45,X/46,XY chromosomal constitution will present as typical males (Chang *et al.*, 1990). As these men do not regularly come to medical attention, there is little or no information about their outcome with respect to growth, puberty, cardiovascular status, co-morbidities, fertility or risk of gonadal tumors. The remainder are characterized by great phenotypic variability, ranging from newborns with isolated hypospadias or ambiguous genitalia to females who have Turner syndrome. Of all girls diagnosed with Turner syndrome, 10%–12% have a 45,X/46,XY mosaic karyotype (Gravholt *et al.*, 2017). The External Masculinization Score (EMS) can be used to describe the degree of genital virilisation in neonates and infants, but is difficult to apply in typical females (Ahmed *et al.*, 2000).

Little correlation exists between the proportion of the different cell lines in peripheral blood, fibroblasts or even gonads and the observed phenotype (Cools *et al.*, 2007). Characteristics typically associated with Turner syndrome are often present. These include amongst others short stature, short 4th metacarpal and metatarsal, horseshoe kidney, wide-spaced nipples, shield thorax and facial dysmorphisms. Mild cognitive defects, learning disabilities and autism spectrum disorders may also be part of the phenotypic spectrum (Martinerie *et al.*, 2012; Tosson *et al.*, 2012).

Growth

Girls and boys who have a 45,X/46,XY karyotype are at high risk for adult short stature, similar to girls who have 45,X monosomy. Short stature may be the only physical sign in affected children, both boys and girls. Growth failure in association with a history of hypospadias or undescended testes should always prompt karyotyping. Although commonly administered nowadays, growth hormone therapy seems to result in improved height gain mainly on the short term, while adult height is disappointing and apparently with no better outcomes in treated as compared to untreated individuals. No differences have been observed between girls and boys, or those who entered puberty spontaneously or after hormonal stimulation. These data need confirmation in a larger sample (Richter-Unruh *et al.*, 2004; Martinerie *et al.*, 2012; Lindhardt Johansen *et al.*, 2012; Bertelloni *et al.*, 2015).

Cardiovascular status

Only a limited number of small-scale studies have systematically searched for congenital cardiac defects in children who have 45,X/46,XY karyotypes. Left side defects, mainly bicuspid aortic valve and aortic coarctation have been found in 4/9 females and 0/7 males (Tosson *et al.*, 2012); in 3/20 males (Martinerie *et al.*, 2012), and in 3/8 females and 5/10 males (De Groote *et al.*, 2013). Data on cardiovascular pathology in adolescents and adults with this condition are even more scarce, but suggest an increased risk for hypertension and dilation of the ascending aorta (De Groote *et al.*, 2013). Near-fatal cardiac failure, secondary to aortic root dilation has been described (Bakoto *et al.*, 2011). These data come from highly selected cases, additional evidence resulting from systematic screening of 45,X/46,XY individuals for cardiovascular pathology is highly needed.

In summary, although numbers are small, cardiovascular pathology in 45,X/46,XY individuals seems to occur to the same extent as in Turner syndrome, irrespective of phenotype, with the exception perhaps of nonsymptomatic males. While awaiting further data, it is recommended to apply the same cardiac surveillance protocol in both 45,X/46,XY males and females as in Turner syndrome (Gravholt *et al.*, 2017).

Other features

When searched for, other features typically associated with Turner syndrome are observed with increased frequency in girls and boys with 45,X/46,XY karyotypes. Amongst those are autoimmune thyroiditis, elevated liver enzymes, recurrent otitis media, conductive hearing loss and scoliosis. Although children with Turner stigmata may be more likely to develop such comorbidities, data are too limited to make final conclusions on this matter (Tosson *et al.*, 2012; De Groote *et al.*, 2013).

In summary, in the absence of further evidence, it is advised to include all individuals who have 45,X/46,XY karyotypes in the same follow-up and screening programs as women who have Turner syndrome, irrespective of phenotype or presence of associated features (Gravholt *et al.*, 2017). The correlation between the relative proportion of the different cell lines, condition-related stigmata, genital/gonadal phenotype and involvement of other organ systems is unclear so far. Care for these individuals is best embedded in an experienced multidisciplinary team.

Gonadal histology

Gonadal histology is highly variable but correlates to a certain extent with the child's phenotype: 45,X/46,XY girls with Turner syndrome typically have bilateral streak or sometimes absent (regressed) gonads; genital ambiguity is often associated with the presence of dysgenetic testes or undifferentiated gonadal tissue, whereas at least one scrotal testis is usually present in phenotypic males. Representative examples are shown in **Fig. 1**. Asymmetrical mesonephric (Wolffian) and paramesonephric (Müllerian) duct development in agreement with the ipsilateral gonad is common and this finding in a 46,XY individual should prompt gonadal karyotyping to exclude gonadal sex chromosome mosaicism. Functional ovarian tissue, i.e. germ cells enclosed in primordial and maturing follicles, is extremely rare in 45,X/46,XY, as oocyte meiosis is incompatible with the absence of a second X chromosome (Cools *et al.*, 2011a,b; Wunsch *et al.*, 2012; Lindhardt Johansen *et al.*, 2012; Lepais *et al.*, 2016).

Gonadal (testicular) function

Gonadal function is tightly related to gonadal histology. Streak gonads, usually seen in 45,X/46XY girls with typical female genitalia, are composed of nonfunctional fibrotic tissue, devoid of germ cells, granulosa cells and theca cells, hence no hormone production is expected (Cools et al., 2011b). Gonadal function is highly variable in girls and boys with partial gonadal dysgenesis (testicular dysgenesis and/or undifferentiated gonadal tissue), who mostly present with ambiguous genitalia. An estimate of gonadal hormone production can first be obtained during the postnatal gonadotropin surge or after human Chorion Gonadotropin (hCG) stimulation, but levels do not necessarily correlate with gonadal function in puberty or thereafter (Martinerie *et al.*, 2012). Very limited data suggest that pubertal onset is spontaneous in most, if not all, 45,X/46,XY boys with typical male genitalia and in many undervirilised 45,X/46,XY males (Lindhardt Johansen *et al.*, 2012; Martinerie *et al.*, 2012). The latter however may need hormone replacement therapy later in life. In early adulthood, high gonadotropin levels, low-normal testosterone and low inhibin B levels have been found in four men with typical male phenotypes and an uneventful course of puberty, suggesting absent spermatogenesis and progressive decrease of Leydig cell function over time in these men. Of note, three out of four had structural abnormalities of the Y chromosome, in particular large deletions on Yq, including the AZF region, which contains many genes important for spermatogenesis (Lindhardt Johansen *et al.*, 2012).

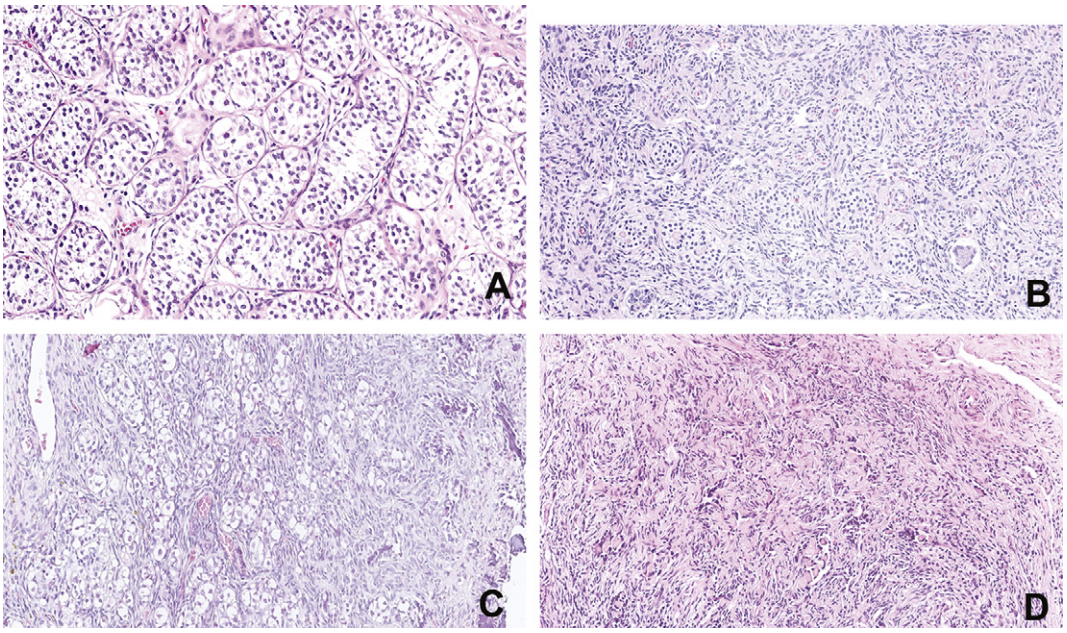

Fig. 1 Gonadal development in 45,X/46,XY individuals. Representative examples are shown of gonadal development patterns typically encountered in individuals who have a 45,X/46,XY karyotype. A gradient in degree of "testicularisation" can be observed from A–D. (A) Normal testis, HE, 200 ×, (B) dysgenetic testis: aberrantly shaped tubules, reduced in number and in a background of stromal tissue, HE, 200 ×, (C) undifferentiated gonadal tissue: germ cells and sertoli/granulosa like cells, poorly organized in primitive sex cord structures, HE, 200 ×, (D) streak gonad without functional cells, HE, 200 ×.

Gonadal tumor risk and indications for gonadectomy

Gonadectomy can be performed because of gonadal tumor risk, hormone production discordant with gender identity, or both (van der Zwan *et al.*, 2015). Gonadal germ cell tumors occur with increased frequency in 45,X/46,XY DSD. The peak incidence most likely follows that of the general male population, which is in early adulthood. Invasive germ cell tumors are preceded by premalignant changes, termed germ cell neoplasia in situ (GCNIS) in the testis and gonadoblastoma in the dysgenetic gonad. These lesions are presumably present from birth or early childhood onwards but may remain quiescent for one to three decades (Rajpert-De Meyts *et al.*, 1998).

The degree of gonadal differentiation is hypothesized to be inversely related to tumor risk (**Fig. 2**) (Cools *et al.*, 2011a). In one relatively large study, gonads comprised of dysgenetic testicular and/or undifferentiated gonadal tissue were more likely to harbor preneoplastic lesions as compared to scrotal testes with no or very mild signs of dysgenesis. Streak gonads by definition have no germ cells that can give rise to neoplastic transformation. However, gonadal differentiation can be largely heterogeneous within the same gonad, hampering conclusive risk assessment on the basis of a single biopsy in such cases. In addition, it was hypothesized that an individual's phenotype reflects—to a certain extent—gonadal morphology. Indeed, it was observed that (pre) neoplastic lesions were mainly encountered in girls and boys who had ambiguous genitalia, and to a much lesser extent in typical males, who mostly had bilateral scrotal testes, and typical females, who mostly had bilateral streak or regressed gonads (Cools *et al.*, 2011a). This observation has been confirmed in three independent series (Lindhardt Johansen *et al.*, 2012; Martinerie *et al.*, 2012; Wunsch *et al.*, 2012).

Given the absence of gonadal function in girls who have 45,X/46,XY and Turner syndrome, prepubertal gonadectomy is recommended (Gravholt *et al.*, 2017). A decision regarding prophylactic gonadectomy in boys with partial gonadal dysgenesis who have a considerable risk for germ cell tumor development on the one hand but may benefit from endogenous hormone production on the other is sometimes extremely difficult; repeat gonadal biopsies and expert evaluation to detect early malignant changes can be informative (Hersmus *et al.*, 2012; Lindhardt Johansen *et al.*, 2012). In girls with partial gonadal dysgenesis, unwanted virilisation in puberty may further guide the decision regarding gonadectomy (van der Zwan *et al.*, 2015).

46,XX/46,XY Chimerism (and Variants)

46,XX/46,XY chimerism is defined as the existence of two or more cell lines of different genetic origin in one individual and arises at or immediately after fertilization. 46,XX/46,XY chimerism may lead to ovotesticular DSD (see below).

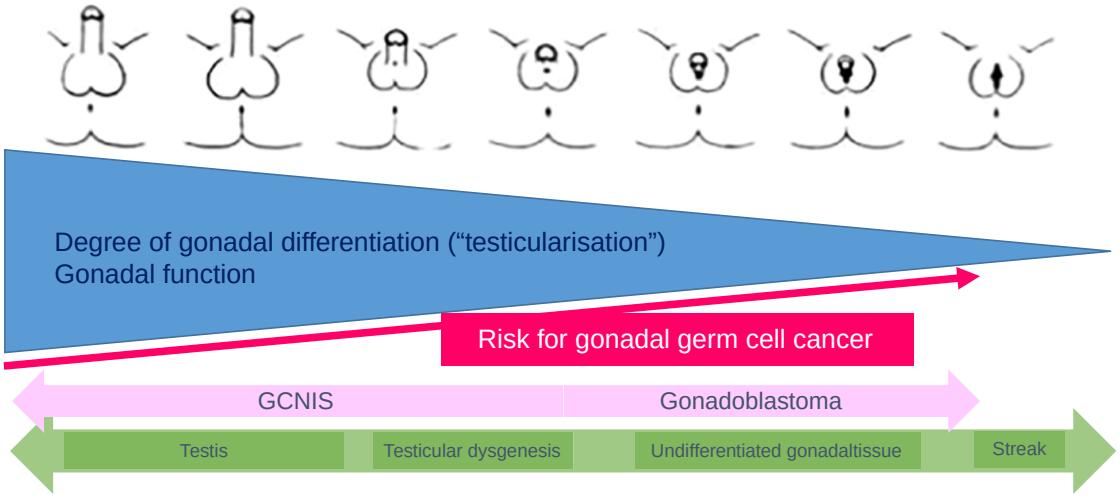

Fig. 2 Risk for development of germ cell tumors in individuals who have a 45,X/46,XY karyotype. Gonadal function decreases with decreasing gonadal differentiation ("testicularisation"). A high level of "testicularisation" is generally associated with a more virilised genital phenotype and lower germ cell tumor risk. Undifferentiated gonadal tissue has the highest risk; streak tissue, by definition, has no germ cells. Germ cell neoplasia in situ is the precursor lesion in the testis, gonadoblastoma is typically found in association with undifferentiated gonadal tissue.

46,XX Testicular and Ovotesticular DSD

46,XX^{SRYpos} Testicular DSD

85% of individuals with XX testicular DSD have typical male genitalia and present as infertile adults ("XX males"), sometimes with gynaecomastia (Delot and Vilain, 1993). The diagnosis is sometimes made prenatally, following karyotyping for maternal or other reasons. A minority of cases may present with milder undervirilisation defects, such as isolated cryptorchidism or hypospadias. Wolffian ducts develop normally and Müllerian structures are absent. Most of these cases harbor an Xp:Yp translocation containing *SRY*. Preferential inactivation of the Y-bearing X chromosome and cryptic mosaicism with SRY expression confined to the testes have been implicated in incomplete virilisation (Fleming and Vilain, 2005).

Single case reports and very small series suggest normal cognitive and psychomotor development but short stature in most 46,XX^{SRYpos} boys. Although pubertal onset appears to be spontaneous and at an appropriate age, hypergonadotropic hypogonadism is gradually installing. Testosterone production generally declines over time, requiring hormone replacement therapy. As most of the Y chromosome, including the AZF region, is lacking, 46,XX^{SRYpos} men are infertile (Gunes *et al.*, 2013; Boucekkine *et al.*, 1994; Delot and Vilain, 1993).

A gonadal biopsy most often reveals testicular differentiation with small (infantile) Sertoli-cell only tubules and Leydig cell hyperplasia in pubertal patients. In older individuals, tubules become increasingly sclerotic and the normal testicular architecture is gradually replaced by general fibrosis (**Fig. 3**). It is generally accepted that 46,XX^{SRYpos} men have no increased risk for the development of testicular germ cell tumors, given the early loss of germ cells and absence of most of the Y chromosome, in particular the *testis specific protein on Y* (*TSPY*) region, which has been implicated, amongst others, in the pathogenesis of these tumors (Cools *et al.*, 2006).

Other Forms of 46,XX Testicular and Ovotesticular DSD

Ectopic SRY expression is not usually involved in conditions characterized by 46,XX (ovo)testicular DSD and ambiguous genitalia. Few other genetic causes have been identified, such as gain-of-function changes of male sex-determining genes or its regulatory regions, mainly *SOX9*, or loss-of-function mutations of female sex-determining genes, for example, *RSPO1*, which has been implicated in a rare syndrome characterized by XX testicular DSD, palmoplantar hyperkeratosis and a susceptibility to develop squamous cell carcinoma (Baetens *et al.*, 2017a; Tomaselli *et al.*, 2008; Hyon *et al.*, 2015). Genomic rearrangements (duplications as well as a microdeletion) disrupting the regulatory region of *SRY*-related genes such as *SOX3* and *SOX10* have been described. It has been hypothesized that ectopic gonadal expression of these genes at a critical stage of development has triggered SOX9 transcription and subsequent initiation of the male pathway in these cases (Haines *et al.*, 2015; Polanco *et al.*, 2010; Baetens *et al.*, 2017a).

It becomes increasingly clear that proper and complete sex determination is secured by continuous repression of the opposite pathway at the gonadal level (Bashamboo and McElreavey, 2015). Thus, loss of activation or incomplete development of one pathway inevitably implies partial activation of the opposite pathway due to loss of antagonism. *NR5A1*, apart from its crucial role in testis development, has in a transgenic mouse model, been implicated in activation of early ovarian-determining genes such as

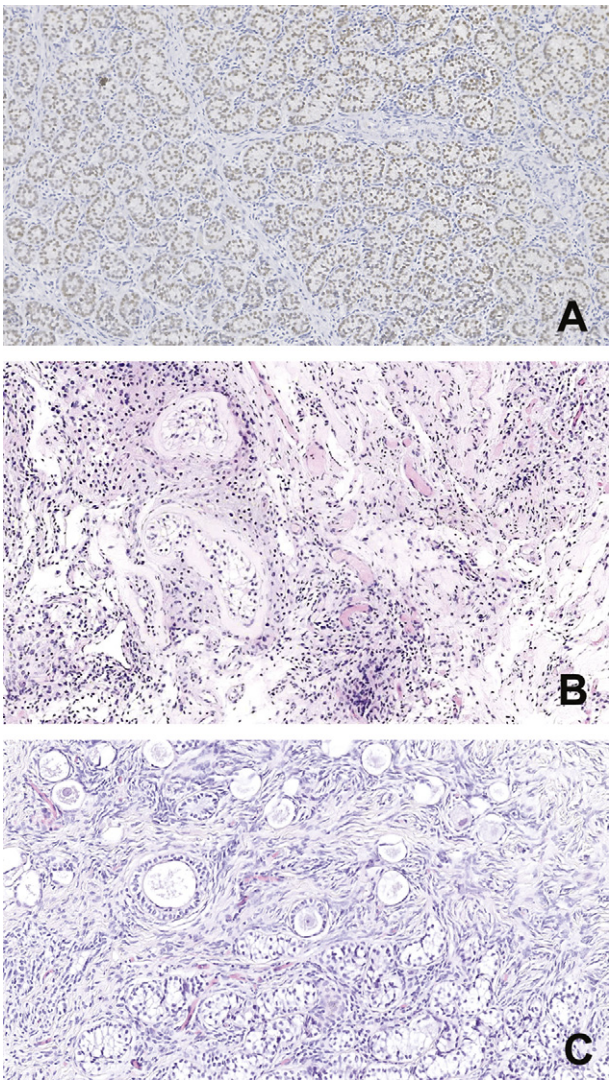

Fig. 3 46,XX testicular and ovotesticular DSD. (A) Infantile testis in a boy with 46,XX (SRY negative) testicular DSD, displaying regularly shaped small Sertoli-cell only tubules. All Sertoli cells stain positive for SOX9, demonstrating noncanonical, SRY independent SOX9 activation. SOX9 staining, 200 ×. (B) Atrophic testis in a 40 years old 46,XX^{SRYpos} man, with a typical male phenotype and a recent diagnostic work-up for infertility. HE, 200 ×. (C) Ovotestis in a girl who has the *NR5A1* c.274C>T (p.Arg92Trp) mutation. Ovarian tissue in the upper part of the picture, testicular differentiation in the lower part. HE, 200 ×.

WNT4/β-catenin (Combes *et al.*, 2010). Recently, multiple families have been described in which a specific mutation in *NR5A1* c.274C>T (p.Arg92Trp) has led to ovotesticular or testicular DSD in some 46,XX family members while others are asymptomatic carriers (Bashamboo *et al.*, 2016; Baetens *et al.*, 2017b; Igarashi *et al.*, 2017). Interestingly, in one of these families, two sibings with this specific mutation were investigated, one diagnosed with 46,XY gonadal dysgenesis and raised as a girl, and another diagnosed with 46,XX testicular DSD and raised as a boy (Bashamboo *et al.*, 2016). Although the exact molecular mechanism remains to be elucidated, it has been hypothesized that the p.Arg92Trp variant specifically interferes with NR5A1-mediated activation of ovarian development, resulting in loss of suppression of the testicular pathway in affected individuals (Bashamboo *et al.*, 2016; Baetens *et al.*, 2017b; Igarashi *et al.*, 2017) (**Fig. 4**) (Baetens *et al.*, 2017b; Bashamboo *et al.*, 2016). Possibly other amino acid substitutions at the same position may result in similar phenotypes (Swartz *et al.*, 2017).

The term ovotesticular DSD should be reserved for individuals who have well differentiated and functional testicular as well as ovarian tissue (i.e., Leydig cells and seminiferous tubules with or without germ cells and ovarian follicles composed of granulosa cells, theca cells and ova) either combined in an ovotestis or as asymmetrically developed gonads (**Fig. 3**) (Cools *et al.*, 2011b). Most, if not all cases have a 46,XX karyotype. Large pedigrees have been described in which some individuals have ovotesticular DSD, some have testicular DSD and others are asymptomatic carriers so it is believed that, at least in some cases, the condition is characterized by variable penetrance (Parma *et al.*, 2006).

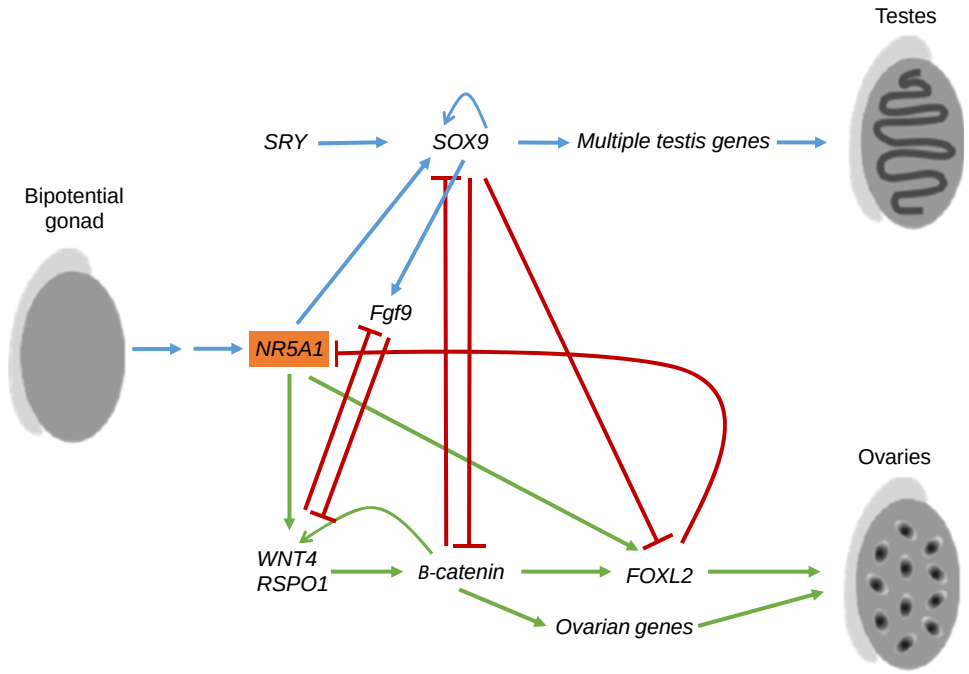

Fig. 4 Current simplified model of agonistic and antagonistic pathways determining gonadal differentiation. Testis-promoting actions are in blue, ovary promoting actions are in green, antagonistic actions in red. Incomplete activation of one (either male or female) pathway unavoidably results in loss of repression of the opposite pathway. *NR5A1* may act as a key hub in this model. Figure modified from Baetens, D., Stoop, H., Peelman, F., Todeschini, A.-L., Rosseel, T., Coppieters, F., Veitia, R. A., Looijenga, L. H. J., De Baere, E. and Cools, M. (2017b). NR5A1 is a novel disease gene for 46,XX testicular and ovotesticular disorders of sex development. *Genetics in Medicine* **19**, 367–376.

Very few long-term outcome data in individuals who have ovotesticular DSD are available. The testicular and ovarian parts both produce sex steroids at puberty and may lead to combined phallic growth and breast development in individuals with retained gonads. Germ cells are rarely present in the testicular part and tend to disappear before puberty; spermatogenesis has not observed, and the testis tubules undergo hyalinization and sclerosis in adults. In contrast, follicles are usually abundant in the ovarian part in younger individuals and may undergo ovulatory changes after puberty. Although in the past, presumed fertility potential has often been decisive in decisions on gender of rearing in neonates with ovotesticular DSD, scarce data indicate that also ovarian function may decrease over time and that males with this condition may have equal or better psychological outcomes (Verkauskas *et al.*, 2007). Care for individuals with 46,XX testicular or ovotesticular DSD should be provided by an experienced multidisciplinary DSD team.

Intersexuality: Gender Assignment and Psychosocial Care☆

Heino FL Meyer-Bahlburg, New York State Psychiatric Institute, New York, NY, United States and College of Physicians & Surgeons of Columbia University, New York, NY, United States

Glossary

Disorders of sex development (DSD) Inborn conditions in which the development of chromosomal, gonadal, or anatomical sex is atypical. Conditions of genital ambiguity or intersexuality constitute a subset of DSD.

Gender assignment The decision-making process involved in declaring a newborn a "boy" or "girl."

Gender dysphoria Persistent dissatisfaction or unhappiness with the assigned gender.

Gender identity The basic sense of being a girl or boy, woman or man, or a different category of gender, such as a hermaphrodite or a trans(gender). Also known as core gender identity.

Gender reassignment The decision-making process involved in revising the original assignment decision later, which can happen at any age of the individual.

Gender-role behavior All behaviors in which the genders differ in a given time and place. Some examples are rough-and-tumble play of childhood, courtship and sexual behavior in adolescence, and aggression and parenting behavior in adulthood. Also known as gender-related behavior or sex-dimorphic behavior.

Gender-role identity The degree to which a girl or boy, or a woman or man, perceives herself or himself as being feminine or masculine.

Sexual orientation The degree to which an individual erotically responds to male or female sex partners, as reflected in romantic/erotic attractions, fantasies, dreams, and also in overt sexual behavior, often rated on the 7-point Kinsey scale ranging from 0 (exclusively heterosexual) to 6 (exclusively homosexual). Also known as "sexual responsiveness."

Transsexual A person with gender identity disorder who seeks, or has undergone, gender reassignment, often along with hormone treatment and genital surgery.

Gender Assignment Policies

Introduction

In most newborns, gender assignment is unproblematic and instantaneous. The newborn is assigned to the gender that corresponds to the appearance of the genitalia, and the vast majority of individuals will develop a stable gender identity commensurate with the original assignment. In a very small number of newborns, the genitalia are not clearly those of a boy or girl, but are ambiguous or intersexed. Examples of such variants of sex development are chromosomal (46,XX) females with androgen excess due to congenital adrenal hyperplasia (CAH), chromosomal (46,XY) males with a defect in testosterone biosynthesis or with varying degrees of androgen insensitivity secondary to genetic defects of the androgen receptor, or children with genitalia that are atypical in other ways, for instance, 46,XY infants born without a penis (penile agenesis).

The standard medical term currently used for such variants of somatic sex development is "disorders of sex development" (DSD; Hughes *et al.*, 2006), often re-read as "differences" or "divergences of sex development," especially by patients and patient advocates who are concerned about the stigma of "disorder" labels (Lin-Su *et al.*, 2015; Johnson *et al.*, 2017a). In the current article, I will use the term "intersexuality," because "DSD" also applies to large groups of individuals with other variants of sex development in which gender assignment is not in question. The medical categorization of somatic sex needs to be distinguished from the growing use of identity labels or legal terms for gender categories other than the traditional male or female, e.g., "non-binary" or "intersex." Overall, gender is more accurately conceptualized as a bimodal continuum rather than a strictly binary category system (Meyer-Bahlburg *et al.*, 2016).

In patients with intersexuality, the decision regarding gender assignment is complex, may require a number of medical tests to identify the cause of the problem, and involves prognostic considerations and value judgments. In fact, it is these cases that force a clarification of the relative importance of factors presumed to be involved in gender identity development—on the biological side, genes and sex hormones, and on the psychosocial side, gender assignment, social learning mechanisms such as reinforcement and modeling, and cognitive factors such as a person's evaluation of his/her body and behavior in comparison to perceived gender norms.

 doi:10.1016/B978-0-12-801238-3.04121-0

The True-Sex Policy

The classical approach to gender assignment in the case of genital ambiguity, which goes back to at least Aristotle, has been to determine the true sex and to assign gender accordingly (Meyer-Bahlburg, 1998). The assumption under this policy was that the true sex is revealed by a definitive, single biological criterion. In antiquity, the decision was based on the appearance of the external genitalia. In cases of genital ambiguity, Aristotle had already recommended basing the decision on the "predominant sex." In conjunction with the rapid advances in medicine during the second half of the nineteenth century, the histology of the gonads became the decisive criterion of true sex, with sex chromosomes and other genetic indicators following suit in the middle of the twentieth century. It was generally assumed that, if gender assignment had been carried out correctly, that is, in agreement with the true sex, the final outcome would be a heterosexual man or a heterosexual woman, in agreement with the assigned gender. There were problems with the true-sex policy, however. The presumed definitive criterion of the true sex did not always agree with a person's somatic appearance as a man or woman, and also did not always agree with the person's gender identity, and could therefore lead to dramatically adverse social and legal consequences for the intersexed individual.

The Optimal-Gender Policy

On the basis of a critical examination of the true-sex policy and studies of the overall psychosocial outcome and quality of life of intersex patients, John Money and the Hampsons at Johns Hopkins Hospital in Baltimore, Maryland, formulated an optimal-gender policy during the 1950s (Meyer-Bahlburg, 1998). This policy had a number of underlying assumptions. (1) There is no single biological criterion that determines the development of psychological gender; rather, there is a cascade of biological processes that culminate in the development of gender identity. (2) Socialization factors have the decisive role in gender-identity formation. (3) If one minimizes the barriers to socialization in the assigned gender, the outcome will be a heterosexual man or a heterosexual woman, in agreement with the assigned gender. (4) The condition of the body and particularly the genitalia limits the psychosocial and especially psychosexual functioning of the intersexed person in later years. Therefore, the newborn with intersexuality should be assigned to that gender that permits the optimal psychosexual and psychosocial functioning when all available medical treatment options are taken into account. So, in contrast to the question of the true-sex policy—"Is this a boy or a girl"?—the optimal-gender policy asked "Will this newborn have a better function later in life as a male or a female?"

From the central role of socialization followed the concept of the birth of an intersex newborn as a psychosocial emergency, with the implication that the decision time for gender assignment should be kept as short as possible. Another consequence was the recommendation of early feminizing or masculinizing surgery of the external genitalia so that their appearance would be as similar to the gender norm as possible and would therefore not interfere with gender-typical rearing conditions and body-image development. A third consequence was the instruction to keep the intersex status of the child secret from all people who do not belong to the core family and to educate the child gradually about the condition, in line with his or her cognitive development. These guidelines were intended to prevent the parents from developing chronic doubts about the gender of their child and to protect the child from stigmatization by other people, but have frequently led to parental attempts of preventing the disclosure of details of the medical history to the intersex children themselves, sometimes even after they attained adulthood.

The True-Brain-Sex Policy

Increasingly since the mid-1990s, the optimal-gender policy has come under criticism. One reason is that also under this policy some individuals turn out dissatisfied with their assigned gender and may seek gender reassignment, which is made more difficult if the external genitalia have been operated on to be more compatible with the originally assigned gender. A second argument is that, even without later gender change, genital surgery carries a risk of damage to sexual functioning in adolescence and adulthood (see below). Third, the optimal-gender policy is blamed (although unjustly attributed to its authors; see above) for keeping the medical facts secret, especially from the patient him- or herself, which contributes to the maintenance of the social stigma of intersexuality and thereby to a negative self-image and shame of the intersexed individual. Many intersex activists, therefore, argue for early comprehensive disclosure of their medical history to intersex patients. A fourth criticism of the optimal-gender policy derives from the extensive data—initially from animal research, then from studies on DSD syndromes by Money and Ehrhardt (1972) and their team, and subsequently by many others—regarding the influence of sex hormones on the developing brain and long-term sex-dimorphic behavior. Because of these data, some biological determinists suggest that the decisive factor for gender identity formation is the prenatal androgenization of the brain and that psychosocial factors have only a secondary role. If such a "true-brain-sex policy" is valid, gender assignment decisions should be based on the degree of androgenization/masculinization of the brain, and minimization of barriers to socialization is unimportant. However, because brain imaging techniques are not yet capable of rendering such assessments, these theorists must fall back on the status of the genitalia as a—rather problematic—indicator of brain androgenization/masculinization (see below).

Policy Effects on Gender Assignment

The three major policies outlined above may lead to quite varied decisions on gender assignment. Two cases will illustrate this: (1) a chromosomally female (46,XX) newborn with extreme genital masculinization (Prader stage V) due to prenatal androgen excess

Table 1 Gender assignment as a function of policy

Disorder	*True-sex policy*	*Optimal-gender policy*	*True-brain-sex policy*
Penile agenesis	Male	Female	Male
CAH/Prader stage V	Female	Female	Male

associated with classical congenital adrenal hyperplasia (CAH) and (2) a chromosomally male (46,XY) newborn with penile agenesis. According to the true-sex policy, case (1) should be raised female because of the clearly female histology of the gonads (i.e., ovaries) and female chromosomes (see **Table 1**). By contrast, a 46,XY newborn with penile agenesis would be assigned to the male gender, because of the normal-male histology of the testicular gonads and the clearly male karyotype. Under the optimal-gender policy, case (1) would be assigned to the female gender, because the external genitalia can be feminized so as to permit coitus and to thereby retain the option of conception and pregnancy, because the internal female reproductive organs are intact. The 46,XY infant with penile agenesis would also be assigned to the female gender, because the surgical de novo construction of a functioning penis is not yet possible and therefore sexual functioning as a male would be compromised. Advocates of the true-brain-sex policy would recommend assigning the CAH case to the male gender because of the putative effects of prenatal androgens on the brain and recommend the same for the case of penile agenesis. Some activists recommend assigning the intersex child to the gender that seems to offer the more promising outcome, but to do so provisionally and to consider from the outset the possibility of later gender change and therefore not to operate on the genitals before the age of consent, unless medically necessary.

