Venous thrombotic and CV risks can be decreased by using E2 administered by a nonoral route compared with oral estradiol. Estrogens used in the WHI, CEE, are known as thrombogenic for years (Stangel *et al.*, 1977; Elkik *et al.*, 1982a). In Europe, estradiol (E2) is the first-line prescription. It can be administered by oral or transdermal/percutaneous (TTS) route. A major difference exists between these two routes: TTS administration at standard doses used for MHT (**Table 2**) has no effect on VTE risk and risk of stroke. This evidence is coming from observational and case–control studies conducted in France, United Kingdom, and the United States (Scarabin *et al.*, 1997; Canonico *et al.*, 2007, 2008, 2010, 2016; Renoux *et al.*, 2010a,b; Simon *et al.*, 2016). Unfortunately, there are no RCT on the venous events with TTS, but the biological plausibility of a lower effect on coagulation of TTS is very likely since studies show less activation of blood clotting (Scarabin *et al.*, 1997; Canonico, 2015). Similarly other hepatic proteins such as lipids, angiotensinogen, and C reactive protein (CRP) are less modified with this route (Elkik *et al.*, 1982b; Lacut *et al.*, 2003). The interpretation is that oral route is associated with a greater hepatic impact than TTS E2 administration; this is known as the hepatic first-pass effect. The intrahepatic concentrations are far greater when an oral administration and thus trigger activation of coagulation. Using TTS route, the concentration of estrogens which reaches the liver is equivalent to the rest of the circulation, as in physiologic state of E2 secretion by the ovaries. E2 is the main circulating estrogen whereas using oral administration E2 is metabolized to estrone at the level of digestive mucosa and increasing concentrations of estrogens then reaches the liver (Dupont *et al.*, 1991). Induction of blood clotting is also dose dependent. Increasing administration of estrogens even by an extradigestive route can be associated with activation of coagulation. This can explain that in the study on stroke from United Kingdom (Renoux *et al.*, 2010a, b) use of patch >50 μg was associated with an increased risk. Stroke seems to be more directly dependent on hypercoagulability than MI. In addition in the large E3N cohort, transdermal and oral E2 had favorable effects on DT2 (de Lauzon-Guillain *et al.*, 2009). Concerning BC risk, both routes of administration carry the same risk (Lyytinen *et al.*, 2006; Stuenkel *et al.*, 2015b).

The type of progestin and the regimen may be important to decrease some events; VTE, metabolic risk, endometrial cancer, and BC risk

Progestins are nonselective steroids which have different properties according to their binding to and agonist or antagonist effects on the androgen, glucocorticoid, and mineralocorticoid receptors. Progesterone, retroprogesterone (dydrogesterone), or synthetic progestin can be used in MHT. The aim is to protect the endometrium against the proliferative effects of estrogens in women with uterus. It was validated long time ago that in sequential treatment, progestins have to be administered at least 12 days months^{-1} in association with estrogens. More recently, several studies reported that a sequential administration was at higher risk for the endometrial cancer than continuous combined administration. Interestingly, in obese/overweight women, CHT decreases the RR

Table 2 Risk factors for breast cancer

High risk ≥fourfold

- BRCA mutation, high family history without mutation (premenopausal)
- Biopsy with atypical hyperplasia, LCIS, DCIS
- Thoracic radiotherapy especially at a young age
- Increased breast density (Birad 4) (four categories breast imaging-reporting and data system (BIRADS) according to American College of Radiology)

Intermediate risk ≤twofold

- Family history at older age
- Obesity (postmenopause), × 1.2–2.5
- Diabetes × 1.2–2
- Birad 3 × 2
- Reproductive factors:
  - young age at menarche (premenopausal breast cancer > postmenopausal) × 1.20–1.50
  - age at FFTP ≥35 years (premenop > postmenop) × 1.36
  - Nulliparity × 1.3
- Sedentarity
- Alcohol × 1.05–1.4

of endometrial cancer in a large observational study (Beral *et al.*, 2005). Synthetic progestins appear to equally protect the endometrium (Allen *et al.*, 2010). However, progesterone has been reported to be associated with an increased risk of endometrial cancer (Allen *et al.*, 2010; Fournier *et al.*, 2014). One of the possible explanations is a problem of compliance since progesterone does not exist in association with E2, women can forget to take the pill. Indeed in two randomized trials, progesterone was not associated with an excess of endometrial hyperplasia compared with a synthetic progestin (The writing group for the PEPI trial, 1996; Jondet *et al.*, 2002). Consequently, it is important to explain the importance of compliance to the progestin in combination with estradiol to the treated women (Gompel, 2012). The risk of endometrial cancer is remnant during long term, contrary to BC. At the opposite, progesterone (and dydrogesterone) has different CV impact and can also carry different level of BC risk. From observational and case–control studies, it is observed that micronized progesterone and dydrogesterone are neutral in terms of metabolic risks and risk of VTE (Canonico, 2015; Fineberg, 2000). In addition, they are less associated with BC than combined treatment with synthetic progestins at least up to >5 years of treatment (Fournier *et al.*, 2005, 2008; Lyytinen *et al.*, 2009; Cordina-Duverger *et al.*, 2013; Asi *et al.*, 2016). Conversely, norpregnane derivatives were associated with a higher risk of VTE (Canonico *et al.*, 2010).

The population in which is prescribed MHT and lifestyle can modify the risk of BC

The importance of breast density in the risk of BC is reported by several studies which suggest that women with high breast density have an increased risk of BC without MHT but even greater with MHT (Kerlikowske *et al.*, 2010; Hou *et al.*, 2013). Women with atypical hyperplasia can have a greater risk from MHT but with conflicting results (Dupont *et al.*, 1989; Arthur *et al.*, 2017). In the WHI ET, women with family history of BC and a personal history of benign breast disease (BBD) did not experience a decrease in BC risk (Anderson *et al.*, 2012). Exercise and losing weight can decrease the risk of BC, whereas sedentarity and putting on weight increase the risk (Pizot *et al.*, 2016; Rosner *et al.*, 2017). Women with high BMI do not seem to have a greater risk of BC than their baseline risk if taking MHT in observational studies (Ritte *et al.*, 2012).

Other Endpoints

- Ovarian cancer (serous and endometrioid differentiation) is reported to be mildly increase with MHT in a metaanalysis but with possible bias (Collaborative Group on Epidemiological Studies of Ovarian Cancer *et al.*, 2015). In most observational studies, estrogens alone are at higher risk than CHT on the ovarian cancer but not in this metaanalysis and a minority of studies (Reid *et al.*, 2017). Some studies show an effect with duration whereas others do not (Collaborative Group on Epidemiological Studies of Ovarian Cancer *et al.*, 2015; Reid *et al.*, 2017). The effect decreases after cessation of the treatment (Reid *et al.*, 2017). Interestingly in survivors of invasive high grade ovarian cancer, MHT (mostly estrogens) in three RCTs improved survival of the patients (Guidozzi and Daponte, 1999; Li *et al.*, 2012; Eeles *et al.*, 2015).
- Gastrointestinal cancers: In addition to colorectal cancers which are decreased in women using MHT, upper Gastro-intestinal (GI) and liver cancers were recently reported to be also of a lower prevalence in women using MT.
- Tibolone: it is a progestin belonging to the normethyltestosterone derivative with metabolites with androgenic and estrogenic properties. It was shown to be effective on climacteric symptoms to a less extent than CHT, and in a RCT was associated with increased of stroke in older women (Formoso *et al.*, 2016). It probably carries the same level of BC risk than CHT (Stuenkel *et al.*, 2015a, b). It was shown to prevent fractures in a RCT of osteoporotic women (Cummings *et al.*, 2008) but increased the risk of recurrence in BC patients (Kenemans *et al.*, 2009). It does not increase mastalgia and has beneficial effects on libido due to its androgenic potency. It is a second-line prescription in young postmenopausal symptomatic women without contra-indication to MHT, displaying mastalgia using estrogens, loss of libido not restored by MHT, or breakthrough bleeding.
- An association between CEE (0.45 mg) and a selective estrogen receptor modulator (SERM), bazedoxifene (20 mg), is labeled in the United States and Europe (DUAVIVE). The concept is to combine CEE at low dose with a SERM which will antagonize the proliferative effects on the endometrium and breast. Mastalgia are less prevalent than the standard treatment and breast density is less increased; data are lacking however on BC risk (Harvey *et al.*, 2013; Mirkin *et al.*, 2016). The efficacy on VSM symptoms is also lower than with CEE alone. The incidence of endometrial hyperplasia is low and it increases BMD at the spine and hip (Pinkerton *et al.*, 2014). The RR of VTE and arterial diseases is not evaluated but both agents can activate coagulation.
- Estetrol is an estrogen physiologically produced during pregnancy, under development. It has a lower affinity for ERα than E2. Alone it has estrogenic activity at higher concentrations than E2 (100-fold); it is an antagonist in combination with E2 in preclinical models of breast (Gérard *et al.*, 2015). It is currently evaluated in the treatment of menopause and was shown to decrease VSM (Coelingh Bennink *et al.*, 2016). Its endometrial and breast safeties remain to be studied.

In Practice

- The first consultation is the time to evaluate the importance and type of climacteric symptoms, including urogenital disorders and sexual dysfunction. Individual and familial risk factors of the woman have to be gathered. CV, metabolic, cancer, and osteoporosis risks have to be evaluated. Increased CV risk factors and BC risk need to be managed and could contraindicate MHT. Information on nutrition, including calcium intake and alcohol, benefits of exercise, stop smoking, gynecological follow-

up, and cervical and breast screening, is also delivered. Measure of BMI and blood pressure with breast and gynecological examination are performed as well as pap smears (according to the local guidelines) and a prescription of mammogram in the context of national screening if it exists or as opportunistic screening if not usually every 2 years after 50 years. Lipid fractions and glycaemia levels are measured. Measure of vitamin D levels and of bone mineral density (BMD) is not systematically recommended. It is however mandatory in case of risk factors for osteoporosis such as family history of osteoporotic fracture, personal history of amenorrhea, low BMI, corticosteroid treatment, excessive alcohol intake and smoking, or a previous spontaneous fracture. Following menopause, the decrease in BMD is maximal during the first 2 years so that a BMD can be performed after this term in the absence of MHT. However, some recommendations state to perform it once in older women (>65 years) (Shifren *et al.*, 2014). The FRAX score developed by the World Health Organization and validated in many countries can help to calculate a 10-year risk of fracture and the level of risk which could beneficiate from a treatment (FRAX Tool, 2017). There are also some scores which can help to predict CV risk at 5 or 10 years, based mostly on gender, age, BP, HDL/total cholesterol, and in some smoking, usCRP (HeartScore France, 2017; Framingham Coronary Heart Disease Risk Score, 2017; Reynolds Risk Score, 2017). They are not all validated in all populations. In the United States, the Reynolds score or the Framingham score are most used, whereas the "SCORE" (from European Society of cardiology) has been validated in most European countries. If the lipid and BP values are normal and if there is neither diabetes nor smoking, then the risk is low. In case of diabetes, metabolic syndrome, smoking, and high risk maybe present and evaluation of the presence of plaques is recommended even if the tools for doing so are not consensual. In intermediate situations, according to the age of the patients and duration of risk factors, such evaluation can also be useful. Echography of the arteries, exercise tolerance test, stress echography, coronary calcium score, etc. can be used (Stuenkel *et al.*, 2015a). The actual consensus from WHI results and preclinical data is that MHT prescribes before the apparition of plaques can be safe but in the presence of significant atherosclerosis, estrogens are proapoptotic on the instable plaques which can then migrate and induce a CV event. Concerning BC risk, similarly, the risk can be stratified as low, moderate, or high risk. This quantification is, however, more complex for BC than for CV risk. The risk factors are many (**Table 2**) and scores do not predict with a very good accuracy of the risk. High risk exists in the presence of a strong family history of BC, atypical hyperplasia at a biopsy, breast density grade D at mammogram, and history of thoracic irradiation (**Table 2**). In those patients, MHT is not recommended and nonhormonal treatment should be privileged. Moderate/intermediate risk (**Table 2**) is associated with postmenopausal BC at first degree in the family, reproductive factors increasing the risk, breast density grade C, and biopsy with proliferative disease. In those patients, thorough evaluation of the balance between benefits and risk is necessary as well as a deep discussion with the patient (**Table 4**).

- If the woman is willing to take hormone treatment and has no contraindication, we thus recommend to start at medium doses by a combination of transdermal (37.5 μg day^{-1}) or percutaneous E2 (0.75 mg–1 mg day^{-1}) and micronized progesterone or dydrogesterone. A continuous administration is associated with less bleeding than sequential administration. In France, we use a combined administration during 25 days of the month which minimizes the breakthrough bleeding compared with a nonstop administration. However, some patients cannot stop during 5 days since they are symptomatic of having an increased prevalence of migraine. There are no safety data to oppose to a continuous administration in those patients rather a stop of 5 days. Continuous administration using synthetic progestins has been reported in observational studies to be associated with less endometrial cancer and more BC (Lyytinen *et al.*, 2009; Bakken *et al.*, 2011; Beral *et al.*, 2005; Allen *et al.*, 2010). There is no data for progesterone and dydrogesterone comparing sequential and continuous administration side effects. Then adaptation of the dose of treatment has to be made in a next consultation which also will monitor efficacy, clinical tolerance, and occurrence of side effects including metrorrhagia; those have to be systematically explored by echography ± hysteroscopy. Regular follow-up at least once a year will help to diagnose any new event and adapt the need of the treatment to the symptoms.
- In case of estrogen intolerance (mastalgia, benign breast disease, adenomyosis/bleeding), progesterone, progestin, or tibolone can be of some efficacy on VSM (see above for tibolone). Progesterone has some demonstrated efficacy on sleep disorders and probably anxiety.
- If the woman is not willing to take an MHT or have contraindications alternatives can be prescribed. This concerns in particular women who are BC survivors. The most studied agents are selective serotonin receptor inhibitors (SSRI) and selective noradrenaline receptor inhibitors (**Table 3**). They are less effective than estradiol on climacteric symptoms but RCTs have shown a greater efficacy than placebo. Venlafaxine, fluoxetine, paroxetine, citalopram, or gabapentin (a gamma-aminobutyric acid (GABA) receptor ligand) have been evaluated in RCTs (Stuenkel *et al.*, 2015a, b). Paroxetine cannot be associated with tamoxifen because of their interaction with the CYP2D6 cytochrome and the metabolism. Their efficacy is slow, it takes at least 2/3 months to be optimal, and side effects can occur. Doses have to be progressively increased in case of failure (**Table 3**). Transdermal clonidine appears to have some efficacy (Stuenkel *et al.*, 2015a) but is not available outside of United States (**Table 5**).
- Most of complementary therapies have not been validated in sufficient trials. Their efficacy remains controversial. Phytoestrogens cannot be prescribed to women with BC. Yoga, acupuncture, relaxation, and meditation can help in some extent and have been particularly studied in BC survivors (Koch *et al.*, 2017; Chien *et al.*, 2017). Black cohosh and St John's Wort have been associated with adverse effects and interactions with medications and should therefore be used with caution. Stellate ganglion blockade has been shown to reduce VSM, but the follow-up is still short (Walega *et al.*, 2014).
- Treatment of vulvovaginal atrophy (VVA).

Table 3 Products used in MHT (not available in all countries)

(1) Estrogens
Oral estrogens
Micronized estradiol(E2): 0.5, 1.0, 2.0 mg day^{-1}
E2 valerate: 1.5 mg day^{-1}
Conjugated estrogens (CEE): 0.3, 0.45, 0.625 mg day^{-1}
Transdermal estrogens
E2 patch 0.025–0.1 mg once or twice weekly
E2 percutaneous gel 0.25–1.5 mg
E2 transdermal spray 1.5 mg
Vaginal ring
E2 acetate 0.05–0.10 mg day^{-1} systemic levels of estradiol provide relief of VMS
90-day duration/ring

(2) Progestin
Oral progestin
Micronized progesterone: 100, 200 mg day^{-1}
Dydrogesterone: 10 mg day^{-1}
Medroxyprogesterone acetate (MPA): 2.5, 5, 10 mg day^{-1}
Norethindrone: 0.35 mg day^{-1}
Norethisterone acetate: 5.0 mg day^{-1}
Megestrol acetate: 20, 40 mg day^{-1}
Chlormadinone acetate: 5, 10 mg day^{-1}
Medrogestone: 5 mg day^{-1}
Nomegestrol acetate: 3.75, 5 mg day^{-1}
Promegestone: 0.125, 0.25, 0.5 mg day^{-1}
Intrauterine system progestin
LNorg 20 μg released per day IUS for 5-year use
6 μg day^{-1} IUS for 3-year use
Vaginal gel progesterone 4%, 8% 45- or 90-mg applicator

(3) Combination hormone therapies
Oral
CEE + MPA 0.3–0.625 mg per 1.5–5 mg day^{-1} cyclic or continuous
E2 + Neta 0.5–1 mg per 0.1–0.5 mg day^{-1} continuous
E2 + drospirenone 0.5–1 mg per 0.25–1 mg day^{-1} continuous
E2 + norgestimate 1 mg per 0.09 mg day^{-1}
E2 + dydrogesterone 1–2 mg per 5–10 mg day^{-1} cyclic and continuous
E2 + cyproterone acetate 2 mg per 1 mg day^{-1} continuous
E2 + MPA 1–2 mgper 2–10 mg day^{-1} continuous
CEE + BZA 0.45 mg per 20 mg day^{-1} continuous
Transdermal
E2 + Neta 50 g per 0.14–0.25 mg per patch twice weekly
E2 + LNorg 45 g per 0.015 mg per patch once weekly

Table 4 Absolute or relative contraindications to MHT

(1) CV risk factors
If >10% high risk (SCORE), absolute contraindication
Diabetes
Metabolic syndrome
5%–10% moderate risk (to be discussed)
(2) VTE history or risk: E2 oral route
(3) BC survivors
High risk
Moderate BC risk (to be discussed)
(4) Endometrial cancer survivors (according to their stage)
(5) Meningioma

Table 5 Nonhormonal alternatives to MHT and their doses

Paroxetine: 7.5–25 mg
Venlafaxine : 65–150 mg
Desvenlafaxine:100–150 mg
Citalopram: 10–20 mg
Gabapentin: 900–2400 mg
Pregabalin: 150–300 mg

It is a prevalent symptom, often not told, which can be associated with pain, discharges, and dyspareunia (Gandhi *et al.* 2016). VVA may also worsen incontinence. Topical estrogens, moisturizers, and lubricants can help to treat the symptoms and improve dyspareunia. Administration of topical estrogens as estradiol, estriol, and promestriene twice a week is usually sufficient and carries no proliferative effect on the endometrium. A vaginal ring which delivers 5 μg of E2 and last 3 months is also available. They are indicated in the various type of incontinence in combination with physiotherapy. Adjunction of a progestin is not necessary. Recent data suggests no increase in the risk of BC, CV events, nor endometrial cancer in women who have used topical estrogens (Crandall *et al.*, 2017). In women with BC using aromatase inhibitors, however, use of topical estrogens is not recommended but moisturizers and lubricants can be used. In some countries, ospemifene (60 mg day^{-1}) is available for the treatment of VVA moderate to severe. It is a SERM with significant agonist activity and thus activates the coagulation. In addition it can worsen VSM symptoms. The endometrial safety is still to be established at long term but they were no significant hyperplasia at 1 year of treatment (Constantine *et al.*, 2015).

Two new therapies for VVA need more long-term safety data. Vaginal LASER therapy is developed to treat vaginal dryness, sexual dysfunction, but the long-term efficacy and safety remains to be demonstrated (Pitsouni *et al.*, 2017). Daily intravaginal 0.50% DHEA (6.5 mg) (PRASTERONE) is under study. It seems of a certain efficacy but safety data still remain to be shown.

Conclusions

MHT is still the most effective treatment for climacteric symptoms and help protecting against osteoporosis. The choice of route of estrogen and type of progestin can decrease side effects of the treatment. It is mandatory to evaluate the individual risks of the patient before administrating MHT. Alternatives exist but of lower efficacy. The consultation is a great opportunity for giving information about lifestyle and prevention of cancer and CV risk to women consulting at the time of menopause.

Hormonal Treatment of Breast Cancer

Stéphanie Bécourt and Marc Espié, Saint-Louis Hospital, Paris

Abbreviations

AIs	Aromatase inhibitors
AKT	Protein kinase AKT
CDK4/6	Cyclin-dependent kinases 4 and 6
DFS	Disease-free survival
DMFi	Distant metastasis free interval
DNA	Deoxyribonucleic acid
ER	Estrogen receptors
ERK	Extracellular signal-regulated
ESR1–ESR2	Estrogen receptor alpha and beta
FDA	Food and Drug Administration
GnRH (LH-RH)	Gonadotropin releasing hormone
HR	Hormone receptor
MEK	MAPK-kinase
mTOR	Mammalian target of rapamycin
NASBA	Nucleic acid sequence-based amplification
OFS	Ovarian function suppression
OS	Overall survival
PFS	Progression-free survival
PI3K	phosphatidylinositol 3-kinase
PR	Progesterone receptor
RAF	Rapidly accelerated fibrosarcoma
SERD	Selective estrogen receptor downregulator
SERM	Selective estrogen receptor modulator

Introduction

Breast cancer is the most common cancer worldwide, and the second leading cause of cancer death (Aguas *et al.*, 2005).

Many factors, such as age, genetics, family history, diet, alcohol, and obesity, have been implicated in its etiopathogenesis.

Endogenous and exogenous steroid hormones, such as estrogens and progesterone, have also been implicated in its pathogenesis, due to their significant effects on cell growth, differentiation, and function in the breast and other tissues.

The first medical evidence was the suppression of estrogen levels through oophorectomy to cause regression of metastatic breast cancer (Beatson, 1983). Similar effects were observed after adrenalectomy and hypophysectomy in postmenopausal women with breast cancer (Jordan, 2009).

This led to the development of endocrine therapies, with the principal goal of depriving tumor cells of estrogen to induce tumor regression. Endocrine therapies can be given preoperatively (neoadjuvant), postoperatively (adjuvant), and in the metastatic/advanced disease setting (palliative treatment).

Common classes of drugs used for this purpose include the selective estrogen receptor modulators (SERMs), selective estrogen receptor downregulators (SERDs), aromatase inhibitors (AIs), and luteinizing hormone releasing hormone (LH-RH) agonists like buserelin and goserelin (**Fig. 1**).

Steroid Hormones

Steroid Hormones and Their Receptors

Steroid hormones and their receptors include estrogens, progesterone, and androgens. They are manufactured from one common parent molecule, cholesterol, via a reaction catalyzed by several enzymes (Weinberg *et al.*, 2005).

Estrogen is produced by two different organ systems.

In premenopausal women, the vast amount of estrogen (estradiol-17 β and estrone) is produced by the ovaries, in response to the pituitary-derived luteinizing and follicles-stimulating hormones.

In postmenopausal women, precursors of estrogen (testosterone and androstenedione) are produced by the adrenal gland and converted to estradiol and estrone via aromatization.

Steroid hormone receptors bind to steroid hormones such as estrogens and progesterone and relay their signals. Cancers dependent on steroid hormones include breast, prostate, ovarian, and endometrial cancer.

Estrogen Receptors

Estrogen signaling occurs via the standard classical steroid receptor mechanism.

Estrogen diffuses through the cellular membrane and binds monomeric ER protein. This binding leads to a conformational change in ER and induces receptor dimerization. Then, the ligand/receptor complex binds to estrogen response elements in the promoter regions of estrogen-responsive genes enhancing transcription.

The cellular response depends on tissue-specific nuclear ER coregulatory proteins: coactivators and corepressors.

 doi:10.1016/B978-0-12-801238-3.64351-9

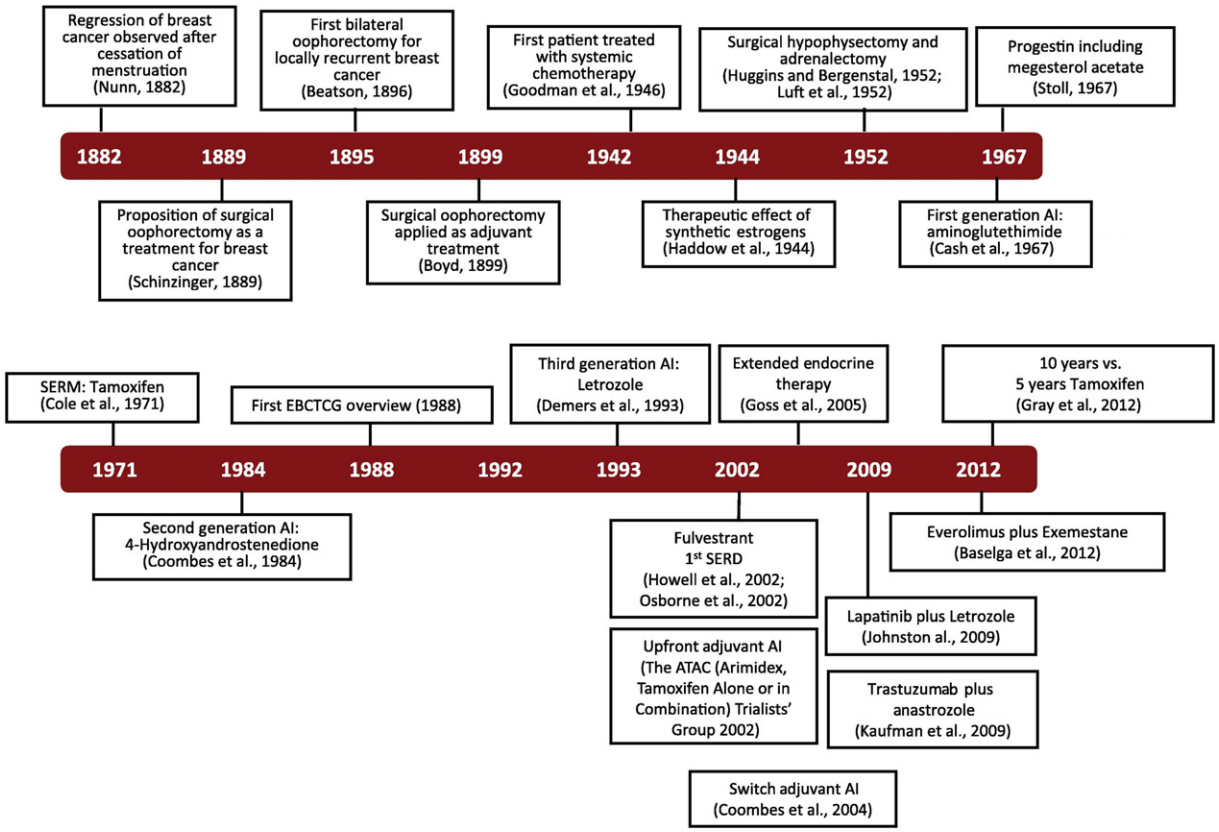

Fig. 1 Historical overview of the development of endocrine therapy and targeted therapy for breast cancer.

There are two separate homologous ER isoforms, ER-α and ER-β, encoded by two separate genes, ESR1 and ESR2, respectively (Kato *et al.*, 2005).

ER has been identified as a nuclear protein, associated with the breast cancer cell membrane, and its effects is mediated through a cascade of tyrosine kinases and phosphatases, resulting in a gene activation through nuclear transcription factor modulation (Massarweh *et al.*, 2008).

The receptor–ligand interaction causes significant effects on growth, differentiation, and functioning of many tissues (such as mammary gland, uterus, bone, cardiovascular system, and brain). Prolonged or excessive receptor–ligand interaction may lead to hyperproliferation and malignant transformation, especially in the breast and uterus.

Measurement of Hormone Receptors

During the more than 30 years of analysis of ER, several methods with differing biochemical principles, analytic sensitivity, and analytic precision have been used (Wittliff *et al.*, 1980).

Until about 1990, ER protein was quantified using a variety of ligand-binding assay (Lamy *et al.*, 2006), with homogenization of fresh-frozen tumor followed by centrifugation.

In the 1980s, the availability of monoclonal antibodies to ER had a profound impact on the methodologies for ER assay. Quantification was initially by enzyme immunoassay, with cutoff values approved by the US Food and Drug Administration (FDA) of ER positivity >10 fmol/mg cytosol protein.

In the 1990s, immunohistochemical assays were developed for the assessment of ER/progesterone receptor (PR) status (Malara *et al.*, 2006). The cutoff to distinguish "positive" from "negative" cases, and to consider endocrine therapy in patients, is $\geq 1\%$ ER-positive tumor cells in the United States, whereas it is $\geq 10\%$ ER-positive tumor cells in France.

The intensity of the marking is quoted as follows: 0 (no staining), 1+ (weak and incomplete membrane staining), 2+ (strong, complete membrane staining in $<30\%$ of the invasive tumor cells or weak/moderate heterogeneous complete staining in more than 10% of invasive tumor cells), or 3+ (strong complete homogenous membrane staining in more than 30% of the invasive tumor cells).

Some new methods, like NASBA (nucleic acid sequence-based amplification) or analysis by RT-PCR can also be performed, with high sensitivity and specificity (Lamy *et al.*, 2006).

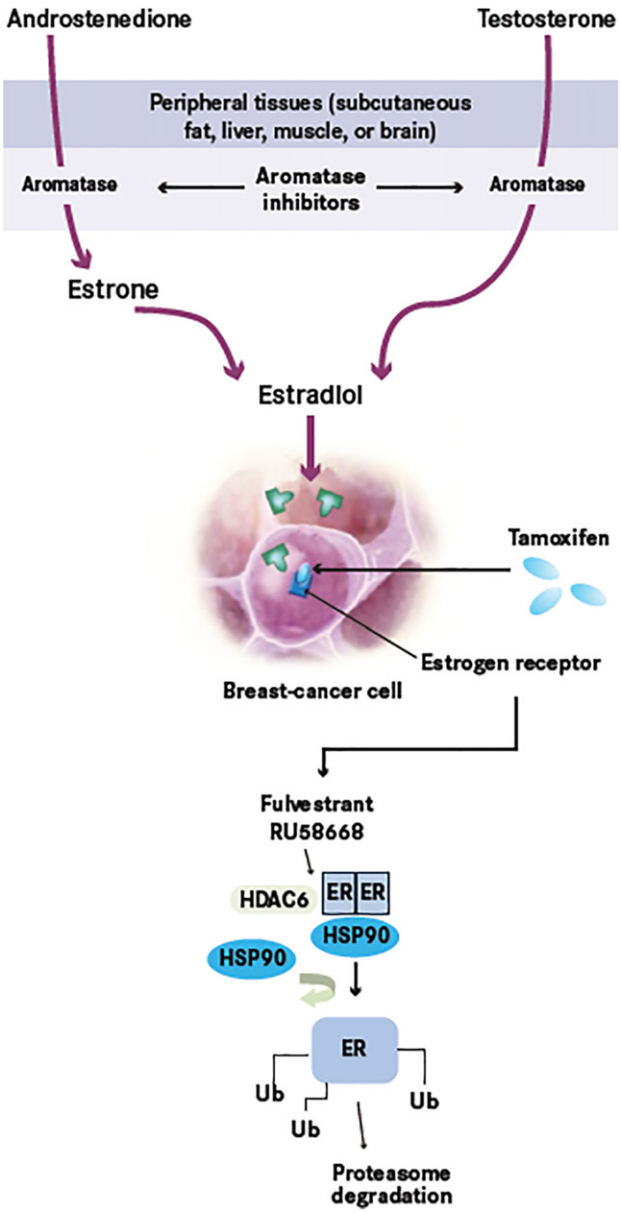

Fig. 2 Principles of hormonal therapy. From Smith, I. E. and Dowsett, M. (2003). Case vignettes in metastatic breast cancer, partially adapted -Aromatase inhibitors in breast cancer. *N Engl J Med*. **348**, 2431–2442.

Hormonal Therapy: Principles (Fig. 2)

➢ ER targeting
- By competitive inhibition of ER: SERM (selective estrogen receptor modulator)
- By ER degradation: SERD (selective estrogen receptor downregulator)

➢ Decreasing circulating estrogen levels
- LH-RH agonists before menopause
- AIs in postmenopausal women

ER Targeting

- By competitive inhibition of ER: SERM

These drugs act as receptor binding competitors of estrogen and block their effects. They bind to the ligand-binding domain of the ER and cause a conformational change in this domain.

The most common is tamoxifen, a nonsteroidal antiestrogen used in treatment of breast cancer, and in prevention in some countries (like the United States) (Cole *et al.*, 1971). It exerts a strong antagonist action at the mammary level and partial agonist on other tissues (endometrium, bones, vessels) (Weinberg *et al.*, 2005).

- By ER degradation: SERD

They are antiestrogens with no agonist activity, and more potent than SERMs.

The most common is fulvestrant, a steroidal antiestrogen. Fulvestrant has a 100-fold higher affinity than tamoxifen to the ER, with no agonist activity in the uterus (Howell *et al.*, 2000).

It is routinely used at the metastatic stage in postmenopausal patients.

Decreasing Circulating Estrogen Levels

- *AIs* in postmenopausal women

AIs block the enzyme involved in estrogen biosynthesis (aromatase cytochrome P450), to stop the production of estrogens from androgens, which is the main pathway of estrogen production in postmenopausal women.

Third-generation AIs have been developed; nonsteroidal (anastrozole, letrozole) and steroidal (exemestane).

These drugs are active in postmenopausal women, or undergoing suppression of ovarian function.

- LH-RH agonists

LH stimulates the ovaries to produce estrogen. GnRH, such as LH-RH, downregulates its own production in the hypothalamus through a reversible reaction. Common examples include buserelin, goserelin, leuprorelin, and triptorelin.

Strategies in the Use of Endocrine Therapy in the Management and Prevention of Breast Cancer

Adjuvant Monotherapy

Tamoxifen

At the end of the 1970s, the antiestrogen tamoxifen was introduced and became the mainstay of adjuvant treatment for patients with estrogen receptor (ER)-positive breast cancer (Jordan, 2008).

It has been first used in advanced breast cancer, then in early breast cancer and ductal carcinoma in situ, and more recently in breast cancer chemoprevention in some countries (Clemons *et al.*, 2002).

In ER-positive early breast cancer, 5 years of adjuvant tamoxifen significantly reduce breast cancer recurrence and mortality throughout the first 10 years and 15 years, respectively (Early Breast Cancer Trialists' Collaborative Group (EBCTCG) *et al.*, 2011).

The most described adverse effects of tamoxifen are menopausal symptoms including hot flashes, fatigue, weight gain, and more rarely vaginal dryness, low libido, mood swings, and nausea. It leads to a significant increase in the risk of uterine cancers and thromboembolic events.

Aromatase inhibitors

Despite the clinical success of tamoxifen, development of drug resistance and endometrial cancer led to the requirement of alternative hormonal therapy, such as nonsteroidal AIs (anastrozole and letrozole) and steroidal AIs (exemestane).

Several randomized trials have compared AIs to 5 years of tamoxifen as primary adjuvant treatment of postmenopausal women with early breast cancer.

The ATAC trial compared 5 years of tamoxifen with 5 years of anastrozole, and showed at the 100 months analysis a significantly improved DFS (HR 0.85, $P = 0.003$) in the anastrozole group, but no improvement in overall survival (Arimidex, Tamoxifen, Alone or in Combination (ATAC) Trialists' Group *et al.*, 2008).

The Breast International Group 1–98 study (BIG 1–98) compared 5 years of tamoxifen with 5 years of letrozole, and showed at the 51 months analysis a significant improvement of DFS (HR 0.82, P = 0.007), and a nonsignificant trend to improved overall survival (Coates *et al.*, 2007).

The TEAM (Tamoxifen, Exemestane Adjuvant Multicenter) trial, comparing 5 years of tamoxifen to 5 years of exemestane, showed no significant difference in DFS, but the trial recorded a high rate of treatment discontinuation and unplanned crossover (Derks *et al.*, 2017).

A meta-analysis of the ATAC and BIG trials revealed that the AIs, compared with tamoxifen, achieved a 2.9% absolute decrease in recurrence (9.6% for AIs vs. 12.6% for tamoxifen; $P < 0.00001$) and a nonsignificant reduction in breast cancer mortality (Dowsett *et al.*, 2010).

The most described adverse effects of AIs are arthralgia, myalgia, tendinitis, carpal tunnel syndrome, osteoporosis and fractures, cardiovascular and cardiac toxicity, hypercholesterolemia, hypertension, vaginal dryness, and libido disorders.

Adding an ovarian function suppression (OFS) to treatment

OFS, with triptorelin or goserelin, and ovarian ablation, with bilateral oophorectomy or bilateral ovarian irradiation, have been investigated in premenopausal women in the TEXT trial (Tamoxifen and EXemestane Trial) and SOFT trial (Suppression of Ovarian Function Trial) (Regan *et al.*, 2013).

The TEXT trial evaluated the outcome between patients receiving 5 years of exemestane plus triptorelin versus tamoxifen plus triptorelin.

The SOFT trial evaluated 5 years of OS in patients receiving tamoxifen plus triptorelin, exemestane plus triptorelin, or tamoxifen alone.

A combined analysis of TEXT and SOFT trials, including 4690 patients, showed an improved DFS among patients receiving exemestane plus OFS (91.1%) versus tamoxifen plus OFS (87.3%) (HR 0.72, $P < 0.001$). There was no difference in OS. In the SOFT trial, there was no difference in DFS between patients receiving tamoxifen plus OFS compared with tamoxifen alone ($P = 0.10$).

Sequential Therapy

The BIG 1–98 trial (BIG 1–98 Collaborative Group *et al.*, 2009) compared letrozole monotherapy to tamoxifen monotherapy and sequential therapy of 2 years of letrozole followed by 3 years of tamoxifen or 2 years of tamoxifen followed by 3 years of letrozole. After a follow up of 71 months, no significant difference was observed in terms of DFS or OS.

The EBCTCG meta-analysis (Dowsett *et al.*, 2010), involving 9856 women, pooled these two trials (ATAC and BIG 01–98 trials) and showed lower recurrence rates with AIs, alone or after 2 or 3 years of tamoxifen, compared with tamoxifen.

Several trials investigated the effect of switching (2–3 years of tamoxifen followed by 2–3 years of AI for a total of 5 years) versus continuing with tamoxifen. The EBCTCG meta-analysis pooled four trials (German Adjuvant Breast Cancer Group, Arimidex-Nolvadex, Intergroup Exemestane Study/BIG 02–07, Italian Tamoxifen Anastrozole Trial), and demonstrated overall superiority of the switch scheme with a decrease of recurrence and in breast cancer mortality (Dowsett *et al.*, 2010).

Extended Adjuvant Endocrine Therapy

Clinical studies have shown that women with early-stage hormone-positive breast cancer have a prolonged risk for recurrence, and half of them happen after 5 years of adjuvant endocrine therapy (Early Breast Cancer Trialists' Collaborative Group (EBCTCG) *et al.*, 2011).

A recent study (Pan *et al.*, 2017) showed that breast-cancer recurrences continue to occur steadily throughout the study period from 5 to 20 years, after 5 years of adjuvant endocrine therapy.

Several trials have investigated the potential therapeutic benefits of extended endocrine therapy beyond the traditional 5 year period either with tamoxifen, AIs, or a combination.

Tamoxifen

Five trials have evaluated the role of extended tamoxifen therapy beyond 5 years.

The three first trials did not show any additional benefits beyond the 5-years period: the NSABP B-14 trial (2001) (Benson, 2001), the Eastern Cooperative Oncology Group (ECOG, 1996) (Tormey *et al.*, 1996), and the Scottish Adjuvant Tamoxifen Trial (2001) (Stewart *et al.*, 2001).

Two larger trials, Adjuvant Tamoxifen: Longer against Shorter (ATLAS) (Davies *et al.*, 2013) trial and Adjuvant Tamoxifen—To Offer More (aTTom) (Azim and Saadeldeen, 2014) trial, showed a statistically significant benefit for disease recurrence ($P < 0.0001$), breast cancer mortality ($P = 0.002$), and overall survival ($P = 0.005$) in their combined results.

A meta-analysis published in PloS One in 2014 (Al-Mubarak *et al.*, 2014), including five trials, has compared the benefits of extended adjuvant tamoxifen (>5 years) with adjuvant tamoxifen (5 years). There was no difference in the risk of recurrence or in all-cause death. Subgroup analysis suggested a greater effect size among lymph-node positive patients.

AIs and tamoxifen

Several phase III clinical trials evaluated the effect of AI use in the extended adjuvant therapy setting.

In the MA.17 trial (Goss *et al.*, 2005), 5187 postmenopausal patients were randomized, receiving 5 years of letrozole or placebo after 5 years of adjuvant tamoxifen. It showed, in patients with the extended letrozole treatment, a significantly improved DFS, a reduction in recurrence risk of 42%, a reduced risk of distant metastasis, and an improved overall survival in node-positive patients ($P = 0.004$).

The NSABP B-33 trial (Mamounas *et al.*, 2008) studied extended AI therapy using exemestane, and showed a nonsignificant improvement of DFS ($P = 0.07$).

A meta-analysis of some trials (Chia *et al.*, 2008) found that AI therapy after 5 years of adjuvant tamoxifen was associated with a 2.9% decrease in recurrence rate and a 0.5% reduction in breast cancer mortality rate.

The IDEAL trial (Blok *et al.*, 2018) showed no superiority in terms of DFS, OS, or DMFi of 5 years over 2.5 years of extended adjuvant letrozole, after an initial 5 years of adjuvant endocrine therapy.

The phase 3 DATA trial (Tjan-Heijnen *et al.*, 2017) assigned postmenopausal women with hormone receptor-positive early breast cancer after 2–3 years of adjuvant tamoxifen to either 3 or 6 years of anastrozole treatment. The 5-year DFS was not significantly different between the two groups ($P = 0.06$), and patients in the 6-year treatment group had more adverse events (arthralgia, myalgia, osteopenia, osteoporosis).

Indications of extended endocrine therapy

The optimal combination and length of adjuvant endocrine therapy is controversial. There is no formal criteria to define the patients that would benefit most from the treatment.

Extending hormonal therapy should be decided based on patient's clinicopathological characteristics and available molecular signatures, such as Prosigna (PAM50) (Filipits *et al.*, 2014) and EndoPredict (Dubsky *et al.*, 2013), which can predict risk for late distant recurrence after endocrine therapy in postmenopausal women.

Side effects and adherence of the patient to treatment are essential to take into account before deciding.

Mechanisms of Resistance to Hormonal Therapy

Introduction

Approximately 70% of advanced breast cancers are considered "hormone responsive," defined by expression of the ER, PR, or both.

In reality, not all of these tumors are truly sensitive to manipulation of the ER pathway, with approximately 20% of HR+ metastatic breast cancers proving refractory to first-line endocrine therapy (McGuire *et al.*, 1977).

The emergence of resistance to endocrine manipulation is inevitable with advanced breast cancer. Although clinicians are encouraged to consider second- and third-line endocrine therapies for patients who initially benefited from first-line treatment (NCCN 2016), the clinical benefit rate declines from approximately 70% for first-line to around 30% for second or more lines of therapy (Chia *et al.*, 2008).

The mechanisms of endocrine resistance are becoming better understood, and treatment strategies are developed.

Mechanisms of Resistance and Emerging Therapies for HR+ Breast Cancer

ESR1 mutations

Mechanism

Loss of ER expression occurs in only 10% of metastatic tumors (Sighoko *et al.*, 2014).

Mechanisms of resistance can be driven by the emergence of additional mutations in the target oncogene.

Attention has recently focused on mutations in the gene *ESR1*, which encodes ERα, resulting in ligand-independent activation of ERα.

ESR1 mutations are rare in a treatment-naïve setting, and become more frequent in metastatic and pretreated ER+ breast cancers (Toy *et al.*, 2013). Robinson *et al.* (2013) indicate an *ESR1* mutation rate in advanced HR+ breast cancer of approximately 22%. PALOMA 3 study found 25% of mutation rates among patients with progression on endocrine therapy, and the SoFEA study 39% of mutation rates.

Highly recurrent mutations were noted at two residues in the ligand-binding domain: p.Tyr537Ser/Asn and p.Asp538Gly (Li *et al.*, 2013).

Emerging therapies

In the case of identification of mutations of ESR1, a group of agents resulting in degradation of ER: the selective estrogen receptor downregulators (SERDs), represented by fulvestrant, seem to have efficacy. They act as ER antagonists without any tissue-specific agonist properties. Fulvestrant binds to the ligand-binding domain of ERα, resulting in a conformation incompatible with transcriptional activation (Wardell *et al.*, 2011).

Prospective and retrospective analysis of ESR1 mutation status in plasma circulating tumor DNA indicated improved outcomes with fulvestrant compared with exemestane among patients with ESR1 mutations, whereas no difference was seen in patients who were ESR1wildtype (Fribbens *et al.*, 2016).

The dose of fulvestrant revealed to be superior in the phase III CONFIRM study is 500 mg on days 1, 15, 29, and every 28 days thereafter (Di Leo *et al.*, 2014). It requires intramuscular administration because of its poor oral bioavailability.

Growth factor receptors, PI3K/AKT/mTOR and RAF/MEK/ERK pathway activation

Mechanisms

Overexpression and/or amplification of growth factor receptors are associated with the emergence of endocrine resistance (Frogne *et al.*, 2009; Turner *et al.*, 2010). They converge on the PI3K/AKT/mTOR and RAF/MEK/ERK pathways.

PI3K pathway hyperactivation promotes estrogen-independent ER transcriptional activation, whereas PI3K inhibition results in increased estrogen dependence, providing a rationale for combined endocrine therapy and PI3K inhibition in endocrine-resistant breast cancer (Ghayad *et al.*, 2008; Bosch *et al.*, 2015).

The PIK3CA gene is mutated in up to 40% of human breast cancers. The frequency of PIK3CA mutations is not increased in metastatic compared with primary breast cancers (Meric-Bernstam *et al.*, 2014; **Fig. 3**).

Emerging therapies

- mTOR inhibitors, represented by everolimus

mTOR position in the PI3K/AKT pathway makes it an attractive target to reverse emerging endocrine resistance.

The phase II TAMRAD study (Bachelot *et al.*, 2012) evaluated the oral mTOR inhibitor everolimus in combination with tamoxifen versus tamoxifen alone in patients with metastatic ER+ HER2-negative breast cancer progressing after prior AI therapy. It showed a significant improvement in time to progression and overall survival in patients with secondary endocrine resistance.

The phase III Bolero 2 trial evaluated the mTOR inhibitor everolimus in combination with the steroidal AI exemestane versus exemestane alone in patients with advanced ER+ HER2-negative breast cancer in progression after prior nonsteroidal AI therapy. It showed better PFS with everolimus-exemestane versus exemestane alone (6.9 vs. 2.8 months), but increase in grade 3–4 toxicities including stomatitis, anemia, dyspnea, fatigue, and pneumonitis.

- PI3K inhibitors

Inhibition of PI3K may obviate some of the feedback activation, improving pathway inhibition (Chandarlapaty, 2012). Pictilisib and buparlisib are pan-class 1 PI3K inhibitors.

The LOTUS phase 2 study, published in the LANCET Oncology in 2017, compared ipatasertib (an oral AKT inhibitor) plus paclitaxel versus placebo plus paclitaxel as first-line therapy for metastatic triple-negative breast cancer. It showed a significantly longer progression-free survival in patients who received ipatasertib.

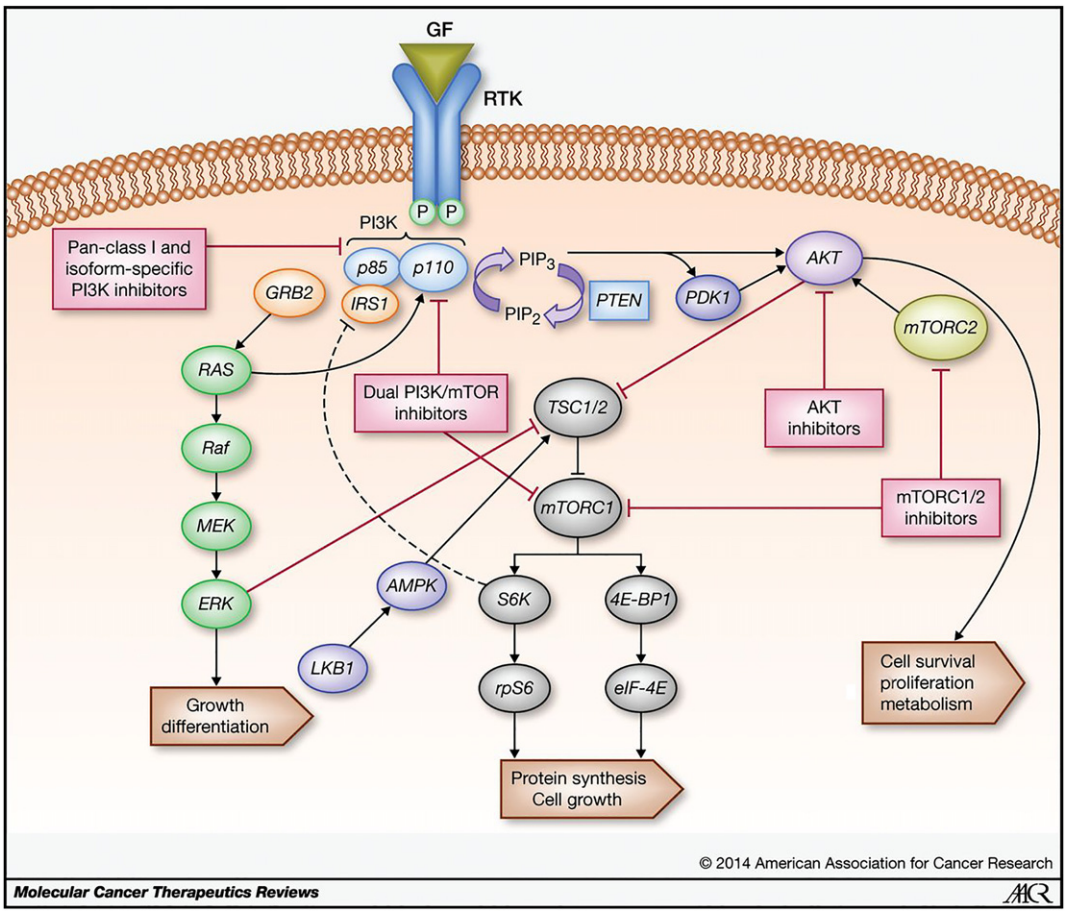

Fig. 3 The PI3K/AKT/mTOR pathway and drug targets.

Cell cycle checkpoint alterations

Mechanisms

Progression through the G1-S phase requires phosphorylation of the retinoblastoma protein (Rb) by the cyclin-dependent kinase CDK4 or CDK6, a family of serine-threonine protein kinases, in complex with cyclin D1, D2, or D3 (Morgan, 1997).

Many tumors increase cyclin D-dependent activity to escape senescence via multiple mechanisms (Cancer Genome Atlas Network, 2012).

Several studies have shown the particular role for CDK4/6 inhibition in ER+ breast cancer cells, including estrogen-sensitive and estrogen-resistant models (Murphy and Dickler, 2015; **Fig. 4**).

Emerging therapies

- CDK4/6 inhibitors

CDK4/6 inhibitors are a new class of selective drugs, offering an effective and tolerable treatment. They induce cell cycle arrest in the G1 phase by preventing phosphorylation of Rb, and may thereby prevent tumor progression.

Today, there are three highly selective CDK4/6 inhibitors in clinical development—palbociclib (Ibrance), ribociclib (Kisqali), and abemaciclib (LY2834219).

Palbociclib and ribociclib were recently approved by the US FDA in combination with letrozole for the treatment of metastatic breast cancer in a first-line setting, as well as palbociclib in combination with fulvestrant for hormone-receptor positive metastatic breast cancer that had progressed on previous endocrine therapy according to the PALOMA-1 (Finn *et al.*, 2015), MONALEESA-2 (Sonke *et al.*, 2017) and PALOMA-3 trials (Turner *et al.*, 2015), respectively.

In the phase III MONARCH 2 trial (Sledge *et al.*, 2017), abemaciclib in combination with fulvestrant significantly improves PFS and ORR, with a tolerable safety profile, in women with hormone receptor-positive and human epidermal growth factor receptor 2-negative advanced breast cancer who progressed while receiving endocrine therapy.

In the MONARCH 3 trial (Goetz *et al.*, 2017), abemaciclib plus a nonsteroidal AI was effective as initial therapy, significantly improving progression-free survival and objective response rates in advanced HR-positive breast cancer.

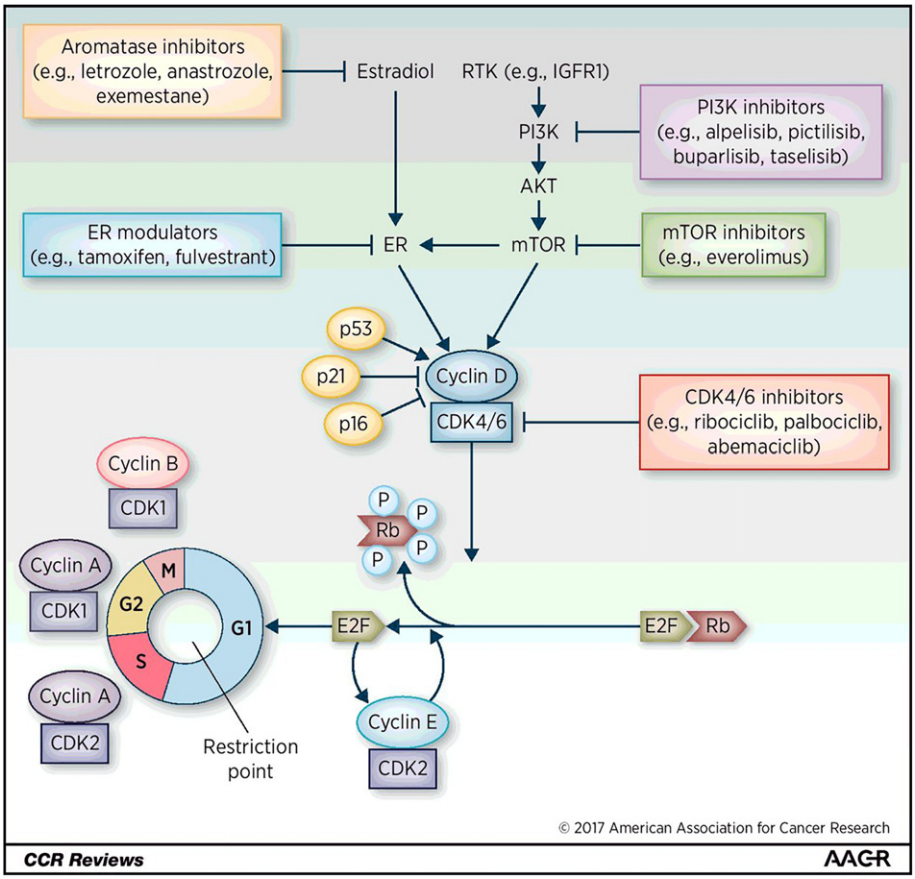

Fig. 4 The role of cyclin-dependent kinase 4/6 inhibition in the cell cycle.

Enhanced autophagy

Autophagy represents a key mechanism by which cancer cells and normal cells deal with various stresses in their environment. Cancer cells demonstrate persistent high levels of basal autophagy. Inhibition of autophagy has been linked to restoration of endocrine sensitivity in preclinical models of endocrine-resistant breast cancer.

Conclusion

Endocrine therapy forms a central modality in the treatment of ER-positive breast cancer. The widespread usage of adjuvant therapy has had a positive impact on overall survival.

Given that women with ER-positive breast cancer remain at long-term risk of relapse, some data have revealed that longer durations of adjuvant therapy result in further survival gains. The optimal duration of adjuvant endocrine therapy remains controversial, with recent data supporting 10 years rather than 5 years of adjuvant tamoxifen in case of bad prognosis.

Endocrine therapy is limited by the development of resistance, whose mechanisms can be modulated by emerging therapies, with the aim of preventing or delaying them.

Hormonal Treatment of Male to Female Transgender

Alessandra D Fisher and Louis Gooren, University of Florence, Florence, Italy and VU Medical Center, Amsterdam, The Netherlands

Background

According to the Diagnostic and Statistical Manual of Mental Disorders, *transgenderism* refers to the broad spectrum of people who transiently or persistently identify with a gender different from their natal sex (DSM 5, APA, 2013). Indeed, male-to-female transgender (or transwomen or transgender women) describes individuals assigned male at birth but who later in life identify and live as women (Hembree *et al.*, 2017). Many, but not all transgender people, seek a social or a somatic transition in order to alleviate the significant distress (called Gender Dysphoria) resulting from the incongruence between the body and the gender identity.

Somatic interventions aim at aligning the body with the perceived gender, and this medical approach should include gender-affirming hormonal treatment. In line with the recent nonbinary multidimensional conceptualization, gender identities and expressions are diverse (Coleman *et al.*, 2011). Thus, gender dysphoric individuals (GDs) could benefit from flexibility in treatment, according to their final goals (Fisher *et al.*, 2014). Indeed, treatment of GDs should be individualized based on a person's desires (Coleman *et al.*, 2011; Fisher *et al.* 2014). This is particularly the case when transwomen's hormonal treatment is considered. Personalizing hormonal treatment is best done in the context of a multidisciplinary team in collaboration with the referring mental health professional and following accepted safety recommendations. Evidence-based protocols for people located somewhere along a dimensional continuum have not yet been developed, however (Hembree *et al.*, 2017).

Gender-affirming hormone therapy has two major aims: (i) to reduce the secondary sex characteristics of the natal sex and (ii) to induce those of the desired gender (Hembree *et al.*, 2017), in line with client's wishes.

In order to reach these goals, in transwomen, it is necessary to decrease endogenous sex hormone levels (androgens) and to replace them with those of the reassigned sex (estrogens, Hembree *et al.*, 2017). Administration of estrogens alone will suppress gonadotropin secretion incompletely (and, consequently, androgen production). Combined therapy, with both estrogens and antiandrogens, is more effective in reducing endogenous androgens into the female range, thus increasing the feminizing effects of estrogens (Gooren *et al.*, 2008).

Antiandrogens

Several compounds are available to inhibit androgen secretion or action (see **Table 1**). *Cyproterone acetate* (CPA, 50–100 mg/d) is the most common antiandrogen used in Europe for male-to-female gender-affirming hormonal treatment. It has also strong progestogenic proprieties, which result in a negative hypothalamic feedback, leading to a reduction in gonadotropin release and, thus, testicular androgen secretion. In addition, CPA competes with androgens for binding to the androgen receptor and inhibits adrenal steroidogenesis (Hembree *et al.*, 2017; Gooren, 2005; Levy *et al.*, 2003). The recommended dose for transwomen is 50–100 mg/d (Hembree *et al.*, 2017); however, because CPA is highly lipophilic and stored in the subcutaneous tissue, lower doses may also be effective in suppressing androgen levels (Tangpricha and den Heijer, 2017). A variety of hepatotoxic reactions have been reported in men receiving a higher dose of CPA (200–300 mg/day) for prostate cancer (Savidou *et al.*, 2006). However, in transgender populations, only a transient elevation of liver enzymes during hormonal treatment has been reported (Wierckx *et al.*, 2014a,b). In line with this data, no significant differences were found in transaminase levels between transwomen under hormonal treatment compared to those not receiving gender-affirming hormones (Fisher *et al.*, 2016). In addition, for its slight glucocorticoid activity, CPA may contribute to the weight gain observed in transwomen during hormonal treatment. An increased risk of meningiomas, which are hormone-sensitive tumors expressing progesterone receptors, has also been reported in CPA users compared to nonusers (Gil *et al.*, 2011; Ter Wengel *et al.*, 2016). Finally, according to some authors, CPA may contribute to the elevation in prolactin levels induced by estrogens (Defreyne *et al.*, 2017).

Spironolactone (100–300 mg/d), an aldosterone antagonist with antiandrogenic proprieties, is mostly used in the United States, where CPA is not available. It has antiandrogenic effects by blocking the androgen receptor, directly inhibiting testosterone secretion and increasing metabolic clearance of testosterone (Moore *et al.*, 2003; Tangpricha *et al.*, 2003). Its use increases the risk of hyperkalemia and has been associated with gastrointestinal bleeding (Gulmez *et al.*, 2008).

GnRH agonists, taken as monthly injections (3.75 mg) or every 3 months (11.25 mg), are very effective in reducing testosterone levels with a low risk of adverse effects (Dittrik *et al.*, 2005); however, they are extremely costly and, therefore, their use is limited.

Nonsteroidal antiandrogens, such as *flutamide* (50–75 mg/day)—which blocks the binding of androgens to the androgen receptor—can theoretically be used; they induce gonadotropin secretion, with a consequent rise of testosterone and estradiol levels (the latter may be desirable in this circumstance). However, due to their liver toxicity and the unavailability of efficacy and safety data in transgender populations, their use is not recommended (Levy *et al.*, 2003).

 doi:10.1016/B978-0-12-801238-3.66087-7

Table 1 Gender-affirming hormonal treatment protocols in male-to-female transgenders

Antiandrogen regimens	
Cyproterone acetate	25–100 mg/d
Spironolactone	100–300 mg/d
GnRH analogs	3.75 mg sc/monthly or 11.25 mg sc/3 months
Estrogen regimens	
Oral estradiol	2–6 mg/d
17-β-Estradiol patch	100–400 mcg/24 h (changing the patch as directed once or twice weekly)
17-β-Estradiol hemihydrate gel	2 mg twice daily
17-β-Estradiol gel	3–4.5 mg daily
Parental estradiol valerate or cypionate	5–30 mg IM every 2 week 2–10 mg IM every week

Finally, the 5-alpha reductase inhibitor *finasteride* (5 mg daily)—which inhibits the conversion of testosterone to 5α-dihydrotestosterone—may be considered as an additional antiandrogen, particularly to slow male pattern balding.

Progestins have also been proposed to suppress gonadotropins and, thus, testosterone secretion. In addition, transgender women often believe that progestins will augment breast development, yet well-designed studies demonstrating additional feminization effects are not available in transgender populations (Wierckx *et al.*, 2014b; Hembree *et al.*, 2017). In addition, breast cancer and cardiovascular diseases have been reported when used in postmenopausal women together with estrogens (Chlebowski *et al.*, 2013; Mueller and Gooren, 2008; Gooren *et al.*, 2004; Rossouw *et al.*, 2002). Finally, other side effects have been reported with progestins, such as water retention and the consequent elevation of blood pressure and weight gain, detrimental lipid changes and depression (Gooren, 2011). Therefore, in consideration of the lack of efficacy and the associated adverse effects, their use is not recommended in gender transition (Hembree *et al.*, 2017).

Estrogens

In order to induce female secondary sexual characteristics, estrogens are required. Typical estrogen dosage in transgender women needs to be two to three times as high as the recommended doses for hormone replacement therapy in postmenopausal women (Moore *et al.*, 2003).

A wide range of estrogenic compounds is available (see **Table 1**), of which 17beta-estradiol represents the treatment of choice. Indeed, the most widely accepted estrogen treatment in Europe consists of oral estradiol 2–6 mg daily (Dekker *et al.*, 2016). Transdermal and injectable routes of administration, avoiding the first-pass effect, have a more favorable lipidic, inflammatory and coagulative profile (Asschemann *et al.*, 2011, 2014). Therefore, transdermal 17beta-estradiol (100 mcg/d) is particularly recommended for transwomen at higher thromboembolic risk (i.e., those older than 40 years, smokers and/or with diabetes or liver disease, Hembree *et al.*, 2017; Van Kesteren *et al.*, 1997; Asscheman *et al.*, 1989). Injectable estrogens are not routinely recommended because they can generate rapid peaks of circulating estrogens, a prolonged time to reach a steady state and a potential risk of patient abuse (Moore *et al.*, 2003).

Oral ethinyl estradiol should be avoided in consideration of the 20-fold increased risk of venous thrombosis and the threefold increase in cardiovascular mortality (Toorians *et al.*, 2003; Asscheman *et al.*, 2011). Moreover, the fact that it is impossible to monitor its blood levels represents an additional important and practical limitation for its use.

Recommendations Before Starting Treatment

Before prescribing gender-affirming hormonal therapy, the treating endocrinologist needs to confirm that the person fulfills diagnostic criteria for GD/gender incongruence and criteria for hormonal treatment (**Table 2**, Hembree *et al.*, 2017).

Moreover, before starting treatment, the treating clinician should evaluate and address conditions that can be exacerbated by this treatment, such as thromboembolic diseases (*high risk*), breast cancer, macroprolactinoma, coronary artery disease, cerebrovascular disease, cholelithiasis and hypertriglyceridemia (*moderate risk*, Hembree *et al.*, 2017). Pretreatment screening is presented in **Table 3**.

Cessation of tobacco use should be strongly recommended to avoid increased risk of thromboembolism and cardiovascular complications (Hembree *et al.*, 2017).

Fertility preservation options should also be discussed before starting treatment (Hembree *et al.*, 2017).

Table 2 Criteria for cross-sex hormone treatment as reported in guidelines on gender-dysphoric/gender-incongruent persons (Hembree *et al.*, 2017)

1. Persistent, well-documented Gender Dysphoria/Gender Incongruence;
2. The capacity to make a fully informed decision and to consent for treatment;
3. Legal age in a given country;
4. If significant medical or mental health concerns are present, they must be reasonably well controlled.

Table 3 Monitoring schedule for transgender females

Pretreatment
Physical examination: weight, blood pressure, waist, body mass index, hair distribution, balding pattern.
Fasting lipid, renal and liver function, glucose, glycosylated hemoglobin, complete blood count, serum estradiol, testosterone, prolactin.
For those taking spironolactone: serum electrolytes (particularly potassium).
Consider BMD testing (according to the natal sex) at baseline, particularly in individuals with existing osteoporosis risk (previous fracture, family history, glucocorticoid use, prolonged hypogonadism, not compliance with hormonal therapy, older than 60 years).
During the first year of hormonal treatment, every 3 months
Physical examination: weight, blood pressure, waist, body mass index, hair distribution, balding pattern, breast development.
Fasting lipid and liver function, glucose, serum estradiol, testosterone, prolactin
Electrolytes (for those taking spironolactone)
During second year of treatment, every 6–12 months
Physical examination: weight, blood pressure, waist, body mass index, hair distribution, balding pattern, breast development.
Fasting lipid and liver function, glucose, glycosylated hemoglobin, complete blood count, hemoglobin, serum estradiol (ideal between 100 and 200 pg/mL) and testosterone (ideal $<$55 ng/dL), prolactin
Electrolytes (for those taking spironolactone)
PSA and digital rectal prostate exam when older than 50 years.
After genital-affirming surgery (when requested), every 12 months
Physical examination: weight, blood pressure, waist, body mass index, hair distribution, balding pattern, breast development,
Fasting lipid and liver function, glucose, glycosylated hemoglobin, complete blood count, hemoglobin, serum estradiol (ideal 100–200 pg/mL) and testosterone (ideal $<$55 ng/dL), prolactin
Additional screening
BMD according to natal sex (if osteoporosis risk exists)
PSA, digital rectal prostate exam according to establish guidelines for biological sex
Mammogram/breast ultrasound according to establish guidelines for assigned sex

Approach in Specific Conditions

Before an Elective Surgical Intervention

Estrogens should be stopped 3–4 weeks before any elective surgical intervention (including gender-affirming surgery) and can be resumed once the person is fully mobilized (Gooren and Delemarre-van de Waal, 2007). After gonadectomy, estrogen treatment should be continued, in order to avoid the signs and symptoms correlated with hypogonadism and to avoid osteoporosis. In those still complaining of male typical sexual hair growth, antiandrogens may remain effective, although their dose may be reduced compared to presurgery.

Postmenopausal Age

Up to now, there is no consensus whether hormonal treatment has to be stopped when client gets older, mirroring the postmenopausal milieu. No data are available in this regard.

Treatment Monitoring

Clinical and laboratory monitoring has to be performed every 3 months during the first year of hormonal treatment and then every 6–12 months (**Table 3**). Routine breast and prostate cancer screening is recommended as in nontransgender individuals (Hembree *et al.*, 2017).

Both serum estradiol and testosterone levels have to be monitored regularly in order to avoid supraphysiologic levels and to minimize the risk of adverse effects (Knezevich *et al.*, 2012). Adequacy of estrogens levels can be monitored by measurement of

serum estradiol levels when oral, transdermal and intramuscular estradiol or its esters are used, but not with conjugated or synthetic estrogens. Theoretically, serum estradiol should be maintained at the mean daily for premenopausal women (100–200 pg/mL) and testosterone levels should be in the female range (<50 ng/dL, Hembree *et al.*, 2017). Treatment doses should be adjusted accordingly. Moreover, body feminization changes should be monitored in order to guide treatment.

Efficacy of Hormonal Treatment

Breast Growth

An increase in breast size usually starts within the first 3 months after the initiation of hormonal therapy and shows a significant progression over 2 years of treatment (Meyer *et al.*, 1986; Fisher *et al.*, 2016). According to these observations, the Clinical Practice guidelines of the Endocrine Society for the endocrine treatment of transgender persons recommend delaying surgical breast augmentation until the person has completed at least 2 years of estrogen treatment (Hembree *et al.*, 2017). Fifty to sixty percent of transgender women have reported their breast formation as quantitatively unsatisfactory and seek augmentation mammoplasty (Gooren and Asscheman, 2013). This may also be the consequence of the fact that the attained size could be disproportionate to the typical male body frame. In addition, in transgender women, breasts are located more laterally on the chest wall and thus the breasts may appear smaller than in natal women with the same size (Wierckx *et al.*, 2014a).

Skin

The reduction of sebaceous gland activity due to androgen deprivation often results in softening and decreased oiliness of skin (Giltay *et al.*, 2000).

Body Hair

Hormonal treatment induces a reduction of sexual hair growth and hair shaft diameter, with hair usually becoming thinner and less pigmented (Giltay *et al.*, 2000). However, facial hair is more resistant to hormonal therapy, particularly in the Caucasian population where a medium Ferriman-Gallwey score of 8 (indicative for hirsutism in natal females, Martin *et al.*, 2008) has been observed after 24 months of treatment (Fisher *et al.*, 2016). Indeed, additional measures, such as electrolysis or laser, are usually necessary to eliminate beard growth.

Voice

Hormonal treatment has no effects on transgender women's voice. Voice therapy can be considered an option to develop a voice within the frequency ranges for a biological female (de Bruin *et al.*, 2000). Alternatively, laryngeal surgery may be suggested in order to change the pitch of the voice, even if it reduces its range.

Testes

Hormonal treatment results in a significant reduction of testis volume (by 40% and 50% after 1 and 2 years of therapy, respectively, Fisher *et al.*, 2016), making it easier to hide male genitals, and, thus, may help alleviating the psychological distress perceived by transwomen.

Sexual Effects

Decrease of sexual desire, spontaneous erections and male sexual dysfunction, often desired by patients, are usually observed within 1–3 months after starting hormonal treatment (Hembree *et al.*, 2017).

Body Composition

Hormonal treatment causes a more feminine body fat distribution, with a decrease of lean body mass and an increase of subcutaneous body fat (Elbers *et al.*, 1999; Van Caenegem *et al.*, 2015; Wierckx *et al.*, 2014a) and a lower waist-to-hip ratio mainly due to an increase in hip circumference. Cardiovascular risk factors may deteriorate, and it is therefore essential to encourage a healthy lifestyle.

Adverse Effects of Hormonal Treatment

Hormonal therapy for transgender females may be associated with adverse effects particularly when supraphysiologic or inadequate doses of sex hormones are used.

Bone Mineral Density

At baseline, transgender females may show significantly lower baseline bone mineral density (BMD) compared to age-matched control men (Van Caenegem *et al.*, 2013). The lower bone mass, together with the often lower vitamin D status, may be explained by the more sedentary lifestyle and less outdoor activities observed in transwomen (Van Caenegem *et al.*, 2013). However, different studies have reported an increase in lumbar spine BMD in transwomen treated with antiandrogens and estrogens (Van Caenegem *et al.*, 2015; van Kesteren *et al.*, 1996, 1998; Wiepjes *et al.*, 2017; Haraldsen *et al.*, 2007) or treated with estrogens and gonadotropin-releasing hormone agonists (Mueller *et al.*, 2005). One prospective study did not find a change in BMD in a small sample transwomen (Haraldsen *et al.*, 2007).

Venous Thromboembolism

A 20-fold increased risk of venous thromboembolism (VTE) has been reported in a large cohort of transgender women receiving hormonal therapy (Van Kesteren *et al.*, 1997). According to a later study from the same group, this increase was found mostly to be associated with the use of ethinyl estradiol than with the use of 17beta-estradiol (Toorians *et al.*, 2003). The more deleterious effect of ethinyl estradiol compared to 17beta-estradiol seems probably linked to effects on activated protein C resistance, due to its molecular structure rather than first-pass liver effect (Toorians *et al.*, 2003). The risk of VTE was also found to be associated with age, being higher in persons older than 40 years, similar to the figure observed in natal females treated with estrogens (Asscheman *et al.*, 1989; Scarabin *et al.*, 2003).

Thus, the use of ethinyl estradiol should to be avoided, and 17beta-estradiol should be considered the treatment of choice. Transdermal preparations are preferred, particularly in subjects older than 40 years. Finally, thrombophilia screening in transgender individuals starting CHT can be restricted to those with a personal or family history of VTE (Hembree *et al.*, 2017; Otto *et al.*, 2010).

Hyperprolactinemia

Estrogen treatments can induce hyperplasia of pituitary lactotropic cells. In the literature, elevations in serum prolactin levels (>1000 mU/L), associated with an enlargement of the pituitary gland, are reported in up to 20% of transwomen during hormonal treatment (Asscheman *et al.*, 1988). Usually, serum prolactin levels return to the normal range after reducing or discontinuing hormonal therapy (Gooren *et al.*, 1985; Bunck *et al.*, 2009). In addition, a recent study has shown a possible contribution of CPA in the prolactin elevation observed in transwomen receiving gender-affirming hormones (Defreyne *et al.*, 2017).

Despite several reports of prolactinomas occurring after high-dose long-term hormonal affirming therapy in transgender women having been described (Gooren *et al.*, 1988; Kovacs *et al.*, 1994; Serri *et al.*, 1996; Cunha *et al.*, 2015; Garcia-Malpartida *et al.*, 2010), the overall risk of prolactinoma can be considered very low.

However, it is recommended to measure prolactin levels before starting hormonal treatment and then at least annually during the first year and, after that, every 2 years (see also **Table 3**). If levels of prolactin are extremely high or persistently increase despite stable or reduced levels of estrogens, a pituitary magnetic resonance imaging (MRI) is recommended (Hembree *et al.*, 2017). In fact, it is of note that the majority of hyperprolactinemia signs and symptoms (such as hypogonadism hypoactive sexual desire, sexual dysfunction and gynecomastia) may not be apparent in transgender women. Another common cause of drug-induced elevated prolactin is the use of psychotropic drugs, and concomitant treatment should be considered during hyperprolactinemia evaluation.

Cancer Risk

Breast cancer has been reported in relatively few cases of hormonally treated transgender women (Ganly and Taylor, 1995; Pritchard *et al.*, 1988; Symmers, 1968; Brown, 2015), though numbers may be rising (Gooren and Asscheman, 2013; Gooren *et al.*, 2015). The data suggest that estrogen therapy does not increase the risk of breast cancer substantially in the short term, but a definitive conclusion cannot be reached particularly in terms of long-term risk. As in natal females, routine breast self-examination, as well as mammogram/breast ultrasounds, according to the established guidelines for assigned sex should be suggested.

It has been assumed that castration in early life protects against prostate cancer. However, a few cases of prostate carcinoma have been reported in transgender females (Dorff *et al.*, 2007; Thurston 1994; van Haarst *et al.*, 1998; Turo *et al.*, 2013; Miksad *et al.*, 2006; Gooren and Morgenthaler, 2014). In addition, some cases have reported of benign prostatic hyperplasia in transgender women treated with estrogens for 20–25 years (Brown and Wilson, 1997; Casella *et al.*, 2005). According to Endocrine Society

guidelines, prostate-specific antigen (PSA) levels and digital rectal prostate examination should be checked according to established guidelines for natal sex (Hembree *et al.*, 2017).

Cardiovascular Health

In transwomen, hormonal treatment showed apparent favorable changes in metabolic profile, with an increase of high-density lipoprotein cholesterol (HDL) and decrease of low-density lipoprotein cholesterol (LDL, Elbers *et al.*, 2004). However, the latter was also associated with transition to smaller, denser and more deleterious LDL, high in triglyceride content (Elbers *et al.*, 2004). In addition, estrogen and antiandrogen treatment induces an increase in weight, body mass index, total body fat, blood pressure, triglycerides and markers of insulin resistance (van Kesteren *et al.*, 1997; Elbers *et al.*, 2004; Elamin *et al.*, 2010; Fisher *et al.*, 2016). Finally, oral, but not transdermal, administration of estrogens was associated with an increase in inflammatory markers involved in the pathogenesis of vascular disease (Giltay and Gooren, 2000; Wilson *et al.*, 2009).

Regarding the cardiovascular risk of estrogens in transgender women, results are still conflicting. The largest cohort of transgender females, followed for a mean of 10 years, showed no increase in cardiovascular risk (Van Kesteren *et al.*, 1997); however, two more recent cohort studies showed an increased risk of mortality due to cardiovascular disease among transwomen following gender-affirming procedures (Dhejne *et al.*, 2011; Asscheman *et al.*, 2011). Indeed, the Dutch cohort study, with a median follow-up of 18.5 years, showed that current, but not past, ethinyl estradiol use was associated with an independent threefold increased risk of cardiovascular death (Asscheman *et al.*, 2011). No increased risk was found in former users who had changed to other formulations and lower doses of 17beta-estradiol (Asscheman *et al.*, 2011); however, it should be noted that only a small percentage of clients studied by Asscheman and colleagues were treated with 17beta-estradiol.

Thus, further research is needed to better clarify the cardiovascular effects of hormonal treatment in transwomen. In any case, the available evidence stresses the importance of avoiding ethinyl estradiol prescription and directing clients toward a healthy lifestyle.

Reproductive Health

A prolonged estrogen treatment induces a reduction of testis volume and has a suppressive effect on sperm motility and density in a cumulative dose-dependent manner (Payer *et al.*, 1979). Similarly, hormonal treatment in transwomen results in a reduction of testis volume (Meyer *et al.*, 1986; Fisher *et al.*, 2016) and in a high incidence of oligozoospermia, asthenozoospermia, and teratozoospermia (Hamada *et al.*, 2014; Lubbert *et al.*, 1992).

Thus, clients requesting hormonal treatment need adequate information about the options available to preserve (e.g., banking of spermatozoa) their fertility potential, before actual treatment takes place (De Roo *et al.*, 2016; Hembree *et al.*, 2017; Wierckx *et al.*, 2012).

Testes Embryology: Cellular Molecular Changes☆

T Svingen, Technical University of Denmark, Søborg, Denmark
LJ Pelliniemi, University of Turku, Turku, Finland

Glossary

Cryptorchidism A developmental defect characterized by failure of the testes to descend into the scrotum.
Embryo The term embryonic refers here to the entire period from fertilization to birth, as gonadal development typically spans the transition between embryo and fetus, and the staging is often poorly defined in many mammals.
Germ cells A general term for the reproductive cells of multicellular organisms. Precursor cells of spermatogonia and oogonia.
Interstitial tissue The tissue between the testis cords, which comprise endocrine Leydig cells, vasculature, mesenchymal cells and peritubular (myoid) cells.
Leydig cell tumor The most common non-germinal tumor of the testis; derived from Leydig cells. It is rarely malignant. It appears among 1-3% of testicular tumors and, although they may occur in children, the median age of appearance is 60 years.
Leydig cells Steroid-producing endocrine cells in the interstitial tissue of the testis. They are regulated by gonadotropic luteinizing hormone from the pituitary and produce testosterone, the major androgenic hormone.
Meiosis A special method of cell division whereby haploid gametes are produced from diploid gonocytes; that is, each daughter nucleus receives half the number of chromosomes characteristic of the somatic cells of the species.
Primordial germ cells The precursors to gonadal germ cells (gonocytes) not yet having colonized the gonadal ridges.
Seminoma A radiosensitive, malignant neoplasm of the testis, thought to be derived from primordial germ cells. They account for roughly half of all testicular germ cell tumors.
Sertoli cells Organizers of initial testis differentiation, later the supporting cells of the testis cord with cytoplasms projecting inward from the basement membrane. They surround and nourish the developing male germ cells (gonocytes) and secrete androgen-binding protein and anti-Müllerian hormone (AMH). Sertoli-Sertoli, Sertoli-spermatogonia and -spermatocyte tight junctions provide a blood-testis barrier
Spermatogonia Euploid male germ cells of an early stage of spermatogenesis, derived from pre-spermatogonia. With the onset of puberty, spermatogonia at the basement membrane (BM) of the seminiferous tubule proliferate by mitotic, then meiotic divisions and give rise to the haploid secondary spermatocytes.
Testicular neoplasms Tumors or cancer of the testis. Approximately 95% of all testicular neoplasms are germ cell tumors.
Testis cords In the embryonic testis; the convoluted solid cylindrical precursors of seminiferous tubules where, after puberty, sperm are produced (spermatogenesis). Testis cords (seminiferous tubules) are composed of developing germ cells and supporting Sertoli cells.

Introduction

The testis has two key functions, spermatogenesis and androgen production. The reproductive function – sperm production – is in a dormant phase until puberty, whereas the androgenic function – male sex hormone production – is central to the regulation of sexual differentiation and development of an individual from a very early stage, as illustrated in **Fig. 1** and **2**. This chapter focuses on embryonic development of the testis and the involvement of testis-derived hormones on masculinization of the embryo.

The testes influence the embryonic development of genital organs and brain by specific hormones (Bocklandt and Vilain, 2007; Svechnikov et al., 2010), as illustrated in **Fig. 3**. These testis-derived hormones are largely produced by Leydig cells, one exception being AMH that is produced and secreted by Sertoli cells. However, before they can be produced and fulfill their androgenic roles, the embryonic testis must first differentiate into a compartmentalized organ through a series of biochemical, cellular, structural, and functional events (Svingen and Koopman, 2013).

The Gonadal Ridge

In the developing embryo the testicular anlagen initially consists of epithelium-covered ridges of mesenchymal cells on the surface of the two mesonephroi running parallel on either side of the body midline (**Fig. 2**). At this stage they are typically referred to as gonadal (or genital) ridges. They are morphologically indistinguishable between the sexes until the seventh week of gestation in

 doi:10.1016/B978-0-12-801238-3.04029-0

Table 1 Gene names and their corresponding symbols (abbreviations) as used in the text

Symbol	*Name*
AMH (MIS)	Anti-Müllerian hormone (Müllerian inhibing substance)
CYP17A1	Cytochrome P450, family 17, subfamily A, polypeptide 1
DAX1(NR0B1)	Dosage-sensitive sex reversal, adrenal hypoplasia congenital, critical region on chromosome X, gene 1 (Nuclear receptor subfamily 0, group B, member 1)
DHH	Desert hedgehog
FGF9	Fibroblast growth factor 9
FOXL2	Forkhead box L2
HSD3B1(3β-HSD)	Hydroxy-delta-5-steroid dehydrogenase, 3 beta- and steroid delta-isomerase 1
INSL3	Insulin-like 3 (Leydig cell)
RXFP2(LGR8)	Relaxin/insulin-like family peptide receptor 2 (Leucine-rich repeat-containing G protein-coupled receptor 8)
PGDS	Prostaglandin D2 synthase
PTCH1	Patched 1
RSPO1	R-spondin 1
SF1(NR5A1)	Steroidogenic factor 1 (Nuclear receptor subfamily 5, group A, member 1)
SOX9	SRY (sex determining region Y)-box 9
SRD5A2	Steroid-5-alpha-reductase, alpha polypeptide 2
SRY	Sex determining region Y
WNT4	Wingless-type MMTV integration site family, member 4

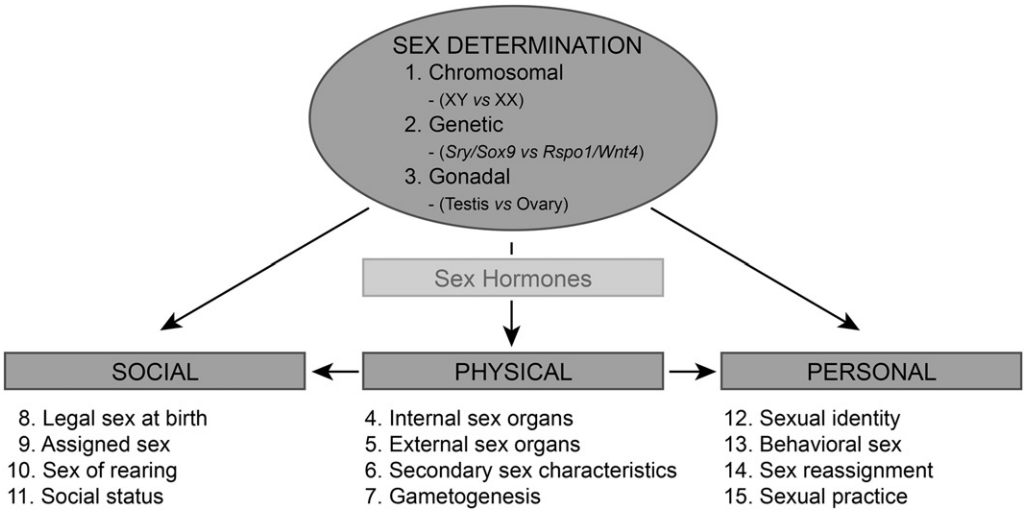

Fig. 1 The central role of testis (or ovary) differentiation in the regulation of sex development, reproductive function, and sexual manifestation in humans and other mammals. The different modalities of sex at various developmental and organizational levels are numbered from one to 15 roughly according to the developmental sequences. Mammalian sex determination is a three-tiered process. First, chromosomal sex (1) is determined at the time of fertilization by the fusion of haploid sperm and egg cells to form a diploid zygote. Second, genetic sex (2) refers to gonadal sex determination, triggered by the Y-linked gene *Sry* (which triggers *Sox9* expression) in XY embryos, or the absence thereof in XX embryos (which allows for expression of pro-ovary genes such as *Rspo1* and *Wnt4*). Third, gonadal sex (3) refers to the differentiation of the indifferent gonads into either testes or ovaries in response to genetic cues, ultimately allowing sex-specific hormones to be produced. Following gonad development, the internal sex organs (4) such as epididymis, ductus deferens and urethra, and the external sex organs (5), the penis and scrotum in males, differentiate in response to hormonal signals. The secondary sex characteristics (6) include shaping of the body and breasts as well as the growth pattern of body hair, which takes place at puberty under the control of testes (or ovaries) together with the pituitary hormones. Gametogenesis (7) refers to the ability of the testes (or ovaries) to produce sperm (or egg) cells. Partially parallel with the development of physical sex, social and personal aspects of sexual development are formed, both by direct and indirect control of sex hormones. The legal sex (8) is determined at birth in normal cases according to the anatomy of the external genitalia. In the case of ambiguity, assigned sex (9) is usually given following more detailed analysis of the chromosomal and genetic status of the individual. The sex of rearing (10) comprises the behavior of parents and/or other significant adults in relation to the growing child. The sex, or perceived sex, of an individual, can also impact on social status (11), including employment opportunities, sporting endeavors, and religious activities to mention a few. Individuals also develop a sexual identity (12) according to internal physical and functional development and the behavior of relatives. This is soon reflected in the manifestation of behavioral sex (13) of a child, or later in adults, according to established roles in each society. In some cases, sex reassignment (14) is performed owing to misinterpretation of the sex at birth or change of subjective sex-identity later in the life. After maturation, sex can also be identified according to anatomical and functional roles in sexual practice (15). From biological, medical, and practical experiences and knowledge, it is evident that any of the modalities constitute a spectrum from normal female through different intersex states into normal male, and that successive developmental phases can be independent and different from the previous phases.

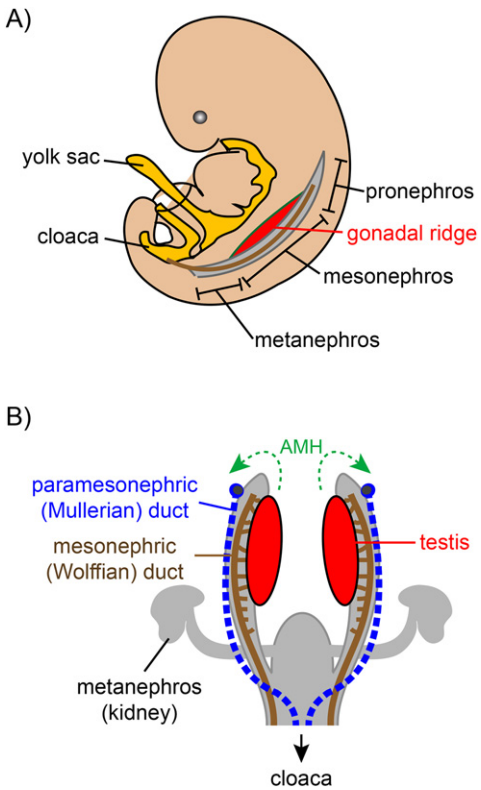

Fig. 2 Gonadal ridge outgrowth, testis differentiation, and establishment of the male reproductive tracts. (a) The gonadal ridges (red) first appear as regional thickenings on the ventral side of the mesonephros, the middle section of the nephrogenic cord that runs parallel on each side of the body midline. The anterior section of the cord is the pronephros (rudimentary kidney) that regresses in mammals, and the posterior section is the metanephros that differentiates into the adult functional kidney. (b) During early embryo development, the rudimentary ductal systems for both male (mesonephric, or Wolffian ducts; brown) and female (paramesonephric, or Müllerian ducts; blue) are present. As the testis differentiates, Sertoli cells produce and secrete anti-Müllerian hormone (AMH; green), which will cause the paramesonephric (Müllerian) ducts to regress (**Fig. 3**), leaving only the mesonephric (Wolffian) ducts to differentiate into the male urogenital structures such as epididymis, vas deferens, and seminal vesicles.

man and by embryonic day 12 in the mouse, after which testicular cords become apparent (Pelliniemi and Fröjdman, 2001; Svingen and Koopman, 2013).

The Testis

Testis development is a complex process involving numerous molecular and cellular events that bring about a sequential differentiation of many cell types that all have specific functions (Svingen and Koopman, 2013). In simple terms, mammalian testis differentiation is triggered by the expression of the sex determining gene *SRY* (located on the Y chromosome) in a few cells within the gonadal ridges of XY embryos. This activates a regulatory cascade that drives differentiation of Sertoli cell, which in turn orchestrate the initial phase of testis development. The Sertoli cells start to aggregate around clusters of germ cells to form irregular cord-like structures, effectively dividing the gonad into two distinct compartments; the testis cords (future seminiferous tubules) and the interstitium. The testis cords grow into loop-shaped tubes connected in each end to the mesonephric base of the testis, which later becomes the rete testis. Peritubular myoid cells then differentiate from interstitial precursors and form a continuous simple epithelial sheath around the testis cords. Together with the developing Sertoli cells, they secrete components that make up a basement membrane that serves both as physical barrier and as structural support for the testis cords. As the cords continue to grow, they buckle in on themselves to form a network of tubules resembling a bowl of spaghetti. The germ cells, now shielded from the interstitial space, enter mitotic arrest and lie more or less dormant until the initiation of meiosis during puberty.