The Status of the Evidence

In response to the increasing controversies, an international consensus conference was held in Chicago in 2005, which reviewed the existing data and began a cautious modification of the predominant policy (Hughes *et al.*, 2006). A definitive consensus about a new management policy has yet to emerge (Lee *et al.*, 2016). The major problem is insufficient data concerning the long-term psychological outcome. Patient-initiated later gender change, for instance, can be observed in intersex individuals in both directions, from male to female and from female to male (and, in some cases, from the assigned gender to "intersex" or another term outside the traditional binary sex/gender system). This is not surprising, because such gender change is also well known—as transsexualism—in non-intersex individuals, but the relative frequency of later gender change is increased in intersex patients and varies with syndrome, syndrome severity, and initial gender assignment. Given the psychological, social, and medical problems that are associated with later gender change, clinicians usually favor a policy that minimizes its occurrence. Thus, long-term follow-up data are needed that will allow clinicians to state the relative frequency of gender change of patients with a given syndrome and degree of severity who were managed under a defined policy and in a particular cultural context. Because gender change can take place as late as in midlife, follow-up studies need to reach at least into that age range. Given the relative rarity of intersex patients, it is not surprising, therefore, that the data thus far available are still unsatisfactory.

As an extreme example, consider the question of gender reassignment in chromosomal males with traumatic loss of the penis in infancy (Meyer-Bahlburg, 2005). One such case, in which reassignment to female at 17–21 months of age was followed by patient-initiated re-reassignment to male in adolescence, has drawn enormous attention among care providers as well as in the media, once his unfortunate story was investigated and published, when he was in his mid-30s. However, only one other case with a history of traumatic loss of the penis in infancy and reassignment to female has been followed into adulthood and published and this person continues to live as a woman without gender dysphoria. Two cases with strikingly different outcomes are not sufficient for evidence-based policy decisions. Even for intersex syndromes that are more prevalent and less shrouded in secrecy than the cases of traumatic loss of the penis, long-term outcome data are hard to come by and those that have become available all suffer from problems that limit their validity: loss to follow-up of patients who have moved and cannot be found, who have died (especially if for other than medical reasons), or who have refused to participate in research (especially if for reasons of disappointment with their medical treatment).

The true-brain-sex policy appears very plausible at first glance, but becomes more problematic on closer scrutiny (Meyer-Bahlburg, 2013). The assumption that the effects of prenatal hormones on the brain are the decisive biological factor in the development of gender and therefore the best criterion for gender assignment is primarily derived from research on the sexual differentiation of brain and behavior in nonhuman mammals, especially rodents, which has yielded several neuroendocrine models of the sexual differentiation of brain and behavior. In humans, most pertinent studies have been limited to androgens. In general, the resulting data allow the preliminary conclusion that effective prenatal androgens are indeed associated with the masculinization of gender-role behavior. However, the core gender identity, for instance, as a girl or as a woman, is compatible with large variability in gender-role behavior, as is vividly demonstrated in girls and women with CAH, thus making a close linkage to prenatal hormones less likely. It also must be kept in mind that in the limited literature available, the association between prenatal androgens and later gender change in girls and women with CAH takes place predominantly in the context of further postnatal and pubertal androgen exposure and the associated increased somatic sexual ambiguity. Therefore, in all likelihood, it is not the prenatal hormonal milieu by itself that determines such later gender change.

Outcome data are also unsatisfactory with regard to the question of impairment of sexual functioning after gender-confirming genital surgery. Most surgical outcome reports are limited to anatomical data and appearance ratings. Those that include data on

sexual functioning often leave much to be desired in terms of sample representativeness, assessment methods, and study details provided, quite apart from the fact that patients who have undergone surgeries with the newer techniques are not yet old enough for sexual functioning studies. Most pertinent studies have been conducted in women with CAH. As a group, they show impaired sexual and genital functioning, presumably both despite corrective genital surgery and because of it (for references, see Meyer-Bahlburg, 2014). From a neuroanatomic standpoint, it is plausible, for instance, that excision of the clitorophallus—widely practiced as a feminizing technique in the 1950s and 1960s—would lead to a diminution of erotic sensitivity and orgasmic capacity, although the limited outcome data available show considerable variability. But surgical techniques have undergone many changes since then and reduction of the clitorophallus rather than excision has become the norm. To evaluate sexual functioning in patients who were operated on with newer surgical techniques, researchers need to wait at least until the patients are sexually active, sufficiently sexually experienced, and able to talk about these intimate details of their lives, and this in a population that is known to be relatively delayed in attaining psychosexual milestones. The same applies to patients with a similarly ambiguous genital status at birth who for one reason or another have not undergone genital surgery and could therefore serve as comparisons. The outcome data currently available, however, have led to recommendations to limit genital surgery in girls and women with CAH to those with marked degrees of genital masculinization (Speiser *et al.*, 2010).

Inferring Brain Masculinization From Genital Masculinization

Adherents of the true-brain-sex policy recommend a male assignment for a newborn with intersexuality if the child's brain was prenatally strongly masculinized, independent of the status of the genitalia. However, how can one determine in a newborn whether and to what extent the brain was prenatally masculinized and/or defeminized? Appropriate brain imaging techniques are not yet available, and even if they were available, it is rather uncertain that the brain is, at the time of birth, already sufficiently sexually dimorphic to show such clear-cut gender dimorphic structures. Some advocates of the true-brain-sex policy therefore suggest using the genital status at birth (staged according to Prader for excess masculinization in chromosomal females and according to Quigley, Sinnecker, or Ahmed for several syndromes of undermasculinization in chromosomal males) as an indicator of brain androgenization/masculinization. There are several problems with this approach (Meyer-Bahlburg, 2013). (1) Genital staging at birth is not suitable for all syndromes of interest. For instance, Prader staging is problematic for many prenatally dexamethasone-treated cases of 46,XX CAH and undermasculinization staging is not at all suitable for certain 46,XY conditions of interest, such as penile agenesis and cloacal exstrophy of the bladder. (2) The growth of the penis does not depend exclusively on sex hormones. (3) The hormone model of genital differentiation is not identical with the hormone models of brain differentiation. As far as is known, the prenatal differentiation of the genitalia is determined by testosterone, dihydrotestosterone, and anti-Müllerian hormone, whereas the sexual differentiation of the human brain primarily depends on androgens, with the roles of estrogens and anti-Müllerian hormone unknown. (4) In the 46,XX CAH syndrome, Prader stage correlates only moderately with masculinization of gender-role behavior. (5) Available (scanty) data on patient-initiated gender change in adults with a given intersex syndrome show little relationship to genital status at birth. (6) Moreover, gender dysphoria occurs in non-intersexed persons as well, although prior to surgery the genitals of transsexuals are fully differentiated and compatible with the original gender assignment. (7) Research has made it likely that contributions to the sexual differentiation of brain and behavior by hormone-independent genetic factors and brain-tissue-specific hormonal factors need to be taken into account. (8) Finally, there may be early effects of the social environment on central nervous system structures, as is already known from animal research. If any social mechanisms participate in the development of gender identity incongruence in persons without somatic intersexuality, they are likely to also contribute to its development in intersex patients. It follows from all of these considerations that the genital status at the time of birth cannot be interpreted as a clear-cut indicator of brain masculinization and later gender identity.

Gender Assignment by Diagnostic Category

Intersex children and their families cannot be left in gender limbo. Despite controversies and uncertainties, clinicians must continue to assist parents in making decisions on gender assignment. The degree of uncertainty varies with the syndrome. In Western countries, 46,XX newborns with CAH, if correctly diagnosed at birth, are usually assigned to the female gender, because the internal reproductive structures (ovaries, fallopian tubes, cervix) permit reproduction, provided that external genitalia and vagina are surgically corrected where necessary. Although many girls with CAH show variable degrees of behavioral masculinization, gender identity typically is female (Dessens *et al.*, 2005). A few CAH females change to male in adolescence or adulthood, apparently mostly in cases of protracted marked genital ambiguity and inconsistent hormonal control. Some genitally highly masculinized 46,XX children with CAH are inadvertently raised as males, especially in resource-poor countries, and the majority of them maintain a male gender identity when correctly diagnosed in later childhood or adolescence. On that basis and in view of the often problematic outcome data on genital surgery, it has been suggested to seriously consider the deliberate assignment to male of 46,XX CAH newborns with extreme degrees of genital masculinization (Lee *et al.*, 2010).

With regard to 46,XY syndromes, there is a consensus that 46,XY newborns with complete androgen insensitivity should be raised as female, because they do not respond to male sex hormones, neither somatically nor in terms of gender-related behavior, and, given that it is more prenatal rather than postnatal androgens that affect gender-related behavior, this policy can be extended to the syndrome of complete gonadal dysgenesis. Even for the syndromes of partial androgen insensitivity and testosterone

biosynthesis defect, there is a consensus that the least undermasculinized cases should be raised male and the most undermasculinized cases should be raised female. However, given the scarcity of long-term follow-up reports on such syndromes, the best cutoff point on the undermasculinization scales for assignment to the male or female gender cannot yet be determined on an empirical basis. What is known about the variability of gender outcome in individuals with a given molecular genotype and endocrine or genital phenotype lets one expect that any cutoff point on an undermasculinization scale will be associated with occasional later patient-initiated gender reassignment, however rare. With regard to cases of micropenis (i.e., a fully differentiated penis with the urethral meatus at the tip, but a (stretched) length of 2½ standard deviations or more below the norm), the Chicago meeting came to recommend male rearing in view of documented equal satisfaction with assigned gender in those raised male or female, and of the fact that patients reared male do not need surgery and are potentially fertile (Hughes *et al.*, 2006). More problematic are the relatively rare pubertal change syndromes such as 5α-reductase-2 deficiency and 17β-hydroxysteroid-dehydrogenase-3 deficiency in 46,XY. At birth, many such children appear more female than male and they are typically assigned to the female gender, unless diagnosed correctly. There are a number of clinical–medical reports from resource-poor countries showing that, in the absence of medical intervention, the majority of such individuals start virilizing dramatically during spontaneous puberty, and many change to the male gender (Cohen-Kettenis, 2005; Mendonca *et al.*, 2016, 2017). Yet, few published data are available on the long-term outcome of such cases when medical intervention is introduced at newborn age or at the beginning of puberty. Similarly, the long-term outcome of those few cases who reportedly have had early hormone replacement therapy to masculinize the genitalia has not yet been documented.

Also problematic is the gender assignment of 46,XY infants who presumably had a normal-male sex-hormonal environment in utero so that the brain was normally masculinized, but who had genital abnormalities for non-hormonal reasons, for instance, in cases of penile agenesis, cloacal exstrophy of the bladder, or traumatic loss of the penis due to a circumcision accident. A review prepared for the Chicago conference showed that a substantial minority of those assigned female became gender dysphoric or changed gender later as compared to only one of those assigned male (Meyer-Bahlburg, 2005). Although the Chicago meeting did not yield a definitive consensus for these intersex syndromes, a subsequent survey of pediatric urologists showed a strong trend away from the female gender assignment of patients with 46,XY cloacal exstrophy (Diamond *et al.*, 2011; Kolesinska *et al.*, 2014).

In the syndrome of ovotesticular DSD, the gender assignment decision is based on considerations of the preponderance of masculine or feminine structures in both the external and internal genitalia and the level of anti-Müllerian hormone, but again there is uncertainty regarding the best cutoff point for male versus female assignment, and more long-term follow-up data are needed for the formulation of a consensus policy. In the case of "XX males" secondary to a translocation of the SRY locus onto an X chromosome and consequent differentiation of a male gonad, there is no doubt that such infants should be raised as boys. Although the rapidly expanding knowledge on multiple genes participating in the sexual differentiation of the gonads and the brain complicates the picture and leads to the discovery of additional genotypes associated with intersex syndromes, it can be expected that these discoveries will help refine both diagnosis and prognosis, especially when complemented by data about sexual brain dimorphism from brain imaging and long-term follow-up data.

Conclusion

Overall, the available data from both earlier and newer studies can be tentatively summarized in the statement that intersex patients show wide variations in the prevalence of gender dysphoria and patient-initiated gender change dependent on the syndrome, syndrome severity, and gender assigned at birth (Meyer-Bahlburg, 2013). Particularly high rates are found in female-raised 46,XY patients with the pubertal change syndromes and in female-raised 46,XY patients with male-typical levels of prenatal androgen exposure as in penile agenesis or cloacal exstrophy of the bladder, whereas the majority of patients with a prenatal androgen milieu intermediate between male-typical and female-typical develop a gender identity commensurate with the assigned gender. Later initiation of gender change by an intersex person appears to be the more likely the more the prenatal and postnatal biological factors and the postnatal psychosocial factors push in the same cross-gender direction. It follows that the gender assignment of the newborn should be based on the best prognosis for the future psychosocial and psychosexual functioning of the patient in the given cultural context, taking into account everything that is known about the likely steroid effects on the brain in the syndrome in question, the hormonal and surgical treatment possibilities, and the long-term outcome in terms of gender, sexual functioning, psychiatric problems, and overall QoL.

Psychosocial Care

Introduction

The issues of gender assignment and genital surgery and the potential implications for the development of gender, sexuality, and parenthood—three highly salient, emotional, moral, and frequently controversial social issues—make intersex conditions a challenge not only for patients and their families, but also for physicians and other professionals involved in their medical and psychosocial care. Moreover, the psychosocial care itself remains in a period of flux, since the optimal-gender policy of the second half of the twentieth century has come under severe criticism, whereas the evidence on which to base systematic improvements where warranted leaves much to be desired, and no systematic randomized trials of psychosocial care procedures for intersex

patients have been conducted. In these circumstances, recommendations for specific treatment options need to be more tentative, and not only the providers, but also the parents and, when old enough, the patients themselves will be burdened by more uncertainties in their decision-making than desirable. In addition, their marked deviation from the sex/gender binary, as traditionally conceived, places individuals with intersexuality at risk for pervasive social stigma. These are the contexts, in which many patients develop psychiatric difficulties.

The professionals involved in the medical and psychosocial care of intersex patients, especially when gender assignment is problematic, may involve multiple disciplines and subspecialties, e.g., specialists in neonatology, pediatric endocrinology, pediatric urology, gynecology, genetics, genetic counseling, and mental health (Rolston *et al.*, 2017; Bakula *et al.*, 2017). To minimize the burden on intersex patients and their families, these professionals should form a smoothly operating team and follow a common policy, also with regard to criteria for decisions on gender. Parents of intersex newborns are typically in a state of high stress while the gender of their child remains uncertain, and most are not in a position to decide between conflicting professional opinions. Those team members—both medical and mental health staff—who have the most influence on decisions regarding gender assignment and genital surgery and those who most likely will be involved with the parents and patients over the coming years must keep up with medical advances, emerging new treatment options, stigma risks, the growing research on psychosocial outcomes, and the prognostic alternatives for both health and psychological development in the intersex field. To be fully effective, they need to acquire up-to-date information on all psychosocially relevant aspects of the patient's syndrome and specific symptoms. For instance, some intersex syndromes may be associated with short stature or neuropsychological impairments, both of which have psychosocial consequences of their own. There is also a need for establishing specialized programs for transition to adult care and for older adults with intersexuality. It is highly desirable that relevant professional societies develop competency criteria and interdisciplinary training programs in intersex care.

Gender Assignment and Reassignment

Gender assignment at birth

The identification of ambiguous genitalia in a newborn only occasionally constitutes a medical emergency. Yet, having a newborn of undetermined gender is stressful for most parents (Crissman *et al.*, 2011; Wolfe-Christensen *et al.*, 2014), and speedy processing of necessary medical tests and rapid decision-making with regard to gender assignment are important. Prolonged periods of nondecision are thought to run the risk of chronically ambiguous or inconsistent gender typing by the family, or of rejection of the child altogether.

Given the diverse factors that influence gender identity development in intersex patients, the decision on gender assignment required in a patient with highly ambiguous genitalia is not only based on medical criteria, but also needs to take into account the differential prognosis for psychological (including psychosexual and reproductive) functioning in either gender role as well as the prognosis for how well the family will be able to cope with either decision. The prognosis of the patient's future functioning must take into consideration the various options of genital surgery and sex-hormone treatment and their respective implications for future functioning, especially in terms of gender-role fit, sexuality, reproduction, and overall quality of life. As gender-related values differ in various societies, cultural factors have significant impact on gender assignment decisions. In many Asian countries, for example, gender assignment to male is more strongly favored and infertility more stigmatized (especially in the female) than in the West (Josso *et al.*, 2011).

Intersex counseling at this stage should involve both parents and the inclusion of other family members should be considered. Legally, gender assignment is the parents' decision, but they are likely to rely on expert medical advice, although there are differences between countries in this regard (Josso *et al.*, 2011). Along with medical education about the nature and origin of the problem and the medical tests involved, the parents must be adequately informed by their clinicians about the diversity of long-range outcomes and not given overly optimistic assurances. Commensurate with their cognitive capacity, the parents need to be made aware of significant gaps in scientists' knowledge about intersex disorders or major controversies about management decisions. Such parent counseling requires a careful balance between providing gross oversimplification on the one hand and too much detail on the other, with a resulting paralysis of decision-making. If either parent is not convinced that the gender decision was correct, appropriate child rearing may be in jeopardy. The recommended form of clinician/parent interaction and, at later stages of the child's development, clinician/patient interaction, in preparation for treatment decisions is the "shared decision making" model along with decision aids and support tools (Siminoff and Sandberg, 2015; Graziano and Fallat, 2016).

Monitoring behavioral development

The psychosocial management needs of intersex patients vary with developmental stage. Once the diagnosis is established and the decision on gender assignment made, an approximate timetable for future medical procedures and preventive psychosocial measures can be projected and visits planned accordingly. Again, a team approach in which medical procedures and psychosocial care are closely integrated is highly recommended. Active outreach by the mental health professional may facilitate prevention of psychosocial problems and adherence to medical treatment.

As for other congenital disorders, regular monitoring of behavioral development is also recommended for intersex children. This includes monitoring for medical problems and treatment compliance, as needed, and monitoring for cognitive and behavioral problems, with a special emphasis on atypical gender-role behavior (Meyer-Bahlburg, 2011; Alpern *et al.*, 2017; D'Alberton

et al., 2017). Some parents (and even some children) need help with handling atypical gender-role behavior. If symptoms of gender dysphoria emerge, parents and the child may need some help in dealing with gender issues and in persistent extreme cases the option of gender reassignment needs to be considered.

Gender reassignment

Sometimes, intersex children are initially misdiagnosed, especially when born outside of intersex-experienced medical settings, and receive their correct diagnosis later from medical specialists. The definitive diagnosis may alter the prognostic considerations and make a gender reassignment desirable. Such reassignment, if well justified, is usually not a problem during infancy, provided the parents are adequately counseled.

After infancy, during the toddler and preschool years, many intersex children develop some degree of gender-atypical behavior, but such behavior by itself does not indicate a problem of gender dysphoria. Parents who are anxious about their child's gender atypicality may need reassurance and counseling. Gender reassignment decisions after infancy, which are quite uncommon, should never be based on purely medical considerations, but require careful psychological evaluation (over a prolonged period of time) of the child's overall behavioral development, with particular attention to the child's gender-role behavior and to any symptoms of gender dysphoria, as well as to the behavioral niche the child has occupied in the family system (Meyer-Bahlburg, 2011).

Gender dysphoria and wishes to change one's gender may also emerge later in adolescence or adult life, usually as the result of a long and gradual process. Even if the problem is of long standing, through counseling the patient can consider various options, and gender change and the attendant hormone treatment and surgical procedures are not the invariable outcome.

Genital Surgery

Some children with intersexuality require genital surgery for medical reasons, e.g., gonadectomy in cases of high malignancy risk. In the majority of cases, however, genital surgery has been performed for psychosocial reasons in order to confirm the assigned gender by genital appearance and to thereby facilitate gender-appropriate rearing, to help develop a gender-typical body image, and avoid social stigmatization and also to facilitate later peno-vaginal intercourse. Because genital surgery is associated with some risk to sexual tissues and erotic innervation and thereby sexual functioning (see above), it has become highly controversial. Some intersex activists and ethicists demand that psychosocially indicated genital surgery be performed only with the informed consent of the mature individual (Chase, 1998; Sytsma, 2006; Wiesemann *et al.*, 2010; Kon, 2015; Feder and Dreger, 2016). Some critics even advocate a moratorium on all genital surgery, unless necessary for strictly medical indications (Diamond and Garland, 2014), and claim—without supportive systematic empirical evidence—that psychological counseling can take care of all attending psychosocial problems that children with marked genital ambiguity and their families may face. Surgeons counter that modern surgical techniques are much improved, although it may still require years until the patients so treated are old enough to provide data on sexual functioning. Experienced clinicians are concerned that obviously ambiguous genitalia put an unoperated intersex child at risk of undue attention and stigmatization. Moreover, in the absence of sufficient sexual experience, even an older adolescent or young adult may not be capable of giving appropriately informed consent. The very fact of genital ambiguity may contribute to the delay of sexual initiation and some patients may never reach that developmental stage. Thus, there is as yet no consensus regarding the issue of early genital surgery (Mouriquand *et al.*, 2016), except to say that milder cases of genital ambiguity are less likely to be operated on than they would have been one or two decades ago and that there is a growing consensus that genital surgery should be confined to intersex-experienced centers of excellence. It is important to note, however, that published surveys have shown that not only most parents of patients with intersexuality favored genital surgery before adolescence (Dayner *et al.*, 2004; Marei *et al.*, 2015; Binet *et al.*, 2016), but also most of the patients did so (Meyer-Bahlburg *et al.*, 2004; Wisniewski *et al.*, 2004; Nordenskjöld *et al.*, 2008; Fagerholm *et al.*, 2011; Zhang *et al.*, 2013; Binet *et al.*, 2016).

If the decision for genital surgery has been made, both medical and psychological considerations determine the choice of age for such surgery. From a psychological perspective, genital surgery is performed more easily in infancy, when counseling for the child is not an issue, and in adolescence, when cognitive maturation facilitates counseling and the patient has achieved a degree of autonomy, than in early and middle childhood. The older the child, the more he or she should be empowered to have the decisive vote in the decision for or against genital surgery and in choosing the time when it should take place. Given the advances in techniques of fertility preservation, this topic needs to be discussed in detail with parents and patients, where applicable (Campo-Engelstein *et al.*, 2017; Johnson *et al.*, 2017b; Slowikowska-Hilczer *et al.*, 2017).

Before and after genital surgery, genital examinations of intersex children and adolescents are frequent. Given the low prevalence rates of the various syndromes of intersexuality, it has been common medical practice to have many different physicians, especially medical students and residents, perform genital examinations on the same patient. However, considerable evidence has accumulated showing that this practice has negative and often severe psychological aftereffects. In medical training, this practice should be replaced by the use of photographs, videotapes, and physical models. Also, older children and teenagers should have a say in the matter whether someone should accompany them during the examination and if so, who that person should be. Useful guidelines for the performance of genital exams have been derived from work with victims of child-sexual abuse (Tishelman *et al.*, 2017).

In adolescence and adulthood, psychosocial monitoring needs to include concerns about romantic relationships and sexual functioning, because of the increased problems associated with genital ambiguity and related surgery.

Sex-Hormone Treatment

During infancy, androgen treatment is sometimes used for chromosomally male children with underdeveloped male genitals to test for an androgen-receptor defect or, if the assignment decision was for male, to enhance penile size. Occasionally, such children show behavioral change that normalizes with the end of the treatment and the parents may need reassurance.

Intersex children who have no gonads or underfunctioning gonads will need sex-hormone replacement therapy to initiate or support pubertal maturation. This is best done at the age when their classmates experience endogenous puberty. Undue delay of pubertal development may add to difficulties in the later development of romantic and sexual relationships.

Information Management

The medical and sexual education of intersex children and their parents and related counseling (including information about how to deal with relatives and friends) is a crucially important part of psychosocial care. The most difficult issue is the disclosure of their medical status and history to the intersex patients themselves, especially to those assigned to a gender discrepant with sex chromosomes and/or gonadal structure. Professionals generally support the right of patients to have access to their medical information and many experienced professionals agree that by the time of graduation from high school the patient should be fully informed, commensurate with the level of cognitive capacity. However, many parents are anxious and would like to postpone full disclosure, sometimes permanently. Appropriate timing of disclosure is important. Early disclosure runs into the problem of cognitive limitations. Late disclosure implies cover-up and deception and may lead to the patient's long-term distrust of and anger at medical professionals and even endanger appropriate future utilization of medical services. Disclosure is best conceptualized as a long-term process starting in late preschool age, with many installments, preferably in conjunction with meaningful events. Substantively, there are the issues of past genital surgery and their tell-tale signs, namely, scars on the abdomen, possibly persisting abnormalities in genital appearance, and plans for future surgery; the need for the induction of puberty by sex-hormone treatment and the maintenance of secondary sex characteristics by its lifelong continuation; the issue of infertility or, better, the potential realization of parenthood by means other than pregnancy or insemination; the question of variability in gender-role behavior among individuals of the same core gender identity; and the potential for romance, sexuality, and sexual pair-bonding—regardless of sexual orientation. All of these issues of functional potential are more important to the average developing intersex person than the details of the molecular structure of genes, the variants of hormone synthesis, receptor defects, enzyme abnormalities, and the organization and activation of neural networks—although the occasional adolescent or adult patient may have specialized interests or even choose a career path in the respective biological sciences and may seek as complete an understanding of his or her biological condition as is possible.

For the developing child and adolescent, the medical information must be carefully tailored to the cognitive maturity level. The fact that the meaning and connotations of terms differ vastly between medical personnel and lay persons makes a deliberate and cautious choice of terminology necessary. The intended medical “truth” may be dramatically at variance with what the patient or parents perceive. Visual aids are often very helpful.

For both the patients and the parents, discussing the medical aspects of intersexuality tends to be highly emotional, so adequate retention is problematic. The author's preferred procedure for the medical education of a newly referred family is that the physician in charge of the overall coordination of care, usually a pediatric endocrinologist or urologist, gives a carefully worded summary of the medical information to the parents, in the presence of the mental health professional, who then takes over. Typically, the parents are asked to recount in detail how they understand the medical condition, its origin, and its prognosis. Then, the instruction is repeated, the parents’ misunderstandings are corrected, and their particular concerns are addressed. At subsequent visits, the procedure is repeated as necessary, keeping in mind that new misunderstandings and different concerns develop over time. Similar procedures are used with intersex children, once they are old enough, except that, in addition, the clinician lets them explain to their parents (in the clinician's presence) what they have learned from the instruction, to open the channels of communication.

Mental Health and Quality of Life

Given the prevailing binary sex/gender system in society, marked deviations in body and behavior as well as in fertility potential from the expectations for typical females and males place individuals with intersexuality at risk for social stigma—experienced, anticipated, and internalized—in all spheres of life (Rolston *et al.*, 2015; Meyer-Bahlburg *et al.*, 2017a,b,c), varying with the cultural background (Meyer-Bahlburg, 2017). Parents of an intersex newborn may be highly distressed (Suorsa *et al.*, 2015), and their reactions may range from rejection to overprotection (Wisniewski, 2017). Many resort to attempts at concealing the problem (Danon and Krämer, 2017), and some may try to pressure children with gender-nonconforming behavior towards gender-typicality. The patients themselves, when becoming aware of the stigma risks, develop various ways of coping, which may include secrecy and the resulting shame, hypervigilance, and avoidance of potential risk situations and people. These challenges are likely contributors to the increased prevalence of anxiety and depression (even including suicidality) and impaired quality of life

reported in many (but not all) long-term follow-up studies of individuals with intersexuality (Schutzmann *et al.*, 2009; Wisniewski and Mazur, 2009; Bennecke *et al.*, 2017; D'Alberton *et al.*, 2015; Engberg *et al.*, 2015, 2017). Additional contributing factors may include glucocorticoid overtreatment in women with CAH (Han *et al.*, 2013; Webb *et al.*, 2017) and, in some syndromes, an association of the specific medical condition with adverse brain development. Given these findings, systematic screening for mental health and QoL and for factors that may adversely affect either is an important task for clinicians following intersex patients (Sandberg *et al.*, 2017) and therapeutic interventions have to be incorporated in the treatment plan as indicated.

Support Groups

One of the recurrent problems for persons suffering from rare disorders and their families is the feeling of isolation and having no one to talk to who really understands what they must cope with. Many support groups have sprung up, including groups specific for intersex persons and/or their parents, and the internet has greatly aided in this development (Asciutto *et al.*, 2011; Bennecke *et al.*, 2015). Generally, such groups have been a great help to many patients and their families. However, the quality of the groups is highly variable and the medical and other information that comes from them is sometimes quite misleading. Thus, frequent exchanges between support groups and professionals are recommended and group participants should be strongly encouraged to seek second opinions from their physicians and other care providers regarding the information they receive.

Ethical and Legal Aspects of DSD/Intersex

Jens M Scherpe, University of Cambridge, Cambridge, United Kingdom
Jameson Garland, University of Uppsala, Uppsala, Sweden

Introduction

Over the last century, medical and legal authorities appear to have had one common interest in the classification of persons who have been considered to have intersex conditions or differences of sex development (DSD)—namely, the juridical reliance on medical personnel to register children as either as "male" or "female" at birth and assist in determining changes to registered gender (Scherpe, 2015; Scherpe *et al.*, 2018). On closer examination, however, it is well documented that legal authorities have had a much greater historical role in the governance of these individuals' gender status than recently thought. For centuries, when the gender of such persons was contested, medical experts played only an advisory role and were often called upon to examine patients to assist determinations of their gender, determinations that affected their legal rights (Dreger, 1998; Reis, 2009). This relationship changed primarily in the 20th century, with the advent of the clinical practice that was purported to definitively establish the gender of children while treating DSDs as "anomalies" that could be "corrected" with medical intervention in infancy and early childhood (Dreger, 1998; Reis, 2009).

In recent years, greater understanding of the numerous rights that are compromised by medically reinforcing gender assignments on children without their participation and consent has generated considerable discussion about the soundness of juridical deference to the clinical management of these conditions as primarily medical matters. The concern has become grave as it has become apparent that irreversible surgical interventions and hormonal therapies have been carried out on infants and very young children without long-term data confirming their necessity, safety, and efficacy. Clinical interventions on children with DSD/intersex conditions thus raises two major issues that fall squarely within the legal domain, namely (1) the designation of a legal gender and the right to a gender identity, and (2) the legitimacy of surgical and other medical interventions, as well as injuries caused by them, particularly on new-borns without the capacity to consent. These matters will be addressed in turn, but before doing so it is necessary to briefly look at terminology and the legal history in this area.

It is of crucial importance to state at the outset that the legal and medical issues for persons directly affected by clinical practices, in principle, are distinct. Nevertheless, as in all areas of medical practice, legal authorities must determine the boundaries of permissible medical intervention, particularly with obligations to protect the human rights of all persons, including vulnerable children, under national and international law. This means in particular that the full and informed consent of the persons concerned, or their representatives, is required for any medical intervention. Given that those providing the necessary consent often will rely on the advice of medical practitioners, this creates specific ethical and legal duties which will be addressed in this contribution.

Terminology

The terminology regarding the issues discussed in this article has been inconsistent and confusing for a considerable time (Hughes, 2018). Much of the discussion of terminology, however, has occurred in a clinical context without consideration of the legal consequences of that terminology. The current dominant terminology emerged from a gathering of clinical experts in the United States in Chicago, Illinois, in 2005. Concerned about the nature of clinical practices on children with intersex conditions, these experts published a "Consensus Statement" on practice recommendations in 2006. The Statement proposed, inter alia, that the diagnostic term "disorder of sex development" (DSD) would be less alarming to parents and patients than terms such as "intersex" and "hermaphrodite," whereas diagnosis of a disorder could be essential to ensure that the care would be covered by private insurance or as health care in public health care systems (Hughes *et al.*, 2006; Lee *et al.*, 2016). Activists supporting the statement generally concluded that such a diagnostic term might be necessary even if care became more patient-centered with a shift toward consent for any surgical interventions (Reis, 2007). The medical profession appears to have adopted the term rapidly following the publication the Consensus Statement (Lee *et al.*, 2016).

Nevertheless, the term "disorder" remains highly problematic. It clinically defines the disorder solely as "congenital conditions in which development of chromosomal, gonadal or anatomical sex is atypical" (Hughes *et al.*, 2006). From numerous persons diagnosed in this manner, however, references to being "atypical" as having a "disorder" has been widely criticized as discriminatory and degrading (Davis, 2015; Reis, 2007). Indeed, in 2016, a broader group of experts revisited the Consensus Statement and formally recognized that that the term is considered stigmatic and unacceptable by some patient groups and support groups (Lee *et al.*, 2016).

The term "disorder" has also raised several medical-legal concerns in creating pressure to "normalize" these "atypical" persons as far as possible, given that what is "normal" or "typical" is dependent on subjective parental and medical perceptions.

Historically, homosexuality and diverse gender identities were once similarly medically classified as disorders, but sexual orientation and gender identity are now legally protected dimensions of an individual's right to private and intimate life under national and international law. Classification as having a "disorder" may also entitle individuals to protection under many national laws for persons with disabilities, even for being perceived as such (Greenberg, 2012), as well as under the UN's Convention on the Rights of Persons with Disabilities. The UN Committee that oversees compliance with that Convention has repeatedly described gender-conforming interventions on children with "intersex conditions" as violations of the children's rights (see e.g., Committee on the Rights of Persons with Disabilities, 2016b,c; Committee on the Rights of Persons with Disabilities, 2017a,b).

Indeed, human rights authorities have now concretized and clarified the rights of persons deemed to have disabilities precisely because their developmental differences are often targeted for adverse and unwanted treatment. The UN Committee on the Persons with Disabilities, for example, has recently explained that Article 2 of the UN Convention on Persons with Disabilities (CPRD) requires such persons to be treated equally so that the label of difference is not used as a mechanism to deny such persons' legal capacity and consent to medical treatments (Committee on the Rights of Persons with Disabilities, 2014). In 2016, the Committee elaborated on this principle and emphasized that gender equality under the CRPD prohibits maltreatment on the basis of "gender"—that is, "the characteristics that a society or culture views as masculine or feminine"—such that "surgery or treatment performed on intersex children without their informed consent" constitutes degrading treatment and abuse (Committee on the Rights of Persons with Disabilities, 2016a). This is not mere semantics. A "disorder" implies not only a defect but "wrongness" and, as said, a need to create "order" to bring back things to "normal." By contrast, difference merely means that the person concerned is not the same as the comparator, in principle without any value judgment or implications for any need of action (although admittedly being declared "different" of course also has the potential to be used in a pejorative and degrading way). Thus, the first "D" in DSD should be understood to mean "differences" rather than "disorder" and is used accordingly in this article. In any event, irrespective of the criticism the Chicago Consensus Statement (and its successors) has received because of its substance (see e.g., Carpenter, 2018; Garland and Diamond, 2018, with further references), DSD as a term now is generally accepted among the biomedical profession and literature as the more precise description of the medical determinations. However, where gender differences or differences of sex characteristics are treated as defects or disorders, the obligations to respect such persons' right to consent to medical treatment under international law cannot be avoided and require heightened oversight.

In the legal debate the term "intersex" seems to dominate and indeed is used by human rights-based advocacy groups, such as Organization Intersex International (OII), as well as all the international human rights authorities discussed in this article. However, it needs to be acknowledged that this term also can be perceived as pejorative. Furthermore, in the legal debate "intersex" sometimes has been appropriated by those advocating a "third gender" beyond the legal male–female binary (Cools *et al.*, 2016). However, because this contribution focuses on the legal aspects of sex classifications, the term intersex in relation to conditions and identities is used, particularly to track human rights recommendations.

Brief Legal Historical Background

There have always been social and legal discussions of intersex, as well as theological ones (on which see e.g., Dormor, 2018; Lavee and Artmann Partock, 2018). It is interesting to note that one of the first comprehensive major legal codifications, the Prussian Code (Allgemeines Landrecht für die preussischen Staaten, ALR) of 1794, already had provisions dealing with the legal status of intersex, as had the Saxonian Code of 1865. Before that, the question of which gender a person was deemed to have (which was particularly important for questions of succession and marriage) was dealt with by customary law and influenced by ancient classical texts and by postclassical literature and scholarship (for a detailed account see Wijffels, 2018). But advances in medical science led to these legislative approaches being abandoned as the perception was that medical intervention could "normalize" the people concerned and make them physically fit their "true gender." This often had tragic, irreversible consequences and led to terrible suffering (see e.g., Garland and Diamond, 2018, with further references), leading to calls for such interventions to be banned (on which see below).

Legal Gender

The Legal Development Concerning Recognition of the Preferred Gender

Until very recently, the legal gender of a person was considered immutably determined at birth as either male or female and registered as such by the authorities. This created significant problems when the registered legal gender later turned out to be false, particularly in cases intersex persons as well as transgender. While in some instances this could be dealt with by seeing the original gender entry as a clerical error that could be corrected, this largely depended on clinical discretion and decisions by administrative agencies or judges to make such changes, which were not always approved.

But beginning in the late 1970s, hand in hand with increasing medical and psychological knowledge about gender identity, and prompted by a string of legal advocacy, legislation began to be enacted in many jurisdictions to permit a change of legal gender on the basis of legal conditions (on this and the general development see the contributions in Scherpe (2015)). A rapid development followed, assisted by landmark decisions of the European Court of Human Rights such as Goodwin v. United

Kingdom (2002) and, more recently, the Inter-American Court of Human Rights Advisory Opinion 24 of November 24, 2017. There is now a strong, emerging consensus that international human rights law recognizes the right of individuals to be legally acknowledged in their preferred gender. Thus, in most Western jurisdictions (but also in some Asian jurisdictions, e.g., Hong Kong and Taiwan, see Liu, 2015; Ho, 2015) today the question is not *whether* changing a legal gender is possible, but rather what the *requirements* for such recognition of preferred gender ought to be, and particularly which, if any, medical requirements needed to be fulfilled. In another seminal decision, the European Court of Human Rights in 2017 held in AP, Garçon & Nicot v. France (2017) that sterility requirements were a violation of the European Convention on Human Rights, and highest national courts in Germany and Italy have similarly held that surgical requirements violate national human rights law (BVerfG, 2011 and Sentenza n. 15138/15). In addition, numerous UN human rights actors (including the UN Special Rapporteur on Torture and Other Cruel, Inhuman or Degrading Treatment or Punishment in 2016) have expressly condemned medical conditions as incompatible with existing human rights norms (on this and particularly with regard to intersex see Ghattas, 2015, 2018, as well as Sandberg, 2018). The 2006 "Yogyakarta Principles on the application of international human rights law in relation to sexual orientation and gender identity" also expressly specify the same. In the light of this, there is a clear emerging trend that legislation enacted in the 21st century no longer requires any medical procedures for legal recognition of the preferred gender but rather is based on the self-determination of the individual (as for example in Malta, Argentina or Denmark, on which see Ní Mhuirthile, 2018; Giosa *et al.*, 2015; Videbæk Munkholm, 2015 respectively). Where such legislation is in place, the medical and legal issues have been completely detached and are independent of each other. But what is crucial for present purposes is that when no medical requirements exist for the recognition of the preferred gender and is based on self-determination, a change of legal gender can be dealt with in a relatively simple administrative or judicial procedure. This therefore drastically reduces the need to determine the "right" gender (or indeed any gender) of a child at birth from the medical perspective, as the original determination of legal gender no longer is immutable and can be changed relatively easily later in life.

Intersex and Legal Gender

While there has been a relatively rapid development for recognition of preferred gender, the legal debate concerning how to classify persons who identify as intersex or who have intersex conditions is still lagging behind. The legal regulation of changes of gender, described below, largely reinforced the registration of two genders as the binary norm. Indeed, the European Court of Human Rights and the European Union, unlike some national constitutional courts (see below), have yet to support a gender-neutral registration or a right to be identified as a status other than male or female. The European Court of Human Rights, pursuant to Article 12, has in fact repeatedly affirmed that states may provide by law that persons registered as one "sex" may only marry someone of the "other" sex (presumably male or female), and that couples that do not fit this paradigm may not have the same rights (Hämäläinen v. Finland, 2014; Oliari and Others v. Italy, 2015).

So far, only the German Constitutional Court has firmly recommended consideration of a gender-neutral registered identity (see below). Proposals have been put forth in Norway and Sweden so that government data on the gender of the population will not be imposed as a legal identity on persons and can be more easily amended (Norwegian Ministry of Finance, 2017; The Swedish State's Public Report, 2017). These proposals have yet to be adopted. Medico-legal dialogue and collaboration, thus, remain essential to ensure that governments reform their laws to facilitate quick changes of registered gender for children born with intersex conditions, as urged by some human rights authorities (see e.g., Parliamentary Assembly of the Council of Europe, Resolution 2191, 2017).

Indeterminate gender

As the legal gender of a person matters for many aspects of their legal relations (for example for marriage or parenthood, although decreasingly so), and the gender binary was only being questioned very recently (on which see below), it was legally necessary for every person to be allocated the "right" legal gender. Historically (on which see above, with references) there was precedent for allowing the person concerned to choose their social and legal gender. But particularly in the 20th century aspects of gender became more medicalized and legalized, meaning that the gender had to be determined definitively at birth. It is only very recently that the laws in some jurisdictions are beginning to take a different position. After recommendation of the German Ethics Council, in 2013 Germany became the first jurisdiction in modern times to expressly legislate that the gender of a person could be left blank in birth registration documents if the gender could not be determined with absolute certainty (on this see Helms, 2018, with further references). While the person concerned could later in life choose to be legally designated male or female, there was no obligation to do so. This meant that for the first time there were persons who legally did not have a legal gender of either male or female. As the reform in question only dealt with legal gender status, none of the consequences of not having a legal gender were addressed, except that the person would have an "X" in the gender category in their travel and identity documents rather than M/F. But more crucially, this did not establish a "third gender" (on which see below), but rather an absence of legal gender for some persons.

This reform was criticized as the category of "undefined" not only inevitably outed the individuals concerned as intersex but also singled them out and stigmatized them. This in turn may lead to aggravating rather than alleviating the pressure on parents and medical professionals with regard to medical decisions about the child, including "normalizing" surgery in order to avoid the adverse consequences of leaving the gender entry as "indeterminate."

"Third gender"?

Furthermore, while many of the persons concerned identify as male or female (irrespective of any medical intervention) and prefer to be legally recognized as such, others do not. But neither do the latter persons concerned perceived themselves to be "genderless" or "indeterminate," they merely do not fit within the legal (and social) gender binary of male or female. This issue was addressed in a landmark decision by the German Constitutional Court in 2017 (BVerfG 10.10.2017) in which it was held that the German law as outlined above violated the German Basic Law (Grundgesetz (GG), the German constitution). By merely allowing a "negative" entry of gender (i.e., a nonentry) rather than a positive entry, the current German law was held to violate the general right of personality (Art. 2(1) GG in conjunction with Art. 1(1) GG) and the constitutional requirement of nondiscrimination and equal treatment (Art. 3(3) GG). The person in question did not see themselves as genderless, but as having a gender other than male and female, and the law had to positively allow for the recognition of such a gender. The court went even further and suggested that instead of establishing a legal gender system beyond the binary it may also be an option to forego registration of legal gender altogether; however, it seems unlikely that this avenue will be pursued by the legislature. In any event, the Court stipulated that the new law to remedy this situation had to be in place by the end of 2018, meaning that Germany will then be the first jurisdiction with a statutory legal gender framework beyond the binary (although at the time of writing it is unclear what exactly the framework will be, but see Althoff, 2018 for some proposals). In some other jurisdictions, including India and Nepal, court decisions have also established a "third gender," but it appears unclear how these decisions have affected legal practice (see Shah, 2018). Furthermore, it is likely (and in the view of the authors of this articles mandated by human rights law) that any legal gender category beyond the male/female binary will not be restricted to cases of (physical) intersex but also open to anyone who does not identify as male or female.

Indeed, creating a "third gender" merely for intersex persons has rightly been criticized very strongly (see e.g., Carpenter, 2018). As already explained above with regard to leaving a gender entry open, such a third category would "other" the persons concerned and potentially leave them vulnerable to discrimination and stigmatization. Persons recognized as being associated with a "third gender" suffer discrimination in countries that recognize such a gender (Towle and Morgan, 2006). Indeed while the Colombian Constitutional Court authorized registry of persons as "intersex" in 2013 (on this see Rubio-Marín and Osella, 2018), it also recognized the need for gender variant persons to have increased protection from discrimination (Garland, 2016). A third gender may also reinforce expectations or claims that medical intervention is necessary for binary sex identification to be considered equal to others. Requiring registry of such persons as intersex, however, is a clear violation of the human rights of the persons concerned and unacceptable, as it should be open to any intersex person to be legally recognized in their preferred gender irrespective of any medical requirement or interventions. As explained above with regard to recognition of preferred gender, the growing consensus is that gender should be a matter of self-identification, and that would of course also extend to any legal gender options beyond the binary. Yet, the concerns about "othering" a child by having a gender that is not male or female remain legitimate. An appropriate approach may be to not register a legal gender of a child until a certain age when they are old enough to socially identify as being of a certain gender and can determine their legal gender themselves. This may be workable as the legal gender of a person (rather than their social gender) practically really only matters in situations which are only faced when of a certain age, such as gender requirements for marriage/partnerships or parenthood (on this see e.g., Althoff, 2018). Such a system would address concerns about "othering," protect bodily integrity and promote autonomy and self-determination.

Medical Intervention, Consent, and Human Rights

National governments have long regulated the practice of medicine by law (Nys, 1994, 2011). Even when their legal frameworks do not include detailed regulations of specific medical procedures and interventions, the lawfulness of a particular clinical decision or treatment practice is still generally governed by two assessments: (1) whether the practice in question conforms to what is often known as a "professional standard" or "standard of care"; and (2) whether informed consent has been obtained by the treating practitioner from the patient or, in the case of a child, the patient's legal guardian (Nys, 1994, 2011). Prior to the 1990s, standard clinical treatment on children with intersex conditions appears to have been presumed lawful in most jurisdictions—and endorsed in others, such as Sweden—on the presumption that it was in accord with legal standards and accepted medical practice (Garland, 2016; Garland, 2018). Without clear knowledge that standard practices lacked long-term data confirming the necessity or safety of these gender-conforming surgeries and related interventions, many legal authorities, if they were aware of these procedures, may have assumed that they were lawful and that parents were fully informed of the risks and uncertainties surrounding them.

Prior to 2006, however, it was already well known that gender-conforming interventions on children with intersex conditions were not supported by long-term data to validate them as necessary or even safe (Grumbach *et al.*, 2003; Karkazis, 2008; Diamond and Garland, 2014). By 2006, the aforementioned Chicago Consensus Statement publicly acknowledged that this lack of data was a "major shortfall" of practice (Hughes *et al.*, 2006). Two expert-led reviews of the best available evidence potentially supporting standard care followed in 2012. The first of these, known as the Annecy Working Party, concluded that the available studies "lack the necessary detail to base further recommendations" upon regarding these interventions (Lee *et al.*, 2012), as well as that the quality of life of surgically altered children was a "poorly researched" area, and that sexual quality of life of patients was overall "impaired" (Schober *et al.*, 2012). The Working Party advised that gender identity could not be predicted in infancy (Liao *et al.*, 2012) and that the claim of necessity or benefit of gender-reinforcing surgeries was a commonly-held perception unsubstantiated by data (Creighton *et al.*, 2012). A second review followed from an American Psychiatric Association Task Force, which reported

that: (1) gender assignment for children with intersex conditions is "complex and fraught with uncertainties," (2) the available clinical guidelines were "uncomfortably nonspecific," and (3) the limited scientific evidence available made it "difficult to draw conclusions sufficient for evidence-based recommendations" (Byne *et al.*, 2012). In 2016, the largest multidisciplinary group of experts in the field to address the issue so far concluded that "data remain inadequate" to address gender assignment on children with intersex conditions and that no consensus exists on "unresolved questions and dilemmas regarding indications, [and] timing and procedures" of gender-conforming interventions (Lee *et al.*, 2016).

Under national laws, therefore, these candid clinical statements of scientific uncertainty regarding the necessity, safety, and benefit of gender-conforming interventions on infants and other children raise two fundamental questions under standards of care: first, whether clinicians may rely on what is "standard" to avoid discipline and liability despite knowing risks of catastrophic harms; and second, whether nations or clinicians under their authority are liable for harms that result from these procedures. Under international law—particularly the United Nations Convention on the Rights of the Child, the International Covenant on Economic, Social and Cultural Rights and the European Convention on Human Rights, and American Convention on Human Rights—states themselves may be responsible for failure to regulate these procedures and have obligations to ensure that their legal systems permit compensation and other remedies for rights violations. The lack of long-term data enabling parents to be reasonably sure that these procedures will benefit the children—supporting their children's gender, sexuality, and desires without imposing harm—also raises concerns as to whether parents actually *can* consent to these procedures as a matter of law.

Standards of Care

Standards of care for medical professionals vary significantly from nation to nation, particularly in the degree to which they require clinicians to perform certain procedures or hold them liable for procedures that cause injury. The differences in these standards are too numerous to be discussed in detail here, and few comparative works exist (Zillén *et al.*, 2017; Nys, 1994, 2011). Many nations appear to defer to what is standard practice as the presumptive, reasonable measure of what valid care is. There are numerous exceptions to this rule, however. Among the Nordic countries, for example, Iceland prohibits procedures on children without their consent that cannot be validated as medically necessary, whereas Sweden does not permit individual personnel to use treatments that have not been validated by science and carefully tested experience (Zillén *et al.*, 2017). France and Belgium permit civil liability for treatments even if they are standard practice if scientific evidence should have warned clinicians of risks of harm (G'Sell-Macrez, 2011; Nys, 2011). Germany permits liability for preventable and manageable harms that could have been avoided in practice decisions, particularly where procedures are not medically indicated (Sommer *et al.*, 2016). Even in nations that have more deferential standards toward customary practices, it is not clear that clinicians will be able to rely on assumptions that any particular practice is "standard" or "customary" to avoid liability. Currently, there is no audit of practice to determine what clinicians are doing on the whole (Frader, 2015). The Global DSD Consortium's acknowledgement that there is no consensus whether infant surgery is effective or necessary further undermines a claim that experts agree as to what the standard of care should be (Lee *et al.*, 2016). Much medical literature, indeed, appears to assume that clinicians are making individualized decisions based on what parents prefer case-by-case, rather than on objective scientific criteria (Mouriquand *et al.*, 2014; Schober *et al.*, 2012; Creighton *et al.*, 2012).

Clinicians concerned with liability for failure to provide "standard" care must recognize that such liability turns on whether the state in question has failed to ensure protection of the right to life under national and international law, or when the failure to provide treatment is a cause of actual physical injury. Here, it bears noting that even the key studies at Johns Hopkins University that led to the adoption of the practice of surgical intervention on infants and young children with intersex conditions confirmed that persons examined with atypical genitals, who were examined by the researchers, did not show any signs of "psychologic nonhealthiness," as well as that gender-conforming interventions could wait until teenage years (Money *et al.*, 1995a,b). No clear data has emerged to contradict these findings ever since. Few medical complications associated with intersex conditions are known to require medical intervention in infancy (Hughes *et al.*, 2006; Creighton *et al.*, 2012; Zillén *et al.*, 2017). The necessity of other interventions, such as surgery to reduce urinary tract infections, has not been established by quality scientific data (Nabhan *et al.*, 2011). For conditions such as cancer from atypical gonadal development, the evidence-based reviews are generally in agreement that "watchful waiting" and testing until the child could be informed is possible in many cases and, in some cases, removal may not be required (Hughes *et al.*, 2006; Creighton *et al.*, 2012). Children who cannot menstruate due to their development may, if allowed to choose, prefer different options, depending on their gender identity and the degree of intervention that they wish (Houk and Lee, 2010). Overall, it is important to emphasize that no clinical consensus statement from expert-practitioners has rebutted the view that the "only scientifically sound and ethical way to ensure that the surgery coincides with each child's gender identity and interests in how his or her body might appear" is to wait until the child can consent (Diamond and Garland, 2014).

Finally, it should be noted that while gender-conforming interventions as "treatments" for anomalies may have been presumed lawful under general standards of care, the scientific validity and uncertainty surrounding the necessity and safety of these procedures raises the question of whether they violate other laws specifically regulating other medical interventions unless exemptions are permitted on the grounds of medical necessity. Laws prohibiting sterilization of minors and female genital surgeries, for example, generally have exceptions for medical necessity, but where medical necessity is lacking, these laws may impose criminal penalties (Garland, 2016). Similarly, criminal laws often prohibit the irreversible removal of organs or other acts

associated with these interventions, such as vaginal "dilation," that may traumatize a child (Garland, 2016). Clinicians should consult authorities within their jurisdictions to inquire whether the lack of evidence of the necessity of these procedures on infants raises questions about their presumed legality.

Informed Consent

Many legal questions regarding consent to medical interventions on minors begin with the question of who may consent. The default rule in most jurisdictions is that parents are presumed to have the right to consent to medical interventions or at least to participate in those care decisions unless they conflict with the rights of the child. However, many nations permit minors to consent to medical procedures, some by virtue of age limits (such as 14 or 16) and others based on determinations of their maturity and ability to understand the information presented to them (see e.g., European Union Agency for Fundamental Rights, 2015). At the same time, many nations restrict some surgeries to adults, for example, if they have the effect of sterilization or change of gender (see e.g., European Union Agency for Fundamental Rights, 2015). In this sense, calls for permitting gender-conforming procedures only when the minor consents require further assessment of how such consent would be regulated in each jurisdiction. To the extent that *parental* participation is required, however, it bears noting that the parents' "right" to make decisions in matters regarding the child is often wrongly suggested in expert practitioners' commentary to be an unqualified right (Lee and Houk, 2014; Mouriquand *et al.*, 2014). In reality, it is a widely accepted legal principle that parents' rights to refuse or consent to medical procedures may be overridden by legal authorities with medical support or when qualified by law. By that same measure, clinicians lack the authority to override parental consent without the approval of legal authorities. As the jurisprudence of the European Court of Human Rights indicates, these rules do not favor parents or clinicians, although the requirement for legal oversight certainly has curtailed the authority of parents (Afiri and Biddari v. France 2018; Gard and others v. United Kingdom, 2017). These same rules have led to findings of violations of the rights of children when clinicians disregard the consent of parents without express legal permission (M.A.K. and. R.K. v the United Kingdom, 2010; Glass v. United Kingdom 2004). The European Court of Human Rights has also recognized that the rights of minors in intimate health care matters are separate from—and superior to—the right of the parent (P and S v Poland, 2012). It is well accepted, in fact, that medical procedures that parents may wish (such as sterilization, change of gender, or female genital surgeries) may be regulated and prohibited by law, and others, such as male circumcision, may be regulated for patient safety.

Regardless of who consents, there is a broad international consensus that the law on informed consent requires that information must be provided to the patient or the patient's caregiver in a manner that is clear and unbiased regarding risks and uncertainties for all safe alternatives (Nys, 1994, 2011). The determining factor is that the patient or the patient's caregiver must be able to make an informed choice based on reliable information. In most countries that recognize informed consent, breach of informed consent is actionable in courts. In Europe, violations of informed consent in public hospitals are directly actionable in national legal orders and compensable as rights violations, even if physical harm did not occur (Ioniţă v. Romania, 2017). It is equally well recognized that a patient generally has the right to be ill unless a lack of treatment causes serious risk of harm to the life or health of the patient (Pleso v. Hungary, 2012). Invasive non-consensual treatment that is not medically necessary is considered degrading treatment under international law (Jalloh v Germany, 2006; Pretty v. United Kingdom, 2002).

In this light, informed consent regarding gender-conforming interventions on minors with intersex conditions is extremely problematic in current practice. The Chicago Consensus Statement, for example, emphasized that "open communication with patients and families is essential and participation in decision-making is encouraged" and "the health care team will work with the family to reach the best possible set of decisions in the circumstances" but portrayed informed consent as a matter that varies among jurisdictions, without any guidance to clinicians as to how they should advise patients of catastrophic and unpredictable outcomes (Hughes *et al.*, 2006). The same Statement, along with the Global DSD Consortium, also recommended female gender assignments with a conservative estimate of 1 in 20 rejection rate for certain children. They also indicated that parents and clinicians might decide on a female assignment for children in individual cases who are genetic males despite a 50% or greater reported dissatisfaction with gender assignment among such children (Hughes *et al.*, 2006; Lee *et al.*, 2016). As other observers have noted, the medical literature itself often misrepresents data on patient satisfaction with gender assignment and infant surgery and raises concerns about how parents are presented with such data (Baratz and Feder, 2015; Diamond and Garland, 2014). On the whole, it remains unclear how parents can ever be sufficiently informed to consent to or refuse clinician's recommendations to consider gender-conforming interventions when expert-led reviews have concluded that there is inadequate evidence to support such recommendations (Byne *et al.*, 2012; Liao *et al.*, 2012). Indeed, as early as 2006, the US National Institutes of Health concluded that there was "insufficient data to guide the clinician and family in sex assignment" in such cases (National Institute of Health, 2006).

Of even greater concern, perhaps, is that parents might consent to procedures despite being told of the risks (Dayner *et al.*, 2004). As several practitioner-led statements and reviews of evidence indicate, parents themselves do not develop attachment that they may expect with their children after gender-conforming surgeries and often find it difficult to realize that their needs and desires will be different than the needs of their children (Schober *et al.*, 2012; Hughes *et al.*, 2006). There is also considerable evidence that parenting ability may be impaired by stress in their decision-making for children with intersex conditions (Garland, 2016; Garland and Diamond, 2018). As the Colombian Constitutional Court recognized in 1999, the legitimacy of parental consent in these cases is not only suspect because the interests of the child are profoundly personal but because the parents may

see their children as "minorities" that need to be "normalized," such that the children run the risk of being discriminated against by their own parents (Sentencia SU-337/99, 1999). For all of these reasons, multiple human rights authorities have come to the conclusion that the consent of children with intersex conditions themselves to any medically unnecessary surgery is imperative.

Human Rights

Over the last decade, human rights authorities have become increasingly concerned that irreversible and invasive medical interventions on infants and young children with intersex conditions constitute violations of multiple rights of children, often in a single medical procedure. In 2006, a group of experts in human rights promulgated a series of statements of rights known as the Yogyakarta Principles, derived from general international law generally when applied to sexual and gender minorities. These rights include that no child should be "irreversibly altered by medical procedures in an attempt to impose a gender identity without the full, free and informed consent of the child in accordance with the age and maturity of the child" (Yogyakarta Principles, 2006). Since then, multiple authorities from the United Nations, the Council of Europe, the European Union and the Organization of American States have endorsed this view and called on nations to ensure that gender-conforming medical interventions on children with intersex conditions do not take place without their consent (Zillén *et al.*, 2017; Ghattas, 2018). Within their competences, these authorities have identified multiple rights that may be violated in a single operation on a child, such as: (1) the right to physical and psychological integrity, (2) the right to privacy in intimate matters and identity, including the right to a gender identity and sexual life, (3) freedom from torture, inhuman and degrading treatment, (4) freedom from experimentation, (5) the right to the highest attainable standard of health, including the right to protection from practices prejudicial to their health, and (6) the right of the child to be heard in matters affecting the child (Zillén *et al.*, 2017). As of March 2018, only Malta has enacted legislation to require consent to gender-conforming procedures (Ní Mhuirthile, 2018).

Perhaps not surprisingly, some published clinical reactions to human rights recommendations have perceived them as pejorative and interfering with clinical judgment and parental decision-making (Lee and Houk, 2014; Mouriquand *et al.*, 2014). Much of this reaction, however, reflects a need for greater understanding of the scope of the rights at stake. Under international law, for example, "degrading treatment" is often paired with "torture" if it is nonconsensual medical treatment, invasive, unnecessary, and causes serious physical pain and suffering or lasting aggravation or consequences for the person's health (UN Special Rapporteur, 2013; Jalloh v Germany, 2006). This includes treatment for an actual medical condition that is made worse by the intervention (Pretty v. United Kingdom, 2002). As several authorities have noted, involuntary sterilization of the disabled is now well-recognized as a human rights violation but still persists for many children with DSD (WHO, 2014). Similarly, the traditional reliance on parental rights to justify these surgeries is not consistent with evolving legal norms recognizing the rights of children, particularly enshrined in the UN Convention on the Rights of the Child, which has been ratified by all but two nations in the world (the United States and Somalia) and constitutes an international consensus that children may need to be protected from harmful decisions made by their parents, including in health care matters (Committee on the Rights of the Child, 2006). The European Court of Human Rights and Inter-American Court of Human Rights have taken the same view in the obligation of governments to have legal frameworks in place to protect children from physical and psychological harm (Söderman v. Sweden, 2013; Inter-American Court of Human Rights, 2017).

For these reasons, human rights authorities are now urging national legal orders to regulate these procedures—not to ban them—primarily to ensure that the care is patient-centered so that clinicians can confirm that the patients desire the treatment and understand the risks, but of most importance so that treatment does not come with the uncertainty of imposing a gender or sexual preference on a child who may have different interests as an adult. In October 2017, the Parliamentary Assembly of the Council of Europe has therefore recommended that all nations should (1) prohibit medically unnecessary sex-"normalizing" surgery, sterilization and other treatments practiced on intersex children without their informed consent, (2) "ensure that, except in cases where the life of the child is at immediate risk, any treatment that seeks to alter the sex characteristics of the child… is deferred until such time as the child is able to participate in the decision," (3) ensure holistic patient-centered and expert care, (4) ensure that intersex persons have effective access to health care throughout their lives, (5) provide training to psychological and other professionals concerned, including conveying a clear message that intersex bodies are the result of natural variations in sex development and do not as such need to be modified, (6) ensure that adequate psychosocial support mechanisms are available for intersex people and their families throughout their lives, and (7) ensure that children surgically altered without their consent receive compensation for harm (Parliamentary Assembly of the Council of Europe, Resolution 2191, 2017). These views have been incorporated into the Yogyakarta Principles in 2017 and are likely to have ramifications in human rights calls for years to come.

Neonatal Diabetes Mellitus

Abdelhadi Habeb, Prince Mohammed bin Abdulaziz Hospital for National Guard & Taibah University, Al-Madinah, Kingdom of Saudi Arabia
Asma Deeb, Mafraq Hospital, Abu Dhabi, United Arab Emirates

Definitions, and Classification of NDM

The term neonatal diabetes mellitus (NDM) is used to describe uncontrolled hyperglycemia that present within the first 6 months of life and needs treatment (Rubio-Cabezas *et al.*, 2014). Although some of these children present beyond the first 4 weeks of life, which is classical definition of neonatal period, the term NDM has been widely used in the literature as most patients are believed to be born with this form of diabetes; however the time required for presentation varies between infants.

Some infants with NDM continue to require life-long treatment for their diabetes and classified as permanent NDM (PNDM), while others go into remission after few weeks or months and are labeled to have transient NDM (TNDM). Interestingly, most children with TNDM can relapse around puberty with diabetes resembling type 2 diabetes (T2DM) (Docherty *et al.*, 2013). In both TNDM and PNDM, patients can have diabetes as an isolated phenomenon or in association with other extrapancreatic features that can form a recognized inherited syndrome (syndromic NDM).

Epidemiology

NDM is a rare form of childhood diabetes and its frequency varies between different populations. Recent data showed that the incidence of NDM is higher in areas with high consanguinity such as the Middle East reflecting the genetic etiology of this form of diabetes. The highest reported incidence rate was 1: 21,000 in Northwest Saudi Arabia (Habeb *et al.*, 2012a) followed by 1 in 30,000 in Abu Dhabi, UAE (Deeb *et al.*, 2016b). A lower rate ranged between 1 in 90,000 and 1 in 500,000 was reported from Europe (Demirbilek *et al.*, 2015; Grulich-Henn *et al.*, 2010; Shield *et al.*, 1997; Slingerland *et al.*, 2009; Stanik *et al.*, 2007; Wiedemann *et al.*, 2010). The frequency of TNDM and PNDM are almost equal in Europe; however, in areas with high consanguinity, PNDM appears to be more prevalent (Deeb *et al.*, 2016b; Demirbilek *et al.*, 2015; Habeb *et al.*, 2012a) (**Fig. 1**). The lower frequency of TNDM in consanguineous populations could be explained by the more sporadic nature of the TNDM compared to PNDM. However, it is possible that some TNDM cases are not recognized or under reported.

Etiology and Pathogenesis

Over the last two decades, there has been rapid advances in the understanding of the etiology of NDM. It is now well established that NDM is a heterogeneous form of monogenic diabetes (MGD) characterized by insulin deficiency. To date, mutations in more than 20 genes that can either control the β-cell function and survival or regulate the pancreatic mass, have been identified in more than 80% of NDM cases (De Franco *et al.*, 2015). Mutations in these genes can decrease insulin secretion by different mechanisms; reducing the pancreatic mass, impairing the pancreatic β-cell function or increasing its destruction. The genetic causes, and associated phenotypes of different forms of NDM are illustrated in **Table 1** (**Fig. 2**).

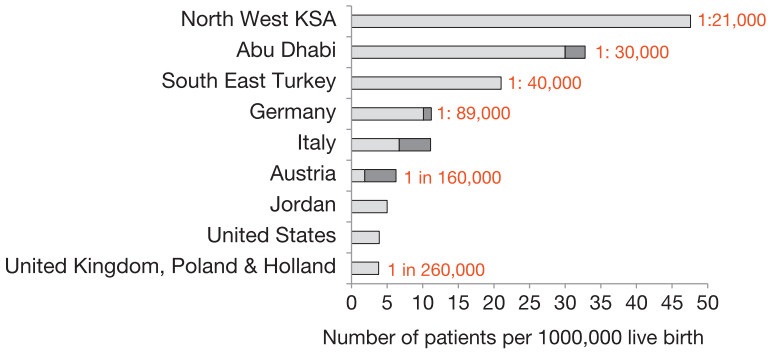

Fig. 1 Incidence of NDM worldwide: The light gray represent PNDM and the dark gray is TNDM. KSA; Kingdom of Saudi Arabia. Reproduced with permission from Deeb, A., Habeb, A. and Kaplan, W. (2016). Genetic characteristics, clinical spectrum, and incidence of neonatal diabetes in the emirate of Abu Dhabi, United Arab Emirates. *American Journal of Medical Genetics Part A* **170** (3), 602–609.

Table 1 Summary of the genotype and phenotype of NDM subtypes

Genetic cause	*Mode of inheritance*	*Neonatal diabetes subtype and treatment*	*Additional features*
6q24	Sporadic	Transient; insulin	Intrauterine growth retardation, macroglossia, umbilical hernia, neurological features (rare)
KCNJ11	Sporadic, dominant	Transient, permanent; sulfonylurea	Developmental delay with/without epilepsy (20% of cases)
ABCC8	Recessive, dominant and sporadic	Transient, permanent; sulfonylurea	22% have DEND syndrome (developmental delay with/without epilepsy)
INS	Recessive, sporadic	Transient, permanent; insulin	None
HNF1B	Recessive	Transient; insulin	Pancreatic hypoplasia, renal cysts
ZFP57	Sporadic, recessive	Transient	Intrauterine growth retardation, neurological features
SLC2A2	Recessive	Transient, insulin	Fanconi Bickel syndrome (hepatorenal glycogen accumulation, renal tubular acidosis, hyperlipidemia, hypophosphatemic rickets)
GATA4	Recessive	Transient, permanent; insulin	Congenital heart malformation, exocrine insufficiency
GATA6	Recessive	Transient (rare), permanent; insulin	Congenital heart malformation, neurological defects, hypothyroidism, gut and hepato-biliary malformation, exocrine insufficiency
EIF2AK3	Recessive	Permanent; insulin	Skeletal dysplasia, liver dysfunction, developmental delay
FOXP3	X-linked, recessive	Permanent; insulin	Eczema, enteropathy, other autoimmune features
GCK	Recessive	Permanent; insulin	None
GLIS3	Recessive	Permanent; insulin	Congenital hypothyroidism, renal cysts
IER3IP1	Recessive	Permanent; insulin	Microcephaly, epilepsy
MNX1	Recessive	Permanent; insulin	Sacral agenesis, neurological defects NEUROD1, cerebellar hypoplasia, sensorineural deafness
NEUROD1	Recessive	Permanent; insulin	Cerebellar hypoplasia, sensorineural deafness, visual impairment
NEUROG3	Recessive	Permanent; insulin	Congenital malabsorptive, diarrhea
NKX2-2	Recessive	Permanent; insulin	Severe neurodevelopmental defects
PDX1	Recessive	Permanent; insulin	Exocrine insufficiency
PTF1A	Recessive	Permanent; insulin	Cerebellar agenesis
RFX6	Recessive	Permanent; insulin	Intestinal atresia and/or malrotation, gall-bladder agenesis
SLC19A2	Recessive	Permanent; insulin and thiamine	Thiamine-responsive megaloblastic anemia (sensorineural deafness, thrombocytopenia, stroke, cardiac and visual defects)
STAT3	Sporadic, dominant, germline	Permanent, insulin	Autoimmune enteropathy, primary hypothyroidism, pulmonary disease, juvenile arthritis, dental disease, eczema
LRBA	Recessive	Permanent, insulin	Autoimmune lymphoproliferative disease, hepatosplenomegaly, thrombocytopenia, enteropathy, autoimmune hemolytic anemia

The genetic etiology and clinical spectrum of PNDM vary between populations and are influenced by the parental consanguinity. Studies in Europe, Japan, and the United States have shown that PNDM is usually isolated and de novo mutations in either of the genes encoding the two subunits of the ATP-sensitive potassium (K_{ATP}) channel of the β-cell membrane (KCNJ11 or ABCC8) are the commonest cause of PNDM (Flanagan *et al.*, 2006; Shankar *et al.*, 2013; Suzuki *et al.*, 2007) followed by *INS* (preproinsulin) gene mutations (Docherty *et al.*, 2013). In contrast, in areas with high consanguinity, PNDM is usually associated with extrapancreatic features with mutations in the *EF2AK3* leading to Wolcott Rallison syndrome being the commonest cause (Rubio-Cabezas *et al.*, 2009; Habeb *et al.*, 2018).

The majority of TNDM cases are caused by imprinting defect in the 6q24 chromosome leading to over expression of the *PLAGU* gene (Docherty *et al.*, 2013; Mackay *et al.*, 2014; Temple and Shield, 2002). Other causes of TNDM include activating mutations of the K_{ATP} channel genes (*KCNJ11* and *ABCC8*), *HNF1B* and *INS* gene mutations (Edghill *et al.*, 2008; Gloyn *et al.*, 2005). Interestingly all genetic causes of TNDM can also lead to PNDM.

Clinical Presentation

Patients with NDM usually have low birth weight, reflecting the role of insulin in antenatal growth, and can present throughout the first 6 months of life.