Concomitant with testis cord development, early vascularization takes place with the formation of a distinct artery, the coelomic vessel, along the length of the gonad at the coelomic side (opposite the mesonephric side). Smaller arteries develop between the testis cords, with development of venous and lymphatic networks occurring later. The steroidogenic Leydig cells differentiate within the interstitial space and start producing androgens under the stimulation of human chorionic gonadotropin

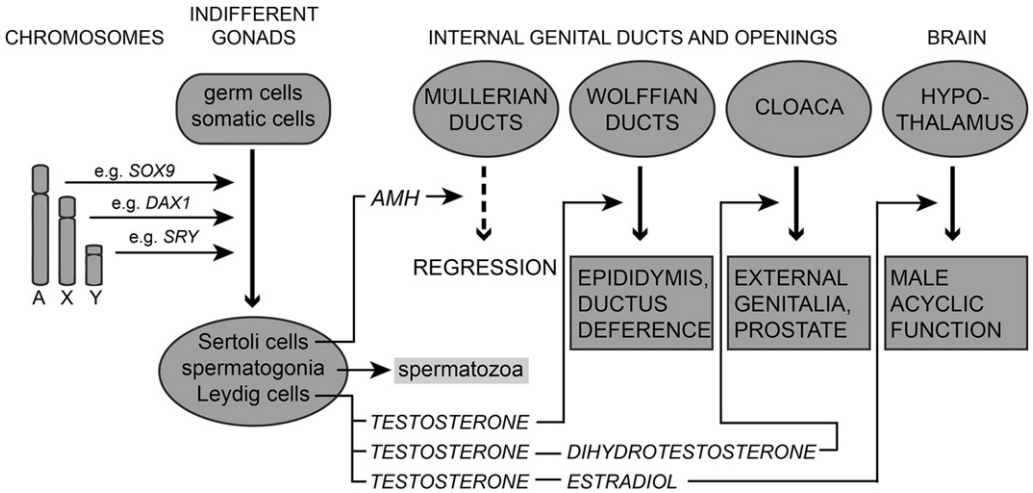

Fig. 3 The differentiation of testis and its subsequent activities in regulating the development of genital organs and brain in the male direction. The regulatory genes controlling testis differentiation are located on the autosomes (A), X chromosomes (X), and the Y chromosome (Y), exemplified by *SOX9*, *DAX1*, and *SRY* respectively. Genes involved in sex determination and differentiation typically have male (M) or female (F) promoting (or directing) functions. In most mammals, including humans, the gonadal sex determining factor is the Y-linked gene *SRY*. Its upregulation in XY gonadal ridges leads to expression of the crucial testis differentiation factor *SOX9*, which again regulates the expression of several downstream testis differentiation factors, for instance *AMH, DHH* and *PGDS*. The expression of SOX9 also suppresses ovary-promoting factors such as *WNT4*, *RSPO1*, and *FOXL2*. Following early differentiation, the fetal testis produces factors (primarily testosterone and AMH) that act on peripheral tissues and organs ultimately directing the fetus to develop into a male phenotype. Under the influence of these gene products, the indifferent gonads consisting of germ cells and undifferentiated somatic cells develop into a microscopically identifiable testis with cylindrical cords (consisting of Sertoli cells and spermatogonia) and the interstitial tissue (containing the Leydig cells). The Sertoli cells secrete AMH, which causes the female paramesonephric duct to regress and thus prevents the development of the oviduct, uterus, and vagina. The Leydig cells secrete testosterone, which via the circulation reaches the embryonic mesonephric duct and stimulates its differentiation into epididymis and ductus deferens. In a similar fashion, after conversion of testosterone into dihydrotestosterone, the prostate and external genitalia develop from the cloacal region of the embryo. Another conversion of testosterone into estradiol takes place in the brain, where the regulatory neurons in the hypothalamus will develop male acyclic function, thus preventing the later start of a menstrual cycle that develops in the female brain without perinatal exposure to testosterone.

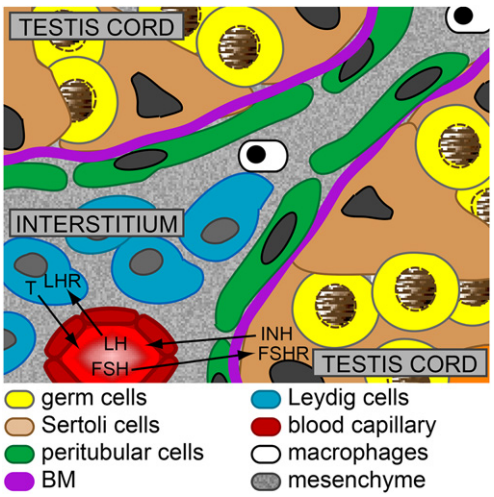

Fig. 4 Histological organization in the embryonic testis. The testicular cords consist of Sertoli cells (light brown) and spermatogonia (yellow). Together with peritubular myoid cells (green) encasing the testis cords, they deposit a basement membrane (BM; purple). The testis cords, future seminiferous tubules, are elongated and curved cylinders, much like spaghetti in a bowl. The tissue between the testis cords is referred to as the interstitium and consists of several cell types, the most prominent being the Leydig cells (blue). The interstitium also contains embryonic connective tissue (mesenchyme; grey background), vascular structures (red), macrophages (white), and peritubular myoid cells (green). The embryonic Sertoli cells produce anti-Müllerian hormone (AMH), which diffuses into the adjacent paramesonephric (Müllerian) ducts and causes their regression (see **Figures 2(b)** and **3**). During the late embryonic period the Sertoli cells have a receptor (FSHR) for the follicle-stimulating hormone (FSH) produced by the pituitary gland. The Sertoli cells also secrete inhibin (INH), which via the circulation is carried into the pituitary gland, where it inhibits the secretion of FSH. The interstitial Leydig cells secrete testosterone, which is locally transported into the peritubular cells and Sertoli cells, whereas testosterone reaches the other more distant target organs by testosterone secretion into the blood circulation through the testicular capillaries. In humans, the fetal Leydig cells are first regulated by hCG via the luteinizing hormone receptor (LHR) in their plasma membrane and later by luteinizing hormone (LH) via the same receptor.

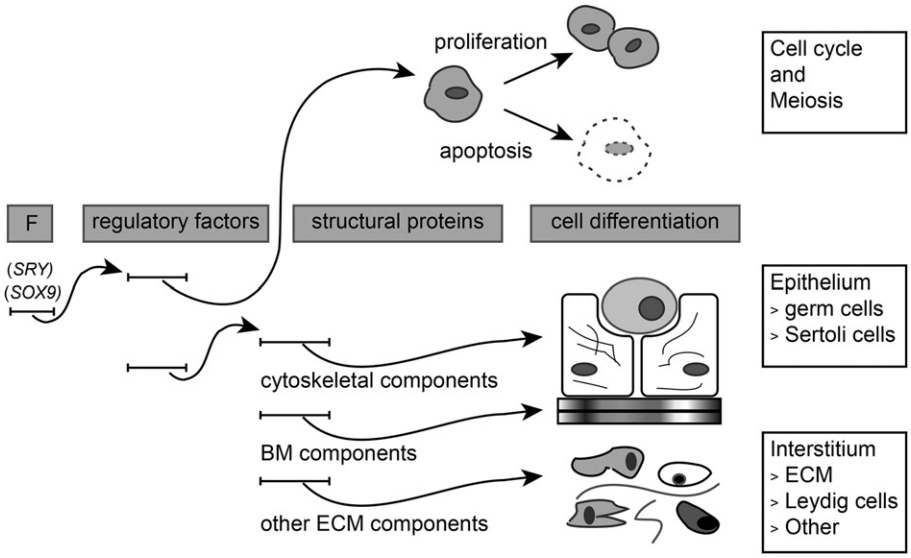

Fig. 5 Regulatory pathways driving testis organogenesis. Initially, sex determining and differentiation factors (F) drive the bipotential gonadal ridges toward a testicular fate. In most mammals, the Y-linked gene *SRY* acts as the male sex determining factor, leading to upregulation of *SOX9* and subsequent testis differentiation. In turn, SOX9 is a direct regulator of several genes in the Sertoli cells such as *AMH* and *DHH*; factors that directly act on other cell types and tissues. In simple terms, upstream regulators such as SOX9 act on other regulators that guide and regulate successive differentiation and proliferation events in other testicular cells, culminating in a compartmentalized and fully functional endocrine organ. During these events, some cells are also cleared by apoptosis, itself a crucial mechanism aiding morphogenesis. Although some primary targets of the testis differentiation factors (e.g., SOX9) are known, most remain to be identified. The segment lines depict genes and the arrows show the route and fate of the gene products, encompassing transcription factors, intermediate signaling molecules, as well as structural, secretory, and other proteins required by cells and the extracellular matrix (ECM). For instance, cytoskeletal components regulating cell shape and motility, basement membrane (BM) components separating and supporting epithelial tissues such as testicular cords in the testis, and ECM components such as collagens and fibronectin in the interstitium of the testis. The interstitial cells have protein components different from those in epithelial cells. The rate of cell cycle, apoptosis, and later meiotic divisions determine testicular growth-rate. The internal organization of the originally undifferentiated epithelial tissue into the testicular cords, which comprise the germ cells and Sertoli cells, is a diagnostic feature of testicular differentiation at the light microscopic level.

(hCG) from the placenta. Notably, hCG has emerged in primates and is typically not present in other mammals where the pituitary luteinizing hormone (LH) likely exerts similar actions.

Testosterone is necessary for proper somatic masculinization of the embryo. The most important regulatory hormones and their functions are described in **Fig. 4**. The interstitium also contains connective mesenchymal cells and macrophages.

Regulatory Mechanisms

The genetic and hormonal pathways that are involved in gonadal sex determination, testis differentiation and ultimately regulation of testicular function are extensive. Here we will highlight some of the most central and best studied, starting with testis determination by *SRY* expression. Once the transcription factor SRY has been activated in a subpopulation of somatic cells, it transcriptionally activates *SOX9*, which has emerged as the key regulator of Sertoli cell differentiation and thus testis development more generally. In turn, SOX9 (an SRY-related transcription factor) activates downstream target genes that themselves regulate various aspects of Sertoli cell differentiation, as well as juxtacrine and paracrine signal transduction pathways acting on other cells and tissues. For instance, regulatory loops involving the para-/autocrine factors FGF9 and PGD2 help ensure the differentiation and recruitment of a critical number of Sertoli cells necessary for testis development, whereas SOX9/SF1 synergistic transactivation of *AMH* ensures the secretion of AMH required for regression of the (female) paramesonephric (Müllerian) ducts (Svingen and Koopman, 2013; Wilhelm and Koopman, 2006). Another secreted factor produced by Sertoli cells is DHH, which influences the differentiation of both peritubular myoid cells and Leydig cells by acting on PTCH1 receptors that are present on most interstitial cells in the early embryonic testis (Franco and Yao, 2012).

The Leydig cells are the source of androgens (the most important being testosterone), which are synthesized *de novo* from cholesterol by the action of several enzymes including HSD3B1 and CYP17A1. Testosterone is in turn secreted into the endocrine circulation where it acts to stimulate the development of accessory sex organs and secondary sex characteristics, including those of the brain (Bocklandt and Vilain, 2007; Virtanen and Toppari, 2014). Leydig cells also produce the peptide hormone INSL3, a key factor inducing testicular descent by acting on the RXFP2 receptor located on the gubernaculum ligaments (**Fig. 5**).

Diseases

Diseases or disorders affecting testis development and/or function can include everything from failure to develop testes altogether during embryonic life, to infertility issues or testicular cancer in adulthood. Here, we will only briefly discuss disorders linked to embryonic development of the testis and not diseases caused by external factors later in life.

In contrast to the embryonic ovaries, the testes produce hormones that play a cardinal role in the regulation of sexual differentiation of the individual, before as well as after birth. Therefore, abnormal development or function of the embryonic testis can often manifest as partial or complete feminization of reproductive organs at birth. The most severe form of testicular disorder is the total lack of testes, as in XY pure gonadal dysgenesis, or Swyer syndrome (Michala et al., 2008). The underlying cause is mutations in genes necessary for early growth and differentiation of the genital ridges, such as *SRY* and *SF1*. As the testes fail to develop, there is no production of either AMH or testosterone, resulting in the formation of female rather than male internal and external reproductive organs and genitalia. This is one of many so-called disorders of sex development (DSD), congenital conditions in which 'development of chromosomal, gonadal, or anatomical sex is atypical' (Hughes et al., 2006). Other examples could include Leydig cell hypoplasia caused by loss-of-function mutations in the luteinizing hormone receptor (LHR), resulting in obstructed androgen production (and mild-to-severe feminized phenotypes such as hypospadia, micropenis or ambiguous genitalia); Klinefelter syndrome (Aksglaede and Juul, 2013), the presence of at least one extra X chromosome in the male karyotype, with typically mild (often undetected) phenotypic traits, although infertility is common; 5-alpha-reductase 2 deficiency (Costa et al., 2012), which is caused by mutations in the *SRD5A2* gene in genetic males and where affected individuals often are born with ambiguous or female external genitalia.

The most common disorder associated with the testis is cryptorchidism (undescended testis) (Virtanen and Toppari, 2014), where one or both of the testes are still located in the abdominal cavity or in the inguinal canal of the newborn. If the testis remains undescended after 4–6 months, medical intervention is important, as the undescended testis is prone to reduced (or lack of) spermatogenesis causing fertility issues, and potentially cancer development later in life.

Testicular neoplasms are fortunately rare and account for around 1% of cancers in men (Ferlay et al., 2010). Most common are germ cell tumors (95%) that, despite comprising a heterogeneous group of tumors, all are believed to originate from the primordial germ cells (Oosterhuis and Looijenga, 2005; Rajpert-De Meyts, 2006). The remaining 5% are somatic tumors and include cancers such as testicular lymphoma, Sertoli- or Leydig cell tumors. Consisting of hormone-producing cells, the Leydig cell tumors can cause strange symptoms by stimulating peripheral organs such as the genitals, hair follicles, and pituitary gland.

Glossary

Androgens Steroid hormones regulating development of male sexual characteristics.
Blood-testis-barrier *Cellular* barrier (tight band gap junction between Sertoli cells) separating the seminiferous tubules into a basal and adluminal compartment.
Cytokines Cell signaling molecules involved in autocrine, paracrine and immune regulation.
Follical Stimulating Hormone, FSH Gonadotropic hormone produced in the pituitary which stimulates Sertoli cells.
Leydig cell Interstitial cells producing testosterone on LH stimulation.
Luteinizing hormone, LH *Gonadotropic* hormone produced in the pituitary which stimulates testosterone production in Leydig cells.
Peritubular cell Smooth muscle cells surrounding seminiferous tubules, involved in testicular cord formation and transport (by peristaltic movement) of mature sperm into the epididymis.
Sertoli cell Testicular somatic cells and epithelial constituents forming the structural backbone of the seminiferous tubules. Sertoli cells form a syncytial-like epithelium with embedded layers of differentiating germ cells.
Spermatogenesis The process of male gametogenesis from undifferentiated spermatogonia to mature spermatozoa including sequential mitotic and meiotic divisions.
Testosterone Male sex hormone stimulating androgen dependent cellular functions and the development of male-specific sexual characteristics.

Stem Cell Niche

Term "Stem cell niche" was first introduced by Schofield in 1978 to describe the role of microenvironment in tissue-specific stem cell function (Schofield, 1978). Niches are exclusively specific to the tissue-specific stem cell populations (e.g., intestinal/hair-follicle/neural/testicular/bone marrow stem cells). Niche function is regulated by somatic cells depending on the developmental stage-specific requirements of the tissue (as in neuronal stem cells, symmetric or asymmetric divisions occur depending on the developmental stage-specific functional necessity) (Mione *et al.*, 1997)

Testicular Stem Cell Niche

The in vivo microenvironment of testicular stem cells also referred to as the "testicular stem cell niche," plays a significant role in maintaining the "stemness" and regenerative potential of these cells. The niche provides adequate nourishment, nutritional and

 doi:10.1016/B978-0-12-801238-3.65193-0

structural support to spermatogonial stem cells (SSCs) to maintain their self-renewal and differentiation potential (Fuchs *et al.*, 2004; Kanatsu-Shinohara and Shinohara, 2013). The testicular niche is presumably composed of components and growth factors secreted by Sertoli cells, peritubular cells, interstitial cells, germ cells, immune cells like macrophages, vasculature, blood-testis barrier (BTB) and basement membrane. Niches are constituted before the ultimate expansion and differentiation of SSC initiates (Oatley and Brinster, 2008; De Rooij, 2009). Recolonization of germ cells after transplantation experiments substantiates the presence of germ cell niches in testis. Depending on the distinct testicular organizational patterns (like U shaped, cystic and epithelial testis in Nematodes, *Drosophila* and Mammals, respectively), niche structures may vary in various organisms (Ramm *et al.*, 2014). Testicular niches are well studied in model organisms like *Drosophila* (Sheng and Matunis, 2011). However, the structural organization and functional role of niches in regulating spermatogenesis in other species, has yet to be completely understood. Some studies in mouse investigating spermatogonial populations provide evidence that SSC niche is most likely avascular. In contrast, lineage tracing studies in mouse, equine species (stallions and mules) and 3D-remodeling of rodent niches provide evidence that testicular niches are localized in close proximity to vasculature and interstitial region (Chiarini-Garcia and Russell, 2001; Chiarini-Garcia *et al.*, 2003; Yoshida *et al.*, 2007; Chan *et al.*, 2014; De Falco *et al.*, 2015). It has been shown that relocation of spermatogonia results in modified vascular dynamics, thus indicating a role of vascular components in defining the niche region. Although some additional molecular factors (like vascular endothelial growth factor (VEGF)) might be involved in linking vasculature in the interstitial region to the germinal epithelium (Nowak *et al.*, 2008; Yoshida *et al.*, 2007; Potter and DeFalco, 2017) (**Fig. 1**).

Different studies investigated the role of the somatic microenvironment and growth factors secreted by testicular somatic cells in development of the germline stem cell niche, and in SSC colonization, self-renewal, differentiation, apoptosis, de-differentiation and trans-differentiation of stem cells (**Table 1**). Amongst the somatic cells, Sertoli cells are considered to be the most significant constituent of the niche. Thus the number of Sertoli cells is supposedly key determinant of the number of germ cell niches and SSC numbers present in the testis. This has been substantiated by several clinical studies which show correlation of reduced Sertoli cell numbers with impaired spermatogenesis in humans (Hai *et al.*, 2014). Transplantation studies show a significant role of Sertoli cells in efficient SSC colonization of the testis. Recolonization was observed to be more efficient in neonatal recipients compared to adults (Carlson and Conboy, 2007). Studies show that SSCs associate with Sertoli cells by using laminin receptor (using transmembrane proteins α6 and ß1-integrin), chemokine receptor (CXCR4), RAS-related C3 botulinum substrate 1 (RAC1), a Rho-GTPase, translocate and recolonize the niche (Kanatsu-Shinohara *et al.*, 2008, 2012; Takashima *et al.*, 2011). Transplantation studies indicate the role of "adhesion molecules: α6 and ß1-integrin" in SSC homing in the basement membrane (De Rooij *et al.*, 2008; Kanatsu-Shinohara *et al.*, 2008). Kit ligand produced by Sertoli cells and its receptor C-kit is present in type A spermatogonia. Expression of C-kit is observed in differentiating germ cells (Rossi *et al.*, 1993; Sorrentino *et al.*, 1991).

In vitro studies show that maintenance of adequate levels of "Glial cell-line derived neurotrophic factor (GDNF)," a ligand of Gfra1 produced by Sertoli cells is necessary for maintenance of SSC numbers in the testes (Yomogida *et al.*, 2003). A specific feedback mechanism is supposedly involved in regulating adequate GDNF levels in the testis. An increase in GDNF levels leads to a reduced germ cell load and results in an increase of clusters of undifferentiated SSCs. A decrease in GDNF levels evokes a depletion of SSCs (Tadokoro *et al.*, 2002). It is speculated that other growth factors including fibroblast growth factor (FGF2), epithelial growth factor (EGF), leukemia inhibitory factor (LIF), insulin-like growth factor 1 (IGF1) may be complimenting GDNF in regulating SSC numbers (Oatley and Brinster, 2012). GDNF shows a fluctuating expression profile during specific epithelial stages (low during stage 7–8 and 9–11, and high during stage 2–6) (Johnston *et al.*, 2011; Sato *et al.*, 2011; Grasso *et al.*, 2012). In rodents and hamsters, Sertoli cells during different developmental stages show specific FSH expression patterns. FSH is considered to stimulate GDNF expression which is involved in SSC self-renewal; high GDNF expression corresponds with high FSH production. Both FSH and GDNF are thus reportedly involved in SSC localization (De Rooij, 2009; Oatley *et al.*, 2011). In primates, expression of GDNF in peritubular cells has been reported in response to androgen action, but not in Sertoli cells (Potter and DeFalco, 2017). GFRA1 expression has been observed in primate spermatogonia (Ad and Ap); although a heterogeneous expression profile was detected in humans. The functional role of GDNF/GFRA1/Ret pathway in primates is not completely understood.

"Retinoic acid (RA)" also acts on Sertoli cells via RA receptors (RARs), thus fine-tuning Sertoli cell-germ cell interactions. Local RA concentration fluctuates with the epithelial cycle and appears to initiate differentiation of SSCs (Sugimoto *et al.*, 2012). RA induction reportedly stimulates undifferentiated SSCs towards meiotic differentiation; meiotic arrest in germ cells was observed when RA synthesis was disrupted (Potter and DeFalco, 2017). Direct RA action in inducing differentiation is reported by rise in Stra8 and Kit expression and drop in POU5F1 and ZBT16 expression (Dann *et al.*, 2008; Zhou *et al.*, 2008; Busada *et al.*, 2015; Yang *et al.*, 2016). Vitamin A (source for RA) deficiency in mouse testis leads to impaired spermatogenesis (Griswold, 2016). RA is also known to be involved in BTB restructuring and spermatogenesis (Chung and Wolgemuth, 2004; Chung *et al.*, 2005, 2010; Hasegawa and Saga, 2012).

"Fibroblast-like growth factor (FGF2)" is secreted by Sertoli cells. Some studies indicate a significant role of FGFR receptors in spermatogonial selection and clonal expansion. In adult humans, FGFR is found to be expressed by small clones and undifferentiated spermatogonia which seldom divide (Von Kopylow *et al.*, 2012). It significantly enhances SSC self-renewal as patients with higher FGF2 levels show disturbed testicular function beginning at the spermatogonial level especially at older ages (Apert Syndrome, Goriely *et al.*, 2005).

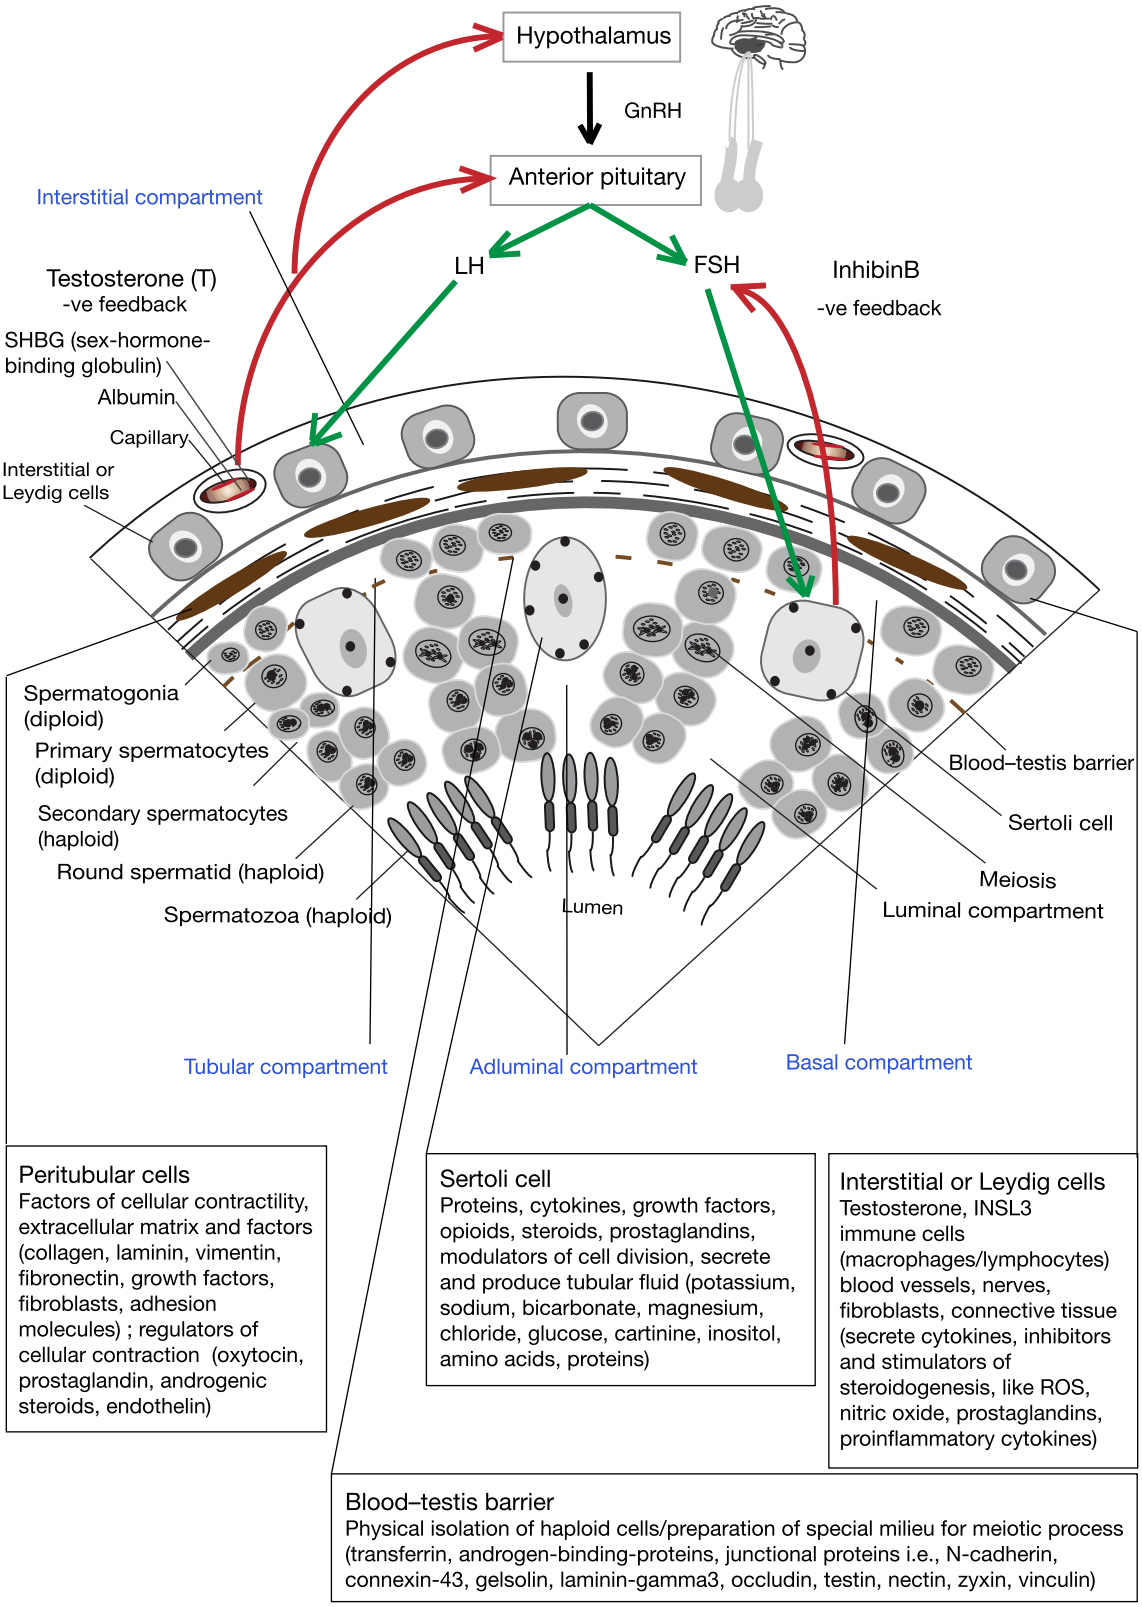

Fig. 1 Testicular niche with structural and functional organization of a testis. Testis comprises of dual compartments: Tubular and Interstitial. Tubular compartment is further subdivided into basal and adluminal compartment, which comprise of undifferentiated and differentiating cell types, respectively. Sertoli cell and peritubular cells are the two somatic cell types present in the tubular compartment. Interstitial compartment comprises of interstitial and immune cells. Endocrine regulation is controlled by the HPG axis. Growth factors secreted by testicular somatic cells either act independently or work synergistically with other niche factors to regulate Spermatogenic function, SSC renewal, proliferation and differentiation.

Table 1 Role and Function of testicular niche factors

Secreted niche component	*Name*	*Secreted/ expressed by*	*Role/function*	*Potentially affected by*	*References*
Growth factors	*GDNF*	Sertoli cells	SSC self-renewal, maintains SSC numbers in testis	FSH	Meng *et al.* (2000), Yomogida *et al.* (2003), and Kubota *et al.* (2004)
	FGF	Multiple testicular cells	Clonal expansion and spermatogonial selection, self-renewal, mitotic divisions, Sertoli-germ cell interactions	FSH	Von Kopylow *et al.* (2012), Goriely *et al.* (2005), Takashima *et al.* (2015), and Kubota *et al.* (2004)
	CSF1	Leydig cells, perivascular compartment	SSC self-renewal, proliferation, niche regulation, adult spermatogonial behavior	Unknown	Kokkinaki *et al.* (2009), Oatley *et al.* (2009), and Potter and DeFalco (2017)
	SCF	Multiple testicular cells	Apoptosis, cell proliferation, differentiation and migration	Unknown	De Rooij (2009)
	LIF	Peritubular cells	Maintenance of pluripotency, Cell proliferation, differentiation of gonocytes to SSCs	Unknown	Pellegrini *et al.* (2003) and Jung *et al.* (2010)
	IGF1	Multiple testicular cells	SSC self-renewal and survival, stimulates steroidogenesis	LH	Kubota *et al.* (2004), Oatley *et al.* (2009), Wang *et al.* (2015), and Cannarella *et al.* (2018)
	NGF	Multiple testicular cells	Involved in meiotic division, tubular integrity	LH	Nieschlag *et al.* (2010)
	TGFα & ß	Multiple testicular cells	Stimulates steroidogenesis	LH	Nieschlag *et al.* (2010)
	EGF	Sertoli cells	SSC proliferation, Meiotic initiation	LH	Oatley *et al.* (2009) and Chen *et al.* (2016)
	VEGF	Multiple testicular cells	SSC renewal, endothelial cell proliferation, survival, migration and permeability	Unknown	Oatley *et al.* (2009) and Potter and DeFalco (2017)
	SDF1 (or CXCL12)	Somatic cells	PGC migration	Unknown	Oatley *et al.* (2009)
	Activin A/B	Multiple testicular cells	Differentiation, steroidogenesis	FSH, LH	Nagano *et al.* (2003), Li *et al.* (2017), and Stanton (2016)
	BMP4	SSCs	Differentiation	Unknown	Nagano *et al.* (2003), and Pellegrini *et al.* (2003)
	Retinol	Multiple testicular cells	Initiation of meiosis, Differentiation of gonocytes, spermatogonia	Unknown	Hogarth and Griswold (2010, 2013) and Agrimson *et al.* (2016)
Transcription factors	e.g., *Ckit, Neuregulin1*	SSCs	Differentiation	Unknown	Stassen *et al.* (1999) and Oatley *et al.* (2009)
	Plzf	SSCs	SSC renewal and differentiation	Unknown	De Rooij (2009)
	Taf4b	SSCs	SSC maintenance	Unknown	De Rooij (2009)
Adhesion molecules	*Cadherin and Integrins (like α6 and ß1 Integrin, CDH1)*	SSCs	SSC homing (?), maintenance of undifferentiated SSC pool	Unknown	Oatley *et al.* (2009) and Chen *et al.* (2013)
Cytokines	Like ROS, nitric oxide, prostaglandin, pro-inflammatory cytokines	Immune cells (like macrophages, lymphocytes)	Inhibitors and stimulators of steroidogenesis	LH	Nieschlag *et al.* (2010)
Junctional Proteins	N-cadherin, connexin-43, gelsolin, laminin gamma-3, occludin, testin, nectin, vinculin, zyxin, claudin	BTB, Sertoli cells	Maintenance of BTB integrity and function	Androgens, LH, FSH	Holstein *et al.* (1996) and Stanton (2016)
Extracellular matrix and factors	Collagen, laminin, vimentin, fibronectin, growth factors, fibroblasts	Basement membrane, Peritubular cells	Maintenance of tubular and BTB integrity, BTB function	Unknown	Nieschlag *et al.* (2010)
Regulators of cellular contraction	Oxytocin, prostaglandin, androgenic steroids, endothelin, panactin, desmin, smooth muscle, actin	Multiple testicular cells (primarily peritubular cells)	Transport of mature sperm	Unknown	Holstein *et al.* (1996), Romano *et al.* (2005), and Nieschlag *et al.* (2010)

Table 1 Continued

Secreted niche component	*Name*	*Secreted/ expressed by*	*Role/function*	*Potentially affected by*	*References*
Non receptor protein kinases	c-Src, c-Yes	BTB	BTB integrity	Unknown	Cheng and Mruk (2002, 2012)
Steroids	Testosterone	Leydig cells	Regulates spermatogenesis, maintenance of BTB integrity and function	LH	Cheng and Mruk (2012) and Walker (2009, 2010)
	Estradiol-17ß	Multiple testicular cells	Regulates BTB function, influences spermatogenesis	LH, FSH	Cheng *et al.* (2011) and Cheng and Mruk (2012)

Interstitial cells stimulate 17-β HSD (hydroxysteroid dehydrogenase) secretion which influences rise in testosterone production. In testis, testosterone binds to "Androgen Receptor (AR)" or "Androgen-Binding Protein (ABP)" and influences spermatogenesis (Potter and DeFalco, 2017). By binding to cytoplasmic AR, testosterone allows secretion and shift of cytoplasmic AR to nuclear location and facilitates its DNA-binding transcription factor function (like modulation of transcription factors *Igf1r*) (Blok *et al.*, 1992; Zhu *et al.*, 2000). In adults, AR is involved in effecting synergistic function of Sertoli cells and adhesion molecules involved in BTB (Blood-testis barrier) formation (Chang *et al.*, 2004; Meng *et al.*, 2005; Wang *et al.*, 2006). Interstitial cells also secrete INSL3 (Insulin-like Factor 3), which presumably influences spermatogenesis via LGR8, found to be expressed in interstitial and mature germ cells (Foresta *et al.*, 2004; Anand-Ivell *et al.*, 2006).

"Insulin-like growth factor 1 (IGF1)" is involved in proliferation of testicular cells showing IGF1R expression (Sertoli cells, Interstitial cells, SSCs and differentiating germ cells). In vitro studies show that interstitial cells regulate their expansion, differentiation and testosterone production through IGF1 secretion in culture. IGF1 influences SSC propagation in conjunction with GDNF, it cannot influence SSC proliferation independently. IGF1 influences synthesis of DNA and acts through IGF1R and AKT signaling pathway, instead of MAP kinases employed by GDNF (Kubota *et al.*, 2004; Wang *et al.*, 2015).

"Colony stimulating factor 1 (CSF1)" expressed in interstitial and peritubular cells is supposedly involved in increasing colony forming potential of spermatogonia, SSC self-renewal, colonization and niche regulation (Oatley *et al.*, 2009). Together with GDNF/FGF, it influences SSC proliferation without impacting rate of proliferation (Oatley *et al.*, 2009). Increased expression of Colony stimulating factor 1 (CSF1) receptor was observed in undifferentiated SSCs (Kokkinaki *et al.*, 2009; Oatley *et al.*, 2009; Potter and DeFalco, 2017). Different studies also report the role of macrophages in influencing spermatogenesis through secretion of CSF1, RA, other cytokines and chemotactic factors (Kokkinaki *et al.*, 2009; Oatley *et al.*, 2009; De Falco *et al.*, 2015).

Growth factors in the niche like "Activin A, BMP4 and SCF" are reportedly involved in germ cell differentiation. In vitro studies show role of these factors in inhibiting self-renewal, and stimulating differentiation (De Rooij, 2009). "Regulatory proteins" including Cdc42, Rho, Rac GTPases, Arp2/3 involved in cellular motility, are secreted by both Sertoli and germ cells. Although Sertoli cells are nonmotile in vivo, they supposedly form pores and extensions in vitro when cultured (Mruk *et al.*, 1997). Actin proteins and signaling molecules secreted by germ cells are reportedly involved in germ cell locomotion (Xiao *et al.*, 2014).

In addition, "intercellular adhesion molecules" ICAMs (1, 2, 3, 4, 5) c-Yes and c-Src (members of nonreceptor protein tyrosine kinase family) expressed by both Sertoli and germ cells and Focal adhesion kinase (FAK) expressed in basal membrane also influence germ cell transport (Xiao *et al.*, 2014). Translocation of preleptotene spermatocytes at epithelial stage 8, through the BTB to the adluminal compartment results in disintegration of old BTB and formation of a new BTB (Xiao *et al.*, 2014). "Cytokines" like Transforming Growth factors TGFß2 and ß3, Tumor necrosis factor TNFα, Interleukin-IL1α play a significant role in regulating BTB restructuring and dynamics (Cheng and Mruk, 2002).

Soma-germline interactions play a significant role in regulating testicular homeostasis through signaling pathways. These factors might also influence aging processes affecting testicular stem cells in older males. Studies show that during aging, somatic components do not retain their innate functional and nourishment potential, thus resulting in decreased functional efficiency of stem cells. However, when stem cells from older males were transplanted in younger hosts, transplanted cells demonstrate normal regenerative potential and function (Carlson and Conboy, 2007). This substantiates a significant role of niche factors in functional regulation of stem cells. The role of stem cell niches and growth factor enriched microenvironment appears to be central in determining the fate of germ cells (Oatley and Brinster, 2012). Decline in niche function causes impaired spermatogenesis, thus giving rise to subfertility or infertility in men (Oatley and Brinster, 2012).

In the past few years, several in vivo and in vitro studies investigated the role of different transcriptional regulators and testicular factors as illustrated in **Table 1** in maintaining homeostasis and modulating stem cell fate decisions (like self-renewal or differentiation) (Kanatsu-Shinohara and Shinohara, 2013; Kanatsu-Shinohara *et al.*, 2014, 2016b; Takashima *et al.*, 2013; Chan *et al.*, 2014; Kimura *et al.*, 2014; Takashima *et al.*, 2015; Morimoto *et al.*, 2015). However, there is very limited understanding on biological function and components of the niche, how the niche regulates the stem cell pool and which specific factors are functionally involved in maintenance of homeostasis, self-renewal and differentiation (Kanatsu-Shinohara and Shinohara, 2013).

Endocrine Regulation

GnRH synchronously regulates spermatogenesis and steroidogenesis, two autonomous feedback mechanisms which control LH-testosterone and FSH-inhibin axis (Plant and Marshall, 2001). LH-testosterone axis controls androgen production, whereas FSH-inhibin axis controls sperm production (Schlatt and Ehmcke, 2014). LH and FSH are produced in the anterior pituitary. These heterodimers are composed of noncovalently linked α and β subunits, α subunits are common in both hormones; however distinct β subunits regulate their specific biological functions (Combarnous, 1992). LH action on Leydig cells stimulates androgen production which in turn controls androgenization, by stimulating male-specific phenotypic features. FSH receptors are exclusively expressed in Sertoli cells (Dankbar *et al.*, 1995). FSH action on Sertoli cells regulates the expansion of Sertoli cells and thereby determines the number of niches and the size of the SSC pool, which limits maximal sperm production. In primates, FSH works in concert with testosterone for maintenance of spermatogenic function (Schlatt and Ehmcke, 2014). Inhibin B levels are considered an important indicator for the pituitary and serve as a feedback signal to the hypothalamus, to determine sperm production capacity (Schlatt and Ehmcke, 2014; Ramaswamy *et al.* 2000a,b, 2003).

Germ Cell Differentiation, Male

My-Thanh Beedle and Michael D Griswold, Washington State University, Pullman, WA, United States

Introduction

Spermatogenesis is the process by which males produce spermatozoa. This process takes place within the seminiferous tubules that contain both germline cells and somatic cells. Sertoli cells are large columnar somatic cells that span from the basement membrane to the lumen of the seminiferous tubules and serve as support cells that surround the developing germ cells. Sertoli cells provide structural support, essential nutrients and regulatory factors for germinal cell development (Griswold, 1998; de Rooij and Russell, 2000). Between the seminiferous tubules in the interstitial space are macrophages, Leydig cells, blood and lymphatic vessels. The steroidogenic Leydig cells are of central importance as these cells generate and secrete the male hormone testosterone that is required to initiate and maintain spermatogenesis.

Most of what is known about the spermatogenetic process has been obtained using rodent models because numerous gene ablation/overexpression models exist, in which spermatogenesis is arrested at different developmental stages. Despite the immense amount of interest that has been devoted to understanding the molecular controls committing spermatogonia to their differentiation pathway, much still remains to be learned. The focus of this article is to provide a brief review of the key signaling pathways and molecules implicated in regulating spermatogonial differentiation.

Male Germ Cell Development: A Primer

In the male mouse, germ cell competence is induced at embryonic day 6.5 (E6.5) in the proximal epiblast as directed by signals arising from the extraembryonic ectoderm (Lawson and Hage, 1994). These precursor cells will transition into the primordial germ cells (PGCs) and will then migrate through the dorsal mesentery to reach the genital ridges between E10.5 and E12.5 (Ginsburg *et al.*, 1990; Lawson and Hage, 1994; Richardson and Lehmann, 2010; Saitou, 2009; Molyneaux *et al.*, 2001). Once at the genital ridges, PGCs become surrounded by the developing Sertoli cells, forming the seminiferous cords. The PGCs, now called gonocytes or preferably, prospermatogonia that will proliferate for several days until around 15–16 days post coitum (dpc) when they enter quiescence (Donovan *et al.*, 1986; Tam and Snow, 1981; Kluin and de Rooij, 1981; Vergouwen *et al.*, 1991; Moreno *et al.*, 2010). Two to three days after birth, the arrested gonocytes will: (1) resume mitotic proliferation, (2) migrate from the center of the tubules to the basement membrane, and (3) transition into spermatogonia (Ginsburg *et al.*, 1990).

Shortly after birth the germ cells within the developing testis consist of stem cells and progenitor cells or undifferentiated spermatogonia. The spermatogonial stem cells (SSCs) can self-renew or divide to form two progenitor spermatogonia (A_{paired} or A_{pr}) that are connected by an intercellular bridge (de Rooij and Russell, 2000). These A_{pr} spermatogonia can undergo additional divisions to form syncytial chains of 4, 8, 16, and 32 bridge-connected cells, collectively called the $A_{aligned}$ (A_{al}) spermatogonia (de Rooij and Grootegoed, 1998). The proliferation of the syncytial chains is random with regard to the cycle of the seminiferous epithelium. The progression of A_{al} undifferentiated spermatogonia to differentiating (A1) spermatogonia (A to A1 transition) is a critical regulatory point, as it represents the irreversible commitment of spermatogonia to proceed through meiosis (de Rooij, 2001; Griswold 2016).

In response to an extrinsic signal (retinoic acid), the undifferentiated population will differentiate without a mitotic division to form the first differentiating A_1 spermatogonia. This differentiation step and the subsequent mitotic divisions primes the germ cells to become competent to enter meiosis and eventually results in the production of spermatozoa. Thus, the A to A_1 transition is tightly controlled both temporally and spatially and it is this transition that leads to the cycle of the seminiferous epithelium. In the mouse the A_1 spermatogonia will undergo five additional mitotic divisions to form chains of A_2, A_3, A_4, intermediate (In), and the B spermatogonia (Aponte *et al.*, 2005; Phillips *et al.*, 2010; de Rooij and Russell, 2000). The B spermatogonia will transition into the preleptotene spermatocytes, which will proceed through the first meiotic division to form the secondary spermatocytes. The second meiotic division follows rapidly and gives rise to haploid round spermatids that will then undergo drastic morphological changes during spermiogenesis to become immature spermatozoa. These spermatozoa will the complete their maturation process as they transit through the epididymis.

FSH, Testosterone and Retinoic Acid

Both FSH and testosterone are known to be necessary for normal spermatogenesis in mammals and both have their primary action on Sertoli cells. Gene deletion experiments for the FSH receptor have shown that FSH action is not normally required for fertility but that it ultimately governs the number of Sertoli cells and the size of the germ cell pool (Krishnamurthy *et al.*, 2000). In

 doi:10.1016/B978-0-12-801238-3.11110-9

androgen receptor gene deletions, progression of round spermatids to elongating spermatids was inhibited when the androgen receptor function was deleted in Sertoli cells, but progression through meiosis was surprisingly not completely blocked. In one of these studies the numbers of spermatocytes, round spermatids, and elongated spermatids were reduced to 64%, 3%, and 0% respectively, when compared to WT (de Gendt *et al.*, 2004).

In contrast to androgens and gonadotropins, retinoic acid (vitamin A) can act directly on germ cells and promote the development of A spermatogonia to A1 differentiating spermatogonia (for review see (Griswold, 2016)). The essential role of vitamin A for spermatogenesis was established in 1925, when researchers found that rodents fed a vitamin A deficient (VAD) diet were infertile (Wolbach and Howe, 1925). Morphological examination of VAD testes demonstrated the loss of the advanced germ cells and the presence of only Sertoli cells and undifferentiated spermatogonia within the seminiferous tubules indicated the presence of a block in spermatogonial differentiation (van Pelt and de Rooij, 1990, 1991; Gaemers *et al.*, 1996, 1998; Huang and Hembree, 1979; Ismail *et al.*, 1990; Morales and Griswold, 1987; Mitranond *et al.*, 1979). An exogenous injection or dietary replenishment of retinoids reinitiated spermatogenesis by stimulating the arrested A_{al} spermatogonia to differentiate into A_1 spermatogonia, resulting in the production of spermatozoa within retinoid rescued testes (van Pelt and de Rooij, 1990; Clagett-Dame and Knutson, 2011; Griswold *et al.*, 1989; Huang and Hembree, 1979; Morales and Griswold, 1987; Wilson *et al.*, 1953; Wolbach and Howe, 1925). These foundational experiments demonstrated that retinoic acid plays a critical role in regulating spermatogonial differentiation.

The action of RA on the expression of target genes is mediated through two families of nuclear hormones receptors: the retinoic acid receptors (RARs) and the retinoid X receptors (RXRs). Each of these two receptor families consists of three subtypes, α, β, and γ (Chambon, 1996). In cells, RA binds and activates these nuclear receptors which are bound as RAR–RXR heterodimers to retinoic acid response elements (RAREs) in the regulatory regions of target genes (Bastien and Rochette-Egly, 2004). Mouse models with a depletion of either RARα or RXRβ are sterile (Lufkin *et al.*, 1993; Kastner *et al.*, 1996). Although loss of the RARγ receptor located in developing germ cells does not result in sterility, morphological analysis demonstrated that depletion of the RARγ receptor does result in an impairment of the A to A1 transition (Gely-Pernot *et al.*, 2012). Accordingly, ectopic expression of *Rar*γ induced the differentiation of RARγ-negative undifferentiated spermatogonia (Ikami *et al.*, 2015). Studies of mutant mice lacking multiple RARs or RXRs have also provided evidence that retinoid signaling is essential for spermatogonial differentiation (Gely-Pernot *et al.*, 2012, 2015). In addition, when a dominant-negative mutant of RAR was used to conditionally block retinoid signaling specifically in germ cells, the corresponding mutant was not only sterile but also had a complete block in spermatogonial differentiation (Chen *et al.*, 2016).

Testicular Gene Products Directly Affecting Germ Cell Differentiation

Recent technical advances have allowed for a more detailed description of some of the gene products made by testicular germ and/or somatic cells that directly affect germ cell differentiation. Some of the more central factors and well-studied gene products are discussed below.

Sertoli Cell Ligands/Germ Cell Receptors That Regulate Germ Cell Differentiation

Kit/*Kitl*: A commonly used marker of spermatogonial differentiation is KIT (c-KIT), a tyrosine kinase receptor that is located on the surface of germ cells (Besmer *et al.*, 1993). KIT is expressed in a variety of cell types in the postnatal testis ranging from A_{al} spermatogonia to preleptotene spermatocytes and Leydig cells (Manova *et al.*, 1990; Yoshinaga *et al.*, 1991; Schrans-Stassen *et al.*, 1999; de Rooij *et al.*, 1999). The KIT receptor is activated by the binding of its ligand, KITL (also called stem cell factor, SCF), secreted by neighboring Sertoli cells. Upon activation via KITL binding, the KIT receptor stimulates a signaling cascade across the plasma membrane to regulate cellular events (Motro *et al.*, 1991; Marziali *et al.*, 1993). This signaling cascade initiated by KIT has been shown to be critical for the survival, proliferation, and differentiation of spermatogonia. Mutations in either *Kit* (such as *Dominant White Spotting, W*) or *Kitl* (such as *Steel, Sl*) disrupt the KIT/KITL signaling pathway and lead to sterility. Accordingly, analysis of mouse models with heterozygous mutations in the *Dominant White Spotting* locus (*Kit*) or *Steel* locus (*Kitl*) resulted in a block at the A to A1 transition (de Rooij *et al.*, 1999; Koshimizu *et al.*, 1991; Sawada *et al.*, 1991). These observations were further confirmed when another mutant line, *Sl17h/Sl17h* ($Kitl^{Sl}$), containing a splicing defect in the cytoplasmic tail of the KITL protein was shown to contain only Sertoli cells and actively proliferating undifferentiated spermatogonia within the seminiferous epithelium (de Rooij and Grootegoed, 1998; Brannan *et al.*, 1992; de Rooij *et al.*, 1999). Transplantation experments in which wild-type germ cells were transplanted into $Kitl^{Sl}$ mutant recipents revealed that the transplanted spermatogonia expanded and proliferated, however no differentiaion of donor spermatogonia into A_1 spermatogonia was observed (Ohta *et al.*, 2001). Collectively, these studies with mutated KIT or KITL proteins demonstrate that the signaling cascade regulated by KIT/KITL receptor ligand complex is necessary for the irreversible transition of undifferentiated spermatogonia into A_1 differentiating spermatogonia.

Glial cell line-derived neurotropic factor (GDNF): GDNF, an extrinsic factor secreted by the Sertoli cells, is a distant member of the transforming growth factor-β (TGF-β) superfamily of proteins (Saarma, 2000). GDNF is a key factor involved in the self-renewal of undifferentiated spermatogonia but also modulates the ability of spermatogonia to respond to differentiation signals (Meng *et al.*, 2000). Since mice with a null mutation in *Gdnf* die during the first postnatal days, mice with a heterozygous null mutation in *Gdnf*

were examined for the effects of GDNF on spermatogenesis. Testes from those animals displayed a progressive loss of spermatogonia, often resulting in Sertoli cell-only seminiferous tubules (Meng *et al.*, 2000). However, mice containing a transgene overexpressing *Gdnf* displayed an accumulation of undifferentiated spermatogonia, correlating to a block in the ability of spermatogonia to differentiate (Meng *et al.*, 2000). Intriguingly, attempts to rescue this block in differentiation by RA administration resulted in apoptosis of the undifferentiated spermatogonia (Meng *et al.*, 2000). This impaired ability of spermatogonia in the GDNF overexpressed testes to respond to differentiation signals and proceed along their differentiation pathway resulted in infertility (Meng *et al.*, 2000). GDNF mediates its signaling through a receptor complex comprising of the GDNF family receptor alpha 1 (GFRα1) and a ret. receptor tyrosine kinase (RET) (Golden *et al.*, 1999; Yomogida *et al.*, 2003). These receptor complexes are localized to the surface of the undifferentiated spermatogonia (Buageaw *et al.*, 2005; He *et al.*, 2008; Jijiwa *et al.*, 2008; Johnston *et al.*, 2011). Mutations in any of these signaling components results in spermatogenic phenotypes that are analogous to that of GDNF null mice (Buageaw *et al.*, 2005; Jijiwa *et al.*, 2008; Naughton *et al.*, 2006).

Regulatory Factors Endogenous to Germ Cells

PLZF (promyelocytic leukemia zinc finger) or Zbtb16: PLZF is a transcriptional repressor that is expressed in undifferentiated progenitor spermatogonia and was the first gene shown to be essential for stem cell self-renewal in the mouse testis. Homozygous mutant mice produced low numbers of spermatozoa and the germ line was increasingly depleted with age (Buaas *et al.*, 2004).

Inhibitor of differentiation 4 (ID4): ID4 is the first clear marker for spermatogenic stem cells. In adult mouse testes ID4 is expressed exclusively in single cells presumably representing the stem cell population (Chan *et al.*, 2014). These observations suggest that the spermatogenic stem cell population consists of a subset of the A_s or A_{single} cells. When germ cell populations containing ID4-GFP genes were isolated, sorted by ID4-GFP expression and transplanted, all of the transplantation success that indicated the presence of stem cells was in the ID4-GFP positive population (Chan *et al.*, 2014) (**Fig. 1**).

Deleted in azoospermia-like (DAZL): DAZL is an RNA-binding protein belonging to the DAZ (deleted in azoospermia) family of proteins (Reijo *et al.*, 1995). Unlike the *Daz* gene cluster which is found only on the Y chromosome in humans and old-world primates, the single-copy *Dazl* gene is an autosomal homolog that is highly conserved throughout evolution in humans, monkeys, rodents, flies, frogs, fish, and worms (Yen *et al.*, 1996; Reijo *et al.*, 1995; Ruggiu *et al.*, 1997; Cooke *et al.*, 1996; Saxena *et al.*, 1996; Houston *et al.*, 1998; Maegawa *et al.*, 1999; Eberhart *et al.*, 1996). As the name infers, deletions in the *Dazl* gene are strongly associated with infertility in both sexes (Tung *et al.*, 2006; Reijo *et al.*, 1995; Vogt *et al.*, 1996). Due to the clinical significance of mutations in the *Dazl* gene, a lot of interest has been devoted to understand the underlying cause of spermatogenic arrest. Studies have shown that expression of DAZL is germ cell specific and it can be detected postnatally in B spermatogonia, preleptotene spermatocytes, zygotene spermatocytes, and pachytene spermatocytes (Ruggiu *et al.*, 1997, 2000). It has been suggested that DAZL enables germ cells to initiate meiosis in response to retinoic acid (Lin *et al.*, 2008).

Spermatogenesis and oogenesis specific helix-loop-helix (SOHLH): The SOHLH proteins are basic helix-loop-helix transcription factors that play critical roles in cell differentiation. SOHLH1 is expressed in A_{al} through B spermatogonia while SOHLH2 is expressed in A_s through A_4 differentiating spermatogonia (Ballow *et al.*, 2006a,b; Toyoda *et al.*, 2009). As with mutants that display a disruption in spermatogonial differentiation, *Sohlh1* null testes lack differentiating populations; however, proliferating

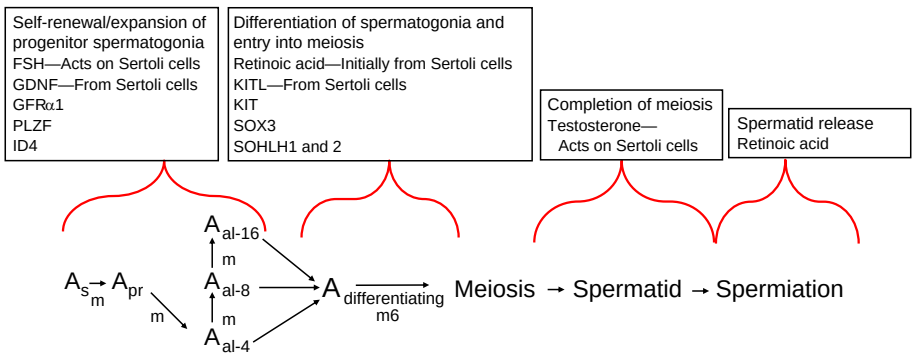

Fig. 1 Summary of male germ cell development from stem cells to sperm formation in the mouse. The major steps in this development and the factors influencing the process are shown. The first steps involve the expansion (m) of cell numbers from A_s (spermatogenic stem cells) into syncytial chains of A_{al} (A aligned) spermatogonia up to as many as 16 cells. This pool of progenitor spermatogonia is influenced by the actions of FSH and GDNF through the Sertoli cells and directly by GFRα1, PLZF and ID4 expressed in the germ cells (see text). In the presence of retinoic acid most of the pool of progenitor cells become differentiating spermatogonia that undergo 6 mitoses (m6), express KIT, Sox3 and the SOHLH proteins and ultimately form preleptotene spermatocytes. In the first wave of cells becoming differentiating spermatogonia the source of the retinoic acid is the Sertoli cells. In subsequent waves of cells the source of retinoic acid may be the more advanced *gem* cells (Griswold 2016). The advancement of preleptotene spermatocytes into meiosis also appears to require retinoic acid. Testosterone acting through Sertoli cells is required for the completion of meiosis and retinoic acid is required once again for the release of spermatozoa into the lumen of the seminiferous tubules.

undifferentiated spermatogonia can still be observed in 8-month old testes (Ballow *et al.*, 2006a). *Sohlh2* null mice show degenerating colonies of A_2–A_4 differentiating spermatogonia and have a disrupted appearance of KIT+ spermatogonia, which is also suggestive of a block in spermatogonial differentiation (Hao *et al.*, 2008; Toyoda *et al.*, 2009). Since these transcription factors can form homo- or heterodimers and mRNA expression of one factor increases when the other is disrupted, it was proposed that they may: (1) function together and (2) functionally compensate for each other to regulate the expression of genes involved in spermatogonial differentiation (Massari and Murre, 2000; Ballow *et al.*, 2006a; Hao *et al.*, 2008; Toyoda *et al.*, 2009; Suzuki *et al.*, 2012). These SOHLH proteins are additional transcriptional regulators that play essential roles in regulating the A to A_1 transition.

SRY-box containing gene 3 (SOX3): Sox3 is a member of the high mobility group (HMG) family of transcription factors (Collignon *et al.*, 1996). The single-exon gene encoding *Sox3* is located on the X-chromosome and is closely homologous with the SoxB1 family of genes, which includes *Sox1* and *Sox2* (Collignon *et al.*, 1996; Schepers *et al.*, 2002). Immunohistochemistry analysis showed that SOX3 is specifically expressed in the undifferentiated spermatogonia (A_s, A_{pr}, and A_{al}) (Rizzoti *et al.*, 2004; Raverot *et al.*, 2005). Laronda and colleagues conditionally eliminated *Sox3* from germ cells using the vasa-cre (Laronda and Jameson, 2011). These mice displayed an accumulation of spermatogonia and a drastic reduction in the number of differentiating spermatogonia. It is worth noting that this block in spermatogonial differentiation induced by elimination of *Sox3* is not permanent, as adult mice testis tubules displayed relatively normal spermatogenesis. Clearly, more research will be needed to determine the mechanism by which *Sox3* influences spermatogonial differentiation and the mechanism by which *Sox3* null males are able to recover.

Conclusions

Spermatogonial differentiation marks the irreversible commitment of spermatogonia to undergo meiosis and results in the production of spermatozoa. Despite the central importance of spermatogonial differentiation to male fertility, we still remain largely in the dark about the molecular controls which regulate this critical transition. It is becoming increasingly clear that this regulatory point is highly sensitive to perturbations, as disruptions to key signaling pathways and molecules (some of which were discussed above) result in a halt in spermatogenesis at this transition. The identification of these signaling molecules and pathways has provided us with considerable insights; however, the leaky phenotypes that are observed in some null models (e.g., SOHLH and SOX3 proteins) have made interpretations of the exact point at which spermatogonial differentiation is arrested difficult to ascertain. Our understanding of these arrest phenotypes is further hampered by our limited understanding and ability to distinguish between the different subpopulations of differentiating spermatogonia. Future studies aimed at dissecting the molecular details underlying each of the differentiating spermatogonia subpopulations may further elucidate the molecular mechanisms regulating the commitment of spermatogonia into meiosis and through spermiogenesis.

Endocrine Control of Spermatogenesis☆

TM Plant and S Ramaswamy, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA and Magee-Womens Research Institute, Pittsburgh, PA, USA
Karel De Gendt, Catholic University of Leuven, Leuven, Belgium

Glossary

Apoptosis Programmed cell death; benign process of cell suicide.

Azoospermia, oligozoospermia, and teratozoospermia Absence of spermatozoa in the ejaculate, low concentration of spermatozoa in the ejaculate, and sperm with abnormal morphology, respectively.

Paracrine factor Growth factor or signaling molecule released by cells into the extracellular medium and acting on neighboring cells.

Spermatids Haploid germ cells, differentiating progressively from round spermatids to elongated spermatids and sperm in a process known as spermiogenesis.

Spermatocytes Tetraploid germ cells undergoing two successive meiotic divisions to produce haploid round spermatids.

Introduction

The adult testis has two main functions: the production of sperm and the production of androgens (primarily testosterone). These functions are intimately coupled and are controlled by two gonadotropins secreted by the anterior pituitary: luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Both of the gonadotropins are composed of two peptide subunits, a common α-subunit and a unique β-subunit that confers biological activity on each heterodimer. LH acts on the Leydig cells located in the interstitial compartment of the testis to stimulate the synthesis of testosterone, which is required to initiate spermatogenesis at puberty and maintain the process in the adult. An important action of testosterone is on the Sertoli cells to promote germ cell proliferation and development. Sertoli cells are the somatic component of the seminiferous tubules where spermatogenesis occurs. FSH acts in concert with testosterone, also by an action on the Sertoli cells. The production of the gonadotropins, in turn, depends on intermittent stimulation by the neuropeptide, gonadotropin-releasing hormone (GnRH), which is synthesized in the hypothalamus and is secreted in a pulsatile manner into the hypophyseal-portal circulation under the control of the GnRH pulse generator in the arcuate nucleus. Kisspeptin is considered to relay the output of the pulse generator to the GnRH neuronal network. The gametogenic and steroidogenic output of this neuroendocrine axis is regulated by testicular feedback signals, primarily testosterone and inhibin B (Fig. 1). This article first describes the fundamental aspects of spermatogenesis and then discusses the endocrine control of the process with a particular focus on testosterone and FSH, the major hormones that are directly involved.

Organization of Spermatogenesis

Spermatogenesis is the process through which diploid stem cells (spermatogonia) multiply and divide into haploid cells that then differentiate into mature spermatozoa. In humans, and in many other species, this is a continuous process resulting, from puberty onward, in the production of vast numbers of spermatozoa (some 10^8 spermatozoa/day or 1000 per heartbeat!). The spermatogenic process is complex but can be divided into five major phases or steps: (1) balance of spermatogonial stem cell (SSC) differentiation and self-renewal; (2) mitotic amplification and differentiation of the spermatogonial progeny of SSC differentiation; (3) entry of differentiating spermatogonia into meiosis with subsequent formation of primary spermatocytes, secondary spermatocytes, and (haploid) round spermatids; (4) differentiation of round spermatids leading to the formation of elongated spermatids and spermatozoa – a complex process known as spermiogenesis and characterized by major morphological changes to the cell, such as the appearance of an acrosome, the formation of a flagellum, and nuclear condensation; and (5) spermiation, the release of spermatozoa into the tubular lumen.

The spermatogenic process is remarkably organized, both spatially and temporally (Figs. 2 and 3). Spatially, developing germ cells move from the periphery of the seminiferous tubules toward the central lumen. In doing so, they are supported by Sertoli cells with which they develop intimate morphological and functional interactions. During their migration and before completion of meiosis, germ cells cross a very tight barrier (blood–testis barrier) formed by specialized junctions situated at the base of

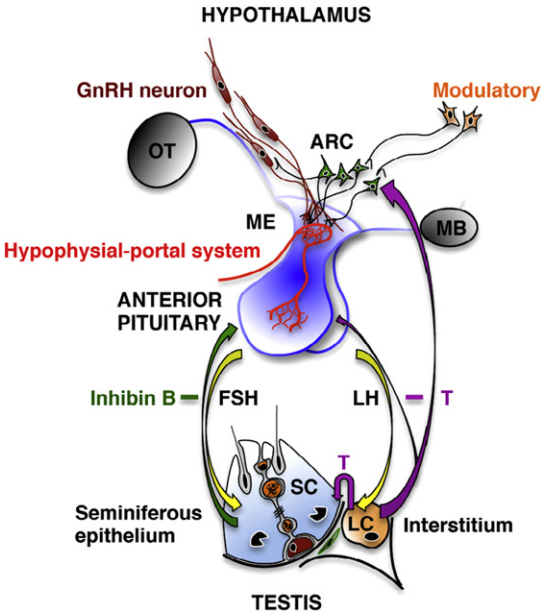

Fig. 1 The neuroendocrine axis governing testicular function. The GnRH pulse generator, resident in the arcuate nucleus (ARC) of the hypothalamus, drives pulsatile release of GnRH into the hypophyseal-portal system. GnRH, in turn, stimulates the synthesis and secretion of the gonadotropic hormones (luteinizing hormone (LH) and follicle-stimulating hormone (FSH)) from the anterior pituitary. LH stimulates the secretion of testosterone (T) by the Leydig cell (LC) in the interstitium of the testis. High intratesticular levels of T exert a paracrine action on the Sertoli cell (SC), which is also targeted by circulating FSH, and together, T and FSH act in concert to control spermatogenesis. LH secretion is regulated by a negative feedback action of T, which is exerted primarily on the GnRH pulse generator to decelerate the frequency of pulsatile GnRH release. FSH, on the other hand, is regulated by a direct negative feedback action of inhibin B at the level of the anterior pituitary. The axis is modulated by many factors such as nutrition, stress, and metabolism. While modulation occurs at all three levels of the hypothalamic–pituitary–testicular axis, the role of the hypothalamus in this regard is particularly important. OT, optic tract; ME, median eminence; MB, mammillary body.

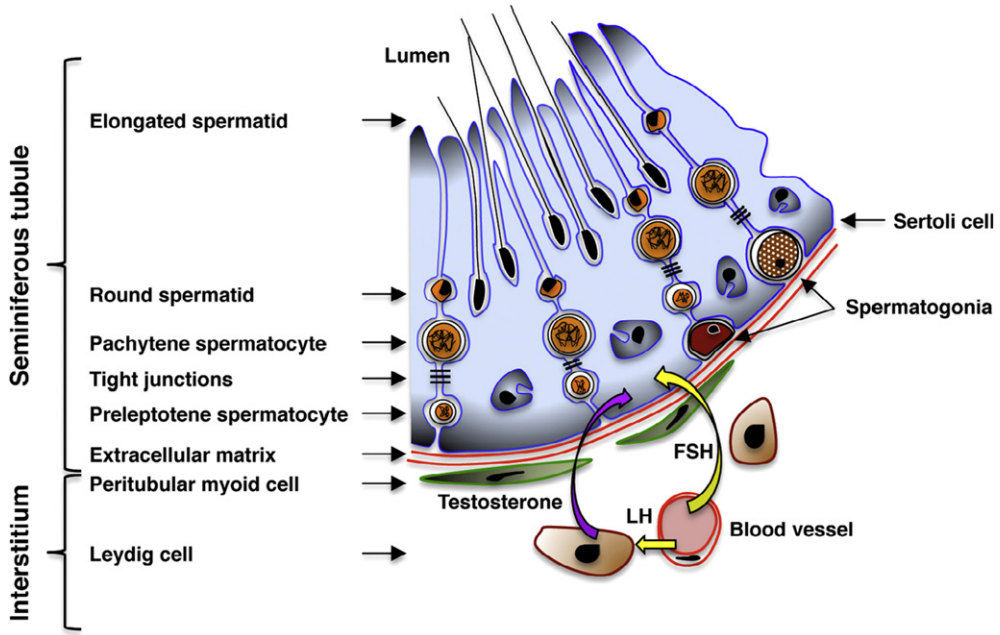

Fig. 2 Schematic of the organization of the seminiferous tubule and interstitium and the endocrine inputs to the germinal epithelium (blue): note that the action of LH on the Sertoli cell is indirect and mediated by the paracrine action of testosterone secreted from the Leydig cell.

neighboring Sertoli cells. This structure is very important since it enables a unique immune, ionic, protein, and nutrient milieu to be maintained in the adluminal compartment, which is stringently controlled by the Sertoli cell and is essential for completion of spermatogenesis.

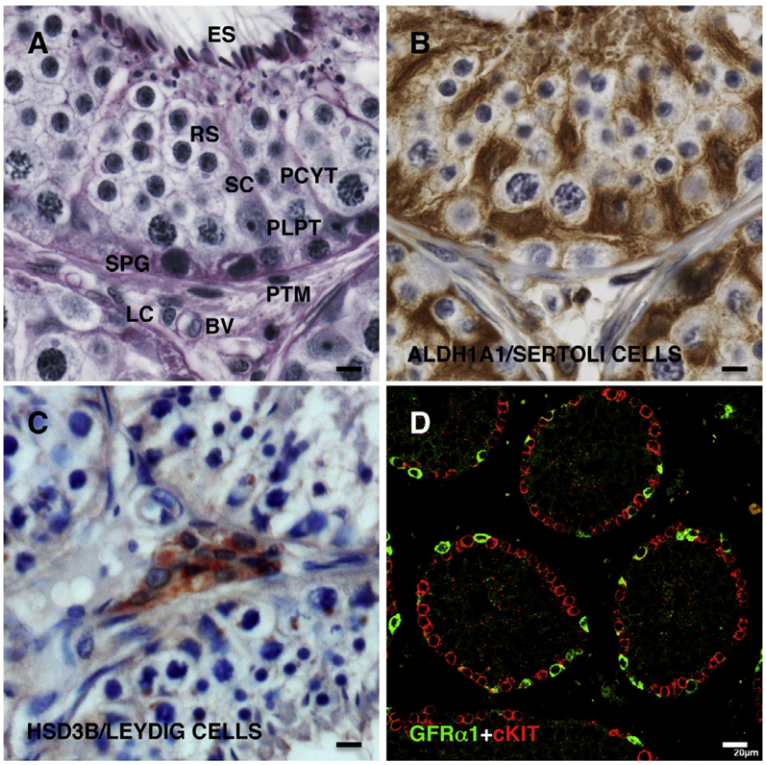

Fig. 3 Cellular architecture of the testis of the adult rhesus monkey. (a) Cross section of a seminiferous tubule stained with periodic acid–Schiff–hematoxylin to show the germ cell and somatic cell types in the adult testis. (b) Cross section of a seminiferous tubule highlighting Sertoli cell architecture by immunohistochemical staining for ALDH1A1 (brown), a Sertoli cell protein. (c) Immunohistochemical staining for HSD3B (brown), a steroidogenic enzyme showing the distribution of Leydig cells in the interstitium. (d) Confocal projection of dual immunofluorescence image of seminiferous tubules stained for GFRα1 (green) marking undifferentiated spermatogonia and cKIT (red) marking differentiating spermatogonia. LC, Leydig cell; BV, blood vessel; PTM cells, peritubular myoid cells; SC, Sertoli cell; SPG, spermatogonia; PLPT, preleptotene spermatocyte; PCYT, pachytene spermatocyte; RS, round spermatid; ES, elongated spermatid; ALDH1A1, aldehyde dehydrogenase 1 family member A1; HSD3B, hydroxysteroid dehydrogenase 3β. Scale bars, 10 μm (a–c) and 20 μm (d). All sections, 5 μm.

Spermatogonial differentiation is initiated in small distinct areas of the tubules and spreads as a synchronized wave to adjacent tubular segments. This temporal organization, coupled with invariant cell cycle times of each of the cell types in the spermatogenic lineage, results in a wave of a species-specific set of germ cell associations moving through the tubules. Each of the cellular associations is known as a stage of spermatogenesis. In human, six stages are typically described. The duration of a spermatogenic cycle (16 days in human) is the time required for a given segment of the tubule to pass through all of the successive stages. The complete development from spermatogonium to spermatozoon in human requires approximately 74 days (more than four cycles), and the spermatogenic stages are arranged in an intertwining helical pattern within the tubules. As a result, a transverse tubular section may display several different stages. In rats and mice (14 and 12 stages, respectively), the situation is simpler as transverse tubular sections reveal only one particular spermatogenic stage. Not surprisingly, Sertoli cell gene expression and function are tightly correlated with the stages of the spermatogenic cycle, with the germ cells dictating the kinetics of the Sertoli cell cycle. Such a temporal organization of spermatogenesis guarantees that, in nonseasonal breeders, sperm are continuously produced and the male is always fertile.

SSC Biology

SSCs, which reside on the basement membrane of the seminiferous tubule, are responsible for the ability of the adult testis to maintain the production of sperm over protracted periods of time, a characteristic that is exemplified in our own species. SSCs are defined by their longevity and ability to produce differentiating progeny and, concomitantly, to self-renew to maintain their own population. Under physiological conditions, mitoses leading to differentiation on the one hand and to self-renewal on the other are balanced by control mechanisms that are poorly understood. SSC fate (i.e., the decision to self-renew or to differentiate) is viewed to be governed by an interplay between the SSC and a specialized microenvironment known as a SSC 'niche' that is created by somatic elements of the seminiferous tubule primarily by neighboring Sertoli cells. The progeny of SSCs that is committed to the path of differentiation undergoes a species-dependent number of amplifying mitotic divisions that lead to spermatogonial clones of increasing size as the lineage progresses prior to meiosis. Early generations of spermatogonia are viewed as undifferentiated cells, while later generations are classified as differentiating spermatogonia. This classification is based on nuclear

morphology revealed by chromatin staining patterns and by expression of molecular markers of cell differentiation revealed by immunohistochemistry. The massive rate of sperm production by the mammalian testis may be achieved by utilizing differing strategies. For example, in rodents, a large number of amplifying spermatogonial divisions are the dominant determinant of sperm output, while in primates, the size of the SSC population appears to take on greater importance. Our understanding of the biology of SSC has been obtained largely from studies of rodents and, particularly, the mouse, a genetically tractable species. In these species, isolated undifferentiated spermatogonia, known as A single (A_s) spermatogonia, are considered to be the SSC, although an element of 'stemness' is apparently retained by the early generations of undifferentiated spermatogonial clones. Self-renewal results from the division of an A_s that is immediately followed by completion of cytokinesis, while commitment to the pathway of differentiation is indicated by an incomplete cytokinesis, which leads to a pair of undifferentiated spermatogonia know as 'A_{pr}.' The molecular determinants of such decision-making by SCCs are poorly understood, but adhesion molecules and members of the transforming growth factor-β family have been implicated. As clonal amplification progresses A_{pr} become A aligned (A_{al}) spermatogonia with clones of 4, 8, and 16 cells represented as A_{al4}, A_{al8}, and A_{al16}, respectively. Several signaling molecules, such as GDNF family receptor alpha-1 (GFRα1), promyelocytic leukemia zinc finger, basic fibroblast growth factor (FGF2), and nanos homolog 2 (NANOS2), have been identified that support the proliferation of undifferentiated spermatogonia, while other signaling molecules such as spermatogenesis- and oogenesis-specific basic helix–loop–helix 1 and 2 (SOHLH1 and 2) and Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog (KIT) are associated with spermatogonial differentiation.

In highly evolved primates, such as the monkey and human, a somewhat different strategy for the sustained production of premeiotic cells appears to have evolved that enables male fertility in these species to be maintained for decades. From classical studies by Clermont, two major types of undifferentiated spermatogonia are recognized: A dark (Ad), characterized by dense, homogeneous staining chromatin, and A pale (Ap), characterized by granular heterogeneous staining chromatin. Under physiological conditions, Ad divide rarely in the postpubertal testis, but Ap, on the other hand, are mitotically active with a cell cycle of approximately 10 days in the monkey. The majority of the Ap population divides each cycle in synchrony: half of the dividing cohort producing the first generation of differentiating spermatogonia while the other half of the cohort completing a self-renewing division. It is likely that Ap are not immortal, as is effectively the case for A_s in rodents, but rather have a finite life span and when lost are replaced from the pool of Ad, which are considered 'reserve' stem cells. The molecular signals that underlie (1) the decision of Ap to commit to differentiation or to self-renew and (2) maintenance of Ad in a quiescent state, presumably G0, have not been investigated.

Blood–Testis Barrier

The blood–testis barrier is formed between adjacent Sertoli cells at the time of puberty and divides the seminiferous epithelium into a basal compartment, containing spermatogonia and early spermatocytes, and an adluminal compartment containing all later germ cell types. This physicobiochemical barrier provides an immune-privileged site within the seminiferous epithelium for the completion of meiosis and production of round spermatids and completion of spermiogenesis and spermiation. The molecular composition of the blood–testis barrier includes actin-filament bundles, tight junction proteins, ectoplasmic specializations, desmosomes, and gap junctions. Complex mechanisms allow the germ cells to enter the adluminal compartment through the blood–testis barrier. This breach of the barrier occurs at a specific stage of the cycle when preleptotene spermatocytes (basal compartment) differentiate to pachytene spermatocytes (adluminal compartment). Breakdown of the barrier on the adluminal side of the spermatocyte and the restructuring of a new barrier on the basal side unfold in a simultaneous manner. Disintegration of the barrier requires endocytosis by the Sertoli cells of tight junction proteins (e.g., occludin), gap junction proteins, actin filaments, and basal ectoplasmic specializations. Recreation of the barrier may involve recycling of the junctional complex proteins or the synthesis of newly formed components. The simultaneous dissociation of the old barrier and the recreation of a new barrier allow for the maintenance of the unique environment of the adluminal compartment of the seminiferous epithelium.

Factors Controlling Quantity and Quality of Sperm Output

The efficiency and quality of sperm production depend on at least three determinants: a genetic program inherent to the germ cells themselves, a number of variables defining maximal spermatogenic capacity, and a series of regulatory factors deciding whether the system is used at maximal capacity or not. This article focuses only on the second and third of these determinants in which hormones play a definite role. The role of factors inherent to the germ cells themselves is probably illustrated most clearly by germ cell transplantation experiments showing that essential characteristics, such as the duration of the spermatogenic cycle, are maintained when, for example, rat germ cells are transplanted into a recipient mouse testis.

The capacity of the testes to produce sperm differs considerably from species to species. In humans, for instance, total daily sperm production expressed per gram of testis is five times lower than that in rat, rabbit, or rhesus monkey. Maximal spermatogenic capacity depends on the number of germ cells that can be supported by an individual Sertoli cell, the total number of Sertoli cells, the number of undifferentiated germ cells entering the spermatogenic cycle, and the type and number of germ cells that are lost during the entire process. The number of germ cells that can be nurtured by an individual Sertoli cell varies considerably from species to species. It is three times lower in human than in rabbit or rat. The total number of Sertoli cells

determines the ceiling of sperm output and the maximal size of the testis. Sertoli cell proliferation is maximal in the perinatal period and ceases at the time of puberty concordant with Sertoli cell maturation and the formation of tight inter-Sertoli cell junctions. In primates, the onset of puberty is associated with a second peak in Sertoli cell proliferation. An important regulator of Sertoli cell replication is FSH, and, accordingly, absent or reduced levels of FSH will limit Sertoli cell numbers, testis size, and sperm output. There is evidence for the monkey that testosterone also regulates Sertoli cell number. Thyroid hormone may also affect testicular size. Hypothyroidism restricted to the prepubertal period delays Sertoli cell maturation, thereby prolonging the period of Sertoli cell proliferation, and increases testicular size as well as sperm output in the adult if a euthyroid condition is restored postpubertally.

The number of undifferentiated spermatogonia entering the spermatogenic cycle varies with species. In rodents, but not in primates, this number is such that the adult testes operate at their spermatogenic ceiling and explains why unilateral orchidectomy postpubertally in rodents is not associated with compensatory hypertrophy of the remaining testis, as it is in primates (see later text for mechanism).

Finally, large numbers of germ cells undergo apoptosis during germ cell development. In rat, cell losses are observed mainly during spermatogonial stages and may exceed 75%. In human, losses seem to be most pronounced during meiosis and may reach as high as 40%. This reduction in germ cells probably reflects the limited germ cell supportive capacity of Sertoli cells and may also prevent further progression of chromosomally aberrant germ cells through spermatogenesis. Disturbances in the endocrine and local control mechanisms affecting spermatogenesis may markedly increase germ cell apoptosis.

Endocrine Control of Spermatogenesis

An overwhelming amount of data indicates that gonadotropins are the major hormones controlling spermatogenesis. Partial or complete inhibition of germ cell production is observed after procedures that suppress gonadotropin secretion (e.g., hypophysectomy, administration of GnRH receptor antagonists or long-acting agonists, and immunization against GnRH) or selectively reduce the secretion or action of either LH (e.g., supraphysiological doses of testosterone) or FSH (FSH antibodies). None of these procedures are completely effective and selective, however. Moreover, the effects of a particular intervention may differ depending on the species studied and whether the selected end point is initiation, maintenance, or restoration of spermatogenesis. It is safe to say that quantitatively and qualitatively, normal spermatogenesis requires both LH (testosterone) and FSH, but that the individual actions and interactions of these hormones remain only partially understood. Reports of rare mutations of the gonadotropin β-subunits and receptors in men and the development of analogous knockout animal models have offered, and are continuing to provide, additional insight into the relative role of FSH and testosterone in regulating spermatogenesis.

Testosterone and Spermatogenesis

Testosterone plays a critical role in driving spermatogenesis in mice, rats, and highly evolved primates, and this is best illustrated by the findings that this androgen alone can initiate and restore spermatogenesis and fertility in a number of experimental models where FSH is extremely low or absent, including severely hypogonadotropic mice deficient in GnRH (*hpg*) and hypophysectomized monkeys. Interestingly, in the Djungarian hamster, a seasonally breeding rodent, FSH treatment alone has been reported to stimulate spermatogenesis in regressed testis in the absence of an increase in intratesticular testosterone levels. Stereological approaches to the study of spermatogenesis and particularly the so-called optical disector model have contributed considerably to a more quantitative evaluation of the effects of androgens on germ cell development. In rats, testosterone seems to be essential for the adhesion of round spermatids to Sertoli cells. In the absence of the steroid, round spermatids are sloughed from the epithelium and spermatid elongation fails. Spermiation is also under the control of testosterone as is the cyclical disintegration and reorganization of the blood–testis barrier. Rodent and primate models provide little evidence that androgens promote spermatogonial proliferation.

In many target organs, androgen action is mediated by so-called active metabolites. Testosterone can be 5α-reduced to form dihydrotestosterone (DHT), a more potent androgen with a higher affinity for the androgen receptor (AR). Given the low level of 5α-reductase in testicular target cells, however, testosterone rather than DHT is considered to be the active androgen in the testis. Intratesticular levels of testosterone are 20–50 times higher than those observed in the circulation. While these high levels of the androgen have been considered to be required for initiation and maintenance of spermatogenesis, recent studies with mice have challenged this view.

The effects of testosterone are primarily mediated by AR, a member of the nuclear receptor superfamily. Most studies, however, have failed to demonstrate AR in germ cells indicating that androgens drive spermatogenesis indirectly by an action on somatic cells in the testis. This view is supported by transplantation experiments where AR-deficient germ cells (^{Tfm}X/Y mice) introduced into the seminiferous tubules of azoospermic mice expressing a functional AR resulted in qualitatively normal donor-derived spermatogenesis. Elegant studies over the last decade of the consequences of transgenetically ablating AR in specific somatic cells within the testis of mice have provided much needed information regarding the cell biology of androgen action underlying spermatogenesis. The Sertoli cells, which express AR, are considered the major target of testosterone action. Sertoli cell AR knockout mice are infertile with spermatogenesis arrested during meiosis, although, interestingly, the testis of these mice contain normal numbers of Sertoli cells. Peritubular myoid cell AR knockout mice are also infertile, but how these somatic cells affect the germ cells is poorly understood. It is important to recognize that in most transgenic mouse models, ablation of AR occurs

perinatally, and therefore, under these conditions, it is not possible to separate the impact of deficits in AR signaling during development from those required for maintenance of spermatogenesis in the adult. Nevertheless, it is probably reasonable to conclude that androgen-sensitive somatic cells in the testis act in concert to produce an environment that permits spermatogenesis to occur at 'basal' levels (see succeeding text) sufficient to maintain fertility.

The identity of specific genes and associated molecular events in the somatic cells of the adult testis that are regulated by AR to drive spermatogenesis remain incompletely understood. However, it is clear that testosterone's action in this regard is complex and that multiple families of genes are involved. Moreover, it has recently emerged that AR, in addition to its classical action within the nucleus to regulate gene transcription, may also mediate testosterone action on the Sertoli cell as a membrane receptor coupled to established signal transduction pathways.

Testosterone can also be aromatized to 17β-estradiol, which can act via one of the estrogen receptors (ER-α or ER-β). Aromatase activity and estrogen receptors are widely distributed in the somatic and germinal elements of the testis and in the efferent ducts. Moreover, fertility defects have been described in mice with a knockout of the ER-α or aromatase. Some of these defects may be related to defective fluid resorption at the level of the efferent tubules and retrograde accumulation of fluid, causing Sertoli cell dysfunction. Only two men with mutations resulting in aromatase deficiency and one man with a mutated ER-α have been described. Data available are too limited to allow definitive conclusions, but there are indications that here too germ cell development may be impaired.

FSH and Spermatogenesis

As may be inferred from the discussion of testosterone and spermatogenesis earlier in the text, FSH action in mice, rats, monkey, and man is unlikely to be essential for the initiation of spermatogenesis at puberty and for maintenance of adult fertility. This view is reinforced by studies of FSHβ or FSH receptor knockout mice, which are fertile, although they have small testes with reduced Sertoli cell number, and by a report of five Finnish men who are homozygous for a mutation in the FSH receptor that severely impairs incorporation of the protein into the membrane and therefore signal transduction. As expected, these men have reduced testicular volume but two of them had fathered two children each. Semen examination revealed a variable degree of oligozoospermia and teratozoospermia, but none of the five men displayed azoospermia. Taken together, these observations suggest that FSH is required for quantitatively and qualitatively normal spermatogenesis, but that, in the presence of normal testicular testosterone production, fertility is possible in the absence of FSH action. It should be noted, however, that the foregoing view appears to be at odds with reports on two men with loss of function mutations in FSHβ that were associated with azoospermia in the face of adequate androgen action as indicated by normal virilization. Moreover, under some conditions, FSH surprisingly may be able to maintain spermatogenesis in the presence of low concentrations of androgens. Relevant to this issue is the anecdotal description of a hypophysectomized patient undergoing testosterone treatment to maintain normal circulating levels of this steroid. The subject was fertile despite undetectable levels of gonadotropins; spermatogenesis appeared to be maintained by an activating mutation of the FSH receptor.

As is the case with testosterone, FSH does not act on the germ cells directly but activates specific receptors on the Sertoli cells. The FSH receptor belongs to a large family of membrane receptors that are coupled to G proteins and that are characterized by seven hydrophobic helices forming the transmembrane domain. This family also comprises the receptors for LH and TSH. Ligand binding results in the activation of the adenylate cyclase signaling pathway and other signaling pathways and induces a cascade of protein phosphorylations.

Stereological studies in rodents and in monkeys suggest a major and specific role for FSH in the proliferation of spermatogonia. In addition, FSH seems to favor spermatocyte and round spermatid development. In both cases, germ cell survival is most likely supported. Finally, and in cooperation with testosterone, FSH may promote the release of mature spermatozoa from Sertoli cells. The last two effects might be related to the actions of FSH on cytoskeletal elements and on the specialized Sertoli cell junctional apparatus.

Interactions of Testosterone and FSH

The data discussed in the preceding text indicate that both testosterone and FSH affect multiple steps in the spermatogenic process, though to a variable degree. Although under some conditions one of these hormones may maintain spermatogenesis in the absence of the other, qualitatively and quantitatively normal spermatogenesis requires both hormones. A major determinant of the relative signaling by AR and FSH receptor throughout the spermatogenic process appears to involve feedback controls between germ cells and the Sertoli cells. This is reflected by the findings that phasic but nonparallel changes in AR and FSH receptor concentrations (and presumable signaling) in the Sertoli cell are observed during the spermatogenic cycle. In the rat, for example, stages VII and VIII of the spermatogenic cycle, when elongated spermatids are being released, exhibit maximal AR expression and low FSH receptor content. Additional interactions between signaling pathways activated by the two hormones are observed. For example, AR concentration in Sertoli cells is upregulated by FSH, whereas maturation of Leydig cells and production of androgen are promoted by Sertoli cell-derived paracrine regulators produced under the influence of FSH. Again, the importance of these interactions may vary with species. The exact molecular and cellular mechanisms by which testosterone- and FSH-induced changes in Sertoli cell function ultimately govern germ cell development remain far from understood.

Feedback Control of Sperm Output

Studies of the monkey employing an experimental model known as a testicular clamp that allows for a selective, physiological increase in either FSH or LH stimulation to be imposed on the testis have provided results that have led to the hypothesis that the rate of sperm production by the primate testis under normal conditions is set by the circulating concentration of FSH. In this model, the role of LH is posited to produce the high intratesticular concentrations of testosterone that guarantee a basal level of sperm production that is amplified in direct relationship to the intensity of the circulating FSH signal. The primary action of FSH to stimulate spermatogenesis is to amplify the first generation of differentiating B spermatogonia. Whether this is achieved by increasing the proliferation of the undifferentiated precursors or by facilitating the survival of B spermatogonia or by both mechanisms remains to be determined.

The blood concentration of FSH is, in turn, set by a negative feedback action of inhibin B that is exerted directly at the level of the anterior pituitary to selectively suppress secretion of this gonadotropin. Accordingly, a reduction in inhibin B, as may be achieved experimentally by hemicastration, leads to an increase in FSH levels. Interestingly, the error signal in the feedback loop, that is, the reduction of circulating inhibin B, is maintained, and as a consequence, the hypersecretion of FSH is sustained resulting in hypertrophy of the remaining testis as spermatogenesis is driven to its ceiling by the exaggerated and sustained FSH signal. The dynamics of the LH–testosterone negative feedback are more plastic, and compensatory cellular mechanisms are rapidly recruited resulting in the remaining testis doubling its testosterone output and LH secretion returning to control levels within 48 h.

Osteocalcin

Since the publication of the previous edition of this book, the bone has been shown to function as an endocrine organ. In the context of the testis, recent studies of transgenic mice have provided evidence that osteocalcin, an osteoblast-specific secreted protein, plays a role in maintaining testosterone secretion by the Leydig cell. Osteocalcin signals via a G-protein receptor (GPRC6A) that is expressed by the Leydig cell. Moreover, two men with primary testicular failure exhibiting low testosterone levels and sperm counts have recently been reported with loss of function mutation of GPRC6A. The precise contribution of this bone hormone to the classical negative feedback loop regulating testosterone secretion remains to be established.

Male Contraceptives

The most widely investigated approach to hormone-based male contraception rests on the idea that the administration of physiological or slightly supraphysiological amounts of testosterone suppresses LH secretion, reduces the high intratesticular concentrations of testosterone, and inhibits spermatogenesis. At the same time, libido and potency are maintained by the 'normal' circulating levels of the androgen. The specific type of testosterone or testosterone analog used has been varied and is on occasion combined with a progestin to amplify the feedback suppression of gonadotropin. Impairment of spermiation may be a key to achieving azoospermia with androgen-based contraceptives. As explained earlier in the text, testosterone is considered to be directly responsible for the maintenance of spermatogenesis under normal conditions. However, under conditions in which intratesticular testosterone levels are reduced, an upregulation of 5α-reductase activity has been observed. These findings suggest that differences in the ability to activate this reaction could contribute to the observed interracial and interindividual differences in the efficiency of testosterone-based contraceptives. To date, testosterone-based contraception has generally been associated with poor acceptance due to complications and concerns of toxicity and poor efficacy, and this has led in recent years to a search for novel, nonhormonal, and testis-specific contraceptives.

Conclusion

Quantitatively and qualitatively normal spermatogenesis requires both FSH and high local concentrations of testosterone, but it appears that sperm production and fertility may be maintained by high concentrations of androgens in the absence of FSH. During prepubertal and early pubertal development, FSH plays a key role in determining the ultimate number of Sertoli cells and the spermatogenic capacity of the adult testis. Testosterone and FSH influence many steps in the spermatogenic linage including the maintenance of the blood–testis barrier, which is obligatory for the completion of meiosis and maturation and release of the haploid progeny. The extent to which hormones regulate SSC behavior, however, is less clear. Testosterone and FSH affect germ cell development indirectly by modulating the function of somatic testicular cells and particularly of Sertoli cells, which express both AR and FSH receptors. The genes, gene families, adhesion molecules, and paracrine signals that underlie the harmony between Sertoli cells and germ cells as they mature and move toward the tubular lumen are only partially understood, but contemporary technologies for (1) high-throughput sequencing of DNA and RNA, (2) examining cell-specific RNA profiles, and (3) transgenic manipulation are beginning to clarify these issues. Androgen-based contraceptives, which act both by suppressing intratesticular androgen levels and by lowering circulating concentrations of FSH, have been explored for many years, but consistent efficacy, in the absence of side effects and with wide acceptance, has not been achieved.

Acknowledgments

The authors are most grateful to Professor Guido Verhoeven, Catholic University of Leuven, for graciously encouraging us to use the previous chapter on the Endocrine Control of Spermatogenesis that he coauthored for the first edition of the *Encyclopedia of Endocrine Disease*, as the framework for this article. The immunohistochemistry shown in Fig 2B was performed by Seyedmehdi Nourashrafeddin. Work conducted in the laboratory of TMP was supported by NIH grants HD16851 and HD08610.

Gonadotropin-Releasing Hormone (GnRH) Development and Actions

Margaret E Wierman, University of Colorado Anschutz Medical Center and Eastern Colorado Veterans Affairs Health Care System, Aurora, CO, United States

Introduction

Over the last 25 years, research has demonstrated that the GnRH neuronal population originates in the olfactory placode and the neurons migrate with olfactory neurons during embryogenesis to the cribriform plate and then diverge to their final home in the forebrain (Wierman *et al.*, 2011). They extend their processes to the anterior pituitary to 5%–10% of the pituitary cells, termed gonadotropes. GnRH receptors in the gonadotropes receive the intermittent secretory signal from GnRH neurons and tranduce the secretory pattern to differentially regulate the production of FSH and LH. Fast, high amplitude GnRH pulses favor LH secretion, whereas low frequency and amplitude GnRH pulses favor FSH secretion (Spratt *et al.*, 1986). This differential pattern is particularly critical in the female reproductive axis to ensure a normal ovulatory cycle.

Developmental Ontogeny of the GnRH Neuronal System

In contrast to other hypothalamic releasing factors that control pituitary hormone secretion, GnRH neurons are not born in the brain but have a unique developmental migratory program to reach their final destination in the hypothalamus in a dispersed neuronal network. In rodents, GnRH neuronal migration begins on embryonic day 10.5–11 and is completed by day 15–16 resulting in about 800 neurons (Schwanzel-Fukuda and Pfaff, 2002). During migration, the neurons express low levels of GnRH mRNA and protein. Identification of the many factors that modulate this early migration and later control of GnRH secretion at the time of sexual maturation are areas of active research. Cell adhesion molecules, intracellular kinases and other factors control neuronal survival and movement along the developmental pathway. Soluble factors such as γ-amino butyric acid (GABA), semaphorins and netrins are examples of components of the early migratory environment (Wierman *et al.*, 2011).

In the human, a few thousand GnRH neurons are arranged in a neuronal network. Secretion of GnRH requires a pulsatile pattern of hormone delivery to appropriately activate the GnRH receptor. Immortalized GnRH neuronal cells and primary neurons demonstrate that the GnRH "pulse generator" is intrinsic to the neurons (Mellon *et al.*, 1990). However, extensive new information has outlined the role of other hypothalamic factors including Kisspeptin, NPY, dynophin and tachychinins from KNDy neurons and other neurotransmitters as well as microRNAs to modulate GnRH neuronal activity centrally (Seminara, 2006; Navarro *et al.*, 2007; Messina *et al.*, 2016; Terasawa *et al.*, 2018). These factors play important roles during sexual development and in the adult. Neuronal decreases in GABAergic activity and increased Kisspeptin, glutaminergic, norepinephrine, and neuropeptide Y activities are important in the activation of the GnRH neuronal pulsatile release at the time of sexual maturation. Transforming growth factor-α/erbgB-1 and neuregulin/erbB-4 secretion from associated glial cells and nitric oxide from adjacent endothelial cells are additional factors and modulate GnRH release (Prevot *et al.*, 2010).

GnRH Receptors

The pituitary GnRH receptor is a G protein-coupled receptor that couples with Gqα to activate the inositol phosphate signaling pathway (Bliss *et al.*, 2010). Unlike most GPCRs, the GnRH receptor lacks a large cytoplasmic C-terminal tail. Receptor phosphorylation in the C-terminus responds to intermittent compared to continuous activation. Constant activation leads to receptor desensitization and internalization. Phospholipase C transmits the signal to diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP3). DAG activates the intracellular protein kinase C pathway, and IP3 stimulates release of intracellular calcium. Protein kinase C activation in response to GnRH also leads to increases in the mitogen-activated protein kinase (MAPK) pathways in pituitary gonadotropes. These pathways control gonadotropin subunit synthesis and gonadotropin (FSH and LH) release into the circulation to act at the gonads to ensure reproductive development and function.

Disorders of the GnRH/GnRH Receptor System

Failure of the GnRH neurons to migrate, survive and/or secrete appropriately results in a central disorder of the reproductive axis. There has been an explosion of new factors identified that impact the GnRH neuronal migratory path or secretory program to cause pubertal disorders in the human (Balasubramanian *et al.*, 2010; Sykiotis *et al.*, 2010; Shaw *et al.*, 2011). Hypogonadotropic hypogonadism (HH) refers to patients who present with significantly delayed or absent pubertal development, hypogonadism and

 doi:10.1016/B978-0-12-801238-3.95842-2

infertility. HH reflects a defect in GnRH secretion or GnRH signaling to the pituitary. HH occurs in 1/5000 men and 1/8000 women and reflect genetic mutations which can be autosomal dominant, recessive, X-linked or sporadic. Kallmann syndrome refers to HH with anosmia and is due to mutations in genes that impact early GnRH neuron migration along the olfactory neurons. Defects in the KAL-1 gene and protein anosmin-1 results in an aborted migration of the dual system early in development. Mutations in fibroblast growth factor 8 (FGF8) or its receptor FGFR1, the sempahorin SEMA-3A, the prokineticins PROK2 or its receptor PROKR2 among others can result in HH or Kallmann syndrome (Balasubramanian *et al.*, 2010; Sykiotis *et al.*, 2010). Surprisingly, only recently have mutations in the GnRH gene itself been discovered to cause absent pubertal development. Despite intensive investigation only about 30% of the underlying mutations are currently known suggesting additional research is needed to both understand the defects and give clues to the complexity of the control of the reproductive axis.

Other causes of HH involve defective signaling pathways downstream of the GnRH neuron. Mutations in GnRH receptor expression alter the ability of GnRH to activate pituitary gonadotropin synthesis and secretion to a variable extent (Balasubramanian *et al.*, 2010). Rare patients have been found to have mutations of the LHβ or FSHβ gonadotropin subunit genes resulting in defective sexual maturation.

In contrast to a lack of pubertal development, precocious puberty results from premature reactivation of the HPG axis. In girls it is usually idiopathic and in boys often results from a central nervous system tumor. The exact mechanism of premature pubertal development has been of great interest to investigators. Some have suggested that premature activation of the glial production of TGFα to activate GnRH neuronal secretion. Recently, investigators have discovered that a constitutive activating mutation in the Kisspeptin receptor which transduces Kisspeptin secretion to activate GnRH neurons can induce precocity (Abreu *et al.*, 2013; Bessa *et al.*, 2017). Others have shown that mutations in pathways of protein degradation may result in familial precocity (Shi *et al.*, 2014). Additional research is needed.

Clinical Use of GnRH and GnRH Agonists and Antagonists

Once scientists understood the importance of intermittent signal transduction to active the reproductive axis and that continuous exposure to GnRH desensitized the GnRH receptor and function and blocked hormonal secretion, manipulation of the GnRH decapeptide was performed to produce activators and inhibitors of the reproductive axis. In research centers, GnRH which has a short half-life can be administered via a small infusion pump worn at the waist to activate reproductive function in women with HH to induce ovulation and allow pregnancy (Spratt *et al.*, 1986; Santoro *et al.*, 1988). In men, the pulsatile GnRH can be given subcutaneously by an infusion pump to activate spermatogenesis over a 12–24 month period (Spratt *et al.*, 1986). Because of cost and availability, most patients are instead treated with exogenous gonadotropins (recombinant FSH and human chorionic gonadotropin (hCG)) to mimic LH to treat these patients. GnRH agonists when given chronically turn off gonadotropin secretion and are a mainstay of inducing a medical castration in various situations (Yen, 1983; Lahlou *et al.*, 2000; Newton *et al.*, 2016). They are used to turn off early puberty in children with precocity as well as modulating hormone dependent disorders such as endometriosis or leiomyomata in the uterus. In addition, GnRH agonists have been used extensively in hormone dependent malignancies predominantly in prostate cancer patients instead of orchiectomy or sometimes in breast cancer patients. More recently, short acting pure GnRH antagonists have been used to directly block GnRH receptor function to inhibit LH and FSH secretion. They are used occasionally as an adjunct to prevent ovarian hyperstimulation during in vitro fertilization.

Conclusions

GnRH is the hypothalamic hormone that stimulates the pituitary gland to produce FSH and LH. The reactivation of GnRH neuronal secretion triggered by Kisspeptin and other transmitters secreted by KNDy neurons are responsible for the initiation of puberty and completion of sexual maturation. The KnDy neurons may modulate hot flashes in the menopause or other states of gonadal failure and be a target for new treatments (Dacks *et al.*, 2011; Rance *et al.*, 2013). The GnRH–GnRH receptor system has been a target for drug therapies to treat early or delayed pubertal development. These agents also are used to turn on or off sex steroid production in hormone dependent tumors of the prostate and breast. Understanding the complexities of the development and function of GnRH neurons and action allows us to further identify causes of reproductive disorders and devise novel therapies for our patients.

Genes and Gene Defects Affecting Gonadal Development and Sex Determination

Dagmar Wilhelm and Stefan Bagheri-Fam, The University of Melbourne, Parkville, VIC, Australia

Disorders of Sex Development (DSDs)

DSDs are a heterogeneous group of birth defects that are defined as conditions in which the development of the chromosomal, gonadal, or anatomical sex is atypical (Hughes *et al.*, 2006). They often present with abnormal genitalia at birth or failure/delay of puberty, and are estimated to occur in approximately 1:4500 live births. If defects in external genitalia are included, DSDs exist in up to 1:300 newborns, as is observed for hypospadias (misplacement of the urethral opening in boys) (Ahmed *et al.*, 2004). Based on a consensus statement in 2005 (Hughes *et al.*, 2006), DSDs are classified into three broad groups; sex chromosome DSD, 46,XY DSD, and 46,XX DSD. The latter two are further divided into (i) disorders of gonadal development, (ii) disorders in androgen synthesis/action (46,XY DSD) and androgen access (46,XX DSD), and (iii) others, which include, for example, severe hypospadias and vaginal atresia.

In recent years, even though considerable progress has been made in identifying genes that drive sex determination and sex differentiation (for review see Eggers and Sinclair, 2012; Ostrer, 2014), many DSDs are still unexplained at the molecular level. While most 46,XX DSDs are due to 21-hydroxylase deficiency, which causes congenital adrenal hyperplasia, the genetic etiology is unknown for more than 50% of 46,XY DSDs (Ahmed *et al.*, 2013; Baxter *et al.*, 2015; Eggers *et al.*, 2016). The genes that have been described to be associated with DSD were identified through genetic studies of DSD patients and/or animal models, especially genetically modified mice. In this article, we will review genes that are implicated in the development of testis and ovary in mice and humans, and that, when mutated, can lead to DSDs (see **Table 1**).

Bipotential Genital Ridge

The development of testes and ovaries starts with a common precursor, the bipotential genital ridges. They arise through proliferation of the coelomic epithelium at the ventro-medial surface of the mesonephros within the intermediate mesoderm. The genital ridges are first visible at around 10 days post coitum (dpc) in mouse, and during the fourth week postfertilization in human (Byskov, 1986; Satoh, 1991). The somatic cells are joined by primordial germ cells (PGCs) that were specified at the base of the allantois and migrated via the hindgut and the dorsal mesentery to the developing genital ridges (Molyneaux *et al.*, 2001; Saitou *et al.*, 2005).

A number of genes are known to play important roles in the formation of the genital ridges. These include genes that encode the transcription factors GATA4 (GATA binding protein 4), LHX9 (LIM homeobox protein 9), and WT1 (Wilms' tumor suppressor 1) as well as the orphan nuclear receptor NR5A1 (also known as SF1, steroidogenic factor 1). Null mutations in any of these in mice result in gonadal dysgenesis or agenesis (Birk *et al.*, 2000; Hu *et al.*, 2013; Kreidberg *et al.*, 1993; Luo *et al.*, 1994). Of these four genes, *GATA4* functions the earliest, leading to a complete failure of genital ridge formation in mouse, and 46,XY gonadal dysgenesis in human (Lourenco *et al.*, 2011). In contrast, the coelomic epithelium in mice lacking WT1, NR5A1 or LHX9 thickens initially, but then regresses soon after. The hierarchy of these genes has been elucidated in mice with WT1, together with LHX9, upregulating *Nr5a1* through binding in its proximal promoter (Wilhelm and Englert, 2002).

WT1 was initially identified to cause Wilms' tumor, a pediatric kidney cancer, but subsequently shown that mutations can cause 46,XY DSD, including Denys–Drash, Frasier, and WAGR (Wilms' tumor, aniridia, genital anomalies, and mental retardation) syndrome (Barbaux *et al.*, 1997; Jadresic *et al.*, 1990; Pelletier *et al.*, 1991; van Heyningen *et al.*, 1990). Similarly, mutations in *NR5A1* lead to 46,XY DSD with embryonic testicular regression syndrome and 46,XX premature ovarian failure (Achermann *et al.*, 1999; Domenice *et al.*, 2016; Lourenco *et al.*, 2009). *NR5A1* mutations are one of the major causes of 46,XY DSD with a frequency of 10%–15% (Baxter *et al.*, 2015; Lin and Achermann, 2008). In contrast, no mutations in *LHX9* have been associated with human DSD to date.

Sex Determination

The fate of the bipotential genital ridges is decided with the expression of the male-determining gene *Sry*/*SRY* (sex determining region of chromosome Y), which encodes an HMG domain transcription factor, the founding member of the SOX (SRY-box) protein family (Schepers *et al.*, 2002). In mice, *Sry* is expressed during a narrow time window between 10.5 and 12.5 dpc with a peak at 11.5 dpc (Hacker *et al.*, 1995). In humans, *SRY* starts to be expressed between 41 and 44 days post-ovulation (dpo), reaching a peak at 44 dpo, and remains expressed at low levels beyond 52 dpo (Hanley *et al.*, 2000). It has been shown in mice

GOF, gain-of-function; *LOF*, loss-of-function.

that if SRY is not expressed, like in an XX individual, or its expression is too late or too low, the bipotential genital ridge develops into an ovary (Bullejos and Koopman, 2005; Warr *et al.*, 2012). Similarly, mutations in human *SRY* result in 46,XY ovarian DSD. In addition, *SRY* is the major cause of 46,XX testicular DSD in cases in which abnormal X–Y exchange during recombination caused the transfer of Y chromosomal DNA, including the *SRY* gene, to the X chromosome. It is estimated that the *SRY* gene accounts for 10%–15% of 46,XY ovarian DSD and 80%–90% of 46,XX testicular DSD (Cameron and Sinclair, 1997; Hawkins, 1993; McElreavey *et al.*, 1993; Sinclair *et al.*, 1990).

Even though *Sry* was identified as the testis-determining gene in 1990/1991 the regulation of its expression is still not completely understood. Factors regulating its expression are expected to be present in both the XY and XX genital ridge, as a 14 kb genomic fragment, including only the *Sry* gene and its regulatory region, is sufficient to drive male development in XX transgenic mice (Koopman *et al.*, 1991). It has been shown that a critical transcriptional activator of *Sry* expression is the GATA4/ZFPM2 (zinc finger protein, FOG family member 2) complex (Tevosian *et al.*, 2002) and recent data in mice have shown that GATA4 needs to be activated by phosphorylation through p38 MAPK (mitogen activated protein kinase), which is part of an intracellular signaling cascade (Gierl *et al.*, 2012; Warr *et al.*, 2012). This cascade includes the small, acidic protein GADD45γ, which binds to and activates MAP3K4, which in turn results in the phosphorylation and activation of p38 MAPK (**Fig. 1**) (Gierl *et al.*, 2012; Warr *et al.*, 2012). While mouse models with mutations in the genes encoding any of these factors result in greatly reduced or abolished *Sry* expression and subsequent male-to-female sex reversal, none of these genes, with the exception of *GATA4* and *ZFPM2* (Bashamboo *et al.*, 2014; Eggers *et al.*, 2016; Lourenco *et al.*, 2011), has been associated with human 46,XY DSD to date. However, mutations in *MAP3K1*, encoding a kinase closely related to MAP3K4, can lead to 46,XY DSD. Recent studies have shown that human *MAP3K1* mutations are common and cause 10%–18% of cases of 46,XY gonadal dysgenesis (Baxter *et al.*, 2015; Eggers *et al.*, 2016; Ostrer, 2014; Pearlman *et al.*, 2010). Interestingly, in contrast to *Map3k4* in mouse, which results in sex reversal due to loss-of-function of the kinase, the mutations identified in human *MAP3K1* appear to be gain-of-function mutations (Bogani *et al.*,

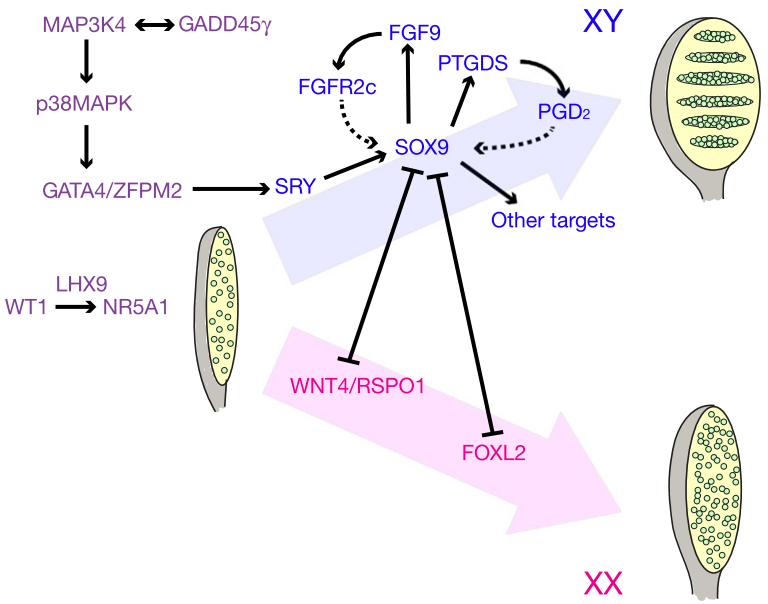

Fig. 1 Sex determination pathways in mouse. Schematic representation of the sex determination pathways in the developing mouse gonads. WT1 together with LHX9 is responsible for the upregulation of NR5A1 in the indifferent genital ridges. All three genes together with GATA4 and ZFPM2 are necessary for the formation of the genital ridges in both sexes. Activation of GATA4/ZFPM2 by MAP kinase signaling results in the up-regulation of SRY expression in XY gonads which in turn up-regulates the expression SOX9. Expression of SOX9 is then maintained by two positive feedback loops involving FGF9 and PGD2, which drives the differentiation of the genital ridges into testes marked by the formation of testis cords that enclose germ cells (indicated as *small circles*). In the absence of SRY, female pathways are activated including WNT4/RSPO1 signaling and the forkhead transcription factor FOXL2, leading to the formation of an ovary. See text for more details.

2009; Loke *et al.*, 2014; Pearlman *et al.*, 2010). Accordingly, deletion of *Map3k1* in mice does not result in sex reversal (Warr *et al.*, 2011), and it would be interesting to test if ectopic activation of MAP3K1 in mice mimics the human phenotype.

Other factors that have been implicated in the regulation of *Sry* expression include WT1 and NR5A1, as well as the epigenetic regulators CBX2 (chromobox 2) and KDM3A (lysine (K)-specific demethylase 3A, also known as JMJD1A, jumonji domain containing 1A). CBX2 is a component of the polycomb multiprotein complex, which is required to maintain the transcriptionally repressive state of many genes throughout development via chromatin remodeling and modification of histones. Disruption of *Cbx2* in mice results in male-to-female gonadal sex reversal due to low *Sry* expression, while in humans a compound heterozygous *CBX2* mutation was found in a female patient with 46,XY ovarian DSD (Biason-Lauber *et al.*, 2009; Katoh-Fukui *et al.*, 1998, 2012). The histone demethylase KDM3A has only been shown in mice, but not in humans to date, to be important for removing the repressive H3 histone methylation mark at lysine 9 within the *Sry* regulatory region (Kuroki *et al.*, 2013). In addition, a recent study has demonstrated that reduced activity of the H3K9 methyltransferase GLP/G9a complex restores *Sry* expression and rescues XY gonadal sex reversal in *Kdm3a* knockout mice. These data indicate that *Sry* expression is controlled by a fine balance between H3K9 demethylase and methyltransferase activities (Kuroki *et al.*, 2017). In summary, genetic studies have identified critical factors involved in *Sry* expression in mouse, as well as bioinformatics analysis described binding sites within the *Sry* promoter (Larney *et al.*, 2014). However, these sites have not been confirmed in vivo to be functional.

Testis Differentiation

The main, or possibly the only, function of SRY is the upregulation of *Sox9* (SRY-box 9; **Fig. 1**) encoding another member of the SOX family of transcription factors (Schepers *et al.*, 2002; Sekido and Lovell-Badge, 2008). Like *Sry*, *Sox9* is both necessary and sufficient for testis development in mouse (Barrionuevo *et al.*, 2006; Chaboissier *et al.*, 2004; Lavery *et al.*, 2011; Vidal *et al.*, 2001). Recent studies provided evidence that duplication of the human *SOX9* upstream regulatory region results in 46,XX ovotesticular DSD with ambiguous genitalia (Cox *et al.*, 2011; Shankara Narayana *et al.*, 2017). In addition, heterozygous mutations in the human *SOX9* gene lead to campomelic dysplasia, a disorder that is characterized by the bowing of long bones and is associated with ambiguous genitalia or male-to-female sex reversal in approximately 75% of XY cases (Foster *et al.*, 1994; Mansour *et al.*, 1995; Wagner *et al.*, 1994). Two closely related SOX factors, SOX8 and SOX10, have been suggested to function redundantly in the remaining patients. Accordingly, duplication of at least the region including *SOX10* in humans leads to ambiguous genitalia or complete sex reversal in 46,XX individuals (Aleck *et al.*, 1999; Nicholl *et al.*, 1994; Seeherunvong *et al.*, 2004). Similarly, in mice ectopic expression of *Sox10* in XX gonads caused female-to-male sex reversal (Polanco *et al.*, 2010). In addition, another member

of the SOX family, SOX3, has also been shown to result in 46,XX testicular DSD when duplicated in humans, and female-to-male sex reversal in mice when ectopically expressed in XX gonads (Sutton *et al.*, 2011).

The expression of *Sox9*, after the initial up-regulation by SRY, is maintained through different positive feedback loop mechanisms, at least in mouse. Firstly, SOX9 binds to its promoter to maintain its own expression (Sekido and Lovell-Badge, 2008). Secondly, *Sox9* expression results in the upregulation of *Fgf9* (fibroblast growth factor 9), and *Ptgds* (prostaglandin D synthase) (Kim *et al.*, 2006; Moniot *et al.*, 2009; Wilhelm *et al.*, 2007). FGF9 binds to its receptor FGFR2c to indirectly activate *Sox9* expression through repression of the ovarian program (Jameson *et al.*, 2012); whereas PTGDS produces prostaglandin D_2, which through binding to its DP receptor leads to the nuclear translocation of SOX9 protein and subsequent up-regulation of *Sox9* transcription (**Fig. 1**) (Malki *et al.*, 2005; Wilhelm *et al.*, 2005). Accordingly, *Fgf9* $^{-/-}$ and conditional *Fgfr2* knockout mice show partial to complete XY sex reversal, while *Ptgds*$^{-/-}$ XY gonads display abnormalities in testis cord organization (Bagheri-Fam *et al.*, 2008, 2017; Colvin *et al.*, 2001; Kim *et al.*, 2007; Schmahl *et al.*, 2004). However, only *FGFR2* has been implicated in 46,XY DSDs in human to date (Bagheri-Fam *et al.*, 2015).

Both, *Sry* and *Sox9*, are expressed in the supporting cell precursors in the developing testis. Expression of *Sox9* drives their differentiation into the first testis-specific cell type, the Sertoli cells. Sertoli cells only proliferate during fetal and neonatal development, and their final number will determine the number of germ cells that can be supported during spermatogenesis to form sperm (Rebourcet *et al.*, 2017; Svingen and Koopman, 2013). Sertoli cells are considered the coordination centers of the developing testis. They will organize themselves around clusters of germ cells to form testis cords, the precursors of the seminiferous tubules of the adult testis. They also produce factors to direct the differentiation of other cell types in the developing testis, including steroidogenic Leydig cells and peritubular myoid (PM) cells (Svingen and Koopman, 2013).

Fetal Leydig cells differentiate in the interstitium between testis cords at around 12.5 dpc in mouse and at 8–9 weeks of human development. They are responsible for the production of androgens, which drive the development of secondary sexual characteristics including the male reproductive tract and external genitalia. Two signaling pathways are important for Leydig cell specification and differentiation, DHH (desert hedgehog) secreted by Sertoli cells, which binds to its receptor PTCH1 (patched 1) on Leydig cell precursors, and Notch signaling. Accordingly, XY *Dhh*-null mice have major defects in fetal Leydig cell differentiation, and the vast majority of adult mice are feminized lacking adult-type Leydig cells (Clark *et al.*, 2000; Yao *et al.*, 2002). Similarly, mutation of *DHH* in humans results in 46,XY DSD (Canto *et al.*, 2004; Umehara *et al.*, 2000). In addition, mutations in an enzyme that is important for hedgehog protein modification and function, HHAT (hedgehog acyltransferase), in mouse and human lead to testicular dysgenesis (46,XY DSD) in addition to other skeletal, neuronal, and growth defects (Callier *et al.*, 2014). Fetal XY *Hhat* knockout mice display smaller testes with a reduced number of testis cords, and fetal Leydig cells are almost completely absent (Callier *et al.*, 2014). The second pathway, Notch signaling has only been shown in mouse to be important for Leydig cell differentiation. Inhibition and constitutive activation of Notch signaling resulted in an increase and decrease of Leydig cell numbers respectively (Tang *et al.*, 2008).

DHH is not only important for the differentiation of Leydig cells, but also for proper development of PM cells. PM cells are long, flattened cells that surround Sertoli cells and together they produce a basal lamina between them which is important for testis cord integrity. PM cells at later stage become contractile and help pumping the sperm from the seminiferous tubules into the epididymis.

Ovary Differentiation

In the absence of the Y chromosome, and therefore the *Sry* gene, the bipotential genital ridges develop into ovaries (**Fig. 1**). In contrast to the developing testis, the ovary does not display major morphological changes during fetal development. However, there is an active gene expression program that drives the development of ovaries. The main drivers are the WNT4 (wingless-type MMTV integration site family member 4)/RSPO1 (R-spondin 1)/β-catenin pathway and the transcription factor FOXL2 (forkhead box L2). Both WNT4 and RSPO1 have been shown to function through the canonical WNT signaling pathway in the developing ovary, inducing the stabilization and accumulation of β-catenin. Loss-of-function of any of the three molecules in mice leads to partial female-to-male sex reversal (Chassot *et al.*, 2008; Jeays-Ward *et al.*, 2003; Liu *et al.*, 2009; Tomizuka *et al.*, 2008; Vainio *et al.*, 1999). In addition, ectopic expression of a constitutive active β-catenin in the developing XY mouse gonads results in male-to-female sex reversal (Maatouk *et al.*, 2008). Similarly, in human, homozygous mutation in *WNT4* or *RSPO1* can lead to 46,XX DSD with female-to-male sex reversal, while heterozygous mutations in *WNT4* are associated with 46,XX DSD and ambiguous genitalia (Biason-Lauber *et al.*, 2004, 2007; Mandel *et al.*, 2008; Parma *et al.*, 2006; Philibert *et al.*, 2008). These findings demonstrate the importance of this signaling pathway for ovarian development.

The second pathway, marked by the transcription factor FOXL2 (**Fig. 1**), appears to work largely independent of the WNT signaling pathway in driving ovarian development. The importance of FOXL2 to the development of ovaries is dependent on the species. Loss of FOXL2 results in complete female-to-male sex reversal in goats (Boulanger *et al.*, 2014; Pailhoux *et al.*, 2001), while it leads to premature ovarian failure, that is, a premature loss of oocytes, in postnatal mice and humans (Crisponi *et al.*, 2001; Schmidt *et al.*, 2004; Uda *et al.*, 2004). Nevertheless, XX double knockout mice that have *Foxl2* deleted together with either *Wnt4* or *Rspo1* show a more severe sex reversal phenotype than the *Wnt4* or *Rspo1* single-knockouts (Auguste *et al.*, 2011; Ottolenghi *et al.*, 2007), demonstrating that *Foxl2* also plays a role in the fetal mouse ovary.

Germ Cell Differentiation

PGCs, once they have reached the developing genital ridges, stop migrating, but keep proliferating. They start their sexual dimorphic differentiation at around 13.5–14.5 dpc in mouse and at week 11–12 in human development, when PGCs in an ovary enter meiosis, whereas PGCs in a testis arrest in mitosis. This bifurcation in the differentiation pathway between males and females is solely dependent on the environment, that is, ovary or testes, PGCs are in. It has been shown that retinoic acid (RA) produced by the mesonephros is able to induce entry into meiosis. In a testis, Sertoli cells, which surround PGCs within testis cords, produce the RA-degrading enzyme CYP26B1 (cytochrome P450, family 26, subfamily b, polypeptide 1) (Bowles *et al.*, 2006; Koubova *et al.*, 2006; Li *et al.*, 2009; MacLean *et al.*, 2007). Therefore, even though RA is also produced by the mesonephros in males, PGCs do not enter meiosis until after birth.

Antagonism Between the Male and Female Pathway

For a long time it was believed that once the decision to make a testis or an ovary is made, it is irreversible. However, in recent years, it became clear that the sex-specific program needs to be actively maintained through repression of the opposite sex not only during fetal development, but also postnatally into adulthood (**Fig. 1**). In the fetal XY gonad, SOX9 is required for the initiation of the male pathway, but it also has been suggested to suppress, directly or indirectly FOXL2 expression (Barrionuevo *et al.*, 2006; Georg *et al.*, 2012). Conversely, FOXL2 has been shown to bind and repress the regulatory region of *Sox9* in the postnatal mouse ovary (Uhlenhaut *et al.*, 2009). In addition, FGF9 and WNT4 appear to act antagonistically to promote the fetal testicular and ovarian developmental pathways respectively (Jameson *et al.*, 2012; Kim *et al.*, 2006). Postnatally, the testis-specific transcription factor DMRT1 (doublesex and mab-3 related transcription factor 1) together with SOX9 repress FOXL2, whereas FOXL2 together with the estrogen receptors directly repress *Sox9* expression (Barrionuevo *et al.*, 2016; Matson *et al.*, 2011; Minkina *et al.*, 2014; Uhlenhaut *et al.*, 2009). If either of these factors is deleted in mice after birth Sertoli cells transdifferentiate into granulosa-like cells and granulosa cells transdifferentiate into Sertoli-like cells respectively.

Conclusions

Since the discovery of the male-determining gene *Sry*, extensive progress has been made in identifying genes and gene regulatory mechanism that drive the differentiation of testes and ovaries, so that in humans mutations in the three major genes *SRY*, *NR5A1* and *MAP3K1*, together with mutations in additional genes, such as *DHH*, *GATA4*, *ZFPM2* and *WT1*, account for up to 43% of all 46,XY DSD (Baxter *et al.*, 2015; Eggers *et al.*, 2016). However, we are still unable to explain the other half of these cases at the molecular level, suggesting that additional, important factors are involved. One of the reasons to explain why we have not identified more crucial genes is that emphasis was placed on sexually dimorphically expressed genes, with the rational that a gene important for testis development should not be expressed in an ovary. However, this disregards the possibility that a gene might be expressed in both testis and ovary, but its target is sexually dimorphic, as has been shown for the DHH-modifying enzyme HHAT (Callier *et al.*, 2014), or that any gene that is expressed in both testis and ovary might play important roles in both organs.

With the development of high-throughput technologies such as whole exome and whole genome sequencing to identify potentially pathogenic gene variants in familiar and sporadic DSD cases, in combination with the establishment of new mouse models using the latest genome editing techniques such as the TALEN and CRISPR/CAS9 systems, a more rapid discovery of important players is expected.

Glossary

Digenicity Protein-altering variants in two or more alleles of different genes.
Domain An independently folded portion of a protein that has a recognizable or characterizable structure of its own; in large proteins, each domain is connected to other domains by flexible regions of polypeptide.
Effector A molecule that couples a ligand-occupied receptor to a second messenger.
Ligand A molecule that binds specifically to a receptor.
Mutation A heritable or de novo change in the nucleotide sequence of a gene.
Receptor A molecule, usually a protein, that binds a specific extracellular signaling molecule and initiates or blocks a response in the cell.
Second messenger Usually a small molecule that is formed in or mobilized into the cytoplasm in response to an extracellular signal; this molecule relays the signal to the interior of the cell.
Signal transduction The process whereby a cell converts an extracellular signal into a biochemical response.
Pharmacoperone (from "pharmacological chaperone") A small molecule that enters cells and serves as molecular framework in order to cause otherwise-misfolded mutant or wild type proteins to fold and route correctly within the cell.

Introduction

Gonadotropin-releasing hormone (GnRH) is a decapeptide produced by specialized neurons predominantly located in the arcuate nucleus of the mediobasal hypothalamus and in the preoptic area of the anterior hypothalamus. The axons of these neurons are projected to various regions of the brain, where the decapeptide acts as neurotransmitter or neuromodulator of reproductive behavior, and to the median eminence, where the GnRH peptide enters the portal circulation, eventually reaching and interacting with its membrane receptor in the gonadotropes. Activation of the GnRH receptor (GnRHR; OMIM 138850; Genomic coordinates (GRCh38):4:67,737,374-67,756,085) (https://www.omim.org/entry/138850?search=gnrhr&highlight=gnrhr) leads to both synthesis and release of the pituitary gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). Chronic exposure to GnRH promotes synthesis of the gonadotropins, which will be stored in secretory vesicles until exocytosis stimulated by GnRH exposure. The coordinated release of LH and FSH allows for an extremely precise control of gonadal function, including gametogenesis and steroidogenesis. The secretion and subsequent interaction of GnRH with its cognate receptor occurs in a pulsatile and intermittent manner. Pulsatile release of GnRH is regulated indirectly by gonadal steroids and directly by a complex network of interactions between the GnRH neurons and other neurons located in the mediobasal hypothalamus, including mainly those belonging to the Kiss1/neurokinin B/dynorphin system (Beltramo *et al.*, 2014; Goodman *et al.*, 2014; Narayanaswamy *et al.*, 2016). Intermittent exposure of the GnRHR to the releasing hormone is extremely important from the functional point of view. First, it prevents the desensitization that leads to refractoriness of the gonadotrope to a subsequent stimulus that may result as a consequence of the continuous exposure of the cell to the decapeptide. Second, it allows for the occurrence of distinct rates and patterns of synthesis and secretion of LH and FSH that follow GnRH exposure.

Decreased synthesis of pituitary gonadotropins and/or alterations in their episodic release from the pituitary may lead to impaired gonadal function and reproductive failure, a condition known in humans as hypogonadotropic hypogonadism (HH) (Chevrier *et al.*, 2011; Noel and Kaiser, 2011; Silveira *et al.*, 2010; Ulloa-Aguirre *et al.*, 2004; Boehm *et al.*, 2015).

The presence of GnRH and a normally plasma membrane (PM) expressed and functioning GnRHR is crucial for pubertal development, sexual maturation, and reproductive competence (Silveira *et al.*, 2010). Mutations in the *GNRHR* may lead to abnormal synthesis of the GnRHR and/or to structural alterations that may potentially alter its functional properties and/or PM expression, the latter making GnRH entirely inaccessible to the receptor (Chevrier *et al.*, 2011; Conn and Ulloa-Aguirre, 2010). Inactivating mutations in the *GNRHR* represent, in fact, a well-known cause of normosmic HH (Chevrier *et al.*, 2011; Ulloa-Aguirre *et al.*, 2004). This article describes the inactivating mutations of the *GNRHR* detected to date and the molecular physiopathogenesis of GnRHR mutants for which data is available. Also included is information on pharmacological approaches that in experimental studies have proved to overcome the functional defect provoked by the mutations, and briefly discuss the impact of

☆*Change History*: January 2018. Alfredo Ulloa-Aguirre, Teresa Zariñán, and Saúl Lira-Albarran updated the text, tables, Fig. 1C, and references.

 doi:10.1016/B978-0-12-801238-3.04015-0

the mutations on the phenotypic expression of HH in individuals bearing such mutant GnRHs as well as the currently available therapeutic options.

The GnRH Receptor

The type 1 GnRHR belongs to the superfamily of G protein-coupled receptors (GPCRs), specifically the β-group of the Rhodopsin family, according to the phylogenetic classification proposed by Fredriksson *et al.* (2003), which is the best-known family in terms of its structural and functional characteristics. Seven transmembrane hydrophobic domains (TMDs) oriented roughly perpendicular to the plasma membrane plane, with an extracellular NH_2-terminus, an intracellular COOH-terminus, and three alternating intra- and extracellular hydrophilic loops connecting the TMDs, characterize the structure of these receptors (**Fig. 1**B and C). The

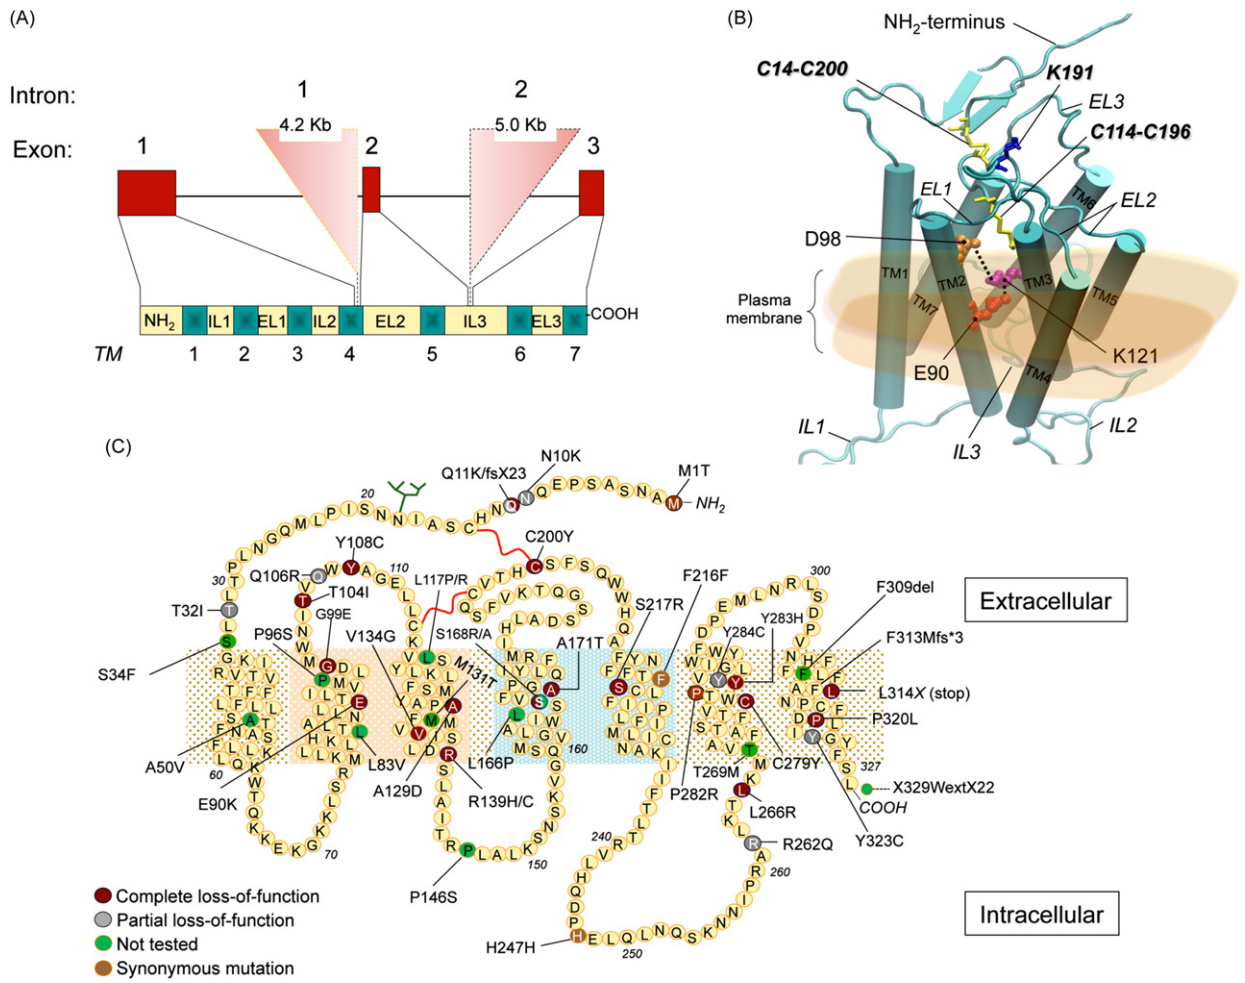

Fig. 1 The human GnRH receptor. (A) Schematic of the human *GnRHR* gene. The open reading frame is distributed among 3 exons (*maroon rectangles*) spanning 18.9 Kb, that encode amino acids 1–174, 175–248, and 249–328, respectively. Intron 1 is located between amino acids 174 and175 in the putative transmembrane domain (TM) 4, and intron 2 is located between amino acids 248 and249 in the intracellular loop (IL) 3 (*shaded inversed triangles*). *EL*, extracellular loop. (B) Predicted model of the human GnRHR showing the seven transmembrane helices (displayed as *rods*) connected by the extracellular (EL) and intracellular (IL) loops (Jardón-Valadez *et al.*, 2008). C14–C200 and C114–C196 disulfide bridges are shown as *yellow sticks*; K191 is represented by *blue sticks*. E90 (at the TM2; *red spheres*) forms a salt bridge with K121 (at the TM3; *purple spheres*) which is eliminated by the E90K mutation which leads to complete HH. Pharmacoperones act to stabilize the E90K mutant by bridging residues D98 (at the extracellular face of TM1; *orange spheres*) and K121 (*discontinuous line*). (C) Sequence of the human GnRHR and location of the loss-of-function mutations identified to date. *Circles* represent amino acid residues. *Red curved lines* represent the position of the C14–C200 and C114–C196 disulfide bridges. The *light orange rectangle* corresponds to the portion of the receptor where the TMs 2 and 3 are located and that are stabilized by the conserved E90–K121 salt bridge or the surrogate D98–K121 bridge (see B) resulting from pharmacoperone action; the *light green rectangle* corresponds to TMs 4 and 5, where mutations are completely recalcitrant (S168R and S217R) or marginally responsive (A171T) to pharmacoperones (Ulloa-Aguirre et al., 2004). Reproduced from Conn, P. M., and Ulloa-Aguirre, A. (2011). Pharmacological chaperones for misfolded gonadotropin-releasing hormone receptors. *Advances in Pharmacology* ***62***, 109–141, with permission from Elsevier.

mammalian GnRHR exhibits more than 85% amino acid identity among the several species that have been cloned. Unlike other members of the Rhodopsin family of GPCRs, the GnRHR exhibits several unique features, including the reciprocal exchange of the conserved D and N residues in TMDs 2 and 7, the replacement of Y with S in the D–R–Y motif located in the junction of the TMD 3 and the intracellular loop (IL) 2, and the lack of the COOH terminal domain (Millar *et al.*, 2004). This latter feature, which is not exhibited by GnRH receptors from nonmammalian vertebrate species such as fish and avian GnRH receptors, is unique among the thousands of members of mammalian GPCRs and is apparently associated with differential physiological regulation (internalization, desensitization, and cell surface PM expression) of the receptor in mammals and nonmammals. Another important feature of the human GnRHR is the presence of a lysine residue at position 191 (K191) in the extracellular loop (EL) 2 (**Fig. 1**B and C). In nonprimate mammals, glutamic acid or glycine (occasionally) are found instead of lysine; in fact, in rodent (rat and mice) GnRHRs the orthologous amino acid is absent, thereby yielding a structure that is one residue smaller (327 amino acid residues). The absence of lysine in this position confers the rodent GnRHRs with an increased PM expression, whereas its presence in the human GnRHR (328 amino acids) limits the amount of GnRHR protein that reaches the PM after synthesis. The mechanism subserving the effect of K191 on PM expression of the primate receptor includes interfering with formation of the C14–C200 disulfide bridge, which is necessary to stabilize the GnRHR in a conformation compatible with endoplasmic reticulum (ER) export. In the rat GnRHR, this disulfide bridge is not essential for receptor expression, as replacement of either of the cysteine residues of the bridge does not affect PM expression (Ulloa-Aguirre *et al.*, 2006). In humans, the GnRHR is located on 4q13.2-3 and consists of three exons and two introns that encode for a 328-amino acid protein (**Fig. 1**A).

The GnRHR is preferentially coupled to the trimeric $G_{q/11}$ protein, localized in the cytoplasm, and associated with the intracellular domains of the receptor. There is evidence that GnRHR also may regulate the activity of the adenylyl cyclase/cyclic AMP/protein kinase A pathway through G_s or G_i proteins, depending on the cell context and experimental paradigm employed. Activation of the GnRHR by its ligand is associated with conformational changes in the receptor molecule that lead to activation of the $G\alpha_{q/11}$ protein subunit followed by its dissociation from the $G\beta\gamma$ complex. The activation of the GnRHR–$G\alpha_{q/11}$ protein complex stimulates the effector enzyme phospholipase-Cβ, which in turn provokes phosphatidylinositol 4,5-biphosphate hydrolysis, leading to formation of the second messengers inositol 1,4,5-triphosphate (IP3) and diacylglycerol. The former diffuses through the cytoplasm, promoting the release of intracellular Ca^{2+} from intracellular stores followed by Ca^{2+} influx via L-type voltage-gated Ca^{2+} channels and acute, calmodulin-mediated secretion of gonadotropins, mainly LH. Diacylglycerol, along with Ca^{2+}, activates the enzyme protein kinase C, triggering a cascade of protein–protein phosphorylation and interactions, including activation of other kinase cascades (e.g., mitogen-activated protein kinase—MAPK- cascade), which eventually lead to the expression of several genes, such as those encoding the gonadotropin subunits and the GnRHR (Naor and Huhtaniemi, 2013). Other signaling molecules involved in GnRH-mediated signaling include phospholipases D and A2, which promote phosphatidic acid and arachidonic acid synthesis, respectively, as well as nitric oxide-stimulated cGMP, and molecules involved in the Wnt/β-catenin signaling cascade and AMP-activated protein kinase (AMPK), the latter apparently involved in LHβ gene transcription (Andrade *et al.*, 2013).

Mutations in the *GNRHR*

Structural alterations in key residues of the receptor molecule or the G proteins may potentially lead to altered function of the receptor–G protein system. Mutations in sites involved in ligand binding usually result in altered receptors unable to recognize the ligand and to become activated (loss-of-function mutations), whereas mutations in sites involved in receptor activation or G protein coupling may lead either to loss-of-function or to constitutive activation (activation in the absence of ligand or gain-of-function) of the receptor molecule. Only one naturally occurring mutation of this latter type has been detected in the human GnRHR (E90K mutation) (**Fig. 1**B and C). This particular mutation leads to a complete form of HH due to the drastic inability of the mutant receptor to traffic from the ER to the PM. The constitutive activity of this mutant could be identified only after promoting its PM expression by exposure to pharmacoperones (see below) (Janovick and Conn, 2010).

Resistance to GnRH by inactivating (loss-of-function) mutations in the *GNRHR* is the most common known genetic cause of normosmic congenital HH and leads to distinct forms of autosomal recessive HH (Chevrier *et al.*, 2011; Ulloa-Aguirre *et al.*, 2004). *GNRHR* mutations may also occur in individuals with sporadic HH, but with a lower frequency (Beranova *et al.*, 2001). Interestingly, patients harboring some *GNRHR* mutations, also present alterations in other genes that lead to HH, including the *PROKR2* or the *FGFR1* (Pitteloud *et al.*, 2007; Silveira *et al.*, 2010; Sykiotis *et al.*, 2010; Gonçalves *et al.*, 2017). Nearly 43 inactivating mutations (including deletions of large sequences and synonymous mutations) in the *GNRHR* have been described as a cause of partial or complete forms of HH (**Fig. 1**C and **Tables 1** and **2**). The detected mutations in the human *GNRHR* are distributed along the entire coding sequence of the receptor, except the IL1 and the extracellular loop (EL) 3. However, two "hot spots" have been identified at residues Q106 and R262 (Q106R and R262Q mutations) (Chevrier *et al.*, 2011).

Although expression of mutated GnRH receptors (*maroon* and *gray circles* in **Fig. 1**C) in in vitro heterologous cell systems has shown that these mutations may influence ligand binding and/or intracellular signal transduction (**Table 2**) (which initially suggested that such mutations disrupted motifs involved in agonist binding, receptor activation and/or interaction with G proteins), studies on several mutants (**Table 2**) have shown that the loss-of-function is rather due to folding defects that lead to impaired intracellular trafficking and reduced PM expression (Conn and Ulloa-Aguirre, 2010). In fact, in a number of these mutant receptors the function may be partially or completely restored in vitro and in vivo by genetic and/or pharmacologic (employing

Table 1 Genotype/phenotype correlates in patients with normosmic HH due to GnRHR mutations or in subjects with simple heterozygous mutations exhibiting reproductive abnormalities or somatic defects associated to HH

pharmacological chaperones or pharmacoperones, Conn *et al.*, 2013) means (Ulloa-Aguirre and Conn, 2016), whenever the mutation does not replace critical residues involved in agonist binding or effector activation (Conn and Ulloa-Aguirre, 2011). For example, the E90K mutation profoundly affects membrane receptor density as a consequence of disruption of trafficking to the PM (Maya-Nunez *et al.*, 2002). Nevertheless, either deletion of K191 (which increases membrane expression and reduces the rate of internalization of the human GnRHR) or exposure to pharmacoperones, efficiently restored membrane expression and agonist-induced, receptor-mediated intracellular signaling of this mutant in vitro (for the mechanism of action of pharmacoperones, see legend for **Fig. 1**B) (Brothers *et al.*, 2004; Conn and Ulloa-Aguirre, 2010; Maya-Nunez *et al.*, 2002). Further, recent studies in an animal model of HH due to the E90K mutation demonstrated that administration of the pharmacoperone IN3 reversed the phenotypic and biochemical abnormalities provoked by the mutation (Janovick *et al.*, 2013; Ulloa-Aguirre and Conn, 2016). The E→K substitution at position 90 prevents the formation of an E90–K121 salt bridge destabilizing the interaction between TMD2 and TMD3 (**Fig. 1**B) required to pass the quality control system of the ER. Consequently, the E90K mutant is retained in the ER. Gaining or losing a disulfide bridge also may result in misfolded GnRHRs. This is the case of the C200Y and the Y108C GnRHR mutants. The C200Y mutation prevents formation of the disulfide C14–C200 bridge required in the human GnRHR to pass the quality control system of the ER, while the Y108C mutation leads to formation of an aberrant disulfide bridge between C108 and C200, provoking gross receptor distortion, which severely impairs its PM expression (Ulloa-Aguirre *et al.*, 2006; Maya-Nunez *et al.*, 2011). The function of the Y108C mutant can be partially rescued by deleting K191 or by pharmacoperone treatment (**Table 2**), and complete rescue is possible only when both rescuing strategies are simultaneously applied (Maya-Nunez *et al.*, 2011). In the case of the A171T mutation (in the TMD4 of the GnRHR) the replacement presumptively disrupts receptor function by impeding conformational mobility of the TMD3 and 4, resulting in stabilization of the receptor in its inactive conformation (Karges *et al.*, 2003); in this particular mutant, exposure to pharmacoperones minimally rescued function (Ulloa-Aguirre *et al.*, 2004). In the S168R and S217R mutations, the thermodynamically unfavored substitutions provoke twisting of the corresponding α-helices moving the EL2 away from the NH_2-terminal domain, impeding the formation of the C14–C200 bridge essential for correct folding and trafficking of the receptor from the ER to the PM (Janovick *et al.*, 2006). Thus, both mutants are completely refractory to genetic or pharmacologic rescue approaches (Conn and Ulloa-Aguirre, 2010). In the L314*X*(Stop) mutation, GnRH binding is practically abolished. In this latter mutation, which leads to partial deletion of the TMD7, the mRNA levels of the receptor are reduced considerably, suggesting that the truncated protein might not be adequately translated and expressed in vivo (Kottler *et al.*, 2000). A truncated nonfunctional GnRHR also has been reported for the homozygous splice junction mutation (G to A replacement) at the intron 1–exon 2 boundary, resulting in a transcript showing splicing of exon 1 to exon 3 (i.e., complete deletion of exon 2) (Silveira *et al.*, 2002).

Individuals with normosmic HH due to *GNRHR* mutations exhibit a strikingly wide spectrum of clinical and biochemical phenotypes, including delayed puberty, variable alterations in pubertal development, late-onset hypogonadism, low or low-normal plasma gonadotropin and sex steroid levels, and impaired response to exogenous GnRH administration and pulsatile pattern of gonadotropin release (de Roux *et al.*, 1999; Abel *et al.*, 2013; Beranova *et al.*, 2001; Gianetti *et al.*, 2012; Tommiska *et al.*, 2013). These alterations usually occur in the absence of anatomical or functional abnormalities of the hypothalamic–gonadotrope axis. Thus, the hypogonadism due to GnRHR mutations can be complete or partial (**Table 1**). The differences between phenotypes in HH due to inactivating *GNRHR* mutations could be related to the particular allelic combination of the coexisting mutations, with the functional activity of a given mutant being more or less severely affected than that exhibited by the other (Leaños-Miranda *et al.*, 2005). In fact, studies in large populations of patients with HH due to GnRHR mutations, found that the reproductive phenotype in patients with biallelic mutations correlated better with the functional severity of the GnRHR mutant than in those harboring monoallelic mutations (Gianetti *et al.*, 2012) (**Table 1**). Nevertheless, the fact that different phenotypes may be present within patients bearing the same molecular alteration or in subjects with simple heterozygous *GNRHR* mutations suggests that other genetic (e.g., coexistence of other mutations also leading to HH (*PROKR2* or *FGFR1*), Pitteloud *et al.*, 2007; Silveira *et al.*, 2010; Sykiotis *et al.*, 2010) or nongenetic (e.g., dominant-negative effects of the mutant GnRHR on its wild-type counterpart,

[a]Studied in silico.

[b]By ClinVar (https://www.ncbi.nlm.nih.gov/clinvar/intro).

PME, Plasma membrane expression studied by immunocytochemistry of tagged-GnRHR or by confocal microscopy of GnRHR-green fluorescent protein (GFP) chimera (E90K). Caution should be exercised in the interpretation of these studies (see Brothers *et al.*, 2003); *RPh*, rescue with pharmacoperones [*C*, complete rescue (response at or above that shown by the Wt GnRHR in the absence of pharmacoperone); *P*, partial rescue (response below that shown by the Wt GnRHR in the absence of pharmacoperone); *M*, marginal rescue]. *LOF*, loss-of-function; *ns*, not studied; +, comparable with Wt GnRHR; –, no measurable effect; ↓ decrease compared to Wt GnRHR.

Leaños-Miranda *et al.*, 2003, 2005) factors may be implicated on the phenotypic expression of the GnRH-resistant HH. Thus, both mechanisms (digenic mutations and dominant negative effects of the mutant GnRHR protein) may account for the severity and variable phenotypic expression of GnRHR mutations. Finally, it is worth mentioning that the HH provoked by certain GnRHR mutations (Q106R, R262Q) can revert spontaneously (Laitinen *et al.*, 2012; Raivio *et al.*, 2007; Sidhoum *et al.*, 2014; Tommiska *et al.*, 2013); the mechanisms subserving this spontaneous reversion, in the absence of coexisting mutations in other genes, are uncertain.

Treatment

Although treatment of HH due to mutations in the *GNRHR* will depend on the particular clinical manifestations and biochemical phenotype of the patient, it may, in general, follow those recommended for other forms of HH due to GnRH deficiency (Ulloa-Aguirre and Lira-Albarrán, 2016; Boehm *et al.*, 2015), keeping in mind that the response to pulsatile GnRH in partial HH might be variable and require a more careful patient selection as well as administration of higher GnRH doses than those usually employed for non GnRH-resistant forms of HH, particularly for ovulation induction (de Roux *et al.*, 1999; Caron *et al.*, 1999; Seminara *et al.*, 2000). In male patients with complete HH, treatment options include administration of testosterone or, preferably, exogenous gonadotropins [FSH and human chorionic gonadotropin (hCG), or human menopausal gonadotropin (hMG)], the latter to promote testicular growth and maturation, stimulate spermatogenesis, normalize serum testosterone levels, and induce development of secondary sexual characteristics. Once puberty has initiated, the patient can be switched to treatment with testosterone indefinitely or until fertility is desired, when gonadotropin treatment should be reinstated. In incomplete forms of HH, treatment with testosterone is usually sufficient to complete sexual maturation and maintain virilization, sexual function, and bone and muscle mass.

Here is important to mention that in patients with GnRHR mutations, HH may revert spontaneously, so a brief withdrawal of treatment with either testosterone or gonadotropins and reassessment of the reproductive axis function with close monitoring of serum testosterone levels are advisable to seek for spontaneous reversion of the hypogonadal state. This will ensure that, in fact, the HH condition reverted and that normalization of reproductive function has occurred. Since reversion may be temporal, long-term monitoring of reproductive function is recommended.

In females, unopposed oral or transdermal estrogen administration may allow optimal breast development. Thereafter, cyclic estrogen-progestin treatment is advisable to provide endometrial protection. When fertility is desired, exogenous gonadotropins may be administered to induce follicular maturation and ovulation, and if spontaneous conception fails, then the patient may undergo IVF treatment (Zernov *et al.*, 2016).

Although pharmacoperones represent the most promising agents to treat HH due to conformationally-, trafficking-defective GnRHR mutants, the development of this particular class of drugs still is under investigation.

Conclusion

GnRH resistance due to inactivating mutations in the *GNRHR* is a common cause of congenital normosmic HH. The reproductive phenotype of patients harboring mutations in the *GNRHR* is highly variable and depends on the allelic distribution of the mutations (mono- vs. biallelic) as well as the coexistence of mutations in other genes also associated to HH (digenic inheritance). Pharmacoperones represent a unique potential therapeutic strategy to overcome the functional defect of the abnormal receptor, whenever the mutation leads to misfolding, impaired intracellular trafficking and altered PM expression. Naturally occurring mutations in the *GNRHR* represent unique models for the analysis of the structure–activity relationships of this particular receptor.

Androgen Biosynthesis and Gene Defects☆

Adina F Turcu and Richard J Auchus, University of Michigan, Ann Arbor, MI, United States

Glossary

Cryptorchidism The condition in which the testes fail to descend into the scrotum and are retained within the abdomen or inguinal canal.

Follicle-stimulating hormone (FSH) A gonadotropin secreted and released by the anterior pituitary. FSH stimulates the ripening of the follicles in the ovary and formation of sperm in the testes by acting on granulosa and Sertoli cells, respectively.

Haploinsufficiency A mutation in only one of the two alleles for an autosomal gene, resulting in a reduced gene dosage for the protein encoded on the normal allele.

Human chorionic gonadotropin (hCG) A hormone similar to the pituitary gonadotropin luteinizing hormone; it is produced by the placenta during pregnancy.

Hypospadias A congenital abnormality in which the labioscrotal folds have not completely fused, so that the opening of the urethra is on the underside of the penis.

Leydig cells The cells interspersed between the seminiferous tubules of the testis. They secrete androgens in response to luteinizing hormone.

Luteinizing hormone (LH) A gonadotropin secreted by the anterior pituitary. LH stimulates androgen synthesis by the Leydig cells of the testis and the theca cells of the ovary; it also stimulates the "luteinization" of ovarian cells after ovulation, forming the corpus luteum, which makes progesterone.

Male pseudo-hermaphroditism A congenital abnormality in which the genitalia of a 46,XY infant are not completely masculinized, despite the presence of testes.

Müllerian structures Structures that develop from the paramesonephric duct in normal females. These include the fallopian tubes, uterus, and upper part of the vagina.

Sertoli cells Cells found in the walls of the seminiferous tubules of the testis. They anchor and nourish the developing germ cells.

Wolffian structures Structures that develop from the mesonephric duct in normal males. These include the epididymis and vas deferens.

Normal Androgen Biosynthesis

All steroid hormone production begins with the conversion of cholesterol to pregnenolone. A "mobile pool" of free cholesterol in the outer mitochondrial membrane (OMM) is physically inaccessible to the side chain cleavage enzyme (CYP11A1, P450scc), which resides in the inner mitochondrial membrane (IMM). Stimulation of Leydig cells with chorionic gonadotropin (hCG) or luteinizing hormone (LH), both of which bind to the same LH/CG receptor, increases intracellular cyclic AMP (cAMP). The rise in cAMP induces the expression and activation of the labile steroidogenic acute regulatory (StAR) protein, which allows the cholesterol to flow from the OMM to the IMM, where CYP11A1 converts the cholesterol to pregnenolone. The microsomal enzyme CYP17A1 (P450c17) sequentially oxygenates pregnenolone (the 17α-hydroxylase reaction) and cleaves the C17–C20 bond (the 17,20-lyase reaction), yielding dehydroepiandrosterone (DHEA). Although human CYP17A1 hydroxylates pregnenolone and progesterone with comparable efficiencies, its 17,20-lyase activity is much more efficient for the Δ^5-steroid 17α-hydroxypregnenolone (17Preg) than for its Δ^4-congenor 17α-hydroxyprogesterone (17OHP). Consequently, DHEA is the substrate for 17β-hydroxysteroid dehydrogenase type 3 (17βHSD3), which reduces DHEA to Δ^5-androstenediol, and 3β-hydroxysteroid dehydrogenase/isomerase type 2 (3βHSD2) converts this Δ^5 steroid to testosterone (T). The sequence of these latter two reactions (17βHSD3 and 3βHSD2) may also proceed in reverse, with androstenedione (AD) as the intermediate. T produced by the testis diffuses into peripheral tissues and those tissues that contain the enzyme 5α-reductase type 2 (SRD5A2) (i.e., prostate, genital skin) metabolize T to the potent androgen dihydrotestosterone (DHT). The importance of all of these steps and the lack of adequate redundancy are demonstrated by the clinical disorders caused by mutations in the genes encoding the key proteins described herein (Fig. 1).

Disorders of Leydig Cell Stimulation

Hypogonadotropic Hypogonadism

Because fetal T synthesis during weeks 8–12 of gestation is driven primarily by placental hCG, 46,XY children with defects in gonadotropin-releasing hormone (GnRH) or gonadotropin production are born with relatively normal male external genitalia. In

contrast, LH drives T production in late gestation, so micropenis is often present, and these individuals fail to experience puberty. These conditions are introduced below but not discussed in detail, as the complex genetics and physiology are beyond the scope of this section.

Kallmann Syndrome and Congenital Normosmic Hypogonadotropic Hypogonadism

Kallmann syndrome refers to the combination of hypogonadotropic hypogonadism and anosmia. Consequently, 46,XY patients are born with normal male genitalia except for micropenis, and they fail to initiate puberty. The diagnosis is made clinically with endocrine and olfactory evaluation and confirmed with low LH and FSH, FSH > LH, and lack of gonadotropin rise in response to a bolus of GnRH analog. Magnetic resonance imaging (MRI) with attention to the olfactory bulb hypoplasia and midline structure defects is helpful but not essential. At the time of expected puberty, testosterone replacement is commenced. Treatment with pulsatile GnRH using a programmable pump will not only induce sexual maturation, but may restore fertility in individuals of both sexes.

Kallmann syndrome can be sporadic, autosomal dominant, autosomal recessive, or X-linked. The best understood form of Kallmann syndrome results from mutations in the *KAL1* gene, which accounts for 5%–10% of cases and up to half of familial cases with X-linked inheritance. This gene encodes an extracellular matrix protein called anosmin-1 that guides the migration of both the olfactory and GnRH-producing neurons from the olfactory placode to their definitive location in the head and brain. Forms of hypothalamic hypogonadism with or without anosmia may result from mutations in at least 35 other genes, which is beyond the scope of this discussion. In approximately half the cases of Kallmann syndrome and its variants, the molecular basis remains unknown.

Combined Pituitary Hormone Deficiencies and Septo-Optic Dysplasia

Developmental defects in midline structures often ablate hypothalamic–pituitary axes, and the growth hormone and GnRH–LH axes are particularly vulnerable. Severe defects, such as holoprosencephaly, characteristically involve large portions of the brain, but milder developmental defects can involve few structures. Combined pituitary hormone deficiency refers to a group of conditions in which growth hormone deficiency occurs with one or more additional pituitary hormone deficiencies. As the spectrum of these disorders expands, 20–30 genes have been identified, and the phenotype has been found to vary from isolated growth hormone deficiency to panhypopituitarism to hypogonadotropic hypogonadism and many intermediate combinations. Septo-optic dysplasia refers to the combination of optic nerve hypoplasia and hypothalamic–pituitary maldevelopment. Evaluation and management are similar to those for Kallmann syndrome, although vision testing and MRI evaluation are important for guiding follow-up and for prognosis. Mutations in several genes, including *HESX1*, *LHX3*, *FGF8*, *SOX2*, and *PROKR2* have been identified in patients with various forms of congenital hypopituitarism, from isolated hypogonadotropic hypogonadism or growth hormone deficiency to septo-optic dysplasia with multiple pituitary hormone deficits. The clinical severity roughly correlates with the impairment in activity of the mutant proteins when tested in vitro.

Leydig Cell Agenesis or Hypoplasia (Testicular Unresponsiveness to hCG/LH)

In a 46,XY fetus with a mutation in the LH/CG receptor, the Leydig cells fail to develop appropriately, and T production is impaired from conception. This defect leads to varying degrees of genital anomalies at birth, depending on the amount of hCG-

independent T production prior to the tenth week of gestation and the severity of the LH/CG receptor dysfunction. Because secretion of anti-Müllerian hormone by the Sertoli cells is intact, 46,XY children with Leydig cell hypoplasia do not retain Müllerian structures. The testes lack distinct Leydig cells on biopsy, and Sertoli cells may appear at puberty. However, the seminiferous tubules, if present, often show spermatogenic arrest, and the testes degenerate progressively.

The 46,XY infants born with completely female genitalia may not be identified until puberty, when they present with failure to develop breasts and to undergo menarche. Milder forms in 46,XY infants cause undervirilization, including hypospadias, micropenis, and cryptorchidism. 46,XX females homozygous for LH/CG receptor defects will have normal female genitalia and may experience some breast development at puberty, but with amenorrhea and infertility. The diagnosis is confirmed by low or absent T, androstenedione (AD), and 17OHP production in response to hCG stimulation testing. Basal and GnRH-stimulated gonadotropin values are elevated in pubertal subjects.

Management depends on the age of diagnosis and the degree of virilization. When the defects are severe enough to produce phenotypically female genitalia, assignment of the female gender, with gonadectomy and estrogen replacement therapy at the time of expected puberty, is usually recommended. For less severely affected individuals with undervirilized male genitalia, surgery may be necessary to correct hypospadias, and testosterone therapy is used to stimulate phallic development and to virilize the patient at puberty.

Leydig cell hypoplasia is an autosomal recessive condition due to mutations in the gene encoding the LH/CG receptor. Several genetic defects have been reported, including missense, nonsense, and null mutations. The null mutations, such as Arg554Stop, are associated with the most severe clinical phenotypes.

Variants of Congenital Adrenal Hyperplasia

The most common form of congenital adrenal hyperplasia (CAH) is 21-hydroxylase (CYP21A2, P450c21) deficiency, but CYP21A2 is not expressed in the gonads and does not participate in T biosynthesis. Other, less common forms of CAH that involve enzymes or proteins expressed both in the adrenals and the gonads are discussed below.

Lipoid CAH

StAR (Steroidogenic Acute Regulatory protein) Deficiency

Because StAR facilitates the transport of cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane, inactivating mutations in StAR block the production of pregnenolone and thus impair all steroidogenesis, both in the adrenals and in the gonads. Under the stimulation of adrenocorticotropic hormone (ACTH) and LH, cholesterol esters massively accumulate in the adrenal glands and testes, respectively, affording the characteristic enlarged, lipid-laden adrenals from which the name lipoid CAH derives. Secondarily, sterol auto-oxidation products accumulate in the adrenals and Leydig cells, altering cell structure and ultimately leading to cell destruction.

Both 46,XY and 46,XX individuals will have female external genitalia at birth. Affected 46,XY individuals have abdominal, inguinal, or intralabial testes, a blind vaginal pouch, and no uterus or fallopian tubes. Wolffian duct remnants may be preserved in 46,XY individuals secondary to low levels of StAR-independent steroidogenesis. All reported patients are diffusely hyperpigmented from pro-opiomelanocortin and ACTH excess. Because the theca cells of the ovary do not normally make steroids during fetal and neonatal life, the ovaries of 46,XX subjects do not suffer lipid accumulation and cell death during childhood. Consequently, 46,XX subjects may produce enough estrogens in early puberty to undergo some breast development and may even menstruate until lipid accumulation and auto-oxidation obliterate ovarian function as well.

The diagnosis of lipoid CAH is confirmed by low or absent glucocorticoids, mineralocorticoids, gonadal steroids, their precursors, and their metabolites in plasma and/or urine, even after stimulation. In particular, 3βHSD2 deficiency is excluded by documenting low concentrations of not only the active Δ^4 steroids but of the Δ^5 precursors pregnenolone and 17Preg. On abdominal computed tomography scan or MRI, the lipid-laden adrenals are strikingly enlarged, displacing the kidneys in the caudal direction.

Treatment requires replacement doses of gluco- and mineralocorticoids in the newborn period, which must be continued throughout life. All affected 46,XY males have been reared as females, and orchidectomy is advised. Estrogen replacement therapy for individuals of both genotypes is required at puberty to initiate female secondary sexual characteristics, and low-dose testosterone may be used to elicit a female pattern of sexual hair growth. Lipoid CAH is an autosomal recessive disease with a male/female ratio of approximately 3/1; however, this ratio may be skewed by ascertainment bias. This condition is rare in the United States and Europe, but is the second most common form of CAH in Japan and Korea. In one series, mutation Q258X accounted for 80% of the affected alleles from Japanese and Korean subjects, suggesting a founder effect that causes the relatively high incidence of lipoid CAH in these countries. Mutation R182L was found in 78% of affected alleles from Palestinian subjects in the same series. Less severe mutations cause a partial or "nonclassic" form of lipoid CAH, in which sex steroid production is normal or mildly impaired, yet cortisol production is deficient, leading to clinically significant adrenal insufficiency. This discrepancy is likely due to the much larger amounts of cortisol synthesis necessary to sustain normal physiology, compared to testosterone or estradiol.

Side Chain Cleavage Enzyme (CYP11A1 or P450scc) Deficiency

For many years, it was hypothesized that homozygous CYP11A1 deficiency caused lipoid CAH, but an absence of CYP11A1 would preclude placental progesterone synthesis and promote spontaneous abortion after the eight to tenth week. However, haploinsufficiency of CYP11A1 has been shown to produce a milder clinical picture of lipoid CAH than in StAR deficiency. Tajima and associates described a 46,XY patient with clitoromegaly, a blind vaginal pouch, hyperpigmentation, and absent Müllerian structures. This patient was raised as a female, and testes were removed from the inguinal region. Adrenal insufficiency with hyperplasia did not occur until the child was 4 years old, and no mutation was found in the gene for StAR. Instead, one allele of the gene for CYP11A1 had a 6 bp in-frame insertion, adding G-D between D271 and V272. This mutant enzyme had no activity and appeared to impair the function of wild-type CYP11A1 when expressed in the same cells, suggesting a partial, dominant-negative mode of action, leading to less severe disease in early childhood rather than infancy.

Treatment is similar to that for StAR protein deficiency, with gluco- and mineralocorticoid replacement to prevent life-threatening adrenal insufficiency at the time of diagnosis, plus estrogen replacement therapy at the time of puberty.

3βHSD2 Deficiency

The 3βHSD enzymes catalyze the conversion of the Δ^5 steroids pregnenolone, 17Preg, DHEA, and Δ^5-androstenediol to their corresponding Δ^4 steroids progesterone, 17OHP, AD, and T, respectively. One of these conversions is required in the biosynthesis of all active steroid hormones, so severe 3βHSD2 deficiency will also result in a form of CAH with impaired androgen production.

46,XY individuals with 3βHSD2 deficiency most frequently exhibit male pseudo-hermaphroditism with a small phallus, hypospadias, partial labioscrotal fusion, and possibly a urogenital sinus with a blind vaginal pouch. Testes usually lie in the lower inguinal region, and Müllerian structures are absent. Paradoxically, 46,XX individuals often have trace clitoral enlargement and progressive masculinization if undertreated. Severe 3βHSD2 deficiency can present with salt-wasting crisis from glucocorticoid and mineralocorticoid insufficiency within the first week of life. Less severe forms of 3βHSD2 deficiency are usually diagnosed in genetic males because of genital abnormalities, but may be difficult to diagnose in females. Androgen production increases at puberty in both sexes but at a rate that is intermediate for males and females; consequently, girls show signs of androgen excess, but boys often develop gynecomastia. Fertility has been reported in affected individuals of both sexes (**Table 1**).

The diagnosis of 3βHSD2 deficiency hinges on elevated ratios of Δ^5 steroids to their Δ^4 congeners. These ratios, which are already increased at baseline, are accentuated by cosyntropin stimulation and should reach >12 SD above normal (17Preg > 3000 ng dL^{-1} $= 90$ nmol L^{-1}). Adult females with idiopathic hirsutism or polycystic ovary syndrome often have high circulating DHEA-S concentrations with high ratios of Δ^5 to Δ^4 steroids, so extremely elevated ratios are required to confidently diagnose 3βHSD2 deficiency.

Therapy includes early glucocorticoid and mineralocorticoid replacement in severely affected individuals to prevent life-threatening adrenal insufficiency, and this treatment also limits sexual precocity caused by increased synthesis of adrenal androgen precursors. Females require estrogen replacement, while males require testosterone supplementation to achieve full development of secondary sexual characteristics.

Two functional 3βHSD genes are encoded on chromosome 1p13. The type 2 enzyme is the dominant isoform expressed in the adrenals and gonads, and its gene is mutated in 3βHSD2 deficiency. Adult females who present with hirsutism, infertility, and relatively high DHEA-S concentrations do not have mutations in the cognate *HSD3B2* gene. Mutations in the *HSD3B2* gene have been found from residues A10 to G294, with no mutations dominating large series. Salt-wasting subjects have completely inactive alleles, and non-salt-wasting individuals can harbor mutations that retain partial activity when expressed in heterologous systems. The type 1 enzyme is expressed in the placenta but also in liver and skin, and this enzyme accounts for the peripheral conversion of Δ^5 precursors to Δ^4 steroids in 3βHSD2 deficiency, leading to the paradoxical androgen excess in females. Mutations in the gene for the type 1 enzyme have not been reported, although the common N367T gain-of-function allele resists degradation and confers a poor prognosis in patients with castration-resistant prostate cancer.

CYP17A1 (P450 17A1) Deficiencies

CYP17A1 catalyzes both the 17α-hydroxylase and 17,20-lyase reactions. Severe mutations will ablate both activities, but milder mutations may either partially impair both activities or preferentially impair 17,20-lyase activity with 17α-hydroxylase activity remaining relatively normal. Furthermore, the 17,20-lyase activity is particularly dependent on the interaction of CYP17A1 with its redox partners, cytochrome P450 oxidoreductase (POR) and cytochrome b_5. In particular, the presence of cytochrome b_5 increases the 17,20-lyase activity 10-fold but minimally influences 17α-hydroxylase activity. Thus, alterations in redox partners and/or their interactions with CYP17A1 may preferentially impair 17,20-lyase activity.

Combined 17α-Hydroxylase/17,20-Lyase Deficiency

The classical description of severe, combined, 17α-hydroxylase/17,20-lyase deficiency is sexual infantilism and hypokalemic hypertension in both genetic sexes. The presentation in 46,XY individuals varies from completely female external genitalia with a blind vaginal pouch to an undervirilized male genital phenotype with hypospadias and a small phallus. Testes in these subjects

[a]Small undescended testes with absent or decreased numbers of Leydig cells to descended testes of normal size with decreased numbers of Leydig cells. Hypogonadotropic hypogonadism is not included, because boys with this disorder generally have normal genitalia, except for micropenis.

may be intra-abdominal, in the inguinal canal, or in labioscrotal folds. Müllerian structures are absent, and Wolffian derivatives are usually hypoplastic. Severely affected patients will fail to develop secondary sexual characteristics, including pubic and axillary hair. With milder disease, males may develop gynecomastia at puberty and females may progress to Tanner stage 5 with ovulatory menses but infertility. Based on studies with recombinant enzyme, it has been estimated that at least 25% of normal fetal CYP17A1 activities are required for masculinization of the external genitalia. Hypertension with hypokalemia occurs in childhood and is often severe, with myopathy and hypertensive complications at a young age.

The diagnosis should be entertained not only in undervirilized males but also in any phenotypic female with hyporeninemic hypertension, hypokalemic alkalosis, and a suppressed aldosterone. This diagnosis may be confirmed by finding elevated circulating levels of ACTH and the precursors that accumulate proximal to the block in 17-hydroxylation: progesterone, 11-deoxycorticosterone (DOC), corticosterone (B), 18-hydroxy-DOC, and 18-hydroxy-B. Both DOC and B have mineralocorticoid activity, leading to hypertension and hypokalemia. However, signs of adrenal insufficiency rarely develop, because the weak glucocorticoid B is present in abundance. Gonadotropins are elevated at puberty, and serum concentrations of aldosterone, 17OHP, cortisol, and sex steroids are low or absent.

Treatment includes replacement of glucocorticoids to suppress DOC and B secretion and thereby to normalize potassium homeostasis and blood pressure. Mineralocorticoid receptor antagonists, such as spironolactone, can be used to reduce the doses of glucocorticoids and to prevent iatrogenic Cushing syndrome. At puberty, sex steroid replacement is indicated, and gonadectomy should be performed in 46,XY patients assigned a female sex of rearing due to increased risk of malignancy. One live birth has been reported in a 46,XX patient with incomplete deficiency, which required progesterone suppression with dexamethasone, ovulation induction, and in vitro fertilization.

Mutations have been identified throughout the *CYP17A1* gene, and some of the encoded proteins with missense mutations retain partial activity when expressed in heterologous systems. Most mutations that yield a completely inactive enzyme also destabilize the enzyme structure and ablate heme binding. Recurrent mutations include deletion of F53; R96W or Q; R239Q or X; Y329D, X, or ins/del; H373D, N, or L; P406R; a CATC duplication following I479; and deletions or duplications starting at D487. In Brazil, 17-hydroxylase deficiency is the second most common cause of CAH, due to the founder mutations W406R and R362C.

Isolated 17,20-Lyase Deficiency

When only the 17,20-lyase activity is deficient, adrenal glucocorticoid and mineralocorticoid synthesis is normal, but testosterone synthesis is impaired. Therefore, serum potassium and blood pressure are normal, but sexual development may be hampered. In 46,XY patients, the external genitalia are that of an undervirilized male, due to some residual 17,20-lyase activity. Müllerian structures are absent, Wolffian derivatives are either hypoplastic or normal, and testes may be intra-abdominal, inguinal, or in the scrotum. In 46,XX females, failure to progress through adrenarche and puberty suggest the diagnosis, but the few cases so far identified have been ascertained as siblings of affected 46,XY affected individuals.

Cosyntropin stimulation tests yields normal or elevated 17-hydroxysteroid values, including cortisol and 17OHP, but DHEA and AD do not rise proportionately. Similarly, hCG stimulation testing will produce an increase in 17OHP concentrations, but AD and T do not rise normally. The ratio of the rise in the C_{19} steroids to their C_{21}, 17-hydroxy precursors is the most discriminatory parameter for diagnosing isolated 17,20-lyase deficiency, such as 17OHP/AD >50. Detailed hormonal testing can demonstrate a partial loss of 17-hydroxylase activity, but usually not enough to cause hypertension or hypokalemia, and the nearly complete absence of androgens and estrogens dominates the clinical presentation.

A few cases of isolated 17,20-lyase activity have been confirmed with molecular genetic and biochemical studies. Patients homozygous for mutations R358Q and R347H have been identified in Brazil, and others heterozygous for a null allele and one copy of R347C were described in the Netherlands. These residues, R347 and R358, are both located on the redox-partner-binding surface of the CYP17A1 enzyme. Consistent with the known dependence of the 17,20-lyase activity on the interaction of CYP17A1 with redox partners POR and cytochrome b_5, these mutations at this binding surface appear to preferentially impair 17,20-lyase activity. In contrast, a large kindred from Israel with isolated 17,20-lyase activity carries the homozygous mutation E305G, which is found in the active site and impairs 17Preg binding.

Mutations in the *CYB5A* gene encoding cytochrome b_5 also cause isolated 17,20-lyase deficiency, with or without congenital methemoglobinemia. A deletion in the *CYB5A* gene was described in an undervirilize male, but hormonal analyses were not performed. Subsequently, individuals homozygous for mutations W27X or H44L were identified and characterized endocrinologically, which confirmed isolated 17,20-lyase deficiency. H44 is one of the axial histidine ligands for the heme prosthetic group of cytochrome b_5, and the stop codon at W27 yields a small peptide missing the critical residues for CYP17A1 stimulation. A third genetic form is described in the section on POR deficiency below.

Gonadectomy is recommended in 46,XY subjects raised as females and gender-appropriate sex steroid replacement will be necessary at the time of puberty. Optimal management in 46,XX subjects has not been established.

P450 Oxidoreductase (POR) Deficiencies

POR is a membrane-bound flavoprotein widely expressed in human tissues, which serves as a reductase for all microsomal P450 enzymes, including the steroid hydroxylases CYP17A1 (P450 17A1), CYP21A2 (P450 21A2), and aromatase (CYP19A1, P450 19A1). POR transfers two electrons from NADPH to the receiving enzymes.

Patients with POR deficiency may exhibit features similar to deficiencies of CYP17A1, CYP21A2, and aromatase, in various combinations and severities. Patients of both sexes may present with ambiguous genitalia, similar to 3βHSD deficiency. The function of 17,20-lyase is predominantly disrupted by POR defects, resulting in low C_{19} steroids and consequently in underdeveloped genitalia in 46,XY fetuses. Homozygous mutation G539R yields a steroid profile very similar to isolated 17,20-lyase deficiency due to mutations in *CYP17A1* or *CYB5A*. POR mutations that simultaneously disrupt aromatase function prevent the placental conversion of fetal C_{19} steroids to estrogens, thus contributing to maternal virilization. Furthermore, excessive 17OHP accumulation upstream from the enzymatic dysfunction can be diverted via the so-called "backdoor pathway" to the most potent androgen, DHT, which is generated bypassing AD and T. This DHT production causes the paradoxical virilization of 46,XX cases despite low C_{19} steroid production postnatally.

POR deficiency should be suspected when clinical and hormonal evidence support dysfunction of multiple P450 enzymes, most commonly of CYP17A1 and CYP21A2. Additionally, these patients may present skeletal malformations, such as craniosynostosis, radiohumeral or radio-ulnar synostosis, and femoral bowing, as part of the Antley–Bixler syndrome (ABS) or other eponymic conditions. ABS cases with disordered steroidogenesis all have POR mutations and autosomal recessive inheritance. Approximately 50% of ABS cases lack steroidogenesis defects and derive from gain-of-function mutations in fibroblast growth factor receptor type 2 (*FGFR2*), with autosomal dominant inheritance.

Two missense mutations account for most POR deficiencies: A287P, encountered in patients of European ancestry, and R457H, the most common mutation in Japan and Korea. Deficiency of aromatse has been associated with mutation R457H but not mutation A287P.

Defects Affecting Only Testosterone and Dihydrotestosterone Production

The final two genetic disorders discussed involve the terminal steps of T and DHT biosynthesis. These two conditions are unique in that only males (46,XY) experience clinical manifestations that are solely due to androgen deficiency in utero. Furthermore, other enzymes partially compensate for the genetic deficiencies, but only at puberty.

17β-Hydroxysteroid Dehydrogenase Type 3 (17βHSD3) Deficiency

The human genome contains several 17βHSD isoforms, but 17βHSD3 is the enzyme that is defective in the clinical entity "17βHSD deficiency," also known as "17-ketosteroid reductase deficiency." The 17βHSD3 enzyme catalyzes the conversion of C_{19}, 17-ketosteroids to 17β-hydroxysteroids using NADPH as cofactor: AD to T, DHEA to Δ^5-androstenediol, 5α-androstanedione to DHT, and 5α-androsterone to 5α-androstanediol. Because 17βHSD3 is expressed exclusively in the testes, the loss of this enzyme impairs androgen biosynthesis only in males.

Most affected 46,XY individuals with 17βHSD3 deficiency have predominantly female external genitalia with a blind vaginal pouch. Surprisingly, Wolffian derivatives, such as the epididymis, vas deferens, seminal vesicles, and ejaculatory duct, are present, suggesting that an alternate pathway in these tissues enables some testosterone production, perhaps mediated by the 17βHSD type 5 isoform. Testes are usually located in the inguinal canal, and Müllerian structures are absent.

Most of these children are raised as females. At puberty, testicular AD production increases, and significant extraglandular conversion of this AD to T elicits marked physical changes. The phallus enlarges and can reach lengths of 4–8 cm; the voice deepens, male pattern body hair develops, and muscle mass increases. Several affected individuals have changed gender role from female to male in adolescence because of the prominent physical and psychological masculinization they experience. GnRH agonist therapy will stop these changes. In contrast, 17βHSD3 is not expressed in the human ovary, so 46,XX patients with this disorder are asymptomatic.

The diagnosis is based on markedly elevated AD concentrations in the face of low T in the neonatal period or in adolescence. The discrepancy in the AD/T ratio is accentuated with HCG stimulation. In the past, affected 46,XY males were frequently raised as females and underwent castration followed by estrogen substitution therapy at puberty, but infants with adequate phallic structures and mild hypospadias may be reared as males and undergo genitoplasty if necessary. This approach anticipates the tendency for gender reversal associated with virilization at puberty. Even within members of a kindred with identical genotypes, however, affected individuals vary in their decisions about gender reversal at puberty when reared initially as females. If the patient is reared as a male, T replacement at puberty might be necessary to achieve full masculinization and to prevent the development of gynecomastia. Spermatogenesis is absent if the deficiency is complete or nearly complete, due to lack of intratesticular T synthesis.

Most mutations in the gene for 17βHSD3 are located on exon 9 and impair all enzyme functions. One common mutation, identified in both Brazilian and Palestinian subjects, is R80Q, which lies in the nucleotide-binding domain and primarily disrupts the binding of cofactor but not of steroid. Genotyping is often necessary to establish the diagnosis when steroid testing is ambiguous or if gonadectomy has been performed.

5α-Reductase Type 2 (SRD5A2) Deficiency

The disorder 5α-reductase deficiency (also known as pseudo-vaginal perineoscrotal hypospadias) provides strong genetic evidence that DHT is required for complete formation of the male external genitalia in human beings. The 5α-reductases catalyze the conversion of T to its 5α-reduced metabolite DHT, and the type 2 isoform executes this transformation in the prostate and genital skin. Consequently, 46,XY male infants with a deficiency in the type 2 enzyme are born with hypospadias and a phallic structure that resembles an enlarged clitoris, often bound in chordee. The urogenital sinus with a blind vaginal pouch opens on the perineum, and the scrotum is bifid, with testes located in the inguinal canal or labioscrotal folds. With the abundance of T, Wolffian structures are well differentiated, and Müllerian structures are absent. The ejaculatory ducts terminate in the blind vaginal pouch or onto the perineum next to the urethra, and the prostate is hypoplastic.

As is the case in 17βHSD3 deficiency, masculinizing changes occur at puberty as circulating T concentrations rise into the normal adult male range. The voice deepens, muscle mass increases, the phallus grows to 4–8 cm, and the subject may experience erections. The testes enlarge, the scrotal structure becomes rugated and pigmented, and spermatogenesis may occur, but is often impaired from cryptorchidism. Facial hair and body hair are sparse and acne and temporal hair recession do not occur, presumably because DHT production is low. As in 46,XY infants with 17βHSD3 deficiency, most 46,XY individuals with 5α-reductase deficiency are reared as females but reverse gender role with the masculinizing changes of puberty, and in some cultures where the disorder is endemic, this process has achieved a socially acceptable status. However, unlike 17βHSD3 deficiency, gynecomastia does not develop. The 46,XX females with 5α-reductase deficiency are phenotypically normal at birth, but at puberty they have decreased body and pubic hair and delayed menarche yet normal fertility.

Diagnostic testing includes measurement of serum T and DHT, and a T/DHT ratio >30 unambiguously confirms the diagnosis. One pitfall of testing is that after puberty, the activity of the type 1 isozyme may provide measurable levels of DHT, emphasizing the importance of the T/DHT ratio. In contrast, a T/DHT of 8.5 should be used to increase the sensitivity in early infancy, when androgen levels are low compared with puberty. Although not always necessary, molecular diagnostics of the *SRD5A2* gene aids in making the diagnosis definite in selected cases, particular when androgens are low and testing is equivocal. Analysis of urinary steroids using gas chromatography/mass spectrometry is also used for diagnosis, even following gonadectomy, using the ratio of 5α-/5β-reduced cortisol metabolites.

Treatment of 5α-reductase deficiency is DHT therapy, often applied as a cream to the genitalia, to increase phallic length and to facilitate hypospadias repair. Supraphysiologic dosing of T in adults may generate adequate DHT via a partially functional type 2 enzyme and/or via the type 1 isoform.

Approximately 40% of children with 5α-reductase deficiency are born to consanguineous parents; uniparental disomy has also been described. The founder mutation R246W is prevalent in the Dominican Republic, where the disease is common, but other mutations are found in other kindreds there. A 20 kb deletion that includes the *SRD5A2* gene is prevalent in Papua New Guinea, and an A insertion into amino acid 251 causes 5α-reductase deficiency in a Turkish cluster. Several mutations are found in Brazil, and Q126R is the most common. The type 1 isozyme is expressed in the liver up to 2–3 years of age and in nongenital skin. Mutations in the type 1 isozyme have not been described.

Reproductive and Nonreproductive Actions of Testosterone

Introduction

Testosterone is an important regulator of male sexual differentiation, reproductive and nonreproductive behaviors, development of secondary sex characteristics, spermatogenesis, muscle and bone mass, erythropoiesis, and metabolism (Bhasin and Jameson, 2018; Bhasin *et al.*, 2018). Testosterone may exert its biologic effects directly by itself or indirectly through its conversion to its two major metabolites: 5α dihydrotestosterone (DHT) and estradiol 17β (Bhasin and Jameson, 2018; Bhasin *et al.*, 2018). The beneficial effects of testosterone on bone resorption, high-density lipoprotein cholesterol, atherosclerosis progression, sexual desire, and fat mass require its conversion by CYP19A1 (aromatase) to estradiol 17β (Bhasin and Jameson, 2018; Bhasin *et al.*, 2018; Finkelstein *et al.*, 2013, 2016; Vanderschueren *et al.*, 2014). Conversion of testosterone to DHT by a family of steroid 5α-reductase enzymes is obligatory for mediating its effects on the differentiation of the urogenital sinus and the genital tubercle (Bhasin and Jameson, 2018; Bhasin *et al.*, 2018). Testosterone's conversion to DHT also is believed to mediate its effects on hair growth, scalp hair loss, prostate growth, and acne; however, it is not clear whether this conversion is obligatory for mediating its effects on the prostate, skin, and the hair follicle (Bhasin and Jameson, 2018; Bhasin *et al.*, 2012, 2018). Testosterone's conversion to DHT is not required for testosterone's effects on muscle and bone, plasma lipids, and erythropoiesis (Bhasin *et al.*, 2012; Page *et al.*, 2005; Amory *et al.*, 2004).

Testosterone and the Androgen Receptor

Many actions of testosterone and DHT, including its effects on sexual differentiation of urogenital structures, spermatogenesis, muscle and bone, and erythropoiesis, are mediated through the classical androgen receptor (AR) (Bhasin and Jameson, 2018; Bhasin *et al.*, 2018). As a member of the nuclear receptor superfamily, AR is a 919 amino-acid (aa), 110 kDa, ligand-inducible intracellular transcription factor that mediates most of the biological effects of testosterone and its androgenic derivatives, including DHT (Roy *et al.*, 2001; Tan *et al.*, 1988; Jenster *et al.*, 1991; Trapman *et al.*, 1988). AR possesses three characteristic structural domains: ligand binding domain (LBD, CTD), DNA binding domain (DBD), and transactivation domain or N-terminus domain (NTD) (Roy *et al.*, 2001; Tan *et al.*, 1988; Jenster *et al.*, 1991; Trapman *et al.*, 1988), The LBD in the C-terminus (690–919 aa) is highly conserved and confers ligand specificity. The DBD (545–675 aa) also is well conserved and binds to the androgen response elements or other transcription factors bound to the androgen response elements in the AR promoter. The NTD (1–514 aa) is not well conserved, has been difficult of crystallize, and contains several unstructured domains. Unliganded AR is primarily located in the cytoplasm; in response to ligand binding, AR undergoes distinct conformational changes, leading to recruitment of co-regulators and chaperone proteins, translocation to the nucleus, dimerization, chromatin remodeling, DNA binding and eventual regulation of transcriptional activity of AR-responsive genes (Kuil and Mulder, 1994, 1995; Tyagi *et al.*, 2000; Kemppainen *et al.*, 1992; Trapman *et al.*, 1990). The three domains of AR act in concert to conformationally gate the response to agonist or antagonist binding.