Unlike older children and adults, the diabetes symptoms can be difficult to detect at this age group by families and general practitioners which can often lead to a delay in making the diagnosis. Infants with NDM can be asymptomatic and discovered accidently while measuring blood glucose for other reasons. It is therefore a good practice to measure blood glucose or test urine for glucose in any child admitted to hospital with unspecific presentation. Common symptoms of hyperglycemia at this age include, poor feeding, failure to thrive, vomiting, polyuria (frequent nappy changes), dehydration, and ketoacidosis. Occasionally

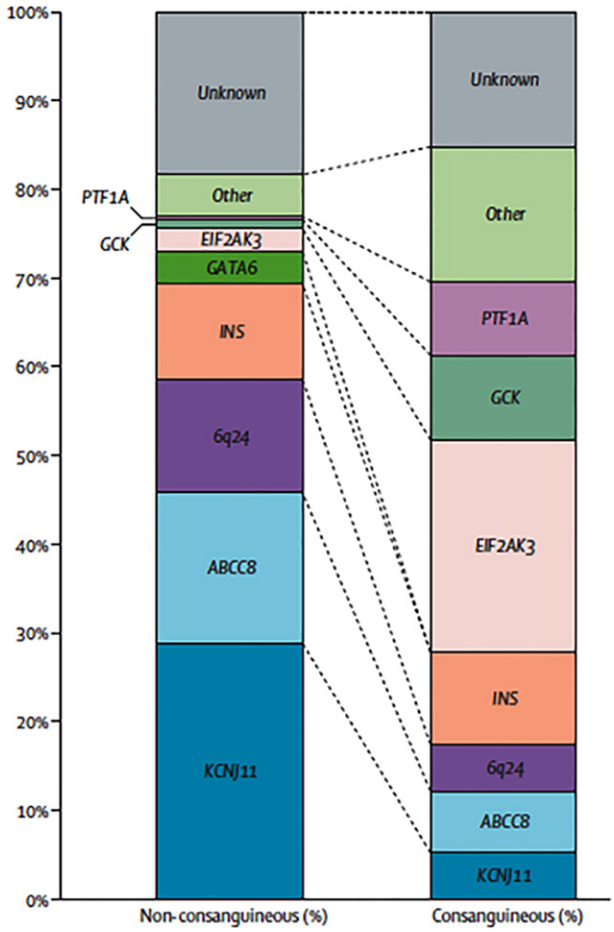

Fig. 2 Comparison of genetic causes of neonatal diabetes in nonconsanguineous ($n = 790$) and consanguineous groups ($n = 230$). Tested in Exeter molecular genetic laboratory. Consanguinity is defined by parents being second cousins or more closely related or by the presence of 1 · 56% or higher total homozygosity. Reproduced with permission from De Franco, E., Flanagan, S. E., Houghton, J. A., et al. (2015). The effect of early, comprehensive genomic testing on clinical care in neonatal diabetes: An international cohort study. *Lancet* **386** (9997), 957–963.

the diagnosis of NDM is delayed because the above symptoms can be seen in other conditions such as gastroenteritis and respiratory or urinary infection that are more common at this age.

The combination of persistent hyperglycemia with glycosuria is usually sufficient to make the diagnosis of NDM. In children beyond the first 2 months of life, the high HbA1c can be useful to confirm the diagnosis of NDM. However, the diagnosis can be a challenge in newborns with sepsis where insulin resistance can cause hyperglycemia (Mittal *et al.*, 2013). In addition, some metabolic condition such as methylmalonic acidemia, can have an initial presentation that mimic diabetic ketoacidosis (Dejkhamron *et al.*, 2016; Saini *et al.*, 2015). Unlike children with NDM, hyperglycemia in infants with metabolic conditions is often easily controlled with small dose of insulin and on the recovery stage hypoglycemia becomes obvious.

At presentation it is difficult to predict clinically whether the infant has TNDM or PNDM as patients can have similar symptoms of hyperglycemia. It is worth remembering that in some forms of syndromic NDM, diabetes can precede the development of other extrapancreatic features which can develop later during the course of the disease. Reported extrapancreatic features in patients with NDM are listed in **Table 2**.

Clinical Evaluation of a Child With NDM

The aim of the initial assessment of children with NDM is to confirm the diagnosis, start the appropriate treatment, detect associated extrapancreatic features and identify the genetic cause. The latter is crucial as it can guide the best treatment option for the patient, predict the development of some extrapancreatic features, avoid invasive procedures to diagnose associated features and provide the family with accurate genetic counseling.

The clinical evaluation of a newly diagnosed child with NDM follows the usual approach of history taking, clinical examination and guided investigations.

Table 2 Common reported extrapancreatic features in patients with neonatal diabetes

Neurological	*Face, eye, and ear*
Developmental delay	Macroglossia
Brain malformation	Glaucoma
Epilepsy, stroke	Microphthalmia
Microcephaly, lissencephaly	Optic atrophy
Diabetes insipidus	Visual impairment
Central respiratory dysfunction	Deafness
Gastrointestinal	*Hepatic*
Failure to thrive and diarrhea	Deranged liver enzymes
Pancreatic hypoplasia/aplasia	Intermittent hepatitis
Intestinal atresia	Hepatic cysts
Biliary abnormalities	Hepatomegaly
Gall-bladder agenesis	Hepatic fibrosis
Autoimmune enteropathy	
Hematological	*Musculoskeletal*
Thrombocytopenia	Rickets
Lymphoproliferative syndrome	Sacral agenesis
Autoimmune hemolytic anemia	Skeletal dysplasia
Megaloblastic anemia	Juvenile arthritis
Endocrine/metabolic	*Cardiovascular*
Hypothyroidism	Arrhythmia
Hypercholesteremia	Conduction defects
Hypertriglyceridemia	Congenital heart disease
Hypergalactosemia	
Kidney	*Others*
Renal cysts	Low birth weight
Impaired renal function	Eczema
Renal failure	Umbilical hernia
Renal tubular acidosis	Interstitial lung disease

The value of clinical history and examination in NDM

The combination of parental consanguinity and history of previous child with NDM, or unexplained infantile death usually points toward autosomal recessive NDM. The presence of one parent with diabetes diagnosed within the first year of life could indicate K_{ATP} channel diabetes, which can be better managed with sulfonylurea (SU) than insulin (Pearson *et al.*, 2006; Rafiq *et al.*, 2008). The history of maternal gestational diabetes or mild hyperglycemia in either parents raises the possibility of NDM due to biallelic glucokinase (*GCK*) gene mutations in the child, and heterozygous GCK MODY in the parent. This is particularly the case if the child has a very low birth weight and presented in the first few days of life (Njolstad *et al.*, 2003) (see below). Finally, history of TNDM in parents or a sibling in early life may predict that the child could have TNDM.

The severity of intrauterine growth retardation (IUGR) and timing of presentation may point toward a specific form of NDM. For example, the combination of severe IUGR and hyperglycemia within the first week of life is typically seen in biallelic *INS*, *GCK*, and *GLIS3* mutations (Docherty *et al.*, 2013; Edghill *et al.*, 2007; Njølstad *et al.*, 2001), while patients with *INS* and *GCK* mutations have isolated NDM, children with GLIS 3 mutations have distinct phenotype including primary hypothyroidism, glaucoma and liver disease (Dimitri *et al.*, 2015).

Children with NDM should be thoroughly examined for the presence of extrapancreatic features (see **Table 2**). Some of these features may need early intervention because they carry higher morbidities than diabetes, for example, glaucoma, liver dysfunction, hypothyroidism and pancreatic exocrine dysfunction. Detailed phenotypic assessment is also important for prioritizing the genetic testing. For example, the presence of NDM, skeletal dysplasia and intermittent hepatitis indicate that direct sequencing of the *EIF2AK3* gene is needed to confirm WRS (Rubio-Cabezas *et al.*, 2009) and the combination of NDM, hepatomegaly and rickets raises the possibility of Fanconi Bickel syndrome (Sansbury *et al.*, 2012) which can be confirmed by *SLC2A2* sequencing and thus avoiding the need for liver biopsy. It is worth remembering that some of the features such as skeletal deformities can develop months and years after the diabetes and that some features can be intermittent such as hepatitis in WRS (see below). The clinical examination of children with NDM should include proper ophthalmology, hearing, neurological and cardiac assessment.

Initial investigations of children with NDM

In addition to the urinalysis, measurement of blood glucose, HbA1c, and genetic testing, children with NDM need further hematological, biochemical, radiological and genetic tests guided by the clinical findings (**Fig. 3**). The authors recommend that all children with NDM have the following baseline tests: hemoglobin, white blood counts, platelets, liver function test, urea, creatinine, TSH, fT4, c-peptide, stool elastase and abdominal ultrasound for kidneys pancreas and bladder. It is worth remembering that when assessing for pancreatic aplasia/hypoplasia in neonate, fecal elastase and fats are more reliable than pancreatic

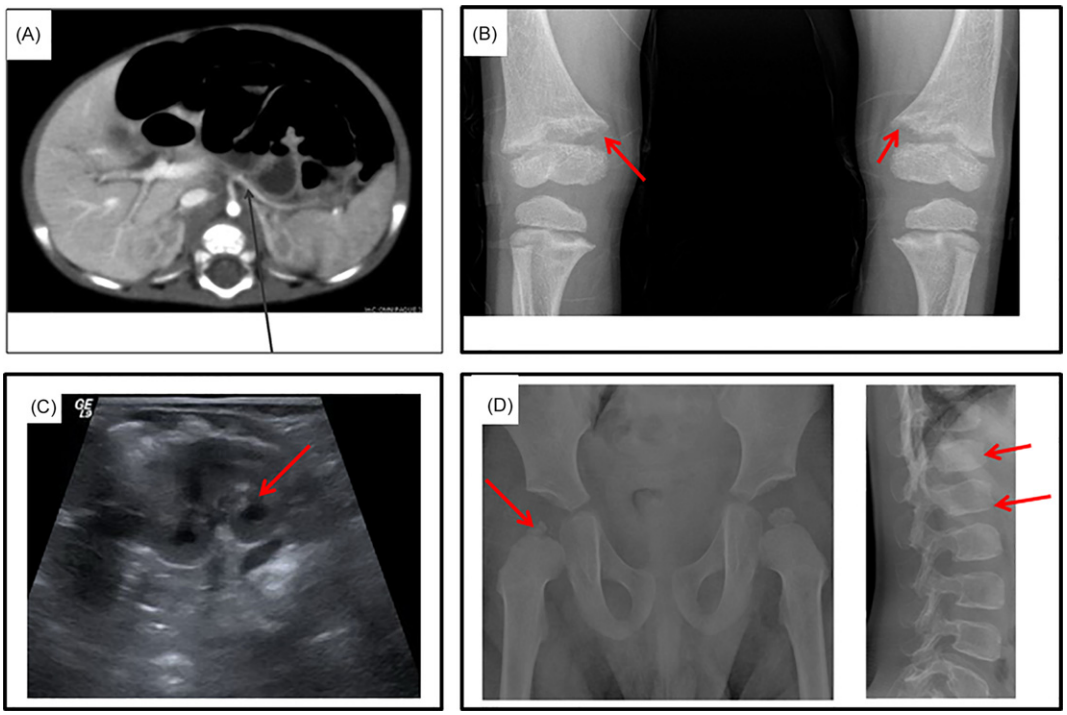

Fig. 3 Radiological features detected in some children with neonatal diabetes: (A) computerized tomography of the abdomen showing pancreatic aplasia; (B) active rickets in both knees in a patient with Fanconi–Bickel syndrome; (C) renal ultrasound scan showing renal cysts in GLIS 3 and WRS, (D) skeletal dysplasia in WRS (fragmented femoral head and thoraco-lumbar vertebra).

scanning (Weedon *et al.*, 2014). The rest of tests depends on the phenotype, for example, if there is skeletal deformities, skeletal survey is important to detect epiphyseal dysplasia associated with WRS, which is the commonest cause of NDM in consanguineous parents (Edghill *et al.*, 2008).

The routine measurement of pancreatic autoantibodies is not necessary as they are usually negative and their presence at this age doesn't rule out monogenic diabetes. In fact, most infants with positive autoantibodies found to have MGD triggering autoimmunity rather than the classical multifactorial autoimmune type 1 diabetes (see below).

Genetic testing for NDM

More than 80% of NDM patients have genetic cause and it is now recommended that molecular genetic testing for infants with NDM before 6 months should be performed as soon as the diagnosis is confirmed. Knowledge of the genetic cause of NDM has many clinical benefits: first, it can guide the best treatment for example patients with KATP are better managed by SU and starting thiamine in those with *SLC19A2* mutations can resolve the anemia and some patients may become off insulin. Secondly, it can predict the development of some extrapancreatic features such as skeletal dysplasia and intermittent hepatitis in WRS and finally provides the family with accurate genetic counseling with the options for future pregnancies such as the use of pregestational diagnosis (PGD) and selection of unaffected fetus (Deeb *et al.*, 2016a).

Genetic testing for NDM is freely available in some laboratories in Europe and North America with some providing rapid testing for subtypes where results alter treatment such as K_{ATP} channel mutations. Traditionally, genetic testing is based on direct sequencing of a specific gene guided by the clinical phenotype. However, the development of NGS whole exome sequencing it is now possible to test for all 22 genes responsible for NDM using one kit (Ellard *et al.*, 2013).

In some patients, certain combination can be detected with the diabetes and it is possible that the genetic diagnosis can be predicted before conducting the genetic tests. For example, the combination of NDM, congenital hypothyroidism and glaucoma is diagnostic for *GLIS3* mutations (Dimitri *et al.*, 2015) and the triad of diabetes, anemia and deafness is diagnostic for thiamine responsive megaloblastic anemia (Shaw-Smith *et al.*, 2012).

Management of NDM

Similar to other forms of childhood diabetes, the clinical management of NDM is multidisciplinary and encompasses parental education, dietary management and pharmacotherapy. Children should be screened regularly for the presence of extrapancreatic features and referred to the appropriate service for further management.

In addition to the standard diabetes educational package, parents of infants with NDM should be alerted for the possibilities TNDM and the symptoms and evolving nature of some extrapancreatic features. It is important to be aware that families of infants with NDM need a longer period of hospital based education compared to other forms of diabetes. Because of the genetic nature of NDM, parents should be referred for genetic counseling as soon as the genetic cause is identified.

The dietary management of diabetes at this age is a challenge. This is particularly due to the rapid physical growth and the change in nutritive requirement in this age group. Breastfeeding makes assessment of intake and insulin dosages fairly inaccurate and weaning into solid food can be difficult. Conventional preprandial glucose readings might not be genuinely preprandial and many assumed preprandial readings are in fact postprandial which impacts adversely on the dose of insulin to be given (Deeb, 2017).

Pharmacotherapy in NDM

At diagnosis, all children with NDM should be started on insulin. However, the need for insulin therapy can be revised once the result of the genetic testing became available. NDM is one of conditions where the concept of pharmacogenomics or targeted therapy is vividly illustrated. For example, patients with K_{ATP} channel mutations are sensitive to SU and should be given a trial of switching from insulin to SU (Pearson *et al.*, 2006; Rafiq *et al.*, 2008) and those with TRMA due to SLC19A2 mutation can achieve better glycemic control and may become off insulin by adding thiamine (Habeb *et al.*, 2018).

All NDM patients should continue on insulin except patients with K_{ATP} mutations. Insulin therapy is a challenge in infants as they require very small doses of insulin. In addition, infants have less subcutaneous tissue which results in variable absorption and sensitivity for insulin. The need for ultra-small doses of insulin to cover the small carbohydrate intake imposes a major challenge and optimal glycemic control is difficult to achieve due to the risk of hypoglycemia when strict control is attempted. Insulin pump therapy can be the ideal solution for this problem particularly in infants on continuous feeding, those on total parental nutrition or infants on frequent breastfeeding (Tubiana-Rufi, 2007). In our experience, insulin pumps with continuous glucose monitoring (CGM) are the safest way to control blood glucose at this age. CGM is particularly useful in infants prone to nocturnal hypoglycemia in whom sensor augmented pump therapy is the safest solution. Insulin pumps might not be available in some parts of the world where neonatal diabetes is more common. In these areas, the use of multiple daily injection can be an alternative with a suitable ratio of basal to prandial insulin. Diluting insulin is another method for providing ultra-small doses of insulin. However, it is associated with a considerable degree of human errors and inaccuracy (Ruan *et al.*, 2015).

Because K_{ATP} channel diabetes is the commonest cause of NDM in nonconsanguineous populations, some authors suggested to start all NDM imperially on SU as genetic testing can be costly and not easily available in certain parts of the world (Carmody *et al.*, 2014). However the authors feel that this practice is not justifiable as some international laboratories are offering free genetic testing for NDM and the results of KATP in particular can be available within days. Also in some parts of the world KATP are not common cause of NDM and some KATP mutations require higher dose and longer period of time to respond. In addition, SU can cause side effects of diarrhea and hypoglycemia and cause parental disappointment if the diagnosis of $K_{ATP\ is}$ excluded on genetic study (Deeb, 2016).

Genetic Counseling

Genetic counseling is an important part of the management of NDM. Few forms of NDM subtypes are not inherited but the majority are caused by single gene defects and thus the risk for future pregnancies depends on the mode of inheritance. Some forms of monogenic NDM are caused by sporadic mutations. It is, therefore, important to define the carrier status of the parents. If the parents have no mutations and the child have heterozygous mutation, for example, K_{ATP} diabetes and some INS mutations, the offsprings will have 50% chance to be affected. However, when parents are carriers the siblings of those with recessive mutations will have 25% risk. Detailed recurrence risk in certain NDM subtypes are discussed under specific subtypes (see below).

Reducing consanguinity is a challenge in some cultures; however, knowledge of the mutation of certain NDM with poor prognosis would allow for antenatal diagnosis with termination of pregnancy. An alternative option for certain families is the technique of pregestational diagnosis, which allow for the selection of unaffected zygotes, particularly for families with more than one affected child (Deeb *et al.*, 2016a).

Common Subtypes of NDM

6q24 Diabetes

Abnormalities of the imprinted region on chromosome 6q24 leading to overexpression of *PLAGL1* and *HYMAI* genes are responsible for approximately 70% of patients with TNDM (Docherty *et al.*, 2013). To date, three molecular causes of 6q24 diabetes have been reported: paternal uniparental disomy (UPD) of chromosome 6, that is, both alleles inherited from the father, paternal duplication of the 6q24 region and abnormal methylation of the maternal allele (Mackay *et al.*, 2014; Temple and Shield, 2002). The latter can also be due to bilallelic *ZFP57* gene mutations.

Patients with 6q24 diabetes often have IUGR and develop severe nonketotic hyperglycemia during the first week of life. In majority of them, the diabetes remits in few months but relapses around puberty with a picture resembling early-onset type 2 diabetes which can respond to SU. During remission, transient hyperglycemia may occur during intercurrent illnesses. In a large series of TNDM due to 6q24, more than 50% of 134 patients have associated extrapancreatic features of which macroglossia and umbilical hernia were the commonest (Docherty *et al.*, 2013). These congenital abnormalities occurred less frequently in the 6q24 duplication. Recently UPD 6q24 abnormalities were detected in three young adults with early onset nonautoimmune diabetes (Yorifuji *et al.*, 2015) and children with PNDM (Cao *et al.*, 2017; Flanagan *et al.*, 2007).

Genetic counseling for families with 6q24 TNDM depends on the underlying molecular mechanism. Methylation defects and UPD of chromosome 6 are essentially sporadic and therefore the risk of recurrence in siblings and offspring is low. For paternal duplication of the 6q24 region, males have a 50% chance of transmitting the disease to their children. In contrast, females will pass on the duplication, but their children will not develop the diabetes. However these asymptomatic carrier may pass the disease to their offsprings. Methylation defect due to mutations in *ZFP57* show an autosomal recessive inheritance with recurrence risk is 25% for siblings.

Neonatal Diabetes Due to Mutations in the K_{ATP} Channel Genes

In outbreed populations, $\mathbf{K_{ATP}}$ channels mutations are the commonest cause of PNDM and the second most common cause of TNDM (De Franco *et al.*, 2015; Rubio-Cabezas *et al.*, 2014).

K_{ATP} channels are octameric complexes consisting of four Kir6.2 subunits and four SUR1 subunits, encoded by the *KCNJ11* and *ABCC8* genes, respectively. The channels control insulin secretion by coupling cell metabolism to electrical activity of the β-cell. Any increase in the intracellular glucose membrane results in a rise of the ATP/ADP ratio which makes the K_{ATP} channels close. This closure results in depolarization of the cell membrane with influx of calcium into the cell which triggers the insulin secretion. Activating mutations in the genes encoding the *KCNJ11* or *ABCC8*, prevent the closure of K_{ATP} channel and subsequently insulin secretion in response to hyperglycemia.

More than 90% with *KCNJ11* mutations have PNDM and approximately 10% of them present with TNDM (Babenko *et al.*, 2006; Ellard *et al.*, 2007; Flanagan *et al.*, 2007). In contrast, two-third of patients with *ABCC8* mutations have TNDM (Ellard *et al.*, 2007; Proks *et al.*, 2006). Compared to patients with 6q24 abnormalities, children with TNDM due to K_{ATP} channel mutations present slightly later, have milder intrauterine growth retardation and their diabetes usually remits later and relapses earlier than in 6q24-TNDM.

Patients with K_{ATP} channels diabetes have low or undetectable C-peptide levels and frequent presentation with diabetic ketoacidosis and around 20% of patients with diabetes due to *KCNJ11* mutations have associated neurological symptoms reflecting the expression of K_{ATP} channels in neurons and muscle cells (Babenko *et al.*, 2006; Flanagan *et al.*, 2007). The neurological features vary from the typical severe DEND (developmental delay, epilepsy, and neonatal diabetes) syndrome to a milder form and more frequent (intermediate DEND) which is characterized by NDM, moderate developmental delay without epilepsy. In contrast, neurological features are less frequent and often milder in patients with *ABCC8* mutations (Babenko *et al.*, 2006; Ellard *et al.*, 2007; Proks *et al.*, 2006).

Most patients with K_{ATP} channel diabetes can be transferred from insulin to oral SU. In fact, they can achieve better control with less hypoglycemic episodes on SU compared to insulin (Pearson *et al.*, 2006; Rafiq *et al.*, 2008). The SU doses required per body weight are higher than those for adults with type 2 diabetes (around 0.5–2.3 mg/kg/day of glibenclamide) but many patients have been able to progressively reduce the dose after transition while maintaining excellent glycemic control. Some reports showed that SU may penetrate blood–brain barrier and that SU may partially improve some of the neurological features (Battaglia *et al.*, 2012; Gurgel *et al.*, 2007). The main reported SU side effects in children are transient diarrhea and staining of the teeth on chronic use (Codner *et al.*, 2005; Kumaraguru *et al.*, 2009).

Activating mutations in *KCNJ11* causing NDM are heterozygous with 90% of them arising spontaneously without family history of NDM, but familial cases show an autosomal dominant inheritance. The recurrence risk for the offspring of an affected patient is 50%. Whilst most activating mutations in *ABCC8* are also heterozygous, some patients are homozygous or compound heterozygous for two different mutations and their NDM is recessively inherited (Flanagan *et al.*, 2007; Proks *et al.*, 2006). In this case, the risk of NDM for future siblings is 25%; but almost nil for the offspring. Germline mosaicism (mutations present in the gonads but not detectable in blood) has been reported in some families (Edghill *et al.*, 2007). Therefore, unaffected parents of a child with an apparently de novo mutation should be advised that the recurrence risk in siblings is low but not negligible.

Neonatal Diabetes Due to Mutations in *INS* Gene

Both heterozygous and biallelic (homozygous or compound heterozygous) *INS* mutations can cause NDM through different mechanisms.

Heterozygous *INS* mutations are the second commonest cause of PNDM and can occasionally result in TNDM (De Franco *et al.*, 2015; Edghill *et al.*, 2008). The diabetes is slowly progressive and results from accumulation of the misfolded proinsulin protein in the endoplasmic reticulum (ER). This leads to ER stress and β-cell apoptosis. Patients with heterozygous INS mutations have

isolated diabetes and similar birth weight to those with K_{ATP} but present slightly later (Edghill *et al.*, 2008). In some families diabetes present beyond 6 months of age and the same mutation can cause PNDM and TNDM within the same family (Deeb *et al.*, 2016b). Most heterozygous *INS* mutations are sporadic but about 20% of probands have a positive family history of autosomal dominant NDM.

Biallelic *INS* mutations have also been described as a cause of isolated NDM (Garin *et al.*, 2010). In contrast to the heterozygous *INS* mutations, the diabetes results from lack of insulin biosynthesis during pre- and postnatal period. As a result, patients with biallelic mutations have much lower birth weight and earlier presentation compared to those with heterozygous INS mutations. The diabetes is recessively inherited with 25% recurrence risk in siblings; but in the absence of consanguinity, a very low risk for the offspring of the patient is expected.

Wolcott Rallison Syndrome

Wolcott–Rallison syndrome (WRS) is the commonest cause of PNDM in consanguineous pedigrees and Arab population (Habeb *et al.*, 2012b; Rubio-Cabezas *et al.*, 2009). This syndrome is caused by recessive loss of function mutations in the *EIF2AK3* gene. The *EIF2AK3* gene encodes a protein called pancreatic PKR-like endoplasmic reticulum kinase (PERK), which plays a key role in detecting and initiating the cellular response to endoplasmic reticulum stress, insulin secretion and trafficking. Failure of appropriate PERK response results in accumulation of misfolded proteins, which leads to cell damage and apoptosis.

The cardinal features of WRS are PNDM, skeletal dysplasia and non-auto immune intermittent hepatitis which can progress to acute fatal hepatic failure (Habeb *et al.*, 2015). Other reported features include renal dysfunction, failure to thrive, developmental delay, neutropenia and hypothyroidism. Patients can initially present with isolated diabetes within the first few months and subsequently develop the extrapancreatic features (Rubio-Cabezas *et al.*, 2009). Occasionally, diabetes presents as late as 3–4 years old. The prognosis of WRS is poor with the majority of patients die within the first decade with acute hepatorenal failure.

The management of WRS should be through a multidisciplinary team including endocrinologist, gastroenterologist and orthopedic surgeon. The diabetes is insulin dependent and the management of skeletal dysplasis is generally conservative. It is important to ensure that families of affected children recognize early symptoms of liver dysfunction and that patients with WRS have a clear plan prepared to avoid delay in starting the management of acute hepatic failure. Liver transplantation was successfully used to save the life of one child and three other children had multiple organs (liver, kidney and pancreas) transplantation and earlier results are encouraging (Elsabbagh *et al.*, 2017; Habeb *et al.*, 2015; Rivera *et al.*, 2016). The clinical importance of conducting the genetic testing for this condition is vividly illustrated in helping a couple carriers of WRS with affected children to have a healthy child using the PGD technology (Deeb *et al.*, 2016a).

Neonatal Diabetes Due to *GCK* Mutations

Biallelic mutations in the gene encoding the glucokinase (GCK) enzyme are responsible for less than 2%–3% of cases of PNDM (De Franco *et al.*, 2015). The GCK enzyme is considered as the glucose sensor of the β-cells because it allows the β-cell to secrete the proper amount of insulin in response to the degree of the blood glucose. It does this function by catalyzing the rate-limiting step of glucose phosphorylation. Mutations in both alleles of the *GCK* gene (homozygous or compound heterozygous) results in complete glucokinase deficiency. The GCK related NDM is caused by the inability of the β-cells to secret insulin in response to hyperglycemia. As a result of the severe insulin deficiency, the diabetes often presents within the first few days of life and infants have severe IUGR. Apart from diabetes, patients do not show any extrapancreatic features (Njolstad *et al.*, 2003; Njølstad *et al.*, 2001; Rubio-Cabezas and Ellard, 2013). It is worth remembering that heterozygous mutations in the *GCK* gene result in familial mild nonprogressive hyperglycemia, also called GCK MODY. Therefore, NDM due to GCK mutations should be considered in infants born to parents with asymptomatic mild hyperglycemia. For this reason, it is recommended to measure fasting blood glucose in the parents of any child with NDM, even in the absence of consanguinity or family history of diabetes. This type of PNDM is inherited in a recessive manner so the recurrence risk for future siblings is 25%.

Neonatal Diabetes With β-Cell Immunity

Unlike older children, diabetes in infants presenting in the first 6 months of life is very unlikely to be due to autoimmune etiology. Those infants who test positive for β-cell autoantibodies are likely to have gene mutations triggering the autoimmune process. Several novel syndromes with autoimmune diabetes due to monogenic immunodysregulation have been identified. IPEX syndrome (Immune dysregulation, Polyendocrinopathy, Enteropathy, X-linked) is caused by *FOXP3* mutation which is an essential transcription factor for the development of regulatory T cells and has a role in their ongoing suppressive action (Verbsky and Chatila, 2013). Pathogenic variants of STAT3, STAT1, LRBA, IL2RA, CTLA4 have also been implicated in triggering autoimmune-based diabetes and other systemic illnesses and reported to cause diabetes (Flanagan *et al.*, 2014; Goudy *et al.*, 2013; Johnson *et al.*, 2017; McDonald *et al.*, 2017). All these genes affect the tolerance mechanism in the body. Their mutation impairs the balance

between effective immune response and autoimmunity. Autoimmune diabetes triggered by monogenicity can be of early onset within the 6 months of life and thus fulfilling the criteria of NDM.

Future Development

With the rapid advances of molecular genetic techniques and wide application of the WES and whole genome sequencing, it is expected that more genetic causes of neonatal diabetes will be discovered. This would help in identifying the best therapeutic approach for neonatal diabetes. Recent study showed that it will be feasible to screen for neonatal diabetes using dried blood spot glucose measurement (McDonald *et al.*, 2017). This will help detecting infants with NDM early before they decompensate into DKA. Recent attempts and of liver, pancreas and kidney transplantation for infants with WRS are promising and it is expected that such therapy would be more used to save lives of these patients.

Conclusions

NDM is rare form of diabetes and most cases are caused by genetic defects in genes that control beta cell function or pancreatic mass leading to a state of insulin deficiency. It is important that all patients with diabetes diagnosed in the first 6 months of life are thoroughly assessed to identify associated features and have genetic testing. The latter is important as it can select the best treatment for the child and provide the family with proper genetic counseling.

Congenital Hyperinsulinism

Indraneel Banerjee and Maria Salomon Estebanez, Royal Manchester Children's Hospital, Manchester, United Kingdom; and University of Manchester, Manchester, United Kingdom
Karen E Cosgrove and Mark J Dunne, University of Manchester, Manchester, United Kingdom

Glossary

Congenital hyperinsulinism A complex disorder of hypoglycemia due to excess and dysregulated insulin secretion. Usual presentation is in the neonatal period, although later presentations can also occur. Although termed congenital hyperinsulinism, not all forms have defined genetic basis.

Diffuse congenital hyperinsulinism Congenital hyperinsulinism affecting the whole of the pancreas, in contrast to focal congenital hyperinsulinism where an isolated part of the pancreas is affected. Medical therapy is a first line option; in severe cases and in those unresponsive to medication subtotal pancreatectomy may be required.

Focal congenital hyperinsulinism A solitary hyperfunctioning endocrine rich lesion in the pancreas usually caused by a combination of inheritance of a paternal heterozygous mutation in *ABCC8/KCNJ11* and loss of maternal heterozygosity. If focal lesions are resected completely, cure from hyperinsulinism and hypoglycemia can be achieved.

Hyperinsulinism A state of excess insulin production leading to hypoglycemia. Hyperinsulinism represents functionally active insulin, in contrast to hyperinsulinaemia which implies insulin resistance.

Hypoglycemia A state of low glucose levels. Normal glucose levels range between 4 and 6 mmol/L. By consensus, hypoglycemia is diagnosed when blood glucose levels are less than 3.0 mmol/L.

K-ATP channel gene mutations A significant proportion of children with congenital hyperinsulinism have genetic mutations in components of the potassium channel which regulates insulin secretion in response to glucose levels in the pancreatic beta cell. This channel is responsive to cellular energy levels (ATP) and is therefore termed the K-ATP channel. *ABCC8* and *KCNJ11* coding for the proteins SUR1 and Kir6.2 in the channel can undergo mutations to cause K-ATP channel dysfunction and therefore dysregulated and excess insulin secretion.

PET-CT scanning This refers to positron emission tomography (PET) using the radiochemical 18-fluoro-dopa coupled with CT scanning for anatomical localization. PET-CT scanning is currently the best available investigation to identify and localize focal lesions.

Subtotal pancreatectomy Pancreatic surgery that involves resection of the majority of the pancreas, leaving a rim of tissue between the bile duct and the C-curve of the duodenum.

Introduction

Congenital hyperinsulinism (CHI) is a condition of severe and recurrent hypoglycemia in childhood characterized by excessive and dysregulated insulin secretion. Insulin released from pancreatic beta cells is normally tightly coupled to circulating serum glucose concentrations (**Fig. 1**) primarily mediated by the ATP-sensitive K^+ (K-ATP) channel (Dunne *et al.*, 2004; Ashcroft and Rorsman, 2013). In the normal state, mealtime glucose surges lead to proportionate and predictable insulin secretion while lower levels of glucose switch off insulin production to achieve euglycaemia. In CHI, feedback regulation is disordered leading to excess and inappropriate amounts of insulin causing severe hypoglycemia. In early childhood, the immature neonatal brain is susceptible to hypoglycemia-induced injury. In CHI, excess insulin suppresses counter-regulatory hormone responses and the production of ketones, which serve as alternative fuel for brain neurons in the absence of glucose. Therefore the combination of low glucose and low ketones renders the CHI brain particularly vulnerable to neuronal damage and prone to the risk of lifelong serious neurodisability. It is not surprising that a third to a half of cohorts with CHI have some form of adverse neurodevelopment, with severe cases incurring epilepsy and visual cortical blindness (Menni *et al.*, 2001; Meissner *et al.*, 2003; Avatapalle *et al.*, 2013).

CHI is a rare cause of hypoglycemia, reported as occurring in 1:50,000 in the general population (Dunne *et al.*, 2004; Stanley, 2016). The incidence of CHI probably represents the severe end of the spectrum, including those with persistent and severe CHI and those requiring pancreatectomy. The incidence does not take into account transient forms such as hyperinsulinism in babies born small for gestational age and perinatal stress, and late presenting forms, occurring in 10% of patients. In consanguineous populations, the incidence is considerably higher at 1:2500. Over the past few years, several CHI cohorts have been reported from around the world; however, no attempt has been made to investigate population incidence and prevalence of the disease.

Diagnosis

The diagnosis of hyperinsulinism rests on the detection of insulin at the time of hypoglycemia. However, insulin, which has a short half-life (4–6 min), may not be detectable at all times due to sampling delay and inaccurate measurement. Conversely, modern highly sensitive insulin assays may detect minimal quantities of insulin, particularly in the first 1–2 days of life when the glucose-insulin coupling

 doi:10.1016/B978-0-12-801238-3.64974-7

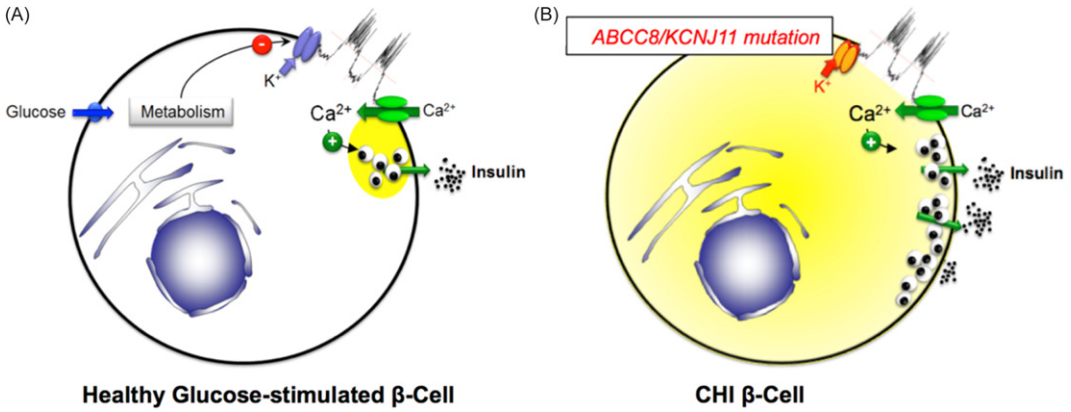

Fig. 1 Stimulus-secretion coupling in β-cells. (A) A simplified model of ionic events in islet β-cells that account for glucose-induced insulin secretion. Glucose uptake and metabolism result in closure of ATP-sensitive K^+-channels leading to a depolarization of the membrane and Ca^{++}-entry. Increases in the intracellular Ca^{++} concentration trigger insulin release. In the CHI β-cell, panel (B), loss of ATP-sensitive K^+-channel function due to gene defects leads to inappropriate electrical activity, uncontrolled Ca^{++} influx, and insulin release.

mechanism is immature (Thornton *et al.*, 2015). The presence of a high glucose infusion rate (GIR >8 mg/kg/min) is a strong indicator of insulin-mediated hypoglycemia as is the absence of ketogenesis. However, suppression of ketogenesis may be incomplete in some forms of CHI, for example those due to glucokinase (*GCK*) mutations (Sayed *et al.*, 2009). In older children who consume a combination of solid and liquid foods, estimating GIR is not fully reliable. Some treatment centers use a glucagon test as a diagnostic marker; a 1.0 mg intramuscular/intravenous dose of glucagon increases blood glucose levels by 1.7 mmol/L (30 mg/dL) within 40 min (Palladino and Stanley, 2011; Finegold *et al.*, 1980) to indicate a strong likelihood of CHI.

A caveat in the diagnosis of CHI lies in the very definition of hypoglycemia, which remains contentious. There are several reasons to consider hypoglycemia at blood glucose levels below 3 mmol/L (54 mg/dL), with evidence mainly from animal experiments of neuroglycopaenia (Cryer, 2007). Hypoglycemia investigations can be performed at variable blood glucose levels, depending on local guidelines, thereby introducing diagnostic bias. It is worth ensuring the diagnosis of CHI is supported by more than one criterion and that other more common causes of hypoglycemia, such as neonatal sepsis have been excluded.

Classification

CHI is a heterogeneous disease eluding a simple and consistent classification. It is helpful to understand the disease in distinctive patterns and groups, some clinical in nature and some based on genetic, imaging, and tissue investigations.

Focal and Diffuse CHI

Traditionally CHI is considered as focal or diffuse, based on histopathological phenotypes of pancreatic tissue. Focal CHI occurs if a solitary part of the pancreas shows evidence of islet cell enrichment in contrast to neighboring tissue with mostly exocrine components. On the other hand, diffuse CHI is diagnosed if most of the pancreas is affected by "hyperfunctioning" and poorly formed islet structures associated with ductal epithelia—nesidioblastosis—scattered diffusely throughout the organ (Rahier *et al.*, 1984). The diagnostic value of nucleomegaly is important. Islet cells with nuclear enlargement, four-times larger than adjacent islet endocrine cells and five-times larger than nuclei in exocrine cells, is a natural feature of the neonatal pancreas. However, the presence of several cells with enlarged nuclei in islets is almost pathognomonic of diffuse CHI (Han *et al.*, 2016). In our experience the detection of more than two enlarged nuclei in as few as 10% of islets is diagnostic of diffuse CHI.

It is important to pursue the diagnosis of focal CHI as treatment with partial resection of pancreatic tissue could be curative and spare long-term medication, side effects and prolonged hospitalization. In contrast, the first line treatment of diffuse CHI is medical therapy. Surgery to remove the majority of the pancreas (subtotal pancreatectomy) is reserved for those who do not respond to or have side effects with medical therapy.

The ability to identify focal CHI has been a real step change in the clinical management of CHI. Focal CHI diagnosis is based on the initial finding of a paternal heterozygous mutation in the genes encoding the K-ATP channel, *ABCC8*, and *KCNJ11*, assuming recessive inheritance. In association with paternal inheritance of *ABCC8/KCNJ11* mutations, loss of maternal heterozygosity (LOH) will lead to silencing of the compensatory allele and clonal expansion due to inhibition of cell cycle repressors located in the vicinity (**Fig. 2**). However, pancreatic LOH cannot be diagnosed without pancreatic surgery and biopsy. Therefore an alternative investigation is required to diagnose Focal CHI.

Focal lesions are associated with higher concentrations of beta cells and pancreatic neurons converting dopa to dopamine. This observation is utilized by the 18-fluoro-dopa PET-CT (PET-CT) scan, which is the investigation of choice to identify and localize a focal lesion (**Fig. 3**). Dopa tagged to the radiochemical 18-fluorine is taken up avidly and retained by the focal lesion. In focal CHI,

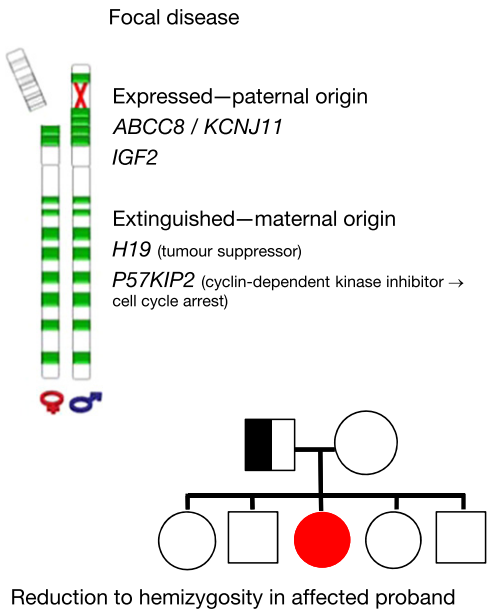

Fig. 2 Pathogenesis of focal CHI. Inheritance of a *ABCC8/KCNJ11* mutation on the paternal allele and loss of heterozygosity on the maternal allele (containing cell cycle suppressors) leads to unopposed mutant gene expression and hyperplasia leading to expansion of islet-rich pancreatic domains, resulting in a discrete focal lesion within the pancreas.

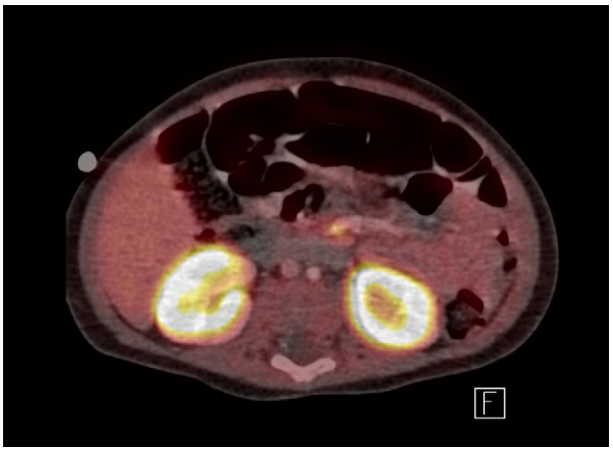

Fig. 3 Focal CHI identified by 18-fluoro-dopa PET-CT scanning; lesion takes up and retains 18-fluoro-dopa in comparison to the rest of the normal pancreas.

the lesion is imaged as a region of altered "brightness" in contrast to the rest of the pancreas following 40–60 min of injection of 18-fluoro-dopa. In diffuse CHI, the pancreas takes up 18-fluoro-dopa uniformly but does not retain radioactivity in a single region.

The diagnosis of focal CHI may be complicated by the fact that some mutations in *ABCC8/KCNJ11* are dominant, not recessive, giving a diffuse phenotype. PET-CT scanning itself may give false positives and negatives with earlier success (Hardy *et al.*, 2007) not being replicated in later studies (Arya *et al.*, 2014). While focal lesions have characteristic histology with isolated islet cell rich domains (**Fig. 4**), heterogeneity in the description is recognized with some focal lesions having looser organization than others. Focal lesions are identified at frozen section biopsy at the time of pancreatic surgery. The lesser quality of frozen section staining may contribute to diagnostic difficulty than when using conventional section and insulin immunostaining. Although focal lesions can be identified on 2-dimensional scans, finding a small lesion buried within the pancreatic tissue can be a challenge (**Fig. 5**); in such cases, a number of frozen section biopsies may be required to localize the lesion. In rare cases, larger focal CHI involving almost the entire pancreas may masquerade as unusual diffuse CHI as margins of normal tissue are difficult to identify. Margin identification is also difficult in lesions with tentacle-like extensions into normal tissue. Therefore, despite rapid advances in genetic and imaging investigations, the search for a focal lesion may prove elusive. A complicating factor is the entity of atypical CHI (Han *et al.*, 2017). Atypical CHI is characterized by islands of tissue with hyper functioning phenotype, with adjoining

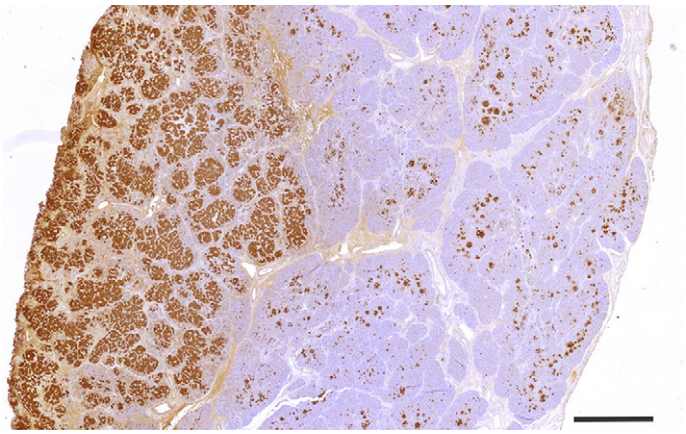

Fig. 4 Histopathological characteristics of Focal CHI show endocrine rich tissue stained brown, with adjoining normal tissue containing mainly exocrine tissue with scattered endocrine components (normal islets). *Scale bar*, 0.1 mm.

Fig. 5 Focal lesions may not be readily visible at the time of lesionectomy. In this laparotomy procedure, the focal lesion was identified within the uncinate process, to the right of the artery forceps and just above the left sided retractor. This surgical image is from the same patient as in the 18-fluoro-dopa PET-CT scan in **Fig. 3**.

endocrine and exocrine tissue appearing normal. However, there is no clear consensus about the nature and etiology of atypical CHI, which may account for 10%–15% of all cases.

The diagnosis of focal CHI relies heavily on genetic mutation testing, followed by 18-fluoro-dopa PET-CT scanning. Whilst genetic testing is increasingly available worldwide through international research collaborations, not all centers have the infrastructure or the expertise to interpret imaging results. 18-fluoro-dopa is a technically challenging radiochemical to produce and has a short half-life of 110 min. To inject a radioactive dose of 4 Mbq/kg, sufficient to inject in a relatively large child, a much larger yield has to be generated at the cyclotron site, possibly in excess of 300 Mbq, to allow for quality control experiments, transport to the PET-CT site and radioactive decay. Another factor to consider with 18-fluoro-dopa PET-CT scanning is the amount of ionizing radiation to which young children are exposed. Compared to the background UK average radiation of 2.2 mSv per year and a single chest X-ray of 0.02 mSv, 18-fluoro-dopa PET-CT scans provide 12–15 mSv at a very young age. New targets for the development of more selective ligands with fewer side effects include islet somatostatin receptors and glucagon-like peptide-1 receptors, although these remain experimental (Pattison and Hicks, 2017).

Transient and Persistent CHI

It is well recognized that small for gestational age babies and those who suffer perinatal stress may have varying degrees of hyperinsulinism causing hypoglycemia. The cause is not genetic and may be related to cellular stress responses inducing glucose-insulin dysregulation in postnatal life. In those without known genetic mutations, more than 50% resolve over a variable time range, extending to 8 years in some cases (Banerjee *et al.*, 2011). It is interesting to know that disease due to both dominant and recessively inherited mutations in *ABCC8/KCNJ11* may also reduce in severity and resolve, adding to the notion of natural history modification of disease. It is not known why genetic disease, including histologically proven focal CHI may resolve over time.

The differentiation of transient and persistent forms of disease is important as patients and families often enquire about long-term prognosis. However, transient CHI does not imply less severe disease, as the prevalence of severe adverse neurodevelopment is similar between transient and persistent CHI (Avatapalle *et al.*, 2013). Importantly there are no biomarkers to predict resolution or length of treatment at the time of diagnosis, although it is generally accepted that diffuse CHI due to recessively inherited *ABCC8/KCNJ11* homozygous mutations is unlikely to show complete disease resolution.

The resolution of diffuse CHI due to dominantly acting *ABCC8/KCNJ11* mutations may be reassuring to families in the short term but raises the possibility of later life maturity onset diabetes (MODY) due to an unexplained switch from hyper to hypoinsulinism. Such families need counseling regarding symptoms of diabetes not only for the child but also for the parent with the mutation.

Genetic and Unknown Causes of CHI

The most common genetic mutations causing CHI occur in the K-ATP channel genes *ABCC8* and *KCNJ11*. Other rarer genetic mechanisms have been identified and are listed in **Table 1**. Glutamate dehydrogenase deficiency *(GLUD1* mutation) has a phenotype of protein sensitivity, increased frequency of seizures and variable age at presentation. Mutations in the hepatocyte nuclear factor 4 alpha (*HNF4A)* can cause early life hypoglycemia and a switch to hyperglycemia in later life. Mutations in the enzyme hydroxyacyl Coenzyme A dehydrogenase (*HADH*) mutations are relatively common in consanguineous populations after *ABCC8/KCNJ11* mutations have been excluded.

A significant proportion of CHI patients do not have a known genetic cause of disease (**Table 2**) (Banerjee *et al.*, 2011; Jahnavi *et al.*, 2014; Shah *et al.*, 2007; Del Roio Liberatore *et al.*, 2015; Fan *et al.*, 2015; Sang *et al.*, 2014; Gong *et al.*, 2016; Rozenkova *et al.*, 2015; Bellanne-Chantelot *et al.*, 2010; Mohnike *et al.*, 2014; Senniappan *et al.*, 2015; Faletra *et al.*, 2013; Sogno Valin *et al.*, 2013; Yorifuji *et al.*, 2011; Park *et al.*, 2011; Sandal *et al.*, 2009; Al-Agha and Ahmad, 2013; Fernandez-Marmiesse *et al.*, 2006; Martinez *et al.*, 2016; Siklar and Berberoglu, 2016; Kapoor *et al.*, 2013; Snider *et al.*, 2013). Those with persistent severe disease probably have an unrecognized monogenic mutation which may eventually be revealed with increasing genetic research. It is possible that dysfunctional genetic networks may play a part in etiology, although there is no direct evidence for this. In those with resolving CHI with no identified gene mutations, mechanisms for causation and resolution remain largely unexplained.

Syndromes and Associations

A number of syndromes are associated with hyperinsulinism and hypoglycemia (**Table 3**) (Stanley, 2016; Arnoux *et al.*, 2012), however, the cause for hyperinsulinism remains unknown in most. Some children with the overgrowth condition of Beckwith–Wiedemann syndrome (BWS) have hypermethylation in chromosome 11; the cause for hyperinsulinism is not clear. Most respond to diazoxide treatment and achieve remission within a few months. In the majority of syndromes and genetic conditions associated with CHI, hypoglycemia appears to respond to conventional treatment and shows a resolving natural history. However, hypoglycemia may be missed, particularly if mild or occurring infrequently. The search for hypoglycemia may complicate the clinical management of complex conditions such as congenital central hypoventilation due to *PHOX2B* mutations. However it is important to recognize and treat hypoglycemia in these syndromes to prevent additional hypoglycemia-related morbidity and neurodisability.

Genetic Etiology

12 genetic mutations causing CHI have been identified over the years since the first description of sulfonylurea receptor mutation encoded by *ABCC8* (**Table 1**). Examination of international cohorts (**Table 2**) suggest most mutations occur in *ABCC8* and

Table 1 Genetic associations of CHI

Class	*Gene*	*Protein*	*Inheritance*	*Histology*
Ion channels	*ABCC8*	SUR1, subunit of K-ATP channel	Recessive or dominant	Focal or diffuse
	KCNJ11	Kir6.2, subunit of K-ATP channel	Recessive or dominant	Focal or diffuse
	CACNA1D	L-type calcium channel α-subunit	De novo	Diffuse
Enzymes	*GLUD1*	Glutamate dehydrogenase	Dominant	Diffuse
	GCK	Glucokinase	Dominant	Diffuse
	HADH	Short chain L-3-hydroxyacyl-CoA dehydrogenase	Recessive	Diffuse
	PGM1	Phosphoglucomutase 1	Recessive	Diffuse
	HK1	Hexokinase 1	Dominant	Diffuse
Transporters	*SLC16A1*	MCT1, pyruvate transporter	Dominant	Diffuse
	UCP2	Mitochondrial uncoupling protein 2	Dominant	Diffuse
Transcription factors	*HNF1A*	Hepatocyte nuclear factor 1α	Dominant	Diffuse
	HNF4A	Hepatocyte nuclear factor 4α	Dominant	Diffuse

Twelve genes currently known to associate with the pathology of CHI have been classified into functional groups.

Table 3 Developmental genetic syndromes associated with hyperinsulinism

Syndrome	*Gene*	*Locus*	*Inheritance*	*Clinical features*
Beckwith–Wiedemann	IGF2/H19/ CDKN1C/KCNQ1	11p15.5	S	Pre and postnatal overgrowth, organomegaly, hemihypertrophy, risk of embryonal tumors
Kabuki	KMT2D/ KDM6A	12q13.12/ Xp11.3	S	Distinctive facial appearance, short stature, skeletal abnormalities, developmental delay, heart defects
CDG (1a/1b)	PMM2/MPI	16p13.2/ 15q24.1	AR	Neurological impairment, gastrointestinal problems, cardiomyopathy, seizures, short stature
Sotos	NSD1	5q35.2–q35.3	S	Pre and postnatal overgrowth, dolichocephaly, distinctive facial features, developmental delay
Timothy	CACNA1C	12p13.33	AD or S	Long QT, arrhythmias, heart defects, syndactyly, immune deficiency, autistic spectrum disorder
Costello	HRAS	11p15.5	AD or S	Short stature, developmental delay, coarse facial features, papillomata, joint laxity, cardiac defects, tumor risk
Ondine	PHOX2B	4p13	AD or S	Congenital Central Hypoventilation syndrome, Hirschsprung's disease, risk of nervous system tumors
Turner	?	X	S	Short stature, ovarian failure, lymphedema, skeletal abnormalities, kidney problems, heart defects
Usher Ic	–	11p15–p14	AR	Severe diazoxide unresponsive hyperinsulinism, sensorineural deafness, pigmentary rethinopathy

S: Sporadic. References (Stanley, 2016; Arnoux *et al.*, 2012).

KCNJ11, comprising of the so-called channelopathies, followed by others occurring with variable frequency. CHI-associated mutations in *ABCC8* or *KCNJ11* cause loss of function of K-ATP channels located in the pancreatic β-cell membrane. K-ATP channel activity provides the essential link between increasing blood glucose levels and the subsequent secretion of insulin via regulation of the β-cell's membrane potential. Under normal conditions, metabolism of fuels such as glucose leads to the production of ATP within β-cells, alters the ratio of ATP:ADP concentration and causes closure of K-ATP channels (**Fig. 1**). This leads to depolarization of the β-cell membrane and activation of voltage-dependent Ca^{2+} channels. Opening of these Ca^{2+}

channels permits entry of Ca^{2+} into the β-cell and triggers the Ca^{2+}-dependent exocytosis of insulin-containing secretory vesicles. When K-ATP channel activity is suppressed or absent due to *ABCC8/KCNJ11* mutations, the β-cell membrane becomes inappropriately depolarized, Ca^{2+} entry occurs and triggers insulin secretion irrespective of blood glucose levels. Thus, in patients with *ABCC8/KCNJ11* mutations, the critical regulatory link between blood glucose concentration and insulin secretion is lost, often causing severe CHI that is unresponsive to medical therapy.

It is recommended that testing for *ABCC8/KCNJ11* mutations is performed in children with severe CHI, primarily to identify possible focal CHI. Rapid *ABCC8/KCNJ11* gene testing by Sanger sequencing is an important investigation tool guiding clinical management (De Leon and Stanley, 2007; Christesen *et al.*, 2007). However, in children responsive to conventional medication in moderate dosage, genetic analysis could be delayed. In centers with expertise in next generation sequencing of whole genomes, panel gene testing incorporating known genetic causes may be a preferred and relatively inexpensive option, although timescales to turnover are necessarily longer.

CHI mutations outside the K-ATP channel genes may cause metabolopathies where islet metabolism is affected, causing an increase in intracellular ATP:ADP ratio, closure of K-ATP channels and insulin secretion. *GLUD1* mutations are a typical example; *GLUD1* encodes glutamate dehydrogenase which is responsible for the oxidative deamination of glutamate to alpha-ketoglutarate. Mutations in the GTP-binding allosteric regulatory site of *GLUD*-1 cause the enzyme to produce alpha-ketoglutarate inappropriately. Since alpha-ketoglutarate is a substrate for the Kreb's cycle, this leads to ATP production, K-ATP channel closure and eventually to insulin release. Mutations in glucokinase (*GCK*) increase rates of glycolysis, similarly leading to an increase in ATP production and secretion of disproportionate quantities of insulin. Mutations in *HADH*, encoding the lipid enzyme hydroxyacyl Coenzyme A dehydrogenase are thought to disrupt the regulation of glutamate dehydrogenase and increase its activity inappropriately; this causes an increase in intracellular ATP generating an inappropriate increase in insulin secretion. CHI patients with metabolopathies usually respond well to diazoxide, a drug that opens K-ATP channels. Other gene mutations, for instance in *HNF4A*, are not directly linked to metabolic perturbations. Mutations in *HNF1A* and *UCP2* seem to be restricted to specific populations and may demonstrate a founder effect. It is not known if the other genetic mutations listed in **Table 1** occurring less frequently directly cause or simply associate with CHI.

Candidate gene discovery has led to improved knowledge of genetic etiology of CHI and has revealed new genetic causes of the disease. Deep sequencing and whole genomic sequencing techniques have enhanced the search for known mutations now being identified in deep intronic areas previously missed by conventional Sanger sequencing of exons and exon-intron boundaries. However, candidate gene discovery in cohorts of patients with persistent disease is yet to identify major new genes that enhance the understanding of disordered insulin secretion.

An additional tool to assist gene discovery is the investigation of network biology and the CHI interactome (Stevens et al., 2013, 2014). Although this remains largely experimental at this stage, network biology for CHI has been found to independently predict relationships between islet cell proliferation, enhanced vascularization and the association of novel drug targets—for example with sirolimus (Szymanowski *et al.*, 2016). Therefore analysis of pancreatic gene expression data is worthwhile not simply to establish causation but also to suggest new drug candidates for the treatment of CHI.

Treatment

General Principles

It is important to recognize and treat severe hypoglycemia promptly to prevent brain injury. Neonatal hypoglycemia is a common occurrence with causes ranging from substrate deficiency to sepsis. CHI is a relatively rare cause of hypoglycemia in the postnatal period, but the diagnosis must be considered if hypoglycemia is severe, persistent and associated with high GIR. In severe neonatal hypoglycemia, oral feeds are unlikely to correct hypoglycemia adequately. In most cases, intravenous access is required to infuse 10% dextrose solutions. Standard rates (90–120 mL/kg/day) of 10% dextrose in the first few days of life provide 6–8 mg/kg/min which may not be enough to keep up with high GIR requirements in CHI. A common tendency is to increase the volume of fluids to increase dextrose delivery; however, this strategy is more likely to cause fluid overload and potentially right sided heart failure.

If possible, a peripherally sited central venous catheter or an umbilical catheter should be considered to infuse higher concentrations of dextrose, between 15% and 20% in solution. In an emergency, where central access is not achievable and hypoglycemia is persistent, intraosseous access may be necessary. However, neonatal bones are fragile and may fracture with potential for extravasation of high concentration dextrose in soft tissue. Therefore a surgically or radiologically sited central intravenous access should be considered soon after diagnosis.

Additional carbohydrates could be delivered by enteral feeding if hypoglycemia is manageable. In young children, neutral tasting carbohydrate powder supplements (e.g., Vitajoule™, Polycal®) could be added to milk feeds. In older children, slow-release starch could also prevent hypoglycemia. Some children are dependent on enriched feeds and require continuous feeds during the day or night or both to maintain glycemic stability.

A key feature of the management plan of CHI is monitoring in hospital and at home. Conventional laboratory methods of measuring blood glucose are not feasible for frequent monitoring and heelprick/fingerprick blood glucose measurements using handheld glucometers may be used. However, these methods are not completely reliable, particularly in the lower range of glucose levels. A suitable compromise may be the use of point of care testing devices which offer greater reliability and are simple to use in a hospital setting. Frequent (1–2 hourly in acute situations) point of care testing glucose levels could be used to guide clinical

management. At home, most parents use handheld glucose meters to test premeal blood glucose levels. The frequency of testing is usually lesser than in the hospital and rarely more than four times a day. One alternative to blood glucose levels is the use of subcutaneous continuous glucose monitoring (CGM). Most CGM devices require additional calibration with blood glucose levels, although factory calibrated devices are also available. CGM is rarely used in acute hypoglycemia, where subcutaneous glucose has a 5-min lag phase and is therefore less reliable than blood glucose testing. Although there are no validation studies of CGM in CHI patients, CGM could be used to determine trends, particularly overnight in the stable phase of CHI patients at home.

Glucagon

To improve hypoglycemia, one choice is to commence glucagon infusion in a dose of 5–10 μg/kg/h through a peripheral intravenous cannula if central access is not forthcoming. Patients with CHI are sensitive to glucagon, which reduces glucose requirement providing much needed stability. Some centers administer a standard 1000 microgram dose of glucagon diluted in small volume fluid run over a 24-h period, regardless of body weight. For a child weighing 4 kg, this equates to a dose just over 10 μg/kg/h. This method has the advantage of simplicity and may minimize drug error through miscalculation. Glucagon effectively allows reduction of the volume of dextrose solution infusion, thereby reducing fluid overload and electrolyte imbalance. Glucagon can be administered alongside clear solutions in central venous catheters but coadministration of parenteral nutrition is best avoided. Glucagon can be administered subcutaneously as an infusion, although the formulation is designed for bolus intramuscular injections. In slow moving small caliber catheters, currently available preparations of glucagon fibrillate and precipitate, thereby rendering drug delivery unreliable. Hence, although generally very effective for short-term glycemic stabilization, long-term glucagon therapy has been unrealistic. However, recent advances in both solubility and stability of natural glucagon and the development of modified glucagon, has raised the possibility of using glucagon over longer periods of time.

In some children with severe CHI, intravenous glucagon remains the only medical treatment option as other drugs fail to have desired activity or are poorly tolerated. Long-term use of high dosage glucagon will impact upon hepatic glucose storage and can be associated with the risk of thrombosis. A rare occurrence is a migratory rash called necrolytic migratory erythema, for which glucagon has to be stopped (Fig. 6).

Fig. 6 Necrolytic migratory erythema following long duration treatment with glucagon.

Diazoxide

Diazoxide is an antihypertensive which also acts to keep the K-ATP channel in the "open" state, permitting beta cell membrane stability and reducing excursions in insulin secretion. Diazoxide is the only medicinal product licensed by the Food and Drug Administration in the United States for the treatment of CHI. The dose of diazoxide varies between 5 and 15 mg/kg/day in three divided doses with usual starting doses in the lower part of the range. Doses are usually titrated upwards every 2–3 days depending on response. In some centers, the reverse approach, that is, a higher dose of diazoxide (15 mg/kg/day) may be used to investigate drug responsiveness. However, large dose diazoxide is more likely to be complicated by side effects than escalating lower dose treatment.

One of the commonest side effects of diazoxide in the early stages of treatment is fluid retention. It is important to ensure fluid administration is not excessive and restricted to less than 150 mL/kg/day. Chlorothiazide, which has some synergistic action, is useful as an adjunct diuretic in a dose of 7–15 mg/kg/day in two divided doses. Chlorothiazide can cause loss of electrolytes with consequent hyponatraemia and hypokalemia. If diazoxide is continued over a longer period of time, fluid retention features become less prevalent. Therefore, chlorothiazide is rarely required for the longer-term treatment with diazoxide. Patients on diazoxide should be carefully monitored for efficacy and side effects. In the maintenance phase, it is advisable to use the lowest dose that ensures the majority of blood glucose levels remain in the normal range, that is, 4–6 mmol/L minimizing readings lower than 3.5 mmol/L. Diazoxide causes taste disturbances, although most neonates appear to tolerate medication satisfactorily. Occasionally side effects such as reduced white cell and platelet counts can occur. Rarely diazoxide can cause hyperglycemia, associated with ketogenesis, mimicking the clinical scenario of diabetes. Diazoxide is also known to cause pulmonary hypertension, more common with fluid overload, existing cardiac anatomic defects, and prematurity. Another life-threatening complication of diazoxide is pericardial effusion, which may occur with relatively low dosage. If in doubt, a cardiac review and an echocardiogram is advisable. Some centers routinely recommend echocardiography at the start of treatment, particularly as cardiac muscle hypertrophy occurs commonly and requires review. In the longer term, most children on diazoxide develop hypertrichosis (Fig. 7). Excess body hair is more noticeable with doses greater than 5 mg/kg/day and reduces as treatment is weaned and stopped.

The product concentration of diazoxide in suspensions can be variable with a range of "specials" formulations being available. Unfortunately, treatment efficacy can vary depending on the drug concentration; therefore the choice of a reliable manufacturer with approved quality control for safe and effective treatment with diazoxide is essential.

The length of treatment with diazoxide depends on individual phenotype severity and drug response. As described in the section on transient CHI, the severity of disease may reduce in some patients, being more likely in those without identified genetic mutations (Banerjee *et al.*, 2011; Salomon-Estebanez *et al.*, 2016). In such cases, it is useful to reassess drug dose at every clinical contact. Children stopping diazoxide may require the demonstration of tolerance to a food fast, that is, demonstrate euglycaemia and generate ketones.

Octreotide and Other Somatostatin Analogues

Octreotide, a nonspecific somatostatin analogue, acting on somatostatin receptor subtypes 2 and 5, achieves beta cell membrane stability by interacting with a variety of ion channels and reduces insulin secretion through several nonionic processes. Octreotide is usually given by subcutaneous bolus injections four to five times a day but can also be administered by continuous intravenous or subcutaneous infusions, the latter delivered by insulin pump devices. The usual starting dose is 5 μg/kg/day, which may need to be increased to 25 μg/kg/day in steps to achieve euglycaemia. Some centers advocate doses ranging between 30 and 50 μg/kg/day to maintain euglycaemia and prevent pancreatic surgery. A common occurrence with octreotide is the phenomena of tachyphylaxis, whereby initial efficacy is not sustained and progressively greater drug concentrations are required to achieve treatment effect. Octreotide has been associated with serious side effects including necrotizing enterocolitis and hepatitis. Therefore, treatment with octreotide should be initiated and monitored by a specialist treatment center.

Fig. 7 Diazoxide related hypertrichosis can be significant, present over the extremities, forehead, and extending down the back.

While octreotide has a short half-life of 100 min and has to be injected several times during the day, an alternative is to use long-acting somatostatin analogues (long-acting slow release octreotide and somatuline autogel) as once a month subcutaneous or intramuscular preparations. Small cohort studies suggest benefit but concerns remain over depot preparations associated with long-lasting side effects such as hepatic dysfunction in early childhood (van der Steen *et al.*, 2017).

Nifedipine

Nifedipine is a calcium channel antagonist that blocks calcium-mediated exocytosis of insulin from beta cells. In vitro experiments suggest clear action of nifedipine on dysregulated beta-cell function (Lebrun *et al.*, 1997), which would imply a positive clinical benefit. However, equivalent in vitro doses are much higher than those in clinical practice and are likely to be associated with unacceptable side effects such as hypotension. Nifedipine has been used on and off in CHI patients with variable results; however, recent evidence suggests no positive benefit (Güemes *et al.*, 2017).

Other Therapy Options

The mammalian target of rapamycin (mTOR) inhibitors, everolimus and sirolimus have been used in patients with CHI where treatment with diazoxide and somatostatin analogues have failed. Small cohorts have reported modest success, but side effects, mainly from immunosuppressive effects detract from any meaningful benefit (Szymanowski *et al.*, 2016; Banerjee *et al.*, 2017).

Polyunsaturated fatty acids (PUFA) have been used as a food supplement in the management of patients with CHI already treated with diazoxide (Skae *et al.*, 2014). While effects are modest in a pilot trial, PUFA is safe and unlikely to interfere with other treatments when used as an adjunct. However, further studies are required to evaluate if PUFA could be used more widely in clinical practice.

New Drug Development

Treatment of CHI has not progressed significantly beyond diazoxide and somatostatin analogues over the last three decades. However, there have been recent activity promising newer treatments on the horizon. Drug trials in older CHI patients have suggested the possibility that inhibition of the glucagon-like peptide-1 receptor (GLP-1R) in beta cells has positive benefits. Exendin 9–39 acts independent of the K-ATP channel mechanism of insulin release to reduce insulin secretion. Another promising drug candidate is "soluble glucagon." Whilst conventional formulations of glucagon are complicated by fibrillation, novel glucagon formulations have been developed that may be used subcutaneously as long-term therapy. These advances include the use of a modified formulation to solubilize glucagon, and the synthesis of a modified glucagon variant that is water-soluble. Another drug considered for clinical trial is an allosteric monoclonal antibody that binds the insulin receptor with high affinity to reduce insulin effect. Current preparations are intravenous, but offer the promise of more acceptable routes of administration and the possibility of preventing subtotal pancreatectomy, thereby preventing diabetes for life. Other novel therapeutic approaches that might be promising are enhancers of trafficking or chaperones of defective K-ATP channels and highly selective agonists of somatostatin receptors.

Pancreatic Surgery

In focal CHI, lesionectomy is the treatment of choice. For lesions in the body and tail of the pancreas, laparoscopic approaches may be used for resection. For lesions in the head, uncinate process and proximal body, a laparotomy approach may provide improved access to the pancreatic bed, which is deep in the abdomen. Whilst lesions identified by 18-fluoro-dopa PET-CT scans may be easily identifiable, the 3-dimensional nature of the pancreas and the small size of the lesion make surgical localization difficult (**Fig. 5**). In open laparotomy, lesions can be palpable as a "pea in a sponge" as the consistency is firmer than the rest of the pancreas; however, in focal lesions that are less tightly organized and in those without a capsule, palpability may not be reliable. Haptic sensation, and hence palpability is excluded in laparoscopic pancreatectomy. In all cases, frozen section histopathology is crucial to identify the lesion. Focal CHI histopathology is characterized by densely crowded islets with little exocrine tissue (**Fig. 4**), in contrast to diffuse CHI characterized by large nuclei, foamy cytoplasm and a mixture of exocrine and endocrine tissue (**Fig. 8**). It is helpful to identify a margin of normal pancreatic tissue adjoining the focal lesion, although this is not always visible. In some cases, focal lesions have tentacle-like extensions into normal tissue that are not easily resectable and cause postoperative hypoglycemia. Focal lesions that are adjacent to the bile duct are difficult to access and resect without causing significant damage to important structures. For such lesions extensive surgical procedures that involve duodenectomy may be required. However, conservative approaches with medical therapy may also be undertaken, particularly as there is some evidence that focal lesions may resolve over time. Thus, although focal lesions should in theory be resectable and achieve cure from hypoglycemia, considerable surgical skill and expertise is required from specialist teams, with some degree of uncertainty persisting after surgery.