Crystal structure of C-terminus LBD of the nuclear hormone superfamily displays highly conserved arrangement of 12 α helices (Sack *et al.*, 2001; Pereira de Jésus-Tran *et al.*, 2006; Bohl *et al.*, 2007). While AR contains 11 helices, they are still numbered from 1 to 12 (helix 2 is skipped) to reflect the shared functional organization with helix 12 acting as a mobile, conformational gate. Ligand binding is associated with significant rearrangement in the immediate vicinity of the involved residues as well as in distant residues in other domains. The LBD is attached to the 80 aa DBD organized in two zinc-coordinated, tetra-cys sequence repeats through a hinge region (Verrijdt *et al.*, 2003, 2006). The DBD binds with high affinity to the androgen response elements (AREs) to trigger transcriptional activity. While AR shares affinity for consensus reads 5′-TGTTCT-3′ (clARE) with other nuclear receptors, such as GR and PR, it also has selective ARE (selARE), including PB-ARE2 and Slp-HRE2. These interactions of the DBD and ARE regulate the recruitment of enhancers/promoters to the macromolecular transcriptional assembly (Cato *et al.*, 1987; Schoenmakers *et al.*, 2000). The crystal structures of liganded LBD and DBD have been described, but no crystallographic or solution NMR structures have been solved for the NTD or its fragments. It is conceivable that the conformational flexibility of NTD enables intra- and interdomain steric interactions.

AR utilizes two activation function regions located in the N-terminal domain (AF-1) and the C-terminal LBD (AF-2). These surfaces regulate NTD/CTD interaction as well as the recruitment of co-activator and co-repressor proteins in a ligand-specific manner (Heinlein and Chang, 2002; Bevan and Parker, 1999; Heemers and Tindall, 2007; Estébanez-Perpiñá *et al.*, 2007). The AR

AF-2 plays two functional roles: (a) in the unliganded state, it associates with FxxLF (residues 23–27), WxxLF (residues 433–437) motifs observed in the NTD to keep the AR in an inactive conformation; and (b) in the ligand-bound state, it recruits coregulators that possess LxxLL and FxxLF motifs, including p160 family, ARA55, ARA55, ARA70, NCoRs, and SRCs. Selective recruitment of the coregulators elicits ligand-specific, AR mediated transcriptional activity. Within the AR-AF1, two transcription activation units, Tau-1 and Tau-5 have been described (Jenster *et al.*, 1995). The presence of both Tau-1 and Tau-5 is obligatory and sufficient for activity of the isolated AR-NTD and the full-length AR; mutations in Tau-1/Tau-5 render the AR protein inactive.

Collectively, the transcriptional activity of AR is regulated by a spatiotemporal interplay between domains and motifs. Ligand binding and coregulator protein-induced conformational dynamics enable the domains to exhibit multiple functional roles.

Modulation of Testosterone' Bioavailability and Action by Binding Proteins

Circulating testosterone is bound with high affinity to sex hormone–binding globulin (SHBG) (30%–45% in men and 70% in women) and with substantially lower affinity to albumin (50%–68% in men and ~25% in women), cortisol binding globulin, and orosomucoid; only 1%–4% of circulating testosterone is in the unbound or free form (**Fig. 1**) (Bhasin and Jameson, 2018; Bhasin *et al.*, 2018; Goldman *et al.*, 2017; Zakharov *et al.*, 2015). Free testosterone refers to the circulating unbound fraction of testosterone; according to the free hormone hypothesis, this is the fraction of circulating testosterone that is able to cross the cell membrane and exert biologic effect. The term bioavailable testosterone refers to the fraction of circulating testosterone that is not bound to SHBG, and reflects the view that albumin-bound testosterone may dissociate at the capillary level, especially in tissues and organs with long transit time such as the liver and brain, and become "bioavailable" (Bhasin and Jameson, 2018; Bhasin *et al.*, 2018; Goldman *et al.*, 2017). Under certain situations, SHBG may transport testosterone intracellularly through a megalin-mediated endocytic process (Goldman *et al.*, 2017). The binding proteins may regulate the transport, bioavailability, and clearance of testosterone and modulate its biologic effects.

The Effects of Testosterone on Sexual Function

Testosterone regulates many domains of sexual function, including sexual desire; spontaneous sexual thoughts and fantasies; attentiveness to erotic cues; the duration, magnitude, and frequency of nocturnal penile erections; volume of ejaculate; and, overall sexual activity (**Table 1**) (Bhasin *et al.*, 2007; Bhasin and Basson, 2016). Davidson and colleagues established that the primary role of testosterone is to increase sexual motivation and thoughts; their studies demonstrated that hypogonadal men experienced fewer sexual thoughts and fantasies, fewer spontaneous erections, and lower overall sexual activity than eugonadal men (Kwan *et al.*, 1983). However, hypogonadal men and eugonadal men exhibited similar erectile responses to visual erotic stimuli. When androgen-deficient men were treated with testosterone, the frequency of sexual fantasies and thoughts, number of spontaneous erections, and overall sexual activity increased (Kwan *et al.*, 1983). However, their erectile response to visual erotic stimuli did not change. These pioneering experiments by Davidson led to the prevalent view that spontaneous but not stimulus-induced erections are androgen-dependent. The primary role of testosterone is to increase sexual motivation and thoughts (*libido*).

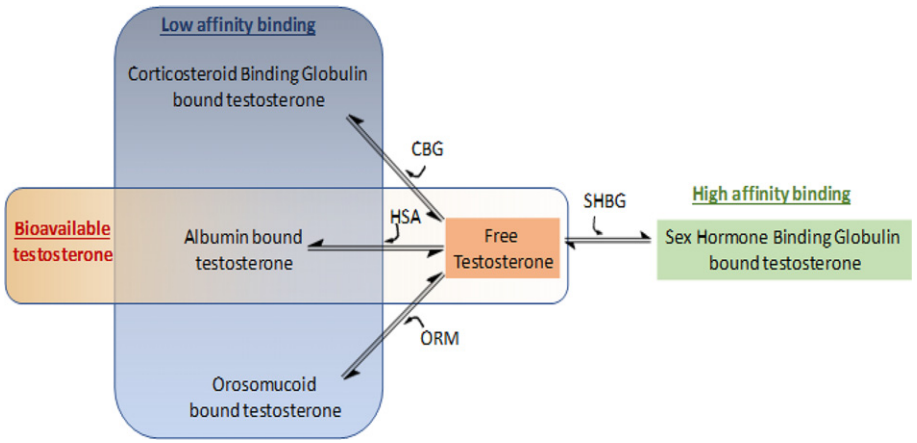

Fig. 1 The regulation of the bioavailability of circulating testosterone by its cognate binding proteins. Most of the circulating testosterone is bound to at least one of four binding proteins: sex-hormone binding globulin (SHBG), albumin, cortisol binding globulin, and albumin, and only 2%–4% of circulating testosterone is free. Testosterone binds with high affinity to SHBG and with substantially lower affinity to albumin, CBG, and orosomucoid. The term bioavailable refers to that fraction of circulating testosterone which is not bound to SHBG and reflects the belief that non-SHBG bound testosterone, being bound with low affinity to albumin can dissociate at the capillary level and become "bioavailable."

Table 1 Effects of testosterone on sexual function in men

- Increases the frequency of spontaneous sexual thoughts and sexual fantasies
- Increases attentiveness to erotic cues
- Increases the frequency, duration, and magnitude of nighttime erections
- Increases the frequency of spontaneous erections
- Increases overall sexual activity
- Improves libido, erectile function, satisfaction with intercourse, and overall sexual activity in hypogonadal men

Randomized large trials of testosterone have shown that testosterone treatment of hypogonadal men with low libido improves libido, erectile function, and overall sexual activity more than placebo (Steidle *et al.*, 2003; Brock *et al.*, 2016; Cunningham *et al.*, 2016; Snyder *et al.*, 2016); systematic reviews and meta-analyses have confirmed these findings (Corona *et al.*, 2014; Boloña *et al.*, 2007; Jain *et al.*, 2000). Testosterone does not improve sexual function and activity in men who do not have low testosterone levels (Basaria *et al.*, 2015).

Testosterone replacement therapy does not improve ejaculatory function in men with low testosterone levels and ejaculatory dysfunction (Paduch *et al.*, 2015). There have been no randomized trials of testosterone in men with orgasmic disorders.

Testosterone regulates a number of processes that culminate in penile erection (Lugg *et al.*, 1995; Prigo-Rocha *et al.*, 1993; Chamness *et al.*, 1995; Giuliano *et al.*, 1993; Reilly *et al.*, 1997a,b; Heaton and Varrin, 1994; Shabsigh *et al.*, 1998; Mills and Lewis, 1999; Mills *et al.*, 1998). Testosterone regulates nitric oxide synthase expression and activity in the cavernosal smooth muscle of rats (Lugg *et al.*, 1995; Prigo-Rocha *et al.*, 1993; Chamness *et al.*, 1995). There is additional evidence that non-NO-dependent pathways may also be androgen sensitive in the erectile response (Giuliano *et al.*, 1993; Reilly *et al.*, 1997a,b; Heaton and Varrin, 1994). Androgens exert a trophic effect on cavernosal smooth muscle (Shabsigh *et al.*, 1998). Castration results in impaired erectile response to central and peripheral stimulation and a decrease in penile tissue concentration of nitric oxide synthase-containing nerves; testosterone replacement reverses these abnormalities (Heaton and Varrin, 1994). Testosterone has trophic effects in maintaining the mass of the bulbospongiosus and ischiocavernosus muscles; the contraction of these muscles contributes to the achievement of peak rigidity just prior to ejaculation (Mills and Lewis, 1999). Testosterone enhances blood flow into the penis (Mills and Lewis, 1999; Mills *et al.*, 1998; Aversa *et al.*, 2003). Furthermore, during ganglionic stimulation, veno-occlusion fails to occur in castrated rats (Mills *et al.*, 1998; Fournier *et al.*, 1987). Collectively, these data indicate that testosterone plays an important role in regulating erectile mechanisms at multiple levels.

Androgen deficiency and erectile dysfunction are two independently distributed conditions, each with a distinct pathophysiology. However, the two conditions often overlap, particularly in older individuals and in those with comorbid conditions (Korenman *et al.*, 1990). Phosphodiesterase 5 inhibitors can improve erectile function in eugonadal and hypogonadal men (Tsertsvadze, 2009). Randomized controlled trials have failed to demonstrate further improvements in erectile function with the addition of testosterone to an optimized regimen of phosphodiesterase 5 inhibitors (PDE5I) (Spitzer *et al.*, 2012; Buvat *et al.*, 2011). However, we do not know whether testosterone replacement therapy would improve subsequent erectile response to PDE5Is.

Anabolic Effects on the Skeletal Muscle (Table 2)

Testosterone is a potent anabolic hormone which increases skeletal muscle mass, maximal voluntary muscle strength, and muscle power in healthy men (Bhasin *et al.*, 1996, 2001). Testosterone replacement also increases fat-free mass and maximal voluntary strength, and decrease fat mass in healthy hypogonadal men, HIV-infected men with weight loss, and in men with chronic obstructive lung disease or end stage renal disease (Bhasin *et al.*, 1997, 2000, 2005a; Grinspoon *et al.*, 1998; Casaburi *et al.*, 2004; Wang *et al.*, 2000). Randomized clinical trials in middle-aged and older men with low or low-normal testosterone concentrations have also demonstrated greater gains in lean body mass and grip strength with testosterone administration compared with placebo (Bhasin *et al.*, 2005b; Snyder *et al.*, 1999; Page *et al.*, 2005; Kenny *et al.*, 2001, 2002; Blackman *et al.*, 2002; Basaria *et al.*, 2010; Travison *et al.*, 2011; Srinivas-Shankar *et al.*, 2010; Storer *et al.*, 2008, 2017; Nair *et al.*, 2006; Emmelot-Vonk *et al.*, 2008; Liverman and Blazer, 2004). The loss of fat mass induced by testosterone therapy is distributed evenly between appendicular and trunk compartments and within each of those compartments between superficial subcutaneous, and deep intramuscular, and visceral fat compartments (Woodhouse *et al.*, 2004).

In spite of a clear demonstration of the gains in muscle mass and strength by testosterone administration, the effects of testosterone replacement on performance-based measures of physical function have been inconsistent across studies. In older men with mobility limitation, testosterone replacement improves VO_{2peak} (Storer *et al.*, 2016), self-reported function, and some performance-based measures of physical function that are more closely related to lower extremity muscle strength and power, such as stair climbing speed and power (Basaria *et al.*, 2010; Travison *et al.*, 2011; Storer *et al.*, 2008). However, testosterone's treatment effect on 6-min walking speed and distance in randomized trials has been small, and its clinical meaningfulness remains unclear (Snyder *et al.*, 2016).

Testosterone-induced increase in muscle strength is related to the gains in muscle mass; testosterone does not improve the specific force of the muscle (Storer *et al.*, 2003). Thus, testosterone administration does not improve the contractile properties of the skeletal muscle. Testosterone administration induces muscle fiber hypertrophy and increases the cross-sectional area of both type 1 and type 2 skeletal muscle fibers; testosterone does not change the absolute number of type 1 or type 2 muscle fibers or their relative proportion (Sinha-Hikim

Table 2 Effects of testosterone on the skeletal muscle

Effects on skeletal muscle histomorphology

- Hypertrophy of type 1 and 2 muscle fibers
- Increased mitochondrial mass and quality
- Increased number of myonuclei and satellite cells

Effects on body composition

- Increase in whole body, appendicular, and trunk lean mass
- Decrease in whole body, subcutaneous, intermuscular, and abdominal fat

Effects on measures of skeletal muscle performance

- Increased maximal voluntary muscle strength in both upper and lower extremity muscle groups
- Increased muscle power
- No change in specific force

Effects on aerobic performance

- Attenuation of age-related decline in VO_{2peak}

Effects on self-reported and performance-based measures of physical function

- Improvements in self-reported function, including perception of walking ability
- Improved stair climbing speed and power
- Small improvement in 6-min walking distance

et al., 2002). Testosterone increases the number of myonuclei and muscle satellite cells, but it does not alter the myonuclear domain (Sinha-Hikim *et al.*, 2003). Thus, the primary action of testosterone is to induce skeletal muscle fiber hypertrophy by increasing the number of satellite cells.

Testosterone promotes the differentiation of mesenchymal progenitor cells into the myogenic lineage and inhibits their differentiation into the adipogenic lineage (Bhasin *et al.*, 2003; Sinha-Hikim *et al.*, 2006; Singh *et al.*, 2003, 2006). In addition, testosterone has been postulated to improve net muscle protein balance by stimulating muscle protein synthesis, decreasing muscle protein degradation, and improving the reutilization of amino acids (Ferrando *et al.*, 2002; Urban *et al.*, 1995). Testosterone stimulates circulating growth hormone secretion and IGF-1 levels although circulating IGF-1 is not obligatory for mediating testosterone's effects on the skeletal muscle (Serra *et al.*, 2011).

Testosterone's anabolic effects on the skeletal muscle are mediated largely through the classical AR and are blocked by AR antagonists. Testosterone's binding to AR leads to a conformational change in AR, enables it to associate with other co-regulators, including β catenin, stabilizing the latter (Singh *et al.*, 2009). The liganded AR along with β catenin and other associated chaperon proteins translocate into the nucleus and binds to the transcription factor TCF-4 (**Fig. 2**) (Singh *et al.*, 2009). The quaternary complex then binds specific DNA regions to regulate the transcription of Wnt-target genes including follistatin, which blocks the action of several members of the TGF β family (Singh *et al.*, 2009; Braga *et al.*, 2012), including myostatin and activins (**Fig. 2**). Follistatin plays an important role in mediating the anabolic effects of testosterone on the muscle; blocking follistatin action abrogates testosterone's effects on myogenic differentiation (Braga *et al.*, 2012). The administration of recombinant follistatin (rFst) increases muscle mass in mice, but has no effect on prostate mass (Jasuja *et al.*, 2014). Microarray analysis of mRNAs from prostate and levator ani of castrated male mice treated with vehicle, testosterone, or rFst revealed that testosterone and rFst shared the regulation of many transcripts in levator ani; however, in prostate, 593 transcripts in several growth-promoting pathways were differentially expressed after testosterone treatment, while rFst showed a negligible effect with only nine transcripts differentially expressed. Among pathways that were differentially responsive to testosterone in prostate, we identified ornithine decarboxylase (Odc1), an enzyme in polyamine biosynthesis, as a testosterone-responsive gene that is unresponsive to rFst (Jasuja *et al.*, 2014). When we administered testosterone with and without α-difluoromethylornithine (DFMO), an Odc1 inhibitor, to castrated mice, DFMO selectively blocked testosterone's effects on prostate, but did not affect testosterone's anabolic effects on the muscle (Jasuja *et al.*, 2014). Thus, co-administration of testosterone and an Odc1 inhibitor offers a novel therapeutic strategy for prostate-sparing anabolic therapy (Jasuja *et al.*, 2014).

Testosterone's Effects on Erythropoiesis

Testosterone administration increases hemoglobin, hematocrit, and red cell mass (Coviello *et al.*, 2008; Calof *et al.*, 2005), and has been used to treat anemia of inflammation and chronic kidney disease. Testosterone also is efficacious in correcting unexplained anemia of aging (Roy *et al.*, 2017) and inflammation (Guo *et al.*, 2016). The erythropoietic effects of testosterone are related to testosterone dose, circulating testosterone concentrations, and age (Coviello *et al.*, 2008). Older men experience greater increments in hemoglobin and hematocrit than younger men, after adjusting for testosterone dose (Coviello *et al.*, 2008). Erythrocytosis is the

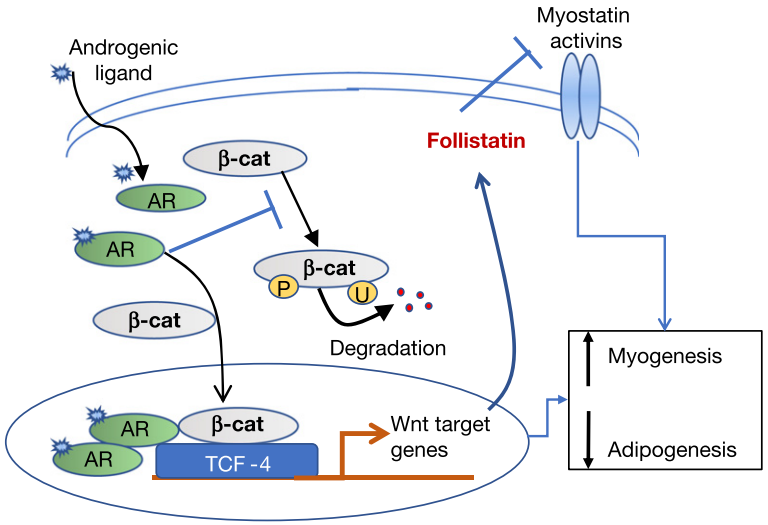

Fig. 2 The molecular mechanisms by which testosterone regulates the differentiation of mesenchymal progenitor cells through activation of Wnt signaling. The effects of testosterone on mesenchymal progenitor cell differentiation are mediated largely through the activation of Wnt signaling. After ligand binding, the androgen receptor undergoes conformation change and binds to beta catenin, stabilizing the latter, and preventing its degradation. The AR-beta catenin complex which may include additional chaperone proteins translocated into the nucleus and after binding TCF-4 regulates a number of Wnt-target genes, including follistatin, which blocks the action of a number of TGF β family members, such as myostatin and activins. Follistatin plays an important role in mediating the regulation of mesenchymal progenitor cell differentiation into the myogenic lineage and inhibiting their differentiation into adipogenic lineage.

most frequent adverse event noted in testosterone trials, and is an important dose-limiting adverse effect of testosterone therapy (Calof *et al.*, 2005).

The mechanisms by which testosterone increases hemoglobin and hematocrit are incompletely understood. Testosterone stimulates iron-dependent erythropoiesis through multiple mechanisms (Guo *et al.*, 2013). Testosterone increases iron availability and iron incorporation into the red cells by inhibiting hepcidin (Guo *et al.*, 2013; Bachman et al., 2010, 2014). Testosterone inhibits hepcidin transcription through its interaction with BMP-Smad signaling (Guo *et al.*, 2013). Testosterone administration promotes the association of liganded-AR with Smad1 and Smad4 to reduce their binding to BMP-response elements in the hepcidin promoter in the liver (Guo *et al.*, 2013). Testosterone increases erythropoietin production and resets the erythropoietin to hemoglobin set point (Bachman *et al.*, 2014). In older mice, testosterone may also improve red cell survival (Guo *et al.*, 2014).

Effects on Bone Metabolism

Sex steroids are important contributors to sex differences in bone mass and strength, and fracture risk (Vanderschueren *et al.*, 2014; Khosla *et al.*, 1998; Riggs *et al.*, 2004). Men have greater bone mass and strength than women in part because of the greater cortical bone acquisition during puberty (Vanderschueren *et al.*, 2014). Testosterone increases bone mass and strength through multiple pathways either by binding to the AR itself or indirectly through its conversion to estradiol 17β and signaling through the estrogen receptor α (ERα) (Finkelstein *et al.*, 2016; Vanderschueren *et al.*, 2014). AR is expressed in the osteoblastic and osteoclastic lineages, and by chondrocytes (see Vanderschueren *et al.*, 2014 for an excellent review of this topic, Kasperk *et al.*, 1989). Testosterone promotes apoptosis of osteoclasts and exerts antiapoptotic effects on osteoblasts and osteocytes (Kousteni *et al.*, 2001). Testosterone regulates the differentiation of bone progenitor cells into osteoblasts and osteoclasts and reduces the number of bone remodeling cycles (Khosla *et al.*, 1998; Kasperk *et al.*, 1990). Testosterone directly stimulates periosteal bone formation; additionally, genetic studies suggest that testosterone also regulates trabecular bone via AR in osteoblasts and osteocytes, independent of its aromatization to estradiol (Callewaert *et al.*, 2009; Moverare *et al.*, 2003; Venken *et al.*, 2006). Thus, AR actions, independent of its aromatization, contribute to greater periosteal bone formation and enhanced trabecular bone development during puberty in male mice (Callewaert *et al.*, 2009; Moverare *et al.*, 2003; Venken *et al.*, 2006). Estradiol acting via ERα in osteoblast lineage cells regulates cortical as well as the trabecular bone mass (Vanderschueren *et al.*, 2014; Bord *et al.*, 2001; Syed *et al.*, 2011; Venken *et al.*, 2006). Activation of ERα signaling, the dominant mediator of estrogen actions in bone, stimulates periosteal and trabecular bone formation and inhibits endocortical and trabecular bone resorption in female mice (Vanderschueren *et al.*, 2014; Bord *et al.*, 2001; Syed *et al.*, 2011; Venken *et al.*, 2006). Thus, both AR and ERα actions play a role in male cortical and trabecular peak bone mass acquisition (Vanderschueren *et al.*, 2014; Kousteni *et al.*, 2001; Kasperk *et al.*, 1990; Callewaert *et al.*, 2009; Moverare *et al.*, 2003; Venken *et al.*, 2006; Bord *et al.*, 2001; Syed *et al.*, 2011).

Testosterone also regulates bone mass and bone strength indirectly through its anabolic effects on muscle mass and muscle strength (Vanderschueren *et al.*, 2014). Increase in muscle mass and strength may also reduce fall propensity and reduce fracture risk.

Testosterone replacement therapy in severely hypogonadal improves areal bone mineral density (aBMD) as well as volumetric BMD (vBMD) (Snyder *et al.*, 2000; Katznelson *et al.*, 1996; Benito *et al.*, 2005; Zhang *et al.*, 2008; Al Mukaddam *et al.*, 2014). Testosterone treatment of hypogonadal men improves trabecular architecture and estimated bone strength (Zhang *et al.*, 2008; Al Mukaddam *et al.*, 2014; Snyder *et al.*, 2017). Meta-analyses of randomized trials of testosterone in older men with low or low normal levels have reported improvements in vertebral aBMD (Tracz *et al.*, 2006). In community-dwelling older men, 65 years or older, who had unequivocally low testosterone levels and symptoms of low libido, mobility problems or low vitality, testosterone treatment for 1 year increased vBMD of trabecular bone in the spine more than placebo and increased estimated bone strength of trabecular bone in the spine more than placebo (Snyder *et al.*, 2017). Testosterone also significantly increased whole bone vBMD and strength of the spine and trabecular and whole bone vBMD and strength of the hip (Snyder *et al.*, 2017). Testosterone's efficacy in reducing fracture risk in men with osteoporosis has not been studied.

Effects on Mood and Depressive Symptoms

In the TTrials, testosterone treatment had a small positive effect on mood and depressive symptoms (Snyder *et al.*, 2016). The magnitude of each of these effects was small and their clinical meaningfulness remains unclear.

Multiple lines of evidence support the hypothesis that a major subset of persistent depressive disorder (PDD) in men—defined as mid-life-onset, low-grade, chronic depression—might be responsive to testosterone replacement (Seidman, 2003; Almeida *et al.*, 2008). Epidemiological studies have demonstrated an association between lower testosterone levels and chronic low-grade depression (Seidman *et al.*, 2002; Markianos *et al.*, 2007; Shores *et al.*, 2004). Testosterone, whether administered alone or as an augmentation strategy in conjunction with traditional antidepressant therapy, tends to be ineffective in men with major depressive disorder (MDD) (Seidman *et al.*, 2001, 2005; Orengo *et al.*, 2005; Pope *et al.*, 2010). However preliminary evidence suggests that testosterone therapy can improve depressive symptoms in men with low-grade, late-onset depression (Seidman *et al.*, 2009; Shores *et al.*, 2009; Bloch *et al.*, 1999). These data suggest that testosterone replacement might be efficacious as a treatment for this subgroup of men with late-onset, low-grade PDD (previously referred to as dysthymia in DSM-4), but not in men with MDD.

Testosterone's Effects on Reproductive and Nonreproductive Behaviors (Table 3)

Testosterone regulates the expression of many sexually dimorphic reproductive behaviors in rodents and higher mammals, including mounting and ejaculation (Fielder *et al.*, 1989; Bhasin *et al.*, 1988; Muller, 2017). Testosterone also influences territorial scent marking, and promotes aggression and competition among males of many mammalian species at the time of mate selection (Fielder *et al.*, 1989; Steensland *et al.*, 2005; Fischer *et al.*, 2007; Carrillo *et al.*, 2011; Le Greves *et al.*, 1997). Androgens induce both offensive and defensive behaviors in rats, hamsters, and nonhuman primates, and activate the associated signaling molecules and their receptors (Steensland *et al.*, 2005; Fischer *et al.*, 2007; Carrillo *et al.*, 2011; Le Greves *et al.*, 1997). Rats treated with androgens exhibit enhanced dominant behavior in a competition test compared to controls (Steensland *et al.*, 2005; Fischer *et al.*, 2007; Carrillo *et al.*, 2011; Le Greves *et al.*, 1997; Henderson *et al.*, 2006; Kindlundh *et al.*, 2003; Schwartzer and Melloni, 2010; Breuer *et al.*, 2001). The brain pathways associated with aggression include neural circuits that utilize signaling by excitatory amino acid systems (e.g., glutamate, GABA), and monoaminergic and peptidergic neurotransmitters (Fischer *et al.*, 2007; Carrillo *et al.*, 2011; Le Greves *et al.*, 1997; Henderson *et al.*, 2006; Kindlundh *et al.*, 2003; Schwartzer and Melloni, 2010). The key brain regions involved in aggressive behavior include the anterior hypothalamus, periaqueductal gray, and amygdaloid nuclei, particularly the central and medial amygdala. Androgens enhance ß endorphin in the VTA and may thereby activate the brain reward system (see Wood, 2008 for a review). Rats and mice display conditioned place preference to testosterone and male hamsters will self-administer testosterone to the point of death (Wood, 2008; Arnedo *et al.*, 2000). Interestingly, the opioid antagonist naltrexone can block testosterone self-administration in hamsters (Johansson *et al.*, 2010). These observations, combined with others, suggest that opioidergic mechanisms may be involved in the hedonic pathway to androgen dependence (Wood, 2008; Arnedo *et al.*, 2000; Johansson *et al.*, 2010).

Table 3 Effects of testosterone on reproductive and nonreproductive behaviors in mammals

Reproductive behaviors
• Promotes mounting and ejaculation, reduces latency to mount, and ejaculate and post-ejaculatory interval
• Promotes competition and aggression among males of many mammalian species
Nonreproductive behaviors
• Promotes territorial scent marking
• Induces offensive and defensive behaviors
• Enhances dominant behavior
• Conditioned place preference for testosterone

Testosterone Effects on Cognition

Sex differences between men and women in several domains of cognition have supported the hypothesis that testosterone exerts domain-specific effects on cognition (Maccoby and Jacklin, 1974). Although there are substantial interindividual differences in performance, as a group, on average, men perform better than women in tests of visuospatial cognition and women perform better than men in tests of verbal memory and verbal fluency (Maccoby and Jacklin, 1974; Shute *et al.*, 1983). Women with congenital adrenal hyperplasia with high testosterone levels score higher on tests of spatial cognition and individuals with androgen insensitivity syndrome perform worse on tests of spatial cognition than age- and sex-matched controls (Maccoby and Jacklin, 1974).

Androgen receptors are expressed in specific brain regions (Simerly *et al.*, 1990), and some organizational effects of testosterone on brain are mediated through AR-mediated mechanisms (Lustig, 1994). Androgens stimulate neurite arborization, facilitating intercellular communication (Lustig, 1994). Testosterone may also exert nongenomic effects and affect neurotransmitters such as serotonin, dopamine, acetylcholine, and calcium signaling (Fernández-Balsells *et al.*, 2010; Khaw and Barrett-Connor, 1992). The nongenomic effects of testosterone are less well characterized than genomic effects. Testosterone also is aromatized to estradiol within brain regions, and some effects of testosterone may be mediated through estrogen receptor. Testosterone's organizational effects on reproductive and nonreproductive behaviors during critical development windows of sexual differentiation have been well characterized in preclinical models.

Intervention trials have provided inconsistent data on the effects of testosterone therapy on verbal memory and visual-spatial cognition (Cherrier *et al.*, 2001). In older men with low testosterone levels, testosterone treatment compared with placebo did not improve delayed paragraph recall, visual memory, spatial ability, executive function, subjective memory complaints, or immediate paragraph recall (Resnick *et al.*, 2017). Testosterone also did not improve measures of cognition in older men with minimal cognitive impairment (Resnick *et al.*, 2017). It is not known whether testosterone can prevent progression from minimal cognitive impairment to dementia and retard the development of Alzheimer disease.

Testosterone's Effects on Metabolic and Cardiovascular Risk

We do not know whether testosterone replacement increases the risk of major adverse cardiovascular events in hypogonadal men (Liverman and Blazer, 2004; FDA, 2017; EMA, 2018). Testosterone exerts a number of physiologic effects, some of which may be beneficial and some potentially deleterious to the cardiovascular system (**Table 4**) (Liverman and Blazer, 2004). Testosterone acts a vasodilator by inhibition of L-type calcium channels, resulting in increased coronary and penile blood flow; testosterone acts like the dihydropyridine calcium channel blockers to reduce calcium influx into vascular smooth muscle, thereby promoting vasodilation (Scragg *et al.*, 2004). Testosterone decreases whole body, subcutaneous and intra-abdominal fat (Bhasin *et al.*, 2001; Woodhouse *et al.*, 2004); it reduces vascular reactivity and improves endothelial function; and, it shortens QTc intervals (Gagliano-Jucá *et al.*, 2017).

The potential deleterious effects of testosterone that could increase the risk of cardiovascular events, include the increase in hematocrit (Calof *et al.*, 2005; Fernández-Balsells *et al.*, 2010), a small but significant reduction in plasma HDL cholesterol (Fernández-Balsells *et al.*, 2010), induction of platelet aggregation presumably via stimulation of thromboxane A2, and sodium and water retention, which could contribute to edema formation or exacerbation of preexisting heart failure. In preclinical models, testosterone promotes smooth muscle proliferation and increases VCAM expression. Testosterone increases the levels of both prothrombotic as well as antithrombotic factors.

Testosterone has been shown to retard atherosclerosis in some preclinical models but not in others. Testosterone induces myocardial hypertrophy in some mouse strains, but not in others. Some randomized trials have reported increase in blood pressure, but these data are not consistent across trials.

The effects of testosterone on insulin sensitivity also are inconsistent across trials. Low total, but not free, testosterone levels have been associated with central adiposity, insulin resistance and diabetes risk (Khaw and Barrett-Connor, 1992; Haffner, 1996; Makhsida *et al.*, 2005; Muller *et al.*, 2004). Total testosterone concentrations are highly correlated with SHBG concentrations and SHBG concentrations are independently associated with the risk of diabetes and metabolic syndrome (Ding *et al.*, 2009; Bhasin *et al.*, 2011). In fact, free testosterone levels are either not associated or only weakly associated with metabolic risk (Bhasin *et al.*, 2011). In models of severe androgen deficiency, such as in men receiving androgen deprivation therapy, or men experimentally rendered hypogonadal by administration of GnRH agonists or antagonists, there is an acute worsening of insulin sensitivity (Pitteloud *et al.*, 2005). However, the effects of testosterone on measures of insulin sensitivity in intervention trials have been inconsistent in RCTs (Singh *et al.*, 2002).

The relationship of testosterone and coronary artery disease and cardiovascular events in cross-sectional and prospective cohort studies has been inconsistent (Ohlsson *et al.*, 2011; Srinath *et al.*, 2015; Khazai *et al.*, 2016; Corona *et al.*, 2011). Some epidemiologic studies have reported a negative relationship between testosterone concentrations and common carotid artery intima-media thickness, a measure of subclinical atherosclerosis (Srinath *et al.*, 2015; Khazai *et al.*, 2016).

Low total testosterone levels have been associated with higher risk of all-cause mortality, especially cardiovascular mortality (Araujo *et al.*, 2011). Epidemiological studies can only show association but cannot prove causality; reverse causality cannot be excluded. It is possible that testosterone is a marker of health, and those who are higher risk of dying have lower testosterone levels.

The number of venous thromboembolic events in randomized trials of testosterone have been too few to permit strong inferences. Some retrospective analyses have suggested an increased risk of venous thromboembolism during the first few months

Table 4 Potential beneficial and deleterious physiologic effects of testosterone on the cardiovascular system

Potentially beneficial effects

- Increased coronary blood flow
- Decreased whole body and abdominal fat mass
- Improved vascular reactivity
- Reduced QTc interval

Potentially deleterious effects

- Increased hematocrit
- Lowering of HDL cholesterol
- Increased platelet aggregation
- Increased vascular smooth muscle proliferation
- Salt and water retention

Inconclusive or inconsistent effects

- Myocardial hypertrophy in some strains but not others
- Retards early atherogenesis in some animal models but not in others
- Increases the circulating levels of both prothrombotic and antithrombotic factors
- No consistent increase in blood pressure in randomized trials

of testosterone therapy (Baillargeon *et al.*, 2015; Martinez *et al.*, 2016). Most cases of venous and arterial thrombotic events have occurred in men with preexisting hypercoagulable condition (Glueck *et al.*, 2016).

Several retrospective analyses of the association of testosterone administration with mortality and cardiovascular events have been published, but these studies have yielded conflicting results (Vigen, 2013; Sharma *et al.*, 2015; Anderson *et al.*, 2016; Muraleedharan *et al.*, 2013; Cheetham *et al.*, 2017; Borst *et al.*, 2014; Alexander *et al.*, 2017). These retrospective analyses of electronic medical records suffer from many limitations: the inclusion of heterogeneous study populations; differences in the duration of intervention; the use of variable definitions; and a lack of prospective ascertainment of cardiovascular outcomes (Vigen, 2013; Sharma *et al.*, 2015; Anderson *et al.*, 2016; Muraleedharan *et al.*, 2013; Cheetham *et al.*, 2017; Borst *et al.*, 2014; Alexander *et al.*, 2017). Treatments indications, treatment regimens, on-treatment testosterone levels and exposure differed among studies (Vigen, 2013; Sharma *et al.*, 2015; Anderson *et al.*, 2016; Muraleedharan *et al.*, 2013; Cheetham *et al.*, 2017; Borst *et al.*, 2014; Alexander *et al.*, 2017). They also suffered from a potential for residual confounding in that the patients assigned to testosterone therapy differed from comparators in baseline cardiovascular risk factors. A number of meta-analyses have examined the association between testosterone replacement and cardiovascular events, major cardiovascular events, and death in RCTs (e.g., Alexander *et al.*, 2017). Most of these meta-analyses have not shown a statistically significant association between testosterone and cardiovascular events, major cardiovascular events, or deaths (Alexander *et al.*, 2017). These meta-analyses are limited by the heterogeneity of randomized trials included in these analyses (Kloner *et al.*, 2016). The trials also were heterogeneous with respect to eligibility criteria, testosterone dose and formulation, and intervention durations. The variable quality of adverse event recording in clinical trials has been well-documented, and was particularly apparent in these trials. The small size of many trials and the inclusion of pilot studies with very small sample sizes was another constraint. Cardiovascular outcomes were not prespecified, they were often defined post-hoc, and were of varying clinical significance. The major cardiovascular events were not adjudicated, not specified prospectively, and the total number of major cardiovascular events was too small to draw strong inferences.

There are no published randomized trials that were long enough or large enough to determine the effects of testosterone therapy on CV events. In two RCTs in middle-aged and older men, testosterone replacement therapy did not affect the rate of atherosclerosis progression assessed using common carotid artery intima-media thickness or coronary artery calcium scores (Basaria *et al.*, 2015; Budoff *et al.*, 2017). In the TTrials, testosterone treatment was associated with a greater increase in the volume of noncalcified plaque volume (Budoff *et al.*, 2017).

Hormone Replacement Therapy in Men☆

Cindy Pham, Christina Wang, and Ronald S Swerdloff, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, CA, United States

Glossary

Androgens Androgens are steroid hormone that bind to the androgen receptor to exert actions on the male reproductive tract. Androgens are required for pubertal development, male secondary sex characteristics development and fertility.

Male hypogonadism Male hypogonadism is men with testosterone deficiency and disruption of spermatogenesis

Introduction

Over the past several decades, there have been progress in the field of testosterone (T) replacement therapy with many new formulations, routes of administration and delivery systems. Currently, T treatment is indicated for symptomatic male hypogonadism (Bhasin *et al.*, 2010) (*Note*: New guidelines will be published by the Endocrine Society in 2018). This article will review criteria for T replacement, benefits, potential adverse effects, and current treatment modalities. Recent controversies and issues concerning long-term cardiovascular and prostate safety, the relative benefits and risks of treating older men with androgen deficiency will be briefly addressed.

Increasing Trends of T Prescriptions

The primary indication of T therapy is for the treatment of male hypogonadism. The T prescribing trends have increased about three fold in the United States (US) from 2001 to 2011 (Baillargeon *et al.*, 2013).This trend is common to many countries in the developed world (Gabrielsen *et al.*, 2016, Handelsman, 2013). The rising trend of T prescription is associated with studies reporting that about 25% of the men treated either did not have serum T measured or did not meet the criteria for treatment recommended by the Endocrine Society before start of T treatment (Baillargeon *et al.*, 2013). The rise in initiation of T treatment may be related to televised direct-to-consumer marketing in the US (Layton *et al.*, 2017). Because of the possible "overuse of T" in men (Gabrielsen *et al.*, 2016), the US. Food and Drug Administration (FDA) examined the indications for T treatment. They concluded that the principle use of T replacement therapy remains for men with "classic" hypogonadism that is caused by specific well-recognized medical conditions. They questioned the need to replace T in older men with low serum T levels who lack a distinct, well-recognized cause of hypogonadism because there is no definitive evidence that increasing serum T concentration in older men is beneficial and safe (Nguyen *et al.*, 2015). In contrast to this opinion, a placebo controlled double blinded interventional set of studies in 790 men over age 65 supported by the National Institutes of Health in the US (the T trials) demonstrated significant benefits to sexual activity and desire, bone mineral density, anemia and modest improvements in mood. This 1 year study was not powered in in size nor duration for the above major cardiovascular and prostate events (Snyder *et al.*, 2016, Snyder *et al.*, 2018). Physicians encountering men with symptomatic low T concentration need to discuss and weigh the benefits and risks and allow the patient to participate in the decision of T replacement.

Criteria for Androgen Replacement and Diagnosis of Male Hypogonadism

The guidelines from The Endocrine Society and other professional societies recommend that the diagnosis of T deficiency should be based on persistently low serum T level and signs and symptoms consistent with T deficiency (Bhasin *et al.*, 2010). Common more specific signs and symptoms of T deficiency are decrease in libido, erectile function, muscle mass and strength, bone mineral density, and hair (face, body); presence of gynecomastia, and small testes. Other less specific symptoms include lack of energy; increase in visceral fat; sleep disturbances; and negative mood such as irritability, nervousness, and inability to concentrate.

In addition to symptoms and signs, the diagnosis of male androgen deficiency can be confirmed by measuring a total serum T level. Serum T should be measured in the morning, between 7 and 10 am, when T levels are highest—a reflection its diurnal pattern/variation. The diurnal variation is much less pronounced in middle aged and older men (Bremner *et al.*, 1983, Diver *et al.*,

☆*Change History*: April 2018. Cindy Pham, Christina Wang, and Ronald S. Swerdloff rewrote the entire article.

This article is an update of Chee Yeung Chan and Julianne Imperato-McGinley, Hormone replacement therapy, male, In *Encyclopedia of Endocrine Diseases*, edited by Luciano Martini, Elsevier, New York, 2004, pp. 443–449.

Table 1 Benefits and risks of T replacement

Benefits	*Risks*
• Improve sexual function	• Acne, oily skin
• Maintain secondary sex characters	• Decrease testis volume
• Increase bone mass	• Suppress spermatogenesis
• Increase muscle mass and strength	• Erythrocytosis
• Decrease visceral adiposity	• Weight gain, fluid retention
• Increase hematocrit/hemoglobin in unexplained anemia	• Decrease HDL, increase LDL: HDL ratio
• Improve mood	• Gynecomastia (with some preparations)
• Improve physical activity and balance?	• Sleep apnea?
• Reduce insulin resistance, fasting glucose, hemoglobin A1C?	• Prostate dysfunction (benign prostate hyperplasia, prostate cancer)?
• Coronary vasodilation, improve heart failure.	• Increased cardiovascular disease risk?
• Decrease cardiovascular disease risk	

2003). A subnormal T level is more easily noted during a time when normal T levels should be high. It is also recommended that blood should also be drawn while fasting as glucose ingestion decreases the serum T concentration. If the levels of T are near the lower limit of the reference range, measurement should then be repeated to achieve greater diagnostic confidence. Studies have shown that 30% of men with an initial low T level would have serum T within the normal range on repeat measurement (Brambilla *et al.*, 2007). The preferred reliable method for T assessment is by liquid chromatography–tandem mass spectrometry (LC–MS/MS) though many immunoassays have been recently harmonized against a standard LC–MS/MS method yielding more accurate results (Rosner *et al.*, 2013). Using a standardized T measurement, the reference range of serum T in large populations of adult men from Europe and US have recently been established (19–39 years, 264–916 ng/dL) (Travison *et al.*, 2017). In patients with T levels near the lower limit of normal or when suspicion of aberrant sex hormone binding globulin, measuring free T level, preferably by equilibrium dialysis method or estimation by formulae may provide additional information. It should be noted that the commonly available free T analogue immunoassays provide no additional information than total T and are not useful in clinical diagnosis of hypogonadism (Goldman *et al.*, 2017). Despite this report the adjunctive use of free T measurements to assist in the diagnosis of men with borderline T measurements is recommended by some experts.

Once T deficiency has been established, primary (testicular/gonadal) and secondary (hypothalamic–pituitary) hypogonadism can be distinguished by obtaining serum luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels. Low FSH and LH levels suggest secondary hypogonadism and serum prolactin and MRI of the sella may discover the cause of hypogonadism.

Routine screen men for T deficiency in the general population for hypogonadism is not recommended due to the incidence of high false positives. In addition, studies have shown minimal benefits in treating asymptomatic men with a low T level. Low T levels also occur among men suffering from an acute illness or using certain medications, such as opioids and glucocorticoids, that suppresses T concentrations. In these men withdrawal of the medication or recovery from an acute illness may restore serum T to the normal range.

Benefits and Risks of Testosterone Treatment (Table 1)

T replacement therapy has been shown to be beneficial in men diagnosed with symptomatic hypogonadism (Ceponis *et al.*, 2017). The consistent main benefit is improvement in sexual function, increase in lean and bone mass and decrease in fat mass. Moderate to strong improvement in sexual function is reported in younger (Isidori *et al.*, 2005a, Wang *et al.*, 2004) and mild to moderate in older men (Legros *et al.*, 2009, Snyder *et al.*, 2016). Sexual desire and activity are increased which is often followed by improvement in erectile dysfunction. Consistent improvement in lean mass and decrease in fat mass and visceral adiposity are associated with T replacement in both younger (Isidori *et al.*, 2005b, Wang *et al.*, 2000) and older hypogonadal men (Page *et al.*, 2005, Srinivas-Shankar *et al.*, 2010). In some of these studies improvement in muscle strength are also seen but sometimes this improvement is not translated to improvement in physical activity (Srinivas-Shankar *et al.*, 2010, Snyder *et al.*, 2016). T treatment is associated with increase in bone mineral density and bone strength (Wang *et al.*, 2004, Amory *et al.*, 2004, Isidori *et al.*, 2005b, Snyder *et al.*, 2017) however T treatment has not been studied to demonstrate a reduced fracture rate. Improvement of mood and energy are reported in some studies and the improvement (Snyder *et al.*, 2016, Basaria *et al.*, 2015, Steidle *et al.*, 2003, Wang *et al.*, 2000) (**Table 1**). Though small studies suggest that T treatment may improve cognition (Cherrier *et al.*, 2001), a recent large placebo controlled trial showed that T replacement did not improve cognitive ability in older men with memory impairment compared to placebo group (Resnick *et al.*, 2017).

It is well known that T causes erythrocytosis in a small but significant proportion of men which may be a limiting factor in T replacement specially in older men (Coviello *et al.*, 2008). T stimulates the bone marrow but more recently shown to be related to reduced hepcidin, increased iron in cells and elevated hemoglobin (Guo *et al.*, 2013). Recently in a placebo-controlled trial in older hypogonadal men, T treatment increased hemoglobin in men with unexplained anemia such that at the end of 12 months treatment over 50% were no longer anemic (Roy *et al.*, 2017). On the other hand, elevated hematocrit and hemoglobin levels are

putative risks for hyper-viscosity and thromboembolism. Some studies have shown that T treatment reduces insulin resistance and improve glucose levels in men with metabolic syndrome and type 2 diabetes but these studies are not conclusive (Jones *et al.*, 2011, Kalinchenko *et al.*, 2010). Other studies reported improvement of congestive heart failure and decrease in angina symptoms after T treatment in small number of subjects. These data have to be confirmed in larger placebo controlled studies (Malkin *et al.*, 2006, Malkin *et al.*, 2004).

Testosterone replacement therapy causes a decrease in HDL-cholesterol which may be associated with a small decrease in total cholesterol (Fernandez-Balsells *et al.*, 2010). The decrease in HDL-cholesterol appeared to be less with transdermal T delivery systems. The significance of reduced HDL-cholesterol levels on cardiovascular disease risk in men treated with T is not clear. In addition to the concentration of HDL-cholesterol, the density of HDL particles and the metabolism of HDL are important factors.

Testosterone administration does not cause benign prostatic hyperplasia or cause prostate cancer. Prostate cancer is an androgen dependent cancer and may grow with T treatment. However a metaanalysis showed no increase in prostate disease after T replacement (Fernandez-Balsells *et al.*, 2010). Recent data showed that once the prostate cancer has been treated and the patient has clinical cure, T therapy can be considered if the patient has symptomatic androgen deficiency without adversely affecting overall or cancer specific mortality (Kaplan *et al.*, 2014).

Currently, there is inconclusive evidence to support a definitive connection between T replacement therapy and cardiovascular morbidity (Kloner *et al.*, 2016). Past epidemiological studies suggest that low T concentrations are related to increase in all cause and cardiovascular mortality (Shores *et al.*, 2006, Khaw *et al.*, 2007). A placebo controlled trial of T replacement in older frail men reported increased cardiovascular adverse events in the T treated compared to the placebo group (Basaria *et al.*, 2010). A similar study on T replacement in older frail men showed improved physical function but did not find increased cardiovascular adverse events (Srinivas-Shankar *et al.*, 2010).Retrospective cohort studies and metaanalyses of controlled trials yielded controversial conclusion. Two large cohort studies found a significant increase in cardiovascular events associated with T use (Vigen *et al.*, 2013, Finkle *et al.*, 2014), whereas two others found a significant reduction in all-cause mortality (Shores *et al.*, 2012, Muraleedharan *et al.*, 2013). Another study found no significant change in the risk of myocardial infarction among men treated with T (Baillargeon *et al.*, 2014). The metaanalyses also had conflicting findings—one reported an increased risk of broadly defined cardiovascular-related adverse events among T users (Xu *et al.*, 2013); the other reported no additional risk of major adverse cardiovascular events (Corona *et al.*, 2014). Although the limitations and potential confounders or biases in these studies preclude a clear conclusion regarding the role of T therapy in adverse cardiovascular outcomes, a possible association cannot be overlooked. The US Food and Drug Administration (FDA) recommended that a well-designed, randomized, controlled study of T treatment in T deficient men involving over 6000 men be conducted to specifically evaluate cardiovascular outcomes. This study is underway sponsored by pharmaceutical companies.

Contraindications to Testosterone Treatment

Absolute contraindications to androgen replacement therapy are untreated or active androgen-dependent tumors, such as prostate and male breast cancer, and elevated hematocrit or hemoglobin level (hematocrit $>54\%$ or hemoglobin >17 g/L). Androgen treatment may cause fluid retention, and may precipitate or aggravate heart failure or sleep apnea. Patients with symptoms or signs of moderate or of severe congestive heart failure or sleep apnea should be treated and controlled before initiating androgen replacement therapy (Bhasin *et al.*, 2010).

While there is minimal evidence to implicate T in the development or aggravation of benign prostate hyperplasia (BPH), if a patient has significant lower urinary tract obstructive symptoms due to BPH then the symptoms should be controlled before instituting T replacement. If the patient is considering having a family, then androgen treatment may not be the best therapeutic choice, alternative treatment with human chorionic gonadotropin or antiestrogens may be considered if the hypothalamic–pituitary testis axis is intact and the patient does not have primary testicular failure.

Precautions Before Initiation and Monitoring of T Treatment

Before initiation of T treatment, men >40 years of age and older should have a digital rectal examination and a serum PSA performed to assess prostate abnormalities. In patients with palpable prostate nodule, induration, or PSA $>$ 4 ng/mL or PSA $<$ 3 ng/mL in men at high risk of prostate cancer, such as African Americans or men with first-degree relatives with prostate cancer, a referral to a urologist before start of T treatment is appropriate. Men who had lower urinary obstructive symptoms, obstructive sleep area and congestive heart failure should be treated for their medical conditions before initiation of T treatment. A baseline complete blood count, liver function tests and lipid panel should be available before start of T treatment.

Current Testosterone Treatment Options (Table 2)

The patient with T deficiency has many options for T replacement. The formulations currently available are listed in **Table 2**. All these delivery systems have proven efficacy in clinical trials. Thus, the selection of a therapeutic regimen should be based on

Table 2 Available testosterone preparations

Formulation	*Preparation*	*Regimen*	*Advantages*	*Disadvantages*
Intramuscular: intermediate duration	Testosterone enanthate or testosterone cypionate	100–200 mg q 2 weeks IM; 50–100 mg q 1 week SC	Most available and affordable	Fluctuating hormone levels Higher risk of increase hemoglobin and hematocrit Rare postinjection cough
Intramuscular: long-acting	Testosterone undecanoate	750 mg initially 750 mg at week 6 750 mg q10 week	Most convenient (longer injection intervals)	Injection site pain Postinjection cough (pulmonary oil microembolism?)
Oral (not in US)	Testosterone undecanoate	40–80 mg twice or three times/day	Convenient	Low serum T concentrations before next dose
Transdermal	1%	50–100 mg/day	Stable T levels	Expensive
• Gel • Solution • Patch	1.62% 2% 2% 2–4 mg/patch	20.25–81 mg/day 10–70 mg/day 30–120 mg/day 2–8 mg/day	No transfer to others	Transference to others on close skin contact Skin irritation, rash
Transmucosal	Buccal testosterone Intranasal testosterone	30 mg twice per day 5,5 mg/nostril 3 times/day	Stable T levels Stable T levels	Gum irritation minor Dislodgement from gum Multiple dosing required per day
Subcutaneous implants	Testosterone pellets (US 75 mg, non-US 100–200 mg)	150–750 mg every 3–6 months 400–1200 mg every 3–6 months	Stable T levels for 3–4 months	Minor surgical procedure Risk of pellet extrusion, infection, fibrosis

patient's preference in relation to pharmacokinetics, convenience, treatment burden, and cost. The decision is made by the patient with the physician providing the available information and discussing the pros and cons of each preparation. It has been proposed that initiation of T replacement in older men should start with a short acting gel rather than an injectable lasting 10 weeks' duration. The rationale is that if an adverse reaction occurs, for example, elevation of PSA, the gel can be stopped and androgen action withdrawn quickly. The development of selective androgen receptor modulators has not been directed for T replacement for hypogonadism but for other indications such as sarcopenia and physical dysfunction of aging or associated with chronic medical illness. These may be steroidal or nonsteroidal drugs and may have prostate growth sparing effect. However because many of these compounds are modified androgens (Kumar *et al.*, 1992) or novel nonsteroidal structures (Dalton *et al.*, 2013), they would not be aromatized (Attardi *et al.*, 2008) and may not have the positive effects of T on bone mass and fat mass due to the conversion to estradiol.

Monitoring Testosterone Replacement

The goal of T therapy in hypogonadal men is to restore the serum T to mid normal range and alleviate symptoms. Thus, serum T level should be measured after drug administration based on the pharmacokinetic characteristics of the specific preparation for dose adjustments. Since serum T levels are maintained in a relatively steady state by transdermal gels (Swerdloff *et al.*, 2000) and lotions, T levels can be measured at any time after the levels have plateaued, usually about a week after initial application. In older men, considerable within-individual variation of serum T occurred when serum T was measured on different days. Serum levels of T 8–12 h after application of transdermal T gel appeared to best reflect average serum T over 24 h (Swerdloff *et al.*, 2015).

The injectable T preparations, T enanthate and cypionate after an IM injection peaks at 2–3 days and troughs at 10–14 days. Serum T should be measured before the next injection to ensure trough levels are near the lower end of the reference range for adult men, and that there is no accumulation of T. Serum T should be periodically measured at day 7 to ensure that serum T levels are within normal limits. These T esters have been administered as a subcutaneous injection every week and serum T levels are more stable. Once a stable dose is determined, frequent measurement of serum T levels is generally not necessary unless dose adjustments are made. With T undecanoate injections, blood should be drawn prior to the next injection in order to establish the timing of future injections.

Since administration of T may unmask histological prostate cancers by increasing serum PSA levels, measuring PSA early after treatment initiation, for example, 1 to 3 months, is recommended. Thereafter, PSA should be checked on a yearly basis according to the urological practice applicable to each man.

Hemoglobin and hematocrit should be checked at 3 months and then after each dose adjustment followed by yearly intervals. Subjects whose hemoglobin level is high before treatment should be monitored more carefully. Following practice guideline, a yearly liver function test and lipid profile may be performed.

Conclusion

Androgen replacement therapy should be considered for all hypogonadal men with persistently low serum T levels and symptoms of T deficiency who meet the criteria for replacement. T replacement therapy should not be initiated in those with contra-indications to androgens use. The goal of T therapy is to restore serum T to mid normal range and alleviate symptoms. Therefore, it is important to have a baseline evaluation and laboratory results for serial monitoring of therapeutic response, adverse effects, and adherence. T replacement has shown in many studies to improve sexual function, energy and mood, increase muscle mass and strength, as well as bone mineral density. With numerous T preparations available and many more in development, selecting an androgen regimen can be tailored to each patient's individual needs and preferences. Selective androgen receptor modulators may have the potential of optimizing beneficial effects while minimizing potential adverse effects. With care, androgens can be used efficaciously and with minimal potential side effects.

Glossary

Azoospermia The absence of sperm in the ejaculate.
Gonadotropins The pituitary hormones, luteinizing hormone and follicle-stimulating hormone, which regulate spermatogenesis in males.
Oligozoospermia The presence of ≤ 3 million sperm/mL in the ejaculate.
Severe oligozoospermia The presence of ≤ 1 million sperm/mL in the ejaculate.

Introduction

In the United States, male contraceptives account for nearly one-third of all contraceptive use (Daniels *et al.*, 2015); worldwide, men represent approximately one-quarter of all contraceptive users (Ross and Hardee, 2016). Male contraceptives include methods of pregnancy prevention that men use directly or that require their cooperation for correct and consistent use. These methods include vasectomy, condoms, withdrawal, and fertility awareness. While vasectomy is one of the safest and most effective methods of contraception, it is essentially irreversible. The other reversible methods of male contraception, if used over the long-term have a relatively high failure rate, with unintended pregnancies occurring among 13%–20% of users over the course of a year (Sundaram *et al.*, 2017). As men may be invested in decisions to both plan for and prevent pregnancy, and as some couples may not be able to rely on more effective, reversible methods of female contraception, alternative options are needed. From a public health standpoint, the widespread use of effective methods of contraception by reproductive-age men and women would help to prevent pervasively high rates of unintended pregnancy worldwide, estimated at $>40\%$ of pregnancies (Singh *et al.*, 2010), as well as decrease the global population's currently unsustainable rate of growth. Specifically, alternative contraceptive options for men would provide a model for engaging men in sharing the burden of pregnancy prevention that has been disproportionately shouldered by women throughout human history. While a new method of male contraception has yet to be approved for widespread use, clinical trials of hormonal methods have received the most attention for their demonstrated efficacy and acceptability. This article will focus on the development of hormonal male contraception.

Mechanism of Action

The primary mechanism of action of hormonal male contraception is the suppression of spermatogenesis, thereby preventing the development of mature spermatozoa, and fertilization and pregnancy in the female partner. Spermatogenesis is regulated by the pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), both directly and indirectly (see **Fig. 1**). Spermatogenesis occurs within the seminiferous tubules in the testis, which house Sertoli cells and the germ cells. Sertoli cells are stimulated by FSH to facilitate the development and differentiation of spermatogonial stem cells into spermatozoa. Leydig cells, circumscribing the seminiferous tubule, are stimulated by LH to produce and maintain the critical concentration of intratesticular testosterone (T) required to initiate and complete spermatogenesis. There is crosstalk between Sertoli and Leydig cells. The secretion of gonadotropins by the pituitary requires the pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus; therefore, either GnRH deficiency, nonpulsatile stimulation, or exogenous administration of T, progestins and estradiol can inhibit the pituitary secretion of gonadotropins, leading to the downregulation of Sertoli cell function and Leydig cell-mediated T production in the testis. The decreased production of T in the testis results in decreased serum concentrations of T. Symptoms and signs of hypogonadism (e.g., sexual dysfunction, fatigue, loss of muscle mass, infertility) can result if serum systemic T levels are not maintained at physiologic levels with exogenously administered T or other androgens. Inhibitors of the hypothalamic–pituitary–gonadal axis are shown in **Fig. 1**. The suppression of the hypothalamic–pituitary–gonadal axis for the purposes of hormonal male contraception thus entails the use of hormonally active agents to both suppress intratesticular T and

☆*Change History*: April 2018. Brian T. Nguyen prepared the updated and answered queries related to the table, figure, and references.

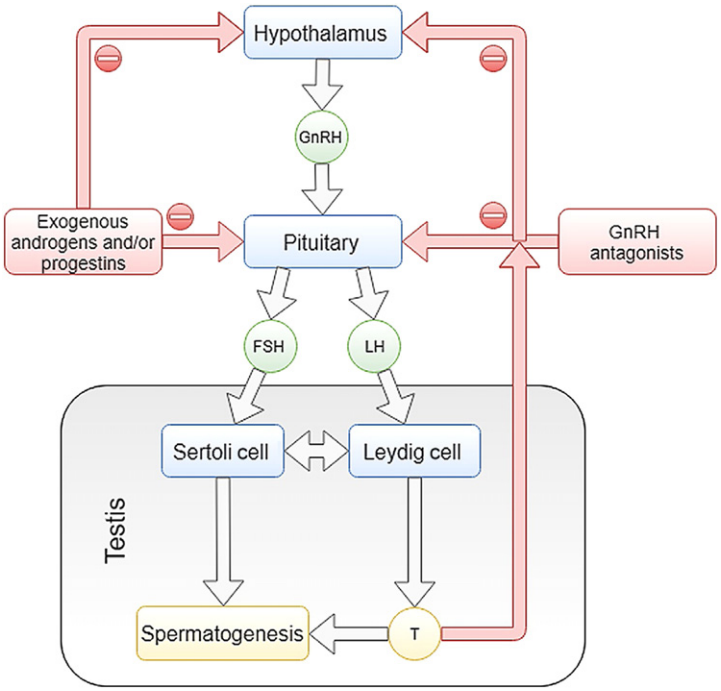

Fig. 1 The endocrinology of spermatogenesis and hormonal male contraception. The *gray arrows* show the physiologic pathway promoting spermatogenesis with the *red arrows* showing inhibitory influences. Endogenous T acts via negative feedback pathways to inhibit both GnRH release from the hypothalamus and gonadotropin (LH and FSH) release from the pituitary, leading to low intratesticular T levels. Exogenous androgens and/or progestins, as well as GnRH analogues reversibly manipulate this physiological response. *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone; *FSH*, follicle-stimulating hormone; *T*, testosterone.

sperm production, while maintaining serum systemic levels of T to avoid hypogonadal side effects. This can be accomplished by androgen-only regimens and androgen combinations with other agents, such as progestins or GnRH antagonists (Wang and Swerdloff, 2010; Wang *et al.*, 2016).

Hormonal Male Contraceptive Regimens: Androgen Alone

Unmodified testosterone (T), as produced physiologically from the testis, was an expected, initial candidate androgen for use as hormonal male contraception. Ingested orally, unmodified T is well-absorbed, however it is rapidly degraded by first-pass metabolism in the liver. Novel, modified oral androgens are currently being studied in clinical trials (Ayoub *et al.*, 2017; Surampudi *et al.*, 2014). Unlike the earlier 17-alkylated androgens, these newer androgens have no apparent effect on liver function. Transdermal delivery of T by gels and lotions forms a subcutaneous reservoir, which delivers a steady release of T to the body. Transdermal T preparations are combined with a progestin to allow more rapid suppression of spermatogenesis (Ilani *et al.*, 2012). Testosterone implants have also been used for hormonal contraception but are more efficacious when administered with an injectable progestin (Turner *et al.*, 2003b). Intramuscular, depot preparations of T for hormonal male contraception, such as T enanthate or T undecanoate, are esterified by adding a fatty acid side chain to the T molecule to form T esters. Esterification reduces hepatic breakdown and the lipid soluble esters form a depot after IM injection prolonging their duration of therapeutic action (World Health Organization Task Force on Methods For the Regulation of Male Fertility, 1990; World Health Organization Task Force on the Regulation of Male Fertility, 1996; Gu *et al.*, 2009). The following sections will limit the review to preparations that were used specifically in contraceptive efficacy trials where pregnancy in the female sexual partner was the primary endpoint for the study (**Table 1**).

Testosterone Enanthate Injections

Testosterone enanthate (TE) is an esterified version of testosterone with a half-life of 4.5 days. In comparison, unmodified T has a half-life of 10 min (Nieschlag *et al.*, 2012). TE has been used for T replacement for hypogonadal men for many years with a good safety profile. Following many small studies demonstrating the efficacy of TE administered as intramuscular (IM) injections suppression of sperm output to very low levels (Patanelli, 1978), TE was used in a multicenter contraceptive efficacy trial where men received weekly IM injections of TE 200 mg for 12 months following confirmation of azoospermia. Among 271 healthy, fertile men, 157 completed the suppression phase of the trial and became azoospermic. The mean latency time until azoospermia

[a]This is the Pearl Index, a commonly indicator of contraceptive efficacy by comparing failure rate.
[b]Participants in this trail entered the efficacy phase upon achieving two sperm concentrations showing azoospermia, no spermatozoa in ejaculate.
[c]Participants in this trial entered the efficacy phase upon achieving two sperm concentrations of <5 million/mL for three consecutive samples. Given early findings of five pregnancies with three occurring among participants with a sperm concentration >4 million/mL, the threshold required to enter the efficacy phase was reduced to <3 million/mL.
[d]The proportion of participants observed to reach the threshold for efficacy is low by design to additionally test the suppressive effect of finasteride, a 5α-reductase inhibitor.
[e]The efficacy phase of this trial included one participant who received a single dose of oral finasteride 5 mg daily for 3 months along with an additional T implant 800 mg.
[f]The single pregnancy observed during the efficacy phase was attributed to sperm rebound.
[g]Participants in this trial initially received T implant every 6 months; however, failure to maintain eugonadal T levels prompted replacements every 4 months.
[h]This trial was terminated early due to the frequency of side effects reported by participants.
IM, intramuscular; *T*, testosterone; *TE*, testosterone enanthate; *TU*, testosterone undecanoate; *DMPA*, depot medroxyprogesterone acetate; *NETE*, norethisterone enanthate.

was approximately 120 days. During the efficacy phase, a single pregnancy was observed following 1486 months of cumulative exposure in 119 couples, giving a Pearl index of 0.8 per 100 person-years (95% CI: 0.02–4.5) (World Health Organization Task Force on Methods For the Regulation of Male Fertility, 1990). The Pearl index is a commonly used measure of contraceptive efficacy, calculated using the number of pregnancies, the number of couples at risk of pregnancy, and the time during which they are using the method. For comparison, Pearl indices for marketed oral contraceptives for women range between 0.29 and 2.86 per 100 person-years (Trussell and Portman, 2013). The favorable results of this trial of azoospermia led to a second international, multicenter trial where entry into the efficacy phase was allowed for men achieving oligozoospermia (initially arbitrarily defined as $\leq$5 million/mL ejaculate). Among 399 couples, 349 completed the suppression phase and demonstrated sperm concentrations of $\leq$5 million/mL. These couples entered the efficacy phase and over 180 person-years of exposure, 5 pregnancies were observed. As three of the pregnancies occurred among couples where the man's sperm concentration was $>$4 million/mL, the threshold for entry into efficacy phase was reduced to $\leq$3 million/mL. Following this change in entry criteria for 49.5 person-years, the trial noted 4 pregnancies, none of which occurred to men with azoospermia. The mean latency time until reaching the revised definition of oligozoospermia ($\leq$3 million/mL) was 68 days. The overall Pearl index for the trial was 1.4 (95% CI: 0.4–3.7) per 100 person-years, which was again comparable to hormonal contraceptive methods used by women. Median time to recovery of normal sperm concentration was 112 days (World Health Organization Task Force on Methods For the Regulation of Male Fertility, 1996). These proof of concept studies demonstrated that hormonal suppression of spermatogenesis to azoospermia was feasible for nearly 70% of participants, rising beyond 95% when suppressing to oligozoospermic levels (**Table 1**). Further, suppression to these levels ensured contraceptive efficacy and was reversible to the normal range of sperm concentrations in 98% of participants completing follow-up. However, this approach had two drawbacks: (1) unsatisfactory pharmacokinetics of TE injections resulted in widely fluctuating levels of T and the need for frequent, weekly injections; (2) high doses of TE were utilized to induce and maintain adequate suppression of spermatogenesis, causing supraphysiologic levels of T, which may have impacted the incidence of side effects and overall acceptability of the preparation. Side effects encountered in these studies were likely androgen-related, including acne, weight gain, behavioral effects, lowered high-density lipoprotein cholesterol (HDL-C), and increased hematopoiesis. For these reasons, longer acting T esters and alternative administration strategies were sought.

Testosterone Implants

Following the success of the WHO's TE trials, T implants were proposed as a long-acting preparation to avoid the frequent injections and associated high peaks and troughs of intramuscular TE injections. T implants are small cylindrical pellets containing crystalline T that are inserted into the subcutaneous tissue of the lower abdominal wall under local anesthesia. T implants were able to suppress sperm counts to a degree comparable to TE injections while maintaining a lower average serum T levels, such that androgenic side effects were less frequent than those seen in the TE injection trials (Handelsman *et al.*, 1996, 1992). In a multi-dose efficacy trial conducted in Australia, T implants 800 mg (4 $\times$ 200 mg) were administered to 36 men, 17 (47%) of whom reached sperm concentrations of $<$1 million/mL within 6 months. Eight men who were unable to suppress adequately via T implants at 800 mg doses were given T 1200 mg (6 pellets), 5 of whom then reached sperm concentrations of $<$1 million/mL within 3 months. Sixteen couples entered the efficacy phase where no pregnancies were reported following 214 months of exposure. Sperm concentrations returned to normal values on average within 10 months and only one man complained of acne from the 1200 mg group. While those who maintained sperm concentrations of $\leq$1 million/mL of ejaculate did not experience pregnancies, several men still could not be suppressed even at T 1200 mg, suggesting that methods with T alone might not be sufficient. Additionally, acceptability of this method may be dampened by the need for minor surgical procedural insertion and the incidence of implant extrusion, which occurred in 10% of insertions (McLachlan *et al.*, 2000).

Testosterone Undecanoate (TU) Injections

TU is partially absorbed by the intestinal lymphatics when given orally; it has low bioavailability and requires twice or thrice daily dosing, making it a poor candidate for an oral contraceptive. However, its preparation in tea seed oil (in China) and castor oil (in Germany) for use as an IM injection has yielded longer-lasting T depots with more favorable pharmacokinetics than TE. A Phase II contraceptive efficacy trial of IM TU injections was conducted in China, enrolling 308 men who received an initial loading dose of TU 1000 mg IM, followed by TU 500 mg at monthly intervals until they reached severe oligozoospermia (defined as $\leq$3 million/mL). Only 9 men were unable to achieve levels sufficient to enter the efficacy phase (failure of suppression in 2.9% of participants). No pregnancies occurred among the 296 couples who entered the 6-month efficacy phase and maintained adequately low sperm concentrations over a 143 person-year length of exposure. The only pregnancy observed during the efficacy phase was in the case of a man who demonstrated sperm rebound, where sperm concentration rose above the threshold for contraceptive efficacy after suppression. The mean length of time required for achieving azoospermia was 108 days (Gu *et al.*, 2003). Of note, the link between sperm rebound—seen in 2.3% of men in the efficacy phase—and pregnancy in this study, as predicted by concentrations between 1.1 and 3 million/mL led to recommendations to decrease the threshold for contraceptive efficacy to $\leq$1 million/mL. These recommendations were made with the recognition that future trials and practical, marketed methods could not require users to obtain more frequent confirmatory semen analyses to detect sperm rebound after suppression to severe oligozoospermia was attained. Decreasing the threshold for contraceptive efficacy to $\leq$1 million/mL thus may provide a wider margin for user error or method

insufficiency and would be expected to prevent incidental pregnancy (Aaltonen *et al.*, 2007). The subsequent Phase III contraceptive efficacy trial, using the same regimen thus defined the criterion for entry into the efficacy phase at ≤1 million/mL. The trial recruited 1045 Chinese men, 855 of whom entered the 24-month efficacy phase after reaching the contraceptive threshold (failure of suppression in 4.8% under the new criteria). 733 couples completed the study, giving a total of 1554 person-years of contraceptive exposure, during which nine pregnancies were observed, six of which could be attributed to sperm rebound concentrations between 2 and 8 million/mL—a failure rate of 1.1% at 24 months. Sperm rebound during the treatment phases of the study occurred in 1.3% of participants. The most frequent adverse events reported were injection site discomfort, acne, coughing after the injection, changes in mood and behavior, and skin rashes or facial swelling. After stopping the injections, all but two of the participants' sperm concentrations returned to the fertile reference range; recovery to normal values required 182 days on average (Gu *et al.*, 2009).

Current Developments With Androgens

The National Institutes of Health is developing several modified androgens that are bioavailable when administered by mouth where preclinical studies showed no hepatotoxicity. These androgenic compounds also bind to the progesterone receptor with transactivator activities. These compounds are promising for use as single-agent hormonal male contraceptives that possess both androgenic and progestational activity (Attardi *et al.*, 2011, 2006). Some of these new modified androgens are in phase 1 clinical trials and preliminary results demonstrate dose-dependent pharmacokinetic profiles and gonadotropin/T suppressive activity, as well as good safety and tolerability (Ayoub *et al.*, 2017; Surampudi *et al.*, 2014).

Ethnic Variations in Androgen Alone Regimens

While the contraceptive efficacy trials of TU injections provided substantial evidence of both efficacy and acceptability, as indicated by continuation rates beyond 85% of participants beyond 2 years (Gu *et al.*, 2009), the trials were conducted solely on Chinese men and their results may not translate to non-Asian or Caucasian users. The WHO-sponsored international efficacy trials of TE injections observed substantial ethnic disparities in the effectiveness of male hormonal contraceptive preparations using androgens alone where azoospermia was achieved by 91% of Chinese men compared to 60% of non-Asian men. The effect of T on lipids and liver function enzymes also varied by ethnicity in these studies (Ilani *et al.*, 2011). The need for preparations that could provide suppression across all ethnic groups and increase rates of suppression to azoospermia or oligozoospermia prompted studies that combined androgens with other hormonally active, gonadotropin-suppressing compounds such as progestins and GnRH antagonists.

Combined Hormonal Male Contraceptive Regimens: Androgens and GnRH Antagonists or Progestins

Gonadotropin-releasing hormone (GnRH) antagonists and exogenous progestins can inhibit gonadotropin secretion, reduce systemic T levels, and suppress spermatogenesis in men. Several different progestin or GnRH antagonist and androgen combinations have been studied.

GnRH Antagonists

GnRH antagonists are synthetic analogs of GnRH that bind to the GnRH receptors in the pituitary, rapidly suppressing the secretion of gonadotropins. Suppression is sustained throughout the time during which GnRH antagonists are administered and reversible within 1–2 weeks when treatment is stopped. These characteristics led to attempts at combining GnRH antagonists with T to increase the proportion of men achieving azoospermia, noting more complete suppression with the combination than with T alone (Bagatell *et al.*, 1993, 1995). Furthermore, when the GnRH antagonist, Nal-Glu, was used to initiate suppression, this suppression could then be maintained with the regular administration of T alone (Swerdloff *et al.*, 1998). Although this combination was found to have contraceptive potential, GnRH antagonists have a short half-life and limited oral bioavailability, warranting the need for frequent subcutaneous injections. Additionally, they are expensive and are associated with local, histamine-like skin irritation at the injection sites, making the preparation unlikely to be an acceptable one. Orally bioavailable or long-acting depot preparations of potent GnRH antagonists that are in development may have a place in male hormonal contraception in the future.

Progestins

The combined administration of T with a progestin can suppress gonadotropins to near undetectable levels and more completely suppress spermatogenesis to concentrations ≤1 million/mL than preparations using androgens alone. Multiple progestins, commonly used in hormonal contraceptive preparations for women, have thus been tested in combination with T preparations. However, the results of trials combining individual progestins in combination with T have varied, likely due to the unique properties of the various progestins used, but also possibly linked to different regimens of T administration among trials.

Cyproterone acetate (CPA) is a unique progestin for its direct antiandrogenic activity via concurrent blockade of T at the receptor level along with gonadotropin suppression as a progestin at the hypothalamus/pituitary. Its combination as an oral pill taken daily with weekly IM injections of TE, while able to achieve azoospermia in 100% of participants in a small trial ($n = 10$) and at half the time compared to men receiving TE alone, however was associated with dose-dependent decreases in hemoglobin and body weight (Meriggiola *et al.*, 1996; Wang and Yeung, 1980). As these effects were likely related to CPA's antiandrogenic properties, use of this combination has been limited. Levonorgestrel (LNG), given its safety profile when used for hormonal contraceptive among women, was extensively studied with a variety of androgens to determine its potential for male hormonal contraception. In one trial of sperm suppression combining weekly IM injections of TE with daily oral administration of LNG 500 μg, more rapid and complete sperm suppression was achieved than with TE alone—9.9 versus 15.3 weeks and 67% versus 33% azoospermia, respectively (Bebb *et al.*, 1996). Further study with lower doses of LNG (250 and 125 μg) did not compromise sperm suppression rates, however the trials noted dose-dependent decreases in levels of HDL cholesterol and weight gain (Anawalt *et al.*, 1999). Similar findings of complete azoospermia hindered by decreasing HDL cholesterol levels were noted in trials combining TE with desogestrel (DSG), an oral third-generation progestin with potent progestational activity and low androgenicity (Wu *et al.*, 1999). While the clinical significance of metabolic effects, such as the decrease in HDL, associated with the use of oral progestins for male hormonal contraception is unclear, concern that the chronic depression of HDL cholesterol levels may be associated with increased risk of cardiovascular disease has dampened interest in these combinations. However, preparations that could decrease overall exposure to supraphysiologic serum T levels and their associated risks without impacting contraceptive efficacy, such as long-acting or parenteral methods, remain promising.

Depot medroxyprogesterone acetate (DMPA) was combined with T implants in a study aimed at developing a method of male hormonal contraception that could circumvent the metabolic effects thought to be linked to daily progestin administration, with the added benefit of not requiring frequent administration. DMPA added to a suboptimal T implant dose of 800 mg could produce more effective suppression than T implants given at a 1200 mg dose (Handelsman *et al.*, 1996). A contraceptive clinical efficacy trial was then conducted in Australia where 55 men were enrolled, receiving T implants at 800 mg doses every 6 months and IM injections of DMPA 300 mg every 3 months. While the trial had to be amended to increase the frequency of T implant administration to every 4 months to avoid sperm rebound and symptomatic androgen deficiency, the participants received a median of 12 months of treatment without switches between treatment intervals. No pregnancies resulted following 426 person-months of exposure among 51 couples; azoospermia was maintained by nearly all participants through the efficacy phase of the trial. Time to suppression and the proportion of participants who were able to achieve azoospermia were improved markedly with the addition of DMPA. The effects were reversible. Unlike the trials combining T with LNG, CPA, or DSG, no significant weight changes or metabolic effects resulted. Lethargy and sexual dysfunction resulting from androgen deficiency seen among participants in the 6-month T implant interval were not seen when giving T implants at 4-month intervals (Turner *et al.*, 2003a). The limitation of DMPA, however, is its long duration of action such that recovery of the hypothalamic–pituitary–testis axis and spermatogenesis may be prolonged.

Complementing efforts to develop long-acting parenteral progestin and T combinations, one study examined the contraceptive potential of the subdermal etonogestrel (ENG) implant. ENG is the active metabolite of DSG and has been used with documented safety in the female contraceptive implants, Implanon® and Nexplanon®. In this study, 28 men were randomized to receive one or two ENG 68 mg implants in combination with T implants 400 mg, with azoospermia achieved in the majority of participants and without significant changes in HDL cholesterol levels (Anderson *et al.*, 2002). Inconsistent suppression among participants receiving a single ENG implant, however, warranted further development of preparations that provide higher doses of ENG within a single implant. A large multicenter trial sponsored by two pharmaceutical companies combined high and low dose ENG implants with TU IM at two doses. The study enrolled 354 men and 89% of men achieved a sperm concentration of $\leq$I million/mL at 4 months and suppression was maintained in 91% of men at 42/44 weeks of treatment. Recovery to normal sperm concentration took about 17 weeks. This study was unique in that a placebo was embedded in the different arms to evaluate possible adverse events. When compared to the placebo group, men in the active groups reported more weight gain, acne, sweating and libido changes. This study confirmed the efficacy of this androgen–progestin combination, but suggested that optimization may be achieved with changing the dose or the mode of delivery of the steroids (Mommers *et al.*, 2008).

More recently in 2008, the WHO, along with the Contraceptive Research and Development Program (CONRAD), led a late Phase II international contraceptive efficacy trial of norethisterone enanthate (NETE) 200 mg and TU 1000 mg IM injections. NETE is a depot progestogen administered via intramuscular injection and then converted to its metabolically active form, norethisterone. The trial recruited 320 men to receive injections every 8 weeks; 274 achieved severe oligozoospermia and entered a 12-month efficacy phase, during which 4 pregnancies were observed, giving a Pearl index of 2.18 per 100 person-years (95% CI 0.82–5.80). While six men exhibited sperm rebound during the efficacy phase, they were not linked to pregnancies. There was no difference in the rates of sperm suppression by ethnic group and adequate suppression was achieved in over 95% of men, thus highlighting the role of adding progestins to androgen preparations in overcoming the limitations of androgen-only methods (Behre *et al.*, 2016). The most common adverse events were acne ($n = 147$), increased libido ($n = 122$), injection site pain ($n = 74$), and emotional disorders ($n = 54$). While the frequency of adverse events led the WHO's Human Reproduction Program Research Project Review Panel to recommend halting further injections before the planned end of the study, the majority of adverse events were considered mild and $>$80% of participants reported willingness to use this method of contraception at their final visit (Behre *et al.*, 2016). It should be noted that most of the adverse events were reported in one Asian center. Moreover, because TU was administered without the loading

dose commonly utilized in clinical practice to rapidly raise serum T levels to the eugonadal range, there may have been times during the earlier part of the study where serum T levels were below the reference range and likelier to incur side effects.

The latest development in male contraceptive progestins is Nestorone® (NES), a 19-nor-progesterone-derived progestin with selective affinity for the progesterone receptor to the exclusion of androgenic, estrogenic, and minimal glucocorticoid activity at therapeutic doses (Kumar *et al.*, 2000; Sitruk-Ware *et al.*, 2003). Consequently, NES is not expected to be associated with undesirable side effects seen with the use of other androgenic progestins, such as weight gain or mood changes. NES gel (8 or 12 mg), when applied daily transdermally with T gel (100 mg T in 1% T gel), has been shown to induce severe oligozoospermia among >88% of users while maintaining normal serum total and free T concentrations. Adverse effects were minimal with the exception of mild to moderate acne in 21% of men, an effect thought to be related to the dose of T used in the study (Ilani *et al.*, 2012). The combination of NES and T into a single topical gel with reduced volume and lower T dose is expected to simplify application and improve adherence. This has been shown to suppress gonadotropins to a level expected to inhibit spermatogenesis as in the previous study (Mahabadi *et al.*, 2009). In 2018, the National Institute of Child Health and Human Development (NICHD) will conduct an international Phase 2b trial examining the contraceptive efficacy of daily applications of this combined NES/T transdermal gel in 450 couples. Following a suppression phase to confirm contraceptive effect (<1 million/mL) among male participants, couples will rely solely on the contraceptive gel for 12 months for the prevention of pregnancy. This study will incorporate an acceptability component.

Safety and Potential Side Effects of Hormonal Male Contraception

Studies on hormonal male contraceptive preparations in men began in the 1970s and to date, androgen and androgen plus progestin combinations have been relatively safe and well tolerated. Yet, no method of hormonal male contraception has been approved for clinical use. Relatively few clinical trials have been conducted with sufficiently large numbers of participants over a prolonged time period. Consequently, data that would accurately inform the incidence of side effects and rare adverse events associated with hormonal male contraceptive use are limited. The requisite safety data would not be available until a product is marketed for general use in men, after which postmarketing studies can be performed to monitor long term, off-target effects. However, the shared physiology and hormonal treatment of hypogonadal men with androgen replacement provides a model for anticipating similar side effects that might arise when using hormonal preparations to concurrently suppress intratesticular T production and optimize serum T levels. The side effects that are associated with the use of androgens for replacement therapy in symptomatic hypogonadal men are well-known, however their manifestation may depend on variations in dosing and routes of administration. Common side effects include acne, oiliness of the skin, weight gain, mood changes including depression, and fluctuations in libido. Laboratory-based changes include reductions in high-density lipoprotein (HDL) cholesterol and increases in hemoglobin and hematocrit. The adverse effects of progestins on men are not known, as they have not previously been administered to men clinically nor have their effects been characterized separately from those of androgens. Potential adverse effects have been identified in some contraceptive clinical trials, however they may be minimized by optimizing the doses of androgen and progestin to balance the suppression of spermatogenesis against potential side effects in future trials. These dose-finding studies were lacking before some of the larger contraceptive efficacy studies begun.

With respect to long-term side effects, a systematic review and meta-analysis of T replacement therapy in adult men did not find any significant effects on the incidence of prostatic or urologic adverse events. While it is unlikely that T replacement increases the risk of prostatic hyperplasia or cancer, none of the included studies examined exposures beyond 3 years (Fernandez-Balsells *et al.*, 2010), for which reason long-term effects on the prostate are still unknown. With respect to cardiovascular risk, results from a cohort study based on a healthcare database noted increased cardiovascular disease risk among men who were 65 years old or older, but not in younger men without preexisting heart disease (Finkle *et al.*, 2014). Analyses of such healthcare databases however, may not reflect clinical practice because a substantial number did not meet guidelines for starting T replacement (Baillargeon *et al.*, 2015). Several epidemiological studies (Vigen *et al.*, 2013; Shores *et al.*, 2012) and meta-analyses of randomized controlled trials (Corona *et al.*, 2016; Xu *et al.*, 2013) highlighted the controversy over the risk of major acute coronary events (MACE) and stroke among men with low T concentrations who receive replacement therapy. Nevertheless, the United States Food and Drug Administration and experts in the field recognize the inadequate amount of evidence and the need for long-term, adequately powered safety trials (Nguyen *et al.*, 2015) and recommend a longer term study to specifically address whether T treatment will increase the long-term risk of cardiovascular disease. Such a study is in progress.

Potential Noncontraceptive Benefits

Women who use hormonal methods of contraception receive several noncontraceptive benefits, not limited to the prevention of acne, menstrual irregularities, anemia, benign breast disease, ovarian cysts, and gynecologic cancers (Mishell, 1982; Kaunitz, 2002). While not the primary outcome of interest in hormonal male contraceptive trials, noncontraceptive benefits may similarly be expected to arise among some men. Based on trials of T replacement therapy, these men may expect to experience some increases in sexual desire, erectile function, energy, and mood, as well as hemoglobin, lean body mass, muscle strength, and bone density (Corona *et al.*, 2014; Isidori *et al.*, 2005a, b).

Summary and Conclusions

Despite numerous developments in hormonal contraceptives for women, including long-acting reversible methods such as the subdermal implant and intrauterine device, rates of unintended pregnancy remain persistently elevated. As data from the United States' National Survey of Family Growth indicate high rates of dissatisfaction leading to contraceptive discontinuation among couples (Moreau *et al.*, 2007), and as women are disproportionately burdened with the responsibility and risk, as well as the loss of resources associated with contraceptive use (Kimport, 2017), the availability of a novel male contraceptive could have far-reaching public health and sociocultural benefits. Yet while hormonal male contraceptives are one of the most studied methods that may be closest to being marketed, several barriers may prevent their widespread uptake.

Logistically, the use of any male hormonal contraceptive requires confirmation of sufficient suppression of spermatogenesis for contraceptive efficacy, thereby adding both an additional step for the user, as well as uncertainty about its efficacy at the individual level. In clinical trials of various male hormonal contraceptive preparations, the majority of participants could achieve sufficient suppression. However, a minority of men were unable to reach at least severe oligozoospermia within a reasonable timeframe, thereby limiting the potential impact of hormonal preparations studied to date. Additionally, even if a man intends to use a male hormonal contraceptive, he may have to wait as long as 60 to 70 days to achieve suppression of the hypothalamic–pituitary-–testicular axis and spermatogenesis. Nevertheless, a precedent for contraceptive latency and need for confirmation is already seen among vasectomy users who have to wait at least 2–4 months before confirming azoospermia via postvasectomy semen analysis (Sharlip *et al.*, 2012). This lag time after vas occlusion reflects the duration of time needed to turnover preexisting spermatozoa (Misell *et al.*, 2006) and for the mature spermatozoa to traverse the reproductive tract. Further research will be needed to develop methods with latency periods as short as those seen in women's methods—women who initiate hormonal methods need only wait 7 days for contraceptive protection (Curtis, 2016). As male hormonal contraceptives do not provide protection from sexually transmitted infections, they will likely be adopted by monogamous couples. In this context, the choice of contraceptive method used will likely be planned and coordinated such that the obstacles mentioned above are unlikely to deter potential users.

Public-funded research has reached a stage where the realization of male hormonal contraception is within reach. Further progress will be dependent upon public outreach to increase awareness and support of male contraceptive development efforts, which may be strengthened by efforts to engage men in family planning and reproductive responsibility. A change in culture and attitudes that provides men with reproductive choices via the promise of novel male contraceptives may attract investments from the pharmaceutical industry.

Estrogen and the Male☆

Agnė Kadusauskienė and Jonas Čeponis, Lithuanian University of Health Sciences, Kaunas, Lithuania

Glossary

Adrenarche A period that begins prior to puberty, at 7 or 8 years of age, when plasma concentrations of adrenal androgens begin to rise.

Aromatization The conversion of testosterone to estradiol (E_2) and of androstenedione to estrone (E_1) in the tissues that contain the aromatase enzyme.

Gynecomastia A benign proliferation of the glandular tissue in the male breast (histological definition); the presence of firm palpable tissue extending concentrically from the nipple (clinical definition).

Introduction

With new scientific advances during recent years, estrogen can no longer be regarded as a "female hormone." Our understanding of the role of estrogen in male physiology was fundamentally challenged when a man with a null mutation of estrogen receptor-α (ERα) was first described in 1994. The major shift in thinking regarding estrogen action in males was further fueled by the descriptions of men with inactivating mutations of the aromatase gene, the development of knockout mouse models with defects of the estrogen receptor (ERKO) and the aromatase gene (ArKO), the discovery of a second estrogen receptor, ERβ, and their numerous isoforms. This article provides an overview of the role of estrogen in male physiology and pathophysiology.

Estrogen Physiology in the Male

Adult males produce about 100 times more testosterone than estrogen under normal circumstances. The total production rates of estradiol (E_2) and estrone (E_1) are 45 and 66 μg/day (160 and 220 nmol/day), respectively, with only about 15% of E_2 secreted directly by the testis. Consequently, in a healthy young adult male, approximately 85% of circulating E_2 and all of E_1 are derived from peripheral conversion of testosterone and androstenedione by aromatization. Once androgens are converted to estrogens, the process is irreversible. The *CYP19* gene, located on chromosome 15q21, encodes the human P450 aromatase enzyme. The expression of the *CYP19* gene is regulated by tissue-specific promoters. It is expressed in the placenta, ovary, testis, prostate, liver, bone, heart, brain, muscle, hair follicles, breast, and (most important) adipose tissue where most of peripheral aromatization takes place.

Aromatase activity in peripheral tissues tends to increase with age and body size. Mouse models have shown that obesity-associated white adipose tissue inflammation increases aromatase gene expression (Polari *et al.*, 2015). In an obese male man, it was found that subcutaneous adipose tissue cell size rather than aromatase expression is related to low T (Bekaert *et al.*, 2015). Men over 50 years of age have a 50% increase in total E_2 with little change in free E_2 in part due to elevated levels of sex hormone-binding globulin (SHBG). Opposite to ageing, obesity is associated with a significantly lower SHBG (Cooper *et al.*, 2015). Increased adipose tissue leads to lower T levels that maintain deposition of visceral fat and may lead to a chronic hypogonadal state, called the hypogonadal–obesity cycle (Cohen, 1999, 2001). Data on E_2 levels in obese men have been inconsistent across studies, as some reported increased E_2 levels (Schneider *et al.*, 1979; Zumoff *et al.*, 1981), while others reported no changes or even lower levels (Abate *et al.*, 2002; Colangelo *et al.*, 2009; Dhindsa *et al.*, 2011).

Pituitary secretion of luteinizing hormone (LH) controls secretion of E_2 and testosterone from the testis. E_2 and testosterone, in turn, provide negative feedback at the level of the hypothalamus and anterior pituitary to regulate gonadotropin secretion. Similarly to testosterone, testicular E_2 secretion is stimulated whenever plasma LH/human chorionic gonadotropin (hCG) levels are elevated. Elevated levels of estrogen, either through endogenous or exogenous route, can reduce testicular testosterone secretion through suppression of LH release. Furthermore, excess estrogen stimulates SHBG synthesis in the liver, resulting in increased bound testosterone with a reduction in plasma-free testosterone.

Two estrogen receptor (ER) subtypes have been identified: ERα and ERβ. ERα has at least three different isoforms, and ERβ has at least five different isoforms (Li *et al.*, 2015). ERβ is far more widely distributed in the body than ERα. ERs are expressed at many

☆*Change History*: May 2018. Jonas Ceponis and Agnė Kadusauskiene made changes to updated sections "Estrogen Physiology in the Male", "Roles of Estrogen in Male Physiology: Lessons from Males With Estrogen Deficiency States", "Estrogen and the Male Skeleton", "Estrogen and the Prostate", "Gynecomastia", "Estrogen and the Male Reproductive System", "Conclusion"; added new sections "Effects of Estrogen on Metabolism", "Estrogen Effect on Male Cardiovascular System", "Estrogen and Central Nervous System"; updated Table 2, added Tables 1, 3, 4, and 5.

This article is an update of Judy K. Lee, Julianne Imperato-McGinley Imperato-McGinley, Estrogen and the male, In Encyclopedia of Endocrine Diseases, edited by L. Martini, Elsevier, New York, 2004, pp. 29–34.