Children with diffuse disease should be managed by medical therapy if possible. However, if medically unresponsive, subtotal pancreatectomy may be required to reduce hypoglycemia. This procedure involves skilful mobilization of the pancreas, splenic artery, and other important structures, while preserving the integrity of the bile duct (**Fig. 9**). Most of the pancreas is resected,

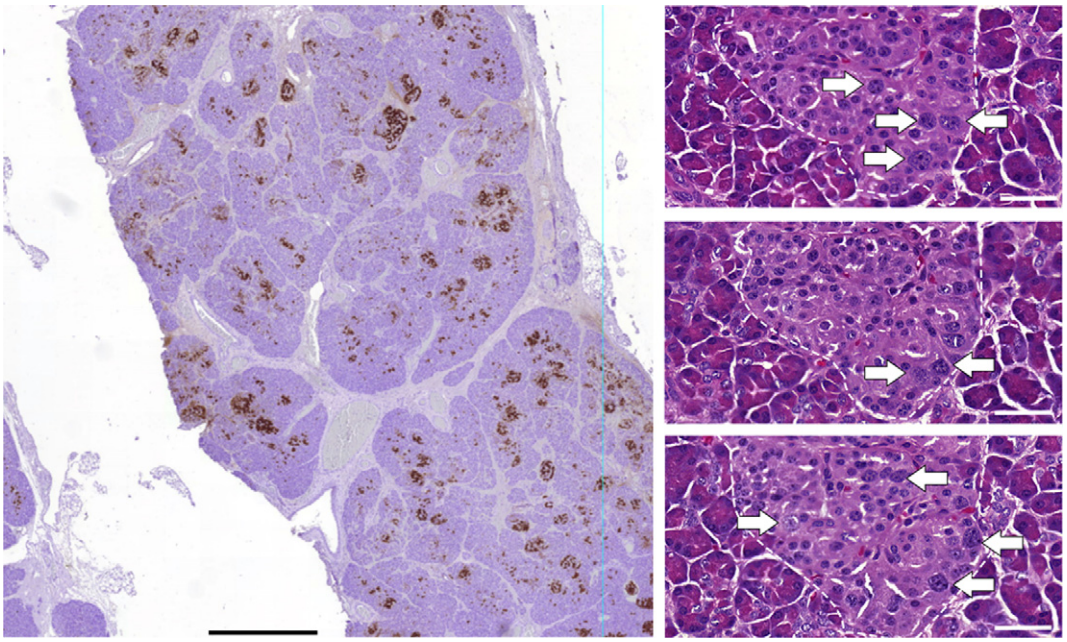

Fig. 8 Diffuse CHI characterized by a mixture of endocrine and exocrine tissue scattered throughout the pancreas (left-hand panel, scale bar 0.1 mm) and large and irregular nucleii in some cells within islets. The right-hand panel shows serial sections of tissue to illustrate the presence of multiple enlarged nuclei, indicated by *arrows*. Note that most of the nuclei appear in successive 5-μm sections of tissue.

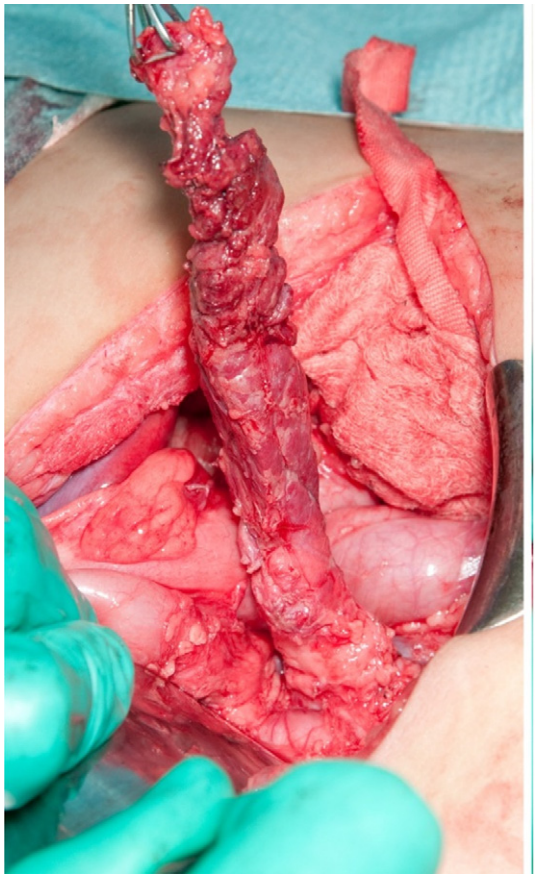

Fig. 9 Subtotal pancreatectomy in diffuse CHI; here the pancreas has been carefully dissected free of important structures such as the splenic artery and elevated by the tip of the tail. The common bile duct is an important structure that needs to be preserved when removing the head of the pancreas.

keeping a 5% rim of tissue between the wall of the duodenum and bile duct. Frozen section histology is usually not required if the diagnosis of diffuse CHI is anticipated prior to surgery. In some late-presenting cases with no identified genetic mutations, atypical CHI histology may be found.

In the postoperative period following subtotal pancreatectomy, euglycaemia is usually achieved, but a significant proportion (around 30% or more) may remain persistently hypoglycemic. Postoperative hypoglycemia tends to be manageable by medical therapy, although second-look surgery may be required to remove further pancreatic tissue. A few children become hyperglycemic after surgery and require insulin treatment. In most patients, hyperglycemia becomes prominent by adolescence, resulting in diabetes by the teenage years (Beltrand *et al.*, 2012).

As subtotal pancreatectomy invariably leads to diabetes, there is a push to preserve pancreatic tissue by extensive medical therapy and intense nutritional therapy. However, such an approach has to be carefully balanced against the risks of persistent hypoglycemia and subsequent brain damage. Also, quality of life of the child and family has to be considered if intensive feed/medical regimens are used.

Feeding Problems

Feeding problems are commonly present in many CHI patients. Sucking and swallowing problems are often present in the early stages but food aversion can persist for much longer. The cause for feeding problems is not clear but is likely to be multifactorial. The pressure to ensure carbohydrate intake and the reliance on intravenous, nasogastric and gastrostomy feeding can lead to a neglect of oral feeding. Side effects from medications, prolonged periods of hospital stay, absence of a stimulating environment and heightened parental anxiety all contribute to perpetuate food-avoiding behavior. It is interesting to know that feeding problems in patients with focal CHI rapidly resolve after lesionectomy, indicating a cessation of inhibitory influences to feeding processes.

Feeding problems are complex to resolve and take time, perseverance and advice from speech and language therapists. Inability to feed can provoke parental anxiety; it is important to provide knowledge, reassurance and support to the parents to turn the feeding process into a pleasurable experience. Medication is not usually advised, although gastro-oesophageal reflux, a deterrent to feeding, could be minimized by antireflux treatment with ranitidine or omeprazole.

Multidisciplinary Team Coordination

Patients severely affected by hypoglycemia require multidisciplinary input from teams rather than individuals. The team effort comprises of pediatric endocrinologists, specialist nurses, dietitians, speech and language therapists, biochemists, radiologists, nuclear medicine physicians, surgeons, and histopathologists (**Fig. 10**). Specialist nurses experienced in CHI help parents and families guide their way through the stress of diagnosis, information overload, uncertainty and prolonged hospitalization. Clinical psychologists are also important to improve the patient journey and to assess the impact of CHI on neurodevelopment and quality of life.

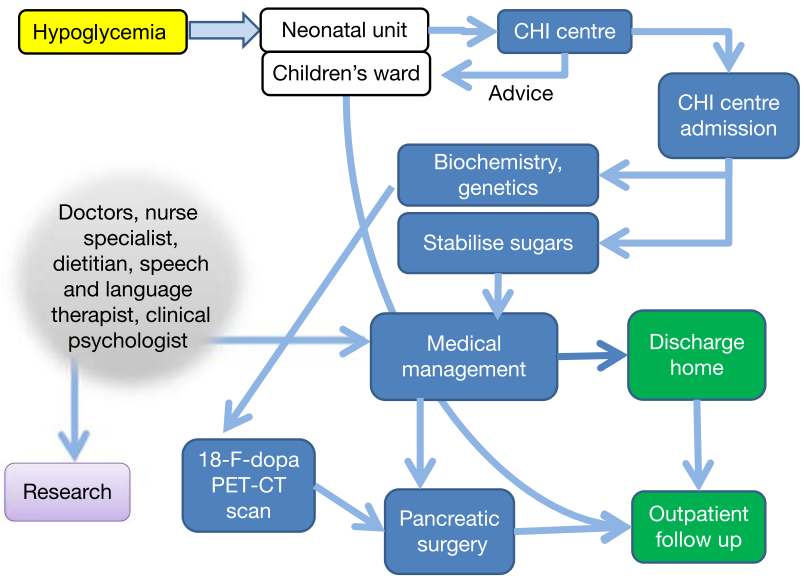

Fig. 10 Complex coordinated care required in the management of patients with CHI. The child with CHI could be managed in the local hospital with support from the CHI center, but if hypoglycemia is severe and unstable may require admission to a CHI expert center for clinical management by a multidisciplinary team.

Long-Term Outcomes

Neurodevelopment

Hyperinsulinism leads to both hypoglycemia and hypoketonaemia, that is, a loss of essential metabolic fuels for the neonatal brain. Therefore, severe and recurrent hypoglycemia in CHI is significantly detrimental to neurodevelopment. It is not surprising that a high proportion of children with CHI have adverse neurodevelopment. In various observational studies over the last 15 years, the rates of cognitive and developmental delay have not declined in various cohorts (Menni *et al.*, 2001; Meissner *et al.*, 2003; Avatapalle *et al.*, 2013). There is mounting evidence that the depth and severity of hypoglycemia in early life, not the duration of disease may determine the extent of brain injury. Therefore, children with transient hypoglycemia may develop significant neurodisability and lifelong morbidity. It is important to recognize that older children may also develop CHI, a diagnosis that is easily missed in emergency departments. Late presenting CHI children have adverse cognitive function, suggesting missed opportunities in treatment contributing to neuronal damage (Salomon-Estebanez *et al.*, 2017).

A developmental review should form part of any CHI management strategy. If delayed development is suspected, a more formal developmental tool should be used to quantify the extent and nature of delay. Formal assessment by tools such as Bayley Scales of Infant and Toddler Development and Weschler Intelligence Scale for Children may be used but are age-specific, time-consuming and not always available. A suitable screening tool such as the Vineland Adaptive Behavior Scales Questionnaire may be used before formal referral to a developmental pediatrician. If severe neuroglycopaenia is suspected, brain magnetic resonance imaging may be considered (**Fig. 11**).

Severity Trajectory of CHI

CHI is a heterogeneous condition with different causes, modes of presentation and responsiveness to treatment. Although termed congenital, not all causes are genetic. Further, genetic causes cannot be identified in all cases where genetic etiology is suspected. Therefore, there is considerable diversity in patterns of disease, which largely remain unexplained. It is well recognized that some

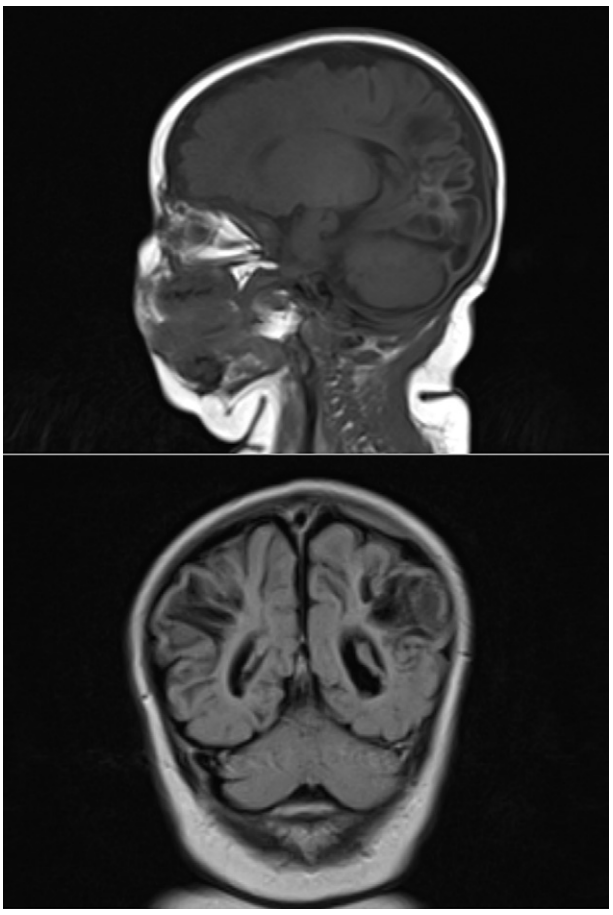

Fig. 11 Severe perinatal hypoglycemic encephalopathy with extensive bilateral parieto-occipital and posterior temporal gliosis along with focal cystic encephalomalacia.

children have a resolving nature of illness, also known as transient CHI, in contrast with those requiring medical treatment or surgical treatment, also known as persistent CHI (Banerjee *et al.*, 2011). Mechanisms of severity reduction and disease resolution remain unknown and are not explained by gene mutation status; a significant proportion of children with recessive and dominantly inherited *ABCC8*/*KCNJ11* mutations may also resolve (Salomon-Estebanez *et al.*, 2016).

In view of the changing natural history of CHI, it is helpful to review medication dosage at each follow up appointment to reduce the burden of medication whilst ensuring satisfactory glycemic profiles. For children stopping medication, demonstration of age-appropriate fasting tolerance may be useful for further reassurance. It is advisable to test blood glucose levels during episodes of concurrent illness as children are likely to become hypoglycemic at such times due to inadequate nutritional intake and altered metabolism.

Risk of Diabetes

Patients with focal CHI undergoing successful lesionectomy are effectively cured and do not develop diabetes. In contrast, those undergoing subtotal pancreatectomy develop hyperglycemia and diabetes, usually by mid puberty. In children with dominantly inherited mutations in *ABCC8*/*KCNJ11*, there is a risk of later life diabetes, although the risk and the timing of diabetes are difficult to confirm. Similarly, in those patients with *HNF4A* mutations, a flip from neonatal hypoglycemia to maturity onset diabetes in young (MODY) occurs in later life. The cause for the phenotype switch remains unknown, but needs to be considered and discussed with the family.

Transition to Young Adult Life

CHI is a disease in early childhood and in some patients has a resolving natural history. However, a proportion of patients continue to require medication into young adult life with hyperinsulinism remaining persistent and problematic. Others who undergo pancreatic surgery may become diabetic in adolescence requiring insulin treatment as adults. Transition from childhood into young adult life becomes important in these individuals. Considering that a significant proportion of children have some degree of cognitive compromise, issues of independence, adherence to treatment and patient safety become important. These issues are best addressed in a gradual process of transition mainly through the puberty years. In young adult life, medical follow up should continue under the supervision of an adult endocrinologist with interest in adult CHI.

Parent and Family Perspectives

CHI is a very significant condition causing stress to parents and families. Neonates diagnosed with CHI are often admitted for prolonged periods in hospital with the uncertainties of diagnosis, treatment response and future prognosis. Most parents benefit from face-to-face discussions reiterating complex information, which is difficult to assimilate. Information leaflets may be given, although most parents do not find written information very helpful. Alternative sources of information include websites run by international charities or those maintained by specialist services. Other sources of information include white board animation videos using freely available online content which have the added advantage of voice in addition to text, reinforcing information uptake in an efficient manner.

The wellbeing of families can sometimes become neglected when medical attention is solely targeted at improving glucose status. It is the role of the entire CHI team, particularly the clinical psychologist, to discuss psychosocial wellbeing during clinical management. Early engagement and communication with the team is crucial to information assimilation and understanding. In time, parents become well versed in CHI and are a valuable source of information and experience. Increasingly parent-led charities are making major contributions to CHI management through their expression of priorities and by actively engaging clinicians, scientists, and other families to push the frontiers of care.

Beckwith–Wiedemann Spectrum

Eamonn R Maher, Cambridge Biomedical Campus, Cambridge, United Kingdom

Beckwith–Wiedemann syndrome (BWS, MIM #130650) is a human imprinting disorder that results from altered expression or function of imprinted genes located on the short arm of chromosome 11 (at 11p15.5). BWS was described independently by Beckwith (1963) and Wiedemann (1964) >50 years ago and has been the subject of >1000 publications (Brioude *et al.*, 2018). Though BWS is a rare disorder (maximum incidence ~1 in 10,000) (Mussa *et al.*, 2017), it has been widely studied as an exemplar of how disordered genomic imprinting may be associated with human disease and because of the variable clinical features, diagnostic difficulties and complex genetics of the disorder (Brioude *et al.*, 2018). Recently a large multidisciplinary group of international experts produced a consensus statement covering clinical, molecular genetic and management aspects of the disorder suggested that BWS should be considered as part of clinical and molecular spectrum known as Beckwith–Wiedemann spectrum (BWSp) (Brioude *et al.*, 2018). This article adopts this classification and covers clinical and molecular aspects of BWSp.

Genomic Imprinting and Human Imprinting Disorders

Molecular investigation of human imprinting disorders such as BWS, Silver–Russell syndrome (SRS), Angelman syndrome and Prader–Willi syndrome have provided important insights into the role of genomic imprinting in health (Eggermann *et al.*, 2015). Genomic imprinting is an epigenetic process affecting about 100 human genes. Whereas non-imprinted genes are generally expressed from both parental alleles, imprinted genes are preferentially expressed from either the maternal or paternal allele (e.g., *IGF2* is expressed from the paternal allele and *CDKN1C* is expressed from the maternal allele) (Reik and Walter, 2001). Imprinted genes usually occur in clusters and imprinting depends on the presence of an imprinting control centre (IC) that is marked by the presence of a differentially methylated region (DMR) (i.e., methylation occurs on either the maternally or paternally inherited allele). The methylation status of an IC DMR is established during gametogenesis and is maintained during the wave of genome demethylation that occurs early in embryogenesis (see **Fig. 1**). Maintenance of IC DMR methylation requires DPPA3 (also known as PGC7/Stella) and the KRAB zinc finger protein ZFP57 (Sanchez-Delgado *et al.*, 2016). Imprinting disorders can result from a variety of mechanisms including a mutation in the coding sequence of an imprinted gene or often, as in BWS, altered methylation (loss or gain) at the IC DMR that can result in biallelic expression or biallelic silencing of an imprinted gene such as *IGF2* or

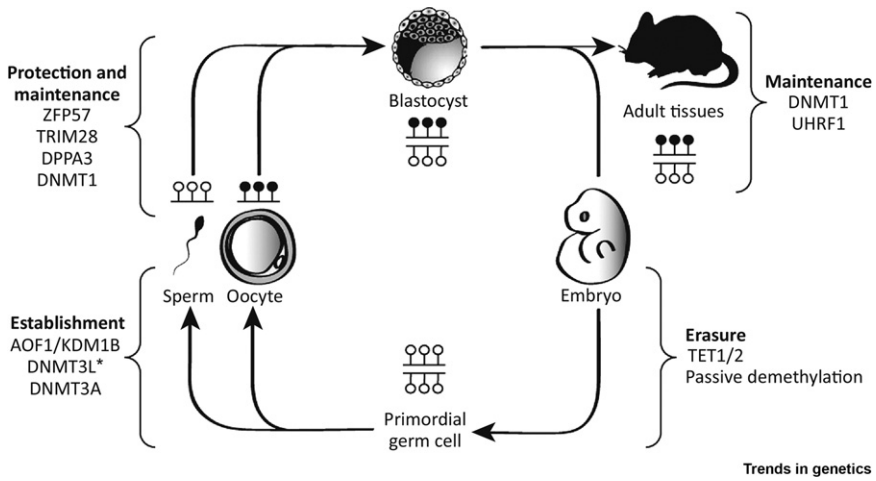

Fig. 1 The Life Cycle of Epigenetic Changes at Imprinted Loci in Mice. Regions of differential methylation are established in the germline and protected from preimplantation reprogramming by the maintenance factors DNMT1, ZFP57, and DPPA3. The allelic methylation is then preserved by the semiconservative action of DNMT1-UHRF1. In primordial germ cells of developing embryos, the DNA methylation at imprinted DMRs is erased so that the new profiles can be established according to the sex of the embryo. This complex procedure involves histone demethylation of H3K4 and the subsequent recognition and DNA remethylation by the DNMT3L-DNMT3A complex. *Note that *DNMT3L* is not expressed in human oocytes, suggesting different recruiting methods between species. Reproduced from Sanchez-Delgado, M., Riccio, A., Eggermann, T., Maher, E.R., Lapunzina, P., Mackay, D. and Monk, D. (2016). Causes and consequences of multi-locus imprinting disturbances in humans. *Trends in Genetics* **32**(*7*): 444–455 with permission.

 doi:10.1016/B978-0-12-801238-3.04114-3

CDKN1C (Eggermann *et al.*, 2015). Imprinted genes appear to be preferentially implicated in prenatal growth and development and, in general, paternally expressed genes (e.g., *IGF2*) promote growth and maternally expressed genes (e.g., *CDKN1C*) suppress growth (Fowden *et al.*, 2011).

Definition and Etiology of BWSp

The wide phenotypic variability of BWS (clinical and pathological features are listed in **Table 1**) and the detection of mild forms of the disorder through molecular testing has resulted in wide variations in the proposed clinical diagnostic criteria for the disorder (Brioude *et al.*, 2018). The International BWS Consensus Group (IBCG) suggested the concept of BWSp and proposed a scoring system for BWSp that included both clinical and molecular data (see **Table 1** and **Fig. 2**). Individuals with isolated lateralised overgrowth (ILO) and a chromosome 11p15.5 molecular abnormality (see below) would be diagnosed as BWSp whereas those with ILO and no molecular abnormality are outside the definition (unless further more sensitive molecular testing revealed a molecular defect) (Brioude *et al.*, 2018). A clinical diagnosis of classical BWS (as part of BWSp) can be made in the presence of normal molecular testing if the IBCG score ≥ 4 (see **Table 1**). A child with a score of <4 and no molecular abnormality might have suspected BWSp but fall outside of the current definition.

In most cases the etiology of BWSp is unknown. Up to 15% of cases may have a family history but the majority are sporadic and the recurrence risk is low (see later). No specific environmental factors have been identified but there is an excess risk of BWS after assisted reproductive technology (ART) births (Maher, 2005; Mussa *et al.*, 2017). The increased risk of BWS after ART has been attributed to failure to maintain genomic methylation at ICs during in vitro embryo culture (though other factors including infertility per se may be implicated) but although the relative risk may be increased up to 10-fold the absolute risk of having a child with BWS after ART is very small (about 1 in 1000) (Mussa *et al.*, 2017).

Molecular Genetics of BWSp

BWSp results from a variety of genetic and epigenetic mechanisms that result in increased *IGF2* expression and/or loss of expression or inactivation of *CDKN1C* (see **Figs. 3** and **4**). The multiple mechanisms that might cause BWSp, including paternal uniparental disomy (upd(11)pat), cytogenetic abnormalities (paternally inherited duplications and maternally inherited balanced translocations/inversions), epigenetic alterations at imprinting centres (IC), *CDKN1C* mutations and imprinting centre copy number abnormalities (Choufani *et al.*, 2013; Brioude *et al.*, 2018). The often mosaic nature of molecular abnormalities in BWSp

Table 1 Clinical features and scoring system for Beckwith–Wiedemann spectrum

Cardinal features (2 points per feature)
Macroglossia
Exomphalos
Lateralized overgrowth
Multifocal and/or bilateral Wilms tumor or nephroblastomatosis
Hyperinsulinism (lasting >1 week and requiring escalated treatment)
Pathology findings: adrenal cortex cytomegaly, placental mesenchymal dysplasia or pancreatic adenomatosis
Suggestive features (1 point per feature)
Birthweight >2 SDS above the mean
Facial naevus simplex
Polyhydramnios and/or placentomegaly
Ear creases and/or pits
Transient hypoglycemia (lasting <1 week)
Typical BWSp tumors (neuroblastoma, rhabdomyosarcoma, unilateral Wilms tumor, hepatoblastoma, adrenocortical carcinoma or phaeochromocytoma)
Nephromegaly and/or hepatomegaly
Umbilical hernia and/or diastasis recti

For a clinical diagnosis of classical Beckwith–Wiedemann syndrome (BWS), a patient requires a score of ≥ 4 (this clinical diagnosis does not require the molecular confirmation of an 11p15 anomaly). Patients with a score of ≥ 2 (including those with classical BWS with a score of ≥ 4) merit genetic testing for investigation and diagnosis of BWS. Patients with a score of <2 do not meet the criteria for genetic testing. Patients with a score of ≥ 2 with negative genetic testing should be considered for an alternative diagnosis and/or referral to a BWS expert for further evaluation. *BWSp*, Beckwith–Wiedemann spectrum; *SDS*, standard deviation scores.

Reproduced from Brioude, F., Kalish, J.M., Mussa, A., *et al.*, (2018). Expert consensus document: Clinical and molecular diagnosis, screening and management of Beckwith–Wiedemann syndrome: An international consensus statement. Nature Reviews. Endocrinology, 14(4), 229–249. https://doi.org/10.1038/nrendo.2017.166. [Epub ahead of print] PMID: 29377879 with permission.

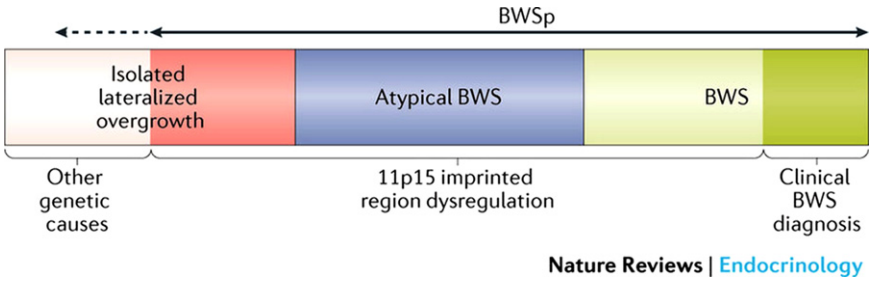

Fig. 2 The Beckwith–Wiedemann spectrum (BWSp). BWSp includes patients with a clinical diagnosis of Beckwith–Wiedemann syndrome (BWS) with or without an (*epi*) genetic change at the BWS locus on chromosome 11p15, patients with "atypical BWS" (defined as fewer cardinal and suggestive features than those needed for a clinical diagnosis of BWS) and an (epi)genetic change at the BWS locus, and patients with "isolated lateralised overgrowth" and an (epi)genetic change at the BWS locus. The *dotted arrow* indicates that some patients with apparent isolated lateralised overgrowth and no 11p abnormality may subsequently be found to have an 11p15 abnormality on testing of additional tissues or with a more sensitive assay. Patients with clinical BWS and no detectable 11p15 abnormality might be further investigated with additional clinical evaluation and consideration of other syndromes, which may have features overlapping with BWSp (see **Table 3**) and appropriate testing for those syndromes may be warranted. Reproduced from Brioude, F., Kalish, J.M., Mussa, A., *et al.* (2018). Expert consensus document: Clinical and molecular diagnosis, screening and management of Beckwith–Wiedemann syndrome: An international consensus statement. *Nature Reviews. Endocrinology*. **14**(4), 229–249. https://doi.org/10.1038/nrendo.2017.166. [Epub ahead of print] PMID: 29377879 with permission.

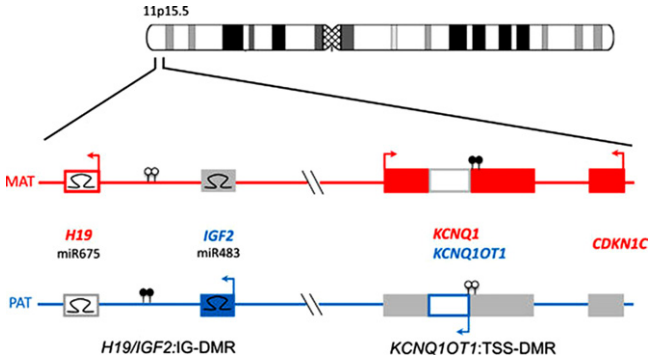

Fig. 3 The imprinted gene cluster in 11p15.5. It is divided in two functional domains whose imprinting is dependent on distinct ICRs (*H19/IGF2*: IG-DMR, *KCNQ1OT1*:TSS-DMR). (*Filled boxes*, protein coding genes; empty boxes, noncoding genes; Ω miRNAs; filled lollipops, methylated regions; empty lollipops, unmethylated regions; *red*, genes expressed from the maternal (mat) chromosome; *blue*, genes expressed from the paternal (pat) chromosome. *Arrows* above the genes, transcription direction of sense genes; *arrows* below the genes, transcription direction of anti-sense genes). Reproduced from Eggermann, K., Bliek, J., Brioude, F., et al. (2016). EMQN best practice guidelines for the molecular genetic testing and reporting of chromosome 11p15 imprinting disorders: Silver-Russell and Beckwith–Wiedemann syndrome. *European Journal of Human Genetics* **24**(*10*), 1377–1387with permission.

can make a molecular diagnosis challenging (Brioude *et al.*, 2018). The IBCG recommended that when a diagnosis of BWSp is suspected testing should usually be offered if the IBCG score is >2 (except for cases of isolated exomphalos) (see **Table 1**). A flow chart summarizing the molecular investigation of BWSp is shown in **Fig. 5**.

Molecular investigations of sporadic suspected BWSp: The most frequent causes of sporadic BWSp are upd(11)pat (~20% of cases), loss of maternal allele methylation at the centromeric 11p15.5 imprinting domain DMR (known as IC2 or *KCNQ1OT1*:TSS DMR) (~50% of cases) or gain of maternal allele methylation on the telomeric 11p15.5 imprinting domain DMR (known as IC1 or *H19/IGF2*: intergenic (IG) DMR) (H19/IGF2:IG-DMR) (~5% of cases) (**Figs. 3** and **4**). Each of these major molecular mechanisms can be detected by assaying IC1 and IC2 methylation status (patients with upd(11)pat) have IC2 loss of methylation (LOM) and IC1 gain of methylation (GOM) and so investigations such as methylation-sensitive multiplex ligation-dependent probe amplification (MS-MLPA) are generally the first line investigation for a suspected case of BWSp (Eggermann *et al.*, 2016a,b). If a positive diagnosis is made then the recurrence risk for each of these anomalies will be low unless IC1 GOM is secondary to a IC1 CNV or mutation (the former can be detected by MS-MLPA) (see **Table 2**). Testing may be negative if (a) upd(11)pat or a methylation abnormality is present in a mosaic form, (b) there is an alternative molecular cause of BWSp such as a *CDKN1C* mutation (~5%

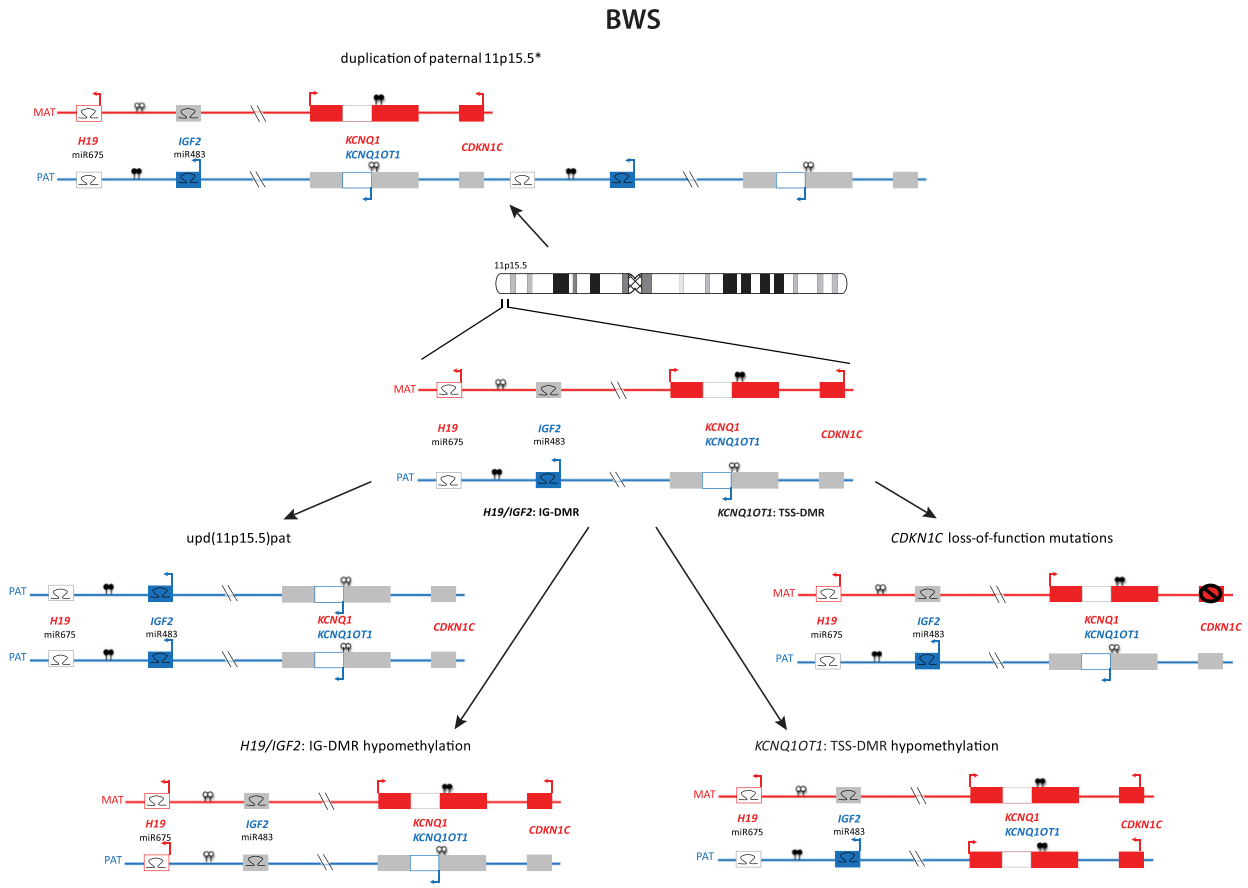

Fig. 4 Molecular mechanisms of BWSp. Reproduced from Eggermann, T., Perez de Nanclares, G., Maher, E.R., et al. (2015). Imprinting disorders: A group of congenital disorders with overlapping patterns of molecular changes affecting imprinted loci. *Clinical Epigenetics* **7**, 123 with permission

of sporadic cases and 50% of familial cases), a chromosome 11p15.5 duplication or inversion (~2% of cases) or (c) there is an unrelated cause (e.g., other overgrowth disorder such as Sotos syndrome (see **Table 3**).

Given that a negative result for an initial IC1 and IC2 methylation status test cannot exclude a diagnosis of BWSp, further investigations are commonly instigated to detect mechanism that might not have been detected by MS-MLPA (Brioude *et al.*, 2018) (see **Fig. 5**). The choice of the second line investigations is dependent on the phenotype: in a child with mild features and hemihypertrophy, mosaicism could be present and further investigations using more sensitive methods to detect upd (11)pat (e.g., single nucleotide polymorphism (SNP) arrays) or altered IC1/IC2 methylation status (Brioude *et al.*, 2018). Conversely, the presence of exomphalos is correlated with a *CDKN1C* mutation or LOM at IC2 (which results in loss of expression of *CDKN1C* from the maternal allele) (Cooper *et al.*, 2005) and so a normal IC1 and IC2 methylation status result in a child with evidence of classical BWS would suggest that *CDKN1C* mutation analysis as the next investigation (Brioude *et al.*, 2018).

Multilocus imprinting disturbance (MLID) is a phenomenon seen in patients with imprinting disorders in which there are epimutations at multiple IC DMRs (Sanchez-Delgado *et al.*, 2016). In a subgroup of patients with Transient Neonatal Diabetes Mellitus (TNDM, OMIM 601410), an imprinting disorder caused by aberrant imprinting of the *PLAGL1* imprinted domain (containing the PLAGL1:alt-TSS-DMR), MLID was found to be often associated with biallelic mutations (autosomal recessively inherited) in *ZFP57* (Mackay *et al.*, 2008). MLID has also been described other imprinting disorders and occurs in a subset (~30%) of patients with BWSp and IC2 LOM (but not in other molecular subgroups) (Azzi *et al.*, 2009). Most such cases are sporadic but in a few cases mutations in the maternal effect genes (the mother harbors biallelic mutations) *NLRP2* and *NLRP5* have been reported (Meyer *et al.*, 2009; Docherty *et al.*, 2015). In some studies and association of MLID in BWSp with ART has been reported (Tee *et al.*, 2013). Though complex or unusual phenotypes have been described in some patients with BWSp and MLID (e.g., a SRS-like phenotype), in most cases with MLID no additional clinical features are found and testing for MLID is not performed routinely unless a link to *NLRP2*/*NLRP5* is suspected (Brioude *et al.*, 2018).

Molecular investigations of familial BWSp: Germline loss-of-function mutations in *CDKN1C* are the most frequent cause of familial BWS (Lam *et al.*, 1999; Brioude *et al.*, 2015). As *CDKN1C* is imprinted and predominantly expressed from the maternal

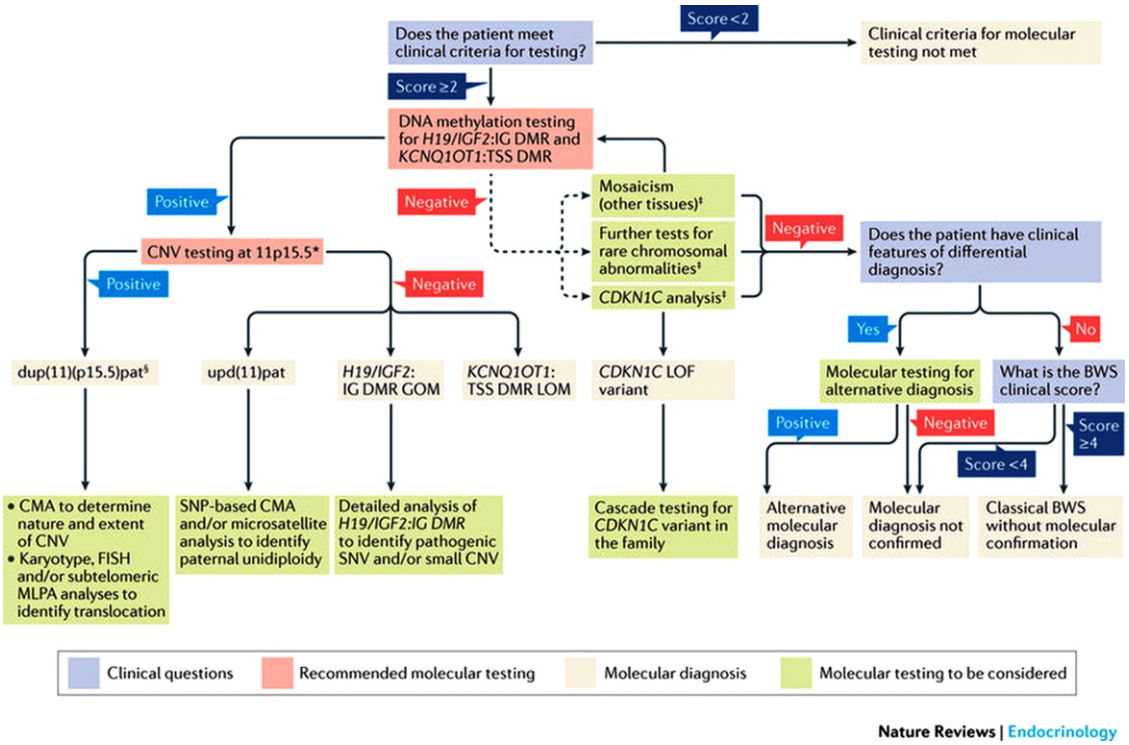

Fig. 5 Flowchart for investigation and diagnosis of Beckwith–Wiedemann syndrome. The figure summarizes the molecular diagnostic pathway for investigation of suspected Beckwith–Wiedemann spectrum (BWSp). Patients with clinical features reaching a score of ≥2 should be genetically tested. It is recommended that first-line testing should assay the methylation status of *H19/IGF2*:intergenic (IG) differentially methylated region (DMR) (also known as IC1) and *KCNQ1OT1*:transcriptional start site (TSS) DMR (also known as IC2). If not estimated simultaneously with DNA methylation, DMR copy number should then be determined in all patients with IC1 and/or IC2 methylation abnormalities. These assays can yield positive molecular diagnosis of BWSp with IC2 loss of methylation (LOM), IC1 gain of methylation (GOM), segmental paternal uniparental isodisomy (UPD) of 11p15.5 (upd(11)pat) or copy number variation (CNV; most commonly duplication of paternal 11p15.5 (dup(11)(p15.5)pat)). Further molecular tests can be considered to determine underlying mechanism of methylation abnormality, UPD or CNV. If DNA methylation testing is negative, further molecular tests can be considered to identify mosaic methylation abnormalities, pathogenic *CDKN1C* variants or rare balanced chromosomal rearrangements. If all molecular tests are negative, differential diagnosis should be considered. However, a diagnosis of classical Beckwith–Wiedemann syndrome (BWS) is made in the presence of a clinical score of ≥4 even in the absence of the molecular confirmation of an 11p15 anomaly. CMA, chromosome microarray analysis (can be oligonucleotide-based and/or single-nucleotide-polymorphism-based platforms); FISH, fluorescence in situ hybridization; LOF, loss of function; MLPA, multiplex ligation-dependent probe amplification; SNP, single nucleotide polymorphism; SNV, single nucleotide variation. *CNV status may be determined simultaneously with methylation testing. ‡See main text for indications for testing. §Deletion of maternal 11p15.5 (del(11)(p15.5)mat) may be detected with lower frequency. Reproduced from Brioude, F., Kalish, J.M., Mussa, A., *et al.*, (2018). Expert consensus document: Clinical and molecular diagnosis, screening and management of Beckwith–Wiedemann syndrome: An international consensus statement. *Nature Reviews. Endocrinology* **14**(*4*), 229–249. https://doi.org/10.1038/nrendo.2017.166. [Epub ahead of print] PMID: 29377879 with permission.

allele, paternally inherited mutations have no or minimal phenotypic effects. In contrast, the risk of BWS in the children of a mother who harbors a *CDKN1C* mutation is 50%. Such parent-of-origin effects are a characteristic feature of genomic imprinting disorders (Eggermann *et al.*, 2015). Other causes of familial BWSp include chromosomal abnormalities and IC1 (and rarely IC2) copy number variants (CNVs) (Eggermann *et al.*, 2016a,b). Single nucleotide substitutions in IC1 been described to cause familial BWSp but molecular testing is not readily available and so their frequency is difficult to establish. Rarely BWS with MLID may be associated with homozygous or compound heterozygous biallelic mutations in *NLRP2* or *NLRP5* in the mother (see above). In cases of familial BWS the risk of BWS in other family members will depend on the precise molecular cause and, in the case of *CDKN1C*, 11p15 CNVs or rearrangements, the parent-of-origin (see **Table 2**).

*Prenatal diagnosis of BWS*p. Though most cases of BWS occur sporadically and the recurrence risk is low (see **Table 2**), in cases of familial BWS the parents may consider prenatal diagnosis. If familial BWSp is associated with previously characterized *CDKN1C* mutation or CNV then the laboratory procedures for determining if the fetus is affected will be fairly standard. However, molecular testing for BWSp in the context of no previous family history as a result of the detection of a BWS-related fetal structural anomaly (e.g., exomphalos) detected by an ultrasound scan may be more challenging (Eggermann *et al.*, 2016b). As with postnatal molecular investigations, the mosaic nature of the epigenetic abnormality may lead to false negative testing results and there may be concerns that testing the epigenetic status of cultured chorionic

Table 2 Summary of Beckwith–Wiedemann spectrum molecular defect categories and recurrence risk

Molecular defect	*Frequency of molecular defect*	*Mosaicism observed*	*Risk of recurrence*	*Characteristic clinical features (compared with other molecular subgroups)*
IC1 GOM	5%	Yes	If no genetic anomaly is present, <1% If genetic anomaly (for example, pathogenic SNV of copy number variant in the DMR) is present, 50%; dependent on parental origin	Low frequency of exomphalos High risk of Wilms tumor
IC2 LOM	50%	Yes	If no genetic anomaly is identified, <1% If a *cis*-acting genetic anomaly is present, 50%; dependent on parental origin	High frequency of exomphalos Low risk of Wilms tumor
upd(11)pat	20% (see also paternal unidiploidy)	Yes	<1%	High incidence of lateralized overgrowth Low frequency of exomphalos High risk of Wilms tumor and hepatoblastoma
Loss-of-function *CDKN1C* variants	5% (40% in familial cases)	Only rarely	50% on maternal transmission	High frequency of exomphalos Low risk of Wilms tumor
dup(11)(p15.5) pat	~2%–4%	No	50% on paternal transmission Risk of SRS on maternal transmission	—
Deletions involving 11p15	1%–2%	No	Dependent on extent and position of CNV, and parent of origin	—
Mosaic paternal unidiploidy (genome-wide paternal UPD)	Up to 10% of upd(11)pat	Yes	Low	High frequency of neoplasia
MLID	33% of IC2 LOM cases	Yes	Low unless an in *trans* genetic variant is identified	Unclear

DMR, differentially methylated region; dup(11)(p15.5)pat, duplication of paternal 11p15.5; GOM, gain of methylation; LOM, loss of methylation; MLID, multilocus imprinting disturbance; SNV, single nucleotide variation; UPD, uniparental isodisomy; upd(11)pat, paternal uniparental isodisomy of 11p15.5.Reproduced from Brioude, F., Kalish, J.M., Mussa, A., *et al.*, (2018). Expert consensus document: Clinical and molecular diagnosis, screening and management of Beckwith–Wiedemann syndrome: An international consensus statement. Nature Reviews. Endocrinology 14(4), 229–249. https://doi.org/10.1038/nrendo.2017.166. [Epub ahead of print] PMID: 29377879 with permission.

villus cells or amniocytes could lead to testing errors. Hence prenatal testing should be undertaken in specialist centres and the results subjected to multicentre audit (Eggermann *et al.*, 2016b).

Clinical Features and Management of BWSp

In this section, the major features and principles of clinical management of BWS are described. For further details see Brioude *et al.*, 2018).

Macroglossia

This is a cardinal feature of BWSp and has been reported in ~90% of children diagnosed with classical BWS (Elliott *et al.*, 1994; Cooper *et al.*, 2005). The tongue is enlarged in all three dimensions and may cause feeding difficulties, persistent drooling, impairment of articulation and orthodontic problems (Shipster *et al.*, 2012). Rarely, when severe, macroglossia may cause respiratory obstruction and obstructive sleep apnoea and surgery may be required in the neonatal period but generally, if surgery is performed, it takes place between 1 and 3 years of age (Kadouch *et al.*, 2012; Shipster *et al.*, 2012). The appearance of macroglossia tends to diminish with age (through reduced growth rate and growth of the mandible to accommodate the tongue) but around 40% of children with BWS may undergo surgical reduction (Elliott *et al.*, 1994). The cosmetic and functional results from tongue reduction are usually good but surgery should be performed in a specialist centre that can offer long-term follow up from a multidisciplinary service (Brioude *et al.*, 2018).

Anterior Abdominal Wall Defects

Occur in around two-thirds of patients with BWSp (most commonly umbilical hernia and then exomphalos (omphalocele) or diastasis recti. (Elliott *et al.*, 1994; Maas *et al.*, 2016). Exomphalos may be detected by prenatal ultrasound scan and lead to prenatal testing for BWSp (see above). A molecular diagnosis of BWS is made in 10%–20% of fetuses with an exomphalos detected

Table 3 Differential diagnosis of Beckwith–Wiedemann spectrum

Disorder	*Inheritance*	*Molecular findings*	*Clinical features*	*References*
Simpson–Golabi–Behmel syndrome	X-linked recessive	Mutation in *GPC3*	Pre and postnatal overgrowth Macrocephaly Variable learning disability Umbilical hernia Diastasis recti Organomegaly Cardiac anomalies Diaphragmatic hernia Skeletal anomalies including postaxial polydactyly Supernumerary nipples Cleft palate Macroglossia Embryonal tumors (especially Wilms tumor) Coarse facial features	Li et al. (2001)
Perlman syndrome	Autosomal recessive	Homozygous mutations in *DIS3L2*	Prenatal overgrowth Developmental delay Hypotonia Nephromegaly Hyperinsulinism High risk Wilms tumor High neonatal mortality Facial features: prominent forehead, deeply set eyes, depressed nasal bridge, tented vermilion upper lip	Astuti et al. (2012)
Costello syndrome	Autosomal dominant (frequent *de novo* mutations)	Activating mutation in *HRAS*	Polyhydramnios, often severe Increased birth weight due to oedema Macrocephaly Short stature Severe feeding difficulties and failure to thrive in infancy Mild to severe intellectual disability Cardiac anomalies, cardiomyopathy, arrhythmia Ulnar deviation Deep palmar and plantar creases Embryonal tumors (rhabdomyosarcoma and neuroblastoma) Coarse facial features Papillomata	Kerr et al. (2006)
Sotos syndrome	Autosomal dominant (frequent *de novo* mutations)	Mutation in or deletion of *NSD1*	Tall stature Macrocephaly Mild to severe intellectual disability Scoliosis Seizures Cardiac anomalies Renal anomalies Neonatal hypotonia, jaundice and feeding difficulties Facial features: broad and prominent forehead, sparse frontotemporal hair, downslanting palpebral fissures, malar flushing, tall chin	Tatton-Brown et al. (2005)
Weaver syndrome	Autosomal dominant (frequent *de novo* mutations)	Mutation in *EZH2*	Tall stature Macrocephaly Variable intellectual disability Camptodactyly Soft/doughy skin Umbilical hernia Facial features: broad forehead, widely spaced eyes, pointed chin, large ears and retrognathia in early childhood	Tatton-Brown et al. (2013)

(*Continued*)

Table 3 Continued

Disorder	*Inheritance*	*Molecular findings*	*Clinical features*	*References*
Malan syndrome	Autosomal dominant	Mutation in the DNA-binding domain of *NFIX*	Postnatal overgrowth Rarely prenatal overgrowth Decrease of height overgrowth with age Persistent macrocephaly Invariably intellectual disability Frequent autism and anxiety Hypotonia Brain anomalies Slender body build Facial features: long face, prominent forehead, short nose, long philtrum, tall chin	Malan et al. (2010)
PTEN hamartoma tumor syndrome	Autosomal dominant	Mutation in *PTEN*	Prenatal overgrowth Macrocephaly Hypotonia Intellectual disability Autism spectrum disorder Dermatological features including genital freckling, trichilemmomas, papillomatous papules, acral keratosis Lipomas Hamartomatous intestinal polyposis High risk of thyroid, breast, endometrial and other cancers	Marsh et al. (1997)
PIK3CA related overgrowth spectrum	Somatic mosaic	Somatic activating mutation in *PIK3CA*	Segmental overgrowth syndromes including fibroadipose hyperplasia, CLOVES syndrome, hemihyperplasia multiple lipomatosis syndrome (HHML), megalencephaly-capillary malformation (MCAP)	Lindhurst et al. (2012)

Reproduced from Brioude, F., Kalish, J.M., Mussa, A., *et al.*, (2018). Expert consensus document: Clinical and molecular diagnosis, screening and management of Beckwith–Wiedemann syndrome: An international consensus statement. Nature Reviews. Endocrinology. https://doi.org/10.1038/nrendo.2017.166. [Epub ahead of print] PMID: 29377879 with permission.

on prenatal ultrasound scan but testing is not indicated in neonates with exomphalos and no other features of BWSp (Porter *et al.*, 2009; Brioude *et al.*, 2018). The frequency of exomphalos is differs between molecular subgroups of BWS being significantly higher in those with *CDKN1C* mutations or IC2 LOM (which is associated with loss of *CDKN1C* expression from the maternal allele) than in those with UPD or IC1 GOM (Cooper *et al.*, 2005).

Pre and/or Post Overgrowth

In a large study of >400 patients with BWS, macrosomia at birth (defined by birth length and/or birth weight above +2.0 SDS) was reported in 43% of cases (40% had a birthweight > +2.0 SDS) (Brioude *et al.*, 2013). Although BWS has traditionally been classed as an overgrowth syndrome (and the differential diagnosis may include other overgrowth disorder such as Sotos syndrome and Simpson-Golabi-Behmel syndrome; see **Table 3**) the definition of macrosomia can differ from study to study and macrosomia may not be present in milder cases with mosaic molecular abnormalities. Hence the IBCG guidelines designated a birthweight >2 SDS above the mean as a suggestive rather than a cardinal feature (Brioude *et al.*, 2018). Children with IC1 GOM have a significantly higher birthweight than those with IC2 LOM or a *CDKN1C* mutation (Brioude *et al.*, 2013). Overgrowth tends to ameliorate in older children but though there is a paucity of data on adult height in children with BWSp, in one study just over 50% of adult patients had a height above +2.0 SDS (Brioude *et al.*, 2013). Overgrowth may be asymmetrical (*Lateralised overgrowth*/hemihypertrophy) and lateralised overgrowth is most common in BWSp patients with upd(11)pat (Ibrahim *et al.*, 2014). Leg length discrepancy can be problematic and treated by shoe lifts for milder forms (<2 cm) but surgical intervention might be considered in more severe forms (Brioude *et al.*, 2018).

Neonatal Hypoglycemia

This frequent complication of BWSp (reported in around 60% of patients (Maas *et al.*, 2016) is usually transient and resolves within a few days. Severe untreated hypoglycemia may be associated with neurological damage and so all neonates with possible BWSp should be screened for hypoglycemia (and treated id detected). In a subgroup of patients with BWSp, hypoglycemia is severe and persists beyond a week and may require drugs such as diazoxide or somatostatin analogues or even, in severe refractory cases, pancreatectomy (Al-Zubeidi *et al.*, 2014; Laje *et al.*, 2013). Patients with upd(11)pat and a coincident paternally transmitted KATP channel may have very severe and persistent hypoglycemia and molecular testing BWSp (particularly mosaic upd(11)pat should be considered in cases of congenital hyperinsulinemic hypoglycemia (CHI) without a detectable CHI gene mutation even if other features of BWSp are not apparent) (Kalish *et al.*, 2016).

Embryonal Tumors

Although only a minority (~7%) of children with BWSp will develop an embryonal tumor, compared to population controls the relative risk is greatly increased. The most commonly reported BWSp-associated embryonal tumors are Wilms tumor, hepatoblastoma and neuroblastoma, though rhabdomyosarcoma and pancreatoblastoma have been reported (Maas *et al.*, 2016). Median age of Wilms tumor diagnosis in BWSp around age 2 years (Maas *et al.*, 2016). A key finding has been the identification of genotype–phenotype correlations that have demonstrated that the tumor risk and tumor types vary between molecular subgroups (Cooper *et al.*, 2005; Maas *et al.*, 2016). The highest risk (~28%) is seen with IC1 GOM and the most common tumor type in this subgroup is Wilms tumor (occasionally neuroblastoma and pancreatoblastoma (<1% risk)) (Maas *et al.*, 2016). The next highest risk subgroup is upd(11)pat in which the overall tumor risk is 16% and Wilms tumor is most common (~8%) followed by hepatoblastoma (3.5%), neuroblastoma (1.4%) and adrenocortical carcinoma (1.1%) (Maas *et al.*, 2016). Amongst those with uniparental disomy, the risk of embryonal tumor appears to be higher in the subgroup (~10% of those with disomy) with genome-wide uniparental disomy than in those upd(11)pat (Kalish *et al.*, 2013). Germline *CDKN1C* mutations have an embryonal tumor risk of 6.9% (neuroblastoma (2.8%), Wilms tumor (1.4%). The most common molecular causes of BWSp, IC2 LOM, is associated with the lowest overall tumor risk (2.6%) and the risk for individual tumor types is <1% (Maas *et al.*, 2016). Finally in those with a clinical diagnosis of classical BWS but no detectable molecular abnormality the overall tumor risk is 6.2% (Wilms tumor risk (4%) and other tumor types each <1%) (Maas *et al.*, 2016).

Recognition of the increased embryonal tumor risk in BWSp led to suggestions that screening should be performed to enable earlier diagnosis and prolong survival and/or reduce treatment-related morbidity. Screening has been most commonly advocated for Wilms tumors (renal ultrasound) and hepatoblastoma (liver ultrasound ± serum alpha-fetoprotein (AFP) levels). However, there has not been universal agreement as to whether abdominal ultrasound surveillance should be offered to all cases of BWSp or should be targeted to higher risk groups and as to whether serum alpha-fetoprotein levels should be monitored. Two recent consensus group reports came to differing conclusions regarding targeted screening and suggested that the surveillance programmes might differ between the United States and Europe (Kalish *et al.*, 2017; Brioude *et al.*, 2018). Within Europe there is broad agreement that abdominal ultrasound (every 3 months from diagnosis until age 7 years should be routinely offered to patients meeting the definition of BWSp except for those with IC2 LOM (for whom no screening is offered) (Brioude *et al.*, 2018). Such targeted screening enables ~50% of children with BWSp to be excluded from surveillance. However, recent recommendations for surveillance from a group of experts predominantly from North America specified that all children with BWS should be offered screening for Wilms tumor and hepatoblastoma (from birth or diagnosis) by full abdominal ultrasound every 3 months until age 7 years and serum AFP measurements every 3 months until age 4 years) (Kalish *et al.*, 2017). Both groups based their recommendations on similar estimates of tumor risks (Maas *et al.*, 2016) but the differing recommendations reflected differences in medical practice (including medicolegal practice) between Europe and North America (Kalish *et al.*, 2017; Brioude *et al.*, 2018). Prospective audit of targeted and universal surveillance will provide an evidence base for reconciling the geographical differences in surveillance programmes.

Other Congenital Anomalies

Era creases and ear pits are common in BWSp (33% and 21% respectively), facial naevus flammeus occurs in ~45% of cases and a cardiac anomaly in up to 10% of cases (Maas *et al.*, 2016). Learning disability is infrequent in BWSp but can be associated with a history of prematurity, severe neonatal hypoglycemia, genome-wide uniparental disomy or unbalanced chromosome 11 rearrangements. Nephromegaly is reported in about a quarter of cases and cortical and medullary renal cysts, hypercalciuria and nephrolithiasis are reported to be more common in BWSp (Mussa *et al.*, 2012). In children with BWSp who do not have surveillance for Wilms tumor, it has been recommended that nephrourological evaluation should be undertaken at surveillance and in all cases at transition to adulthood (Brioude *et al.*, 2018).

Late Onset Complications

There is relatively little information on late-onset complications of BWSp. Though there have been occasional reports of adult onset neoplasia there does not seem to be an association with common adult-onset cancers. An increased frequency of male infertility has been reported but no large-scale studies have been undertaken. It has been recommended that adults with BWSp might seek genetic counseling advice before starting a family at that stage, any potential concerns about fertility can be reviewed and referrals for further investigation made as appropriate.

Conclusion

The diagnosis and management of BWSp can be challenging and requires close liaison between health care practitioners in multiple clinical specialties. Effective clinical management is facilitated by the designation of an experienced clinician to coordinate acre and oversee referral to relevant specialists. In addition, close liaison with clinical scientists may be required to ensure

that appropriate molecular testing is performed, especially when first line molecular testing is negative but clinical suspicion of BWSp remains.

McCune–Albright Syndrome☆

Erica A Eugster, Riley Hospital for Children at Indiana University Health, Indianapolis, IN, United States

Glossary

Café au lait pigmentation Pigmented cutaneous lesions, ranging from light to dark brown, that are caused by an excess of melanosomes and are one of the major cutaneous manifestations of several diseases.

Fibrous dysplasia of bone A disturbance of medullary bone in which bone undergoing physiological lysis is replaced by abnormal proliferation of fibrous tissue, resulting in asymmetric distortion and expansion of bone.

G proteins Intracellular proteins activated by ligand-bound receptors; serve as second messengers of the receptor-initiated response to intracellular elements, such as enzymes, to initiate an effect.

Mosaicism The juxtaposition in an organism of genetically different tissues, implying that some cells in a given tissue may have a gene mutation while adjacent cells do not.

Precocious puberty The appearance of secondary sexual development in children who are younger than the lower end of the normal age range for the onset of puberty.

Introduction

Donovan McCune and Fuller Albright first recognized the constellation of clinical features that comprise McCune–Albright syndrome during the mid-1930s. In 1991, the molecular genetic basis for the disease was discovered to be an activating mutation in the GNAS1 gene, which encodes for the stimulatory Gsα-subunit involved in intracellular signaling. During the decades following the original description, tremendous progress has been made in illuminating many aspects of this complex disorder. This progress has included an elucidation of the potential clinical manifestations, an expanded understanding of the physiological consequences of abnormal G protein signaling, and an ever-increasing identification of promising new therapies. Although it is rare, McCune–Albright syndrome is one of the most diverse and fascinating diseases known to modern medicine.

The Etiology of McCune–Albright Syndrome

The heterozygous missense mutation from which this condition originates occurs sporadically in a postzygotic cell line during embryological development. Factors resulting in an increased susceptibility to this mutation or those influencing the exact timing at which it occurs have not been identified. The consequence of the postzygotic nature of the mutation is that it exists in a mosaic pattern among and within the various cell types and tissues in the body. Even within an affected tissue, only a portion of the cells will bear the mutated GNAS1 gene. The physical characteristics of the disease are caused by abnormal function of cells containing the mutation, whereas the unaltered cells behave normally. The fact that the number and distribution of these abnormal cells vary widely from individual to individual, as well as from tissue to tissue, results in tremendous heterogeneity in the scope and severity of clinical findings.

The human GNAS1 gene contains at least 13 exons and is located on chromosome 20. The defective Gsα in McCune–Albright syndrome results from a missense mutation resulting in the substitution of a single amino acid within the protein structure. In the vast majority of patients, this consists of an exchange of asparagine at the 201 position for histine or cysteine. Substitution of glutamine at the 227 position has also been identified in patients with activating Gsα mutations. The locations of these mutations within the GNAS1 gene are depicted in Fig. 1. Under ordinary circumstances, the heterotrimeric G protein, consisting of α-, β-, and γ-subunits, functions in a highly coordinated fashion during intracellular signal transduction. Acting as a second messenger system, the G protein complex is activated when a ligand binds to its receptor, stimulating an exchange of bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on the surface of the Gsα-subunit. The Gsα portion subsequently stimulates adenylate cyclase, leading to intracellular cyclic AMP (cAMP) accumulation and downstream gene transcription. Intrinsic GTPase activity within the Gsα-subunit serves to hydrolyze GTP, allowing for a restoration of bound GDP and completion of the signaling cycle. In McCune–Albright syndrome, the completion phase of this cycle is destabilized, resulting in a signaling pathway that becomes and remains "turned on" in an unregulated and autonomous fashion, as shown in Fig. 2. This phenomenon, known as "constitutive activation," leads to hyperfunction and proliferation of affected cells. G protein-mediated cell signaling is ubiquitous

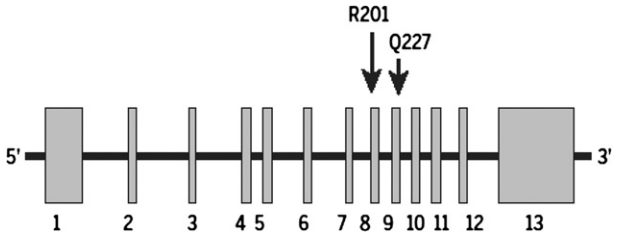

Fig. 1 Schematic of the GNAS1 gene indicating the location of the Arg201 and Gln227 mutations within exons 8 and 9.

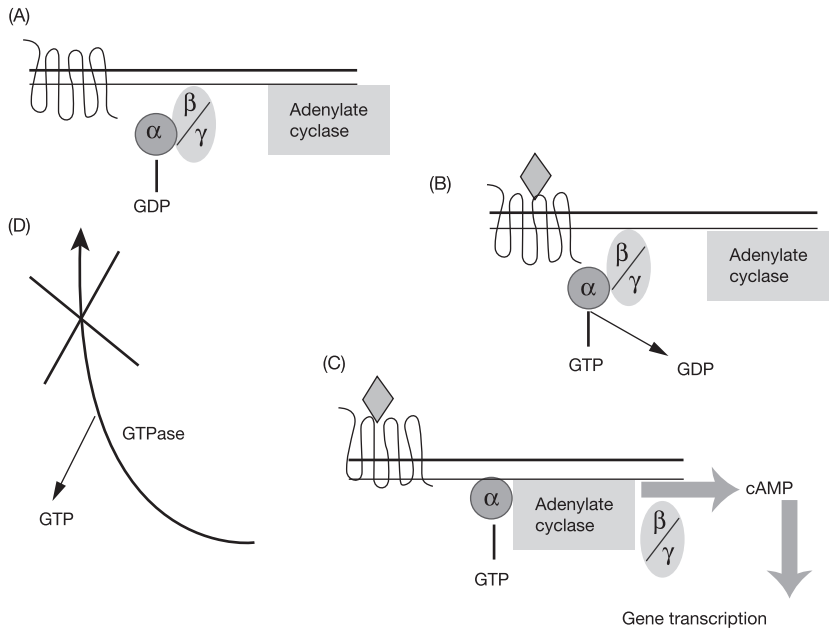

Fig. 2 G protein-mediated signal transduction. Panel (A) depicts the heterotrimeric G protein in the quiescent state, with GDP complexed with the Gsα-subunit. On ligand binding (B), GDP is exchanged for GTP and the α-subunit dissociates from $\beta\gamma$. Activation of adenylate cyclase (C) results in cAMP formation, leading to downstream gene transcription. In McCune–Albright syndrome, intrinsic GTPase activity within Gsα is defective (D), rendering the cell cycle turned "on" independent of ligand binding.

within endocrine glands as well as in many additional cell types, including those found in bone, liver, skin, GI tract and heart. Thus, patients with McCune–Albright syndrome may exhibit a myriad of endocrinopathies and other forms of systemic involvement in addition to the classic triad of features that are most commonly present. Therefore, it is important to conceptualize the disorder as existing within a broad spectrum of potential phenotypic manifestations. Both classic and variant forms of McCune–Albright syndrome are reviewed in the next section.

Clinical Features

The precise incidence of McCune–Albright syndrome is unknown, but it is quite rare. At any given time, pediatric endocrine groups in large academic medical centers around the country typically report that they are caring for anywhere from zero to four patients with the disorder. Manifestations of the disease may arise during the neonatal period or at any time during childhood and adolescence. Failure to recognize features of the disease resulting in a delay in diagnosis is a common problem. Although the true sex ratio is unknown, McCune–Albright syndrome has been reported far more frequently in girls than in boys.

Classic McCune–Albright Syndrome

The combination of precocious puberty, café au lait pigmentation, and fibrous bone dysplasia constitutes the enduring hallmarks of this disease. However, a significant percentage of patients will develop endocrinopathies above and beyond precocious puberty. Therefore, these additional endocrine problems will be considered in conjunction with the other classic features.

Precocious Puberty

The diagnosis of McCune–Albright syndrome is most commonly made following the appearance of precocious puberty. Typically described in girls, a sudden onset of vaginal bleeding is heralded or accompanied by acute breast enlargement. These physical changes are due to autonomous ovarian function characterized by the development of large cysts producing high serum levels of estrogen. Once these cysts resolve, the estrogen withdrawal results in a shedding of the endometrial lining and spontaneous bleeding. The first such episode in girls with McCune–Albright syndrome usually occurs between 1 and 6 years of age, although it may become apparent as early as 4 months of age. The frequency with which subsequent episodes arise is unpredictable and quite varied. Whereas some girls experience extended intervals of ovarian quiescence, others go on to develop recurrent episodes of ovarian hyperfunction with frequent menses. In these cases, additional manifestations of precocious puberty include the appearance of pubic and axillary hair, accelerated growth, and skeletal maturation. Ultimately, untreated progressive precocious puberty results in premature closure of growth plates with significant short stature during adulthood. The precocious puberty observed in boys with McCune–Albright syndrome originates from an analogous hyperfunction of the testes, leading to episodic elevations in serum testosterone levels and the early appearance of secondary sexual characteristics. In both sexes, this premature production of sex steroids is categorized as a form of "peripheral precocious puberty," indicating that it represents a physiological process outside of the central nervous system pathways through which pubertal development is normally mediated. Isolated unilateral or bilateral macroorchidism without biochemical evidence of precocious puberty has also been reported in boys, in whom it presumably results from a Sertoli cell only distribution of the mutant GNAS1 gene.

Reports of ovarian function during the postpubertal period in McCune–Albright syndrome are inconsistent. Although regular menstrual cycles and normal fertility have been reported in some women, there is also evidence that episodic autonomous ovarian activity persists in many patients. Thus, adolescent and adult women with the disorder may experience irregular periods and occasional prolonged vaginal bleeding.

Other Endocrinopathies

The propensity to additional endocrine abnormalities is a feature of McCune–Albright syndrome. In each of these cases, the underlying mechanism relates to excessive cellular function from increased intracellular cAMP formation. Affected endocrine glands exhibit a surplus of hormone production and evidence of cell proliferation. The most frequently encountered endocrinopathy (after precocious puberty) is hyperthyroidism, usually accompanied by an enlargement of the thyroid gland. Somewhat less common is the development of pituitary growth hormone excess, which may also be associated with increased prolactin and causes gigantism if it arises prior to closure of the skeletal growth plates. Rarely, an excess of the adrenal steroid hormone cortisol may occur and subsequently remit during infancy, resulting in transient "Cushing syndrome." Other infrequently reported endocrine problems include hyperparathyroidism and hypophosphatemic rickets. Therefore, periodic testing of blood hormone levels for the early detection of endocrinopathies is a routine part of ongoing follow-up for affected patients. The incidence and clinical features of the endocrine manifestations of McCune–Albright syndrome above and beyond precocious puberty are summarized in **Table 1**.

Café Au Lait Pigmentation

The spectrum of the skin pigmentation exhibited by an affected patient ranges from small discreet birthmarks to dramatic involvement of an entire limb or side of the body. These flat areas are usually faint at birth and become darker and more obvious over time. As implied by the name, the color of these regions is often similar to that of "coffee with milk," although they may be darker, depending on the baseline skin tone. Often ending abruptly at the midline, the areas of increased pigmentation follow the outgrowth of distinct cell populations during early embryological development, a pattern designated as the "lines of Blaschko." Another consistent finding is an irregular border configuration reminiscent of a rocky shore and described as the "coast of Maine," in contrast to the "coast of California" café au lait birthmarks featured in other disorders such as neurofibromatosis. Investigation of biopsied skin cells from these

Table 1 Additional endocrine problems described in patients with classic McCune–Albright syndrome

Endocrine abnormality	*Estimated incidence*	*Clinical features*	*Laboratory features*
Hyperthyroidism	30%–40%	Multinodular goiter	Elevated serum thyroxine and triiodothyronine with suppressed thyroid-stimulating hormone
Renal phosphate wasting	40%–50%	Fibrous dysplasia and bone deformity	Low serum phosphorous and elevated FGF23
Growth hormone excess	20%–30%	Pituitary hyperplasia or adenoma, resulting in gigantism or acromegaly	Elevated serum growth hormone and insulin-like growth factor I
Cushing syndrome	2%–5%	Nodular adrenal hyperplasia during infancy that remits spontaneously	Elevated serum cortisol with low adrenocorticotropic hormone
Hypophosphatemic rickets	2%–5%	Rachitic bone changes	Low serum phosphorous

Fig. 3 Characteristic appearance of a café au lait spot in a patient with McCune–Albright syndrome.

areas has confirmed that the pigmentation is due to increased melanin production within melanocytes containing the activating Gsα mutation. Although uncommon, café au lait macules involving oral mucosa have also been reported and are likely under-recognized. Fig. 3 illustrates the typical appearance of café au lait pigmentation in a patient with McCune–Albright syndrome.