Table 1 Estrogen actions

Onset and duration of action	*Estrogen actions*	*Receptors*	*Location*	*Mode of action*
Rapid and short acting (occurs within seconds)	Nongenomic	GPR30	Cell membrane	Changes in ionic transport through cell surface
Slower (hours) and more stable	Genomic	ERα ERβ	Cell nucleus	Gene expression

ERα, estrogen receptor alpha; *ERβ*, estrogen receptor beta; *GPR30*, G protein-coupled receptor.
Modified after Rochira, V. et al. (2016). Estrogens and male reproduction. MDText.com Inc.

of the sites where aromatase is also expressed, suggesting that many target tissues are locally producing estrogen. Evidence indicate that ERα and ERβ are expressed in bone, adipose tissue, prostate, cells of the immune system, thymus, pituitary gland, heart, the reproductive system, and various regions of the brain.

Both ER subtypes belong to the nuclear receptor superfamily and mediate the classical pathway, however they exhibit different ligand specificity and transcriptional activity (**Table 1**). ERβ has a weaker transcriptional activity compared to ERα. Moreover, co-expression of ERα and ERβ in a cell through complex mechanisms may result in antagonistic effects (Heldring *et al.*, 2007; Rochira *et al.*, 2016). In vitro studies have also shown rapid estrogen effects with short latency between administration of estrogens and their biological effect. These effects are realized through nongenomic estrogen action and are mediated by a cell-surface G protein-coupled receptor (GPR30). There are data to suggest that a monomeric portion of ERα is translocated from the nucleus to the membrane (Hammes and Levin, 2007, 2011).

Data on differential effects of each ER subtype on various systems are discussed in the respective sections below.

Roles of Estrogen in Male Physiology

Lessons From Males With Estrogen Deficiency States

Descriptions of a man with estrogen resistance and a number of men with aromatase deficiency provide insights into our understanding of estrogen action in the male. In 1994, Smith and colleagues described a 28-year-old man with estrogen resistance due to an autosomal recessive missense mutation in exon 2 of ERα, resulting in a complete loss of protein function. He had eunuchoid skeletal proportions with a height of 204 cm, delayed bone age (15 years), open epiphyses, persistent linear growth, and accelerated bone turnover with marked osteopenia. Biochemical testing revealed normal serum testosterone and elevated circulating levels of follicle-stimulating hormone (FSH), LH, E_2, and E_1.

Subsequently, from 1995 to 2017, fifteen unrelated cases of aromatase deficiency secondary to distinct autosomal recessive missense mutations of the *CYP19* gene in men have been reported: twelve adult men, one adolescent and two children (**Table 2**).

Similarly to the man with estrogen resistance, the aromatase-deficient men (24–44 years of age) all had a tall stature (height of 182–204 cm) with continued linear growth, delayed skeletal maturation (bone age of 14.0–18.0 years), open epiphyses, and evidence of severe osteopenia (**Table 3**). Biochemical studies revealed normal or elevated levels of testosterone, LH, and FSH, and showed very low levels of circulating E_2 and E_1 (**Table 4**).

When the ERα-negative man was treated with high doses of estrogen, there were no clinical, hormonal, or metabolic changes. In contrast, the aromatase-deficient men responded dramatically to relatively low doses of estrogen, resulting in correction of the described hormonal abnormalities without side effects such as gynecomastia (**Table 5**).

Observations in estrogen-resistant and aromatase-deficient men have redefined our view of estrogen action and the male skeleton. Other findings from these human models, including the role of estrogen in lipid/carbohydrate metabolism and spermatogenesis, are discussed in subsequent sections of this article.

Estrogen and the Male Skeleton

Despite normal or elevated levels of testosterone, men with impaired estrogen synthesis or action all had delayed epiphyseal closure, severe osteopenia, and evidence of increased bone turnover (**Table 3**). Although these men had normal pubertal onset and normal male secondary sexual characteristics, they did not experience the classic growth spurt associated with puberty. Estrogen stimulates pubertal growth spurt in both sexes by enhancing growth hormone secretion during puberty (Frank, 2003; Rochira *et al.*, 2015). Contrary to prior belief, epiphyseal fusion in males is not mediated by testosterone; rather, it is mediated by estrogen (Vanderschueren *et al.*, 2014). With estrogen treatment, despite declining levels of testosterone, all of the men had complete epiphyseal fusion within 6–9 months and had a progressive increase in bone mass. In one man, after 3 years of continuous estrogen therapy, bone mass increased by 20.7% in the lumbar spine, 15.7% in the femoral neck, and 12.9% in the distal radius (Bilezikian *et al.*, 1998). Thus, androgen alone is clearly not sufficient to promote normal skeletal growth and maturation. Both androgen and estrogen are required for accrual of optimal peak bone mass in men. Estrogen appears to increase bone mass by exerting anabolic as well as antiresorptive effects. While exact mechanisms are not fully known, there is sufficient proof that ERα directly affects osteoblasts, osteocytes, osteoclasts, and chondrocytes, while AR primarily works on osteoblasts and osteocytes.

Evidence from mouse knockout models (α-ERKO, β-ERKO, and ArKO mice) has also contributed to our understanding of estrogen and the male skeleton during recent years. Deletion of the ERα or aromatase gene in the male mouse results in osteopenia with increased

Table 2 Genetic impairments in men with estrogen deficiency states

Patient	*Inheritance*	*Publications*	*Mutation*	*Age (years)*
ERα resistant	Autosomal recessive	Smith *et al.* (1994)	ERα gene (missense)	28

Aromatase deficiency #2		Carani *et al.* (1997)	A single G→A mutation at BP 1094 in exon 9 of the CYP19 gene	38
Aromatase deficiency #3		Herrmann *et al.* (2002)	A C to A substitution in intron V, at position-3 of the splicing acceptor site before exon VI of the CYP19 gene	27
Aromatase deficiency #4		Maffei *et al.* (2004)	Homozygous point mutation at the last nucleotide of exon V (G3A) inactivating CYP19 gene	29
Aromatase deficiency #5		Maffei *et al.* (2007)	Heterozygous mutations ibp380 (T→G) in exon IV and at BP 1124 (G→A) in exon IX inactivating CYP19A1 gene	25
Aromatase deficiency #6		Lanfranco *et al.* (2008)	Heterozygosity due to 23 bp deletion in exon IV and a point mutation in the first nucleotide of intron IX of the CYP19A1 gene	26.8
Aromatase deficiency #7		Baykan *et al.* (2013) and Pignatti *et al.* (2013)	Homozygous R375H guanine-adenine (G-A) mutation in CYP19A1 gene	27
Aromatase deficiency #8		Pignatti *et al.* (2013)	Homozygous for a point mutation in the first nucleotide of intron 3 (IVS3 + 1G>T) in CYP19 gene	26
Aromatase deficiency #9			Homozygous mutation in exon IV (c.434 G>A) leading to Arg to Gln substitution at position 115 (p.R115Q) in CYP19 gene	44
Aromatase deficiency #10				29
Aromatase deficiency #11		Chen *et al.* (2015)	Heterozygous *CYP19A1* mutations (Y81C and L451P) (missense)—partial loss of the enzymatic activity of aromatase	24
Aromatase deficiency #12		MiedLich *et al.* (2016)	Homozygous c.628G>A mutation in exon 5 CYP19 gene	25
Aromatase deficiency #13 weeks		Deladoëy *et al.* (1999)	Homozygote 1—BP (C) deletion in exon 5—CYP19 gene (missense) in CYP19 gene	4
Aromatase deficiency #14		Bouillon *et al.* (2004)	Homozygosity for a C-base deletion in exon 5 of the CYP19 gene	16.4
Aromatase deficiency #15	Bouchoucha *et al.* (2014)	point mutation of CYP19A1 at c.575 G>A in exon 5—nearly a complete loss of aromatase activity	15 months	

BP, base pair.

markers of bone remodeling. In contrast, the skeleton of the ERβ knockout male mouse is phenotypically identical to that of the wild type. It appears that estrogen mediates its effects on the bone primarily through ERα, although both ERα and ERβ are expressed in the bone.

Estrogen is clearly critical for bone mass acquisition in the growing skeleton. However, the inherited states of impaired estrogen synthesis or action do not clearly reflect the role of estrogen in maintaining bone density in the mature adult skeleton. Additional data from nearly all of the cross-sectional observational studies looking at the relationships between sex steroid levels and bone mineral density (BMD) show that E_2, especially the non-SHBG-bound E_2, has a better correlation with BMD than do either total or free testosterone levels (Araujo *et al.*, 2008; Paller *et al.*, 2009; Woo *et al.*, 2012; Slemenda *et al.*, 1997).

In a prospective study, it was found that the BMD in young men (20–40 years of age), when compared with that in elderly men (60–90 years of age), was most closely correlated with E_2 levels (Khosla *et al.*, 2001). In particular, the decreased bioavailable E_2 levels in elderly men appear to be a good predictor of age-related bone loss (Khosla *et al.*, 1998). This relationship was further investigated by giving elderly men physiological hormone replacement after pretreatment with a gonadotropin-releasing hormone (GnRH) agonist and an aromatase inhibitor. Estrogen alone was far more effective than testosterone alone in preventing an increase in bone resorption markers (Falahati-Nini *et al.*, 2000). Estrogen and testosterone combined have positive synergistic effects on bone remodeling. Based on the data, it was estimated that estrogen is responsible for about 70% of the total effect of sex steroids on bone resorption, whereas testosterone (in the absence of conversion to estradiol) accounts for no more than 30% of the effect. Another study reported that when elderly men were treated with an aromatase inhibitor for 9 weeks, they had a significant increase in bone resorption markers and a decrease in bone formation markers when compared with baseline (Taxel *et al.*, 2001). Therefore, a subset of elderly men with low bioavailable E_2 are the most susceptible ones to age-related bone loss similar to the increased risk of bone loss seen in postmenopausal women. In a more recent hallmark study by Finkelstein *et al.*, 189 healthy younger men with GnRH agonist induced hypogonadism were given graded doses of T with or without aromatase inhibition to prevent conversion to E_2 (Finkelstein *et al.*, 2016). Low E_2 levels were consistent with greater bone resorption despite the T levels. It was also shown that E_2 deficiency primarily affected cortical bone due to increased cortical porosity but had minimal

Table 3 Effects of estrogen deficiency states on skeleton

Patient	*Age (years)*	*Stature (cm)*	*Bone age (years)*	*Bone mineral density*
ERα resistant	28	204	15	Severe osteopenia
Aromatase deficiency #1	24	204	14	Severe osteopenia

effects on trabecular structure. Animal models have also shown E_2 affects cortical bone, while effects on trabecular bone are mostly exerted through AR (Ucer *et al.*, 2015; Khosla, 2015; Notini *et al.*, 2007).

Effects of Estrogen on Metabolism

Despite differences of total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels in estrogen-resistant and aromatase-deficient men, serum concentrations of high-density lipoprotein (HDL) cholesterol are uniformly low. The low HDL cholesterol is likely due to low estrogen and unopposed androgen action as with E_2 therapy levels of HDL cholesterol and other lipids improved.

Estrogen deficiency is associated with propensity of developing insulin resistance (**Table 5**). The estrogen-resistant man had axillary *acanthosis nigricans*, a cutaneous marker of insulin resistance, in addition to elevated glycosylated hemoglobin. Similar features were observed in majority of men with aromatase deficiency: 13 of the adult men were overweight and nine had impaired glucose tolerance of varying degree. Most of the impairments resolved with estrogen replacement, with a notable exception of the estrogen-resistant man.

Similar results were shown in healthy men with induced hypogonadism: a decrease in E_2 through blocked aromatization lead to an increase in adipose tissue that was independent of T, while androgens were responsible for lean mass and other muscle parameters (Finkelstein *et al.*, 2013).

There is evidence to suggest that severe estrogen and testosterone ratio imbalance increases insulin resistance in estrogen-deficient men, as well as in rodent models (Mauvais-Jarvis, 2011). Aromatase deficient men are not homogenous, however, as in a patient, described by Chen *et al.*, treatment with estradiol improved glucose levels—but not insulin resistance (Chen *et al.*, 2015).

Data on estrogen effects on insulin sensitivity remains inconsistent in studies done in humans of both sexes, as well as animal models. It seems that favorable estrogen effect depends on a tight physiological concentration of E_2. This theory is supported by findings that supraphysiological levels of E_2 or overstimulation of ER, increase insulin resistance through hyperinsulinemia or a reduction in total glucose transporter 4 (GLUT4) expression (Nadal *et al.*, 2009; Barros *et al.*, 2008).

ERα is more abundant than ERβ in many glucoregulatory tissues. Activation of ERα increases glucose uptake into skeletal muscle when insulin is present; meanwhile activating ERβ alone or both ERs did not show beneficial effect (Gorres *et al.*, 2011). Homozygous ERβ deletion failed to produce insulin resistance in mice (Ohlsson *et al.*, 2000); yet there is evidence that ERβ, despite limited expression, promotes insulin resistance, especially when ERα action is reduced (Mauvais-Jarvis *et al.*, 2013).

Table 4 Reproductive effects of estrogen deficiency states in men

Patient	*Age at diagnosis*	*Testicular size*	*Cryptorchism*	*FSH/LH*	*Testosterone*	*Estradiol*	*Sperm analysis*
ERα resistant	28 years	Normal (20–25 mL)	No	Very high 33/ 37 mIU/ mL	Normal 15.4 nmol/L	Very high 437 pmol/L	25 × 10^6/mL; 18% viable
Aromatase deficiency #1	24 years	Large (>25 mL)	No	Very high 28.3/ 26.1 mIU/ mL	Very high 69.9 nmol/L	Very low <26 pmol/L	N/A
Aromatase deficiency #2	38 years	Small (8 mL)	No	High/normal 13.6/ 8.9 IU/L	Normal 13.5 nmol/L	Undetectable<37 pmol/ L	1 × 10^6/mL; 100% immotile spermatozoa
Aromatase deficiency #3	27 years	Normal (13–14 mL)	No	High/normal 11/ 6.0 mIU/ mL	High 31.2 nmol/L	Low <73 pmol/L	17.4 × 10^6/mL; 10% motility; 55% vitality
Aromatase deficiency #4	29 years	Right 10 mL, left 11 mL (in the inguinal canal)	Bilateral cryptorchidism	High/normal 20/7 mIU/ mL	Low normal 9.37 nmol/L	Undetectable <5.5 pmol/L	Biopsy—total germ cell depletion. Refused semen analysis
Aromatase deficiency #5	25 years	Normal (15 and 14 mL)	No	High/normal 10.12/ 6.75 IU/L	Normal TT 20.2 nmol/L	Undetectable <18 pmol/L	Biopsy –13 mature spermatids per tubule (severe oligospermia)
Aromatase deficiency #6	26.8 years	Normal (16 and 21 mL)	Right cryptorchidism	High/normal 12.5/ 3.1 IU/L	Normal TT 29.1 mmol/L, FT 147.7 pmol/ L	Undetectable	70 × 10^6/mL, 45% motility
Aromatase deficiency #7	27 years	Normal (>20 mL)	No	Normal 18.81/ 8.26 mIU/ mL	Normal 28.4 nmol/L	Undetectable <73 pmol/L	56 × 10^6/mL, 40% motility
Aromatase deficiency #8	26 years	Normal (20 mL)	No	Normal 13.4/ 5.4 mIU/ mL	Normal 23 nmol/L	Undetectable <73 pmol/L	N/A
Aromatase deficiency #9	44 years	Normal (>20 mL)	No	High/normal 18.0/ 5.3 mIU/ mL	Normal 14.2 nmol/L	Undetectable <37 pmol/L	N/A
Aromatase deficiency #10	29 years	Normal (>20 mL)	No	Normal 2.57/ 7.6 mIU/ mL	Normal 18 nmol/L	Undetectable <73 pmol/L	N/A
Aromatase deficiency #11	24 years	Normal (15 mL)	No	Normal 14.4/ 4.8 IU/L	Normal 20.5 nmol/L	Undetectable	129 × 10^6/mL; vitality 97%
Aromatase deficiency #12	25 years	Normal (20 mL)	No	Normal 4.8/ 5.5 mIU/ mL	Normal 30.2 nmol/L	Very low 26 pmol/L	N/A
Aromatase deficiency #13	2 weeks	Normal	No	@2 m/o Normal 3.9/ 12.5 IU/l	High to normal FT 182–44.8 pmol/ L	Low to undetectable 44 —<18 pmol/L	N/A
Aromatase deficiency #14	16.4 years	Normal	No	Normal 8/ 8 mU/mL	High TT 45.3 nmol/L FT 1.46 nmol/L	Undetectable	N/A

Aromatase deficiency #11	26.5	Acanthosis nigricans	Hyperinsulinemia	Impaired	6.9 (n. 4.5–6.3)	No[a]	Improved glycemic levels, insulin resistance worsened
Aromatase deficiency #12	17.5	Acanthosis nigricans	Normal	Normal	4.8	No	N/A

[a]HbA1c within current diabetic levels.

[b]Patient AD#4 developed Acanthosis nigricans at the end of high-dose testosterone treatment.

HOMA-IR, Homeostasis Model Assessment of Insulin Resistance; *ULN*, Upper limit of normal range; *N/A*, data not available.

Direct estrogen actions in glucose homeostasis and energy metabolism mechanisms remain to be fully understood as it is still unclear what tissues and which ERs are targets of estrogen action in insulin resistance.

Estrogen Effect on Male Cardiovascular System

Both ERs are widely expressed within cardiovascular tissues and have multiple effects. It seems that quantity and density of ERs depend on gender, age, estrogen levels, and concomitant diseases. For example, it is well known that more ERs are expressed in female arteries (Nakamura *et al.*, 2005). On the other hand, it was shown that estradiol can be produced locally in the male vasculature and stimulate ERs of endothelial and vascular smooth muscle cells (Vitale *et al.*, 2010).

Hypertension

Both animal models and human studies show that ERβ is important in regulating arterial tone and blood pressure (Zhu *et al.*, 2002; Hodges *et al.*, 2000). ERβ-deficient mice were shown to be hypertensive (Zhu *et al.*, 2002; Pelzer *et al.*, 2005); additionally, administration of ERβ agonist at a dose which did not activate ERα resulted in blood pressure-lowering effect (Arias-loza *et al.*, 2008). Estrogen can also cause arterial vasodilation through nongenomic pathway by activating endothelial cell nitric oxide synthase (Paper *et al.*, 2006).

Atherosclerosis

Endothelial dysfunction is an early contributor to developing atherosclerosis. Low-dose estrogen replacement improved endothelial function and diffuse atherosclerosis in men with aromatase deficiency (Carani *et al.*, 1997; Smith *et al.*, 1994; Chen *et al.*, 2015). Moreover, men who were treated with aromatase inhibitors due to prostate cancer, showed reversible endothelial dysfunction (Mendelsohn and Rosano, 2003; Lew *et al.*, 2003). In line with these findings, defective mutations in estrogen synthesis or ER expression were associated with premature development of atherosclerosis due to reduced endothelial function in men (Vitale *et al.*, 2010).

Ischaemia

Estrogen replacement therapy has been attributed to increased risk of myocardial infarction and death in men (Coronary Drug Project Research Group, 1974). However, recent data has shown potentially beneficial estrogen effects in cellular ischemia models, possibly through reduction in intracellular calcium and sodium during metabolic inhibition, as demonstrated in male mice cardiac myocytes (Sugishita *et al.*, 2001).

Estrogen and the Prostate

Benign prostatic hypertrophy (BPH) is usually found in men over 50 years of age. Estrogen concentration in the stroma increases with age with contributions from peripheral sources and from aromatization of androgen within the stroma. Estrogen can induce squamous epithelial metaplasia and can stimulate growth of the fibromuscular stroma, resulting in BPH. Estrogen also induces synthesis of insulin-like growth factor-1 (IGF-1), which acts to prime the response of epithelium to androgen. Therefore, estrogen can increase epithelial proliferation indirectly by enhancing androgen action.

By increasing the levels of circulating SHBG, estrogen can exert an inhibitory effect on the prostate by reducing the amount of free testosterone available for the androgenic stimulation of prostate. The decrease in the plasma concentration of testosterone is further mediated by the negative feedback action of estrogen on LH secretion. Therefore, in contrast to its growth-promoting effect in BPH, estrogen in pharmacological amounts can reduce the size and function of the epithelial cells of the prostate and has been a form of therapy in prostate cancer. Alternatively, estrogen may exert antiandrogen effects within the tumor cells, or it may be directly inhibitory to the tumor cells.

Epidemiological studies demonstrate geographical differences in incidence rates of prostate cancer, with a 15-fold greater incidence in the United States than in Japan and a 60-fold greater incidence in the United States than in Shanghai, China (Hsing *et al.*, 2000). The geographical differences have been attributed to dietary factors such as soy (phytoestrogens), which may be protective against the development of prostate cancer, in addition to genetic factors (Zhang *et al.*, 2016). The effects of phytoestrogen on BPH are not completely understood, but there are some evidence showing an inhibitory effect on proliferation (Nicholson and Ricke, 2011).

Within the prostate, ERα is located primarily in the stromal cells, whereas ERβ is present in the epithelial cells and seem to exert antagonistic effects. Stimulation of ERα induces proliferation (Wada-Hiraike *et al.*, 2006a; Omoto *et al.*, 2005), which has been related to chronic prostatitis, benign prostate hyperplasia, carcinogenesis, and progression to cancer (Prins and Korach, 2009). Conversely, ERβ seems to inhibit proliferation and promote differentiation (Wada-Hiraike *et al.*, 2006b; Warner and Gustafsson, 2010). Most studies reported decline of ERβ in localized prostate cancer with higher Gleason scores (Leav *et al.*, 2001; Horvath *et al.*, 2001). In support to this data, overexpression of ERβ showed a tumor suppressing effect and was associated with longer patient survival while controlling cell growth, cell cycle progression and apoptosis (Pinton *et al.*, 2010). Mice models suggest that beneficial effect on prostate through ERβ might be caused by downregulating androgen receptor expression (Weihua *et al.*, 2001). Potential therapeutic effects of ERβ-selective agonists need to be further explored.

Estrogen and Central Nervous System

A number of studies have shown estrogen to have neuroprotective, antioxidative, and antiinflammatory effects in the brain (Brann *et al.*, 2007; Fiocchetti *et al.*, 2012; Simpkins *et al.*, 2010; Kramer *et al.*, 2004). Estrogens are involved in various cognitive functions such as learning and memory; effect on physiological and behavioral endpoints including social behavior, cognition, and neurodevelopmental processes has been shown (Brann *et al.*, 2007; Craig *et al.*, 2008; Craig and Murphy, 2007a,b). While estrogens are important for certain aspects of memory, however, estradiol treatment failed to improve short or long-term memory in elderly men (Matousek and Sherwin, 2010).

Through regulation of dopaminergic, serotonergic, and cholinergic neurons, estrogens are involved in several neurotransmitter systems (Koehler *et al.*, 2005). Recent findings suggest that estrogens can work as neuromodulators by themselves locally at the site of synthesis—for example, estrogen effects in the synapse include synaptogenesis, neurotransmission, and synaptic plasticity (Badalà *et al.*, 2014).

There is evidence of de novo estrogen synthesis from cholesterol in the brain; the major site for this seem to be the neurons in the hippocampus (Fester *et al.*, 2011; Badalà *et al.*, 2014). Despite such synthesis, the main source of estrogens in the male brain still comes through local aromatization of testosterone (Badalà *et al.*, 2014). Local aromatization of testosterone leads to dynamic fluctuations in estrogen concentrations that are associated with probably nongenomic effects on various physiological and behavioral effects including social behavior and cognition (Chalovich and Eisenberg, 2005).

Neurodegeneration

Research has shown that estrogens are involved in prevention or slowing of neurodegenerative processes, which may be significant in Alzheimer's and Parkinson's diseases, multiple sclerosis, stroke, and traumatic brain injury (Luchetti *et al.*, 2014; Badalà *et al.*, 2014; Bourque *et al.*, 2015; Suzuki *et al.*, 2009; Tiwari-Woodruff *et al.*, 2007a, b). Both ERs are related to neuroprotective effect in brain through various mechanisms, including antiapoptotic protein-mediated signaling cascades and promotion of mitochondrial viability via regulation of calcium signaling (Nilsen and Brinton, 2004; Simpkins and Dykens, 2008; Zhao and Brinton, 2007; Zhao *et al.*, 2004). It has been suggested that the mechanisms and timing of effects through ERα and ERβ may differ as in mice models of ischemic brain injury and experimental autoimmune encephalomyelitis (an animal model for multiple sclerosis) ERα are induced earlier than ERβ (Tiwari-Woodruff *et al.*, 2007a, b; Tiwari-Woodruff and Voskuhl, 2009; Gillies and McArthur, 2010).

Estrogen-Excess State in the Male

The major clinical signs of estrogen excess in males are gynecomastia, testicular atrophy, erectile dysfunction, and infertility. Estrogen-secreting tumors and other endogenous or exogenous sources of estrogen can induce inhibition of testicular function by inhibiting gonadotropin secretion (**Table 6**).

Gynecomastia

The crucial factor in the development of gynecomastia from any cause may not the absolute level of estrogen but rather the ratio of estrogen to testosterone; the higher the ratio, the greater the likelihood of developing gynecomastia. **Table 6** summarizes the various causes of gynecomastia.

Physiological gynecomastia occurs during the newborn period, during adolescence, and with advanced age. Breast enlargement occurs in approximately 60%–90% of newborns due to stimulation by placental estrogen, and it usually resolves within a few weeks. Pubertal gynecomastia usually has an onset between 10 and 12 years of age and peaks at approximately 13–14 years of age. It affects 30%–40% of adolescent boys, and in the majority of cases it resolves by 17 years of age. The high plasma ratio of E_2 to testosterone in boys with pubertal gynecomastia is likely the result of normal aromatase activity in the testis and the extraglandular tissues before maximum production of testosterone is achieved. The prevalence of gynecomastia in older men ranges from 40% to 65% (Mathur and Braunstein, 1997; Braunstein, 2007); these may include misdiagnosed pseudogynecomastia cases, however prevalence of pseudogynecomastia has shown to be relatively low at around 5% (Dickson, 2012). With advanced age, the increased ratio of estrogen to testosterone favors feminization. However, in elderly men, it is a diagnosis of exclusion given that many elderly patients take medication or have medical problems that may contribute to breast enlargement.

Pathological gynecomastia can be due to a variety of causes, resulting in an alteration of the estrogen/testosterone ratio (**Table 6**). Gynecomastia can be seen in men with androgen deficiency or resistance. When testosterone production or action is compromised, elevated plasma gonadotropin levels further alter the plasma estrogen/testosterone ratio by stimulating the testis to produce more estrogen. Likewise, men with testicular tumors or bronchogenic carcinoma have increased testicular estrogen production largely from the stimulating effects of hCG produced by the tumor. Liver disease, starvation, thyrotoxicosis, and adrenocortical tumors are conditions where increased amounts of aromatizable androgen (i.e., androstenedione) are produced and gynecomastia can occur due to increased availability of this substrate for extraglandular aromatization.

Drugs that alter the ratio of estrogen to androgen at the level of the breast can cause gynecomastia (**Table 6**). There also have been reports of gynecomastia in children who ingested dairy or meat products from estrogen-injected and pregnant cows (Maruyama *et al.*, 2010; Andersson and Skakkebaek, 1999). As mentioned previously, gonadotropin-like substance such as hCG may cause gynecomastia by increasing testicular estrogen synthesis. In addition, drugs that impair testosterone synthesis or action can also cause gynecomastia. Approximately 50% of the men who receive high-dose spironolactone (150 mg/day) develop gynecomastia due to inhibition of both testosterone synthesis and testosterone action (Prisant and Chin, 2005). Spironolactone at low doses (50 mg/day) may cause gynecomastia, although less commonly, by blocking androgen binding to the receptor, with less effect on testosterone synthesis.

Estrogen and the Male Reproductive System

FSH and androgens are known to be important in the regulation of spermatogenesis. There is evidence to suggest that estrogen also plays an important role in spermatogenesis and male fertility. On a cellular level, estrogen may play a role in controlling

Table 6 Causes of gynecomastia

Physiological gynecomastia
Newborn
Adolescence
Elderly
Pathological gynecomastia
Testosterone deficiency
Hypergonadotropic hypogonadism
Klinefelter syndrome
Enzyme defect of testosterone synthesis (17β-hydroxysteroid dehydrogenase, 3β-hydroxysteroid dehydrogenase)
Secondary testicular failure (viral orchitis, trauma, infiltrative disease, renal failure)
Hypogonadotropic hypogonadism (pituitary or hypothalamic causes)
Androgen resistance
Hyperprolactinemia
Estrogen overproduction
Testicular tumors
hCG-secreting tumors (bronchogenic carcinoma)
Adrenocortical adenoma or carcinoma
Severe liver disease
Hyperthyroidism
Recovery from malnourishment
Excess aromatase activity (hereditary)
Drug induced
Estrogens or estrogen agonists (digitalis, phytoestrogens, estrogen creams, diethylstilbestrol)
Clomiphene, gonadotropins
Aromatizable androgens
Antiandrogens or inhibitors of androgen synthesis (spironolactone, ketoconazole, flutamide, metronidazole, cimetidine, etomidate, cyproterone)
Drugs that cause elevated prolactin (phenothiazines, haloperidol, methyldopa, reserpine, metoclopropamide, tricyclic antidepressants)
Others (ranitidine, omeprazole, alkylating agents, cisplatin, busulfan, isoniazid, penicillamine, captopril, enalapril, amiodarone, nifedipine, verapamil, diazepam, phenytoin, amphetamines, heroin, marijuana, alcohol)
Idiopathic gynecomastia

proliferation, development, and function of the Leydig, Sertoli, and germ cells. Estrogen appears to be important in the development and maintenance of the efferent ductules and epididymides. It was shown that in rats the efferent ductule contains the highest expression of ERα in the male tract (Hess *et al.*, 1997). Estrogen effects in efferent ductule have been shown through genetic disruption in ERαKO mouse (Couse *et al.*, 2001; Dupont *et al.*, 2000) or ERs inhibition by antiestrogen (Oliveira *et al.*, 2001, 2002). Estrogen regulates efferent ductule fluid reabsorption by altering the expression of several major ion transporters and aquaporin (AQP) water channels (Fisher *et al.*, 1998; Zhou *et al.*, 2001). Published reports on AQP hormonal regulation have been controversial, but most likely both estrogen and androgen have role in regulating fluid reabsorption in efferent ductule. In rat models AQP-9 is modulated by estrogen in epithelium of the efferent ductule and by 5α-dihydrotestosterone (DHT) in the initial segment of the epididymis, while neither estrogens nor androgens showed effect on regulating AQP-1 (Oliveira *et al.*, 2005). Moreover, regulation of AQP varies among species: in tropical bat neither estradiol nor androgens had any effect on AQP-9 (Oliveira *et al.*, 2013). Meanwhile, in the marine sea bream AQP-1ab was activated by estrogens in proliferating spermatogonia (Boj *et al.*, 2015). More data is needed to better understand AQP hormonal regulation.

Men with estrogen deficiency due to a defect in estrogen action or synthesis usually have abnormal spermatogenesis (**Table 4**). Conversely, men with either exogenous or endogenous estrogen excess can experience azoospermia. The ratio of testosterone to E_2 is perhaps more important in spermatogenesis and fertility than is the absolute level of estrogen. Detailed data on reproductive system hormone levels in men with congenital estrogen deficiency are shown in **Table 4**.

Increased environmental exposure to estrogen in males during fetal development may also have detrimental effects on development and function of the male reproductive system. Pregnant women who took diethylstilbestrol (DES) during pregnancy from 1945 to 1971 had male offspring with a significantly higher incidence of disorders of the reproductive tract, decreased sperm counts, and decreased sperm activity (Reed and Fenton, 2013).

Male Breast Cancer

Breast cancer is responsible for less than 1% of all cancer deaths in men (Giordano *et al.*, 2004). The ratio of female breast cancer to male breast cancer is 100:1 in Caucasians and 70:1 in African Americans. A higher incidence is reported in Jewish men and in men living in a stretch of Bantu-speaking countries in central Africa. Other risk factors include a family history of breast cancer, history of exogenous estrogen exposure, increased circulating endogenous estrogen from chronic liver disease, testicular pathology, and prior chest wall

irradiation (Fentiman *et al.*, 2006). The greatest risk factor for developing male breast cancer is Klinefelter syndrome. The risk in affected men is about 50-fold higher than in men with normal genotype. The risk of male breast cancer appears to be associated with conditions with relative estrogen excess and/or lack of androgen, resulting in an altered ratio of estrogen to testosterone.

Conclusion

During recent years, further knowledge on some of the critical roles played by estrogen in the male has been gained, however, we have just begun to understand estrogen action in men. Sex hormones, including estrogen, through complex regulatory networks and numerous receptors exert diverse effects throughout the body. Further research is needed to clarify exact mechanisms by which estrogen mediates these effects in male physiology.

Gynecomastia☆

Glenn D Braunstein, Cedars-Sinai Medical Center, Los Angeles, CA, United States and University of California Los Angeles, Los Angeles, CA, United States

Glossary

Androgens A steroid, such as testosterone or dihydrotestosterone, which controls the development and maintenance of masculine characteristics.

Aromatase An enzyme complex present in the gonads, fat, liver, skin, and other tissues that convert estrogen precursors such as testosterone or androstenedione into estrogens.

Estrogens Any of several natural or synthetic substances formed by the ovary, placenta, testis, or certain plants that stimulate the female secondary sex characteristics, exert systemic effects such as the growth and maturation of long bones, and are used to treat disorders due to estrogen deficiency and to ameliorate cancers of the breast and prostate.

Gonadotropin A hormone that stimulates the growth and activity of the gonads, especially any of several pituitary hormones that stimulate the function of the ovaries and testes. The pituitary gonadotropins include luteinizing hormone (LH), which in the males stimulates testicular testosterone production and follicle-stimulating hormone (FSH), which stimulates spermatogenesis.

Human chorionic gonadotropin (hCG) A glycoprotein that is produced by the placenta, is excreted in the urine of pregnant women, and acts to stimulate ovarian secretion of the estrogen and progesterone that are required to maintain the conceptus. Production of hCG by tumors or administration of the hormone to males results in stimulation of testicular testosterone and estrogen production.

Sex hormone-binding globulin (SHBG) A high affinity, low capacity sex steroid hormone binding protein which circulates in the blood. Because of the tight binding of the hormones, most of the steroid hormones bound to SHBG are unavailable to target tissues.

Introduction

Gynecomastia represents a benign enlargement of the male breast glandular tissue and is a common clinical finding found in normal individuals without any underlying pathological disorder, but it also may represent a clinical manifestation of a disease. It is the result of an imbalance between estrogen and androgen action at the breast tissue level.

Sources of Androgens and Estrogens in Males

Approximately 95% of the major androgen in men, testosterone, is secreted by the testes, with the other 5% being derived from the adrenal gland production of androstenedione, a weaker androgen, which is converted to testosterone in peripheral tissues. The two major estrogens in males are estradiol and estrone. In contrast to testosterone, only 15% of estradiol and less than 5% of estrone are directly secreted by the testes. The major source of these estrogens is the conversion of androgens to estrogens in extraglandular tissues, including the liver, fat, and muscle. Thus, most of the circulating estradiol is derived from testosterone, and most of the circulating estrone is derived from androstenedione. The enzyme responsible for the conversion of androgens to estrogens is aromatase or estrogen synthetase, which is actually an enzymatic complex that has tissue-specific expression (Braunstein, 1993, 1999).

Both testosterone and estrogens circulate in the bloodstream primarily bound to serum proteins, especially sex hormone-binding globulin (SHBG). When bound to SHBG, the hormones are not available to enter cells. Only the free or unbound component can enter cells and bind with their respective receptors and thereby exert their biological action.

Because gynecomastia is the result of an estrogen/androgen imbalance, it can result from an increase in the production of serum estrogen, a decrease in the production of testosterone, alterations in the concentration of bioavailable estrogen or testosterone, problems with the androgen receptor in androgen target tissues, or an increase in the sensitivity of breast tissue to estrogens.

Prevalence

The age distribution of gynecomastia shows three distinct peaks. The first occurs during infancy, where 60%–90% of all newborns develop palpable breast tissue owing to the transfer of maternal estrogen to the fetus through the placenta. This transient

☆*Change History*: January 2018. Glenn D Braunstein added abstract, updated glossary, added references to the text, updated text (especially in the section dealing with drugs associated with gynecomastia), added relevant web page, and updated the Further Reading section.

enlargement of the breast tissue resolves within several weeks. Puberty represents the second time period where gynecomastia is frequently found. The prevalence figures of pubertal gynecomastia in various studies show wide variation, ranging from 4% to 69%. A reasonable estimate is that approximately a third of boys will develop some degree of clinically apparent gynecomastia during puberty. Gynecomastia generally has its onset between 10 and 12 years of age and peaks between 13 and 14 years of age. The gynecomastia usually involutes within 18 months and is completely resolved by 16–17 years of age in most male adolescents. The final peak of gynecomastia is during adulthood, when up to two-thirds of males between 50 and 80 years of age are found to have some degree of gynecomastia when carefully examined.

Pathological Causes of Gynecomastia

Table 1 outlines the broad categories of causes of gynecomastia. Gynecomastia may be found either in patients with germ cell tumors of the testicle, which secrete human chorionic gonadotropin (hCG), or in patients with Sertoli cell or Leydig cell tumors, which secrete excessive quantities of estrogens. Feminizing adrenocortical adenomas or carcinomas also either directly produce high quantities of estrogens or cause hyperestrogenemia through excessive production of estrogen precursors, such as androstenedione, that are aromatized to estrogens. Some tumors, such as giant cell carcinomas of lung, hepatoblastomas, and gastric or renal carcinomas, may secrete hCG, which stimulates the testes to produce excessive quantities of estrogen, resulting in gynecomastia.

Primary hypogonadism, which is due to a testicular pathology, results in a lowering of testosterone and, in some instances, an elevation of estrogen concentrations. A mild degree of testicular failure can be found in some men as part of the aging process. This may be accompanied by gynecomastia, which in the past has been termed "involutional gynecomastia." Secondary hypogonadism, which is due to a defect in the pituitary or hypothalamus and results in a loss of appropriate gonadotropin stimulation of the testes, is a rare cause of gynecomastia, which results from a decrease in testosterone while estrogens are still produced from adrenal steroid hormone precursors.

Androgen insensitivity from a defect in the intracellular androgen receptor leads to an inability of androgens to act at the target tissues. This results in unopposed estrogen activity and is a rare cause of gynecomastia. Some males with hyperthyroidism from Graves' disease may develop gynecomastia due to an increase in the concentration of SHBG, which binds testosterone more avidly than it binds estrogen, leading to a greater lowering of the free, biologically active testosterone level relative to the free, biologically active estradiol level.

As noted previously, the majority of circulating estrogens in males are derived from peripheral extraglandular aromatization of estrogen precursors. Increased aromatization is found in a variety of clinical situations, including aging, obesity, hyperthyroidism, liver disease, congenital adrenal hyperplasia, and Klinefelter syndrome, and as a primary defect with excessive aromatase activity from persistence of an unregulated fetal aromatase enzyme (Braunstein, 1999).

A number of drugs are also associated with gynecomastia, and the broad groups are listed in **Table 2**. However, many of the individual drugs that have been associated with gynecomastia are based on anecdotal reports or small, uncontrolled series of patients. A strong relationship between the occurrence of gynecomastia and medication use has been shown for androgens and anabolic steroids, estrogens and estrogen agonists, antiandrogens such as flutamide, the antibiotic ketoconazole, cimetidine, spironolactone, and alkalating agents. Drugs with fair evidence of an association with gynecomastia in adults include first and second generation antipsychotics, calcium channel blockers, omeprazole, HIV drugs, alkylating agents, alcohol, and opioids. Anabolic steroid use in adolescents and adults may also be associated with gynecomastia. All of the other drugs reported to be associated with gynecomastia currently fall in the poor level of evidence category (Deepender and Braunstein, 2012). There are a number of other sources of estrogen that occasionally cause gynecomastia. These include the use of over-the-counter phytoestrogens and androstenedione used by athletes. In addition, there may be occupational exposure and percutaneous absorption from antibalding creams or a sexual partner's use of an estrogen-containing vaginal cream.

Evaluation of the Patient With Gynecomastia

The first question that must be answered is whether the breast enlargement is gynecomastia. The proper way in which to examine the male breast is to have the patient lie down with arms extended over or behind the head and for the examiner to take his or her thumb and forefinger and place them spread apart over the patient's breasts with the nipple centered in between. When the two digits are gently moved toward the nipple, gynecomastia will be detected as a firm or rubbery, mobile, round mound of tissue that arises concentrically from beneath the nipple and areola (Braunstein, 2007). The two most important conditions that should be differentiated from gynecomastia are pseudogynecomastia, which represents fatty enlargement of the breast without glandular proliferation, and breast carcinoma. With pseudogynecomastia, there will be no mound of tissue felt as the fingers close in on the nipple. Some of the features of breast carcinoma that distinguish it from gynecomastia include an eccentric location; mass that is hard, firm, and possibly fixed to underlying tissues; skin dimpling; retraction or crusting of the nipple or a frank nipple discharge; and the presence of axillary lymphadenopathy.

Once it is determined that the patient indeed has gynecomastia, the next question is whether medications are involved. A very careful history concerning medications, herb and vitamin intake, illicit drug use, and possible sources of environmental exposure to estrogens should be taken. If the patient is taking a medication known to be associated with gynecomastia, it should be stopped and the patient should be reexamined in 1 month.

The next question is whether the patient is pubertal. Because pubertal gynecomastia occurs frequently and is self-limited, its presence requires only reassurance that gynecomastia is a normal part of the pubertal process as well as a follow-up at 6 months or longer if the gynecomastia persists. Various epidemiological studies have noted that pubertal gynecomastia may persist in 1.3%–20% of males (Nydick *et al.*, 1961; Georgiadis *et al.*, 1994).

Another important question concerns whether the gynecomastia is of recent onset or is painful or tender. Gynecomastia of any cause undergoes the same pattern of histological evolution. The "florid phase" is found during the first 6 months. The breast ducts proliferate and exhibit epithelial hyperplasia, and there is an increase in the periductal and stromal constructive tissue, increased vascularity, and a substantial degree of periductal edema. Between 6 and 12 months is a transitional phase. The "involutional phase" is seen in patients with long-standing gynecomastia that has been present for 1 year or longer. There is a marked reduction in the epithelial proliferation and increased stromal hyalinization, dilation of the ducts, and fibrosis. The presence of pain or tenderness indicates that the patient is in the florid phase and that the gynecomastia has been of relatively recent onset. It is also during this phase that medical therapy directed toward the gynecomastia is most likely to be effective. Once the tissue has entered the inactive or fibrotic stage, medical therapy is unlikely to be beneficial.

The patient should undergo a full physical examination, with particular attention given to the breast exam as described previously, the thyroid for signs of hyperthyroidism, an abdominal examination for signs of cirrhosis or adrenocortical masses, and a careful testicular examination, evaluating for the presence of masses and consistency, especially looking for the reduced size or decreased consistency consistent with hypogonadism.

If the patient is not in the pubertal age group and is not ingesting medications known to be associated with gynecomastia, laboratory investigation should include measurements of hCG, luteinizing hormone (LH), estradiol, and testosterone. An elevated hCG should lead to a testicular ultrasound, looking for a mass that would be compatible with a germ cell tumor. A normal ultrasound suggests that the patient has either an extragonadal germ cell tumor or an hCG-secreting nontrophoblastic neoplasm, which should be evaluated through additional imaging studies. An elevated LH and a decreased testosterone are compatible with primary hypogonadism, whereas a low LH and a low testosterone suggest secondary hypogonadism. In that instance, a serum prolactin should be measured to evaluate the patient for a prolactin-secreting pituitary tumor. If the prolactin is normal, the serum concentration of androstenedione and estrone should be determined. A normal or low level suggests secondary hypogonadism, whereas elevation of these hormones is indicative of the rare 17-ketosteroid reductase enzyme deficiency.

An elevated LH and an elevated testosterone are compatible with either hyperthyroidism or androgen resistance due to an androgen receptor defect. These can be discriminated through measurements of thyroid function tests, including free T-4 and thyroid-stimulating hormone (TSH). An elevated thyroxine (T4) and a suppressed TSH are diagnostic of hyperthyroidism, whereas normal thyroid function tests indicate that the patient has androgen resistance.

A testicular ultrasound should be carried out in patients who have an elevation of the estradiol concentration and a decreased or normal LH level. A testicular mass in this setting is indicative of a Leydig or Sertoli cell tumor. If the testicular ultrasound is normal, an adrenal CT scan or MRI should be performed, looking for an adrenal neoplasm. A normal result from that exam suggests that the patient has increased extraglandular aromatase activity. If all results are normal, it is likely that the patient has idiopathic gynecomastia with enhanced sensitivity of the breast tissue to normal amounts of estrogen or that the inciting factor that initiated the gynecomastia has been corrected.

Treatment

The indication for therapy includes anxiety, embarrassment, and pain. It should be noted that approximately 85% of patients who have gynecomastia of recent onset will undergo a spontaneous resolution, whereas patients with long-standing gynecomastia will have an approximately 10% chance of spontaneous resolution. Also, as noted previously, long-standing gynecomastia is less likely to respond to medical therapy than is gynecomastia of recent onset due to the presence of fibrosis in the breast tissue when the gynecomastia has been present for more than 1 year.

There are several therapies that have been tried for gynecomastia. Although there are many anecdotal reports of improvement on various therapies, there are few well-designed studies that have critically examined the different therapies. Many of the studies have been hampered by small numbers and lack of placebo controls. The medical therapies that have been tried include administration of testosterone and its metabolites, danazol (an impeded androgen with weak androgenic and progestational activity), estrogen receptor antagonists such as clomiphene citrate and tamoxifen, and aromatase inhibitors such as testolactone and anastrazole. The best studied of these therapies is tamoxifen, which does appear to be superior to placebo in regard to reduction of breast pain and tenderness as well as breast size. With the exception of testosterone treatment of hypogonadal males, the use of all of these drugs to treat gynecomastia is considered to be an "off label" use (Gruntmanis and Braunstein, 2001).

In a patient who has long-standing gynecomastia or who fails to have an adequate response to medical therapy, surgical removal of the breast glandular tissue should be considered. There are a number of approaches and methods that include sharp excision, liposuction, or a combination of these methods. The approach that is most commonly used currently involves a periareolar incision, a sharp excision of the breast glandular tissue, and liposuction for contouring the breasts. Complications of the procedures include nipple-areolar numbness, hematomas, seromas, scarring, inverted nipples, nipple necrosis, and depressive deformities of the chest wall as well as inadequate tissue removal along with redevelopment of the gynecomastia.

Male Sexual Dysfunction☆

Amarnath Rambhatla, Wayne State University, Detroit, MI, United States
Jacob Rajfer, David Geffen School of Medicine, Los Angeles, CA, United States

Glossary

Erectile dysfunction The inability to achieve penile erection sufficient for satisfactory sexual activity.
Impotence The inability to achieve penile erection.
Libido Conscious or unconscious sexual desire.
Orgasm The acme or climax of the sexual act.
Sexual dysfunction Disturbances in sexual desire and/or in the psychophysiological changes associated with the sexual response cycle in men and women.

Introduction

Sexual behavior is influenced by three types of forces: biological, psychological, and social. At the biological level, the primary function of sex is reproduction. Sexual functions are regulated by nerves and hormones and are sustained by the circulatory, muscular, and other systems. Psychologically, sex consists of a variety of behaviors and relationships aimed at erotic pleasure and affection. At the societal level, sex pervades numerous facets of life. Sexual activity is given meaning as humans experience its psychological and social contexts.

Sexual activity in a man involves four processes: desire, arousal (attaining and maintaining an erection), consummation (ejaculation and orgasm), and fertilization. Significant difficulty in any of these processes can lead to sexual dysfunction. In men, sexual dysfunction most often denotes erectile dysfunction (ED). ED may be defined as difficulty in obtaining or maintaining a penile erection sufficient to permit satisfactory sexual activity.

In a national survey, 31% of men 18–59 years of age reported that they had sexual dysfunction (Laumann *et al.*, 1999). Moderate or severe ED was reported by 21% of men 30–79 years of age in a community survey in the Boston area (Kupelian *et al.*, 2008). The Massachusetts Male Aging Study (MMAS) has demonstrated that 52% of men between the ages of 40–70 have some degree of ED and by the time a man is in his 50's, he has about a one in two chance of having some form of ED and this prevalence increases by about 10% for every increase in decade (Feldman *et al.*, 1994; Kubin *et al.*, 2003). These data demonstrate that a significant proportion of men as they age will begin to suffer from ED.

Anatomy and Physiology of Penile Erection

Because of its anatomy, the penis can rapidly engorge with blood, increase dramatically in size, and develop rigidity. Within the penis are two paired corpora cavernosa and a corpus spongiosum. The corpus spongiosum, which surrounds the urethra, terminates in the glans penis. A thick fibrous sheath, the tunica albuginea, encases the paired cavernosal tissue, which consists of interconnecting lacunar spaces. Trabeculae form the walls of the lacunae and are composed of thick bundles of smooth muscle, fibroblasts, collagen and elastin. This arrangement enables very high intracavernosal pressure generation and penile rigidity when outflow of blood from the cavernosa is reduced and the lacunae are engorged.

When flaccid, the smooth muscle cells of the corpora cavernosa and its associated arteries are in a state of contraction. Relaxation of these smooth muscles (arterial and cavernosal) increases blood flow into the corpora cavernosa. The increased blood volume coming into the cavernosal spaces raises the intracorporal pressure which then passively compresses the egressing venules shut against the more rigid tunica albuginea. This mechanism of veno-occlusion restricts the outflow of blood from the penis during an erection. After ejaculation or cessation of the erotic stimuli, the smooth muscle in the arteries and lacunar spaces contracts in response to a decrease in neural stimulation. As such, inflow of blood is reduced, venous outflow from the corporal spaces resumes, and the penis returns to a flaccid state.

Neuromuscular Influence

Increased arterial flow causing the penile erection is controlled by the autonomic nervous system. Peripheral innervation consists of sympathetic nerves arising from the T11 to L2 and parasympathetic and somatic nerves arising from the S2 to S4. They reach the

☆*Change History*: April 2018. Amarnath Rambhatla and Jacob Rajfer edited the entire manuscript with major changes in the sections titled neuromuscular influence, vascular erectile dysfunction, diabetes mellitus, hypertension, androgen deficiency, as well as the treatment sections. New sections have been added on stem cell therapy as well as ejaculatory disorders.

This article is an update of Zouhair Bibi, Farid Roman, Max Hirshkowitz and Glenn R. Cunningham, Erectile Dysfunction, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 24–28.

pelvic plexus through hypogastric and pudendal nerves. The glans penis is rich in nerve endings that convey touch, pain, temperature, and vibration. Although neural centers in the lumbosacral spinal cord can cause erection in response to penile stimulation, erections usually are stimulated by olfactory, auditory, visual, and other sensory inputs. These inputs are perceived centrally by the frontal, temporal, parietal, or occipital lobe. Furthermore, they may be stimulated by memory or fantasy. Signals are sent to the visceral brain, to the rhinencephalon, and subsequently to the spinal cord erection center at the level of S2–S4. In a reflexogenic erection, stimulation of the penis leads to transmission of an afferent signal via the pudendal nerve to the sacral erection center. An efferent signal is then transmitted from the sacral erection center via the inferior hypogastric plexus to the cavernous nerves which lead to smooth muscle relaxation.

During the process of an erection that is initiated and maintained by persistent stimulation from the cavernosal nerves, ejaculation will occur when the pudendal nerve via the somatic pathway, stimulates contraction of the pelvic floor muscles, the bulbospongiosus and ischiocavernosus muscles. These muscular events lead to the most rigid phase of an erection and it is during this phase that suprasystolic pressure in the corpora cavernosa ensues. During ejaculation, there is rhythmic contraction of the pelvic floor muscles after semen is deposited into the posterior urethra and then transmitted through the urethra. This is associated with the pleasurable sensation of an orgasm.

On a molecular level, several neurotransmitters are involved in penile erection. Histochemical studies indicate that the corpora cavernosa are rich in adrenergic fibers, acetylcholinesterase-containing (probably cholinergic) nerves, and nerves that are immunoreactive to vasoactive intestinal polypeptide (VIP) and neuropeptide Y. The main neurotransmitter responsible for an erection, however, is nitric oxide which is synthesized from L-arginine by neuronal nitric oxide synthase (nNOS) within the axons of the cavernosal nerve (Ignarro *et al.*, 1990; Rajfer *et al.*, 1992). Nitric oxide from the nerve diffuses passively into the underlying corporal smooth muscle and then activates soluble guanylyl cyclase in the cytoplasm of the smooth muscle cells to form cyclic guanosine monophosphate (cGMP). cGMP then activates certain proteins which open ion channels leading to a decrease in intracellular calcium resulting in smooth muscle relaxation. cGMP is normally degraded by the phosphodiesterase-5 enzyme located in the cytoplasm of the corporal smooth muscle cells, and pharmacological inhibition of this specific enzyme is effective in potentiating corporal smooth muscle relaxation and as such, the erectile process.

Endocrine Influence

In humans, testosterone and dihydrotestosterone (DHT) play critical roles during embryogenesis of the testes, epididymis, vas deferens, seminal vesicles, prostate, and external genitalia. Sex steroids are implicated in imprinting gender identification on the central nervous system. Development of accessory glands, testes, external genitalia, and secondary sex characteristics at puberty depends on normal circulating androgen levels and on target androgen tissue responsiveness. In addition, testosterone mediates the development and maintenance of libido and erectile function. Androgens exert a direct effect on penile tissue to maintain erectile function and androgen deficiency produces a metabolic and structural imbalance in the corpus cavernosum.

With aging, serum total and free testosterone levels fall and sex hormone-binding globulin (SHBG) levels increase (Feldman *et al.*, 1994). Comorbid medical conditions, certain medications, and pituitary function can also influence testosterone levels.

Etiology of Erectile Dysfunction

Vascular

ED frequently is due to vascular dysfunction. Altered blood flow to and from the penis is thought to be the most frequent organic cause of ED. The former is thought to be due to either atherosclerosis and/or arteriosclerosis, while the latter is due to incomplete relaxation of the trabecular smooth muscle. When this latter state occurs, the high intracorporal pressure necessary to achieve compression of the subtunical emissary veins is not achieved and this leads to a "venous leak," which, depending on its severity, can lead to either an inability to attain a rigid erection or very commonly in its earliest stages to maintain an erection once it is achieved. Incomplete smooth muscle relaxation can result from either an intrinsic smooth muscle dysfunction or simple aging or disease induced apoptosis of the smooth muscle itself. The most common associations with arteriogenic impotence include diabetes mellitus, hypertension, hyperlipidemia, cigarette smoking, perineal or pelvic trauma, and pelvic irradiation or surgery. The most common cause of smooth muscle dysfunction is simply aging related apoptosis of the smooth muscle itself.

Diabetes Mellitus

The risk of ED in men with diabetes mellitus is three and a half times more than in men without diabetes with the prevalence being about 53% in diabetic men (Kouidrat *et al.*, 2017). In men with diabetes, ED progresses gradually, and other symptoms and signs of autonomic neuropathy are frequently present. ED is more common in men with severe vascular or neurological complications. ED in diabetic men occurs at an earlier age and is more prevalent than in men without diabetes. Diabetic ED consists of a complex interplay between a variety of factors but can be simplified into neurogenic, hormonal, vascular, and smooth muscle dysfunction. There is evidence to suggest that diabetic men have a lower degree of smooth muscle relaxation mediated by both the

parasympathetic nervous system and endothelial factors (Saenz de Tejada *et al.*, 1989). Animal models have demonstrated selective apoptosis leading to decreased neuronal NOS and nitric oxide (Vernet *et al.*, 1995). The risk for hypogonadism is increased in diabetics compared to nondiabetics. The Hypogonadism in Males Study demonstrated that 50% of diabetic men above the age of 45 are hypogonadal (Mulligan *et al.*, 2006).

Hypertension

Men with hypertension frequently report difficulty in initiating or maintaining erections that are adequate for sexual intercourse. Sometimes this could be due to a side effect of antihypertensive medication. The reported incidence of erectile failure is 14% with propranolol, 9% with hydrochlorothiazide, and 1%–41% with clonidine. However, the more plausible explanation is that hypertension, like ED, also stems from an underlying dysfunction of the vascular smooth muscle, a cell common to both the arterial system as well as the corpora cavernosa (Clavijo *et al.*, 2014). Untreated hypertension is independently associated with increased ED as well as a myriad of health problems and therefore it is imperative that patients work with a primary care physician to help control their blood pressure despite the possible side effects from antihypertensive medications.

Obesity

Central obesity is associated with both hypogonadism and erectile dysfunction. In the European Male Aging Study there was a significant positive correlation between obesity and severity of erectile dysfunction (Corona *et al.*, 2010). Other studies have demonstrated that lifestyle changes to improve obesity lead to an improvement in ED when both conditions coexist (Esposito *et al.*, 2004; Esposito *et al.*, 2009). The presence of ED in an obese individual should be used by clinicians to convince an individual to make lifestyle changes with an improvement/resolution of their ED as a reward.

Neurogenic Impotence

Disorders affecting the spinal cord or the peripheral efferent autonomic fibers to the penis cause partial or complete ED. This may be due to afferent limb interruption of reflexogenic erections as well as to interruption of tactile perception, with projections to supraspinal centers that may be important in maintaining psychogenic erections. Although the reflexogenic erectile mechanism is preserved in men with supra-sacral spinal lesions, the erections usually are poorly maintained without constant tactile stimulation.

Common neurological disorders associated with ED include spinal cord injury, multiple sclerosis, and peripheral neuropathy due to diabetes mellitus or alcoholism. In addition, surgical procedures (e.g., radical prostatectomy, cystoprostatectomy, proctocolectomy) may disrupt the autonomic nerve supply to the corporal bodies. Even in nerve sparing procedures there is evidence that the period of neuropraxia before recovery may lead to smooth muscle atrophy and apoptosis and replacement of the smooth muscle cells by fibrosis (Iacono *et al.*, 2005). This is due to an increase in the concentration of pro-fibrotic substances (Rambhatla *et al.*, 2008) and explains on a scientific basis the rationale for the long-term use of phosphodiesterase 5 inhibitors, recently reported to have antifibrotic and antiapoptotic properties, in the setting of penile rehabilitation after pelvic surgery (Ferrini *et al.*, 2006).

In patients with spinal cord injury, preservation of erectile function is largely dependent on the completeness and level of the spinal lesion. Although 75% of patients with spinal cord injury have some capacity to have penile erections, the erections are only adequate for penetration without assistance in about 25% (Wyndaele *et al.*, 1986).

Endocrine Impotence

Androgen Deficiency

Androgen deficiency is a widely recognized cause of sexual dysfunction. Diminished libido, reduced ejaculate volume, and ED commonly accompany androgen deficiency that develops after puberty. Specific signs and symptoms of hypogonadism are eunuchoidism, low libido, decreased spontaneous erections, and decreased bone mineral density (Bhasin *et al.*, 2010a). According to the Endocrine Society, values below 300 ng/dL (10.4 nmol/L) have a greater likelihood of leading to symptoms (Bhasin *et al.*, 2010a). The Baltimore Longitudinal Aging Study demonstrated that 20% of men in their 60's and 50% of men in their 80's are hypogonadal as measured by a serum testosterone level less than 325 ng/dL (11.3 nmol/L) (Harman *et al.*, 2001). The MMAS also shows that there is a decline in serum testosterone of 1.6% per year as men age (Feldman *et al.*, 1994).

Many patients with ED and testosterone deficiency have pituitary or adult onset hypogonadism. Pituitary and hypothalamic imaging is recommended as well as checking a prolactin level when the morning testosterone level is less than 150 ng/dL (5.2 nmol/L) (Dean *et al.*, 2016). On average, older patients are less likely to experience an improvement in erections due to comorbid medical conditions that cause ED when the condition is treated.

Hyperprolactinemia

ED is common in men with pituitary tumors. 76% of patients with a tumor in the region of the sella turcica reported decreased or absent libido or potency. These patients often have subnormal serum testosterone levels. Prolactin levels are more than 50 μg/L in most patients with prolactinomas. Normalizing minimal hyperprolactinemia does not ameliorate ED. Prolactin levels more than 50 ng/mL (normal 2–18 ng/mL for males) should alert the physician to evaluate medications and thyroid, liver, and renal function as a possible cause for hyperprolactinemia. Studies performing routine measurement of serum prolactin found a low yield of prolactinomas (<1% of patients). Measuring the morning prolactin level is recommended in the setting of a testosterone level less than 300 ng/dL (10.4 nmol/L) and an inappropriately low/normal luteinizing hormone (LH) level or when gynecomastia is present.

Diagnostic Workup of Erectile Dysfunction

The evaluation of patients with ED begins with a thorough history and physical examination. Initial questions should focus on the onset, progression, and duration of the symptoms. The presence of nocturnal erections and the ability to attain erections with a different partner may help to differentiate psychogenic causes from organic causes. It also is important to assess libido, which may indicate androgen deficiency, depression, or excessive stress. The medical history is essential to assess comorbidities commonly associated with ED (especially diabetes, hypertension, peripheral vascular disease, neurological disorders, and coronary artery disease). Because the use of certain drugs is associated with ED, a detailed and complete medication history should be taken. Recent changes in social status, alcohol consumption, and cigarette smoking should be noted.

The physical examination is essential. It should focus on the cardiovascular, endocrine, neurological, and genitourinary systems. Blood pressure, palpation of peripheral pulses, and auscultation for abdominal and femoral bruits should be assessed. Special attention to signs of androgen deficiency (e.g., decreased body and facial hair, gynecomastia, testicular atrophy or decreased testicular consistency, regression in prostate size) must be undertaken. The penis should be examined for fibrous plaques (Peyronie's disease), and the rectal exam should assess the sphincter tone, the bulbocavernosus reflex and the prostate gland.

Appropriate laboratory testing should complement the history and physical examination. Patients should be screened for diabetes as well as for liver and renal disease. Early morning serum testosterone levels should be checked as well as thyroid-stimulating hormone (TSH) if there are signs suggesting thyroid disease.

Nocturnal penile tumescence testing (NPT) and duplex ultrasonography in conjunction with intracavernosal administration of vasoactive agents may be indicated in select patients. Patients with ED and normal NPT usually have psychogenic impotence; whereas abnormal NPT in conjunction with normal sleep usually indicates an organic cause (vascular or neurological). These tests should be performed in centers where there are facilities and expertise to perform and interpret them. If a venous leak is suspected, dynamic infusion cavernosometry can be employed to make a diagnosis. A CT cavernosogram can be completed to determine where the venous leak is occurring, and if it is a localized leak, it may be amenable to surgical correction although long-term results of such surgeries are suboptimal.

Treatment

There are many treatment considerations and options for men with ED. The goal of treatment is to restore the capacity to acquire and sustain an erection. Treatment should address the cause of ED. Patients should be asked to avoid cigarette smoking, excessive alcohol consumption, and drug abuse. Changes in medication, if possible, should be tried as medication may contribute to ED. The major drugs that induce ED are thiazide, beta-blockers, and some antidepressants. Angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARB) generally are associated with the least sexual side effects and can be tried in those men with concomitant hypertension.

Lifestyle modification with diet, exercise, and weight loss, having good glycemic control, works well in preventing ED in diabetic men, but is not a good treatment option once ED has set in. The Look AHEAD (Action for Health in Diabetes) Trial demonstrated that once diabetic ED has started, lifestyle modification does not effectively treat ED (Wing *et al.*, 2010). These men are often dependent on medical or surgical therapy for their ED.

Psychosexual Therapy

When depression and excessive anxiety are associated with ED, psychosexual counseling is indicated. When it is selected appropriately, the success rate for psychosexual therapy can reach 70%. Furthermore, some patients with organic ED can benefit from sex therapy because it reduces anxiety and sexual inhibition. Yohimbine, an alpha-2-adrenergic receptor–blocker, may be effective in some men with psychogenic ED. In a double-blind, placebo-controlled study that evaluated men with psychogenic ED, it was found that 37% of men treated with yohimbine responded to treatment (Riley *et al.*, 1989). However, other studies have not found yohimbine to be beneficial. Nonetheless, an appointment with a practitioner specializing in psychosexual therapy is prudent when psychogenic ED is suspected.

Hormonal Therapy

Testosterone replacement therapy is the treatment of choice for men with hypogonadism. According to the endocrine society guidelines, to make the diagnosis of hypogonadism one needs to have symptoms/signs of hypogonadism as well as biochemical confirmation of a low testosterone level (Bhasin *et al.*, 2010b). There are various formulations that testosterone is available in such as transdermal gel and patches, oral pills, buccal tablets, intramuscular injections, and subcutaneous pellets. Prior to starting testosterone replacement therapy a baseline testosterone, estradiol, PSA, and hematocrit should be obtained. A baseline prostate exam should also be preformed. After starting testosterone replacement therapy labs should be checked at 3 and 6 months and then annually (Bhasin *et al.*, 2010a).

Testosterone replacement therapy has received bad press regarding possible cardiovascular side effects. However, on close inspection of these studies, it is determined that there are significant deficits in study design and the ability to draw conclusions from these studies. Several studies have suggested that testosterone replacement therapy in hypogonadal men leads to better cardiovascular status and overall health (Khaw *et al.*, 2007). Research is finding that even in men with prostate cancer, where testosterone replacement was once contraindicated, it may be safe and can significantly improve quality of life (Kacker *et al.*, 2016).

The other problem that surrounds testosterone replacement therapy is the improper diagnosis and monitoring while on testosterone replacement therapy. A study by Baillargeon and colleagues found that there has been a threefold increase in testosterone prescriptions over the past 15 years, only 51% of men started on testosterone replacement had a diagnosis of hypogonadism, and 25% of men never had a testosterone level checked prior to starting testosterone therapy (Baillargeon *et al.*, 2013). Increasingly, nonspecific symptoms of hypogonadism are being used to make to make the diagnosis of hypogonadism, often times without any biochemical confirmation. Due to improper diagnosis of hypogonadism and the steroid abuse epidemic, the United States Food and Drug Administration has recommended against the use of testosterone to treat age related hypogonadism.

If it is thought that sexual symptoms are due to low testosterone levels, then a 3–6 month trial of testosterone can be started. Data from studies suggest that if an improvement is to occur in the hypogonadal symptom one is treating, that improvement should occur in the first 3 months of treatment. (Wang *et al.*, 2004) If there is no improvement after such a 3 month trial of testosterone replacement therapy, a work up for other causes of sexual dysfunction should be carried out.

Hyperprolactinemia may decrease libido by suppressing gonadotropin-releasing hormone (GnRH), resulting in reduced LH and testosterone levels. Treatment of hyperprolactinemia with a dopamine agonist or surgical removal of a pituitary tumor may restore testosterone levels and potency.

Medical Treatment

After excluding conditions treatable with specific therapies, the clinician should consider treatment with a type 5-phosphodiesterase inhibitor (PDE5i). These drugs provide effective oral therapy for a wide range of conditions leading to ED. PDE5i work by inhibiting the phosphodiesterase type 5 enzyme, resulting in increased intracellular cGMP. cGMP facilitates smooth muscle relaxation of both the arteries to the penis and the trabeculae of the corpora cavernosa. The use of PDE5 inhibitors to treat ED results in about a 70% success rate. Each of the PDE5 inhibitors should be used according to their pharmacokinetic profile. For example, the short half-life of sildenafil, vardenafil, avanafil and udenafil dictate that it should be taken ½ to 1 h before planned intercourse and preferably at least 2 h after a meal since food can inhibit its absorption from the stomach. Tadalafil, a PDE5i with a much longer half life of about 18 h is not subject to the absorption issues of the other PDE5 inhibitors. Its maximum efficacy occurs about 2 to 3 h after taking the pill but its effect can last much longer than the other PDE5 inhibitors. In addition, because tadalafil accumulates in the tissues, daily low doses of the drug can be used to obviate a timing issue with the initiation of sexual activity. Regardless of the PDE5 inhibitor being used, logic dictates that one should ideally begin treatment with a low dose and titrate up to the maximum dose depending on efficacy versus side effects. All PDE5 inhibitors are absolutely contraindicated in patients taking nitrates. Some level of exercise tolerance should be documented prior to initiation of therapy with PDE5i; otherwise a treadmill test should be considered for patients at risk for cardiac disease. Common side effects include headaches, flushing, rhinitis, and visual changes. It is considered a therapeutic failure of these medications when one has failed a trial of at least two different PDE5i on three separate occasions for each medication.

Intracavernosal injections are an effective way of delivering medication directly to the smooth muscle in the penis. This treatment involves injecting vasoactive drugs (e.g., alprostadil, papaverine, phentolamine, atropine) that induce relaxation of the smooth muscles. They work by increasing cyclic AMP and cyclic GMP concentrations within the smooth muscle cell. Intracavernosal injection therapy is especially effective in men with neurogenic impairments such as spinal cord injury and diabetes mellitus. The major side effects are penile pain and priapism. Patients should be counseled on proper injection techniques as improper technique can lead to scarring within the corporal tissue.

Alprostadil also is available for intraurethral application (Medicated Urethral System for Erection [MUSE]). In a placebo-controlled study, 65% of patients treated with MUSE successfully completed intercourse compared with 19% of men treated with placebo. However, this efficacy rate has not been replicated in unselected populations of men with ED. MUSE is usually not as effective as intracavernosal injection therapy.

Medical Devices

Vacuum devices increase the volume of blood in the penis by creating a vacuum around the penis and pulling blood into the corpora cavernosa. After the penis is engorged, a constriction ring is placed at the base of the penis to prevent venous outflow. Once the constriction ring is removed, venous outflow resumes and this leads to loss of the erection. The constriction ring should not be left on for more than 25 min. The induced erection sometimes is sufficient for vaginal penetration and sexual intercourse. Adverse events include pain, bruising, and retrograde ejaculation. Vacuum constriction devices represent an alternative for patients who cannot tolerate type 5 phosphodiesterase inhibitors or who do not wish to use intracavernosal injection.

Surgery

Surgical therapy is offered to patients who are refractory to other less invasive treatments. Vascular reconstruction is sometimes indicated in young patients with a history of pelvic trauma. Skepticism exists regarding other vascular reconstruction or venous ligation surgeries. Penile prostheses are a viable option for patients who cannot be treated medically. There are two kinds of penile prostheses: the semirigid prosthesis and the inflatable prosthesis. The inflatable prosthesis is better accepted and in general is associated with higher satisfaction rates. It also is associated with more frequent mechanical failure than are the semirigid devices. The average life expectancy for the inflatable device is about 10–15 years. If these devices fail, they can be removed and a new device placed.

Stem Cell Therapy

Current treatments for ED focus on a temporary solution to the problem with the exception of placement of a penile prosthesis, however this creates a life long dependence on a device that is subject to potential mechanical failure. Studies are underway with the use of stem cells as a possibility to reverse the pathology seen in ED. There has been some evidence in animal studies to suggest there is benefit to stem cell intracavernosal injection either by growth factor expression, cell engraftment, or cell incorporation (Albersen *et al.*, 2013). We are still awaiting data from clinical trials in humans. Stem cells have the potential to treat ED associated with aging, diabetes, post-prostatectomy, and peyronie's disease.

Ejaculatory Dysfunction

Ejaculatory dysfunction includes problems related to semen transport. Semen consists of sperm and seminal fluid as well as prostatic secretions. These conditions can have implications for reproductive function as well as psychological distress. Ejaculation is the discharge of semen from the male reproductive tract and occurs in conjunction with orgasm. After sufficient stimulation is achieved, under the control of the sympathetic nervous system, emission of sperm and seminal fluid occurs into the posterior urethra. With contraction of the bulbospongiosus muscle, propulsion of semen out of the urethra occurs in the second phase of ejaculation.

Retrograde ejaculation refers to semen going into the bladder instead of out through the urethral meatus. This occurs when the bladder neck muscles do not contract in the propulsion phase of ejaculation. Failure of emission results in no semen being deposited into the posterior urethra. These can be seen in men with neurologic conditions such as multiple sclerosis or the neuropathy from diabetes or as a side effect of medications such as alpha blockers. Treatment consists of correcting reversible causes or a trial of alpha agonists. Anorgasmia refers to the inability to achieve sensation of orgasm. Without an orgasm semen transport will usually not occur although a patient may have an ejaculation but not experience an orgasm. Anejaculation refers to no antegrade or retrograde ejaculation and is usually due to failure of emission or anorgasmia (Alwaal *et al.*, 2015).

Premature ejaculation is when ejaculation occurs before it is desired and can be psychologically distressing. It is particularly troublesome with an intra-vaginal latency time of less than 30 s. It can be either chronic or acquired and can be treated with penile desensitization, topical lidocaine, or serotonin selective reuptake inhibitors (SSRI). Delayed ejaculation is the opposite effect and can be caused as a side effect of certain medications such as SSRI's. Treatment focuses on correcting reversible causes and psychosexual counseling if needed.

Conclusion

Male sexual function is a complex interplay of psychological, neurogenic, vascular, and hormonal factors which leads to an erection and culminates in the transport of sperm out of the urethra with ejaculation. An interruption anywhere along this process leads to male sexual dysfunction. Pathophysiology of each disorder guides the treatment options for men who suffer from these conditions. Current studies are focusing on stem cells to help improve erectile function. Better treatment options are also needed in men with ejaculatory problems. Even though we have made a significant amount of progress so far, future research studies are needed to help improve treatment options in men suffering from male sexual dysfunction.

Androgens and Benign Prostatic Hyperplasia☆

Maritza Farrant and Stephanie T Page, University of Washington, Seattle, WA, United States

Glossary

5-Alpha reductase (5AR) A rate limiting enzyme that converts testosterone to the more potent metabolite dihydrotestosterone (DHT). There are three isoforms of which type 2 is present in the prostate. This enzyme is the target for 5-alpha-reductase inhibitors (5AR-Is) which reduce intratissue DHT levels and AR-mediated activities, thus reducing prostate size and function.

Androgen receptor Steroid hormone group of nuclear receptors which have a dual function, acting as both intracellularly located receptors and as ligand-activated transcription factors. They play a role in prostate development and hyperplasia.

Bladder outlet obstruction (BOO) A symptom caused by an increase in detrusor pressure and reduced flow rate, that may have multiple etiologies.

Cytokines Small secreted proteins released by cells that act on the cells that secrete them (autocrine action), on nearby cells (paracrine action), or in some instances on distant cells (endocrine action). There are both pro-inflammatory cytokines and anti-inflammatory cytokines.

Chemokines Cytokines that stimulate recruitment of leukocytes, hence play a role in inflammation.

Direct rectal examination (DRE) An internal examination of the rectum performed by a physician or other healthcare professional to assess for abnormalities in the prostate, rectum or fecal abnormalities (in the case of gastrointestinal bleeding).

Lower urinary tract symptoms (LUTS) A symptom complex caused by lower urinary tract dysfunction consisting of obstructive and irritative symptoms. It is associated with, but not pathognomonic of, benign prostatic hyperplasia.

Prostate-specific antigen A normal product of the prostate that is secreted via prostatic ducts during semen emission. It may be elevated in serum, under pathologic conditions, such as prostate cancer, infection, or benign prostatic hyperplasia.

Transition zone The part of the prostate most likely to be pathologically enlarged due to benign prostatic hyperplasia. It includes the periurethral part of the prostate and is therefore involved in outflow resistance to the bladder.

Transrectal ultrasound (TRUS) An imaging modality used to evaluate the size and structure of the prostate. It is usually used to help guide prostate biopsies.

Urogenital sinus Present in the embryo and forms both urinary and reproductive organs. The upper part forms the *future urinary bladder*, while the middle and lower part forms the definitive urogenital sinus and, from it, the pelvic and phallic parts of the urethra.

The Role of Androgens in Normal Prostate Development

The Prostate

The prostate is an accessory male reproductive gland that resides in the true anatomical pelvis and forms the proximal part of the male urethra. The embryological development of the prostate gland is dependent on androgens for reciprocal growth of both epithelium and mesenchyme (undifferentiated connective tissue). In the adult prostate, androgens continue to play a role in prostate tissue homeostasis. The most common prostate pathologies are prostate cancer and benign prostatic hyperplasia (BPH); whether androgens and estrogens play a causal role in the development of these conditions is unknown. The only firmly established risk factors for BPH are increasing age, genetics and male gender (with functional testes). BPH has been traditionally associated with lower urinary tract symptoms (LUTS) which may be obstructive, irritative or both. Medical pharmacotherapy for BPH is focused upon both symptom improvement and growth inhibition.

Anatomy

The adult prostate is located below the bladder and surrounds the upper third of the male urethra. It weighs around 20g at 20 years of age and is composed of branching ducts of pseudostratified columnar epithelium surrounded by fibromuscular stroma (Toivanen and Shen, 2017).

Historically the prostate was divided into three lobes based on anatomic studies from the 1900s (Lowsley, 1915) until the McNeal model, which is now widely accepted, was proposed in the 1970s. John McNeal (McNeal, 1984) divided the prostate gland into four zones that are anatomically and histologically distinct and have pathological and histological correlations. McNeal

☆*Change History:* May 2018. Maritza Farrant and Stephanie Page updated the text and references to the entire chapter.

This article is an update of Jaspreet S. Sandhu and Alexis E. Te, Benign Prostatic Hyperplasia (BPH), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 341-344.

noted that the prostate, when examined from different planes (coronal, transverse and longitudinal), demonstrated unique patterns, distinct from the traditional three lobes.

The four prostate zones are: peripheral, central, transitional and anterior. The peripheral zone forms the postero-inferior aspect of the gland and includes approximately 70% of the prostatic volume. This is where the majority of prostate adenocarcinomas occur. The central zone comprises approximately 25% of the prostate volume, contains the ejaculatory ducts, and is the zone that is most commonly affected by inflammatory processes such as prostatitis. The transitional zone represents only 5% of the total prostatic volume, and is where BPH occurs along with nearly 25% of prostatic adenocarcinomas. The transitional zone consists of two lateral prostate lobes together with the periurethral glands. Finally, the smallest zone by volume, the anterior zone, is mostly fibromuscular without glandular structures.

At the cellular level, the surrounding stroma serves to optimize the micro-environment for the epithelial compartment and appears to play a role in gland homeostasis in both the healthy state and during regeneration (Schauer and Rowley, 2011). The mechanisms underlying zonal predilection for different pathologies are unclear. However, gene expression profiling of each zone has revealed specific differences between the gene products that modulate cell-cell and stromal-epithelial interactions (Van Der Heul-Nieuwenhuijsen *et al.*, 2006).

Androgens and the embryology of the urogenital tract and the prostate

At conception, the mammalian embryo has the potential to develop into either female or male phenotype depending on the interplay of four critical structures: the mesonephric (Wolffian) and Müllerian ducts, the urogenital sinus (UGS) and the fetal gonad. Androgens play an integral role in the development, growth and differentiation of the prostate inducing reciprocal mesenchymal-epithelial interactions. Prostate organogenesis has been conceptually divided into four stages: sexual dimorphism, prostate budding, branching morphogenesis and epithelial differentiation.

The prostate arises from the primitive UGS, which is a caudal extension of the hindgut and derived from endoderm (Seifert *et al.*, 2008). Prior to 8 weeks gestation, the UGS and hindgut form a single excretory tract at the embryonic cloaca, which then separates into the urogenital and anorectal tracts, in a cranial to caudal direction. The UGS displays sexual dimorphism, depending on levels of circulating testosterone, with the ability to form either the prostate in males, or upper part of the vagina in females. Male embryos synthesize testosterone in the Leydig cells of the testes from the 9th week post conception (Siiteri and Wilson, 1974). Once testosterone reaches the UGS, it is converted into its more potent metabolite dihydrotestosterone (DHT) by the enzyme 5α-reductase (5AR) (Ekman, 2000). DHT binds to androgen receptor (AR), resulting in downstream nuclear signaling cascades.

During very early embryogenesis, ARs are expressed only in the mesenchyme, not on the epithelial cells. At around 10 weeks, the activation of stromal ARs stimulates growth factors and induces growth in adjacent prostatic epithelial cells resulting in prostate budding at the orifice of the paramesonephric ducts.

In the third stage of prostate organogenesis or branching morphogenesis, epithelial buds from the UGS grow into the surrounding mesenchyme, then elongate and split into a tree-like network of branches with terminal tips. These terminal tips eventually give rise to the epithelial duct system in a process providing the final size and shape of the adult prostate (Risbridger *et al.*, 2005). This process leads to the formation of the different prostatic zones within an initially uni-lobular organ (Timms, 2008). In the final stage, the solid epithelial cords become canalized to form the ductal lumen and cells undergo differentiation to give rise to functional glandular epithelium.

Histology of the prostate

The adult prostate consists of stromal and epithelial elements. The epithelium is organized as glandular acini that secrete into a lumen which then converges upon a duct, and into the urethra. There are three major differentiated cell types.

The luminal epithelial compartment is composed of androgen dependent cuboidal or columnar cells which produce PSA and acid phosphatase. Below the luminal cell layer are basal cells in one or two layers, which are attached to the basement membrane (Kurita *et al.*, 2004; McNeal, 1981; McNeal, 1988). They range from small, flattened cells with condensed chromatin and small amounts of cytoplasm to cuboidal-like cells with an increased cytoplasm and more open-appearing chromatin. These basal cells are less differentiated than secretory epithelial cells and contain no secretory products such as prostate-specific antigen (PSA). The epithelial compartment also contains specific stem cells, and rare bipotent cells, with the ability to differentiate into basal or luminal cells (Barron and Rowley, 2012; Frank and Miranti, 2013).

Of note, the prostate gland has the greatest number of neuroendocrine glands (NE) of all the genitourinary organs in the male, and expresses diverse neurosecretory products including chromogranin A (CGA) and B, serotonin, calcitonin family of peptides, thyroid-stimulating hormone-like peptide and somatostatin. It is thought that prostatic NE cells are involved in the regulation, secretion, differentiation, and proliferation of prostatic secretory and basal cells via exocrine, endocrine, paracrine, and autocrine mechanisms (Schauer and Rowley, 2011). NE cells are found in the epithelial luminal compartment and tend to be more prevalent in the major ducts compared to the acinar tissue.

Finally, the stroma is comprised of AR -positive smooth muscle cells, immune cells, nerves and blood vessels. The basal lamina surrounds the epithelium and forms a barrier between the epithelium and the stroma.

Physiology of the prostate and contribution to male reproduction

The adult prostate is an accessory reproductive gland that plays an important role in male fertility. During ejaculation alpha-adrenergic stimulation results in transport of the seminal fluid containing sperm from the ampulla of the vas deferens into the

posterior urethra. Secretions from the prostate contribute about 30% of the seminal fluid volume, the remainder contributed directly from the seminal vesicles and bulbourethral glands. Enzymes provided in prostatic secretions liquefy the seminiferous fluid to maximize sperm motility. Sperm motility is achieved via the coordinated action of the components of the two main fluids in the human seminal plasma: prostatic fluid which contains kallikreins, a specific subfamily of serine proteases, including prostate specific antigen (PSA) (Kalinska *et al.*, 2016), and semenogelin, a protein involved in the formation of a gel matrix that encases ejaculated spermatozoa secreted by the seminal vesicles (Verze *et al.*, 2016). Together with coordinated release of zinc and citrate (Costello and Franklin, 2016), the co-secretion of these fluids markedly impacts sperm motility and the final stages of spermiation (the maturation of spermatids into mature, motile spermatozoa). Prostatic fluid also increases the pH of the vaginal canal promoting increased sperm viability (Rey *et al.*, 2013; Drabovich *et al.*, 2014).

The role of androgens in adult prostate physiology

Androgens, including testosterone (T) and its more potent metabolite, DHT, play a vital role in prostate physiology. The testes produce greater than 95% of endogenous androgens in men, with the remainder produced as androstenedione by the adrenal cortex. This small amount of non-testicular androgen has a minimal impact on prostate function in physiologically normal males (Partin *et al.*, 1991). Circulating testosterone is taken up by the prostatic epithelial and stromal cells and converted to DHT by the rate limiting enzyme 5AR; type 2). There are three isoforms of 5AR (types 1–3) with type 2 predominantly expressed in the prostate whereas type 1 is the dominant isoform in hair follicles.

Both T and DHT mediate their action via binding to the androgen receptor (AR). The AR belongs to the steroid hormone group of nuclear receptors which include the estrogen receptors (ER), glucocorticoid receptor (GR), progesterone receptor (PR) and mineralocorticoid receptor (MR) (Tsai and O'malley, 1994). The AR is one of 48 human nuclear receptors, a subfamily of receptors that have a dual function, acting as both intracellularly located receptors and as ligand-activated transcription factors (Tan *et al.*, 2015). DHT has a greater binding affinity and a slower rate of dissociation from the AR compared to testosterone, and also upregulates AR synthesis and reduces AR turnover (Swerdloff *et al.*, 2017). The use of 5 alpha-reductase inhibitors (5AR-Is) reduces intratissue DHT levels and AR-mediated activities, thus reducing prostate size and function. These inhibitors have been used to reduce prostate hypertrophy and the symptoms of lower urinary tract obstruction in benign prostate hypertrophy (BPH) (see below).

In contrast to the prostate, there is very little conversion of T to DHT in the testes, thus circulating concentrations of DHT are much lower than T in healthy men. Circulating DHT has little impact on prostate growth. Despite a gradual decline of serum T with aging, intra-prostatic DHT concentrations in elderly men remain similar to those of young men (Bartsch *et al.*, 2002), likely because intra-prostatic 5AR remains active. In fact, intra-prostatic androgens have been shown to be independent of serum levels (Page *et al.*, 2006) and circulating androgen levels are not necessarily reflected within the prostate (Page *et al.*, 2011). Moreover, recent data indicates that DHT can be synthesized in the prostate from substrates other than T in what is termed the "backdoor" pathway and via the intracrine reverse synthesis pathway (Swerdloff *et al.*, 2017). Overall, intra-prostatic DHT is a critical component for maintenance of prostate physiology, but circulating testosterone levels are not a surrogate marker for the intra-prostatic androgen milieu under normal physiologic conditions.

The Role of Androgens in Benign Prostatic Hyperplasia (BPH)

The human prostate gland is one of the only internal organs that continue to enlarge throughout development, during adolescence and throughout adulthood. BPH involves hyperplasia of the of the stromal cell compartment and to a lesser extent, the glandular epithelium of the transitional zone of the prostate gland. Normal male aging is associated with gradual prostate enlargement, with the average prostate increasing from 25–30 g for men in their 40s, to 30–45 g for men in their 60s (Roehrborn, 2005).

BPH is a histological diagnosis, but clinical manifestations occur most commonly after significant prostatic enlargement that impairs bladder emptying, and results in LUTS. LUTS symptoms are divided into two categories; obstructive and irritative. Among the obstructive symptoms are hesitancy, straining, weak flow, prolonged voiding, partial or complete urinary retention, and, ultimately, overflow incontinence. The irritative symptoms consist of frequency, urgency with urge incontinence, nocturia, and painful urination, as well as small voided volumes.

The relationship between BPH, prostatic enlargement, and LUTS is complex. Not all men with BPH develop benign prostatic enlargement (BPE), significant LUTS or compression of the urethra with compromised urinary flow and bladder outlet obstruction (BOO). Other men who do not have histological BPH will develop LUTS due to prostate enlargement or other pathology (Emberton *et al.*, 2008), including prostatitis, prostate cancer, seminal vesical outlet obstruction (urethral stricture, bladder neck sclerosis), or bladder pathology (carcinoma in situ, inflammation and bladder calculi). Thus, clinically significant BPH is defined by the presence of LUTS; however, LUTS can occur without BPH.

Incidence and Prevalence

Clinically significant BPH has negative effects on quality of life (QOL), and represents a considerable health problem for older men. The overall prevalence of BPH has been estimated as 10%, with an overall incidence rate of 15 per 1000 man-years,

increasing with age (3 per 1000 at age 45–49 years, to 38 per 1000 at 75–79 years). Fifty percent of males exhibit some BPH symptoms between ages 51–60 years. Seventy percent of males present with BPH by the age of 70, and incidence increases to eighty percent by the age of 85 (Verhamme *et al.*, 2002). Both increased age and prostate volume increase the risk of symptomatic BPH. In the Olmsted county study (Jacobsen *et al.*, 1999), a retrospective cohort study, 2115 participants 40–79 years old underwent a voiding study and completed the American Urological Association Symptom Index (AUA-SI). A 25% random subsample underwent transrectal sonographic (TRUS) imaging of the prostate to determine prostate volume and measurement of serum PSA. During follow up, 167 men were treated for BPH, yielding an overall incidence of 16/1000 person-years. As expected, there was a strong age-related increase in risk for BPH treatment (3.3/1000 person-years for men 40–49 versus 30/1000 person-years for those >70 years old or older). Men with moderate-severe depressed peak urinary flow rates, enlarged prostate (greater than 30 mL) or elevated serum PSA (>=1.4 ng/mL) had a fourfold increased risk of BPH treatment than those who did not and an increased risk of acute urinary retention. Consistent with these results, a meta-analysis of three large multi-national trials (Marberger *et al.*, 2000) demonstrated the 2-year incidence of spontaneous acute urinary retention was higher in men with enlarged prostates (prostate volume > or = 40 mL) and higher PSA levels.

Risk Factors for BPH

Age and prostate size are the best characterized risk factors for BPH, but hormones likely play some role. It appears that the alteration in the androgen-estrogen ratio may also contribute, especially in the context of metabolic syndrome (MetS) and likely related to obesity (Tyagi *et al.*, 2018), which is also a risk factor. Hyperlipidemia is also associated with an increased risk of BPH (Shih *et al.*, 2018).

Additional risk factors include a positive family history, as early BPH may occur as a familial disease. (Sanda *et al.*, 1994). Increased physical activity, causing decreased vascular tone and oxidative stress (Vuichoud and Loughlin, 2015) decreases the risk of BPH. Alcohol taken in moderation also is associated with reduced risk of BPH (Roehrborn, 2005).

Pathophysiology

The mechanisms underlying the pathogenesis of BPH are complex and likely involve an age-related interplay of chronic inflammation, hormone dysregulation and abnormal wound repair (Schauer and Rowley, 2011).

Inflammation and wound repair

The development of BPH is closely related to an inflammatory microenvironment. The involvement of immune cells is a significant component of the disease. The stroma of patients with BPH produces various chemokines that attract these immune system cells (specifically monocytes, B and T lymphocytes) within the prostatic tissue. These cells produce various cytokines (IFN-c and IL-17) which stimulate the production of chemokines by stromal cells and these appear to contribute to hyperplasia and the development of BPH (Ricke *et al.*, 2011).

It is still unclear whether the development of BPH is due to preexisting inflammation causing hyperplasia or if prostate hyperplasia itself promotes inflammation. Studies have shown that patients with prostatitis have higher chances of developing BPH/LUTS. Chronic inflammation, which generally follows an acute inflammatory process caused by infectious agents, appears to be hormonal or metabolic abnormalities (La Vignera *et al.*, 2016), which may drive the inflammatory process. Of note, an inflammatory prostate phenotype with tissue remodeling has been demonstrated in male rabbits with low serum T and high E2, and MetS (Corona *et al.*, 2014; Vignozzi *et al.*, 2012). This has led to the idea that hypogonadism may play an important role in the development of prostate inflammation. Contributors to the development of BPH in the context of MetS include insulin resistance, pelvic atherosclerosis, and local inflammation. Increased insulin levels are associated with stimulation of the IGF-1 receptor, higher IGF-1 levels, and lower IGF-1 binding. There is also higher cytosolic-free calcium in smooth muscle and neural cells, activation of the sympathetic nervous system and increase in the prostatic smooth muscle tone. Atherosclerosis is associated with ischemia of the prostate and bladder tissues (La Vignera *et al.*, 2016). MetS itself is also involved with the production of key inflammatory cytokines (Rohrmann *et al.*, 2005; Gacci *et al.*, 2015; Lotti *et al.*, 2014; Vignozzi *et al.*, 2014).

Studies have also shown both the stroma and epithelial compartments in BPH contain reactive myofibroblasts, typical of the wound repair of inflammation-induced fibroses, and in cancers such as in the lung, liver and kidney (Schauer and Rowley, 2011). Transforming growth factor-β (TGFβ), appears to play a role in the differentiation of fibroblasts into myofibroblasts and remodeling of the stromal cells and is therefore regarded as a key inducer in the reorganization of pathogenic prostatic stromal cells (Sampson *et al.*, 2013). Other growth factors mainly secreted by stromal cells act in an autocrine or paracrine manner to maintain prostate cellular homeostasis. These growth factors include insulin-like growth factor (IGF) and fibroblast growth factors (FGFs). Alterations of these interactions can modify the balance between cell proliferation and death leading to the development of BPH (Vignozzi *et al.*, 2014).

The role of androgens

Androgen exposure during puberty is required for growth and development of the prostate, specifically DHT (see above). This is clearly demonstrated by the phenotypic changes resulting from mutations in the 5alpha-reductase-2 gene (5AR-2). Affected 46XY

individuals have high normal to elevated plasma testosterone levels with decreased DHT concentrations and elevated testosterone/DHT ratios. The prostate in adulthood is small and rudimentary, and facial and body hair is absent or decreased. Neither BPH nor prostate cancer have been reported in these patients. (Imperato-McGinley, 2002). Similarly, the prostate is small in mice with 5alpha-reductase-2 gene deletions or treated with specific 5AR-Is (Zhu and Imperato-McGinley, 2009).

The role of androgens in the development of BPH, following normal prostate development, is unclear. Firstly, serum testosterone concentrations decline with age, whilst the incidence of BPH increases (Harman *et al.*, 2001; Lenzi *et al.*, 2009). Secondly, studies have shown no correlation between prostate size and circulating testosterone levels (Roehrborn, 2008; Vignozzi *et al.*, 2014). Finally studies in older men receiving exogenous testosterone replacement therapy, resulting in elevated serum DHT levels and normal T levels, have shown minimal increases in prostate size, no impact on prostate androgen concentrations, and no known increased risk of prostate disease or LUTS (Swerdloff *et al.*, 2017).

However, the potency of 5AR-Is in reducing prostate hypertrophy and LUTS provides evidence for a role for androgens in maintaining BPH. It is important to note that 5AR-Is act on the intra-prostatic hormonal milieu reducing intra-prostatic DHT. Circulating DHT, which is much less than intra-prostatic levels, is unlikely to play a role in the pathogenesis of BPH (Vignozzi *et al.*, 2014). In addition, it appears that stromal cell AR, rather than the epithelial cell AR, promotes the development of BPH via modulation of stromal-epithelial cell interactions in both normal and abnormal prostate development (Emery *et al.*, 2007; Wen *et al.*, 2015). In addition, suppression of AR in transgenic mice that spontaneously develop BPH as a result of prolactin (PRL) overexpression has suggested that PRL may contribute to stromal cell proliferation (Lai *et al.*, 2013).

The role of estrogen

Although the prostate is commonly thought of as an androgen target tissue, estrogen also appears to play a role in both normal prostate physiology and in the development of BPH. In men, the major circulating estrogen is formed from aromatization of testosterone (via CYP19/aromatase) into estradiol-17β (E2) (Nicholson and Ricke, 2011). As men age they develop an increased estrogen to androgen ratio (due to decline in serum androgens and lesser decrease in E2) (Gray *et al.*, 1991; Roberts *et al.*, 2004) which can coincide with the development of BPH. E2 is produced in fat and, to a lesser extent, muscle in men, with only 20% secreted by Leydig cells in the testes.

E2 plays important roles in bone health, lipid metabolism and in the brain in men. However, serum levels of E2 do not necessarily reflect prostate concentrations of E2 (Vermeulen *et al.*, 2002). It has been postulated that local prostatic E2 production may influence local estrogen regulated processes and may be involved in prostatic hyperplasia (Ellem and Risbridger, 2009). Estradiol acts via two receptors, ERalpha and ERBeta, both of which are expressed in the human prostate but have differing functions. Both ERs have proliferative and antiproliferative effects on prostate cells, via multiple mechanisms including apoptosis, aromatase expression and paracrine regulation via prostaglandin E2 (Ho and Habib, 2011). Finally, estrogen may be enriched in the stroma of men with BPH, further supporting a role for E2 in the pathophysiology of BPH, although definitive data is still lacking.

Like endogenous estrogens, exogenous estrogens such as phytoestrogens, (polyphenols, flavonoids, and isoflavonoids), selective estrogen receptor modulators (SERMs), and endocrine disruptors (bisphenol-A and insecticides) may also affect estrogen action in men (Nicholson and Ricke, 2011). SERMs are compounds which modulate the activity of estrogen receptors (ERs) and may have agonist or antagonist effects in tissues, depending on the individual SERMs. The utility of SERMs in BPH remains to be evaluated but therapeutic SERMs are a promising treatment option for BPH. In contrast, exposure to BPA, DES, or E2 in developing rodents causes increased prostate susceptibility to adult-onset of dysplasia and hormonal carcinogenesis (Macey and Raynor, 2016). Although the role of BPA and other environmental estrogens in BPH has not been fully determined in humans, the effects of endocrine disruptors are likely to be observed in estrogen target tissues such as the prostate.

Clinical Evaluation

Symptomatic BPH is characterized by lower urinary tract symptoms (LUTS) that include both voiding (obstructive) symptoms and storage (irritative) symptoms. Given the difficulties in accurately diagnosing BPH in men presenting with LUTS, an initial evaluation recommended by the "American Urological Association (AUA) Guidelines on the Management of Benign Prostatic Hyperplasia (http://www.auanet.org/guidelines/bph.cfm) includes a clinical history, use of a validated questionnaire to assess symptoms, a physical examination with digital rectal examination (DRE), urinalysis and serum PSA measurement (Kevin *et al.*, 2014).

Scoring systems

There are several scoring systems currently available to quantify symptoms of BPH. The American Urologic Association (AUA) Symptom Index is widely used and consists of seven questions that assess emptying, frequency, intermittency, urgency, weak stream and straining with each graded with a score of 0-5. The International Prostate Symptom Score (IPSS) is a modification of the AUA Symptom Index adding a single question assessing the quality of life or bother score based on the patient's perception of the problem (Barry *et al.*, 1992). The questionnaire is self-administered and elicits a response score ranging from 0 to 35 points. Men scoring from 0 to 7 points are classified as not or mildly symptomatic, those scoring between 8 and 18 points as moderately symptomatic, and those scoring 19 points or greater as severely symptomatic (Roehrborn, 2005).

Progression of BPH

Given the natural history of BPH, studies have sought to identify those men at greatest risk of progression. These factors include worsening of symptoms, reduction of urinary flow rate, increase in prostate volume (PV), and outcomes such as acute urinary retention and the need for surgery either for acute urinary retention or symptomatic relief (Emberton *et al.*, 2008).

Prostate volume (PV) is perhaps the most extensively studied of the risk factors for BPH progression. Men with a PV > 30 mL are more likely to suffer moderate-to-severe symptoms, decreased flow rates, and AUR compared with men with PV < 30 mL (Anderson *et al.*, 2001). An enlarged prostate is also predictive of the need for surgical intervention. Data from the placebo arm of the Proscar Long-term Efficacy and Safety Study (PLESS) demonstrated that PSA is a strong predictor of prostate size, one that is likely to increase in size, as well as the risk of developing LUTS, poor urinary flow, acute urinary retention and/or BPH-related surgery (Roehrborn *et al.*, 1999).

Management of BPH

The initial management for BPH includes watchful waiting or medical therapy, especially in those patients with mild or moderate symptoms and no indications for surgical intervention. Treatment is often undertaken on an elective basis for such patients. Those men who develop complications (including AUR, recurrent UTIs, bladder calculi, hematuria and renal impairment) require treatment. A range of treatment options are available and should be individualized depending on symptoms, success rates, possible complications and patient preference. The standard of care for BPH includes medical and surgical treatment.

Medical therapy

First line medical therapy for men with moderate to severe LUTS secondary to BPH are alpha-blockers, including the second generation drugs terazosin and doxazosin and third generation alfuzosin and amulosin. These agents act on the alpha-1 adrenergic receptors present throughout the smooth muscle of the male urinary tract (including the stroma of the prostate), and at the level of the spinal cord ganglia and nerve terminals, and may also have extra-prostatic effects (Nitti, 2005). These agents relax the smooth muscle within the bladder neck and prostate, reducing the obstruction to urinary flow. They are most effective for men with prostate size of <30 mL (Djavan *et al.*, 2004), and reach maximal effectiveness within a few weeks of initiating therapy (Michel and Vrydag, 2006). The most common side effects, which are reduced in the more uroselective drugs (which are the later generation compounds), include light-headedness, dizziness, headache, nasal congestion and retrograde ejaculation. Despite their slightly different side effect profiles, all four second and third generation alpha-blockers have similar efficacy (Roehrborn, 2005)

While alpha-blockers are effective at improving LUTS for many patients, they do not affect prostate growth or reduce the risk of structural BPH complications. In contrast, 5AR-Is reduce prostate size, via reduction of intra-prostatic DHT, which can result in improved urinary flow rates. 5-ARIs can prevent progression of LUTS secondary to BPH and they reduce the risk of urinary retention and future prostate-related surgery. They are appropriate and effective treatment alternatives for men with LUTS secondary to BPH with known or suspected prostate enlargement.

The two 5AR-Is in clinical use are finasteride and dutasteride. Finasteride is specific for 5AR2 while dutasteride inhibits both 5AR1 and 5AR2. Both appear to be similar in terms of clinical efficacy, however, in contrast to alpha-blockers, maximal efficacy is achieved after 3–6 months of therapy. Side effects may include erectile and ejaculatory dysfunction and reduced libido. It should also be noted that 5-ARIs reduce PSA levels by approximately half, so a baseline measurement at commencement is recommended for individuals electing to use PSA for prostate cancer screening or surveillance (Blankstein *et al.*, 2016).

The combination of an α-blocker and a 5AR-I (combination therapy) is an appropriate and effective treatment for patients with LUTS associated with prostate enlargement based on volume measurement, PSA level (as an indicator of volume), and/or prostate enlargement on digital rectal examination. In early studies of one-year duration or less, combination therapy proved equal to alpha blocker therapy in efficacy and safety, but superior to 5-ARI therapy alone (Kirby *et al.*, 2003; Lepor *et al.*, 1996). However, the Medical Therapy of Prostate Symptoms (MTOPS) Study demonstrated that in the long term, among men with larger prostates, combination therapy is superior to either α-blocker or 5-ARI therapy alone in preventing progression and improving symptoms (McConnell *et al.*, 2003).

A second major combination therapy study was the slightly larger (4000 men) international, four-year, Combination of Avodart and Tamsulosin trial (CombAT) comparing tamsulosin, dutasteride and a combination of both (Roehrborn *et al.*, 2008). The primary endpoints were similar to the MTOPS Study and included progression to urinary retention and need for prostate surgery as well as symptom progression. Combination therapy was shown to be superior to either monotherapy, consistent with the MTOPS study findings.

Phosphodiesterase type 5 Inhibitors (PDE5-Is) have been shown to improve symptoms in some patients with BPH/LUTS, despite being initially approved for erectile dysfunction (Brock *et al.*, 2013; Carson *et al.*, 2014). PDE5-Is increase intracellular cyclic guanine monophosphate (cGMP), causing nitric oxide (NO) mediated reduction in smooth muscle tone in the prostate, detrusor muscle and urethra. There is, however, no effect on prostate size (Blankstein *et al.*, 2016). In terms of efficacy, tadalafil was shown to be as effective as the alpha-blocker tamulosin, with the added benefit of reducing ED (Oelke *et al.*, 2012). A recent small study showed additional administration of tadalafil to patients with LUTS with poor responses to alpha-1 blockers improved both LUTS/BPH symptoms as well as sexual function (Hayashi *et al.*, 2016). Side effects include headache, flushing, back pain and dyspepsia, and PDE5s are contraindicated in patients taking nitrates.

Some complementary and alternative therapies (CAM) have been used for symptoms of BPH. Phytotherapy refers to common plant extracts and herbs as treatment modalities, such as *Seronoa repens* (saw palmetto) and *Pyogeum africanum* (African plum).

However, the active ingredients and therapeutic dosages are unknown for most extracts and supplements, the mechanism of action is poorly understood, and the safety profile and efficacy has not been adequately studied with randomized clinical trials. A meta-analysis (Tacklind *et al.*, 2012) concluded that at double and triple doses, *Seronoa repens* did not improve urinary flow measures or prostate size in men with lower urinary tract symptoms consistent with BPH.

Surgical treatment

Surgery is recommended for those men who fail medical treatment or who develop complications of BPH. In 2015 there were 12.2 million men who were actively managed for BPH/LUTS. 54% of those men had medical management and only 1.1% had surgery or procedure (Amerson, 2015).

There are a now a number of surgical options available including minimally invasive procedures, traditional and newer transurethral approaches using electrosurgical and laser techniques, as well as robotic, open and laparoscopic techniques.

Minimally invasive surgical therapy includes transurethral needle ablation of the prostate (TUNA), transurethral microwave therapy (TUMA), or interstitial laser coagulation. Although these procedures improve flow rates and quality of life (QOL), they lack long term effectiveness when compared to transurethral resection (TURP), and do not play an important role in the long term management of LUTS secondary to BPH (Macey and Raynor, 2016).

The gold-standard treatment for BPH is transurethral resection of the prostate (TURP) which relieves obstruction by removing hyperplastic tissue in the transition zone. In most instances, the surgical procedure requires approximately 60 minutes and most patients are observed for $<=24$ hours in the hospital, dependent upon the risk for bleeding and obstruction. Various different energies have been used for cautery including traditional monopolar and the more popular bipolar electrocautery. Transurethral incision (TUIP) is usually an outpatient procedure that is suitable for men with moderate to severe LUTS and smaller prostates (<30ml). IT is associated with fewer complications but increased need for follow-up secondary procedures (Macey and Raynor, 2016).

Newer laser therapies such as GreenLight Photo Vaporisation (PVP) and Holmium laser enucleation (HoLEP) have improved the traditional TURP, by reducing length of hospital stay, need to stop anticoagulation and faster return to work (Tholomier *et al.*, 2015). Laser therapies are also associated with fewer complications such as bleeding, sexual dysfunction (retrograde ejaculation and erectile dysfunction), UTIs and urinary incontinence (Eltabey *et al.*, 2010).

Open prostatectomy is associated with increased complications when compared to TURP and is usually reserved for men unresponsive to medical therapy, those with very large volume prostates (>80 mL), and those with associated bladder pathology, such as bladder stones or diverticula. Open prostatectomy has excellent long term results with approximately 98% of patients experiencing relief of symptoms and increases in flow rate (Macey and Raynor, 2016), although there are surgical risks including sexual dysfunction and incontinence. Several approaches have been described including robotic, laparoscopic and open prostatectomy (Ferretti and Phillips, 2015). Overall surgery improves symptoms and maximum urinary flow rate (Qmax) but symptoms (particularly urinary incontinence) may persist in up to 15%–20% of men require postsurgical interventions for BPH. Such interventions include detrusor instability (DOA) and periprocedural damage to the urethra (Macey and Raynor, 2016).

Conclusion

The prostate is an accessory male reproductive organ. BPH is the result of hyperplasia of the transitional zone of the prostate, involving the stroma, to a greater extent than the epithelial compartment. The majority of men will develop BPH with advanced age, however not all men will develop LUTS. BPH with LUTS can adversely impact quality of life.

Androgens (testosterone and DHT) play a crucial role in the development and maintenance of the prostate gland micro-environment. The role of androgens in the pathophysiology of BPH in unclear, although it is likely a permissive one. Inflammation appears to drive hyperplasia as men with prostatitis are at increased risk for developing BPH, and hypogonadism may help drive inflammation. Estrogen likely plays a role in promoting prostate hyperplasia, alone and also within the altered estrogen/androgen ratio that occurs with aging. Overall, the pathogenesis of BPH is complex and likely involves an age related interplay of chronic inflammation, hormone dysregulation and abnormal wound repair.

Medical management is targeted towards relief of LUTS. There are various surgical options for men ranging from minimally invasive to open prostatectomy; TURP is the gold standard.

Glossary

Digital rectal exam (DRE) Part of the physical exam in which a gloved, lubricated index finger is inserted into the rectum. The prostate is then inspected for asymmetry, the presence of nodular areas. These findings are considered abnormal and should lead to biopsy to evaluate for the presence of cancer. Occult fecal blood testing and palpation for rectal masses should also be performed.

Gleason grade A pathologic evaluation based on the glandular pattern of prostate cancer as examined at relatively low-power magnification. The predominant and secondary patterns of glands within the tumor are identified and each assigned a grade of 1–5, with 1 being the least aggressive and 5 being the most aggressive pattern. The two grades are added together to provide a Gleason sum score of 2–10 that reflects the aggressiveness of the tumor.

Magnetic resonance imaging (MRI) An imaging modality used to evaluate the prostate.

Peripheral zone The part of the prostate most likely to contain cancer. Most of the peripheral zone is located in the posterior part of the prostate gland, making it accessible to the transrectal approach for procedures.

Prostate biopsy Systematic removal of small amounts of tissue from the prostate that should be done with transrectal ultrasound guidance. Tissue is examined microscopically for the presence of prostate cancer.

Prostate-specific antigen (PSA) A serum marker for the presence of prostate cancer. It is normally produced by the prostate and secreted via prostatic ducts during semen emission. Under pathologic conditions, including prostate cancer, it may be elevated in serum.

Transrectal ultrasound An imaging modality to evaluate for abnormal structures within the prostate and to help guide prostate biopsies.

Pathophysiology

Most prostate cancers are adenocarcinomas that derive from glandular tissue within the prostate and typically progress locally before becoming metastatic. Other prostate tumors (<2%) include intraductal carcinoma (a variant of prostate cancer with more limited response to hormonal manipulation and radiation therapy), carcinosarcomas, squamous cell carcinoma, and urothelial carcinoma involving the prostatic urethra with or without stromal invasion (Nelson *et al.*, 2003).

Epidemiology

Prostate cancer is the second most common cancer diagnosed in men in the United States. Detection of prostate cancer cases peaked in 1995, when there were approximately 244,000 new cases and 44,000 deaths from the disease (Parker *et al.*, 1996). Subsequently, the number of cases detected per year has decreased. There will be an estimated 164,690 new cases detected in 2018, with approximately 29,430 deaths (Siegel *et al.*, 2018). The decrease in death rates is associated with the introduction of the prostate-specific antigen (PSA) test, but a causal relationship between application of PSA and decreased death rate has not been proven. Nearly all cancers are diagnosed in men between ages 45 and 89. The exact cause of prostate cancer is not well delineated, although evidence for both genetic and environmental factors exists.

Etiology

Both genetic and environmental factors affect the risk of development of prostate cancer. Twin studies have suggested that prostate cancer has a greater genetic basis than any other common neoplasm. This is reflected by the familial risk of prostate cancer development that is related to the number of men in the family affected by prostate cancer and the age of detection of tumor. For

☆*Change History*: May 2018. Timothy McClure, Spyridon P Basourakos, JS Sandhu, and Peter N Schlegel updated the text and references to the entire article. This article is an update of Jaspreet S. Sandhu and Peter N. Schlegel, Prostate Cancer, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 125–130.

 doi:10.1016/B978-0-12-801238-3.95929-4

men who have a first-degree relative with prostate cancer detected before age 50, the risk of detection of prostate cancer increases significantly (Carter *et al.*, 1992; Gomella *et al.*, 2001; Kicinski *et al.*, 2011).

The development of familial prostate cancer (defined as the presence of three or more first-degree relatives with disease) is associated with a locus on the long arm of chromosome 1 (HPC-1). Familial prostate cancer affects less than 10% of men with this disease, but it is common (>50% of men affected) for those individuals detected with disease at younger than 53 years of age (Carter *et al.*, 1992). Several other loci have been genetically linked to the risk of development of prostate cancer, including alterations in the androgen receptor gene (Alvarez-Cubero *et al.*, 2013).

The presence of genetic factors affecting the risk of prostate cancer is also supported by data on the incidence of prostate cancer in different racial groups. The prostate cancer incidence rate is highest for men of African American descent (149/100,000 person-years), with intermediate rates for US Caucasian men (107/100,000) and lower rates for men of Asian descent (39/100,000 for Japanese men and 28/100,000 for Chinese men). For Asian men who migrate to the United States, the rate of prostate cancer increases dramatically, although it remains lower than that observed for US white males (Lichtensztajn *et al.*, 2014). Even when corrected for stage of detection and access to medical care, black men with prostate cancer tend to have lower survival rates than white men with the same disease status.

The increase in prostate cancer incidence for men who migrate from Japan to the United States suggests the presence of environmental factors, especially dietary risk factors, in the development of prostate cancer (Loeb *et al.*, 2015). However, there is controversy regarding the role of dietary factors in the development of prostate cancer. Several studies have suggested that dietary fat, especially fat from red meat, appears to be an important risk factor for the development of this disease (Sonn *et al.*, 2005). Other dietary elements may have an acute effect on PSA, a marker for prostate cancer growth. Lycopenes (a substance derived from tomato with antioxidant activity) or soy protein (a phytoestrogen) have apparent antitumoral effects in men with prostate cancer (Rowles *et al.*, 2017). It is not clear whether soy protein acts directly or only through its estrogenic activity against prostate cancer.

Hormonal factors are critical for the development of prostate cancer. Testosterone is necessary for prostate epithelium to grow, and early prostate cancer has been shown to be androgen dependent. There is no evidence that testosterone replacement in hypogonadal men induces the development of prostate cancer or transition from a localized to a more invasive cancer (Morgentaler *et al.*, 2011).

Diagnosis

Detection of Prostate Cancer

Suspicion of the presence of cancer

An abnormal DRE of the prostate or an elevated PSA blood test level suggest the presence of prostate cancer. An abnormal exam includes the presence of nodular areas of the prostate or an asymmetric prostate gland. The presence of either of these factors is an indication for prostate biopsy in men who would benefit from the diagnosis of prostate cancer (men with a >10-year life expectancy and the possibility of localized disease or those with symptoms of metastatic disease).

Prostate-Specific Antigen

Prostate specific antigen (PSA), first described in 1981, is a glycoprotein that is produced by prostate tissue and liquefies coagulated semen (Nadji *et al.*, 1981). PSA is normally secreted outside of the body in urine or semen. If PSA backs up into the body and is present at elevated levels in the blood, then an abnormal condition is present within the prostate. This abnormality may be caused by trauma to the prostate (such as occurs after biopsy or cystoscopy), infection, benign enlargement, or prostate cancer. Therefore, an elevated PSA level does not diagnose the presence of prostate cancer, and prostate biopsy is required to confirm a clinical suspicion of cancer (Adhyam and Gupta, 2012).

Since PSA levels tend to increase with prostatic enlargement, PSA can be normalized to total prostate volume using the index of PSA (ng/mL)/prostate volume (cc). Prostatic enlargement tends to occur with age; therefore, it is possible to assume increased prostatic size as men age. This approach allows assessment of age-specific PSA levels. For men younger than 50 years of age, PSA levels should be 0–2.5 ng/mL. For men 50–59 years of age, normal PSA levels are 0–3.5 ng/mL. For men 60–69 years of age, PSA should be 0–4.5 ng/mL. For men 70–79 years old, PSA levels of 0–6.5 ng/mL are considered normal (Catalona *et al.*, 1994; Loeb *et al.*, 2006).

The specificity of the PSA blood test has been improved by the use of a derivation of the PSA. PSA may exist free in serum or bound to large proteins such as α_1-antichymotrypsin inhibitor. The percentage of free PSA is a measurement of the proportion of PSA protein that is free in the bloodstream versus that which is bound to other proteins. Men with low PSA levels (<1.0 ng/mL) rarely have cancer, and the vast majority of men with markedly elevated PSA levels (>30 ng/mL) have cancer. The percentage of free PSA is useful for determining whether biopsies are needed for men with a PSA between 3 and 10 ng/mL. Prostate cancers tend to release PSA into the bloodstream that is bound to proteins, whereas benign prostatic tissue tends to release more free PSA. Therefore, men with a low percentage of free PSA (<25% free) are more likely to have prostate cancer than men with elevated percentage free levels in the presence of an abnormal serum PSA level (between 3 and 10 ng/mL) (Adhyam and Gupta, 2012; Catalona, 1996).

Prostate cancer screening

PSA based prostate cancer screening has resulted in the majority of men diagnosed with this condition having organ confined, nonmetastatic disease. However, prostate cancer screening has been controversial due to concerns of overtreatment of less aggressive disease and the typically slow time for disease progression in some patients. This limits the ability to demonstrate benefit of screening in cohorts that have not been study over a 15- to 20-year period of time. The United States Preventive Services Task Force (USPSTF) initially recommended against prostate cancer screening with PSA in 2012 due to concerns of overtreatment resulting in increased morbidity with no improvement with prostate cancer mortality (Moyer and U.S. Preventive Services Task Force, 2012). In 2017 the USPSTF revised their initial opinion and in a draft recommendation suggested PSA screening may be beneficial in men between the ages of 55–69 years (U.S. Preventive Services Task Force, 2018). They gave no recommendations in men under 55 and recommended against screening in men 70 years and older. The American Urologic Association recommends the following for PSA based screening: They do not recommend PSA screening in men under 40 years old and in men age 40–54 years old with average risk. Men aged 55–59 may benefit from PSA screening and recommends "shared decision-making." Men over 70 years old or in men with less than 10–15 years of life expectancy are advised not recommended to have PSA screening for prostate cancer (Carter *et al.*, 2013).

The two largest studies that have looked at prostate cancer screening are the European Randomized Study of Screening for Prostate Cancer (ERSPC) and the Prostate, Lung, Colorectal, and Ovarian Cancer Screening (PLCO) trials. The ERSPC trial involved seven countries in Europe and essentially demonstrated that PSA screening reduced the mortality by 21%, but this benefit is seen greater than 10 years (Schroder *et al.*, 2014). The PLCO trial was run in the United States and demonstrated no significant difference in men who were screened compared to men who were not screened (Andriole *et al.*, 2012). A major limitation and critique of the PCLO trial however is that over half of the men in the control arm were already screened.

Other tests for prostate cancer detection

Adjunctive tests used to quantify the risk of prostate cancer with men who have indeterminant PSA levels or elevated levels with prior negative biopsies have been applied. These include PCA-3, a urine test for detection of RNA from the noncoding gene, PCA3, performed after prostatic massage, and 4kScore, a blood test that evaluates a variety of forms of PSA and other proteins, and also taking into account patient characteristics (age, prior biopsy history). 4kScore results are reported as the % risk of the patient having "clinically significant" (larger or more aggressive prostate cancer) (Sartori and Chan, 2014).

Imaging of prostate cancer

The use of ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), PET or other forms of nuclear scintigraphy (bone scan) may be indicated for detection of the location of cancer within the prostate or for evaluation of the extent of disease. US is used as an adjunctive imaging technique during prostate needle biopsy to direct random ("systematic") biopsies, but it has poor performance in localizing sites of prostate cancer inside the gland. CT and nuclear scintigraphy is predominately focused on staging of more aggressive or "higher risk" cancers (e.g., those associated with higher PSA) after a diagnosis has been made (Rifkin *et al.*, 1990). There has been great interest recently in prostate MRI as it can be used for better prediagnosis localization of disease, staging, surgical planning, radiation therapy planning, and the detection of local recurrence after treatment. The American Urologic Association and the Society of Abdominal Radiology recommend prostate MRI's use in men with elevated PSA and a prior negative prostate biopsy (Rosenkrantz *et al.*, 2016). Prostate MRI is increasing being used to help guide therapy, with some trials suggesting it may be useful as an adjunct to PSA screening by helping determine men who need biopsy. Prostate MRI generally detects larger and more aggressive tumors. PET scanning based on detection of PSMA (prostate surface membrane antigen) isolation has been suggested to provide detection of disease in some men where standard scanning or radionuclide scintigraphy is unable to identify sites of disease (Bouchelouche and Choyke, 2016).

Prostate Biopsy

Prostate cancer is detected after patients undergo biopsies of the prostate gland. Historically this is done via a transrectal approach using ultrasound guidance, although transperineal approaches are increasingly used as well. Transrectal ultrasound (TRUS) is used to evaluate prostate size and to ensure that biopsies have an adequate distribution of samples throughout the prostate gland. Typically, at least 12 core biopsies are done sampling the medial and lateral sides of the base, middle, and apex of the prostate on each side. Additional samples of the anterior (transitional zone) can be done as well. Although TRUS is used to guide the biopsies and many tumors are hypoechoic, there is no consistent diagnostic appearance of cancers on ultrasound (Harvey *et al.*, 2012).

Prostate MRI is also commonly used in further evaluating men with persistently elevated PSA levels and a negative biopsy. Lesions that are identified on the prostate MRI are then targeted to increase the accuracy of a prostate biopsy. MR Fusion biopsy machines use a computer which incorporates prostate MRI with real time US images allowing the surgeon to specifically target the area of concern seen on the MRI. This technique improves the accuracy of prostate cancer detection, particularly cancers that need to be treated (Kasivisvanathan *et al.*, 2018; Ahmed *et al.*, 2017).

Latent Versus Clinical Prostate Cancer

More than 90% of prostate cancers are adenocarcinomas. They are present as microscopic lesions in the majority of men older than age 50. These microscopic (latent) tumors cannot generally be detected by standard biopsies and are detectable only at autopsy. Latent tumors progress into clinically detectable prostate cancer in approximately 10% of all men. The mechanisms by which latent prostate cancer progresses to clinically significant and detectable tumors are poorly understood. All racial groups have similar rates of latent cancer, but the rate of progression to clinically significant cancer and death differs greatly. Therefore, some genetic factors appear to act by accelerating the rate of transformation of latent prostatic tumors into clinically significant tumors.

PSA-based screening for prostate cancer does not significantly increase the frequency of detection of small, presumably latent and clinically insignificant cancers. Therefore, it is inaccurate to state that a cancer found on biopsy is unimportant. Longitudinal series of men from Sweden (where prostate cancer management is usually expectant) who have prostate cancer and who live 10 years or more have shown that the majority who are not provided initial treatment die of the disease (Popiolek *et al.*, 2013).

Precursors of Prostate Cancer

There is no in situ carcinoma of the prostate that progresses to an invasive tumor. However, high-grade (grade II or III) prostatic intraepithelial neoplasia (PIN) is associated with invasive carcinomas. For men with high-grade PIN in the absence of an invasive carcinoma on prostate biopsies, a subsequent diagnosis of invasive cancer is made in at least 30%–50%. Low-grade PIN (PIN I) is of no clinical significance. It is not associated with subsequent detection or development of prostate cancer (Bostwick and Cheng, 2012).

Cancer Location and Volume

Based on the site of detection of early palpable and nonpalpable tumors, most (85%) prostate cancers develop out of the peripheral part of the prostate, primarily in the posterior part of the gland. At the time of detection, prostate cancers are usually multifocal, with an average of seven sites observed on serial sectioning of the entire gland. Cancers less than 0.2 cm^3 in volume and of low grade (Gleason sum <7) are rarely aggressive and are most commonly found in autopsy series or in prostates removed for benign prostatic hypertrophy (BPH). Cancers less than 4 cm^3 in volume rarely invade the seminal vesicles or metastasize to pelvic lymph nodes (Epstein *et al.*, 1994).

Grade

Historically prostate cancer was graded using the Gleason system (Gleason, 1966). This approach evaluated the glandular pattern of the tumor as examined at relatively low-power magnification. Cytologic features of the tumor are not considered in the Gleason grading system. The predominant and secondary patterns of glands within the tumor are identified and each is assigned a grade of 1–5, with 1 being the least aggressive (most differentiated) and 5 being the most aggressive (least differentiated) pattern. The two grades are added together to provide a Gleason sum score of 2–10. Gleason score is an important prognostic factor of the progression of prostate cancer and are used to stratify risk with lower risk prostate cancer's being Gleason score 6, intermediate risk prostate cancer being Gleason score 7, and high-risk prostate cancer being Gleason score 8–10. The Gleason grading system was recently replaced with the grade group (GG) system which GG 1 (Gleason score ≤ 6), GG 2 (Gleason score $3 + 4 = 7$), GG 3 (Gleason score $4 + 3 = 7$), GG 4 (Gleason score 8), and GG 5 (Gleason scores 9–10) (Epstein *et al.*, 2016a, b).

Staging

Prostate cancers are staged using the T, N, and M classification system. Localized tumors include clinical T1 or T2 tumors (N0M0), whereas clinical T3 (N0M0) tumors are considered locally advanced, and any nodal or metastatic involvement constitutes systemic prostate cancer. Clinical staging is primarily performed by DRE. The most common stage at which prostate cancers are detected is T1c (a nonpalpable lesion detected on biopsy evaluation of an elevated PSA). Nodal involvement may be detected with computed tomography (CT) of the pelvis, whereas metastases to bone (the next most common site) is primarily performed by radionuclide bone scan. For most men with localized disease (T1c, Gleason sum score 5–6, or PSA <10), there is a $<2\%$ risk of finding metastatic disease on bone scan or CT scan. MRI is not currently recommended in the staging of prostate cancer (Zaorsky *et al.*, 2012).

Treatment

Treatment of prostate cancer is generally limited to those men with a life expectancy >10 years or men with symptomatic metastatic disease. Therefore, it is possible to discuss treatment options for prostate cancer based on the stage of disease diagnosed.

Localized Disease

The goal of treatment of clinically localized disease is the eradication of all local tumor. Despite apparently effective treatment, some men with clinically localized disease may have micrometastatic disease that limits local treatment to a less than 100% success rate. Nevertheless, the majority of men with clinically localized disease are potentially curable with effective treatment.

Watchful Waiting

Many men with prostate cancer have long-term survival without aggressive treatment, this is particularly true for men with Gleason score 6 (Grade Group 1). Alternatively, for men with Gleason grade 8–10 tumors (Grade group 3, 4, 5), the 5-year death rate from prostate cancer without initial treatment may approach 50%. These observations suggest that watchful waiting may be very appropriate for patients with a life expectancy of <10 years and well-differentiated tumors. Only men with expected life expectancy greater than 10 years or symptomatic disease should be considered for treatment. Watchful waiting is reserved for men with major health issues and/or short life in which treatment is avoided to prevent its associated morbidity. Watchful waiting differs from active surveillance in its end point with watchful waiting only initiating treatment when a patient becomes symptomatic from prostate cancer, whereas with active surveillance, definitive curative treatment is delayed, but may still be offered with evidence of disease progression. For most men with more aggressive tumors and longer life expectancy, effective local treatment may be helpful to avoid death from prostate cancer. For younger men with prostate cancer, treatment may be critical to avoid death from this disease (Holmberg *et al.*, 2002; Loeb *et al.*, 2017; Wilt *et al.*, 2012).

Active Surveillance

Active surveillance (AS) is where one carefully monitors localized, low risk prostate cancer with repeated PSA, exams, and prostate biopsies in the hopes of delaying definitive treatment without compromising oncologic outcomes. The benefit of AS is that it helps men avoid the side effects (impotence and incontinence) of treatment for men with limited chance of benefiting from local treatment. AS has been seen to be safe in men with low risk, low volume prostate cancer, with up to 55% of men avoiding treatment and its associated side effects at 15 years. The largest randomized controlled study, the ProtecT trial evaluated 1643 men with localized prostate cancer to either active surveillance, radical prostatectomy, or radiation therapy and found no significant difference in prostate-cancer mortality at 10 years (Hamdy *et al.*, 2016). Indications to stop AS are rising PSA, increasing GG on repeat biopsy, increasing volume of cancer on repeat biopsy, or patient preference.

Radiation Therapy

Prostate cancer can be treated with radiation therapy. Radiation may be delivered to the prostate using external beam radiation therapy (EBRT), which is commonly applied using a three-dimensional conformal technique or brachytherapy delivered by seeds placed directly into the prostate gland, or a combination of both treatments. Radiation therapy can be given with or without androgen deprivation therapy depending on the overall risk of prostate cancer. The effectiveness of radiation therapy is limited by the relative insensitivity of prostate cancer to radiation. With increasing radiation doses, there is a lower risk of subsequent positive biopsies. When radiation doses of 60–70 Gy are delivered to the prostate, positive biopsies occur in 30%–40% of treated patients. These results are not acceptable for long-term cure, although short-term control of cancer may be provided. Only when doses higher than 81 Gy are applied do positive biopsy rates decline below 10%. This dose of radiation is difficult to apply because the small intestine, bladder, and rectum are all highly sensitive to radiation damage. Differences between EBRT and brachytherapy are delivery and dose. EBRT is using giving in fractionated doses over the course of 8–9 weeks to enable total dose of approximately 80 Gy (Mayles *et al.*, 2004; Sydes *et al.*, 2004). There are evolving techniques which allow higher fractioned doses with EBRT targeting that is based on imaging the prostate which allows a higher dose delivery which can thus shorten the treatment time. Brachytherapy is given in a single session by implanting radioactive iodine-125 or palladium-103. The dose delivered with iodine-125 is 145 Gy and 125 Gy for palladium-103 (Goy *et al.*, 2016). More recently, SBRT (short-course external beam radiation therapy) has been applied with similar effectiveness and risks of standard EBRT. The observation of locally persistent prostate cancer (on biopsy) after attempted definitive radiation provides a possible explanation for the slightly lower 10-year disease-free rates observed after radiation therapy compared to results obtained with surgical therapy. However, the difference in survival after treatment of clinically localized disease with different approaches may be due to patient selection biases for treatment approach rather than the effectiveness of the treatment. Selection biases in treatment arms can be controlled to some degree by categorization of disease status based on PSA, clinical stage, and Gleason grade. Unfortunately, disease status has to be categorized to allow comparison of different treatment regimens because randomized trials of treatment modalities for localized prostate cancer have not been performed.

Surgical Treatment

Surgical prostatectomy has been used as a treatment for prostate cancer since 1904. However, successful early results were dependent on the detection of small-volume cancers, which was rare. In addition, a poor understanding of pelvic anatomy resulted in high complication rates (impotence and infection) after surgical prostatectomy. Furthermore, the surgical margins of resection around the prostate are limited by the apposition of the prostate to the bladder and sphincteric muscles as well as the rectum.

Significant advances in the surgical treatment of prostate cancer depended on an improved understanding of the anatomic relationship of the prostate to the nerves that provide erectile function as well as the relationship of the prostate to the sphincteric muscles. These observations were made possible because of the anatomic observation of the relationship of blood vessels to the prostate. With better control of blood loss, identification and preservation of urethral sphincteric muscles and the neurovascular bundles containing the nerves responsible for erectile function became possible (Lepor *et al.*, 1985). Nerve sparing radical prostatectomy (Eggleston and Walsh, 1985) allows preservation of erectile function for 50%–80% of men after radical prostatectomy at selected centers, with incontinence rates of 2%–10%. The rate of complications is related in large part to the age of the patient. Other improvements in surgical techniques include laparoscopic and robotic assisted laparoscopic radical prostatectomy have led to shorter hospitalization times and fewer surgical complications without compromising oncologic outcomes (Lepor, 2005).

Despite the potential risks of surgical therapy, prostate cancer appears to be better controlled with surgery than radiation therapy in most series of patients with 10–15 years of follow-up (Wallis *et al.*, 2016). Thus, radical prostatectomy is the primary choice for treatment of localized prostate cancer for most men who have a life expectancy >10 years and who are candidates for a major surgical operation.

Ablative Therapies

Prostate cancer identification with imaging has continued to improve, especially with prostate MRI. The improvement of detection has led to great interest in the management of prostate cancer with ablation in which the identified region of prostate cancer is treated and the remaining prostate is not treated. Ablative techniques include cryoablation, high intensity focused ultrasound (HIFU), focused laser ablation (FLA), photodynamic therapy (PDT), and irreversible electroporation (IRE) (Chaussy and Thuroff, 2017; Gao *et al.*, 2016; Moore *et al.*, 2009; Scheltema *et al.*, 2017; Sullivan and Crawford, 2009). These techniques may provide similar oncologic outcomes for men with localized disease with an improved side effect treatment profile.

Metastatic Disease

Systemic prostate cancer may involve a wide spectrum of disease, from biochemically detected cancer detectable only on PSA blood test with no evidence of lesions on bone scan or CT scan to symptomatic, extensive metastatic lesions easily seen on bone scan with extensive replacement of bone marrow by disease. The initial treatment of systemic prostate cancer has changed little since the 1940s, when it was demonstrated that hormonal therapy with androgen deprivation can result in dramatic antitumor responses for men with disabling metastatic prostate cancer.

Hormonal Therapy

Androgen withdrawal, by either castration or medical therapy, can result in dramatic responses of PSA levels and clinical disease in the vast majority of men with advanced prostate cancer. Medical therapy usually involves administration of gonadotropin-releasing hormone (GnRH) agonists, which with tonic administration results in ablation of luteinizing hormone (LH) secretion by the pituitary and castrate levels of testosterone production by the testes. GnRH is normally released in a pulsatile fashion from the hypothalamus, in which it directly acts on the pulsatile release of LH (and follicle-stimulating hormone) from the pituitary. Tonic high-level GnRH stimulation of the pituitary (in distinction to pulsatile stimulation) results in a bimodal effect on LH secretion. Tonic pituitary stimulation (as provided by long-acting, potent GnRH agonists) causes an initial surge in LH secretion with increased testosterone, maximally noted approximately 1 week after GnRH agonist treatment. This tonic stimulation results in downregulation of GnRH receptors on the gonadotrope cells of the pituitary so that the pituitary becomes unresponsive to GnRH and LH secretion stops. The net effect of GnRH agonist treatment is an initial increase in testosterone levels (a flare effect), followed by suppression of LH with a decrease in testosterone to castrate levels within 1 month of continued treatment. No flare effect should be seen with repeated doses of an effective GnRH agonist, usually given as a depot injection or implant.

Obstruction of androgen action by competitive androgen receptor blockers can prevent the action of testosterone and other androgens on prostate cancer cells (Lepor and Shore, 2012).

Prostate cancer is remarkably androgen dependent and will usually respond to androgen deprivation for a median duration of 18 months in men with extensive prostate cancer. For some men who are treated with androgen deprivation for a prolonged period of time subsequently have progression of disease, as measured by increased PSA levels which is called castrate resistant

prostate cancer (CRPC). Cessation of the antiandrogens will result in a decrease in PSA levels for many patients. However, further treatment with antiandrogen therapy can be given as well. Antiandrogen therapy includes abiraterone (an androgen synthesis inhibitor) or enzalutamide (an antagonist of the androgen receptor) (Izumi *et al.*, 2017; Evans *et al.*, 2016; Beer *et al.*, 2014). Addition of second-line hormonal therapy can result in substantial benefits in progression-free and overall survival with limited side effects. Since abiraterone results in decreased glucocorticoid production as well as a risk of mineralocorticoid excess, patients are typically cotreated with oral prednisone 5 mg bid during abiraterone therapy (Fizazi *et al.*, 2017).

Chemotherapy

Docetaxel, an antimicrotubular chemotherapy drug, that is FDA approved in CRPC (Zhu *et al.*, 2010). It has been shown to improve survival in men with symptomatic, metastatic prostate cancer in two randomized controlled trials (Petrylak *et al.*, 2004; Tannock *et al.*, 2004). Carbazitaxel, another antimicrotubular chemotherapy drug is FDA approved from men with CRPC who have failed docetaxel therapy (Eisenberger *et al.*, 2017). Several studies have suggested that men with high risk advanced prostate cancer (e.g., those with visceral metastases or high-volume disease) may benefit from combined treatment with docetaxel at the time of initiation of androgen deprivation therapy (Sweeney *et al.*, 2015).

Immunotherapy

Sipuleucel-T is an immunotherapy that is FDA approved in the management of CRPC. It is a vaccine against prostate cancer cells after a patient's white blood cells have been trained to target a ligand specific to prostate cancer (prostatic acid phosphatase-granulocyte macrophage colony- stimulating factor (PAP-GM-CSF recombinant fusion protein). Treating men with Sipuleucel-T has been shown in a multicenter, randomized control trial to have a 22% reduction in mortality (Kantoff *et al.*, 2010).

Radiation Therapy in Metastatic Disease

Metastatic lesions typically respond to either spot radiation therapy of 8 Gy or systemic radiation directed to bony lesions, such as with intravenous injection of radium-223 dichloride, strontium-89, or samarium-153. Relief of pain occurs in 60%–80% of patients with local bone pain from metastatic prostate cancer. For men with solitary symptomatic deposits, local radiation is most appropriate, whereas patients with multiple sites of symptomatic involvement are best treated with systemic administration of strontium-89. Radium-223 dichloride is FDA approved for treatment of patients with painful castrate resistant prostate cancer bony metastasis (Saad *et al.*, 2016).

Conclusion

Prostate cancer is a significant health concern for nearly one in nine men in the United States. The management of prostate cancer is evolving as patient risk stratification has improved with some men being able to be safely monitored with active surveillance, while others can be more appropriately treated with definitive surgical or radiation therapy. Mainstay treatment of localized prostate cancer is surgery or radiation, however ablative therapies will likely become an integral component in the management of localized prostate cancer. Hormonal therapy is the mainstay of systemic therapy, but it is not a curative therapy as most tumors develop cell lines whose growth is androgen independent. Effective systemic therapies for prostate cancer are evolving and now include immunotherapy. Further understanding of the pathophysiology of prostate cancer is progressing rapidly, in conjunction with improved methods of early detection and improved local treatments.

Insulin-Like Peptide 3 (INSL3)

Ravinder Anand-Ivell and Richard Ivell, University of Nottingham, Nottingham, United Kingdom

Introduction

Insulin-like peptide 3 (INSL3), previously called both Leydig insulin-like peptide (Ley-IL) and relaxin-like factor (RLF), was initially discovered in the early 1990s as a testis-specific gene transcript in boar (Adham *et al.*, 1993) and independently in mouse (Pusch *et al.*, 1996). Subsequently, INSL3 has been detected at the mRNA and protein level in the steroidogenic Leydig cells of the testes of all mature mammals studied, including humans (**Fig. 1**; Ivell *et al.*, 1997; Ivell and Anand-Ivell, 2009). Although initially named to link it with the insulin-like growth factors, IGF1 and IGF2, it is structurally and functionally more closely related to the relaxin family of insulin-like peptide hormones, which includes besides the ovarian H2-relaxin, H1-relaxin, relaxin-3, INSL4, INSL5, and INSL6 (Bathgate *et al.*, 2006).

Structure and Evolution of INSL3

INSL3 is produced in Leydig cells as a typical secreted peptide hormone, the mRNA encoding a 16–20 kD pre-pro-peptide which is cotranslationally transported first to the lumen of the endoplasmic reticulum with accompanying loss of the initial N-terminal signal peptide. It is then transported via the Golgi apparatus to secretory vesicles in preparation for secretion, which appears to be accompanied by further cleavage of two internal furin-like proteolytic cleavage sites and the ordering of three cysteine bridges. The final product is an approximately 6 kD A–B heterodimer with sulfhydryl bridges connecting the A and B chains together and a single internal sulfhydryl bridge determining the conformation of the A chain. The connecting C-peptide appears to be lost. Much of this pathway has been determined by analogy to insulin and relaxin processing. In only two species, bull and boar, has the structure of INSL3 actually been determined from the circulation in vivo (Bullesbach and Schwabe, 2002; Minagawa *et al.*, 2012). Moreover in both species, there is probably a large proportion of immunoreactive INSL3 present as the unprocessed B–C–A pro-form, which appears to be equally bioactive with the A–B heterodimer (Minagawa *et al.*, 2012). Certainly, when extracted from testicular tissue and subjected to western blotting the 12–18 kD pro-form predominates (Hombach-Klonisch *et al.*, 2004).

There is no information to date as to whether INSL3 is secreted via the so-called regulated pathway inside cells, or via a constitutive unregulated pathway. The former would imply that secretion of peptide would be dependent upon both synthesis (transcription and translation) as well as a separate process of secretory granule release, as for many pulsatile peptides, whereas the latter would exclude the second process. In support of the constitutive pathway are the observations firstly, that INSL3 secreted into the bloodstream appears only to be dependent upon the number of Leydig cells and their differentiation status, and is acutely independent of the influence of the hypothalamic–pituitary–gonadal (HPG) axis (Ivell and Anand-Ivell, 2009). Secondly, in the human, INSL3 does not follow any kind of diurnal rhythm, unlike testosterone secreted from the same cells (Chong *et al.*, 2015). It should be noted that INSL3 is produced by those cells which make testosterone and where the cytoplasm is almost completely

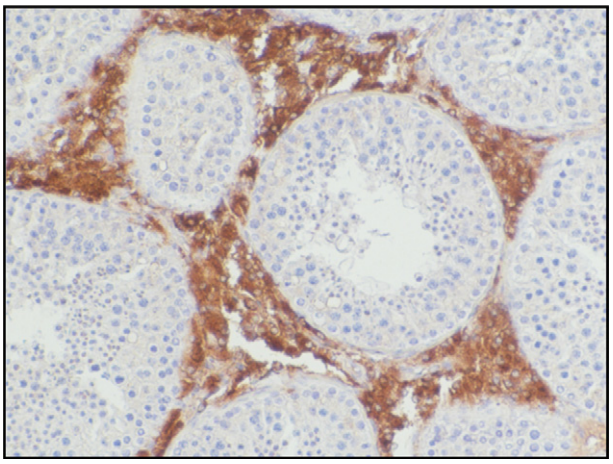

Fig. 1 INSL3 immunohistochemistry of the healthy human testis. The Leydig cells are specifically stained (*brown*) using a polyclonal antiserum which was raised against the INSL3 pro-form (Ivell *et al.*, 1997). Cell nuclei are counterstained blue using hematoxylin.

dominated by the smooth endoplasmic reticulum essential for steroidogenesis. Nevertheless, immunohistochemistry indeed shows considerable specific INSL3 staining in the cytoplasm of Leydig cells, particularly within what appears to be the Golgi apparatus (Balvers *et al.*, 1998).

Most members of the relaxin-like family of peptide hormones belong to what have been called the group of "neohormones" (Anand-Ivell *et al.*, 2013a). These are endocrine molecules which have evolved to address the physiological needs of becoming a mammal. They are hormones which specifically regulate the uniquely mammalian processes such as internal fertilization, implantation and placentation, birth, and lactation, as well as associated physiological adjustments such as osmotic balance during pregnancy. In males, this required prolonged sperm storage in the epididymis at a cooler temperature, and appropriate mating behavior. The former led to the evolution of a scrotum and the requirement for testes to relocate from a peri-renal position to the inguinal region. Studies in knockout mice show that one of the primary functions of INSL3 is to regulate the first transabdominal phase of testicular descent during gestation (Nef and Parada, 1999; Zimmermann *et al.*, 1999) (see below).

However, neohormones like INSL3 needed to evolve from something else. The presence of INSL3 in lower vertebrates such as fish suggests that INSL3 may have had an earlier role as a local autocrine/paracrine factor regulating testis function, including spermatogenesis (Assis *et al.*, 2016). This role is still evident in modern mammals (see below).

The INSL3 Gene

There is a single autosomal gene in the mammalian genome encoding INSL3 (human chromosome 19 p13.11). Altogether the gene encompasses approximately 5000 nucleotides, with the functional gene comprising two exons and a single intron (**Fig. 2**). Data from RNA-Seq and RT_PCR experiments suggest there may be minor alternative splice variants involving additional sequences from within the single intron (Zarreh Hoshyari Khah *et al.*, 1999; Truong *et al.*, 2003; https://www-ncbi-nlm-nih-gov; gene ID 3640). Surprisingly, the INSL3 gene is very close in the genome to the JAK3 (janus kinase 3) gene and in some species, such as the mouse, is actually collocated within a downstream intron of that gene (Koskimies *et al.*, 1997). The INSL3 gene

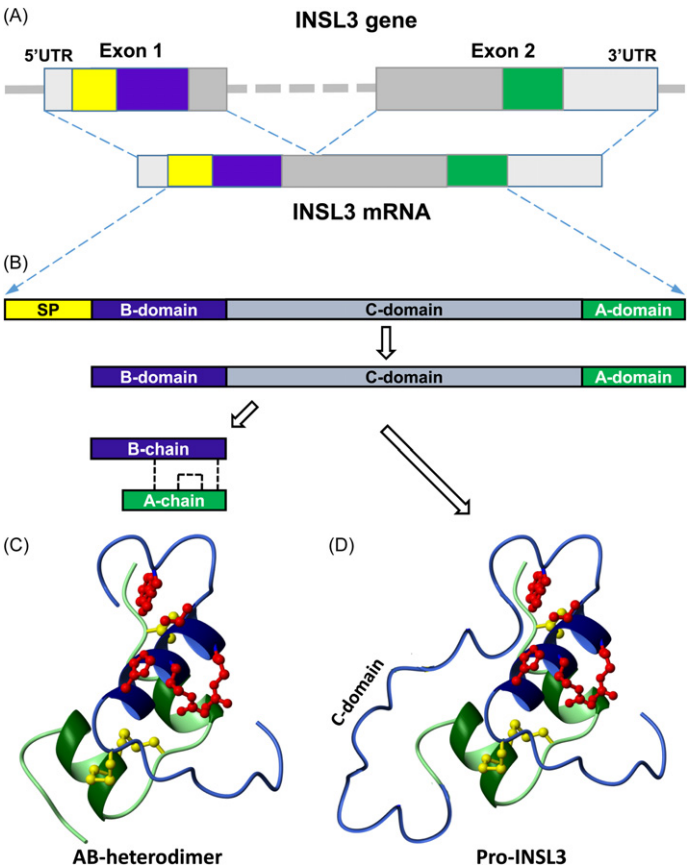

Fig. 2 Scheme to show the structure of the INSL3 gene (A), its derived mRNA, and the primary and secondary translation products (B–D). The preproform first loses its signal peptide (SP) as it is cotranslationally moved to the lumen of the endoplasmic reticulum; the resulting pro-form (pro-INSL3; D) is transported to the Golgi apparatus and thence to secretory vesicles, where it may or may not be cleaved further, with the elimination of the C (connecting) domain, to give rise to the AB-heterodimer (C). Modified after Ivell, R., Wade, J.D., Anand-Ivell, R. (2013). INSL3 as a biomarker of Leydig cell functionality. *Biology of Reproduction* 88, 147.

evidently arose by an ancient gene duplication of the relaxin gene which is still located close to the DMRT1 sex determination locus (human chr. 9p24; Ivell and Grutzner, 2009), and interestingly has maintained some of the original synteny, since the relaxin gene is still located close to the JAK2 gene (Dai *et al.*, 2017a). The proximity to the JAK3 gene also implies that it is likely that all regulatory elements governing the expression of the INSL3 gene are within the confines of only a few thousand nucleotides upstream and downstream of the INSL3 gene, where it does not overlap with JAK3 sequences, since the latter has a quite different pattern of expression.

The regulation of the INSL3 gene has been studied for human, mouse, rat, and bovine sequences (Koskimies *et al.*, 1997; Sadeghian *et al.*, 2005; Tremblay *et al.*, 2009; Dai *et al.*, 2017b). All have in common that the immediate upstream promoter region of about 1000 bp shows the presence of 2 or 3 responsive elements recognizing steroidogenic factor 1 (SF1). Moreover, where it has been studied, one or more of these *cis*-acting SF1 elements is indeed responsible for the activity of the INSL3 gene promoter (Koskimies *et al.*, 1997; Sadeghian *et al.*, 2005; Tremblay *et al.*, 2009; Dai *et al.*, 2017b). The INSL3 gene is thus, like many genes expressed in steroidogenic cells, governed by the interaction of the transcription SF1, or a paralogue like Nur77, with the upstream gene promoter region. Such transcription factors, besides providing cell-type specific activation can also act as platforms for the input from other signaling pathways, either by interaction with other transcription factors or by phosphorylation (Ivell *et al.*, 2014a). There is evidence to suggest that INSL3 may also be regulated by steroid hormones, acting via their specific receptors, although there are no specific steroid receptor responsive elements at least within the immediate region of the INSL3 gene. Using promoter-reporter constructs in mouse Leydig cells, estrogens appear to inhibit and androgens stimulate INSL3 gene expression (Lague and Tremblay, 2009; Tremblay *et al.*, 2009). Studies with other SF1-regulated genes suggest that steroid hormones can have their effect by exploiting nonclassical pathways where the activated steroid receptors do not themselves interact directly with the promoter region (Ivell *et al.*, 2014a).

RXFP2—The INSL3 Receptor

The receptor for INSL3, now known as relaxin family peptide receptor 2 (RXFP2) was the first receptor to be identified for any of the members of the relaxin-like family of peptide hormones. Originally referred to as Great, later as LGR8, and then renamed RXFP2, it was found as a genomic mutation causing cryptorchidism by a failure of the first transabdominal phase of testicular descent, with a very similar phenotype to that caused by deletion of the INSL3 gene (Gorlov *et al.*, 2002; Kumagai *et al.*, 2002). It was later shown that INSL3 is the only ligand able to activate RXFP2, and that INSL3 appears unable to activate any other receptor (Bogatcheva *et al.*, 2003), thus forming a unique ligand-receptor pair. What was truly surprising was that RXFP2 belongs to the group of G-protein coupled receptors with a typical 7-transmembrane region, and thus completely different from the receptors for insulin or the IGFs, which are membrane-linked tyrosine kinase receptors with only a single transmembrane domain. Subsequently, the receptor for relaxin was identified as RXFP1 (previously LGR7; Hsu *et al.*, 2002), as well as those for relaxin-3 and INSL5, RXFP3 and RXFP4, respectively (Bathgate *et al.*, 2006). RXFP1 and RXFP2 are unusual in having very large N-terminal extracellular domains, unlike RXFP3 and RXFP4. These extracellular domains comprise several different modules; at the N-terminus is an LDLa module, this is followed by 10 leucine-rich-repeat structures and then a hinge region before joining the first of the transmembrane domains (**Fig. 3**). Extensive molecular pharmacological studies have now shown that primary binding of INSL3 occurs via its B-chain to different parts of the leucine-rich repeats (Halls *et al.*, 2015). This induces a conformational change which moves the extracellular hormone receptor complex such that contact is made between INSL3 and some of the extracellular loops of the 7-transmembrane domain. At the same time the N-terminal LDLa module is able to induce activation of the receptor and consequently coupling to an intracellular G-protein (Kong *et al.*, 2014). Although there is ligand binding, lack of the LDLa module prevents receptor activation (Kong *et al.*, 2014).

As its name suggests, as a member of the GPCR superfamily, ligand bound RXFP2 leads to activation of an intracellular G-protein. In transfected cell systems where RXFP2 is overexpressed, this is the stimulatory G-protein, $G\alpha_s$ (Heng *et al.*, 2008), activation of which leads to the production of cAMP by adenylyl cyclase. There are few natural cell systems which express functional RXFP2. In bovine ovarian theca cells and also myometrial cells, INSL3 has also been shown to elicit an increase in cAMP production (Dai *et al.*, 2017a), and in Leydig cells INSL3 has been shown to cause an increase in testosterone production (Pathirana *et al.*, 2012), which is also considered a downstream consequence of cAMP production. However, INSL3 has been suggested to activate not $G\alpha_s$, but $G_{i/0}$ via RXFP2 expressed in oocytes (Kawamura *et al.*, 2004).

Considerable work has been done to identify and characterize potential INSL3 agonists and antagonists. For full bioactivity it is essential that the B-chain which interacts with the RXFP2 leucine-rich repeat region maintains the correct conformation. This is dependent upon the correct shape induced by the cysteine-dependent interaction with the more rigid A-chain, which is constrained by an internal cysteine bond. Hence simply scrambling the cysteine bonds, for example, by heating, is sufficient to completely inactivate INSL3. A constrained B-chain dimer has been shown to be an effective antagonist (Shabanpoor *et al.*, 2011), and several amino acids can be removed from the C- and N-termini of the A- and B-chains without jeopardizing activity (Tregear *et al.*, 2009). That these terminal amino acids are less important is also shown by the bioactivity of the pro-form where retention of the C-domain appears to have no quantitative effect on RXFP2 activation (Luo *et al.*, 2009), and can in fact be shortened considerably without loss of activity.

The gene encoding RXFP2 (human chromosome 13q13.1) is relatively large comprising 18 exons (**Fig. 3**A). Most of these encode the extracellular N-terminal domain of the receptor, where each of the 10 leucine-rich repeats is encoded by a separate

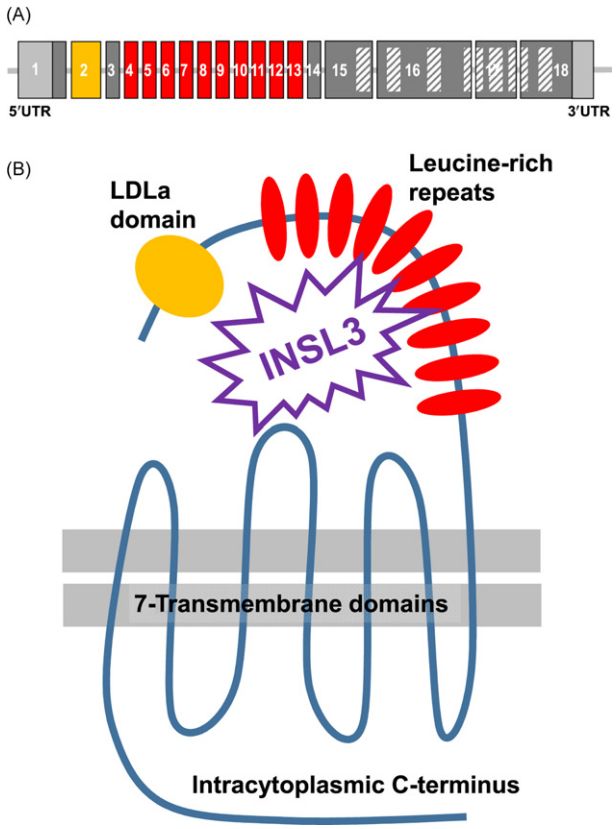

Fig. 3 Scheme to show the exon structure of the RXFP2 gene (A). The regions encoding membrane-spanning domains are indicated by cross-hatching. (B) Simplified structure of the RXFP2 receptor protein. *Yellow* and *red* colors indicate the LDLa and leucine-rich repeat domains, respectively.

short exon. RNA analysis has shown that the RXFP2 gene in different species can be expressed with multiple splice variants, many of which involve the differential splicing of exons 4–13 which encode the leucine-rich repeats (Muda *et al.*, 2005; Anand-Ivell *et al.*, 2006a; Heng *et al.*, 2008; Hanna *et al.*, 2010; Dai *et al.*, 2017a). Mostly such splice variants do not lead to frame-shifts and new stop codons, but merely produce a protein lacking one or more of the leucine-rich repeats. Whether these are expressed and functional is not known, though it seems likely that the binding of INSL3 will be compromised.

RXFP2 transcripts have been identified in several cell-types and tissues, though in few of these has its functionality been verified. Best studied are the RXFP2 receptors on the fetal gubernaculum, particularly in rodents (Kubota *et al.*, 2002; Yuan *et al.*, 2010; Kaftanovskaya *et al.*, 2011; Barthold *et al.*, 2014). These are responsible for the thickening of the gubernacular ligament which retains the fetal testes in the inguinal region during the first phase of testicular descent while the other abdominal organs are growing in an antero-dorsal direction. INSL3 has been shown to induce gubernacular cell growth also in culture (Kubota *et al.*, 2002). It is believed that expression of the RXFP2 gene in the gubernaculum is dependent on androgens produced by the fetal testis (Yuan *et al.*, 2010), though no studies have examined the regulatory elements involved at a molecular level. Within the testes, RXFP2 has been identified at both mRNA and protein level in both humans and rodents within pre- and postmeiotic germ cells and within the Leydig cells themselves, and no other cell types (Anand-Ivell *et al.*, 2006a; Feng *et al.*, 2007; Minagawa *et al.*, 2012). Interestingly, within the ovary, RXFP2 is expressed in the corresponding female cells, namely the oocytes and in the theca interna cells of growing ovarian follicles (Hanna *et al.*, 2010; Dai *et al.*, 2017a). RXFP2 expression has also been identified at the transcript level in bone cells (Ferlin *et al.*, 2008, 2011), brain (Sedaghat *et al.*, 2008), thyroid gland (Hombach-Klonisch *et al.*, 2010), and in the glomerular capsules of the kidney (Fu *et al.*, 2006). The role of INSL3 in these cells is considered in later sections.

INSL3 Antibodies and Immunoassays

Because the native INSL3 molecule is highly constrained with a defined three-dimensional structure, only antibodies which have been raised against INSL3 in its native conformation seem able to recognize the peptide when present in blood and other fluid matrices. Such antibodies do not appear to recognize well INSL3-containing moieties in western blots, probably due to antigenic epitopes being obscured during blotting, denaturation of the correct conformation during electrophoresis, and possibly simple loss of small molecules. In contrast, some antibodies have been raised against unconstrained free terminal peptides from the

B-chain, or against the denatured recombinant pro-form; these appear to be effective in immunohistochemistry or on western blots, particularly where these involve a denaturation step such as antigen retrieval. The effectiveness of the antibodies raised against the pro-form is probably due to the antigenicity of the relatively unconstrained C-peptide domain which is still present. A consequence of such observations is that western blots often only indicate the presence of the larger pro-form of INSL3 and not the 6 kD heterodimer. This does not necessarily mean that the latter is absent in vivo. Furthermore, when measuring INSL3 by immunoassay, this does not reveal the molecular form of the INSL3 which might be present as a secreted pro-form, which is similarly bioactive.

Several immunoassays have been developed against INSL3 from various species. Whilst the time-resolved fluorescent immunoassay (TRFIA) has provided consistent and robust values for INSL3 for more than a decade, with measurements usually as singlets in a range of matrices and low coefficients of variation, and detection limits as low as 10 ng L^{-1} (Ivell and Anand-Ivell, 2009), earlier radioimmunoassay and ELISA formats often gave rise to inconsistent data different from the TRFIA. Recent studies by several assays now confirm that adult men have a median INSL3 in their circulation of between 0.7 and 1.2 μg L^{-1}, depending on age, whereas women have much lower levels ranging from undetectable up to about 100 ng L^{-1} (see below). In other male mammals using different assays, circulating INSL3 can be much higher, up to 20 μg L^{-1} (**Table 1**). Interestingly, there appear to be differences in serum concentration also depending upon breed within a species (Anand-Ivell *et al.*, 2009, 2011), implying a genetic element in determining INSL3 production.

INSL3 in the Fetus

The first phase of testicular descent whereby the testes which, like the ovaries, are originally in a perirenal position, are retained in the inguinal region while the kidneys and other abdominal organs grow away in an antero-dorsal direction, is due to a thickening of the ventral gubernacular ligament and simultaneous relaxation of the cranial suspensory ligament. Loss of either INSL3 or its receptor RXFP2 in the fetus leads to a failure of the testes to relocate to the inguinal region (Ivell and Hartung, 2003). Loss of androgen action as in the *tfm* mouse leads to retention of the cranial suspensory ligament and the positioning of the fetal testes somewhere between the kidneys and the inguinal region, since now both ventral and cranial ligaments are competing to position the fetal testes. The second phase of testicular descent which involves the movement of the testis and epididymis from above the inguinal ring in the abdominal cavity through the inguinal canal into the scrotum, appears to require androgens and possibly also the anti-Müllerian hormone (AMH), which is also responsible for the involution of the Müllerian duct in the male fetus. Whether INSL3 and RXFP2 are involved and/or essential for this second phase of testicular descent is not clear (Yuan *et al.*, 2010).

There are important species differences in the timing of testicular descent in the male fetus (Anand-Ivell and Ivell, 2014). Whereas in humans and in ruminants, the first INSL3-dependent phase begins early, during the transition from the first to second

Table 1 Average blood levels of INSL3 in different mammalian species

trimester of gestation, in pigs and dogs this phase occurs somewhat later during mid-gestation, and in rodents this phase does not occur until close to the end of the third trimester. This is important to understand since factors influencing testicular descent in rodents may have quite different phenotypic associations compared to factors affecting testicular descent in humans. Similarly, the sensitive exposure window for impacts on testis function and testis descent in rodents is quite late (70%–80% of gestation) compared to humans (25%–50% of gestation).

Corresponding to the first phase of testicular descent, analysis of human amniotic fluid samples collected at routine amniocentesis shows highest INSL3 concentration from weeks 12–16 of pregnancy, declining thereafter (Anand-Ivell *et al.*, 2008). In contrast, highest concentrations of INSL3 in fetal rat serum occur on days 17 and 19 of gestation (Anand-Ivell and Ivell, 2014). Importantly, for monotocous species such as the human or the cow, with mostly only a single fetus, fetal INSL3 can only be detected in body fluids derived from male fetuses (Anand-Ivell *et al.*, 2008, 2011); in female fetuses, which have no testes, and where the ovaries are hormonally relatively quiescent, INSL3 is consistently below the level of detection. This is not true for polytocous species, such as the pig, with multiple fetuses within a pregnancy, where we have shown that INSL3 is indeed detectable in amniotic and allantoic fluids as well as in fetal serum from female fetuses, albeit at lower levels than in male fetuses (Vernunft *et al.*, 2016). Detailed analysis of fetal location during pregnancy makes it clear that particularly early in gestation INSL3 is being transported from male fetuses to neighboring female fetuses (Vernunft *et al.*, 2016). Whether this has any consequences for the affected female fetuses is not known.

In the bovine, we could show that INSL3 is evidently also crossing the placenta from male fetuses at mid-gestation to cause a significant increase in circulating maternal INSL3 (Anand-Ivell *et al.*, 2011). Since only male fetuses and neither female fetuses nor the pregnant mothers are producing INSL3, this means that INSL3 is an absolutely fetal gender-specific hormone able to influence either placental or maternal physiology if its receptor RXFP2 is expressed. There are numerous reported instances for women of fetal gender impacting on maternal pathology or physiology (Clifton, 2010; Leon-Garcia *et al.*, 2016); while it has often been assumed that this is due to fetal steroid hormones, these are much less fetal gender-specific than is the case for INSL3 (Anand-Ivell *et al.*, 2008). Future research will determine whether fetal INSL3 is indeed part of a fetal gender recognition system. Another aspect of this is that measurement of maternal INSL3, at least in mid bovine gestation, can be used as an effective indicator of fetal gender (Anand-Ivell *et al.*, 2011). Whether this is true for other species has not been studied.

Testis development and descent is proceeding very actively in the transition from first to second trimester in the human. Thus any factor which reflects this organogenetic activity is also acting as an overarching sentinel of fetal wellbeing in this important but analytically obscure phase of human pregnancy. INSL3 can be considered therefore as a significant indicator of pregnancy health and the effect of a range of environmental impacts (Anand-Ivell and Ivell, 2014). In one study it was shown that mid-gestation amniotic INSL3 was significantly higher in women who later became preeclamptic than in controls (Anand-Ivell *et al.*, 2008). In another study, amniotic INSL3 concentration was negatively affected by maternal smoking, unlike testosterone, and was also negatively impacted by maternal exposures to certain phthalate metabolites, known to affect male reproductive parameters in rodent studies (Jensen *et al.*, 2015). Also the ubiquitous endocrine–disrupting chemical PFOS was shown to be negatively correlated with INSL3 in the same large cohort of human amniotic fluid samples (Toft *et al.*, 2016). Due to improvements in assessment of fetal cell DNA analysis, mid-gestation human amniotic fluid is unlikely to continue being accessed routinely in the future. Nevertheless, this does offer one of the few media which can provide considerable endocrine information about fetal wellbeing. Perhaps improved future methodology might be able to revive this valuable diagnostic opportunity.

As an alternative to measuring INSL3 in amniotic fluid, several studies have attempted to make use of cord blood (Bay *et al.*, 2007; Araki *et al.*, 2014; Mitsui *et al.*, 2015; Chevalier *et al.*, 2015; Fenichel *et al.*, 2015). Inevitably, INSL3 concentration is already reduced in venous fetal blood at term of pregnancy, so long after the events of testis development and descent. As anticipated, significant differences in INSL3 concentration can be detected between cord bloods from male and female fetuses. Moreover, independent studies indeed suggest a negative effect at the population level of maternal phthalate or bisphenol A exposure on cord blood INSL3 levels (Araki *et al.*, 2014; Chevalier *et al.*, 2015). One study also showed a negative relationship between cord blood INSL3 and the incidence of idiopathic cryptorchidism (Fenichel *et al.*, 2015). The latter is somewhat surprising, given that the recent large study of Danish amniotic fluids collected at the end of the first trimester of pregnancy failed to show any relationship between amniotic INSL3 concentration and the incidence of cryptorchidism or hypospadias (Jensen *et al.*, 2015).

In the male fetus, INSL3 is made exclusively by the steroidogenic Leydig cells of the fetal testes, and although these appear to have a common origin with cells of the adrenal gland, the latter do not appear to express INSL3, nor do any cells in the ovaries of female fetuses. There have been numerous experimental studies examining the impacts of a range of putative endocrine disrupting chemicals either in pregnant rodents or using explanted human fetal tissues. Early studies exposing pregnant rodents to estrogens, such as estradiol or diethylstilbestrol (DES), confirmed findings from women treated with DES during pregnancy that this steroid at moderately high concentration effectively impacted on testis development leading to cryptorchidism. This was apparently due to a suppression of Leydig cell differentiation and loss of INSL3 expression (Emmen *et al.*, 2000). Other compounds such as phthalates were shown to have a similar effect, at least in rats, leading to what has been named the "phthalate syndrome" (Foster, 2006), with resultant testicular dysgenesis and cryptorchidism, and loss of INSL3 expression in the late gestation male fetus. Studies with human fetal testis xenograft or explant cultures have only partly confirmed this effect of phthalates on fetal Leydig cell function and INSL3 expression (Albert and Jegou, 2014). More recently, it has been shown that exposure to common analgesics such as paracetamol, aspirin or ibuprofen can also impact on Leydig cell differentiation, using such culture systems (Mazaud-Guittot *et al.*, 2013; Ben Maamar *et al.*, 2017). Importantly, it could be shown that the age of the fetal testis (gestational weeks

10–12) was critical in order to see the negative effects (Ben Maamar *et al.*, 2017), younger or older testes failing to respond, again emphasizing the importance of a critical "window of sensitivity."

Considerable research effort in this area has shown that there are differences between rodents and humans in terms of sensitivity to endocrine-disrupting chemicals and in terms of the time windows of exposure. Moreover, often high experimental exposure levels are required before significant effects are evident. In real life, exposures will always be multiple and complex. Importantly, INSL3 has shown itself to be a sensitive and specific biomarker for testis development during these critical phases, both in the human and in rodent studies.

INSL3 in Male Puberty

Following birth and the descent of the testes into the scrotum there is usually a shorter or longer period of relative hormone quiescence in all mammals. In humans, where this period lasts several years, there is usually a short phase, referred to as the "minipuberty" at about 3 months of age. This is associated with an increase in circulating testosterone thought to be important in masculinizing the brain and perhaps finalizing the location of the testes in the scrotum. There appears to be a small increase in circulating INSL3 at this time in most male infants (Bay *et al.*, 2007), although this has not been studied in depth.

The postnatal prepuberal period is typified by an involuted testis with small relatively undifferentiated Leydig cells, which at least in rodents appear to be a product of an independent lineage from the fetal Leydig cells. These Leydig stem cells are located around the seminiferous tubules and are activated to proliferate and then differentiate under the influence of pituitary LH as puberty progresses. Once puberty is complete, there appears to be very little if any further proliferation of Leydig cells, nor is there any evidence of substantial cell death, such that the complement of Leydig cells present in the testes at the end of puberty remains roughly the same throughout life.

Puberty itself is initiated with the increase in GnRH pulsatility and pituitary gonadotrope activity, leading to increased circulating testosterone levels, and accompanying signs of male hormone activity, such as the onset of spermatogenesis, skeletal development and pubic hair. As end-points, the hormones of the hypothalamic–pituitary–gonadal (HPG) axis, particularly during puberty and particularly for testosterone, are very variable with massive diurnal and within-individual variations. In contrast, INSL3 appears to be a very good monitor of pubertal progression in young male mammals (Ivell *et al.*, 2014b). The reason for this is that INSL3 appears to be secreted only by relatively mature Leydig cells and in a constitutive manner, independently of any acute stimulation or effects of the HPG axis (Ivell and Anand-Ivell, 2009). Circulating INSL3 uniquely reflects the number and differentiation status of the Leydig cells in the testes. Consequently, unlike testosterone, it does not show any diurnal variation (Chong *et al.*, 2015), and repeat sampling within an individual appears to be remarkably consistent. In laboratory rats, INSL3 increases to a maximum at around the time of the first appearance of sperm in the ejaculate (42 days) and subsequently declines to an adult level which changes little in ensuing months (Anand-Ivell *et al.*, 2009). This profile is interesting in that it appears to reflect closely the dramatic activity of the HPG axis during pubertal development, followed by the gradual decline in such activity once puberty has been attained and hormones become stabilized during young adulthood. Unfortunately, similarly detailed profiles are not yet available for other species, including humans. Of the studies carried out in humans, most only continued to Tanner stage 5 (about 14–15 years) and thus preclude later events (Wikstrom *et al.*, 2006; Ferlin *et al.*, 2006; Johansen *et al.*, 2014). Such studies also encompass large between-individual variability due to the differences in the ages at which boys enter puberty. Future research will need to explore the origins of such large variation. Evidence from experimental animals strongly suggests that environmental factors, such as maternal exposure to endocrine-disrupting chemicals can alter the pubertal trajectory (Anand-Ivell and Ivell, 2014). Also childhood nutrition and obesity may significantly impact on pubertal progression (Tinggaard *et al.*, 2012).

INSL3, as the only constitutive Leydig cell biomarker, is optimally suited to investigate the normal physiology and pathology of pubertal progression in male mammals and will ideally complement visual Tanner staging or estimates of scrotal size. Not only can it be used to confirm primary or secondary hypogonadism (Trabado *et al.*, 2014), but as a quantitatively sensitive and constitutive biomarker it offers the potential to differentiate a wide range of pubertal pathologies.

Seasonally breeding mammals, such as deer or hamsters appear to pass through sequential phases of testis involution and regeneration, in a day-length dependent manner, not dissimilar to what occurs in puberty. INSL3 immunohistochemistry of the Leydig cells accurately reflects these differentiation changes (Ivell *et al.*, 2003; Hombach-Klonisch *et al.*, 2004), suggesting that circulating INSL3 could be used effectively as a biomarker to monitor these seasonal changes.

INSL3 and the Aging Male

Measurement of INSL3 in men across the lifespan shows that Leydig cell functional capacity (numbers × differentiation status) appears to decline in old age (Anand-Ivell *et al.*, 2006b). Unlike the other Leydig cell product, testosterone, which declines at the population level at approximately 7% per decade, INSL3 declines at closer to 14% per decade. This difference is due to the fact that testosterone feeds back to the HPG axis and is acutely regulated by LH from the pituitary gland; as testosterone decreases, LH secretion is increased in order to compensate the HPG axis. This does not occur for INSL3, which being constitutively expressed is not acutely stimulated by LH and thus not compensated in the same way. Consequently, INSL3 accurately reflects the overall functional capacity of the Leydig cells, also to make testosterone. Multiple correlation analysis shows that INSL3 correlates closely

with total testosterone, and is negatively associated with smoking, as well as with obesity (as BMI) and muscle weakness (Atlantis *et al.*, 2009). Because INSL3 is expressed constitutively and is not subject to the large within-individual variation observed with testosterone, it is likely that INSL3 will prove to be a very useful biomarker for testis function in future aging studies.

A similar decline with age in testicular INSL3 production is also evident in rodents (Paust *et al.*, 2002; Anand-Ivell *et al.*, 2009), so that these can be used effectively to assess testicular changes in response to aging.

INSL3 and Testicular Cancer

There is little information regarding INSL3 in the context of testicular cancer. Whereas Leydig cell hyperplasia indicates an increase in the number of Leydig cells, these do not appear to show much alteration in INSL3 expression within individual cells (Lakis *et al.*, 2017). In contrast, where Leydig cells have formed true tumors, these cells appear to be less differentiated, showing only very little or no immunohistochemical staining for INSL3 (Klonisch *et al.*, 1999; Lakis *et al.*, 2017). However, where there is marked testicular dysgenesis from various causes, Leydig cells may exhibit a broad range of INSL3 expression (Lottrup *et al.*, 2014).

INSL3 in the Female

Although INSL3 has maximal expression in the male, it is nevertheless also expressed at lower levels in the adult female mammal. It is expressed in the ovary at both mRNA and peptide levels, particularly within the steroidogenic theca interna cells of healthy growing antral follicles (Bamberger *et al.*, 1999; Irving-Rodgers *et al.*, 2002). These are the equivalent cells in the female to the Leydig cells in the male. Using the bovine model, it has been shown that theca cell INSL3 expression is essential to promote the formation of androstenedione by theca cells, and that this is controlled in an autocrine/paracrine manner via RXFP2 receptors present on the theca cells themselves, which respond to INSL3 with an elevation of cAMP (Glister *et al.*, 2013; Dai *et al.*, 2017a). In synchronized bovine cycles, INSL3 has been measured in blood in exact correspondence with the growth of antral follicles within a wave (Satchell *et al.*, 2013). Comparable results have been observed for the human, where INSL3 in the blood of healthy young women also appears to follow a pattern representing repeated waves of follicle growth, achieving a maximum concentration of approximately 100 ng L^{-1} (Anand-Ivell *et al.*, 2013b). Moreover, circulating INSL3 concentration correlates significantly with antral follicle count measured by ultrasound (Anand-Ivell *et al.*, 2013b). Assessment of INSL3 in a large population of women attending an infertility clinic indicated that only low ovarian reserve (reduced) or polycystic ovarian syndrome (PCOS; increased) significantly altered the circulating levels of INSL3 (Anand-Ivell *et al.*, 2013b). Whether, INSL3 is directly involved in the etiology of PCOS is not known, since the higher circulating levels of INSL3 may simply reflect the increased theca cell mass in these subjects. Nevertheless a genetic study has shown a significant association between one INSL3 polymorphism and the incidence of PCOS (Shaikh *et al.*, 2016), indirectly suggesting a possible causative interaction. Measurement of INSL3 in follicular fluid from healthy cows (Dai *et al.*, 2017a) and monkeys (Hanna *et al.*, 2010) shows that concentrations are quite high (>100 μg L^{-1}).

In mice, where the INSL3 gene has been inactivated, the females show reduced fertility with a smaller litter size and fewer corpora lutea (and hence fewer follicles) (Spanel-Borowski *et al.*, 2001). Interestingly, not only theca cells have RXFP2 receptors, but also the oocytes themselves in rodents and cows express RXFP2. How these receptors are involved in oocyte function is not yet clear, though preliminary studies in mice suggest that INSL3 may induce increased intracellular $Ca2^{+}$ in the oocytes (Kawamura *et al.*, 2004). Although the follicles appear to be the major source of INSL3 in the ovary, INSL3 mRNA and immunoreactivity have also been detected in corpora lutea from human, monkey, bovine and mouse ovaries (Bathgate *et al.*, 1996; Balvers *et al.*, 1998; Bamberger *et al.*, 1999; Hanna *et al.*, 2010); however, comparison with the patterns of INSL3 in the blood implies that the corpora lutea are probably not contributing to the circulating hormone.

Because INSL3 is produced mostly from growing antral follicles, it cannot be measured in blood from prepuberal girls (Hagen *et al.*, 2015), nor is it detectable in postmenopausal women (Ivell and Anand-Ivell, 2009).

Physiology of INSL3

INSL3 and Bone Metabolism

Mice in which the INSL3 gene has been inactivated or humans carrying a deleterious mutation in the gene for RXFP2 both consistently exhibit a high degree of osteopenia or osteoporosis (Ferlin *et al.*, 2008). Subsequent studies using cultured osteoblast and osteoclasts indicate that INSL3, acting via RXFP2, can directly modulate bone cell metabolism (Ferlin *et al.*, 2011). This is important since it shows that aging or age-related bone pathology might not only be dependent on diminishing steroid production from the testes or ovaries, as is generally conceived, but that the associated loss of circulating INSL3 is also implicated.

INSL3 and Horn Growth in Ruminants

Not unrelated to bone metabolism, genetic studies in ruminants have also shown that the INSL3–RXFP2 system is evidently also involved in horn growth, with particular SNPs significantly associated with larger and stronger horns (Johnston *et al.*, 2013).

INSL3 and the Kidney

The kidney has been identified as also expressing RXFP2 receptors, specifically within the mesangial cells of the developing glomeruli (Fu *et al.*, 2006). Moreover, treatment of primary rat glomerular cells in culture with INSL3 indicates a significant effect on cell growth (Fu *et al.*, 2006). Taken together with an observed altered electrolyte balance in RXFP2-deficient mice (http://www.informatics.jax.org/), this would indicate that INSL3, at least in the male, may be involved in renal function.

Spermatogenesis

RXFP2 receptors are present on pre- and postmeiotic stages of male germ cells in rodents and humans (Kawamura *et al.*, 2004; Anand-Ivell *et al.*, 2006a,b). Whilst studies in mice have been problematic due to the primary phenotype of cryptorchidism, other studies suggest that INSL3 may exert an antiapoptotic or pro-survival influence on male germ cells. In humans subject to a steroidal contraceptive regimen, it was shown that maximum reduction in sperm counts was attained significantly in those men with lowest circulating INSL3 concentration (Amory *et al.*, 2007). Moreover, active immunization of boars using an INSL3 immunogen also indicated a significant increase in apoptotic germ cells in the testes and reduced testis weight (Sagata *et al.*, 2015). Injection of a specific INSL3 antagonist into the testes of rats also leads to a significant reduction in size of the treated testes with notable germ cell apoptosis (Del Borgo *et al.*, 2006). Analysis of INSL3 peptide in the testes of rats and boars shows that, as expected, greatest INSL3 concentrations are found in the immediate neighborhood of the Leydig cells in the interstitial space (200–400 μg L^{-1}), but nevertheless significant amounts of the peptide are also transported across the blood-testis barrier to reach the seminiferous compartment (**Fig. 4**; Anand-Ivell *et al.*, 2009; Minagawa *et al.*, 2012) and hence are able to interact with RXFP2 on both pre- and postmeiotic germ cells.

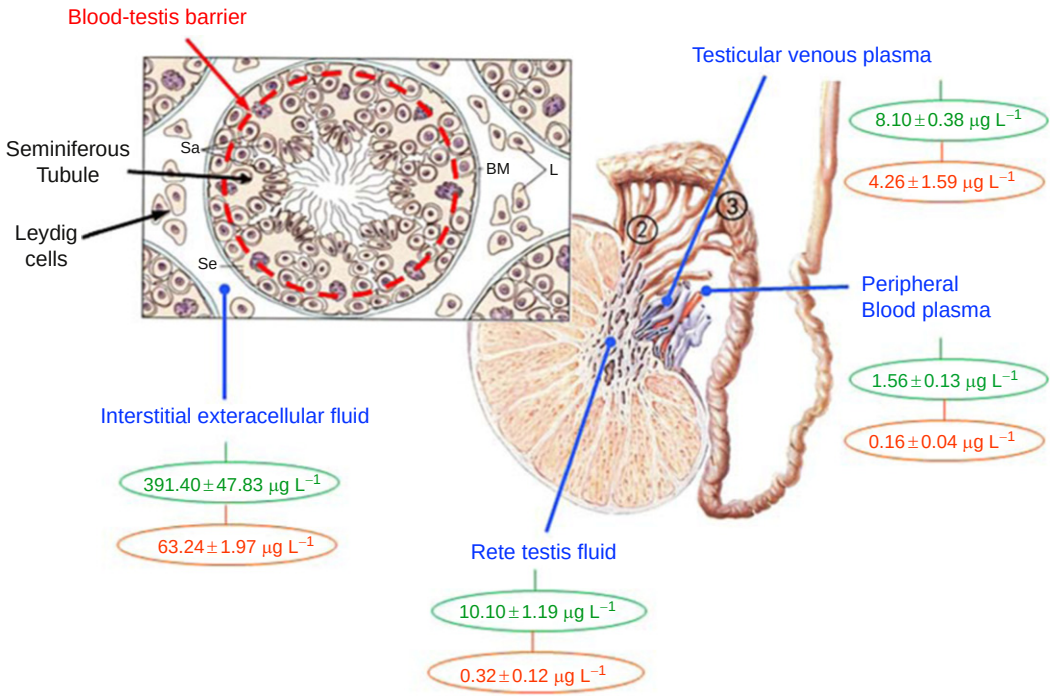

Fig. 4 The dynamics of INSL3 flow within the rat testis. Rat INSL3 was firstly measured (*green* data lozenges) using a species-specific immunoassay in different testicular fluid compartments (as indicated). In a second set of experiments human INSL3 was injected into the interstitial extracellular fluid of the rat testis and its distribution monitored after 30 min using a human INSL3 specific immunoassay (*orange* data lozenges) which did not recognize rat INSL3 at all (for details see Anand-Ivell, R., Heng, K., Hafen, B., Setchell, B., Ivell, R. (2009). Dynamics of INSL3 peptide expression in the rodent testis. *Biology of Reproduction* 81, 480–487, reproduced with permission). The findings clearly show that INSL3 from the interstitial fluid surrounding the Leydig cells is able to be transported not only into the bloodstream but importantly also across the blood-testis barrier to the seminiferous compartment where it can interact with RXFP2 receptors present on male germ cells.

INSL3 and RXFP2 in the Brain

RXFP2 has been described throughout the thalamic region of the rat brain, particularly in those areas of the sensorimotor system responding to dopaminergic innervation (Sedaghat *et al.*, 2008). Moreover, preliminary phenotypic observation suggests mild behavioral impairment and hypoactivity in mice in which the *rxfp2* gene has been inactivated (http://www.informatics.jax.org/), which would support a role for the INSL3–RXFP2 system in the rodent brain. The ligand itself has not been detected in the brain or its regions in mice or bovine by northern hybridization (Pusch *et al.*, 1996; Bathgate *et al.*, 1996), but it is plausible that low levels of peptide may be produced locally within the brain. Whether circulating INSL3 in the blood can cross the blood-brain barrier is not known.

INSL3 and the Adrenal Gland

Although steroidogenic adrenocortical cells appears to share a common embryological origin with at least a subpopulation of fetal Leydig cells, the normal healthy adrenal gland does not express the INSL3 gene in rodents or humans. Nevertheless, certain adrenal pathologies do appear to show INSL3 expression within regions of macronodular adrenal hyperplasia (Lefebvre *et al.*, 2003). Also in a mouse model of pituitary hyperstimulation, caused by gonadectomy, INSL3 can be detected in the neoplastically enlarged adrenal glands (Schillebeeckx *et al.*, 2015).

Other Systems (Thyroid, Mammary, Prostate)

Using a combination of immunohistochemistry and RT-PCR, components of the INSL3–RXFP2 system have also been detected, particularly within the epithelial cells of the thyroid, mammary and prostate glands (Hombach-Klonisch *et al.*, 2000, 2004; Klonisch *et al.*, 2005). Of note is that for the thyroid the system was most expressed in neoplastic and hyperplastic cells, though not in normal tissues (Hombach-Klonisch *et al.*, 2004). The reverse appears to be the case for the mammary gland (Hombach-Klonisch *et al.*, 2000), and for the prostate gland, some carcinoma-derived cell-lines appeared to express both receptor and ligand, as was also suggested by the studies of benign hyperplastic prostate tissue (Klonisch *et al.*, 2005).

Genetics and Variants of INSL3 and RXFP2

Both INSL3 and RXFP2 are autosomally expressed genes. Since they form an essential hormone-receptor system responsible for testicular descent any dominant or homozygous mutation in either gene is likely to lead to cryptorchidism and infertility. Consequently, only mutations are found in the human population which are nonfunctional, recessive, or otherwise spontaneous and extremely rare. For INSL3 there are three common polymorphisms identified, G27A, G126A, G178A, only the last of which leads to a missense mutation (Ala/Thr). However these do not appear to be associated specifically with cryptorchidism and are equally represented in cryptorchids and normal controls (Koskimies *et al.*, 2000; Krausz *et al.*, 2000; Takahashi *et al.*, 2001; Lim *et al.*, 2001; Baker *et al.*, 2002; Feng *et al.*, 2004; Mamoulakis *et al.*, 2014; Huang *et al.*, 2016). Nor does there appear to be any association between these variants and male infertility (Yun *et al.*, 2007). More recently, for a Moroccan population, El Houate *et al.* (2007) identified three new INSL3 variants in 109 cryptorchid men and in none of 270 controls. One of these was in the gene promoter (C-19G), and two were missense mutations in the coding region (G52A, G319A). Of the latter the G52A variant caused a change from valine to methionine and could be shown in vitro to cause a significant reduction in cAMP production using a transfected RXFP2 system (El Houate *et al.*, 2007).

For RXFP2 the situation appears to be similar. Whilst SNPs associated with RXFP2 do turn up as significantly associated in some GWAS studies, for example with temporomandibular disorder in women (Sanders *et al.*, 2017), or with udder conformation traits in cows (Pausch *et al.*, 2016), no variant is consistently and significantly linked to cryptorchidism. Nevertheless, two missense variants (T222P and R223K) both within one of the extracellular leucine-rich repeats, do appear to be suggestively linked to cryptorchidism. In vitro both mutations expressed homozygously in cells appear to compromise membrane expression of the receptor (Bogatcheva *et al.*, 2007). Yet, whereas in an Italian population the T222P mutation associated significantly with cryptorchidism (Ferlin *et al.*, 2009), this was not the case for a Moroccan or a Spanish population (El Houate *et al.*, 2008; Ars *et al.*, 2011). Moreover, for the Italian population in 22 men carrying the T222P mutation 64% had significantly reduced bone mineral density (Ferlin *et al.*, 2008), strongly implying the functionality of this heterozygous missense mutation.