Fibrous Dysplasia of Bone

Of the triad of clinical features observed in McCune–Albright syndrome, the bone disease carries the greatest potential for morbidity. Fibrous bone dysplasia consists of skeletal lesions in which normal tissue has been replaced by abnormal fibrous bone that may take a variety of forms, depending on the location. These abnormal areas may arise anywhere within the body but are most commonly found in the long bones and skull, with multiple sites of involvement being typical. The destruction of normal bone that occurs in the limbs leads to an increased rate of fracture, potentially severe deformities, bone pain, and decreased mobility. Also debilitating are areas of bony overgrowth involving the face that may even result in hearing loss or blindness from impingement of nerve fibers that traverse the skull. As expected, the fibrous dysplasia is caused by the presence of the Gsα mutation within bone-forming cells. With time, both the number and the severity of bone lesions in McCune–Albright syndrome tend to progress, rendering many affected patients confined to wheelchairs by middle adulthood.

Renal phosphate wasting is closely correlated with the total body burden of fibrous dysplasia in McCune–Albright syndrome. Linking the two is fibroblast growth factor 23 which is produced in an unregulated fashion by areas of fibrous dysplasia and inhibits phosphate reabsorption by the kidneys. Elevated fibroblast growth factor 23 is thus thought to be directly responsible for the phosphate wasting and hypophosphatemia common in McCune–Albright syndrome.

Nonclassic McCune–Albright Syndrome

Nonclassic varieties of the disease may be thought of as those in which the prototypical activating mutation is present in an atypical distribution. This may take the form of an isolated tissue bearing the abnormal Gsα protein, an unusual combination or subset of the classic triad, or extremely widespread involvement with multisystemic consequences. Each of these possibilities is described in the following subsections.

Isolated Gsα Mutation

It has now been recognized that the same mutation that causes McCune–Albright syndrome also has an important role in the genesis of a number of sporadic tumors that may arise within endocrine glands and other tissues. In this context, the activating Gsα

mutation is referred to as *Gsp*, an "oncogene," in view of its action as a genetic switch resulting in abnormal cellular growth and neoplastic transformation. Rare tumors of the thyroid gland, GI tract, pancreas, anterior pituitary, testes, and adrenal glands in which this mutation has been found have all been described.

Forme Fruste McCune–Albright Syndrome

Another context in which an isolated Gsα mutation is known to occur is in patients exhibiting an apparent isolated feature of the syndrome. Thus, individuals with isolated fibrous bone dysplasia, isolated recurrent ovarian cysts, and isolated café au lait pigmentation all have been demonstrated to harbor the same activating mutation as that found in the classic form of the disease. In a related scenario, cases have been described in which only one or two of the three classic manifestations are present, a situation recognized as a forme fruste variant of the disorder. Similarly, variations on the theme of the classic triad in which a slightly different cell type or endocrine gland is involved are also possible. New clinical features that have been recently described include abnormalities in the GI tract and pancreas such as polyps, neoplasms and dysplasia. Given the multitude of tissues in which the mutation may occur, the numbers of possible "faces" of McCune–Albright syndrome are seemingly endless.

Multisystemic Involvement

In a few rare cases, widespread distribution of the Gsα mutation has resulted in a devastating, multisystemic form of the disorder. In these patients, the presentation occurs during the neonatal period. Because the classic features are often lacking, however, there is usually a delay in making the diagnosis. Clinical findings in these infants have included severe liver disease, multiple endocrinopathies, heart failure, and even sudden death. It is assumed that these cases represent instances in which the activating mutation occurred very early in embryological life, leading to numerous involved areas within the body. A germline mutation, in which every cell would be expected to have the abnormality, has never been described and would presumably be lethal.

Treatment of McCune–Albright Syndrome

The development of effective and safe therapeutic interventions for the various aspects of McCune–Albright syndrome is an ongoing and evolving challenge. Only with the remote possibility of gene therapy could a cure for the disease ever be envisioned. A number of established palliative treatment options exist, and several novel approaches that may significantly improve the prognosis and quality of life for patients with McCune–Albright syndrome are under investigation. Historic and potential new therapeutic modalities for each of the classic features of the disease are reviewed in this section.

Treatment of Precocious Puberty in Girls

Treatment of precocious puberty is typically reserved for patients with evidence of the progressive form of the condition. Thus, a period of observation is obligatory in all children following the initial episode. In girls with a clinical course for which intervention is indicated, the mainstay of treatment is pharmacological, although ovarian cystectomy has been performed in some cases. Unfortunately, unnecessary oophorectomy has also been performed due to concerns about a possible ovarian tumor and failure to consider McCune–Albright syndrome as a cause for the clinical findings. The goals of therapy are to halt progression of pubertal development, prevent vaginal bleeding, and retard the advanced rate of skeletal maturation that will compromise a child's ability to achieve a normal adult height. The most widely used treatment has been an antiestrogen in the form of an aromatase inhibitor or receptor modulator or blocker. First and second-generation aromatase inhibitors have proved disappointing, as has the third generation compound anastrozole. However, good results have been achieved with the third generation aromatase inhibitor letrozole, which was found to decrease vaginal bleeding, slow the rate of skeletal maturation and increase predicted adult height after an average of 4 years of treatment. There is also evidence to suggest good efficacy with the use of tamoxifen (10–30 mg per day), an antiestrogen with tissue-specific stimulatory and inhibitory actions at the level of the estrogen receptor. Long-term follow-up of girls treated for 3–8 years revealed a cessation of vaginal bleeding and a significant improvement in predicted final heights. Finally, the pure antiestrogen Faslodex has also been shown to be moderately beneficial in attenuating the effects of autonomous ovarian function in girls with McCune–Albright syndrome. Unfortunately, this medication is given by injection, making it less desirable in a pediatric population. Therefore, evidence to date suggests that both letrozole and tamoxifen are viable options for the treatment of girls with precocious puberty and McCune–Albright syndrome.

Treatment of Café Au Lait Pigmentation

Because the impact of the skin pigmentation in McCune–Albright syndrome is essentially cosmetic, this feature of the disorder is typically the least of the patient's and parents' concerns. However, in cases where extensive involvement of frequently exposed skin is present, therapeutic options primarily revolve around the use of laser technologies.

Treatment of Fibrous Bone Dysplasia

Historically, the only therapeutic approach available for the treatment of fibrous bone dysplasia was surgical. Internal rod placement, bone grafting, and curettage have traditionally been reserved for the most severely affected individuals. Surgery remains the mainstay for the treatment of craniofacial fibrous dysplasia although regrowth is common particularly in patients with growth hormone excess. However, there has been considerable interest in the use of bisphosphonates as potential medical therapy for the disease. Although uncontrolled studies involving bisphosphonates in both children and adults with fibrous dysplasia were promising, a randomized controlled trial of alendronate failed to demonstrate improvements in pain, disease burden or functional parameters with this modality. However, newer compounds and novel classes of drugs such as those targeting nerve growth factor hold potential and are under investigation.

Conclusion

Wonderful strides have been made in the knowledge and understanding of McCune–Albright syndrome. The identification of an activating Gsα mutation has afforded valuable insights into normal and abnormal human cellular function, and the development of new therapies continues to improve clinical management. Future collaborative efforts will focus on a determination of the natural history of disease, clarification of remaining enigmas regarding molecular genetics, and designation of optimal treatment strategies for all aspects of McCune–Albright syndrome.

Noonan Syndrome

Michael A Patton and Alistair P Patton, St Georges University of London, London, United Kingdom

Glossary

Chylothorax The presence of lymphatic fluid in the chest.
Cryptorchidism The presence of undescended testes.
Hepatosplenomegaly Enlargement of the liver and spleen.
Hypertelorism Widely spaced eyes.
Ptosis The dropping of the eyelids.

Introduction

In 1963, Noonan and Ehmke reported nine patients (six males and three females) who had short stature; characteristic facies that included apparent hypertelorism, ptosis, and low-set ears who appeared to represent a new syndrome. Several of the males had undescended testes. Chest deformities were frequent and all had valvular pulmonary stenosis. It was differentiated from Turner syndrome as it occurred in both males and females and the chromosomes were normal. Further clinical studies were published including a long-term study of the natural history of the disorder in a cohort of 150 patients over 15 years by Shaw et al. in 2007. From these studies and other research, the classic features of Noonan syndrome were identified and further clinical understanding has developed.

Genetics

In approximately half of the children with Noonan syndrome, the condition will have arisen as a de novo mutation, but the condition is inherited as an autosomal dominant condition which may be passed from generation to generation down either the male or female side of the family. Large families are relatively rarely recognized as there is reduced fertility in males and because the characteristic facial features tend to normalize with age and may be difficult to recognize in adult life. The first breakthrough in identifying the genetic cause came with the mapping of a gene for the condition to the long arm of chromosome 12 in 1994 and subsequently from this the first gene PTPN11 was identified by Tartaglia et al. in 2001. This gene codes for the SHP-2 protein and is an important step in the RAS-MAPK pathway which regulates cell growth (Fig. 1). It was found that only 50% of cases of Noonan syndrome were due to mutations in the *PTPN11* gene but subsequent work identified that mutations in other genes in the RAS-MAPK pathway could cause Noonan syndrome or other similar disorders (see section "Differential Diagnosis"). The genes that are now recognized to cause Noonan syndrome are PTPN11, SOS1, RAF1, KRAS, NRAS, BRAF, and SHOC2. Clinically the features associated with these genes overlap, but PTPN11 most resembles "classical Noonan syndrome" and RAF1 is particularly associated with cardiomyopathy. The genetic basis of around 25% of cases is still undetermined and therefore it is probable that further causative genes will be discovered.

Clinical Features and Diagnosis

The initial diagnosis of Noonan syndrome is based on clinical findings. Characteristic facies are helpful in diagnosis but change with age. In the newborn period, there may be asymmetrical ptosis and the ears may be thick, broad, and posteriorly angulated. A striking feature in the newborn is the presence of redundant loose skin at the back of the neck which is the result of intrauterine edema. When this loose skin resolves, it leads to the development of neck webbing later in childhood. There may also be thickened finger pads from intrauterine edema. In infancy, the head will appear relatively large in relation to the body and the neck may appear short. The eyes are more prominent and ptosis may first be noticed at this stage. The nasal bridge is depressed. As childhood progresses, the facial appearance elongates and assumes a more triangular shape as the chin lengthens. Asymmetric bilateral ptosis and hypertelorism or widely spaced eyes become more apparent. The low hair line and webbing may become more obvious. The hair may be unusually curly. The facial features tend to normalize in the late teens and it may be very difficult to recognize adults with Noonan syndrome from the facial features alone. The ptosis may persist and the deep nasolabial folds may be a useful clinical sign.

Although most patients with Noonan syndrome have an unremarkable prenatal history, in one-third of patients the pregnancy is complicated by polyhydraminos. Since fetal ultrasound has become universal, an increasing number of cases are diagnosed by increased nuchal swelling and hydrops with subsequent genetic prenatal diagnosis.

Feeding difficulties are common in the neonatal period. Approximately 35% have mild to moderate feeding problems and up to 25% have severe feeding difficulties on occasions requiring tube feeding. Studies have indicated an increased incidence of

Fig. 1 The RAS-MAPK pathway showing some of the key genes which may be mutated in Noonan syndrome and related disorders.

gastroesophageal reflux and poor gut motility. However, the feeding problems are usually due to an immature swallowing and resolve in infancy. There is some correlation between prolonged tube feeding and later developmental delay.

Children with Noonan syndrome often present to the endocrinologist with short stature, delayed puberty, and in boys undescended testes. Weight and length are usually normal at birth but the height and weight will usually be between the 3rd and 10th centiles while the head circumference is on the 50th centile. There is often concern about growth in childhood but as puberty and bone age are also significantly delayed, growth may continue into the late teens. The mean final height is 169.2 cm (range 153–188.7 cm) in males and 154.4 cm (range 146.1–167.8 cm) in females. In males, 60% will have unilateral or bilateral cryptorchidism which may affect adult fertility. In females puberty is also delayed with a mean menarche of 14.6 years, but fertility for affected females is normal.

Developmental delay may occur. Motor delay may be partially attributed to muscular hypotonia. The mean age for siting independently is 10 months and for walking unsupported is 21 months. Speech is also delayed with the mean age for simple two word sentences being 31 months. Overall around 10%–15% of affected children will require special educational support but there is a wide range of ability and graduation from college and even the achievement of a PhD degree have been reported. Conductive hearing loss is relatively common, and disorders of visual accommodation are frequent. Hearing and eyesight should be regularly screened.

Almost every system of the body may be affected in Noonan syndrome. More than 90% of patients with Noonan syndrome have a chest deformity with prominent or depressed sternum. The chest is often shield-like with widely spaced nipples. Scoliosis occurs in 5%–10%. Muscular hypotonia is common and often improves with time. Unexplained peripheral neuropathy has been seen. Poor coordination is reported by some parents. Spina bifida occulta, tethered cord, and Arnold–Chiari malformation have all been reported. Although curly hair is often a feature, some patients have both sparse hair and eyebrows. Nevi and freckles are common. Some patients have findings characteristic of both neurofibromatosis and Noonan syndrome (NFNS). Children may form extensive keloids following surgical procedures. Hepatosplenomegaly, usually unexplained, is present in approximately 25% and may incorrectly suggest the possibility of an underlying metabolic disorder. Bleeding problems and easy bruising have been frequently noted. A variety of abnormal clotting factors have been reported, including low levels of factor VIII and factor XI, thrombocytopenia, and platelet function defects. There is no characteristic pattern to these laboratory findings and fortunately serious bleeding is rare. Juvenile myelomonocytic leukemia is a rare myeloproliferative disorder which occurs in a small proportion of children with Noonan syndrome. It may regress spontaneously without treatment or require cytotoxic treatment.

Lymphatic abnormalities occur in less than 20% of patients in Noonan syndrome but may cause serious problems. Intestinal lymphangiectasis leading to protein-losing enteropathy has been reported as well as pulmonary lymphangiectasis. Spontaneous chylothorax has been reported, and persistent pleural effusions following cardiac surgery is a known risk in patients with Noonan syndrome.

More than 80% of patients with Noonan syndrome have some kind of cardiovascular abnormality. Pulmonary stenosis with a dysplastic pulmonary valve is the most characteristic lesion of Noonan syndrome, but several types of cardiac malformation have been described. Atrial septal defect, branch pulmonary artery stenoses, and ventricular septal defect are among those that are frequently reported. Valvar aortic stenosis, subaortic stenosis, patent ductus arteriosus, and coarctation of the aorta have also been reported. In addition, hypertrophic cardiomyopathy, both obstructive and nonobstructive, occurs in 10%–20% of patients. This myocardial hypertrophy is usually noted at birth and may spontaneously regress later in childhood. Unlike the nonsyndromic

Table 1 Causative genes in Noonan syndrome and related disorders

Disease	*Causative genes*
Noonan syndrome	PTPN11, SOS1, RAF1, KRAS, NRAS, and BRAF
LEOPARD syndrome	PTPN11, RAF1, and BRAF
Neurofibromatosis/Noonan	NF1
Cardiofaciocutaneous syndrome	BRAF, KRAS, MEK1, and MEK2
Costello syndrome	HRAS
Noonan with loose anagen hair	SHOC2

familial hypertrophic cardiomyopathy, patients with Noonan syndrome often have involvement of both the right and the left ventricle. Microscopic examination, however, reveals similar findings in both forms—mainly muscle disarray and thick-walled coronary arteries. An unusual electrocardiogram with an indeterminate left axis deviation and a dominant S wave over the entire precordium is frequent, but not clearly related to any specific cardiac malformation. The cause of the electrocardiographic finding is unknown, but it supports the diagnosis of Noonan syndrome.

Since the identification of the causative genes it has become possible to use genetic testing to make the diagnosis. In some centers, the testing will be limited to the PTPN11 gene but as it can only diagnose half of all the cases of Noonan syndrome it is preferable to use a gene panel if possible.

Differential Diagnosis (Table 1)

In females with short stature it is important to exclude Turner's syndrome by chromosome analysis. In the presence of abnormal freckling (lentigines) or deafness, it is important to consider LEOPARD syndrome (lentigines, EKG abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth and deafness). With increased café au lait patches, there may be an overlap with NFNS and it is important to test for the neurofibromin gene and look for other clinical features of neurofibromatosis. With thin slow growing hair in early childhood there may be a very specific variant of Noonan syndrome due to mutations in the SHOC2 gene. With severe developmental delay and coarse facial features, the patient may have cardiofaciocutaneous syndrome due to mutations in KRAS, BRAF, MEK1, or MEK2 or Costello syndrome which is specifically due to mutations in HRAS.

Management

Noonan syndrome presents in several ways and each child will require different management approaches. Fortunately, many children are mildly affected and may essentially be treated as "normal." Because of the high incidence of abnormal eye and cardiac findings, all children should have careful eye and cardiac evaluations. In addition, hearing should be tested. Careful developmental assessment should be carried out before the child begins school so that any potential learning disabilities can be recognized early before the child develops problems in school.

Short stature is of concern to both patients and families. There are several studies on growth hormone and GH therapy. Growth hormone secretion has been found to vary from deficiency through to dysfunctional secretion and normal secretion in different studies. Insulin-like growth factor 1 is more consistently found to be low and is lower in PTPN11 mutation-positive patients. Interestingly, short stature is more common in those with PTPN11 mutations, whereas SOS-1 mutations show a lower prevalence of short stature. All studies show a good short-term response to growth hormone treatment but although improvement of final height may be achieved the results for this are not consistent. It is recommended that treatment should be instigated early and before puberty. In terms of safety there is no evidence to suggest that growth hormone treatment increases the ventricular thickness but cardiac monitoring is recommended during treatment. In terms of malignancy there is no data to suggest an increased incidence occurring with growth hormone treatment but long-term follow up with a larger number of patients should continue long term.

Cryptorchidism will require early surgical treatment but may still be associated with infertility later. With short stature and delayed puberty, the adolescent period may be stressful and additional psychological support may be required.

Bruising and abnormal coagulation tests are common but fortunately serious hemorrhage is rare. It is however prudent to make the anesthesiologist aware of potential complications in undertaking presurgical assessment.

Prader–Willi Syndrome☆

Urs Eiholzer, Claudia Katschnig, and Annik Hauri-Hohl, Paediatric Endocrine Center Zurich (PEZZ), Zurich, Switzerland

Glossary

Hypogonadism Decreased or nonexistent hormone secretion by the gonads. The gonads refer to both sex glands, the female ovaries and the male testes.

Hypothalamic dysfunction Abnormal functioning of the brain region called the hypothalamus. The hypothalamus helps to control the pituitary. The pituitary in turn controls the thyroid, the adrenal glands, the ovaries, and the testes. The hypothalamus also helps to regulate energy balance, body temperature, salt and water balance, and emotions and is involved in growth, milk production, childbirth, and sleep.

Hypotonia Decreased muscle tone, generally in an infant. There is a rag doll-like feeling or sense of floppiness on holding the infant obesity excess body weight, defined as a body mass index over 30 kg/m^2 in adults or, in children, above the 90th or 97th percentile of normal references.

Prader–Willi syndrome is a complex neurogenetic disorder and the most common genetic cause of obesity.

Introduction

Prader–Willi syndrome (PWS) was first described in 1956 in Zurich by Andrea Prader, Alexis Labhart, and Heinrich Willi. They pictured a syndrome characterized by small stature, obesity, hypogonadism, cryptorchidism, and oligophrenia with a history of extreme muscular hypotonia in the neonatal period (Fig. 1). PWS is seen as a complex, multisystem disorder and is the most common genetic cause of marked obesity. Estimates of the incidence range between 1:10,000 and 1:30,000. PWS occurs in all ethnic groups.

The syndrome is caused by an absence of the expression of the paternally active genes in the PWS critical region on chromosome region 15q11.2–q13. In 65%–75% of individuals, this occurs as the result of a deletion of a 5–6 Mb region, in approximately 20%–30% of cases, it is due to maternal uniparental disomy, and in 1%–4% of cases, it is due to a mutation, deletion, or other defect in the imprinting center. PWS and its sister syndrome, Angelman's syndrome, were the first examples of genetic imprinting in humans.

Clinical Picture

Hypotonia

The clinical picture of PWS changes with age. Neonates present with severe hypotonia (Fig. 2) poor reflexes and a weak or absent cry. During the first weeks or even months, infants with PWS have severe feeding difficulties and require special feeding techniques, in most cases nasogastric tubes. Underweight due to poor sucking and swallowing reflexes is a characteristic feature in infancy. Usually in these days, PWS is diagnosed early after birth due to the severe hypotonia.

Obesity

Between the second and fourth years of life, obesity sets in as a consequence of uncontrolled compulsive eating due to the PWS-specific increased appetite or lack of satiation respectively, reduced energy expenditure, and decreased physical activity. Distribution of subcutaneous fat is shifted toward the trunk, with relative sparing of the distal extremities. In contrast to nonsyndromic obesity, increased fat mass in PWS is accompanied by a decrease in lean body mass.

Short Stature

Growth is characterized by moderate intrauterine and postnatal growth delay, slight to moderate delay of bone maturation, lack of a pubertal growth spurt, and short stature as an adult. In the absence of growth hormone replacement, males grow to an average

Fig. 2 Severe muscle hypotonia in an infant with PWS.

adult height of 161.6 $\pm$ 8.1 cm and females to an average of 151.1 $\pm$ 5.5 cm. In some individuals, scoliosis, as well as osteopenia and osteoporosis, may be present.

Hypogonadism

Genital hypoplasia is present in both sexes. Boys usually present with a small penis, cryptorchidism, and a bifid or hypoplastic scrotum. In females, clitoral and labia minora hypoplasia is usually found. In most cases, pubertal development of the gonadal axis is delayed, insufficient, or absent, more so in boys than in girls. No cases of paternity have been reported in PWS, but four pregnancies have been documented in females with PWS. These four resulted in two normal off-springs and two off-springs with Angelmann Syndrome.

Developmental Delay and Mental Retardation

Developmental delay is a major concern in most cases. In particular, speech and motor development are retarded. Speech and language difficulties become apparent from an early age on. Children with PWS usually are able to sit up at 12 months, walk between the ages of 28 and 32 months, and talk in short sentences as late as at 42 months. Most Individuals with PWS present mild to moderate mental retardation and IQ testing indicates an average IQ of approximately 60–70.

Behavioral Problems

During early childhood, a characteristic behavior profile emerges. Even at this early stage, young children typically stick to an activity with more persistence than other children and have difficulty with changes in routine. Nevertheless, younger children are happy, affectionate, and cooperative. After the age of 2 years, children with PWS may become obsessed with food and later develop all kinds of food-seeking strategies and atypical behavior, such as gorging on available food, breaking into locked food storage areas, and getting up at night to forage for food. By the time they reach school age, the compulsiveness and obsession of their behavior become more evident. Typical temper tantrums are often observed. Stubbornness and intolerance of frustration relates in the beginning primarily to withholding of food, but may occur also in other situations at a later stage specially when they feel under pressure and are afraid of not meeting the demands of parents or teachers or simply because of changes in daily routine. In such situations skin picking may also be present. Adolescents are usually described as extraordinarily stubborn, clever, manipulative, moody, and prone to temper outbursts. Prevalence of psychotic illness is markedly elevated and may develop in adolescents and adults. It affects more PWS patients with UPD or the imprinting center defect form of PWS. Psychotic illness will often present rapidly but can also develop insidiously with a marked deterioration in mood and behavior and requires psychiatric assessment. Medication should be prescribed based on a diagnosed psychotic illness. It is important starting with lower than normal doses increasing the dose carefully if necessary. Actually, in PWS, risperidone and aripiprazole are the mostly used antipsychotic drugs in PWS.

Respiratory Abnormalities

Respiratory abnormalities in PWS are well known. An increased incidence of sleep-related breathing disorders has been reported in obese adults with PWS and a primary disturbance of central respiratory control has been demonstrated in young, not yet obese children with PWS. The pathogenesis of respiratory problems seems to be multifactorial in origin, including peripheral and central mechanisms, such as muscular hypotonia and facial dysmorphism as well as hypothalamic and chemoreceptor dysfunction.

Miscellaneous Characteristics

Individuals with PWS have a characteristic face with a narrow bifrontal diameter, almond-shaped eyes, strabismus, and a triangular mouth. Many individuals are hypopigmented with fair hair and blue eyes. Oral characteristics include thick saliva, hypoplastic enamel, and caries. Pain sensitivity is reduced and a tendency to self-injury is observed, especially skin-picking on arms, hands, and feet. PWS children develop characteristic gestures.

Life Expectancy

Life expectancy has been prolonged well into adulthood. Whereas complications of morbid obesity, such as type 2 diabetes and cardiac or respiratory deficiencies have previously doomed affected individuals to an early death. In the past 15 years early diagnosis of the syndrome and quality of medical care of PWS patients have improved significantly. In a so far hopeless situation the treatment option of growth hormone changed the perspectives and quality of life of PWS patients. General care of PWS patients was improved, mainly by avoiding obesity and resultant complications (e.g., diabetes). Today the annual mortality rate of PWS patients is estimated at 1%–4% due to obesity-related complications, gastrointestinal perforations, accidental deaths (e.g., traffic accidents) as well as physiological differences unique to PWS (e.g., central respiratory arrest).

Diagnostic Criteria

Diagnostic criteria for PWS were first proposed by Holm in 1981 and were further developed through a consensus process in 1993. At that time, sophisticated genetic analyses were not yet widely available. Because diagnosis of PWS can be confirmed by genetic testing, clinical diagnostic criteria should be used more often to raise diagnostic suspicion and prompt testing. Accordingly, revised clinical criteria to help identify appropriate patients for DNA testing for PWS have been suggested by Gunay-Algun et al. The differential DNA methylation of several imprinted maternal and paternal loci in the 15q11.2-q13 region provides a powerful tool for assessing paternal-only, maternal-only and biparental inheritance. However DNA methylation cannot distinguish the molecular classes (deletion, UPD, ID), which is important for genetic counseling and genotype-phenotype correlation. Deletions of 15q11.2-q13 have traditionally been diagnosed with chromosomal analysis using FISH (fluorescence in situ hybridization). With

the increasing use of CMA (chromosomal microarray) in clinical genetics, this technique might replace FISH someday as CMA will precisely report the deletion size. If DNA methylation is positive for PWS but no deletion is found, the next step is to distinguish between maternal uniparental disomy (UPD) and imprinting defect (ID) which is done by using DNA polymorphism analysis of chromosome 15 loci on the proband's and parent's DNA.

Metabolism in PWS

Carbohydrate Metabolism

Diabetes mellitus is only rarely seen in PWS children under the age of 16 years. About 15% of adult PWS however develop diabetes as a consequence of severe obesity and/or increased familial or ethnic risk for diabetes.

Children and adolescents generally present with low fasting insulin levels and a normal or even increased insulin sensitivity, but a reduced and delayed insulin response of beta cells in oral glucose tolerance tests. However oral glucose tolerance tests may show an impaired glucose tolerance due to a slower gastrointestinal passage in PWS than in the normal population. Normal insulin sensitivity in PWS seems to be related to the relatively low degree of visceral fat accumulation. Later, the manifestation of a type 2-like diabetes in PWS is assumed to be precipitated by the addition of excessive obesity to impaired insulin secretion.

Energy Balance

The enormous fat accumulation in PWS is caused by an imbalance of energy intake and energy expenditure and a reduced metabolic rate. Patients with PWS have a lower lean body mass which contribute to reduced basal level of energy expenditure. Basal metabolic rate—largely identical to the resting energy expenditure—was found to be decreased by 20% (under growth hormone therapy) to 50% (without growth hormone therapy) in PWS, when related to weight for height, reflecting the decrease in lean mass in this syndrome. Activity-related energy expenditure, assessed by deuterium dilution, is also decreased in PWS. The reason that PWS children and adolescents engage less in physical activity has been ascribed to hypothalamic dysfunction. Hypoactivity with resulting decreased energy expenditure is a large contributor to weight gain in PWS.

Hypothalamic Dysfunction

Despite in-depth knowledge of the genetic condition in PWS, the final link between the chromosomal disorder and the clinical symptoms remains unclear. Hypothalamic dysfunction, as already originally presumed by Prader et al., appears to underlie many of the features of PWS, including hormonal dysfunction, disturbed energy balance, temperature regulation, high pain threshold, and sleep disorders, but no overt structural abnormalities of the hypothalamus have been found yet. It has been shown that growth hormone deficiency due to hypothalamic dysregulation contributes not only to the abnormal growth pattern and osteopenia, but also to the excess of body fat and to the deficit of lean body mass, with reduced energy expenditure as a consequence. The decreased growth hormone (GH) secretion in PWS differs from that seen in simple obesity, where GH secretion is not disturbed, but rather is down-regulated and fully reversible by weight loss. Also hypogonadism has been classically thought to be hypothalamic in etiology. Recent evidence supports primary gonadal failure as a significant contributor to male hypogonadism. The pattern of gonadal dysfunction in females seems to be similar to those observed in males. In most cases, pubertal development of the gonadal axis is delayed, insufficient, or absent, more so in boys than in girls. Precocious development of pubic and axillary hair, however, is a frequent (15%–30%) finding. It is the consequence of premature secretion of adrenal androgens. Single cases with complete precocious puberty are reported in boys with adult testicular volumes and in girls with menarche. Abnormalities in the hypothalamic satiety center and its hormonal circuitry, including orexigenic and anorexigenic gut hormones have been suggested to affect food intake and energy expenditure. The orexigenic plasma Ghrelin is increased in obese PWS individuals compared to any other form of obesity and was supposed to contribute to the hyperphagia of PWS. The studies of other hormones, especially the anorexigenic gut hormones GLP-1 or PYY gave disappointing results. In these days, the hypothalamic hormone Oxytocin became a candidate to improve not only social behavior but possibly also to influence positively hyperphagia in PWS. The first trials with children and adults with PWS however gave conflicting results, improving social interaction, temper tantrums as well as hyperphagia in some patients and worsening these symptoms in others. Longer term studies in different age groups and with different dosages are needed and will certainly be done in the nearest future.

Therapy

Comprehensive Team Approach

Individuals with PWS need a variety of interventions to optimize their growth and development. This includes physical and occupational therapies, dietary management, GH and sex steroid substitution, language and learning disability services, behavior

and family interaction management, support, and care. We call it the five-finger model. The five-finger model includes (1) Restriction of caloric intake aiming to keep weight for height in the upper normal range for age and sex. (2) Growth Hormone Therapy as soon as possible after confirmation of the diagnosis or after of confirmation of growth hormone deficiency by clinical and laboratory tests. (3) Daily physical training conducted by physiotherapists, parents and caregivers. (4) Sex hormone replacement, starting in boys generally at a bone age of 13 years and in girls at a bone age of 11 years if puberty does not start spontaneously. (5) Family coaching and case management supporting parents in all aspects of PWS including social, school, home and insurance questions.

Dietary Restriction

Children with PWS must stick to a strict diet with a reduced energy intake of about 75% of that for healthy children to stabilize the weight balance. A food intake restriction of this extent is possible only with close and strict supervision by parents and caregivers. Instead of counting calories, it is usually easier to check weight every week and to adjust caloric intake to the weight evolution. Consequently, there is a lifelong need for environmental modifications to restrain food intake in PWS. Growth hormone treatment makes weight control easier increasing physical activity, muscle mass and caloric output.

Growth Hormone Treatment

Growth hormone therapy in PWS was initiated in the 1990s. In prepubertal obese children with PWS, administration of GH has a remarkable impact on growth and, in combination with restriction of food intake, also on body composition, resulting in a dramatic change in the phenotype. GH treatment increases height velocity and normalizes growth and body proportions. Some studies show a better effect when Growth hormone therapy is started before the age of 2 years. It is recommended to start the treatment therefore as soon as the diagnosis is assured. Growth hormone dosage is the same as in growth hormone deficiency (i.e., 0.7–1.0 mg/m^2/d) and due to obesity is calculated rather according to body surface area than according to weight. If treatment is instituted early enough, final height prediction will reach the parental target height range after 3 years and short stature as well as small hands and feet will no longer be present. The adult height generally is around -1 SDS of familial target height. GH has a sustained impact on the net loss of body fat, which nevertheless remains elevated and improves the pattern of serum lipids. In addition to the medical benefits, the disappearance of the obese phenotype of prepubertally GH-treated PWS children relieves the patients and their families of stigmatization. A further benefit of GH treatment in PWS is the increase in lean body mass and, subsequently, resting energy expenditure. This leads to a reduction of energy stores, mainly of body fat, if energy intake is not increased. However, the initial deficit in lean body mass is counteracted by GH only during the first year of therapy. In the long term, GH therapy does not further compensate for this deficit, probably because of reduced physical activity. Further favorable effects of GH treatment in PWS were reported on respiratory muscle function, physical capacity, strength, agility, and activity. There are reports of PWS deaths shortly after initiation of growth hormone therapy due to respiratory insufficiency. The question was raised if the growth hormone therapy was the cause of these deaths and after these deaths polysomnography was usually done before initiation of growth hormone therapy. However, one child died the night after a normal polysomnography, that is, the child had not received growth hormone therapy yet. This demonstrates that PWS itself is a risk factor for sudden death. But because an increased risk of respiratory failure in the first 3 months of growth hormone therapy cannot be definitely excluded, a polysomnography should always be performed before initiation of growth hormone treatment. Furthermore, at initiation of growth hormone therapy the child must not have a respiratory tract infection. Scoliosis or kyphosis can be aggravated during phases of fast growth and requires careful orthopedic management.

Physical Therapy and Exercise

Children with PWS have decreased muscle tone and a deep dislike for physical activity. Decreased muscle mass is a consequence of physical hypoactivity. It should therefore be the aim of parents, caregivers and physiotherapists to improve physical activity at a maximum. Physical activity should get the same attention as the reduction of food intake. Physical activity should aim to improve muscle strength and overall physical fitness and as well to prevent scoliosis. Increased physical activity may lead to increased energy expenditure; it promotes a negative energy balance, raises the postexercise metabolic rate, builds muscle mass, and enhances the overall sense of wellbeing. Therefore, the crucial importance of regular physical activity should be clearly communicated to patients, parents, and caregivers.

Sex Hormone Substitution

Although hypogonadism is clearly documented in PWS, and the beneficial effect of sex steroids on the muscle mass and bone health is well known, no consensus statement exists as to the most appropriate regime of sex hormone treatment in PWS. Most authors recommend androgen substitution in males because of its beneficial effects, such as complete virilization, change in voice, prevention of osteoporosis, and increasing muscle mass as well as activity level, but some authors believe that it may lead to a more aggressive behavior and aggravate temper tantrums. One study examining behavior during sex steroid substitution did not

reveal any differences between PWS and their siblings. However, it seems reasonable to start as low as 25% of the recommended normal adult testosterone enanthate dose (200–250 mg) with gradual increase as tolerated to keep low normal serum testosterone levels. In young women with PWS, estrogenic substitution may prevent osteoporosis and although an increase in obesity is feared, it has not yet been scientifically assessed in these patients. Guidelines for hormonal replacement therapy in are tailored individually depending on sexual development, hormonal profiles, bone density and emotional and social needs.

Family Coaching and Case Management

Successful patient management requires a multidisciplinary team. It is important to allow the family to use their own resources, support should set in only when family resources are exhausted. The chorus of the different specialists should be conducted by a leader, a specialist and expert in the different aspects of PWS. It must be considered that each specialist tends to have a tunnel vision of the patient and it is important to keep a general picture of the child.