Taken together, and since none of the mutations are occurring homozygously, we can conclude that some of the missense mutations, though rare, appear to be conferring a susceptibility to cryptorchidism, and possibly to other maladies, evidently working together with other genetic and possibly environmental elements. This was emphasized in data from the Italian population where amongst a large population of cryptorchid boys and taking all variants of INSL3 and RXFP2 together, only 7/600 indicated mutations for all subjects at birth, 7/303 where there was persistent unilateral cryptorchidism, 5/120 where there was persistent bilateral cryptorchidism, and none in a control population (Ferlin *et al.*, 2009). Thus while these heterozygous genetic variants individually may not necessarily confer pathology, at a population level they are significant, also, for example, in association with PCOS incidence (Shaikh *et al.*, 2016). Interestingly, in the case of the involvement of RXFP2 with horn growth in

ruminants, it was shown that this represents a rare example of a genetic trade-off between sexual selection for large horns, and natural selection for simple survival (Johnston *et al.*, 2013).

Summary and Outlook

INSL3 as a New Clinical Biomarker

Because of its constitutive expression and low within-individual variation INSL3 is proving to be a valuable new clinical biomarker for the assessment of Leydig cell status, especially in the context of fetal development, male pubertal development, and in male aging. It may also prove important in the differential analysis of ovarian function in women and in PCOS.

INSL3 as a Male-Specific Hormone

Increasingly, INSL3 is being highlighted as a gender-specific hormone, with male-specific functions in the context of testicular descent and cryptorchidism, in spermatogenesis, and possibly in bone metabolism. Nevertheless, within the female, INSL3 at a local, paracrine level has been shown to be an essential component of ovarian steroidogenesis and follicle development.

Knowledge Gaps

There are still substantial gaps in our understanding of INSL3 physiology. For example, during pregnancy, INSL3 appears to be absolutely fetal gender-specific (unlike testosterone) and thus competent to inform both the mother and placenta, and potentially other fetuses of the existence of a male fetus. Could this offer an explanation for the numerous gestational pathologies with a demonstrated link to fetal gender? We still know very little about other physiological systems where the INSL3/RXFP2 system appears to be expressed, for example, in the thyroid gland or in the kidney. Finally, since INSL3 declines markedly with age, and is absent in postmenopausal women, it might be worth investigating whether INSL3 or an analogue should be included as part of any HRT concept, especially considering its potential role in bone metabolism and pathology.

Epididymis

Maria Christina W Avellar, Federal University of São Paulo, Paulista School of Medicine, São Paulo, Brazil
Barry T Hinton, University of Virginia School of Medicine, Charlottesville, VA, United States

Glossary

Androgen Generic term for an agent, usually a hormone (e.g., testosterone, androsterone), that stimulates the activity of the accessory male sex hormones and the genesis of spermatozoa.

Cryptorchidism The failure of one or both testes to descend into the scrotum, leading to male infertility if the testes are not surgically placed into the scrotum before puberty.

Epididymitis Inflammation of the epididymis.

Testosterone Male sex hormone produced by the Leydig cells within the testis responsible for maintaining male secondary sex characteristics.

Transcription factor Proteins involved in the process of transcribing DNA into messenger RNA by binding to a specific DNA sequence.

Wolffian Duct Eponym for the mesonephric duct. So named after Caspar Friedrich Wolff, who described the ducts in chick embryos.

Basic Development, Structure, and Function

The epididymis originates as a tube/duct from the mesonephros, called the mesonephric duct or the Wolffian duct (also referred to as the nephric duct). As the primitive duct migrates from the rostral end of the embryo to fuse with the cloaca (which will become the bladder), it induces a series of mesonephric tubules from the surrounding mesenchyme. These tubules will eventually form the efferent ducts that connect the testis to the epididymis. During embryonic and postnatal development, there is considerable elongation and coiling such that the epididymis reaches in adulthood approximately 6 m in the human, 3 m in the rat, and 1 m in the mouse. This highly convoluted epididymal duct connects the efferent ductules to the vas deferens. The epididymal epithelium differentiates into a number of cell types (see below) during the postnatal period. In the rat, this postnatal epididymal growth and differentiation is composed of an undifferentiated period between postnatal days 1–15, followed by a differentiation phase between postnatal days 15–44 (when spermatozoa are first observed in the lumen), and finally an expansion period from postnatal day 44 to adulthood (for review see Robaire and Hinton, 2015).

Classically, the epididymis is divided into several regions: initial segment, caput, corpus, and cauda, although some investigators include the initial segment as a part of the caput (**Fig. 1**). With the advent of gene array studies and further exploration of the gross anatomy of rodent epididymides, the epididymis was further subdivided into segments, for example, in the mouse there are 10 segments and in the rat, 19 segments (**Fig. 1**). Comparing regions to segments in the rat: the "initial segment" region corresponds to segments 1–4, the caput corresponds to segments 5–11, the corpus corresponds to segments 12–13 and the cauda corresponds to segments 14–19. Each segment expresses its own repertoire of genes that are unique to that segment and overlap with adjacent segments, for example, in the rat epididymis, the β-defensin gene *Defb42* is only expressed in segment 1, whereas *Defb13* is expressed in segments 8–11 (**Fig. 1**).

Epididymal epithelial cell types that differentiate during the postnatal period include: principal, basal, apical, clear, narrow, and halo cells. Dendritic cells are also found and surround the epithelial cells to varying degrees in each segment. Current studies focus on examining the role(s) of each cell type.

Sperm maturation is a collective term meaning that as spermatozoa progress along the epididymis, they acquire the ability to swim in a forward direction and develop the ability to recognize and fertilize an egg. The exact mechanisms by which sperm maturation occurs are not known although there are some mouse null mutations of certain genes that result in the failure of sperm to undergo maturation. Examples of such genes include *Ros1*, *Dicer1*, *Pten*, *Lgr4*, *Pkd1*, *Foxi1*, members of the β-defensin family, and some members of the *Hox* gene family of transcription factors. Interestingly, either those gene themselves or downstream targets of those genes clearly provide potential targets for a male contraceptive.

In different species, it takes approximately 10–14 days (12 days in man) for the spermatozoa to transit through the epididymis. For most species, spermatozoa are held in a quiescent state by luminal factors and therefore do not propel themselves along the duct. This journey is against an increasing hydrostatic pressure gradient and proceeds even when fluid flow from the testis is prevented by ligation of the efferent ductules. Their transport is achieved by the continuous production and movement of fluid originating from the testis and is augmented by neuromuscular mechanisms that cause rhythmic contractions of the smooth muscle surrounding the epididymal tubule. The epididymal smooth muscle layer increases in both thickness and autonomic innervation as it proceeds from proximal to distal epididymal regions. Neuropeptides (vasopressin, oxytocin, neuropeptide Y, endothelin), prostaglandins (e.g., PGF2α and PGE2), and other factors, are also modulators of epididymal contractions acting on their own receptors that are differentially expressed along the epididymis in various species. The switch from lower scrotal to higher body temperature increases epididymal contractility and significantly accelerates sperm transport through the epididymis;

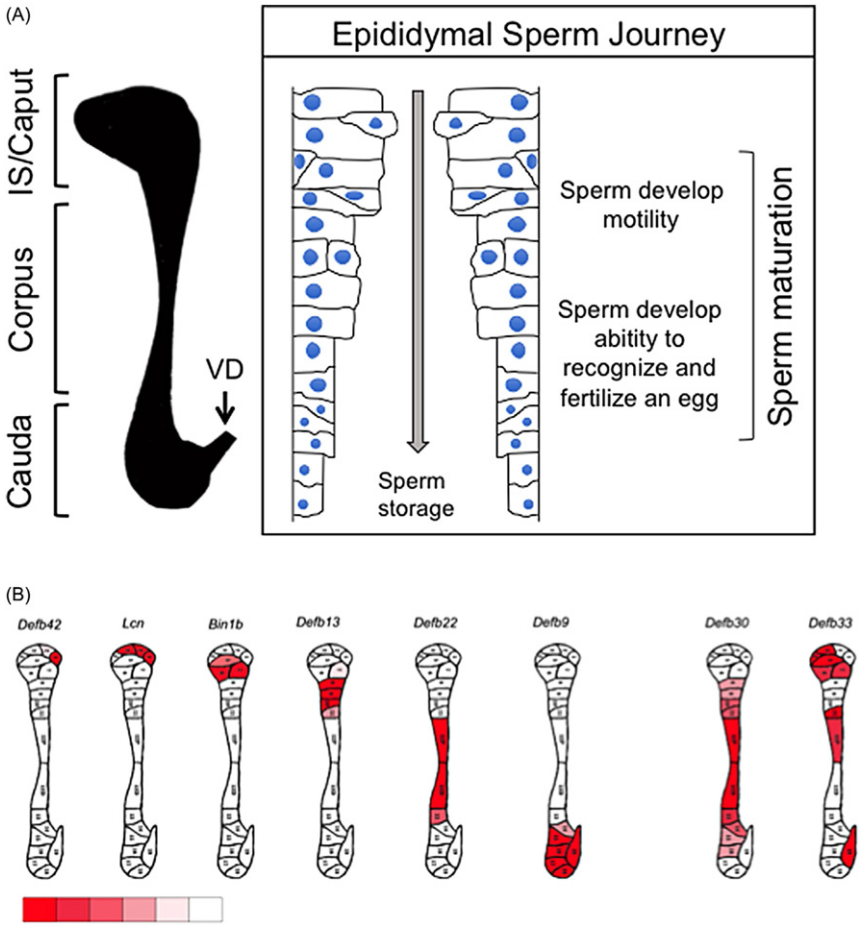

Fig. 1 Classically the epididymis can be divided in different regions: initial segment (IS), caput, corpus, and cauda (A). In the rat, the epididymis can be further subdivided into 19 segments: theIS corresponds to segments 1–4, the caput corresponds to segments 5–11, the corpus corresponds to segments 12–13 and the cauda corresponds to segments 14–19 (Panels A and B). Throughout its length, the epididymal epithelium creates sequential changes in the composition of luminal fluid, e.g. proteins, ions, solutes, and lipids, and forms a barrier to create a unique microenvironment in the lumen, where interactions between epithelial cells and spermatozoa occurs via the luminal fluid (A). These complex interactions are crucial for sperm maturation. Subsequently, spermatozoa acquire the ability for fertilization upon reaching the epididymal cauda, where it is stored until ejaculation (A). The epididymides shown in (B) are a modified figure from Zhang *et al.* (2011) where the expression pattern of lipocalin (*Lcn*) and different β-defensin (*Defb; Defb42, Defb13, Defb22, Defb9, Defb30, Defb33, and Bin1b*) messenger RNAs are used as examples of highly regionalized gene expression pattern along the various segments of the rat epididymis. Original data taken from Jelinsky *et al.* (2007). The color-coded bar below show degree of expression with red being the highest expression. Figures of each epididymis were kindly provided by Prof. Y.L. Zhang, reproduced with the permission of the American Society of Andrology. VD: vas deferens.

thus its dysregulation can have potential deleterious effects on sperm maturation and fertility (for review see Robaire and Hinton, 2015).

Sperm maturation is complete by the time the spermatozoa reach the cauda region where they are then stored before ejaculation (**Fig. 1**). The human epididymis does not have a prominent cauda region; for this reason it has little capacity to store large numbers of spermatozoa, as compared to many other species.

The epididymal luminal fluid environment also provides efficient protection for the transiting and stored spermatozoa against the innate immune system components, harmful xenobiotics, and oxidative stressors (reactive oxygen species, ROS). Tight junctional complexes between the epididymal epithelial cells (collectively referred to as the blood-epididymis barrier) form an important anatomical and physiological barrier that selectively restricts the types of compounds that can enter/exit the epididymal lumen and also establishes a tolerogenic environment for a continuous flow of autoantigenic spermatozoa which are protected from the immune system. Several types of immune cells (dendritic cells, mast cells, macrophages, lymphocytes) and differential epididymal expression of immunoregulatory genes and pathogen-sensing molecules (such as Toll-like receptors) are known to act in concert along the length of the epididymal duct (for review see Rodrigues *et al.*, 2008; Hedger, 2011; Da Silva *et al.*, 2011; Guiton *et al.*, 2013).

The defense mechanisms include the synthesis and secretion of antimicrobial and immunomodulatory proteins (such as cathelidicins and β-defensins), the synthesis and secretion of antioxidant compounds (such as glutathione and taurine) and the

rapid elimination of potential toxicants through the synthesis and secretion of antioxidants (e.g., glutathione, albumin, lactoferrin) and conjugating enzymes (e.g., γ-glutamyl transpeptidase, glutathione-metabolizing enzymes) (for review see Hall *et al.*, 2007; Robaire and Hinton, 2015; Guiton *et al.*, 2013). Because spermatozoa mature in a hyperosmotic environment that is distinctly different in composition from either blood plasma or epididymal interstitial fluid, the epididymal lumen also ensures spermatozoa protection from changes in osmolality that can affect spermatozoal autoregulation of cell volume during epididymal transit (Hinton *et al.*, 1995).

Knockout mice with partial deletion of a cluster of nine β-defensin genes in the chromosome 8 presented sperm dysfunction and male infertility, representing the first in vivo evidence for the importance of β-defensins to male fertility. More recently, the contribution of β-defensins shaping Wolffian duct/epididymal morphogenesis in response to different developmental cues has also been proposed (for review see Dorin, 2015; Ribeiro *et al.*, 2016).

Androgenic Regulation of Epididymal Function

The development and maintenance of the structure and function of the epididymis are dependent on a complex interplay of autocrine, paracrine, lumicrine and endocrine factors (including gonadal and adrenal steroid hormones), among which androgens are the primary regulators. These factors play important roles in the region- and cell-specific expression of epididymal genes (for review see Ribeiro *et al.*, 2016; Silva *et al.*, 2014; Patrao *et al.*, 2009; Murashima *et al.*, 2015a).

Plasma levels of androgens fluctuate throughout male lifespan. Their actions are mediated by the androgen receptor (AR), a steroid-hormone activated transcription factor member of the nuclear receptor superfamily. AR binds both testosterone and its 5α-reduced metabolite dihydrotestosterone (DHT), a more potent androgen.

The epididymis primarily depends on androgens to be fully functional. Disruptions of androgens/AR signaling by changes in either androgen availability and/or AR expression/function (e.g., due to genetic factors and endocrine diseases) can significantly impact epididymal development, structure, and function. Ultimately, malfunction of the epididymis results in male infertility (O'Hara *et al.*, 2011; Murashima *et al.*, 2015a,b).

During prenatal life testosterone, but not DHT, is essential for the stabilization of the Wollfian duct, and then for its morphological differentiation into an epididymis. The dominant role of testosterone ion these events are clinically supported by normal Wolffian duct differentiation in 5α-reductase-deficient patients (which prevents conversion of testosterone to DHT), which confirm that DHT is not present in the Wollfian duct until epididymal differentiation is complete.

Mesenchymal ARs are required for Wolffian duct stabilization, growth (cell proliferation/elongation), and coiling, while epithelial ARs are needed for later development and adult function. Thus, Wolffian duct morphogenesis requires direct androgen action on the mesenchyme to maintain its survival and, through androgen-dependent mesenchyme-derived components, dynamic mesenchyme–epithelium crosstalk that determines the regional specialization of the epithelium. Androgen-targets during these events include gene products such as *inhibin beta A* (*Inhba*), growth factors (e.g., EGF, FGFs), *Wnt5a*, *Dusp6*, *Hoxa10*, among others (see review by Shaw and Renfree, 2014; Murashima *et al.*, 2015a,b).

From later stages of postnatal development to adulthood, AR expression in the epididymal epithelium is in greater abundance than in the stromal cells. In the adult epididymis, androgen levels are higher in the proximal than in the distal regions, one of the main determinants of the highly regionalized pattern of gene expression along this tissue. The spatio-temporal AR gene expression pattern in the adult epididymis of several species is widely known. Postnatally, differential expression of steroid 5alpha-reductases (types 1 and 2) in epithelial cells along the epididymis can reduce testosterone to DHT. The androgen concentration in the epididymal lumen is several-fold higher than that found in the circulation, and the ratio of testosterone to DHT declines as one progresses down the epididymal duct (for review, see Smith *et al.*, 2013; Robaire and Hinton, 2015).

Androgens modulate epididymal function via direct binding of activated AR to putative androgen response elements present in the promoter regions of androgen-dependent epididymal genes (classical genomic androgen signaling; within minutes to hours), via direct association with other transcription factors (such as AP1 and NFKB), or via rapid responses through membrane-bound AR involving intracellular kinase signaling pathways (e.g., MAPKs) that can lead to phosphorylation of AR itself and other growth and transcription factors (not prevented by inhibiting transcription or translation; within seconds to minutes). This latter AR-induced signaling pathway, referred to as nongenomic androgen action may, in turn, ultimately modulate nuclear gene transcription (Robaire and Hamzeh, 2011). In the human epididymis, small noncoding RNAs (called microRNAs) have been identified as factors contributing to epididymal region-specific gene expression profiles. At the posttranscriptional level, microRNAs also influence epididymal postnatal development in an androgen-dependent manner, revealing additional mechanisms by which AR/androgen signaling mechanisms can be attained in the epididymis (Belleannee *et al.*, 2012; Zhang *et al.*, 2010).

Androgen ablation by surgical castration (orchiectomy) of adult males results in a decrease of epididymal weight, associated with apoptosis of epididymal epithelial principal cells and dedifferentiation of the caput epididymal epithelium. The luminal diameter and epithelial cell height decrease, while the intertubular stroma increases, mainly in principal epithelial cells that are particularly more sensitive to androgen levels than other epididymal cell types. Most of these castration-induced changes in the caput, corpus and cauda epididymis can be readily restored to normal (or near normal) by androgen administration. However, experimental efferent duct ligation (which prevents testicular components from entering the epididymis) indicates that both circulating testosterone and other testicular factors are necessary to maintain normal morphology and function of the proximal epididymis, especially the initial segment. Administration of antiandrogens, such as flutamide, to adult or pubescent animals

results in an accelerated sperm transit time through the epididymis, impairment of sperm motility and decreased ability of the cauda epididymis to store sperm (for review see Murashima *et al.*, 2015a; Robaire and Hinton, 2015).

Expression of nuclear AR in interstitial/peritubular cells of multiple species suggests that extratubular cells in the epididymis are also modulated by androgens, possibly contributing to tubule development and function. Paracrine relationships between epididymal epithelium and other adjacent cell types are also observed in adult animals as well (Tomsig *et al.*, 2006; Jimenez-Trejo *et al.*, 2007).

Estrogens in the Epididymis

Estrogens are pivotal in many aspects of male physiology, as demonstrated by the clinical consequences of estrogen-deficient and estrogen-excess states in men. The two classic estrogen receptor subtypes α (ESR1) and β (ESR2) are members of the nuclear receptor superfamily and expressed along the epididymis, mainly in the proximal regions, from different species. The G protein-coupled estrogen receptor-1 (called GPER-1) is also detected in this tissue. Targeted disruption of ESR1 and ESR2 ($Esr1^{-/-}$, $Esr2^{-/-}$, $Esr1^{-/-}$, $/Esr2^{-/-}$) and aromatase enzyme ($Cyp19^{-/-}$) impairs spermatogenesis, steroidogenesis, and male fertility. Animals treated with the antiestrogen ICI 182,780 also display similar outcomes, demonstrating the crucial role of estrogen for male reproductive function. Ablation of estrogen action in the efferent ductules results in a dramatic reduction of the fluid uptake capacity of the ductular epithelium, with consequent infertility. The effects of withdrawing estrogen from the epididymis are less understood. The presence of aromatase in epididymal spermatozoa has also been demonstrated in several species, including human. This enzyme is localized to cytoplasmic droplets, with decreasing presence as spermatozoa are transported along the epididymis (Hess *et al.*, 2011; Hess, 2014; Pereira *et al.*, 2014).

Glucocorticoids in the Epididymis

Glucocorticoids (cortisol in human and corticosterone in rodents) are a class of adrenal steroid hormones known to have complex roles in the male reproductive tract. Their actions are mediated by the glucocorticoid receptor (GR), a member of the nuclear receptor superfamily of ligand-dependent transcription factors. Ligand-occupied GR induces or represses the transcription of several genes by direct binding to DNA response elements and/or by physically associating with other transcription factors.

GR is expressed in the adult rat epididymis. In vivo administration of dexamethasone (synthetic glucocorticoid highly selective for GR) induces ligand-dependent GR nuclear translocation and altered glucocorticoid-responsive gene expression (e.g., inflammatory cytokines) in adult rat epididymis, indicating that GR is fully active in this tissue. Observation of heterologous regulation of epididymal AR and GR expression changes by glucocorticoid and androgen plasma levels, respectively, supports the hypothesis that functional interactions between these two receptors and their ligands occur in this tissue (for review see Silva *et al.*, 2011).

Glucocorticoids may play a role in both absorptive and secretory activities of epididymal epithelial cells (Waddell *et al.*, 2003; Sharp *et al.*, 2007), and in overall epididymal zinc and copper metabolism as well (Nair *et al.*, 1998).

Glucocorticoid ablation by bilateral adrenalectomy (surgical removal of adrenal glands) in rats demonstrated that systemic levels of glucocorticoids are also physiologically required for the maintenance of testicular spermatogenesis and the adequate number and quality of spermatozoa stored in the caudal epididymal regions (Silva *et al.*, 2014). The data emphasize the importance to control hormonal replacement therapy in adrenalectomy patients, especially in the individuals at reproductive age; either under- or over-titrating hormone replacement levels may adversely affect their fertility.

Aldosterone and Epididymis

The rat epididymis responds to the principal mineralocorticoid hormone aldosterone and also to aldosterone antagonists. Their actions are mediated by the mineralocorticoid receptor (MR), a member of the nuclear receptor superfamily of ligand-dependent transcription factors. Although MRs have been localized in epididymal epithelial cells, the specific role aldosterone in influencing epididymal fluid movement remains to be determined. In clear cells, the presence of MR indicate their potential ability to regulate water transport from the epididymal lumen in vivo (for review see Robaire and Hinton, 2015).

Diseases of the Epididymis

There are human clinical issues that result from failure of the Wolffian duct to develop into a fully functional epididymis. Epididymal disjunction is the failure of the mesonephric tubules either to fully form the efferent ducts and/or to fail connect to the testis. This occurs in approximately 2%–4% of the general population but is seen in 25% of adult males that were cryptorchid at birth. This can occur either unilaterally or bilaterally, with varying degrees of male infertility depending upon severity of the disjunction.

Epididymal diseases encompass epididymitis (inflammation of the epididymis), torsion (often associated with testicular torsion; epididymal torsion itself is rare), as well as benign and malignant lesions. Among these pathologies, epididymitis is currently the most common and malignant lesions of the epididymis the most rare.

Benign lesions include cysts, spermatoceles, granulomas, cystadenomas (e.g., seen in von Hippel–Landau syndrome patients), adenomatoid tumors, and leiomyomas. Malignant lesions include lymphomas and, rarely, metastases from the testis, prostate, and kidney. It is estimated that the incidence of epididymal tumors comprises no more than 0.03% of all male cancers, and the mechanism(s) by which the epididymis protects itself from tumorigenesis is unclear.

Disorders in AR/Androgen Signaling and the Epididymis

Severe mutations that completely disrupt the AR activity in XY males can also be associated with the absence of epididymis/vas deferens, whereas patients with milder mutations that allow residual AR activation display normal Wolffian duct development (see review by Shaw and Renfree, 2014). Consistent with this clinical observation, Wolffian duct derivatives are absent in AR knockout (ARKO) mice (Welsh *et al.*, 2009).

Disorders in androgen synthesis and/or action have also been linked to atypical development of the male reproductive tract, including the epididymis. At least 50 different congenital abnormalities of urogenital structures are recognized by the medical term of disorder of sex development (DSD). Recently, it has been proposed that reproductive problems such as primary hypogonadism (testicular failure to produce testosterone), cryptorchidism, hypospadias, testicular germ cell cancer and low sperm count have a common origin in fetal life as a result of impaired testosterone synthesis or action during the masculinization programming window (more recently hypothesized to form the testicular dysgenesis syndrome, TDS). In the rat, TDS occurs between embryonic ages of E15.5 and E17.5, which would most closely correspond to 8–14 weeks of gestation in the human. In addition to genetic causes (e.g., AR mutations), environmental exposure of fetal testes to androgenic and antiandrogenic endocrine disrupting chemicals, including estrogens, is hypothesized as an important factor in TDS susceptibility. Thus, androgen disturbances during this period have the potential to lead to clinical pathologies with long-lasting consequences throughout life (see Welsh *et al.*, 2008 and reviews by van den Driesche *et al.*, 2017; Skakkebaek *et al.*, 2016).

Epididymitis

Epididymitis represents the most frequent cause of scrotal pain and inflammation. It is commonly diagnosed in the investigation of reproductive tract health and infertility factors, representing the fifth most common urologic diagnosed in men of ages 18–50 years. Both sexually transmitted infections (e.g., *Neisseria gonorrhoeae* and *Chlamydia trachomatis*) and typical uropathogens (e.g., Gram-negative bacteria) are of etiological relevance. Epididymitis is clinically relevant since it may induce acute/temporary epididymal dysfunction (symptoms lasting less than 6 weeks) that can ultimately lead to chronic/persistent infertility. Most patients still receive inadequate early diagnosis and therapy, representing a serious threat to men's health, especially in reproductive age. Pathogen detection is an indication for antibiotic therapy aimed at eradicating the pathogen; this treatment, however, does not always prevent permanent sperm parameter abnormalities/infertility, presumably due to the induction of persistent immunopathological processes in the genital tract. In the epididymis, sperm functionality can be compromised by direct damage from the pathogen or indirectly via damage from inflammation-associated molecules such as proinflammatory cytokines or ROS (Pilatz *et al.*, 2015; Michel *et al.*, 2015).

Escherichia coli and *Enterococcus* spp. are among the most prevalent pathogens involved in epididymitis. They commonly reach and colonize the epididymis by ascending through the urethra. The clinical course of epididymitis and its impact on fertility has been studied from animal models that mimic the clinical condition. The in vivo retrograde injection of bacteria, or their pathogen-associated molecular pattern (PAMP) components, into the vas deferens lumen in rats and mice renders a progressively dysfunctional epididymis displaying morphological changes that include epithelial and smooth muscle damage, ductal obstruction, and fibrotic remodeling that are mainly observed in the distal region of the epididymis. Steps toward a mechanistic understanding of acute and chronic experimental epididymitis and its impact on epididymal function in rodents have been used to help identify early diagnosis and targets for adjuvant therapy as tools to diminish the detrimental consequences of chronic lesions that can lead to irreversible loss of fertility and chronic scrotal pain (Turner *et al.*, 2011; Michel *et al.*, 2015; Silva *et al.*, 2018; Schagdarurengin *et al.*, 2016). Clinical epididymitis can also result from non-infectious conditions such as trauma, reflux of urine into the ejaculatory ducts, or idiopathic etiologies (Tracy and Costabile, 2009).

Obstructive Azoospermia

Clinically, in cases of obstructive azoospermia or congenital vas agenesis, spermatozoa can also be aspirated from the epididymis and inseminated in vitro. The fertilization rates with spermatozoa retrieved from different regions of the epididymis vary, with the highest being from cells collected in the most distal regions. After in vitro fertilization (IVF) and transfer, pregnancies have also been reported with spermatozoa recovered from the corpus and proximal caput epididymis. However, the consequences of either pathological conditions of obstructive azoospermia or the use of immature spermatozoa to fertilization remain under investigation.

Epididymal-Related Male Infertility

As reviewed by Turner (2011), there are over a dozen genes or gene products expressed in the epididymis whose dysfunction either significantly reduced or completely eliminated male fertility in a variety of species. The mouse and rat present 75 genes and 110 genes, respectively, that are transcribed *only* in the epididymis (Johnston *et al.*, 2005; Jelinsky *et al.*, 2007), and in the mouse, 35 of those 75 genes transcribe protein products with the signal sequences for secreted proteins (Dean *et al.*, 2008), indicating the unique intraluminal environment required for sperm maturation and storage. Thus, these data confirm how vital the epididymis is to male fertility. Conversely, this information is also used in the development of male contraceptive based on inhibition of epididymal function.

Fertility in Men With Spermatogenesis Abnormalities☆

Katherine Rotker, University of Massachusetts Medical School, Worcester, MA, United States
Mark Sigman, Warren Alpert School of Medicine of Brown University, Providence, RI, United States

Glossary

ART Assisted reproductive technology.
Azoospermia Absence of sperm in semen.
Gonadotoxins Agents or chemicals toxic to the gonads or testicles.
ICSI Intra-cytoplasmic sperm injection.
Infertility Inability to achieve pregnancy after 1 year of unprotected intercourse.
IVF In vitro fertilization.
Oligozoospermia Reduced sperm concentration (<15 million mL).
Spermatogenesis Orderly process whereby immature diploid germ cells pass through two successive meiotic divisions and subsequent cellular remodeling to become haploid spermatozoa.
Varicocele Dilated testicular veins caused by reflux of blood into these veins.

Definition

It is estimated that 10%–15% of couples suffer from infertility and that male factor infertility, by itself or in combination with female causes, is responsible for approximately 50% of these cases (Practice Committee of American Society for Reproductive Medicine, 2012). Male factor infertility can be due to a primary spermatogenesis defect (primary testicular failure), genital duct obstruction (posttesticular failure) or hormonal deficiency (pretesticular failure). Men with primary spermatogenesis abnormalities fit onto a spectrum. At one end of the spectrum are subfertile men with a mild degree of spermatogenic impairment characterized by hypospermatogenesis on testicular biopsy and subnormal semen parameters (reduced sperm concentration, motility, and/or morphology) on semen analysis. At the other end of the spectrum are men with end-stage testicular failure characterized by azoospermia on semen analysis and complete germ cell aplasia or Sertoli cell-only pattern on testicular histology. As such, the evaluation, treatment and prognosis of men with spermatogenic failure can vary depending on the severity of the infertility.

Evaluation

History and Physical Examination

The evaluation of infertile men with spermatogenic failure should begin with a thorough history. The history should include documentation of duration of infertility and any previous fertility treatments. Evaluation of the female partner is important to rule out any significant female factors (e.g., anovulation, tubal obstruction). One must inquire about sexual history including the timing and mechanics of intercourse and use of lubricants. Knowledge of childhood and pubertal development is critical to uncover conditions such as cryptorchidism and delayed pubertal development. A positive family history may suggest a hereditary form of infertility (e.g., cystic fibrosis gene mutations are associated with CBAVD—congenital absence of the vas deferens). A medical history is important to rule out systemic illnesses (such as renal failure or hemochromatosis) which may be associated with impairment of spermatogenesis. A surgical history focuses on prior history of abdominal, pelvic or scrotal surgery (to rule-out iatrogenic genital duct injury). Infections can contribute to infertility by causing scarring and obstruction of the genital ducts (e.g., gonorrhea, chlamydia) or impairing sperm function through the elaboration of spermatoxic cytokines (e.g., prostatitis). Environmental gonadotoxins (e.g., radiation and industrial chemicals) can affect testicular function and fertility (Evenson and Wixon, 2005; Kenkel *et al.*, 2001; Sengupta and Banerjee, 2013). Moreover, lifestyle factors such as smoking and scrotal hyperthermia (hot baths) can be detrimental to sperm function (Rao *et al.*, 2016; Evenson *et al.*, 2000; Kunzle *et al.*, 2003; Richthoff *et al.*, 2008; Sailer *et al.*, 1997; Vine, 1996; Vine *et al.*, 1996; Li *et al.*, 2011; Virtanen *et al.*, 2012). Specific lifestyle measures, such as, minimizing testicular hyperthermia can improve sperm quality (Jung *et al.*, 2001).

☆*Change History*: May 2018. Katherine Rotker and Mark Sigman updated the sections: III Evaluation (A History and Physical Examination, B Semen Analysis, C Hormonal Evaluation, D Imaging Studies, E Hormonal Evaluation, F Genetic Evaluation, G Testicular Biopsy), IV Management (A General Recommendations, B Medical Therapy for Spermatogenic Failure, C Surgical Therapy for Spermatogenic Failure, D Assisted Reproduction). They have updated the ASRM practice guidelines reference to reflect the latest addition and have added several recent references to the reference list.

This article is an update of Armand Zini, Claudia Chokron, Fertility in Men with Spermatogenesis Abnormalities, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 52–57.

 doi:10.1016/B978-0-12-801238-3.04012-5

Medications can influence testicular function and sperm production through one of several mechanisms. Hormonal agents such as androgens (frequently used by bodybuilders), estrogens or antiandrogens can impair normal testicular function by interfering with the hormonal control of spermatogenesis (Meriggiola *et al.*, 1998). Chemotherapeutic agents (e.g., alkylating agents) interfere with spermatogenesis and cause germ cell depletion and reduced sperm production. Sperm-specific toxicants exert their detrimental effects at the posttesticular level (e.g., calcium channel blockers).

The physical examination may provide additional information regarding the etiology of spermatogenic failure. A more female body habitus and hair distribution provide evidence of lack of androgenization which could indicate conditions such as hypogonadism or Klinefelter syndrome. If hyperprolactinemia is suspected, examination of visual fields is important to rule-out a pituitary adenoma. Examination of the abdomen and pelvis is important to rule-out surgical scars and/or hepato-splenomegaly. The penile exam should focus on the assessment of penile length (indicative of normal development) and position of the urethral meatus (for normal deposition of semen). While prostate exam may enable one to assess prostate size, firmness, tenderness it rarely is useful in the diagnosis of causes of infertility due to cysts (congenital, ejaculatory duct), which may be associated with ejaculatory duct obstruction.

The scrotal exam should be performed in a warm examining room to promote relaxation of the scrotum. It is important to record the position (scrotal, inguinal), volume (normal 15–25 mL) and consistency (normally firm) of the testis. Normally, more than 70% of the testis volume is from germ cells alone. Therefore, a soft and/or small testis is indicative of abnormal spermatogenesis. The diagnosis of a varicocele is generally made on physical examination. The detection of a varicocele is greatly facilitated by examining the patient standing. Varicoceles are graded as follows: grade I—palpable only with Valsalva, grade II—palpable without Valsalva, grade III—visible (Dubin and Amelar, 1978). The presence or absence of the vas deferens can be confirmed on physical examination.

Semen Analysis

The semen analysis is the cornerstone of male infertility evaluation. At least two semen samples collected after 2–3 days of abstinence should be analyzed. These can be collected by masturbation or by intercourse using special semen collecting condoms that do not contain spermatocides. The sample should be evaluated within 1 h of production and should be kept at room or body temperature during transport if collected at home (Jarow *et al.*, 2010). Assessment of semen volume is important in that it is indicative of seminal vesicle function (70% of the semen volume is of seminal vesicle origin) and patency of the ducts distal to this gland (ejaculatory ducts). In azoospermic men, a low semen volume may be due to an incomplete sample collection (a common problem), ejaculatory duct obstruction, seminal vesicle agenesis or hypoplasia (associated with congenital absence of the vas deferens), testosterone deficiency, retrograde ejaculation or lack of emission (lack of propulsion of sperm into the posterior urethra). Seminal pH is important to assess in low volume azoospermia as pH less than 7.0 suggests lack of seminal vesicle secretions as is found with CBAVD or ejaculatory duct obstruction, but not with retrograde ejaculation.

Sperm concentration is an indicator of quantitative spermatogenesis and testicular function. The 2010 WHO semen analysis manual has set the lower threshold of the fertile reference range sperm concentration at 15 million sperm per mL (this value represents the lower 5th centile of a population of fertile men) (Cooper *et al.*, 2010). However, spontaneous pregnancies are possible in couples in whom the man's sperm concentration is under 15 million sperm per mL (since 5% of the fertile population fall into this range). Percent sperm motility and sperm morphology are indicators of qualitative spermatogenesis. According to the 2010 WHO semen analysis manual, the percent progressive motility should be greater than or equal to 32%, total motility greater than or equal to 40%, and the percentage of sperm with normal morphology (by strict criteria) should be greater than or equal to 4% (these values represent the lower 5th centile) (Cooper *et al.*, 2010). Although each of the conventional semen parameters (sperm concentration, motility, and morphology) may help to differentiate infertile from fertile men, none of these parameters alone is a powerful discriminator as there is significant overlap between semen parameters of infertile and fertile men). The more parameters that are below the reference range limits, the more likely male infertility is present (Guzick *et al.*, 2001). Indeed, some infertile men have normal semen parameters and are said to have unexplained infertility. Moreover, conventional semen parameters may exhibit a high degree of variability from sample to sample and, as such, there is often a need for at least two analyses.

Specialized sperm function tests have been developed in the hope of better discriminating fertile from infertile men to better predict fertility potential (in vivo and in vitro) than conventional semen parameters. The most promising and well-studied tests of sperm function are the sperm DNA integrity assays (Collins *et al.*, 2008; Simon *et al.*, 2010; Zini and Sigman, 2009). Several assays exist to measure sperm DNA and chromatin damage. However, a significant amount of controversy exists regarding the utility of these tests due lack of standardization of assay protocols and thresholds causing suboptimal sensitivity and specificity. At this time, the Practice Committee of the American Society for Reproductive Medicine and the European Society for Human Reproduction and Embryology have concluded that current data doesn't support its routine use (Practice Committee of the American Society for Reproductive Medicine, 2013; Barratt *et al.* 2010). However, some find it useful in certain situations such as repeated miscarriages whereas its use for determining decisions between IUI, IVF, ICSI, and testicular sperm instead of ejaculated sperm require further studies.

Hormonal Evaluation

Hormonal evaluation is indicated if there is an abnormally low sperm concentration (<10 million/mL), impaired sexual function or clinical findings suggestive of endocrinopathy (Jarow *et al.*, 2010). The initial hormonal evaluation should include

measurement of serum FSH and testosterone (T) levels (drawn in the morning). An abnormal FSH or T should prompt further evaluation with serum LH and prolactin determination. Many men with abnormal spermatogenesis have a normal serum FSH but an elevated FSH clearly indicates an abnormality in spermatogenesis. While many commercial labs have reference ranges for FSH of 18 mIU/mL or higher, most men with normal spermatogenesis have FSH values of less than 5–7.6 (Myers *et al.*, 2009; Schoor *et al.*, 2002). As such these men with high FSH and small testes are not candidates for surgical reconstruction and do not need diagnostic testicular biopsies. However, men with elevated serum FSH may harbor small foci of active spermatogenesis amidst a histologic background that is predominantly characterized by maturation arrest or Sertoli cell only pattern. In these men, sperm may be retrieved through microdissection testicular sperm extraction (micro-TESE) for use in conjunction with IVF/ICSI. Sperm has been found with this technique in this population even when a conventional biopsy showed no sperm (Ramasamy and Schlegel, 2007).

Low serum FSH, T, and LH is suggestive of hypogonadotropic hypogonadism with secondary spermatogenic failure. In these men, a prolactin level is indicated and if elevated should prompt pituitary imaging to rule out a pituitary lesion. These men will often respond to hormonal replacement therapy (in the form of intra-muscular or subcutaneous hCG and FSH or pulsatile subcutaneous GnRH) (Dwyer *et al.*, 2013).

A normal hormonal evaluation is suggestive of normal, active spermatogenesis but does not rule out spermatogenic failure.

Imaging Studies

Scrotal/testicular ultrasound may be used in select cases for assessment of testicular or epididymal masses and presence or absence of varicoceles when physical examination is insufficient. While trans-rectal ultrasound (TRUS) is primarily used to assess prostate anatomy, in infertile men, a TRUS is also used to evaluate the seminal vesicles and ejaculatory ducts when ejaculatory duct obstruction is suspected. At the time of surgical reconstruction, vasography may be performed to confirm and localize ductal obstruction.

Genetic Evaluation

It has been found that severe male factor infertility may be caused by genetic defects and that these may be transmitted to the male's offspring through assisted reproduction. In many cases, this only causes the same problem in the next generation (infertility in a male child), but some genetic defects may cause other diseases, miscarriage, or even early death. As such, appropriate genetic testing and counseling are an essential part of the infertility evaluation in patients with a genetic etiology of infertility. The available clinical genetic tests for male-factor infertility include the karyotype, Y-microdeletion analysis, and evaluation for cystic fibrosis mutations.

Karyotype

The prevalence of chromosomal abnormalities found in the general population is less than 1% (Berger, 1975). It is reported that the prevalence of chromosomal abnormalities in men with severe spermatogenic deficiency is up to 14% (Van Assche *et al.*, 1996). Klinefelter syndrome (47,XXY) is the most common chromosomal abnormality, observed in about 10% of azoospermic men (Becker *et al.*, 1966). Chromosome abnormalities described in infertile men include 47,XYY; 46,XX; translocations; duplications; deletions; and peri-centric inversions. Karyotypic abnormalities are identified in 10%–15% of azoospermic men with sex chromosomal abnormalities dominating. In men with oligospermia, the prevalence of chromosomal abnormalities is about 5%. Sex chromosome abnormalities are seen in 1%–2% while autosome abnormalities constitute the other 3%. In clinical practice, a karyotype is recommended in infertile men with severe oligospermia (<5 million sperm per mL) and nonobstructive azoospermia (Jarow *et al.*, 2010). Of importance, abnormalities such as balanced translocations may become unbalanced translocations during meiosis of spermatogenesis, potentially causing greater abnormalities in offspring (e.g., miscarriage, early postnatal mortality and birth malformations). Clearly, the karyotype analysis is important given the serious reproductive consequences of transferring an abnormal chromosomal complement to the offspring.

Y-chromosome microdeletion

Approximately 10% of men with azoospermia or severe oligospermia (less than 5 million sperm per mL) have a small (micro) deletion of the long arm of the Y chromosome, in an area known as the AZF (azoospermia factor) with subregions AZFa, AZFb, and AZFc (Stahl *et al.*, 2010). Several important spermatogenesis genes reside within this deleted region of the Y chromosome and, as such, explain the observed phenotype associated with Y-microdeletions. It does not appear that men with this condition have any other physical problems apart from the infertility. There is evidence to show that men with a Y-microdeletion will pass on the genetic abnormality to their male offspring through IVF/ICSI (Oates *et al.*, 2002; Stahl *et al.*, 2010). Genetic counseling and Y-microdeletion testing is recommended in infertile men with severe oligozoospermia (<5 million sperm per mL) and non-obstructive azoospermia. Men with NOA (nonobstructive azoospermia) and a complete microdeletion of subregions AZFa and/or AZFb have a very poor prognosis (very low or absent probability of finding sperm with attempts at testicular sperm retrieval while over 50% of those with AZFc deletions have successful testicular sperm retrieval (Hopps *et al.*, 2003; Stahl *et al.*, 2010).

The cystic fibrosis gene and male infertility

The Cystic Fibrosis Trans-membrane Conductance Regulator (CFTR) gene is located on chromosome seven. Over 1700 different mutations of the cystic fibrosis (CF) gene have been reported to date and mutations in this gene are associated with cystic fibrosis and absence of vas deferens. Men with congenital bilateral absence of the vas deferens (CBAVD) can have mutations in the CFTR gene approximately 60%–70% of the time with no other clinical symptoms of cystic fibrosis (Ferlin *et al.*, 2007). In the Caucasian population, the carrier frequency of these autosomal recessive mutations is approximately 4%. CF point mutations along with the 5T variation in intron 8 of the CFTR gene (a polythyimidine sequence containing only 5 bases instead of 7 or 9 in intron 8) are associated with congenital bilateral absence of the vas deferens (CBAVD) in 80% of patients with CBAVD (Mak *et al.*, 1999). However, CF mutations have not been associated with testicular failure or nonobstructive azoospermia (Mak *et al.*, 1999). CF mutations can result in a defective chloride channel and this is associated with production of thick respiratory and GI secretions, leading to the CF phenotype. In male infertility, CF generally results in obstruction of the excurrent duct system due to absence of the vas deferens, resulting in obstructive azoospermia with low volume, acidic semen samples. Genetic counseling and CFTR mutation and 5T testing is recommended in infertile men with congenital bilateral absence of the vas deferens. In addition, since carrier status is common and if present in the female partner, could result in offspring having clinical cystic fibrosis, the male's partner should also undergo testing for CFTR mutations and the presence 5T polymorphism. (Cuppens and Cassiman, 2004).

Testicular Biopsy

Because FSH is a sensitive indicator of the quality of spermatogenesis, a diagnostic testicular biopsy is rarely performed unless done in conjunction with testicular sperm retrieval. Men with prior vasectomy and men with CBAVD generally have normal spermatogenesis and a testis biopsy is not usually indicated. Men with serum FSH above 5–7.6 mIU/mL will likely have non-obstructive azoospermia and a pure diagnostic testis biopsy is not indicated, as it is unlikely to indicate normal spermatogenesis. Thus the diagnostic biopsy will usually not affect management in most patients.

With the advent of advanced assisted reproductive technologies (ARTs), such as intracytoplasmic sperm injection (ICSI), testicular biopsy has more commonly been performed as a therapeutic instead of a diagnostic procedure. In approximately 50% men with NOA have rare foci of normal spermatogenesis in the testis. The sperm may be surgically retrieved and used for ICSI (Schlegel and Li, 1998). Of note, in men for whom diagnostic testicular biopsy does not show spermatogenesis, sperm may still be found through micro-TESE (Ramasamy and Schlegel, 2007).

Management

General Recommendations

Prior to initiating therapy (medical or surgical) for the treatment of male infertility, efforts should be made to eliminate any potential gonadotoxins (agents toxic to the gonads or testicles) and adverse lifestyle factors. A number of medications are known to have adverse effects on sperm production. These medications include hormonal agents (e.g., testosterone or its derivatives), antineoplastic agents (chemotherapeutic drugs) and other miscellaneous drugs. Alpha blockers used for treatment of enlarged prostates may cause impairment of ejaculation. The clinician should review medications with online databases to determine potential gonadotoxicity. Cigarette smoking is associated with decreased sperm counts and sperm function (Vine *et al.*, 1996; Li *et al.*, 2011; Jensen *et al.*, 2014; Virtanen *et al.*, 2012). Similarly, excessive alcohol consumption (binge drinking) has a detrimental effect on sperm production in the testis. Proper nutrition is also important to maintain adequate sperm production. Finally, chronic exposure to excessive heat (hyperthermia) is detrimental to normal sperm production in the testis.

Medical Therapy for Spermatogenic Failure

Nonspecific therapy

In general, nonspecific or empiric therapy for male infertility is ineffective and should not be considered first line therapy unless studies demonstrate clear efficacy and a low risk of complications. However, a number of small, randomized controlled trials have shown that antioxidant supplements and selective estrogen receptor modulators (such as clomiphene citrate) can improve sperm parameters in some men with idiopathic infertility (Chua *et al.*, 2013; Showell *et al.*, 2011). However, most men do not respond, and it is yet not possible to select those patients that may benefit from empiric therapy. Alternatively, for most couples with idiopathic male infertility and spermatogenic failure, assisted reproduction technologies (ART) can be effective and are more effective options. Some couples choose empiric therapy rather than ART due to financial or religious considerations.

Specific therapy

In general, specific medical therapy (targeted to specific pathology, e.g., hormonal replacement for hypogonadotropic hypogonadism) will be effective in improving spermatogenesis and semen quality. A small subset ($<5\%$) of infertile men with spermatogenic failure suffers from endocrine infertility, one of the most effectively treated forms of infertility. Specific causes of

secondary testicular failure include hypogonadotropic hypogonadism, hyperprolactinemia, hypothyroidism, and congenital adrenal hyperplasia.

Hypogonadotropic hypogonadism can be congenital (Kallman syndrome) or acquired (secondary to a pituitary adenoma, pituitary infarction, radiotherapy or idiopathic-unknown). The standard treatment involves replacement of deficient hormones. Typically, patients are treated with intra-muscular or subcutaneous human chorionic gonadotropin (hCG, 500–2000 IU, 2–3 times per week) and adding follicle stimulating hormone (FSH, 150 IU, 2–3 times per week) after several months (Foresta *et al.*, 2000, 2007). Alternatively, pulsatile gonadotropin releasing hormone (GnRH, 2–40 mg, every 2 h by pump) can be administered (Dwyer *et al.*, 2013) but it is more expensive. Generally, this form of treatment results in increased testicular volume and improved semen quality with many men experiencing a return of normal fertility potential.

Hyperprolactinemia can be secondary to a pituitary tumor (generally benign), hypothyroidism, liver disease, medications (antidepressants, cimetidine) or can be idiopathic. Typically, patients are treated with cabergoline (1 mg per week, taken twice per week) rather than bromocriptine due to a better side effect profile. With large tumors, transphenoidal resection of the pituitary adenoma may be recommended.

Hypothyroidism or hyperthyroidism may be associated with depressed sperm production. Treatment is thyroid hormone replacement or ablation/suppression of the hyperactive thyroid, respectively. While this leads to improved sperm production and return of fertility, it is rare for patients with undiagnosed and untreated thyroid disorders to present with infertility such that general screening of all infertile men is not warranted.

Congenital adrenal hyperplasia is a condition caused by a congenital enzyme deficiency leading to suppressed cortisol and aldosterone levels. These patients are treated with steroid replacement and generally this leads to improved sperm production and return of fertility.

Surgical Therapy for Spermatogenic Failure

Varicocelectomy

Varicocelectomy is the only male infertility surgery specifically designed to improve spermatogenesis. Varicocelectomy is indicated in men with a clinical varicocele, abnormal semen parameters and couple infertility (Cortes-Gutierrez *et al.*, 2008). This is based on the demonstration that varicocele is associated with a progressive decline in testicular function (Damsgaard *et al.*, 2016) and that repair of varicocele can improve spermatogenesis. Varicocelectomy is also indicated in men with a clinical varicocele and testicular pain and in the child or adolescent with a clinical varicocele and decreased ipsilateral testicular volume (greater than 4 mL difference between the right and left testis) (Schlegel and Goldstein, 2011).

A large number of studies have evaluated the outcome of varicocelectomy on fertility parameters and most of these studies have demonstrated an improvement in semen quality and pregnancy rates. Overall, varicocelectomy results in a significant improvement in semen parameters and pregnancy rates after varicocelectomy are in the range of 20%–60% (Schlesinger *et al.*, 1994). However, the bulk of the outcome data on varicocelectomy come from uncontrolled or poorly designed controlled studies. Nonetheless, several independent meta-analyses of the (few) randomized trials on varicocelectomy and pregnancy suggest that varicocelectomy increases the probability of natural pregnancy (Baazeem *et al.*, 2011; Kroese *et al.*, 2012).

While studies have indicated that there may be some benefit in repairing varicoceles in infertile men with azoospermia and clinical varicocele (Kim *et al.*, 1999; Matthews *et al.*, 1998) this remains controversial. Although significant improvement in semen quality (appearance of sperm in the semen) is reported in approximately 20% of these men, a clinically significant outcome (with spontaneous pregnancy) is reported in less than 10% of these cases. Preoperative testicular biopsy is predictive of outcome in these cases (Kim *et al.*, 1999). Only men with mature spermatids or spermatozoa on testicular biopsy had a good outcome (appearance of sperm in the semen). Men with maturation arrest or Sertoli cell only pattern on testicular biopsy remained azoospermic postoperatively. In addition, many men who develop sperm in the semen, revert to azoospermia and still require testicular sperm retrieval and ICSI (Schlegel and Kaufmann, 2004).

Surgical sperm retrieval

The advent of advanced assisted reproduction has made it possible for men with spermatogenic failure to father children. In that subset of men with spermatogenic failure and azoospermia, only testicular surgical sperm retrieval coupled with ARTs will allow these men to father children. Although a standard open testicular biopsy can be used to extract testicular sperm in men with spermatogenic failure, microdissection testicular sperm extraction (micro-TESE) has been advocated as the gold-standard approach for sperm retrieval in men with nonobstructive azoospermia. In men with NOA (nonobstructive azoospermia), the probability of finding sperm using micro-TESE is in the range of 40%–60% (Dabaja and Schlegel, 2013). With the testicle opened, the operating microscope enables the surgeon to identify and specifically extract the most dilated seminiferous tubules (indicative of active spermatogenesis) while thinner tubules (indicative of germ cell aplasia) are spared. As such, micro-TESE allows for maximal sperm recovery and minimal tissue extraction. Micro-TESE has been used successfully in azoospermic men with a history of cryptorchidism, prior chemotherapy for cancer and Klinefelter syndrome (Dabaja and Schlegel, 2013). Testicular spermatozoa can then be used in IVF/ICSI with pregnancy rates in the range of 30%–45%.

Assisted Reproduction

The use of assisted reproductive technologies (ARTs) is indicated for couples in which the man suffers from idiopathic spermatogenic failure. ART is also indicated for couples in which the man has a specific cause for the spermatogenic failure but has not responded to conventional therapy (e.g., varicocelectomy for varicocele) or has chosen ART instead of conventional therapy.

In men with a mild degree of spermatogenic failure and borderline semen parameters, three to six cycles of sperm washing with intra-uterine insemination (IUI) combined with ovulation induction may be attempted first (after consideration of female partner factors). IUI is a minimally invasive ART, however, pregnancy rates are in the range of 5%–15% per cycle and are highly dependent on the concentration of motile sperm (the minimum threshold for effective IUI is 3–5 million motile sperm) (Verhulst *et al.*, 2006; Miller *et al.*, 2002).

In those couples where the man has severe oligozoospermia or nonobstructive azoospermia, only the most advanced ART (IVF/ICSI) will allow these couples to achieve a pregnancy. In men with nonobstructive azoospermia, a surgical testicular sperm retrieval procedure is necessary to obtain spermatozoa (see above). IVF/ICSI is also indicated in those couples that have failed to achieve a pregnancy through IUI. The success rates with advanced ART (e.g., IVF/ICSI) continue to improve, with the most recent final live birth per cycle being cited at 41% for women <35% and 24% for women 35–40 (SART National Summary Report, 2014).

Genetics of Male Infertility

Csilla Krausz and Francesca Cioppi, University of Florence, Florence, Italy

Glossary

ART Assisted reproductive techniques.
Asthenozoospermia Reduced sperm motility (≤32% spermatozoa with progressive motility).
Azoospermia Absence of spermatozoa in the ejaculate.
Couple infertility Inability to achieve pregnancy after 1 year of unprotected intercourse.
Cryptozoospermia Identification of spermatozoa only in the sediment of the semen post-centrifugation.
Exome Part of the genome consisting of exons that code information for protein synthesis.
ICSI Intracytoplasmic sperm injection, injection of a single spermatozoa in the oocyte's cytoplasm.
Karyotype The number, size, and shape of chromosomes in an organism.
Moderate oligozoospermia Reduced sperm concentration (<10 million spermatozoa/mL).
Oligozoospermia Reduced sperm count (≤15 million spermatozoa/ml or ≤39 million spermatozoa/ejaculate).
Severe oligozoospermia Reduced sperm concentration (<5 million spermatozoa/mL).
Teratozoospermia Reduced number of spermatozoa with normal shape and size (<5%).

Introduction

Couple infertility is an emerging issue in Western countries, involving about 15% of couples (WHO, 2010). Male reproductive anomalies are present in about half of cases, either as the main reason or as a cofactor for couple infertility (Krausz, 2011). Male infertility is a multifactorial complex pathological condition with highly heterogeneous phenotypic representations, from the complete absence of spermatozoa in the testis to distinct alterations of sperm quality. Recently, male reproductive dysfunction has been classified into four etiologic categories: (i) hypothalamic–pituitary axis dysfunction; (ii) quantitative alterations of spermatogenesis; (iii) qualitative alterations of spermatogenesis; and (iv) ductal obstruction/dysfunction (Tournaye *et al.*, 2017). Genetic factors play an important role in each of these categories, with the highest prevalence in azoospermic men. Indication for genetic testing varies according to the etiology and semen phenotype. For instance, in cases of quantitative alterations of spermatogenesis (severe oligozoospermia/azoospermia), karyotype and Y chromosome microdeletion analysis are routinely performed. In the remaining three etiologic categories and in the case of a specific disease condition, mutation screening in specific candidate genes are indicated. Genetic screening is a diagnostic tool not only in male infertility, but also for pharmacogenetics purposes in relationship with follicle-stimulating hormone (FSH) treatment of idiopathic infertile men.

Chromosomal Anomalies in Oligo/Azoospermia

Karyotype Anomalies

Overview

Chromosomal abnormalities may affect the number or the structure of chromosomes. Their frequency reaches the highest value (15%–16%) in Non-Obstructive Azoospermia (NOA), showing a progressive decline with increasing sperm count (Jungwirth *et al.*, 2012) (**Fig. 1**). Klinefelter syndrome (KS) represents the main genetic cause for NOA, whereas structural autosomal anomalies (translocations/inversions) are relatively more frequent in oligozoospermic men (Jungwirth *et al.*, 2012; Krausz, 2011).

Who should be tested?

The most widely accepted cut-off for karyotype is moderate oligozoospermia. Additional indications for karyotype analysis are family history for recurrent abortions, malformations, mental retardation, or infertility.

Klinefelter syndrome

The most common sex chromosome aneuploidy in humans is the KS, which may manifest with different chromosomal constitution: 47, XXY or mosaic 46, XY/47, XXY, or higher-grade sex chromosomal aneuploidy, that is, 48, XXXY, 49, XXXXY, etc. Although its incidence is high (1:660 in live births and 1:300 in spontaneous abortion), the disease is often undiagnosed due to the large phenotypic variability of the disease. The only constant finding in affected individuals is the presence of small, firm testes due to hyalinization of seminiferous tubules. Azoospermia is present in over 90% of patients, while the remaining semen phenotype can be crypto/severe oligozoospermia (mainly in mosaic cases of KS). After puberty, the large majority of these patients

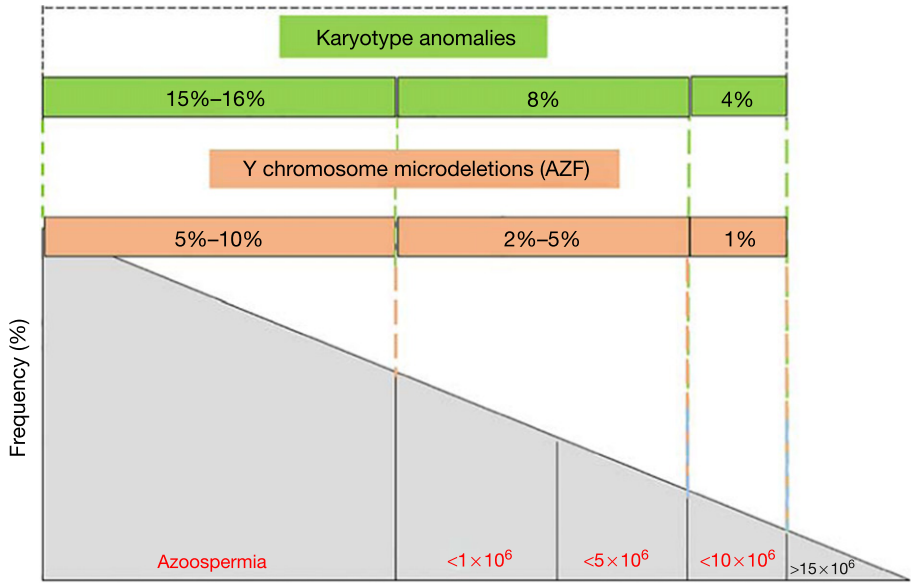

Fig. 1 Frequency of karyotype anomalies and Y chromosome microdeletions (AZF) in quantitative spermatogenic disturbances (from azoospermia to oligozoospermia).

present signs of androgen deficiency; these signs range from hypogonadism with gynecomastia and eunuchoid body proportions to variable levels of undervirilization (Aksglaede and Juul, 2013). In addition to reproductive/sexual dysfunctions, KS patients present higher morbidity for a series of diseases such as metabolic syndrome, autoimmune diseases, venous thromboembolism, and cognitive/psychiatric disturbances (Calogero *et al.*, 2017).

Management

The testicular sperm retrieval from Micro-dissection Testicular Sperm Extraction (micro-TESE) may detect residual foci of active spermatogenesis in the testes of azoospermic 47, XXY adult males (Dabaja and Schlegel, 2013). The average testicular sperm recovery rate is 50%, and spermatozoa can be used for the conception of a biological child through Intracytoplasmic Sperm Injection (ICSI) (Corona *et al.*, 2017). An early diagnosis is relevant for preserving fertility, since germ cell loss is progressive with age and micro-TESE has a higher recovery rate under the age of 30 years (Rohayem *et al.*, 2015). The early diagnosis of KS is relevant not only for fertility preservation but also for the prevention of health complications due to associated general health problems. Preventive measures include androgen replacement therapy, lifestyle changes, metformin, and statins according to the presence/absence of metabolic syndrome.

Translocations/inversions

The most frequent include Robertsonian translocations, inversions, and reciprocal translocations. In 60% of all cases of Robertsonian translocations, a (13;14)-translocation is found. The Robertsonian translocations carriers are healthy, but this abnormality is often found in oligozoospermic patients (about nine times higher in infertile men than in healthy controls) and is rarely observed in azoospermic subjects (Vincent *et al.*, 2002).

Management

Structural anomalies, especially Robertsonian translocations, might become unbalanced in offspring, increasing the risk of aneuploidy and imprinting diseases. For this reason, in cases of assisted reproduction, Preimplantation Genetic Diagnosis (PGD) is advised in order to ensure the transfer of embryos with normal chromosomal constitution.

Y Chromosome Microdeletions

Overview

Following the identification of de novo deletions in azoospermic men, Tiepolo and Zuffardi (1976) suggested the existence of Azoospermia Factor (AZF) region(s) on the long arm of the Y chromosome (Yq). Greater than 20 years later, Vogt *et al.* (1996) and Skaletsky *et al.* (2003) finally defined the AZF regions at the molecular level and identified the gene content of these regions. There are five fragile sites on the Yq leading to different deletions patterns, designated as AZFa, AZFb, AZFb + c (with two different breakpoints), and AZFc deletions (Krausz and Casamonti, 2017). The large majority of clinically relevant microdeletions removes completely one or more of the AZF regions, and occurs rarely in the general male population (1:4000), whereas they occur in 5%–10% of idiopathic NOA patients and in 2%–5% of severe oligozoospermic ones (**Fig. 1**) (Krausz *et al.*, 2014).

There is a strict genotype/phenotype correlation for the complete AZFa and AZFb deletions, that is, the first type of deletion inevitably leads to Sertoli cell-only syndrome (SCOS) while the second causes SCOS or spermatogenetic arrest. On the other hand, the rare partial AZFa and partial AZFb deletions are associated with residual sperm production. The complete AZFc deletions are associated with a variable semen phenotype ranging from severe oligozoospermia (mainly below 2 million spermatozoa/mL) to azoospermia (Krausz and Casamonti, 2017). Among the different partial AZFc deletions, the "gr/g deletion" confers on average a twofold increased risk for oligozoospermia due to the reduced AZFc gene dosage (Krausz and Casamonti, 2017). The phenotypic expression of the deletion may vary in different ethnic groups, depending on the Y chromosome background. In the Caucasian population, the highest risk (OR 4.2, CI 2.0–8.8, $P < 0.001$) has been reported in selected idiopathic oligozoospermic men of Italian and Spanish origin (with a frequency of 3.5%) when compared to normozoospermic controls of the same ethnic origin.

Who Should Be Tested?

All patients with severe oligozoospermia or azoospermia.

Management

Testing for AZF deletions in azoospermic men has a prognostic value for testicular sperm retrieval. In fact, in cases of complete AZFa and AZFb deletions the chance of finding spermatozoa upon surgical testicular exploration is virtually zero, hence TESE is not recommended in these patients (Krausz *et al.*, 2000). In contrast, the testicular sperm retrieval rate in azoospermic men, carrying *AZFc* microdeletion is on average 50% (Oates *et al.*, 2002). All AZF deletion carriers with residual spermatogenesis (AZFc or partial AZFa, AZFb) will transmit the deletion to male offspring, with consequent impaired spermatogenesis (from severe oligo to azoospermia) in the offspring's adulthood. Regarding the "gr/g deletion," the couple should be aware that the deletion (i.e., a genetic risk factor for impaired sperm production) may become a complete AZFc deletion (i.e., a clear-cut causative factor for spermatogenic impairment) in the next generation (Lu *et al.*, 2009; Zhang *et al.*, 2007).

Monogenic Causes of Specific Infertile Phenotypes

Congenital Hypogonadotropic Hypogonadism (cHH)

Overview

Male infertility can be due to congenital or acquired hypothalamic–pituitary axis dysfunction. Multiple factors affect GnRH neuron migration, GnRH gene expression, GnRH pulse generator, GnRH secretion, GnRH receptor expression, and gonadotropin synthesis and release (Kaprara and Huhtaniemi, 2017). Congenital HH (cHH) is a rare complex genetic disease (incidence of 1:8000 males) with variable expressivity, penetrance, and inheritance. cHH may manifest as an isolated or syndromic condition. Kallmann syndrome refers to hypogonadism associated with anosmia/hyposmia. Developmental anomalies may be present in both Kallmann syndrome and in some normosmic cHH, depending on the gene defect (Boehm *et al.*, 2015). The hypogonadal phenotype ranges from absent puberty (usually associated with cryptorchidism, micropenis, and gynecomastia) to milder forms such as delayed puberty and late-onset HH. cHH presents two peculiar features from a genetic point of view: (i) some of the genes involved in this disease (e.g., *FGFR1*, *PROKR2*) may cause both Kallmann syndrome and normosmic cHH with obvious complexity for genetic counseling; (ii) it does not follow the rules of Mendelian inheritance, since in about 20% of cases there is a digenic/oligogenic inheritance, that is, presence of two heterozygous mutations in two or more cHH genes in the same individual.

To date, 35 candidate genes in cHH have been identified (Boehm *et al.*, 2015; Tournaye *et al.*, 2017), and are implicated either in the development/migration of the GnRH neurons or in the neuroendocrine regulation of GnRH secretion or action (**Table 1**).

Who should be tested?

cHH patients after the exclusion of all secondary forms (pituitary tumors, empty sella, etc).

Management

Hormonal therapies are available for the development of secondary sexual characteristics and induction of fertility. Patients who are not interested in fertility should receive testosterone replacement therapy. Since "reversibility" of the gonadotrophin deficiency after testosterone therapy has been described in about 10%–15% of patients (Dwyer *et al.*, 2016), a periodic suspension of the hormonal replacement therapy is recommended for all cHH patients. The administration of gonadotrophins is indicated when patients desire fertility. In about 80% of cHH patients, spermatogenesis can be induced (Dwyer *et al.*, 2016), and pregnancy obtained either spontaneously or through ART. PGD or prenatal diagnosis should be offered to couples, mainly for syndromic cases.

Table 1 Genes implicated in cHH and subdivided according to their predicted functions

Gene	*Chromosome (GRCh38/hg38 assembly)*	*cHH phenotype*	*Other syndromes*
Embryonic differentiation of GnRH neuron			
HS6ST1	2q14.3	KS; ncHH	–

GnRH synthesis			
GnRH1	8p21.2	ncHH	–
GnRH activation			
GnRHR	4q13.2	ncHH	–

In each group, cHH candidate genes are reported according to the numerical order of the chromosomes (from chr1 to crh X) to which they are mapping, with associated cHH phenotypes (KS and/or ncHH) and other complex syndromes. *CHARGE*, coloboma, heart defects, atresia of choanae, retardation of growth and/or development, genital and/or urinary defects, ear anomalies or deafness; *CPHD*, combined pituitary hormone deficiency; *CTO*, contributes to oligogenicity; *D-WS*, Dandy-Walker syndrome; *GHS*, Gordon Holmes syndrome; *HS*, Hartsfield syndrome; *MGS*, Morning Glory syndrome; *PEPNS*, polyendocrine deficiencies and polyneuropathies; *SHFM*, split-hand/ft malformation; *SOD*, septo-optic dysplasia; *WS*, Waardenburg syndrome.

Congenital Absence of Vas Deferens (CAVD)

Overview

Approximately 10% of oligo/azoospermia can be attributed to ductal obstruction/dysfunction, which can be congenital or acquired. Among the congenital forms, CAVD is the most frequent and may occur either as an isolated urogenital disorder or as an atypical symptom of cystic fibrosis (CF). It accounts for 1%–2% of infertile men, 4%–17% of azoospermic men, and up to 25% of those with obstructive azoospermia (OA) (Oates and Amos, 1994). It may affect one (CUAVD) or both vas deferens (CBAVD).

CUAVD is a rare condition (1:100 CAVD patients) associated with either oligozoospermia or normozoospermia, depending on the functional competency of the contralateral testis. It is associated with ipsilateral and contralateral seminal vesicle agenesis in 90% and 20% of patients, respectively. It is worth noting that it is associated with renal agenesis in 79% of cases (Lotti and Maggi, 2015).

The CBAVD is associated with bilateral seminal vesicles agenesis in about half of the patients, in which it is characterized by typical semen alterations, such as low semen volume (<1.0 mL) with an acid pH (<7) and absence of spermatozoa (**Fig. 2**A). In contrast to CUAVD, it usually presents with normal kidneys (renal agenesis occurring in 1 out of 10 patients (Schlegel *et al.*, 1996).

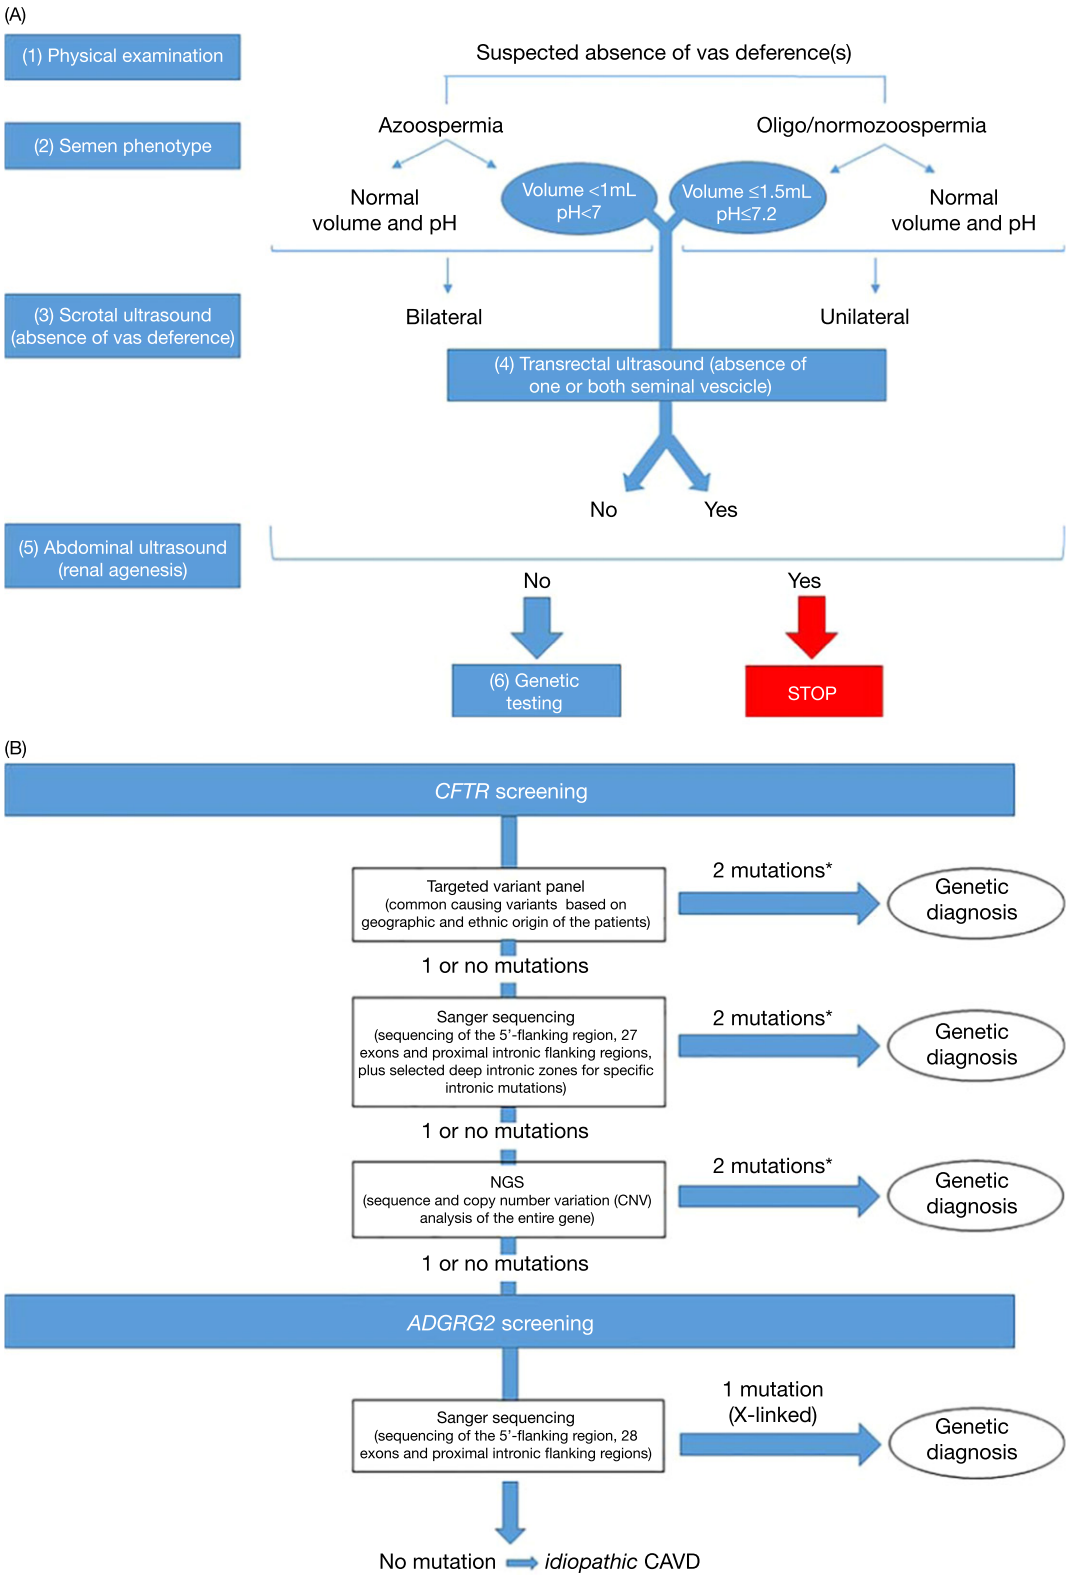

Fig. 2 Flow chart illustrating the diagnostic steps in cases of suspected CAVD. (A) After physical examination, semen analysis (azoospermia or oligo/normozoospermia) is followed by scrotal ultrasound in order to confirm the clinical suspect of bilateral or unilateral absence of vas deferen(s). Transrectal ultrasound is performed when semen analysis is indicative for the bilateral or unilateral absence of seminal vesicle(s). Finally, abdominal ultrasound is performed in order to rule out renal agenesis. (B) *CFTR* screening is the first genetic test in CAVD. The testing is based on an initial targeted variant panel followed by extended Sanger sequencing (in case only one or no mutation is found). Finally, if the patient is wild-type or a carrier of only one mutation, an NGS procedure is recommended. The *ADGRG2* testing should be performed in *CFTR* negative cases. Since *ADGRG2* is an X-linked gene, the presence of only one causative variant in the patient allows the genetic diagnosis of CAVD. The *CFTR* and *ADGRG2*-negative patients are defined as "idiopathic" cases of CAVD. CAVD: congenital absence of vas deferen(s). *Testing of female partner for CFTR.

CAVD is strictly related to *CFTR* gene mutations. >2000 variants have been identified in this gene, and they can be classified in severe and mild mutations depending on their functional effect. The presence of two severe mutations leads to the cystic fibrosis phenotype, whereas two mild mutations or one severe plus a mild mutation are causative for CAVD. Although geographical and ethnic differences have been demonstrated in *CFTR* mutations, the common mutations in CBAVD patients are F508del, 5T, and R117H. The genetic testing is based on three consecutive steps (**Fig. 2**B). After a comprehensive analysis of the *CFTR* gene, in about 20% of cases the origin of CAVD remains unknown. Recently, the *ADGRG2* gene has been identified as a new candidate gene in CBAVD (Patat *et al.*, 2016; Yang *et al.*, 2017). This gene is specifically expressed within the efferent ducts (Obermann *et al.*, 2003), in which most of the testicular fluid carrying immature spermatozoa is reabsorbed. Pathogenic *ADGRG2* variants were reported, accounting for 11%–15% of the CBAVD patients who are *CFTR*-negative (Patat *et al.*, 2016; Yang *et al.*, 2017).

Who should be tested?

Genetic testing of CAVD patients should be preceded by ultrasound scan of the abdominal region in order to exclude renal agenesis (the genetic basis of which is unknown) (Jungwirth *et al.*, 2012) (**Fig. 2**). The female partner of a man with CAVD without congenital kidney anomalies or with CF should be tested prior to assisted reproduction.

Management

Given that the carrier frequency of *CFTR* mutations in subjects with European descent is high (1:25), the *CFTR* panel screening in the female partners is mandatory. If mutations are detected in both partners, the risk of an offspring with CF (or mild forms of CF, depending on the type and combination of mutations) is very high and PGD should be advised to the couple. However, genotype/phenotype correlation is difficult due to different degrees of penetrance of the same mutation in different individuals (Cuppens and Cassiman, 2004).

Partial or Mild Androgen Insensitivity Syndrome (PAIS or MAIS)

Overview

Spermatogenic disturbances in hypoandrogenized men can be due to androgen receptor (AR) dysfunction. The phenotypic spectrum of androgen insensitivity syndromes ranges from complete androgen insensitivity (CAIS; Morris syndrome), characterized by a female phenotype in 46, XY individuals, to partial (PAIS; Reifenstein syndrome) and mild (MAIS) forms, ranging from undervirilized male phenotype with ambiguous genitalia to impaired sperm production with normal male genitalia, respectively (Krausz and Chianese, 2014). The AR gene maps to the X chromosome. Up to now, >1000 *AR* variants have been described, which account for 41% of PAIS cases (regarding the MAIS phenotype, there are no certain estimates in the available mutation databases) (Gottlieb *et al.*, 2012).

Besides pathogenic mutations, two polymorphisms sites in the N-terminal trans-activation domain of the receptor, the polyglutamine tract (CAG)*n* and the polyglycine tract (GGC)*n*, have been proposed as genetic risk factors of male infertility. According to the majority of studies, variations of the GGN repeat length are not associated with infertility (Davis-Dao *et al.*, 2007; Ferlin *et al.*, 2004; Lundin *et al.*, 2003; Rajender *et al.*, 2006; Ruhayel *et al.*, 2004). As far as the polyglutamine tract variation is concerned, the originally described inverse relationship between CAG repeat length and the receptor trans-activation (Davis-Dao *et al.*, 2007; Gao *et al.*, 1996) led to the hypothesis that a longer CAG repeat conferred a higher risk for infertility. This hypothesis has been challenged by novel functional and observational studies reporting that both a longer CAG tract and a shorter CAG tract might have a negative effect on the receptor function, hence an optimal number of CAG repeats is necessary for the highest transcription (Davis-Dao *et al.*, 2012; Nenonen *et al.*, 2011). We can speculate that the optimum range may vary between the genomic and non-genomic actions, and also in different tissues, because the effect of polyQ repeat on transactivation is cell specific, presumably due to distinct profiles of co-regulator proteins (Krausz, 2012). The role of CAG repeats in male infertility is probably more complex than has been previously believed, hence screening for this polymorphism is not indicated in the diagnostic setting.

Who should be tested?

AR mutational analysis is advised only in infertile men with suspected PAIS or MAIS, hence in patients with hypoandrogenization (with or without ambiguous genitalia) with high LH and relatively high testosterone levels.

Monomorphic Teratozoospermia

Overview

The congenital qualitative alterations of spermatogenesis may cause abnormal sperm morphology/motility and some of them can be the consequence of genetic anomalies. Monomorphic teratozoospermia are very rare pathological conditions with autosomal recessive mode of inheritance. Among these disturbances, globozoospermia and macrozoospermia (or sperm macrocephaly) are the most frequent, with a <0.1% and <1% prevalence in the subfertile population, respectively. Both diseases are incompatible with natural conception. Globozoospermia is characterized by round-headed, acrosomeless spermatozoa, which are unable to

fertilize the oocyte. The most frequent and validated genetic cause is the complete deletion of the *DPY19L2* gene (accounting for about 80% of patients) (Ray *et al.*, 2017; Chianese *et al.* 2015). Macrozoospermia is characterized by large-headed and multi-flagellated spermatozoa (Nistal *et al.*, 1977) and is related to *AURKC* gene mutations (90% of patients are homozygous for a deletion of a cytosine in exon 3) (Ray *et al.*, 2017).

Who should be tested?

DPY19L2 testing should be limited to patients with 100% globozoospermia. In cases where a homozygous carrier status for *DPY19L2* mutation is confirmed, the female partner should also be tested for *DPY19L2* deletion. The rationale is the relatively high deletion carrier frequency in the general population (1:85). *AURKC* testing should be recommended in all men affected by macrozoospermia.

Management

In cases of complete globozoospermia due to *DPY19L2* mutations, ICSI is the only therapeutic option. Although ICSI overcomes the absence of acrosin, which serves to spermatozoa to reach the occytes, injected spermatozoa are often unable to activate the oocytes due to the lack of acrosome phospholipase C zeta (Eskandari *et al.*, 2017). In addition, the fertility outcome (pregnancy and live-birth success rates) is relatively poor due to high sperm aneuploidy rates, DNA damage, and epigenetic alterations (Ray *et al.*, 2017).

In cases of macrozoospermia, ICSI is not advised for couples, since *AURKC* mutations are associated with an extremely high aneuploidy rate (in the majority of cases, spermatozoa are tetraploid and thus unable to allow normal embryonic development) (Ray *et al.*, 2017).

Genetic Factors in Idiopathic Oligo/Azoospermia

After a complete diagnostic workup, including the above-described genetic tests, in about 50% of cases of impaired spermatogenesis the etiology remains unknown (Krausz, 2011). These "idiopathic" cases of infertility are likely to be related to yet unidentified genetic/epigenetic and environmental factors. The discovery of the "hidden" genetic factors is relevant for both avoiding unnecessary surgical or empirical treatments and informing the couple undergoing ART about the risk of transmitting genetic alterations to the future offspring.

Different genetic approaches were applied in order to identify the cause of idiopathic infertility. The first one was based on the re-sequencing of candidate spermatogenesis genes (involved in hormonal regulation, cell metabolism/proliferation, and meiosis). These studies have targeted only a few genes in relatively small study populations without obtaining clinically useful results (Krausz *et al.*, 2015; Mitchell *et al.*, 2017). Since at least 2000 genes are involved in spermatogenesis, much expectation was given to "high-throughput" genomic technologies (SNP and CGH arrays) allowing Genome Wide Association Studies (GWAS). Although these approaches led to important advancements in the understanding of a series of complex diseases (Auton *et al.*, 2015; Riggs *et al.*, 2014), GWAS were largely unsuccessful for idiopathic male infertility (Krausz *et al.*, 2015). GWAS based on SNP-arrays identified a few common SNPs with significant but low effect size which may exert a modulating effect on the onset of impaired spermatogenesis, especially if they are present contemporarily in the same individual (Aston *et al.*, 2010; Kosova *et al.*, 2012). Another microarray-based approach is by Comparative Genomic Hybridization array (CGH-arrays), which is used for determining Copy Number Variations (CNVs). In patients with spermatogenic quantitative disturbances, only a few partially overlapping CNVs have been observed in different studies (Krausz *et al.*, 2015 and reference therein). The clinically most promising ones are the *TEX11* intragenic deletion and CNV67 (a deletion which removes between 5.417 and 25.513 kb of DNA mapping to the long arm of the X chromosome in q28) (Yatsenko *et al.*, 2015; Lo Giacco *et al.*, 2014; Shen *et al.*, 2017). These X-linked anomalies may act directly, since no compensatory allele is present in the male genome.

A relevant finding of the array-CGH studies is the presence of a "CNV burden" (especially deletions) in idiopathic infertile patients (Krausz *et al.*, 2012; Lopes *et al.*, 2013; Tuettelmann *et al.*, 2011). A high deletion load may suggest a higher genomic instability in these men, which may have an impact not only on their fertility status but also on their general health. In fact, a CNV burden may well be one of the possible explanations for the higher morbidity and lower life expectancy observed in infertile men in respect to fertile men (Eisenberg *et al.*, 2015; Jensen *et al.*, 2009; Krausz *et al.*, 2012; Salonia *et al.*, 2009).

With the advent of Next Generation Sequencing (NGS), Whole Exome analysis (WES) became feasible and allowed the genetic diagnosis of NOA in consanguineous families (**Table 2**), leading to discovery of 12 novel candidate genes (Arafat *et al.*, 2017; Ayhan *et al.*, 2014; Gershoni *et al.*, 2017; Kherraf *et al.*, 2017; Maor-Sagie *et al.*, 2015; Okutman *et al.*, 2015, 2017; Ramasamy *et al.*, 2015; Tenenbaum-Rakover *et al.*, 2015). Since only homozygous carriers of rare mutations (with $<1\%$ frequency in the general population) in the above 12 genes show azoospermia, the diagnostic value for sporadic NOA cases is questionable. It is highly unlikely that rare mutations can be present in homozygous state in patients with unrelated parents. It remains to be established if the presence of a rare autosomic gene variant in heterozygosis may eventually affect the efficiency of spermatogenesis, that is, be responsible for a milder phenotype (oligozoospermia). Large-scale studies, based on WES of thousands of well-characterized infertile men, are ongoing; the ultimate objective is to provide a comprehensive picture on the genetic determinants of idiopathic oligo/azoospermia.

Table 2 List of genes discovered to be associated with non-obstructive azoospermia (NOA) through Whole Exome Sequencing (WES) studies in consanguineous families

Gene	*Chromosome (GRCh38/hg38 assembly)*	*Associated semen phenotype (s)*	*Genotype in affected individuals*	*References*
DNAH6	2p11.2	NOA	Homozygous	Gershoni *et al.*, 2017
NPAS2	2q11.2	NOA	Homozygous	Ramasamy *et al.*, 2015
SPINK2	4q12	NOA	Homozygous	Kherraf *et al.*, 2017
TEX15	8p12	NOA + SO	Homozygous	Okutman *et al.*, 2015
SYCE1	10q26.3	NOA	Homozygous	Maor-Sagie *et al.*, 2015
TDRD9	14q32.33	NOA + cryptozoospermia	Homozygous	Arafat *et al.*, 2017
MEIOB	16p13.3	NOA	Homozygous	Gershoni *et al.*, 2017
ZMYND15	17p13.2	NOA	Homozygous	Ayhan *et al.*, 2014
TEX14	17q22	NOA	Homozygous	Gershoni *et al.*, 2017
TAF4B	18q11.2	NOA + oligozoospermia	Homozygous	Ayhan *et al.*, 2014
MCM8	20p12.3	NOA	Homozygous	Tenenbaum-Rakover *et al.*, 2015
MAGEB4	Xp21.2	NOA + SO	Hemizygous	Okutman *et al.*, 2017

The genes are reported according to the numerical order of the chromosomes (from chr 1 to chr X) to which they are mapping. Associated semen phenotype, genotype in affected individuals and references are reported for each gene.

SO: Severe oligozoospermia.

Pharmacogenetics in Idiopathic Male Infertility

Single-nucleotide polymorphisms (SNPs) in the genes encoding for the b-subunit of Follicle-Stimulating Hormone (FSHb) and for the Follicle-Stimulating Hormone Receptor (FSHR) have been investigated in relationship with reproductive parameters and with individual responsivity to FSH therapy, opening the way towards a pharmacogenetic approach in idiopathic infertility. One of the major determinants of serum FSH level is the *FSHB*-211G>T in the gene promoter, that is, levels of serum FSH, as well as sperm count, are significantly lower in G/T heterozygous men, and even lower in T/T homozygous carriers (Grigorova *et al.*, 2011). For the *FSHR*, c.-29G>A and 2039A>G (p.Asn680Ser) polymorphisms, homozygous A/A or G/G carriers show a reduced FSH receptor sensitivity with consequent high circulating FSH levels in men with normal sperm count (Grigorova *et al.*, 2014; Tuettelmann *et al.*, 2012).

While FSH therapy together with hCG is a standard treatment to induce fertility in subjects with gonadotrophin deficiency, the use of FSH in normogonadotrophic idiopathic infertile men is a debated issue. According to two meta-analyses, FSH treatment in idiopathic infertile men increases quantitative and qualitative semen parameters and pregnancy rate (Attia *et al.*, 2013; Santi *et al.*, 2015), but only about 50% of patients will respond in terms of improvement of semen parameters (Casamonti *et al.* 2017).

To date, four pharmacogenetic studies have been carried out in relationship with these polymorphisms and all are based on relatively small cohorts (Casamonti *et al.*, 2017; Ferlin *et al.*, 2011; Selice *et al.*, 2011; Simoni *et al.*, 2016). These studies reported a strict correlation between the presence of FSHb (−211G>T) and FSHR (p.Asn680Ser) polymorphisms and response to treatment. In their studies, patients carrying the mutated allele of FSHb and FSHR showed a significantly higher improvement of the "classical" seminal parameters (total sperm count, motility, and morphology) than patients with the "wild type" genotype. On the other hand, Simoni *et al.* (2016) demonstrated that FSH administration is effective in reducing sperm DNA fragmentation in men carrying the combined FSHR p.Asn680Ser homozygous and FSHb −211G>T homozygous genotypes (i.e., "wild type" genotypes). Finally in a recent paper, all three variants (FSHB c.−211G>T, FSHR c.2039A>G, and FSHR c. −29G>A) have been analyzed in relation to total sperm count, total motile sperm count, and hyaluronic acid binding capacity which is a biomarker of sperm maturity (Casamonti *et al.*, 2017). In contrast to the other studies, responsiveness to treatment was independent from *FSHR*/*FSHB* polymorphisms. These controversies clearly indicate that at present, a pre-selection of "responders" to FSH therapy cannot be based on the analysis of these three SNPs. Further large studies are needed to clarify this clinically relevant issue.

Conclusions

Over the past 30 years, besides karyotype analysis, molecular genetic testing became a routine diagnostic tool in male reproductive dysfunction. Currently, genetic diagnosis can be made in about 25% of male infertility providing an important input for clinical decision-making. The polygenic nature of this pathological condition and the relatively high prevalence of unknown etiology suggest that many novel genetic/epigenetic causes are likely to be discovered in the coming years.

Testicular Tumors

Ewa Rajpert-De Meyts, Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Glossary

Germ cell neoplasia in situ (GCNIS) The precursor lesion for testicular germ cell tumors that occur in young adults (seminoma and non-seminoma), previously known as carcinoma in situ, GCNIS consists of developmentally arrested immature germ cells with features of pluripotency located inside testicular seminiferous tubules.

Gonadoblastoma A premalignant lesion, similar to GCNIS, usually present in dysgenetic testes or gonads in individuals with disorders of sexual development.

Leydig cells Cells producing testosterone and other hormones located in the interstitial (inter-tubular) compartment of the testicle.

Non-seminoma A name for a group of tumors derived from immature germ cells characterized by morphological heterogeneity, most common in testis, but can also occur in extragonadal locations.

Seminoma A germ cell tumor derived from immature germ cells.

Sertoli cells Cells nurturing germ cells within seminiferous tubules of the testicle.

Teratoma A subtype of non-seminoma, characterized by somatic differentiation, can contain components resembling any tissue type.

Introduction

Testicular cancer can be derived from several cell types of the testicle, but germ cell-derived tumors constitute the vast majority of cases. Testicular germ cell tumors (TGCT) are most common among adolescents and young men, but can also occur in early childhood (infantile TGCT) and in older men (spermatocytic tumor). The focus of this article is on the most common TGCTs of young men, which are derived from germ cell neoplasia in situ (GCNIS), originally described as carcinoma in situ (CIS) of the testis (Skakkebaek, 1972). Testicular tumors can also be derived from somatic cells within the testicle, and are known as Leydig cell tumors and sex cord-stromal neoplasms. Both are relatively rare in adults but are not uncommon in childhood, and will be briefly mentioned because of their endocrine symptoms.

Pathogenesis of TGCT of adolescents and young adults has a strong developmental component and overlaps with other disorders of the male reproductive system, such as cryptorchidism and mild genital malformations, within the proposed testicular dysgenesis syndrome (TDS) (Skakkebaek *et al.*, 2001; Rajpert-De Meyts, 2006; Juul *et al.*, 2014). All these disorders, but especially testicular cancer have been increasing in incidence around the world, but etiologic factors have not yet been elucidated.

Clinical management of testicular cancer is mainly handled by urologists and oncologists, but endocrinologists or andrologists have an important part, especially concerning the follow-up of the survivors, which requires treatment of androgen insufficiency and infertility, which are frequent in these patients.

Classification, Histopathology and Molecular Features of Testicular Tumors

Histopathology of testicular tumors is very complex, because of their heterogeneity, pluripotency and ability to transdifferentiate. Primary testicular tumors can be derived from germ cells, from Sertoli cells (or their female equivalents, granulosa cells) and from Leydig cells (grouped together as sex cord/gonadal stromal tumors). In addition, there are other very rare tumors occurring in the testis, e.g. rhabdomyosarcoma. The testicle can also be a site of hematolymphoid malignancies: leukemia (mainly in children) and lymphoma (mainly in adults). Detailed classification and pathology of testicular tumors can be found in the WHO consensus classification (Moch *et al.*, 2016). For the use of non-pathologists, a simplified division of testicular tumors into main types is sufficient, as shown in **Table 1**.

Testicular Germ Cell Tumors Derived From GCNIS

TGCT derived from GCNIS; seminoma and non-seminoma, occur predominantly in young adult men. The precursor, GCNIS, consists of developmentally arrested immature germ cells (gonocytes) that persisted outside of fetal/perinatal life and then underwent malignant transformation (Rajpert-De Meyts, 2006; **Fig. 1**). GCNIS cells resemble morphologically fetal gonocytes, and have a similar gene expression profile, with a high level of expression of embryonic pluripotency factors, such as OCT4, NANOG, TFAP2C, LIN28 (Almstrup *et al.*, 2004; Sonne *et al.*, 2009). GCNIS cells are located inside well-developed seminiferous tubules, usually along the basement membrane, in the place of spermatogonia. Gonadoblastoma is a

Table 1 Simplified division of primary testicular tumors, based on the 2016 WHO classification

Germ cell tumors (GCT)

- ● GCT derived from germ cell neoplasia in situ (GCNIS)
- ○ Precursor lesions: GCNIS, gonadoblastoma
- ○ Seminoma, pure
- ○ Non-seminomatous GCT, pure
  - – Embryonal carcinoma
  - – Yolk sac tumor (post-pubertal type)
  - – Choriocarcinoma and other trophoblastic tumors
  - – Teratoma (post-pubertal type)
- ○ Mixed germ cell tumors
- ● GCT unrelated to GCNIS
- ○ Prepubertal (pediatric) tumors
  - – Teratoma (prepubertal type)
  - – Yolk sac tumor (prepubertal type)
  - – Mixed prepubertal type tumors
- ○ Spermatocytic tumor

Sex cord/gonadal stromal tumors

- ● Leydig cell tumor
- ● Sertoli cell tumor (SCT)
- ○ Malignant SCT
- ○ Large cell calcifying SCT
- ● Sertoli–Leydig cell tumors
- ● Granulosa cell tumors
- ○ Juvenile-type
- ○ Adult-type
- ● Mixed and unclassified sex cord-stromal tumors

Hematolymphoid tumors
Miscellaneous tumors

preinvasive lesion, similar to GCNIS, which occurs predominantly in individuals with disorders of sexual development (DSD), also known as intersex syndrome, for example, in patients with mixed gonadal dysgenesis (45X/46XY). Gonadoblastoma consists of groups of cells, which are embedded in poorly developed tubules, containing also small somatic cells, resembling granulosa cells. GCNIS and gonadoblastoma can be present in the same gonad, and combined lesions are not uncommon in patients with TDS (Jørgensen *et al.*, 2015).

Overt seminoma is most often diagnosed in men 25- to 45-year-old, whereas non-seminomatous tumors occur in younger men, mainly in the age group 17–35 years. Seminoma is a histologically homogeneous tumor consisting of a mass of immature germ cells which are virtually identical to GCNIS cells and resemble fetal gonocytes, with a similar gene expression pattern. In addition, nearly all seminomas, and a large subset of GCNIS cases are characterized by prominent lymphocytic infiltration (Hvarness *et al.*, 2013; Klein *et al.*, 2016). Non-seminomatous tumors are histologically heterogeneous and several subtypes can be present as pure or mixed components (**Table 1**). The undifferentiated form is embryonal carcinoma, which is characterized by a high level of expression of pluripotency factors, such as OCT4, but also SOX2, which is downregulated in human germ cells (Perrett *et al.*, 2008). Embryonal carcinoma readily differentiates into somatic components of any tissue type (teratoma) or into extra-embryonic tissue components (yolk sac and trophoblastic tumors). The mixed tumors contain various components of non-seminoma and seminoma, but classified and clinically treated as non-seminoma, which is a more aggressive TGCT (Moch *et al.*, 2016; Rajpert-De Meyts *et al.*, 2016; Verrill *et al.*, 2017).

The genome of all neoplasms derived from GCNIS is characterized by aneuploidy (near tetraploidy), with a pathognomonic for overt seminomas and non-seminomas amplification of chromosome 12, often as isochromosome 12p (Atkin and Baker, 1982; von Eyben, 2004). The tumors can also contain secondary aberrations caused by gene/transcript fusion (Hoff *et al.*, 2016). Another interesting feature of the genome of TGCTs is a very low in GCNIS and seminomas but variable in non-seminomas DNA-methylation (Smiraglia *et al.*, 2002; Kristensen *et al.*, 2013). In addition to protein-coding genes, TGCTs of young adults, including their precursor, GCNIS, but excluding teratomas, produce and secrete specific micro-RNA (miR) similar to embryonic stem cells. This micro-RNA profile is characterized by a high level of miR-371-3 cluster, miR-302 and miR-367 (Voorhoeve *et al.*, 2006; Palmer *et al.*, 2010; Dieckmann *et al.*, 2012; Novotny *et al.*, 2012).

Specific causative gene mutations have not been identified, except secondary gain-of-function *KIT* mutations (predominantly in seminomas), or *KRAS* (predominantly in non-seminomas) (Tian *et al.*, 1999; McIntyre *et al.*, 2005). However, familial risk of testicular cancer is high in comparison to other type of cancers. Brothers and sons of patients with TGCT have an estimated 8–10-

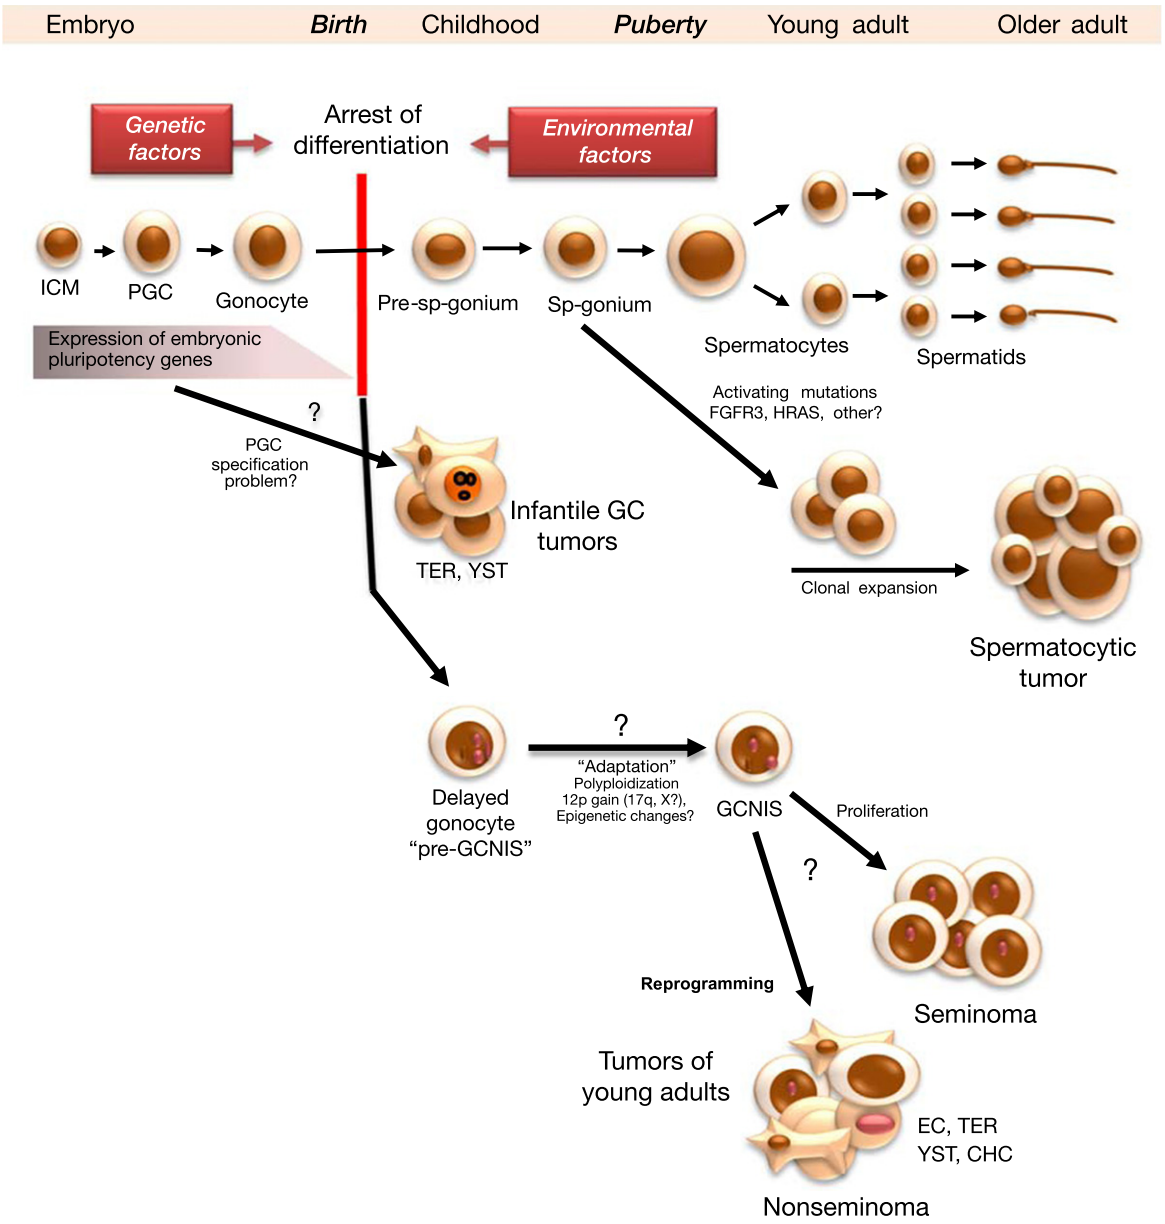

Fig. 1 Schematic histogenesis of testicular germ cell tumors (TGCT) in relation to the normal development of germ cells. Normal germ cell development is shown near the top part of the picture. Rare TGCTs that are unrelated to germ cell neoplasia in situ (GCNIS): infantile germ cell tumors and spermatocytic tumor, are shown in the middle part of the graph. The most common TGCT of young adults (seminoma and non-seminoma) that are derived from fetal germ cells (delayed gonocytes) via the stage of GCNIS are shown in the lower part of the figure. These tumors are likely caused by a combination of genetic and environmental factors acting during early development. Reprinted from Rajpert-De Meyts et al. Lancet 2016, with permission from Elsevier.

fold and 4–6-fold increased risk, respectively (Hemminki and Chen, 2006). This was roughly confirmed by a large study of Nordic twin populations, which estimated the heritability of testicular cancer as more than one third of cases, with about a quarter attributed to shared environment (Mucci *et al.*, 2016).

As mentioned below (in the "Epidemiology of Testicular Cancer" section), predisposition to testicular cancer differs widely in different ethnic groups, with the highest incidence among Caucasians and the lowest among men of African ancestry (Znaor *et al.*, 2014). Several genome-wide association studies (GWAS) have identified a number of possibly predisposing gene variants, some of which have different prevalence among whites and blacks. The strongest genetic markers for an increased risk of TGCT are located within or near the following loci: *KITLG*, *SPRY4*, *DMRT1*, *PRDM14*, *DAZL*, *HPGDS* (Rapley *et al.*, 2009; Kanetsky *et al.*, 2009; Turnbull *et al.*, 2010). Other informative markers are being revealed by meta-analytic GWAS that combine data from very large cohorts (Litchfield *et al.*, 2017; Wang *et al.*, 2017). Interestingly, these predisposing genetic markers represent predominantly

pathways involved in germ cell specification and gonadal development or in DNA repair and telomerase function (Litchfield *et al.*, 2015).

Testicular Germ Cell Tumors Not Associated With GCNIS

In early childhood TGCT can also occur, these tumors comprise two histological types, similar in appearance to the adult types: prepubertal-type yolk sac tumor or mature teratoma (including dermoid cyst) (Oosterhuis and Looijenga, 2005; Moch *et al.*, 2016; **Fig. 1**). The childhood GCTs display also gene expression and micro-RNA profiles similar to the adult equivalents (Palmer *et al.*, 2010; Mosbech *et al.*, 2014; Murray *et al.*, 2015). The etiology and pathogenesis of these tumors is unknown, but the cell of origin is most likely pluripotent primordial germ cell (Murray *et al.*, 2015).

Another rare TGCT, spermatocytic tumor, previously known as spermatocytic seminoma, occurs on the other end of the age spectrum; in older men (40–80 years). This tumor occurs only in testes and is composed of germ cells of three different cell sizes, with phenotypic features and gene expression profile similar to spermatogonia or primary spermatocytes (Looijenga *et al.*, 2006; Lim *et al.*, 2011). Spermatocytic tumors grow from expanding clones of spermatogonia, which underwent genomic changes facilitating their proliferation, such as amplification of chromosome 9 (with *DMRT1* locus), chromosome 20, activating mutations in *FGFR3*, *HRAS*, *NRAS*, or a whole-chromosome aneuploidy (Looijenga *et al.*, 2006; Goriely *et al.*, 2009; Giannoulatou *et al.*, 2017; **Fig. 1**).

Sex-Cord/Gonadal Stromal Tumors (Leydig Cell-, Sertoli Cell- or Granulosa Cell Tumors)

Histopathological division of these rare tumors has been revised in the latest WHO consensus classification (Moch *et al.*, 2016; Idrees *et al.*, 2017). In comparison to TGCTs, Leydig cell tumors, LCT (*leydigioma*) are relatively rare but can occur in all ages, predominantly in adults. In children these tumors can cause precocious puberty, so-called testotoxicosis (Rich and Keating, 2000). LCT resemble morphologically a mass of Leydig cells, and express similar markers. Malignant LCTs have to be distinguished from benign hyperplasia, adenomas and adrenal rest tumors (Lottrup *et al.*, 2015). Histopathological features of malignant LCTs are cytologic atypia with high mitotic activity, angiolymphatic invasion, necrosis, also DNA aneuploidy is consistent with malignant transformation. Molecular background of Leydig cell tumors is not well elucidated. In some malignant LCT, mutations of fumarate hydratase were identified (Carvajal-Carmona *et al.*, 2006). In most childhood cases an activating mutation in luteinizing hormone receptor (*LHCGR*) (Liu *et al.*, 1999; Boot *et al.*, 2011). Precocious puberty, sometimes starting in infancy is caused by excessive gonadotropin-independent production of testosterone and other steroid hormones by the LCT, and the patients appear to be at risk of germ cell neoplasia later in life (Mortensen *et al.*, 2017).

Sertoli cell tumors (SCT) and granulosa cell tumors are mainly diagnosed in children and adolescents and characterized by heterogeneous histopathological features, resembling immature cells of origin. SCT most often form tubular-like structures, while granulosa tumors resemble the ovarian counterparts. These tumors are usually benign. Other, very rare SCT, are grouped into mixed and unclassified category; these are usually unilateral and occasionally malignant (Idrees *et al.*, 2017). SCT are frequently found in association with multiple neoplasm syndromes; Carney complex and Peutz–Jeghers syndrome (Moch *et al.*, 2016). The phenotype of Carney complex includes skin and heart myxomas, skin pigmentation, testicular and adrenal tumors (Carney *et al.*, 1985). The tumors arising in the testes of the Carney patients are usually bilateral and benign, and have a typical histology of are large-cell calcifying SCT (Washecka *et al.*, 2002). Large-cell calcifying SCT can also occur in isolation (Lai *et al.*, 2015). Germline mutations identified in Carney complex most often occur in *PRKAR1A* gene (Kirschner *et al.*, 2000) but other loci on chromosome 2 have also been identified (Stratakis *et al.*, 1996). Tumors that arise in Peutz–Jeghers syndrome are also benign, bilateral and multifocal but are associated with gastrointestinal tumors and often gynecomastia (Hertl *et al.*, 1998). These SCT can be distinguished from those associated with Carney complex by typical intratubular proliferation of lightly eosinophilic cells with prominent basement membrane deposits (Idrees *et al.*, 2017). The genetic cause of Peutz–Jeghers syndrome is a loss-of-function germline *STK11* mutation that encodes for a serine–threonine kinase LKB1, which leads to overexpression of aromatase (Ham *et al.*, 2013).

Epidemiology of Testicular Cancer

This section deals exclusively with testicular germ cell tumors (TGCT) associated with GCNIS, because other types of tumors in the testis are rare and their incidence has not been changing.

The incidence of TGCT has been rising markedly around the world in the second half of the twentieth century, with interesting geographical variability (Chia *et al.*, 2010; Znaor *et al.*, 2014). These tumors are now the most common malignancy among Caucasian young men, but the incidence remains low in Asian and African populations (**Fig. 2**). An interesting exception is a relatively high incidence of TGCT among Maoris of New Zealand (Wilkinson *et al.*, 1994). The incidence trends in testicular cancer are dynamic, with signs of abating in the North-West of Europe, e.g. in Denmark, but dramatically growing rates in the Southern Europe, e.g. in Slovenia or Croatia, and among Hispanic populations of America (Znaor *et al.*, 2014; Ghazarian *et al.*, 2015).

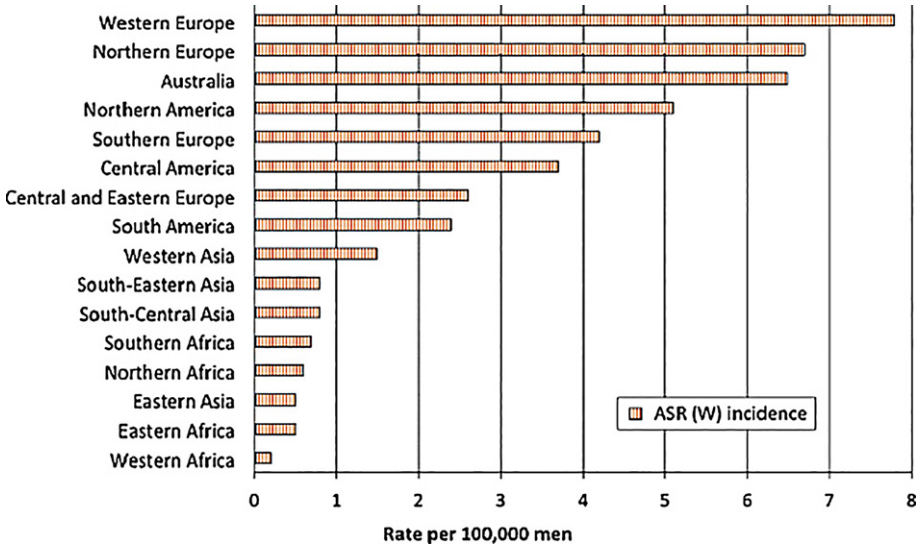

Fig. 2 Incidence rates of testicular cancer in different regions of the world. Age-standardized incidence rates (ASR) for testicular cancer for men of all ages in selected regions and countries of the world, extracted from GLOBOCAN 2008 database. Note that reporting systems varied by country and data quality may have fluctuated between regions. Reprinted from Rosen, A., Jayram, G., Drazer, M., and Eggener, S. E. (2011). Global trends in testicular cancer incidence and mortality. *European Urology* **60**, 374–379, with permission from Elsevier.

Interestingly, the TGCT risk is associated with the calendar year of birth rather than with the age of diagnosis; the so-called birth cohort effect (Bergström *et al.*, 1996).

Individuals with developmental abnormalities of the gonads and sex differentiation (disorders of sex development, DSD) are at high risk of germ cell neoplasia. The risk in DSD individuals varies, but it is greatest in persons with 45,X/46,XY karyotype, and with a partial androgen insensitivity syndrome (Cools *et al.*, 2011; Jørgensen *et al.*, 2015). Cryptorchidism is the most significant risk factor for sporadic testicular cancer (Dieckmann and Pichlmeier, 2004). In addition, inguinal hernia, low birth weight, high maternal age, being born first, late age at puberty, tall stature and poor spermatogenesis were reported associated with a risk of TGCT (Cook *et al.*, 2010; Jacobsen *et al.*, 2000; Lerro *et al.*, 2010; Maule *et al.*, 2012). Increased incidence of cryptorchidism, genital malformations and male infertility at the same time as of testicular cancer was a basis for a hypothesis that these conditions could be etiologically linked within the testicular dysgenesis syndrome (TDS) (Skakkebaek *et al.*, 2001). However, not all cases of genital malformations or infertility are a part of TDS; only those that are linked to early development, and without an obvious genetic aberration, are involved (Jørgensen *et al.*, 2010).

Most epidemiological studies are consistent with the early initiation of TGCT derived from GCNIS but it has been difficult to identify causal factors. Some associations with pre-natal and maternal exposures to xenobiotics/endocrine disruptors have been reported. Early studies investigated estrogens, including in utero exposure to diethylstilbestrol, but were not conclusive (Dieckmann and Pichlmeier, 2004; Strohsnitter *et al.*, 2001). Later studies focused on anti-androgenic organochlorine compounds (e.g. DDT) and phthalates, but human data are very scarce. Some evidence was found for higher serum levels of the persistent polychlorinated biphenyls (PCBs) in mothers of men with TGCTs (Hardell *et al.*, 2006), and of DDE in the serum of patients with TGCT (McGlynn *et al.*, 2008; Giannandrea *et al.*, 2013).

Very few risk factors for TGCT that act in adulthood have been identified. The only consistently reported post-pubertal risk factor for TGCT (mainly non-seminoma) is a heavy marijuana use (Daling *et al.*, 2009; Gurney *et al.*, 2015).

Management of Testicular Tumors

Clinical Diagnosis and Tumor Markers

A testicular mass, either felt by the patient, or detected in an ultrasonic investigation of the scrotum is usually the first presentation of testicular cancer. In some patients, testicular cancer can first manifest as metastatic disease, with usually uncharacteristic symptoms, such as lumbar pain, pulmonary symptoms or palpable lymph nodes. In the cases of some sex-cord stromal tumors, the clinical diagnosis can be related to excessive levels of steroid hormones produced by the tumors; androgens in Leydig cell tumors, estrogens or aromatase in Sertoli cell tumors. Accordingly, warning signs requiring careful differential diagnosis are precocious puberty in young boys, or gynecomastia at any age.

The preinvasive stage of TGCT, GCNIS is usually asymptomatic, so diagnosis at this early stage is rare, and most often happens in individuals from high-risk groups, such as DSD, history of cryptorchidism or infertility. Among the infertile men, the risk is much higher in patients with testicular atrophy and/or poor semen quality, and concomitant testicular microlithiasis (Jacobsen

et al., 2000; Rud et al., 2013; Tan et al., 2010). Diagnosis of GCNIS in requires testicular biopsy, which in most cases should be done bilaterally. Recognition of GCNIS requires experience, so immunohistochemical staining for GCNIS markers (e.g. primordial germ cell markers, such as PLAP or OCT4, mentioned above) are mandatory in all cases (Rajpert-De Meyts et al., 2015). In about 5%–8% cases of unilateral TGCT, GCNIS is present in the contralateral testicle, so a biopsy of the remaining testis is advised at the time of orchidectomy for the primary tumor, at least in men at high risk. A detailed description of the testicular biopsy methods and evaluation can be found in several review articles dedicated to this subject (McLachlan et al., 2007; Dieckmann et al., 2011; Rajpert-De Meyts et al., 2017). There are ongoing efforts to replace testicular biopsy for detection of GCNIS by a less invasive method of detection in a semen sample, which can be taken repeatedly. There is already an cytologic detection method, using an automated double-staining assay for alkaline phosphatase and AP2-gamma or OCT4, which are present only in GCNIS/tumor cells in semen, but further improvement of sensitivity is needed for routine use in the clinics (Almstrup et al., 2011).

Detection of incipient or disseminated TGCT, especially non-seminomas, is helped by circulating tumor markers. Taking a blood sample for these markers is obligatory in the clinics, both, at the time of diagnosis and later during the monitoring of treatment. The commonly used markers are beta chorio-gonadotrophin (β-hCG), α-fetoprotein (AFP), and (in specialized centers) lactate dehydrogenase (LDH, LD-1) (Gilligan et al., 2010; Albers et al., 2011). However, many cases of pure seminoma are marker-negative, so a recent discovery of specific micro-RNA secreted by overt TGCT and GCNIS-cells, both in adult men and children, is very promising (Palmer et al., 2010; Dieckmann et al., 2012; Novotny et al., 2012; Gillis et al., 2013).

Treatment of GCNIS and Tumors Confined to the Testis (Stage I)

All adult patients diagnosed with a preinvasive or overt testicular tumor should be offered semen cryopreservation before treatment. Bilateral GCNIS or GCNIS found in the only remaining testicle after removal of the other, is treated by a low-dose scrotal irradiation (Albers et al., 2011). This treatment preserves Leydig cell function but destroys normal germ cells, so radiotherapy may be postponed if the patient wishes to father a child. Chemotherapy should not be used to treat preinvasive lesions, because it often fails to eradicate GCNIS (Kleinschmidt et al., 2009).

Management of unilateral GCNIS and all types of stage I TGCTs is by radical orchiectomy (Albers et al., 2011). Surgical enucleating of small, well delineated tumors should only be considered in benign somatic cell tumors, e.g. LCT or in very large, resistant to treatment adrenal rest tumors. Pure seminomas have a good prognosis, with only 13%–19% of patients relapsing, so the vast majority of patients with stage I seminoma do not require any treatment after the surgery, and are followed by active surveillance (Nichols et al., 2013; Mortensen et al., 2014). Despite a higher relapse rate of 30%, a surveillance strategy is also practiced by most specialized centers in patients with clinical stage I non-seminomas, but some centers use adjuvant therapy with a single course of chemotherapy in selected patients (Nichols et al., 2013; Tandstad et al., 2014). The majority of relapses occur within 2 years but late relapses can occur in some cases, thus individual management and lifetime follow-up is recommended.

Treatment of Disseminated or Relapsed TGCT

The most common management of overt TGCT with disseminated disease includes surgery, radiotherapy and systemic combination chemotherapy with cytotoxic drugs, such as cisplatin, etoposide, bleomycin, vinblastine and methotrexate. It is important to evaluate the risk in each patient, including staging, prognostic factors and careful check of organ function, in order to select the best treatment with the lowest risk for late toxicity (Rajpert-De Meyts et al., 2016). Monitoring of serum markers is obligatory for accurate prognosis and assessment of treatment. Other prognostic factors are based on histopathologic analysis of tumor tissue and include vascular invasion, degree of neovascularization, a copy number of isochromosome 12p, and expression of proliferation markers and adhesion proteins (George et al., 2003; Albers et al., 2011). Based on the prognostic factors the patient is classified into a good, intermediate or poor prognosis, and the chemotherapy regimens differ accordingly (summarized in Oldenburg et al., 2013; Rajpert-De Meyts et al., 2016). The standard first line regimen is BEP (bleomycin, etoposide and cisplatin), administered three or four cycles depending on the patient's risk category. In patients with poor prognosis or resistance to chemotherapy, salvage regimens and complex surgery for residual tumors are needed. Overall the management is difficult, thus it should be carried out in specialized tertiary centers.

Late Effects and Follow-Up

Depending on the type of tumor, patients should be followed according to variable protocols, taking into account not only the possibility of relapse of the malignancy, but also the health issues related to the lack of one or both testicles, such as sub-fertility, hypogonadism, sexual dysfunction, metabolic syndrome and osteoporosis later in life. Patients with TGCT derived from GCNIS have poor spermatogenesis and decreased fertility even before the overt tumor has developed, and in most men there is further deterioration when the tumor grows (Petersen et al., 1999; Rives et al., 2012). In long-term survivors fertility is decreased and signs of Leydig dysfunction are common (Cvancarova et al., 2009; Bandak et al., 2017). Endocrinologic/andrologic follow-up is important, with close monitoring of testosterone levels, because hypogonadism consist a major risk factor for metabolic syndrome (Willemse et al., 2013).

Additional problems in patients treated with radio- or chemotherapy are the increased risks of second cancers, cardiovascular disease, peripheral neuropathy, ototoxicity and hepatotoxicity (Chovanec *et al.*, 2017). Of importance are quality of life issues related to prolonged anxiety and stress, often lower socioeconomic status or unemployment (Skaali *et al.*, 2011; Smith *et al.*, 2016). A growing consensus is that there is a need of individualized treatment to diminish immediate and late side-effects and attention should be given to the reproductive health and quality of life issues.

Male Oncoinfertility

Bernard Robaire, McGill University, Montréal, QC, Canada
Peter T Chan, McGill University Health Center, Royal Victoria Hospital, Montreal, QC, Canada

Introduction

Oncofertility is a subject that bridges the clinical care and research in oncology and reproductive medicine, with aims to explore and expand options for the reproductive future of cancer survivors and to minimize adverse events in their offspring. The importance of recognizing oncofertility as a discipline is two-folds. First, cancer diagnosis and therapies, from surgeries and radiation therapies to immuno- and chemotherapies, have a significant negative impact on reproductive health. Further, even for young adults and children, at the time of cancer diagnosis, fertility specialists are generally not involved in providing the needed counseling on fertility preservation options and future prospects of fertility risks. It is only after the individual has survived cancer and enters the parenthood-planning state that they seek care from fertility specialists; unfortunately, it is then too late to implement various fertility preservation strategies that could have optimized their chances to be successful in having children.

Indeed, oncofertility is an interdisciplinary subject that demands close collaboration of a multidisciplinary team of health care professionals, ranging from clinicians (including nurses, oncologists, geneticists, reproductive gynecologists and urologists), scientists (including andrologists, embryologists, basic scientists) and to psychosocial experts (including psychologists, social workers, ethicists and legal professionals). In addition to the management of sub- or infertility, oncofertility also incorporates reproductive issues after cancer treatment, such as family planning, complex contraception, hormonal management throughout survivorship, surrogacy, and adoption. The focus of this article will be on the impact of cancer and cancer therapies on male reproductive health and the various options currently available for male fertility preservation.

Epidemiology of Cancer in Boys and Young Men

Common cancers in men that receive most attention in the public media include lung, colon, prostate, skin, and liver cancers. These cancers, however, tend to affect men who have passed the age when most men are concerned about reproductive potential. For boys and young men, the most common cancers include testicular cancer, lymphoma, leukemia, sarcoma, and brain cancers. The incidence of childhood cancer worldwide has been steadily increasing over the past 50 years (American Cancer Society, 2016; Siegel *et al.*, 2017). With an estimated cumulative incidence of 1720 per million, equivalent to a risk of 1 in 581, childhood cancer is indeed one of the leading causes of death among children younger than 15 years of age. According to the recent data from the American Cancer Society, 51,350 boys and men in the United States under the age of 45 will be newly diagnosed with cancer in 2017.

Thanks to tremendous strides in cancer management, including early detection strategies and advances in various treatment modalities such as surgeries, radiation, and combination chemotherapy regimens, the survival rates of many childhood cancers have increased dramatically over the past 40 years (National Cancer Institute, 2009). It is estimated that in North America approximately 1 in 900 of the population aged 20–45 years is a childhood cancer survivor (Bhatia, 2005).

While many of these young cancer survivors can expect a good quality of life, they may also face a series of undesired consequences related to their cancer and cancer therapies. Impairment in reproductive health is a well-known complication of cancer therapy; it occurs in a significant proportion of cancer survivors due to the inhibition of spermatogenesis (spermatotoxicity) of cancer treatments such as chemotherapy and radiation therapy. Many young cancer survivors have not initiated or completed forming a family. Interestingly, surveys indicate that almost 80% of childless cancer survivors report the desire to have children and believe that their experience of surviving cancer will make them better parents (Schover *et al.*, 1999). In a recent study, adolescents prioritized fertility as a top goal after good health (Klosky *et al.*, 2015).

Reproductive Health in Cancer Patients Prior to Cancer Treatment

The reproductive health of cancer patients may be suboptimal even before receiving cancer therapies, as revealed by studies on the sperm density and morphology of prechemotherapy sperm banked samples and on case–control studies of their natural fecundity (Baker *et al.*, 2005; Meseguer *et al.*, 2006; O'Flaherty *et al.*, 2008). This may be due in part to the decline in the physical state (poor nutrition, fever, cachexia, pain, etc.) of the patients from cancer. The psychosocial stress attributed to the cancer diagnosis may play a role in the well-being of the subject. Prolonged periods of sexual abstinence may also contribute to the poor sperm quality before chemotherapy. In testicular cancer, poor sperm profile may be secondary to having only one remaining contralateral noncancerous testis to produce sperm. The remaining noncancerous testis may have compromised reproductive function due to a higher risk of

coexisting intraepithelial germ-cell tumors and abnormal spermatogenesis, both quantitatively and qualitatively (Baker *et al.*, 2005; Dieckmann *et al.*, 2007).

Prior to chemotherapy, 37% of men with testis cancer and 81% of men with Hodgkin lymphoma demonstrate abnormal sperm nuclear chromatin structure despite having normal sperm density and motility (O'Flaherty *et al.*, 2008). Several studies have supported these findings (Ståhl *et al.*, 2009; Rives *et al.*, 2012; Bujan *et al.*, 2013), while some others did not (Ribeiro *et al.*, 2008; Smit *et al.*, 2010). The main concern is that with subsequent cytotoxic cancer therapy, sperm from cancer patients are at risk for further genetic damage.

Cancer Management Strategies

The choice among various cancer management modalities, including surgery, radiation and chemotherapy, depends on the nature and stage of the cancer and the comorbidity of the subject. A combination of these modalities in various orders may be required to achieve optimal cancer control. Complications of each modality also vary. Mechanisms of how each treatment modality may potentially compromise male reproductive health are discussed in this section.

Impact of Surgical Management for Cancer on Male Reproductive Status

The purpose of surgical resection of tumor is to remove the tumor with adequate surgical margins to aim for cure or to debulk the volume of tumor to facilitate the effect of adjuvant therapy with radiation or chemotherapy. A common surgical management for testicular cancer in young males is radical orchiectomy. Removal of one testis affects the total spermatogenic activity in an individual. Men with testicular cancer are at risk of having decreased spermatogenic activity even in the remaining testis. Other surgical managements for cancers in young males may result in damage to the autonomic nervous system required for semen emission leading to infertility despite preservation of spermatogenic function.

Radiation Therapy

Germ cells and somatic cells in testes are prone to damage post radiation. The usual clinical dosage of radiation therapy for cancer ranges from 0.2 to 70 Gy, depending on the nature, stage, and anatomical location of the tumor. A cumulative dosage of 2.5–6 Gy directly to the testes may permanently damage germ cells, leading to prolonged or permanent azoospermia (Clifton and Bremner, 1983). Even for radiation therapy outside the pelvic areas (e.g., paraaortic lymph nodes) with gonadal shielding to reduce the extent of direct gonadal toxicity, the scattering effects of radiation may still contribute to impaired fertility. Such damage to sperm production may be further attributed to damage to cells in the somatic compartment of the testis. Using spermatogonial stem cell (SCC) transplantation in rat, Zhang *et al.* (2007) demonstrated that transplantation of SCCs from irradiated animals into testes of irradiated nude mice permitted differentiation of the donor spermatogonia to spermatozoa. Conversely, transplantation of SCCs from untreated prepubertal rats into irradiated rat testes showed that the donor spermatogonia were able to colonize along the seminiferous tubules, but could not differentiate. Their findings suggest that the defect caused by radiation in the rat testes that hinder spermatogonial differentiation is due to damage to the somatic compartment (Zhang *et al.*, 2007).

Clinically, radiation therapy may have further negative impact on sperm chromatin integrity for men treated with childhood cancers (Romerius *et al.*, 2010) or prostate cancer as adult (Singh *et al.*, 2012). Fluorescence in situ hybridization (FISH) demonstrated an increase in the incidence of sperm aneuploidy on chromosome 18, X and Y in men treated with radiotherapy for testicular seminoma (Le *et al.*, 2014). Taken together, current evidence supports the presence of a significant risk of impairment of the male reproductive status after radiotherapy for cancer.

Chemotherapy

Chemotherapy is generally indicated in advanced and metastatic cancer, although its use in certain cancers, such as germ cell tumors at an early, localized stage, may help to lower the risks of subsequent metastasis. In addition to malignant cells, any rapidly dividing cells, including germ cells at various phases of spermatogenesis, are targets of chemotherapy. Gonadotoxicity of chemotherapy to an individual depends on at least three factors: (1) the nature of the malignancy, which dictates the type of chemotherapeutic agents to be used, (2) the stage of the disease, which dictates the duration and dosages of chemotherapy, (3) host factors, such as the baseline reproductive health of the individual.

Impact of Chemotherapy on Male Reproductive Health: Animal Studies

Using rodents (rats and mice) as models, a large body of evidence has emerged demonstrating that treatment with chemotherapeutic agents usually have dramatic effects on the production of male germ cells (Robaire and Hales, 2003; Anderson and Brinkworth, 2006). Depending on the mechanism by which such agents act on the different phases of spermatogenesis (spermatogonial mitotic cell division, meiosis, or spermiogenesis), consequences can range from complete elimination of germ cells

from the testis, resulting in Sertoli-cell-only syndrome, to no apparent histological effects on spermatogenesis, but functional effects on germ cells (their motility, fertilizing ability, or capacity to produce normal viable offspring). Over the past 20 years, studies on male mediated adverse effects of chemotherapeutic drugs, such as cyclophosphamide (CPA), bleomycin, etoposide, cisplatin, or procarbazine, on fertility and progeny outcome have clearly established some of the underlying molecular mechanisms that result in loss of fertility and altered progeny outcome (Anderson, 2005; Hales *et al.*, 2005; Meistrich, 2009; Downey *et al.*, 2018).

Using CPA or the combination of drugs used for treating testicular cancer (bleomycin, etoposide, and cisplatin, BEP) as model drugs and the rat as the model animal, it has been demonstrated that paternal exposures result in adverse reproductive outcomes that range from increased preimplantation and postimplantation loss or early postnatal death, to growth retardation and congenital malformation; significantly, some of these outcomes are transmitted to subsequent generations (Hales *et al.*, 1992; Downey *et al.*, 2018). It is particularly noteworthy that the action of such drugs on germ cells not only affects the number of germ cells that the testis can produce but also alters markers of chromatin structure (Comet, acridine orange, TUNEL, MBBr, and CMA3 assays, nuclear proteome) in spermatozoa (Delbes *et al.*, 2010). It is clear from animal studies that spermatozoa that have damaged chromatin as a result of paternal drug treatment are capable of fertilizing oocytes (Bieber *et al.*, 2006; Sakkas and Alvarez, 2010; Menezo *et al.*, 2010). These studies have also revealed that the effects of paternal exposure on progeny can be wide ranging. While treatment with BEP caused a decrease in both sperm production and sperm motility, no apparent effects were observed on progeny at the end of gestation, yet postnatal death rates were dramatically increased (Bieber *et al.*, 2006). By contrast, chronic CPA treatment had minimal effects on sperm number and motility, yet a wide range of effects were observed in progeny, ranging from abnormalities at birth to learning deficits as adults and in subsequent generations as well as abnormal reproductive capacity (Auroux *et al.*, 1990; Downey *et al.*, 2018).

The effects of such chemotherapeutic treatments can not only result in DNA breaks and crosslinks but can also cause epigenetic modifications; these include an alteration in DNA methylation profile (Chan *et al.*, 2012) and changes in sperm nuclear proteins (Maselli *et al.*, 2012; Bagheri-Sereshki *et al.*, 2016). Remarkably, proteins implicated in the translational control and post-translational processing of protamine 1 are also significantly elevated 9 weeks post-BEP treatment, suggesting that histone eviction may dictate the DNA availability for protamine binding (Maselli *et al.*, 2013). Males mated to control females 9 weeks after BEP treatment have reduced litter sizes; moreover, the profile of gene expression in the developing testes of their pups is altered (Maselli *et al.*, 2014). Liu *et al.* (2015) reported that exposure of male germ cells to a BEP induces telomere shortening in all stages of rat spermatogenesis. Thus altering epigenetic marks or nuclear proteins in mature spermatozoa impacts on male fecundity, potentially threatening normal progeny development; this raises concerns regarding transgenerational risks of chemotherapy exposure.

Clinical Studies

The assessment of the consequences on progeny outcome of exposure of men to chemotherapeutic drugs presents remarkable challenges. Chemotherapy often results in transient or permanent azoospermia or oligozoospermia in cancer patients (Gandini *et al.*, 2006). Large epidemiological studies, discussed above, have revealed that there is clearly an effect on fertility and time to pregnancy (Green *et al.*, 2010). In addition, the standard semen parameters (sperm number, motility, and morphology, as established by the WHO (World Health Organization, 2010)) are not sufficiently reliable predictors of male fertility (Virro *et al.*, 2004; Payne *et al.*, 2005; O'Flaherty *et al.*, 2008).

Consequently, the focus has shifted in recent years to assessing the nature and quality of chromatin in spermatozoa. In recent comprehensive reviews, Barratt *et al.* (2010) and Zini *et al.* (2014) have outlined our current clinical understanding and uncertainties related to the many assays used to ascertain sperm chromatin quality. Aneuploidy is one of the more striking consequences of anticancer drugs on sperm chromatin quality. Using multicolor-FISH assay in testicular cancer and Hodgkin lymphoma patients before and up to 24 months after the initiation of chemotherapy, Tempest *et al.* (2008) found that at 6 months, all cancer patients showed significantly increased frequencies of XY disomy and nullisomy for chromosomes 13 and 21. Although frequencies of aneuploidy generally declined over time after termination of treatment, increased aneuploidy frequencies persisted in some chromosomes at 24 months.

Using a series of assays that provide complementary information on sperm chromatin structure, for example, extent of single- and double-strand breaks, degree of protamination, cross-linking of sulfhydryl bonds, O'Flaherty *et al.* (2008) have shown that, prior to initiation of chemotherapy, sperm chromatin integrity was poorer in cancer patients than in a control population. After treatment with chemotherapeutics, not only was there the expected decline in sperm production and chromatin quality but also, up to 2 years later, a reduction in spermatozoal chromatin integrity in over 40% of the patients who had a return of spermatogenesis (O'Flaherty *et al.*, 2010). Subsequent multicenter prospective longitudinal studies of Hodgkin and non-Hodgkin lymphomas (Bujan *et al.*, 2014) and testicular germ cell tumors (Bujan *et al.*, 2013) supported these findings.

The negative impact of antineoplastic agents appears to extend beyond the genome in humans as well as it does in animals. It has recently been reported that temozolomide, an oral alkylating agent used for treatment of advanced astrocytoma and melanoma affected sperm quantity and quality (increased aneuploidy rate) as well as epigenome integrity (Heikens *et al.*, 1996). Alteration of spermatozoal DNA methylation profiles has a known association with clinical male infertility with oligozoospermia (Cui *et al.*, 2016). Hypomethylation of normally hypermethylated paternally imprinted loci is associated with neoplasia and other

metabolic and growth defects such as Beckwith–Wiedemann syndrome and disorders in neurodevelopment, cognition and behavior. Further studies are thus required to evaluate if such an imprinting error is corrected after fertilization and the potential extent of transgenerational risks.

Based on the limited studies to date, it is clear that the presence of several cancers in young men results, to varying degrees, in sperm chromatin with reduced integrity. Furthermore, treatment of cancer may cause transient partial or complete loss of spermatozoa. Under some conditions, it is clear that the germ cells that eventually return to repopulate the seminiferous epithelium are still damaged, while under others, they appear to be normal. Whether spermatogonial stem cells (SCC) are able to repair all the damage caused by radiation or chemotherapy or not remains to be established.

Male Fertility Preservation and Restoration Strategies

Sperm Cryopreservation

Sperm cryopreservation or sperm "banking" is currently the only available strategy to preserve male fertility. Ideally, sperm samples should be collected before any cytotoxic cancer therapies, through ejaculation by masturbation after 2 to 4 days of sexual abstinence. Then, sperm samples should be analyzed, frozen, and stored in aliquots in liquid nitrogen for future use. With the advances in and increased access to assisted reproductive technologies (ART's) such as in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI), a very low number of living spermatozoa are required to achieve fertilization; therefore, even sperm samples that are far from meeting the semen parameters set by the WHO may still be used to achieve fertilization.

Young men with newly diagnosed cancer that require cytotoxic therapy experience simultaneously complex psychosocial stress (Rosberger *et al.*, 2010). Important factors that influence the decision of cancer patients to bank sperm include: healthcare providers' role in discussing fertility preservation, importance of fatherhood, current fatherhood status, partner/parent influence, attitudes toward survival, complexity of sperm banking, cultural factors, sexual orientation and cost (Achille *et al.*, 2006). In the absence of fees for sperm banking and subsequent storage, young cancer patients are more willing to participate in sperm banking sessions in order to preserve their fertility prior to cancer treatment, despite the fact that they are under significant level of stress and time constrain to begin cancer treatment. The benefit is that sufficient sperm would be available for their future use, potentially leading to a higher chance of procreation success.

Sperm cryopreservation does have its limitations as a fertility preservation strategy. First, only subjects who have entered adolescence, when "spermarche" begins, can have spermatozoa in the semen for cryopreservation. One study of 62 attempts by adolescents to bank sperm before cancer therapy resulted in totally normal semen in only four subjects (Postovsky *et al.*, 2003). Semen procurement by masturbation may not always be feasible among adolescents, even for those who have spermatogenesis. In fact, for cultural and religious reasons, the act of masturbation may be viewed as inappropriate by parents of young adolescent cancer patients (Rosoff and Katsur, 2003). Alternative methods to obtain mature sperms in adolescents using high-frequency penile vibratory stimulus, electroejaculation, or surgical testicular sperm extraction may be required. The need of sedation/anesthesia (for electroejaculation or surgical extraction) may be too invasive for youngsters. Thus, sperm banking is not universally practiced in pediatric-oncology centers, and few adolescent friendly facilities exist.

For preadolescent boys with cancer, there is currently no accepted and proven option for fertility preservation. Early investigators held the view that being prepubertal during anticancer therapy conferred protection against gonadal damage. However, a study evaluating 12 men who survived childhood malignancy revealed that although puberty had progressed apparently normally in all 12, 8 patients were azoospermic, and only 1 had normal semen analysis 2–16.5 years post chemotherapy (Mustieles *et al.*, 1995). In addition, following treatment of Hodgkin lymphoma in childhood, severe germ cell damage was observed in the majority of patients, even 17 years after chemotherapy (Heikens *et al.*, 1996). Evidently, there is no gonadal protection in the prepubertal male against chemotherapy-induced damage (van Casteren *et al.*, 2009). In fact, some investigators believe that prepubertal testes are more vulnerable to the cytotoxic effects of chemotherapy than adult testes (Revel and Revel-Vilk, 2008).

Pharmacological Strategies

The hypothesis that blocking the hypothalamic–pituitary–gonadal axis prior to the initiation of chemotherapy to preserve the nondividing germ cell or SSC population was first proposed by Glode *et al.* (1981). Hormonal manipulation, including the use of exogenous gonadotropin-releasing hormone (GnRH) analogs and steroids (testosterone) to suppress gonadotropin release, has been investigated as a potential fertility preservation strategy. Since cytotoxic treatment acts mainly on rapidly dividing cells, germ cells have been postulated to be less susceptible to cytotoxic effects if hormone treatments are used to render the testes quiescent. This technique has been successful in some rodents (rats, but not mice) (Meistrich and Shetty, 2008); in addition, in rats the extent of the damage of chemotherapeutic agents extends beyond the germ cells to the somatic cells surrounding them (Zhang *et al.*, 2003). Thus far, clinical trials have not shown any benefit of this method (Thomson *et al.*, 2002). Furthermore, this approach would be ineffective for prepubertal children as the proliferation of germ cells in prepubertal primates appears to be gonadotropin independent (Kelnar *et al.*, 2002).

Fertility Restoration With Germ-Cell Transplantation

Stem cells of the male germ line, termed SSCs, exist in the testis prior to birth. Harvesting either SSCs or tissue blocks from testes for cryopreservation before anticancer therapies offers the hope for prepubertal boys with cancer to preserve fertility and form their family in the future (Nagano, 2004). After the patient is cured and is at an appropriate state of maturity, preserved SSCs, or SSCs derived from frozen tissue blocks, could be autotransplanted back to the seminiferous tubules to regenerate complete spermatogenesis. Cryopreservation of testis tissue from prepubertal boys has revealed that germ cells can be preserved (Keros *et al.*, 2007). An important feature of this strategy is that instead of just preserving fertility, it aims to "restore" fertility. This fertility restoration scheme, based on germ cell or tissue transplantation, has been established with mice and other species (Oatley and Brinster, 2008; Schlatt *et al.*, 2009) and is currently under investigation to extend its application to humans.

To date, several groups have reported different cell culture systems designed to maintain and expand human SSCs (e.g., Nagano *et al.*, 2002; Lim *et al.*, 2010; Sadri-Ardekani *et al.*, 2011; Guo *et al.*, 2015). Further, xenotransplantation of cultured human SSCs to immunodeficient mice—a well-acknowledged and the only available assay for functionality of human SSCs—demonstrated their migration to the niche at the basal membrane of the seminiferous tubules, indicating their SSC capabilities (Nagano *et al.*, 2002). Initiation of human spermatogenesis in the host mice has yet to be achieved; nonetheless, the steady progress in the development of male fertility restoration strategy with SCCs in the past two decades gives hope for breakthroughs that will affect clinical practice.

The advances made in culturing SCCs open an opportunity to combine these advances with the exciting germline genomic editing technology to potentially improve clinical outcomes. Several recent reports demonstrated the feasibility of genetic and epigenetic editing in SSC transplantation (Fanslow *et al.*, 2014; Wu *et al.*, 2015; Chapman *et al.*, 2015; Sato *et al.*, 2017). The use of the CRISPR-Cas9 system can successfully repair mutations, for example, the hemoglobin beta gene in β-thalassemia (Xie *et al.*, 2014), the dystrophin gene in Duchenne muscular dystrophy in patient-induced pluripotent stem cells (Li *et al.*, 2015), and the cystic fibrosis transmembrane conductor receptor locus in cultured intestinal stem cells from patients with cystic fibrosis (Schwank *et al.*, 2013). Potentially, identified cancer-inducing genes can be corrected in SCCs harvested in cancer patient during fertility preservation to reduce or eliminate the risk of transmission of cancer to offspring.

While significant progress has been made in this fertility restoration regime in the recent years, several hurdles must be overcome prior to realizing its clinical application. In addition to using a minimally invasive surgical approach to harvest SCCs (particularly when dealing with preadolescent boys) from the testes and proper isolation of the SCC population for cryopreservation, culture, clonal expansion and subsequent transplantation for spermatogenesis reintroduction, the risk of contamination with lingering cancer cells, as in the case of hematological cancers (e.g., leukemia) or metastatic cancers must be reduced to zero. Several groups have reported mixed results in the elimination of cancer cells when harvesting SCCs (Geens *et al.*, 2007; Hermann *et al.*, 2011; Sadri-Ardekani *et al.*, 2014). Additionally, the costs, risks, success rate and efficacy along with the potential well-being of the offspring produced with the complex interplay of various biotechnologies must be considered through rigorous ethical reflection and societal debate, particularly when genomic or epigenomic editing of the SCCs aimed at correcting adverse mutations may soon be a reality.

The Use of Assisted Reproductive Technologies in Cancer Survivors

For the majority of cancer survivors who desire to have children but have poor sperm quantity and quality, ART's with IVF/ICSI are sought to help them to father their own children (Chan *et al.*, 2001). ICSI is generally required when using cryopreserved gametes for reproduction. With regards to the outcomes of ICSI using cryopreserved sperm, the usage rate of cryopreserved sperm is significantly lower among cancer survivors compared to noncancer patients, for example, for infertility treatment, 11% versus 31%, respectively. Nonetheless, the live-birth rate of offspring with ICSI among male cancer survivors was comparable to that of noncancer patients (Hansen *et al.*, 2005). Specifically, the average success rate of achieving parenthood using cryopreserved sperm was 62.1%, which was at least comparable to the infertile patient population: oligospermic and testicular sperm extraction (TESE) patients (40% and 48.6% respectively). This provides evidence that cancer patients can bank sperm as effectively as men banking for infertility reasons.

Health of Offspring of Male Cancer Survivors

Whereas the nature, mechanisms and extents of gamete damage from cytotoxic anticancer therapies are important research questions, for cancer survivors one of the most important clinical questions is the health risks to their offspring after cancer. Several recent studies reported a nonsignificant risk of adverse offspring health outcomes from cancer survivors. Two studies from retrospective cohort analyses of the Childhood Cancer Survivor Study reported no increase in the risk of still birth, neonatal death (Signorello *et al.*, 2010) and congenital anomalies (Signorello *et al.*, 2012) among survivors of childhood cancer survivors who had undergone radiation and chemotherapy. A Danish case-cohort study also reported no increased risks of genetic disease from cancer survivors exposed to childhood/adolescent alkylating chemotherapies or radiation (Winther *et al.*, 2012). Using data collected from 1953 to 2004 from registries (e.g., national cancer, population birth and hospital discharge registries) on close to 7000 offspring of cancer survivors with congenital anomalies and over 35,000 offspring of these survivors' siblings, another recent

study demonstrated no significantly increase in offspring anomaly rates from cancer survivors, regardless of the age when the cancer was diagnosed; however, there was a significantly higher risk of congenital anomalies in the offspring of survivors with cancer diagnosed in earlier period (1955–64, prevalence ratio 2.77, 95% CI 1.26–6.11) (Seppänen *et al.*, 2016).

While messages from these new studies may be reassuring, a few important points must be noted. First, other earlier and contemporary series observed either increased (Magelssen *et al.*, 2008; Chow *et al.*, 2009; Ståhl *et al.*, 2011) or no increased risks (Mueller *et al.*, 2009; Green *et al.*, 2010; Byrne *et al.*, 1998) of congenital malformations in the offspring of cancer survivors. The inconsistency of the results may be in part related to the differences in samples size and power, definitions of outcomes, study designs and selection bias. Further, it should be noted that most of these data focus on outcomes of offspring from natural conceptions rather than with assisted reproduction—which many male cancer survivors may need with fresh or cryopreserved sperm. Indeed, Ståhl *et al.* (2011) reported a significantly higher risk of birth abnormalities in offspring of men with a history of cancer (relative risk 1.17, 95% CI = 1.02–1.31) with both natural conception as well as assisted reproduction. Perhaps most importantly, these data do not address adequately other important reproductive outcomes such as time required to achieve pregnancy, risks of lower number of offspring or rate of miscarriage, particularly early (<20 weeks) miscarriage; these are some of the endpoints that might be predicted to be affected based on the animal studies described above. Studies of offspring of cancer survivors beyond early developmental stages need to be undertaken to determine whether potential alterations in epigenetic marks can lead to behavioral, immunological, reproductive or other deficits in adulthood.

Taken together, cytotoxic cancer therapies not only will have negative impact on the quantitative and qualitative changes in conventional semen parameters and sperm chromatin quality leading potentially to adverse reproductive outcomes: clinical infertility, increased use of assisted reproduction and potential adverse outcomes in offspring. Even for male cancer survivors who manage to achieve live births naturally or via assisted reproduction, the potential risks of adverse outcomes including congenital malformation, genetic diseases, low-birth-weight cannot be completely eliminated. Further large scale prospective longitudinal studies of cancer survivor cohorts and multicenter cancer registry follow-up studies will shed lights on the actual reproductive risks to allow formulation of proper counseling to these young cancer survivors. Meanwhile, precancer treatment fertility preservation counseling is the key to minimize the potential risks of adverse outcomes in the reproductive status of these patients.

DEDICATION

Professor Luciano Martini, 1927–2017

The other Editor in Chief of the Encyclopedia, Professor Luciano Martini, passed away on July 13th, 2017. He was an internationally acclaimed authority in the field of endocrinology, in particular neuroendocrinology, a brilliant and imaginative scientist, and an impressive and erudite scholar.

Luciano achieved the venerable age of 90, and his long career was full of outstanding scientific achievements, leadership positions in academia and in scientific societies, academies, and committees.

Luciano received his MD degree from the University of Milan in 1950. He then rapidly progressed through junior academic ranks up to the position of Professor and Chairman of the Department of Pharmacology at the University of Perugia in 1968, and subsequently, in 1972, he returned to his *alma mater*, the University of Milan, as full Professor and Chairman of the Department of Endocrinology, a post he held until 2001. He served in Milan as director of the training and research program entitled Physiology of Reproduction for nearly 20 years and attracted to his team top-class Italian and foreign scientists to address his main research interests of neuroendocrine regulation of reproductive functions.

Scientific severity, ethical integrity, fine perception, and deep farsightedness describe best Luciano's character as a scientist. He created in his institute a scientific research group devoted to experimental endocrinology, which grew over the years in size and visibility and became widely recognized internationally. Luciano published more than 400 peer-reviewed and highly cited papers mainly in the fields of neuroendocrinology, endocrine oncology, physiology of reproduction, and steroid and energy metabolisms.

Luciano was a prolific editor of scientific books and journals, which include the two volumes of *Neuroendocrinology* and the nine biennial volumes of *Frontiers in Neuroendocrinology*. He was Editor in Chief of *Comprehensive Endocrinology* published in 12 volumes and the first Edition of *Encyclopedia of Endocrine Diseases*. He served as President in many national and international scientific societies including the International Society of Neuroendocrinology, the Italian Society of Endocrinology, the International Society of Endocrinology, and the European Federation of Endocrine Societies. For his scientific achievements Luciano received honorary doctorates in the universities of Liège, Santiago de Compostela, Pécs, and Milan, and he was the recipient of numerous scientific awards and invited academy memberships.

Luciano's portrait could not be complete if one forgets to mention his life-time passion for music. He was a well-trained and accomplished pianist, a passionate music listener, and an enthusiastic connoisseur of all types of music. He also was an amateur in visual arts and deeply interested in history.

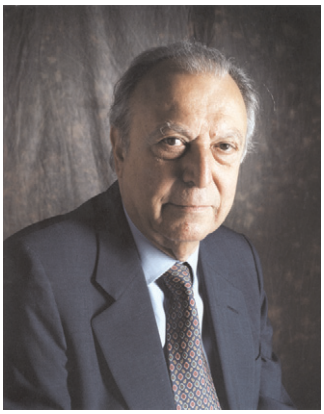
All of us who knew Professor Luciano Martini deeply mourn the loss of a great scientist and friend, the real "Il Maestro", teacher, colleague, and pioneer of modern neuroendocrinology. I trust Luciano would have been proud of this new edition of the Encyclopedia of Endocrine Diseases, and all of us having worked on its production would like to dedicate it to his memory.

Ilpo Huhtaniemi

Editor in Chief
Encyclopedia of Endocrine Diseases, 2nd edition

EDITORS IN CHIEF

Ilpo Huhtaniemi received his MD and PhD at University of Helsinki, Finland, did postdoctoral training in United States (UC San Francisco and NIH, Bethesda), and has been on sabbatical leave in Germany, United States and Scotland. In 1986–2002 he held the post of Professor and Chairman of Physiology at University of Turku, Finland. He moved in 2002 to UK to a Chair in Reproductive Endocrinology at Imperial College London, from which position he retired in 2015. He has received several national and international honors, amongst them a fellowship of The Academy of Medical Sciences, United Kingdom, and a Doctor Honoris Causa at the Medical University Łódź, Poland, and University of Szeged, Hungary. He was the Chief Managing Editor of *Molecular and Cellular Endocrinology* 1999-2017, has served in the Editorial Board of *Endocrinology and Endocrine Reviews* and is/has been the Editor or Editorial Board Member of several other scientific journals (e.g., *European Journal of Endocrinology*, *Clinical Endocrinology*, *Human Reproduction Update*, *Journal of Endocrinology*, *Molecular Human Reproduction*, *Reproduction*, *Asian Journal of Andrology*). He has extensive experience as Official of international scientific organizations (e.g., Past President of International Society of Andrology). His research interests include clinical and basic reproductive endocrinology, in particular the function of gonadotrophins and male reproductive endocrinology. He also has long-term interests in development of male contraception, hormone-dependent cancer, and the endocrinology of aging. He has authored about 700 peer-reviewed research articles and reviews, and his H-factor is 78.



Luciano Martini was born on May 14, 1927, in Milan, Italy. He obtained the degree of Medical Doctor "summa cum laude" on November 24, 1950, from the Faculty of Medicine of the University of Milan, Italy. He was Emeritus Professor of Pharmacology of the University of Perugia, Italy, and Emeritus Professor of Endocrinology of the University of Milan, Italy. He was Doctor Honoris Causa in Medicine of the Universities of Liège, Belgium, Santiago de Compostela, Spain, and Pécs, Hungary, and Doctor Honoris Causa in Biotechnological Sciences of the University of Milan, Italy. He was an author of more than 400 peer-reviewed scientific publications in the fields of endocrinology, neuroendocrinology, pharmacology, physiology of reproduction, steroid biochemistry, and basic oncology. He was elected member of the Accademia Nazionale dei Lincei (Italian National Academy) and of the American Academy of Arts and Sciences (Honorary Foreign Member).

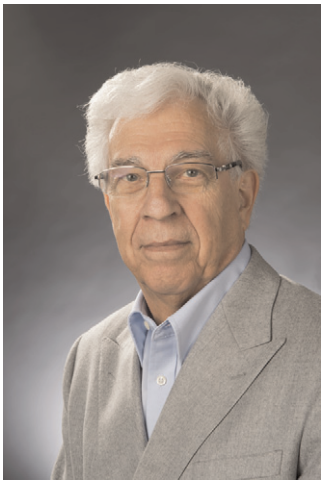
Luciano Martini acted as Editor in Chief of the journal *Frontiers in Neuroendocrinology* from 1990 to 2001, and was a Member of the Editorial Board of *Endocrinology* (Foreign Consulting Editor, 1961–65), as well as of several other speciality journals, such as *Experimental and Clinical Endocrinology*, *Biochemistry*, and *Steroids*. He has acted as Editor of several textbooks (e.g., *Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1966–67, and *Clinical Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1977–82) as well of a series of books under the name *Comprehensive Endocrinology* (13 volumes), Raven Press, New York, 1979–84. He acted as Editor in Chief for the first edition of *Encyclopedia of Endocrine Diseases* (4 volumes), Academic Press-Elsevier, San Diego, 2004.

EDITORIAL BOARD

SECTION EDITORS

Professor **Jean-Jacques Body** has been trained as an endocrinologist and a medical oncologist. He was Head of the Department of Medicine at University Hospital Brugmann in Brussels and Full Professor of Medicine (Internal Medicine) at the Free University of Brussels, (ULB), Brussels, Belgium. He was previously Head of the Internal Medicine Clinic at Institute J. Bordet (Cancer Center of ULB). He has also developed the "Supportive Care Dept" at the same Institute. His particular research interests are osteoporosis and bone metastases. He has a long-standing interest for bone metabolism and turnover in osteoporosis and tumor bone diseases. He has authored or co-authored more than 250 international peer-reviewed papers and he counts more than 200 invited lectures for international meetings.

Felipe F. Casanueva is Professor of Medicine at University of Santiago de Compostela and Head of Department of Endocrinology and Nutrition at University Hospital Santiago. He has been President of the scientific societes, such as: European Federation of Endocrine Societies (EFES), The Pituitary Society, International Society of Endocrinology (ISE) and, Sociedad Española para el Estudio de la Obesidad (SEEDO). Has written more than 50 chapters in international books and published more than 700 papers in international journals. He has received several awards for research at national and international level, such as: Rey Jaime I to the Medical Research, Geoffrey Harris Prize in Neuroendocrinology, Fundación Lilly of Bio-medical Research Clinic, Fundacion Danone – Professional Career – Dr Carlos Martí Hennberg, European Hormone Medal by the European Society for Endocrinology (ESE); he has been named Honorary Doctorate in Medicine of the University of Łódź, Erciyes, and Belgrade, and Honorary Member of the European Society of Endocrinology.



Dr. **Jean-Louis Chiasson** is currently Full Professor of Medicine at the University of Montreal. He is Head of the Research Group on Diabetes and Metabolic Regulation at the Research Center of the Centre hospitalier de l'Université de Montréal (CRCHUM).

Dr. Chiasson obtained his MD at Laval University in Quebec City in 1967. He did his specialty training in Internal Medicine at Laval Univesity and in Endocrinology at McGill University. He then did a research Fellowship in Diabetes at Vanderbilt University in Nashville, Tennessee. In 1974–76 and 1978–80, he was appointed Assistant Professor in the Department of Medicine and Physiology respectively at Vanderbilt University. In 1980, he returned to Montreal as Assistant Professor in the Department of Medicine at the University of Montreal and as Endocrinologist at Hotel-Dieu Hospital, now merged into the Centre hospitalier de l'Université de Montréal.

Dr. Chiasson's research interests include the regulation of carbohydrate metabolism in health and diabetes, as well as the development and evaluation of new strategies for the treatment and prevention of diabetes and its vascular complications. He has contributed over 250 scientific publications and lectures nationally and internationally on various topics on diabetes mellitus, its pathogenesis, its treatment, and its prevention. His scientific contribution puts him in the prestigious club of the 100 most cited publications in the world in the field of diabetes.

Sophie Christin-Maitre received her MD at University of Paris XI and her PhD at University Paris VI, Pierre and Marie Curie, France. She did a postdoctoral training in United States (Massachusetts General Hospital, Harvard University, Boston); she specialized in reproductive medicine. She holds the post of Professor of Endocrinology at University of Sorbonne, Paris, France. She has been the head of the Adult Endocrine Unit, in Hôpital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, since 2011. She is a member of the INSERM research unit UMR S_933, specialized in identifying new genes in reproductive disorders. Her interests include clinical and basic reproductive endocrinology, in particular the management of patients with Turner syndrome, patients with primary ovarian insufficiency, patients with hypogonadisms, and patients with abnormalities of sex development. She has authored approximately 150 peer-reviewed research articles and reviews.

Ulla Feldt-Rasmussen is Professor at Copenhagen University and Chief of Medical Endocrinology, National University Hospital. Her research interests involve the thyroid gland and autoimmunity, as well as pituitary and adrenal dysfunction.

She has published more than 410 papers in peer-reviewed journals on e.g., thyroid hormones and body composition, thyroid autoimmunity and cancer, cytokines as regulators of endocrine cells, influence of thyroid disrupting chemicals on thyroid cells, growth hormone deficiency related to body composition, bone metabolism and other pituitary axes, and transition from adolescent to adult care, as well as several aspects of Fabry disease. In recent years her group has embarked on studies on pituitary function after traumatic brain injury in a nationwide setting, and focusing on diagnostic accuracy of pituitary testing procedures. She has further authored numerous proceedings, textbook chapters, and other publications; as well as organized numerous international meetings and postgraduate courses, and has led several European projects and other collaborations within many areas of endocrinology.

Professor Feldt-Rasmussen reviews for international journals, and is an editorial board member of several endocrine journals. She belongs to many international professional organizations, including the Endocrine Society, ETA, ATA, ENEA, and GRS; she has served as Secretary-Treasurer of ETA and as President of the ETA Cancer Research Network.

Professor Feldt-Rasmussen serves on the advisory boards of several ad hoc endocrine committees, and has received many prestigious prizes including the Mayo Clinic's Haynes Lecturer's Award and ETA's Pinchera Research Prize.

Wouter W. de Herder M.D. Ph.D. (1960) is Professor of Endocrine Oncology at the Erasmus MC in Rotterdam, the Netherlands. In this University Hospital he is chairman of a multidisciplinary group for endocrine oncology (tumorwerkgroep endocriene tumoren) and he is head of the ENETS centre of excellence for neuroendocrine tumors. His major research interests are neuroendocrine and endocrine tumors.

Professor de Herder received his M.D. in 1985 and his Ph.D. in 1990 from the Erasmus University in Rotterdam, the Netherlands.

He is a member of several international and Dutch national societies, such as the Dutch Society for Endocrinology (NVE), the Endocrine Society (USA), the European Society of Endocrinology (ESE), European Neuroendocrine Tumor Society (ENETS) and the North American Neuroendocrine Tumor Society (NANETS). He served as a board member of the Dutch Society for Endocrinology (NVE) (2009–14). He served as chairman (2006–08) and vice-chairman of ENETS (2008–10) (European Neuroendocrine Tumour Society). He is member of the advisory boards of ENETS and NANETS.

Professor de Herder has (co-)published over 400 peer-reviewed papers and book chapters and is a reviewer for many international journals.

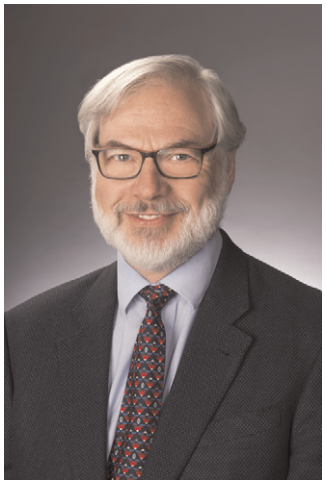
He is a member of the editorial boards of *Neuroendocrinology; Endocrinology, Diabetes & Metabolism Case Reports; Clinical Endocrinology*, and *Endocrine-Related Cancer*.

Professor de Herder has given over 200 invited presentations at Dutch national and international meetings.

Ieuan Hughes is currently Emeritus Professor of Pediatrics at the University of Cambridge and Honorary Consultant Pediatrician at Cambridge University Hospitals NHS Foundation Trust and Cambridge Biomedical Campus. He is the author of more than 300 papers and chapters across the whole range of paediatric endocrinology. His particular expertise is in disorders of sex development for which he coordinated the International Consensus on the approach to the investigation and management of this broad topic. Research interests focus on steroid enzyme deficiencies and molecular mechanisms of androgen action.
Professor Hughes has served on the editorial boards of several journals, including *Clinical Endocrinology*, *Journal of Clinical Endocrinology*, and *Metabolism* and *Archives of Disease in Childhood* where he was also the Associate Editor. He is Past-Secretary and President of the European Society for Pediatric Endocrinology and a recipient of the highest award of the Society, the Andrea Prader Prize. Professor Hughes is a James Spence Medallist of the Royal College of Pediatrics and Child Health for outstanding contributions to paediatric knowledge. He is a Fellow of the Academy of Medical Sciences, a Council Member of the Learned Society of Wales and a Trustee of two charities. The chapter on Disorders of Sex Development in *Williams Textbook of Endocrinology* (now in its 14e) by Hughes and co-authors is considered to be a definitive and up to date regular review of this topic, specific and key to pediatric endocrinology.

Dr. **Gregory Kaltsas** MD FRCP (Lon) is Professor in General Medicine and Endocrinology at the National and Kapodistrian University of Athens, Greece. He was trained in General Medicine in Athens, Greece and London, UK, and in Endocrinology at the Middlesex and St Bartholomew's Hospital, London, UK. He developed a particular interest in neuroendocrinology (pituitary and neuroendocrine tumors) and adrenal physiology and diseases. Upon returning to Greece he established a neuroendocrine network and he is currently running the European Neuroendocrine Tumor Society (ENETS) Center of Excellence at Laiko Hospital in Athens, Greece. He has served as a member of the advisory board of ENETS and of the Executive Committee of the European Neuroendocrine Association (ENEA) and he has been elected in the Executive Committee of the International Society of Endocrinology. He has recently been elected as a representative of the European Society of Endocrinology in the ExCo of the International Society of Endocrinology. He has published more than 300 original papers, reviews, and chapters and serves on editorial boards and as associate editor in several endocrine journals.

Jean-Marc Kaufman obtained his MD and PhD degrees at the Ghent University, Belgium. He was a Senior Postdoctoral Research Fellow (1982–84) in reproductive physiology at the University of Texas Medical School at Houston. He is board certified in Endocrinology and in Nuclear Medicine. In 1985 he joined the staff of the Ghent University Hospital; he headed the department of Endocrinology from 2003 to 2014 and the Laboratory for Hormonology from 1995 to 2014. He was appointed in 1993 Professor of Medicine at the Ghent University (1993) and is past Chair of the Department of Internal Medicine at the Ghent University (2010–14). From October 1st 2014 he is Professor Emeritus at the Ghent University where he is pursuing clinical and research activities. Main research interests are in the assessment, regulation, and action of sex steroids with focus on their role in health, disease, and aging in men, and in osteoporosis in men. He is (co)author of over 300 publications in international peer-reviewed journals.



André Lacroix, MD FCAHS is Professor of Medicine, Division of Endocrinology at Centre hospitalier de l'Université de Montréal (CHUM). His areas of interest include the mechanisms of adrenal Cushing syndrome, primary aldosteronism, adrenal tumorigenesis, the role of aberrant adrenal hormone receptors in adrenal overfunction, as well as new drugs in the therapy of Cushing disease, primary aldosteronism and adrenocortical cancer.
He was trained at the University of Montreal followed by fellowships in Endocrinology and research at Vanderebilt University and National Institutes of Health, USA. He was Chairman of Medicine and Director of Academic Affairs at CHUM. Former President of the Canadian Society of Endocrinology and Metabolism, he is currently chairperson of the International Society of Endocrinology (2016–20), Editor, Adrenal Section of UpToDate and *Encyclopedia of Endocrinology*, Senior Editor of the *European Journal of Endocrinology*. Fellow of the Canadian Academy of Health Sciences since 2008 and Foreign member of the National Academy of Medicine of France since 2016.

Franco Mantero received his MD at the University of Padua, Italy, did postdoctoral training in Switzerland (Clinique Medicale Therapeutique, Hopital Cantonal, University of Geneva) and in United States (University of California, San Francisco), and has been on sabbatical leave in United Kingdom, United States, and France. He held a post of Associate Professor in Medicine at the Institute of Semeiotica Medica, University of Padua (1981–86). In 1986 he moved to the University of Catania to the Chair of Andrology and Endocrinology, in 1992 to the University of Ancona, and in 2000 to the University of Padua to the Chair of Endocrinology and Chief of the Endocrinology Unit of the Department of Medicine. He has received national and international honors, including a Doctor Honoris Causa at the Semmelweis University, Budapest, Hungary.
He has been Editorial Board Member of several scientific journals (e.g., *Clinical Endocrinology*, *Endocrinology*, *Journal of Hypertension*, *Journal of Endocrinology Investigation Steroids*)
He has served as Member of the Council of several international scientific societies (including International Society of Endocrinology, International Aldosterone Conference, Journee Klotz d'Endocrinologie Clinique, ENS@T) and one of the founders of the European Network for the Study of Adrenal Tumors. His research interests include clinical and basic endocrinology of the adrenal gland and endocrinology of hypertension, in particular pathophysiology of mineralocorticoids and primary aldosteronism. He has authored approximately 500 peer–reviewed articles and edited several books and proceedings.

Jorma Toppari, MD, PhD, is Professor of Physiology at the University of Turku and Chief Physician of Pediatric Endocrinology at Turku University Hospital, Turku, Finland. He is also Adjunct Professor in the Department of Growth and Reproduction at the University of Copenhagen, Denmark. He has served as chief editor of International Journal of Andrology (2001–09), and has been on editorial boards of several endocrinological journals, including currently *Endocrinology* and *Journal of Clinical Endocrinology and Metabolism*. He is the past President of the European Academy of Andrology. He has made numerous contributions to the studies on endocrine disruption in the past 20 years. He has published approximately 400 articles on endocrinology.

Jacquetta Trasler is a James McGill Professor in the Departments of Pediatrics, Human Genetics, and Pharmacology and Therapeutics at McGill University and a Senior Scientist at the Research Institute of the McGill University Health Centre (RI-MUHC). She received her MD and PhD degrees from McGill University followed by postdoctoral training in reproductive molecular biology at Tufts University in Boston. She has served as Director of the McGill University MD-PhD Program, Scientific Director of the Montreal Children's Hospital Research Institute (and simultaneously as Deputy Director/CSO of the RI-MUHC), President of the Canadian Fertility and Andrology Society, Member of the Institute Advisory Board for the Canadian Institutes of Health Research (CIHR) Institute of Genetics and currently serves on the CIHR Stem Cell Oversight Committee and College of Reviewers. Her research focuses on epigenetics and epigenomics to better understand the molecular and cellular targets for drug effects on germ cells with implications for the resulting offspring. She has been involved in scientific program organization for numerous meetings in the field of reproductive biology and medicine and is collaborating with national and international colleagues in clinical studies to examine how assisted reproductive technologies, infertility, drug treatment, and folate deficiency and supplementation impact the human epigenome including that of future generations.

Christina Wang, MD is Professor of Medicine, Assistant Dean at the David Geffen School of Medicine at UCLA, and Associate Director for Clinical and Translational Science Institute and a faculty member of the Division of Endocrinology, Department of Medicine, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, California.

Dr. Wang has been involved in many funded basic and clinical research studies. Her current clinical research studies include androgen replacement therapy, hormonal male contraceptive development, late onset hypogonadism, accurate assessment of serum androgens, and diet and androgen metabolism. Her basic research studies focus on the regulation of spermatogenesis and mitochondrial derived peptides in spermatogenesis.

She has authored over 300 peer-reviewed publications, 67 chapters and reviews mainly on male reproductive biology including characterization of the pharmacokinetics and efficacy of androgens in men, trials of hormonal male contraceptive, regulation of germ cell apoptosis, and reproductive aging. Dr. Wang served on the Executive Council, several committees and was the President of the American Society of Andrology (2006–07). She also served the International Society of Andrology as Secretary (2001–05) and Chair of the Program Organizing Committee (2005–09). She was President of the International Society of Andrology (2009–13). She is a member of the Research Group on Methods for the Regulation of Male Fertility of the World Health Organization since 1984 and Chairperson (1991–2002).

She has mentored many physician and scientist and is an advocate of young investigators. Dr. Wang has been invited speaker and distinguished lecturer at many national and international endocrinology, reproductive endocrinology, and andrology conferences.

Julia K. Bosdou
Aristotle University of Thessaloniki, Thessaloniki, Greece

Anja Bosy-Westphal
University of Kiel, Kiel, Germany

Philippe Bouchard
Sorbonne University, Paris, France

Roger Bouillon
Laboratory of Clinical and Experimental Endocrinology, KU Leuven, Leuven, Belgium; and University Hospitals, Leuven, Belgium

Isabelle Bourdeau
Centre hospitalier de l'Université de Montréal (CHUM), Montréal, QC, Canada

Jean-Pierre Bourguignon
University of Liège, Liège, Belgium; and CHU de Liège, Chênée, Belgium

Mary L. Bouxsein
Beth Israel Deaconess Medical Center, Boston, MA, United States; Harvard Medical School, Boston, MA, United States; and Massachusetts General Hospital, Boston, MA, United States

Elvira V. Bräuner
University of Copenhagen, Copenhagen, Denmark

S.D. Brain
King's College London, London, United Kingdom

Glenn D. Braunstein
Cedars-Sinai Medical Center, Los Angeles, CA, United States; and University of California Los Angeles, Los Angeles, CA, United States

Ralph Brecheisen
Maastricht University, Maastricht, The Netherlands

Claire Briet
University Hospital of Angers, Angers, France; and University of Angers, Angers, France

Janet Brown
University of Sheffield, Sheffield, United Kingdom

Thierry Brue
Reference Center for Rare Pituitary Diseases, Assistance Publique Hopitaux de Marseille, La Conception Hospital, Marseille Cedex 05, France; and INSERM UMR-U910, Aix Marseille University, Marseille Cedex 05, France

Antonio Bruni
University of Alberta, Edmonton, AB, Canada

Rosa Maria Bruno
University of Pisa, Pisa, Italy

Aude Bruyneel
Free University of Brussels, Brussels, Belgium

Michael Buchfelder
University Hospital Erlangen, Erlangen, Germany

Krupali Bulsari
Princess Alexandra Hospital, Brisbane, QLD, Australia; and University of Queensland, Brisbane, QLD, Australia

Peter Burckhardt
Hirslanden Clinic, Lausanne, Switzerland

Albert G. Burger
University of Bern, Bern, Switzerland; and University of Geneva, Geneva, Switzerland

Alexander S. Busch
University of Copenhagen, Copenhagen, Denmark

Luca Busetto
University of Padua, Padua, Italy

Gary Butler
University College London Hospital NHS Trust, London, United Kingdom; and UCL Great Ormond Street Institute of Child Health, London, United Kingdom

Véronique Cadoret
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France; and CHRU Bretonneau, Medicine and Biology of Reproduction, CECOS, Tours, France

Lorenzo A. Calò
University of Padua, Padua, Italy

Irene Campi
University of Milan, Milan, Italy

Biagio Cangiano
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Letizia Canu
University of Florence, Florence, Italy

Perrine Capmas
Bicetre Hospital, Le Kremlin Bicetre, France

Carlo Cappelli
University of Brescia, Brescia, Italy; and Endocrine and Metabolic Medicine Unit, ASST Spedali Civili di Brescia, Brescia, Italy

Marta Caretto
University of Pisa, Pisa, Italy

Robert M. Carey
University of Virginia Health System, Charlottesville, VA, United States

Rafael Carmena
University of Valencia, Valencia, Spain

Nancy Carrasco
Yale School of Medicine, New Haven, CT, United States

Olivera Casar-Borota
Uppsala University, Uppsala, Sweden

Livio Casarini
University of Modena and Reggio Emilia, Modena, Italy

James Casella-Mariolo
Sapienza University of Rome, Rome, Italy

C. Casellini
Eastern Virginia Medical School, Norfolk, VA, United States

Lidia Castagneto-Gissey
Sapienza University of Rome, Rome, Italy

Maurizio Castellano
University of Brescia, Brescia, Italy; and Endocrine and Metabolic Medicine Unit, ASST Spedali Civili di Brescia, Brescia, Italy

Frederic Castinetti
Reference Center for Rare Pituitary Diseases, Assistance Publique Hopitaux de Marseille, La Conception Hospital, Marseille Cedex 05, France; and INSERM UMR-U910, Aix Marseille University, Marseille Cedex 05, France

Frederic Castinetti
Aix Marseille University, Marseille, France

Victoria Catalán
University of Navarra, Pamplona, Spain; CIBEROBN, ISCIII, Pamplona, Spain; and IdiSNA, Pamplona, Spain

Victoria Catalán
Metabolic Research Laboratory, University of Navarra, Pamplona, Spain; CIBEROBN, Carlos III Health Institute, Pamplona, Spain; and Instituto de Investigación Sanitaria de Navarra (IdiSNA) Pamplona, Spain

Richard L. Cate
Boston University, Boston, MA, United States

Sophie Catteau-Jonard
Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Anne Caufriez
Free University of Brussels, Brussels, Belgium

Isadora Pontes Cavalcante
University of São Paulo, São Paulo, Brazil

Etienne Cavalier
University of Liège, Liège, Belgium

Jonas Čeponis
Lithuanian University of Health Sciences, Kaunas, Lithuania

Filomena Cetani
University of Pisa, Pisa, Italy; and University Hospital of Pisa, Pisa, Italy

Nathalie Chabbert-Buffet
Sorbonne University, Paris, France

Alan Chait
University of Washington, Seattle, WA, United States

Peter T. Chan
McGill University Health Center, Royal Victoria Hospital, Montreal, QC, Canada

Philippe Chanson
Assistance Publique-Hôpitaux de Paris, Service d'Endocrinologie et des Maladies de la Reproduction and Centre de Référence des Maladies Hypophysaires Rares, Bicêtre Hospital, Le Kremlin-Bicêtre, France; Université Paris-Sud, Le Kremlin-Bicêtre, France; and Institut National de la Santé et de la Recherche Médicale (INSERM) U1185, Le Kremlin-Bicêtre, France

Karen E. Chapman
University of Edinburgh, Edinburgh, United Kingdom

Helaine Laiz Silva Charchar
University of São Paulo, São Paulo, Brazil

F. Charles Brunicardi
University of California Los Angeles, Los Angeles, CA, United States

Evangelia Charmandari
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Sumana Chatterjee
Barts and the London School of Medicine and Dentistry, London, United Kingdom

Eleftherios Chatzellis
251 Hellenic Air Force and VA Hospital, Athens, Greece

Tim Cheetham
Newcastle University, Newcastle-upon-Tyne, United Kingdom

Wassim Chemaitilly
St. Jude Children's Research Hospital, Memphis, TN, United States

H. Chen
University of Alabama at Birmingham, Birmingham, AL, United States

Sabrina Chiloiro
Pituitary Unit, Catholic University of Sacred Heart, Rome, Italy

Luca Chiovato
University of Pavia, Pavia, Italy

E.R. Christ
University of Bern, Bern, Switzerland; and University of Geneva, Geneva, Switzerland

Mirjam Christ-Crain
University Hospital Basel, Basel, Switzerland

Sophie Christin-Maitre
Hospital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, Paris, France; and Sorbonne University, Paris, France

George P. Chrousos
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Janet S. Chuang
Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States

Maria Verena Cicala
South Tyrolian Academy of General Practice, Bolzano, Italy

Francesca Cioppi
University of Florence, Florence, Italy

Frédérique Clément
Project-team Mycenae, Inria Center of Paris, Paris, France

Philippe Clézardin
INSERM, Faculty of Medicine Lyon East, Lyon, France

Hedi L. Claahsen van de Grinten
Radboud University Medical Center, Nijmegen, the Netherlands

Mélanie Claps
University of Brescia, Brescia, Italy

Bart L. Clarke
Mayo Clinic, Rochester, MN, United States

Laurie E. Cohen
Harvard Medical School, Boston, MA, United States; and Dana-Farber/Boston Children's Hospital Cancer and Blood Disorders Center, Boston, MA, United States

Annamaria Colao
University of Naples Federico II, Naples, Italy

Annamaria Colao
Federico II University of Naples, Naples, Italy

Robert Coleman
University of Sheffield, Sheffield, United Kingdom

James J. Colt
Weill Cornell Medicine, New York, NY, United States

Oscar Coltell
Carlos III Health Institute, Madrid, Spain; and University Jaume I, Castellón, Spain

Robert V. Considine
Indiana University School of Medicine, Indianapolis, IN, United States

Lindsay S. Cooley
University of Bordeaux, Pessac, France

Martine Cools
Ghent University Hospital, Ghent, Belgium

Cyrus Cooper
MRC Lifecourse Epidemiology Unit, Southampton General Hospital, Southampton, United Kingdom

Cyrus Cooper
University of Southampton, Southampton, United Kingdom; University of Southampton and University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom; WHO Collaborating Centre for Public Health Aspects of Musculoskeletal Health and Aging, Liège, Belgium; and University of Oxford, Oxford, United Kingdom

Georges Copinschi
Free University of Brussels, Brussels, Belgium

F. Coppedè
University of Pisa, Pisa, Italy

Claire Cordroch
University Hospital of Bordeaux, Bordeaux, France

Dolores Corella
University of Valencia, València, Spain; and Carlos III Institute of Health, Madrid, Spain

Isabel M. Cornejo-Pareja
Virgen de la Victoria Universitary Hospital (IBIMA), Malaga, Spain

Giovanni Corona
University of Florence, Florence, Italy; and Bologna Maggiore-Bellaria Hospital, Bologna, Italy

Dalila B. Corry
David Geffen UCLA School of Medicine, Los Angeles, CA, United States

Karen E. Cosgrove
University of Manchester, Manchester, United Kingdom

Maria Manuel Costa
Centro Hospitalar São João, Porto, Portugal; and Queen Mary University of London, London, United Kingdom

Luís Costa
Hospital of Santa Maria, Institute of Molecular Medicine, Faculty of Medicine, University of Lisbon, Lisbon, Portugal

Mariana Costanzo
Hospital de Pediatría Garrahan, Buenos Aires, Argentina

Carine Courtillot
Sorbonne University, Paris, France

Rafael Coveñas
University of Salamanca, Salamanca, Spain

Danila Covelli
University of Milan, Milan, Italy

Laura E. Cowen
Georgetown University Medical Center, Washington, DC, United States

Brittany Croft
Murdoch Children's Research Institute, Melbourne, VIC, Australia

William C. Cushman
University of Tennessee Health Science Center, Memphis, TN, United States

Daniele Cusi
Bio4Dreams, Milan, Italy

Lanfranco D'Elia
Federico II University of Naples, Naples, Italy

Stella D'Oronzo
University of Sheffield, Sheffield, United Kingdom

Catherine Dacou-Voutetakis
University of Athens, Athens, Greece

Rozenn Dalbies-Tran
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Adrian F. Daly
University Hospital Center of Liège, Liège, Belgium

A.H. Jan Danser
Erasmus MC, Rotterdam, The Netherlands

Jessica Daolio
Arcispedale Santa Maria Nuova of Reggio Emilia, Reggio Emilia, Italy

Emile Daraï
Sorbonne University, Paris, France

Mehul T. Dattani
Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom; and UCL Institute of Child Health, London, United Kingdom

Justin H. Davies
Southampton Children's Hospital, Southampton, United Kingdom

Stephen N. Davis
University of Maryland School of Medicine, Baltimore, MD, United States

Shanlee M. Davis
University of Colorado, Boulder, CO, United States

Adolfo J. de Bold
University of Ottawa, Ottawa, ON, Canada

Giuseppina De Filpo
University of Florence, Florence, Italy

K. De Gendt
Catholic University of Leuven, Leuven, Belgium

Wouter W. de Herder
Department of Internal Medicine—Sector of Endocrinology, Erasmus MC - University Hospital Rotterdam, Rotterdam, The Netherlands

Frank H. de Jong
Erasmus University Medical Center, Rotterdam, The Netherlands

Frank H. de Jong
Erasmus University Medical Centre, Rotterdam, The Netherlands

Peter W. de Leeuw
Maastricht University Medical Center, Maastricht, The Netherlands

Laura De Marinis
Pituitary Unit, Catholic University of Sacred Heart, Rome, Italy

Maria Cristina De Martino
University of Naples Federico II, Naples, Italy

Sabine M.P.F. de Muinck Keizer-Schrama
Erasmus Medical Center – Sophia Children's Hospital, Rotterdam, The Netherlands

Beatriz Marinho de Paula Mariani
University of São Paulo, São Paulo, Brazil

Jean De Schepper
Free University of Brussels, Brussels, Belgium

Miguel Debono
The University of Sheffield, Sheffield, United Kingdom

Peter A. Deddish
University of Illinois College of Medicine, Chicago, IL, United States

Asma Deeb
Mafraq Hospital, Abu Dhabi, United Arab Emirates

Olaf M. Dekkers
Leiden University Medical Centre, Leiden, The Netherlands

Rita Del Pinto
University of L'Aquila, L'Aquila, Italy

Anne Delbaere
Free University of Brussels, Brussels, Belgium

Elaine M Dennison
MRC Lifecourse Epidemiology Unit, Southampton General Hospital, Southampton, United Kingdom

Didier Dewailly
Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Nathalie di Clemente
Pierre and Marie Curie University, Paris, France

Guido Di Dalmazi
Alma Mater Studiorum University of Bologna, Bologna, Italy

N. Di Iorgi
University of Genoa, Genoa, Italy

Paola Di Mauro
INSERM, Faculty of Medicine Lyon East, Lyon, France

Chantal Diaz-Latoud
INSERM, Faculty of Medicine Lyon East, Lyon, France

Michael DiMattina
Dominion Fertility, Arlington, VA, United States

Georgios K. Dimitriadis
University of Warwick Medical School, Coventry, United Kingdom; and Imperial College London, London, United Kingdom

Na Ding
Anhui Medical University, Hefei, China

Maria R. Dionísio
Hospital of Santa Maria, Lisbon, Portugal

S. Dizon
Queen's University, Kingston, ON, Canada

Graham J. Dockray
University of Liverpool, Liverpool, United Kingdom

Marie-Madeleine Dolmans
Pôle de Recherche en Gynécologie, Institut de Recherche Expérimentale et Clinique (IREC), Catholic University of Leuven, Brussels, Belgium; and Cliniques Universitaires Saint Luc, Brussels, Belgium

G.A. Donnan
University of Melbourne, Melbourne, VIC, Australia

Jacques Donnez
Society for Research into Infertility (SRI, Société de Recherche pour l'Infertilité), Brussels, Belgium; and Catholic University of Leuven, Leuven, Belgium

Olivier Donnez
Institut du Sein et de Chirurgie Gynécologique d'Avignon (ICA), Polyclinique Urbain V, Avignon, France

Robert M. Dores
University of Denver, Denver, CO, United States

Maria Dracopoulou
University of Athens, Athens, Greece

A. Drexler
UCLA School of Medicine, Los Angeles, CA, United States

Stenvert L.S Drop
Erasmus Medical Center-Sophia Children's Hospital, Rotterdam, The Netherlands

Ludivine Drougat
Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, United States

Jérôme Dulon
Sorbonne University, Paris, France

Agathe Dumont
Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Typhanie Dumontet
CNRS, INSERM, Clermont Auvergne University, Clermont-Ferrand, France

Leo Dunkel
Queen Mary University of London, London, United Kingdom

Mark J. Dunne
University of Manchester, Manchester, United Kingdom

Leonidas H. Duntas
University of Athens, Athens, Greece

Richard Eastell
University of Sheffield, Sheffield, United Kingdom

Camilla Eckert-Lind
University of Copenhagen, Copenhagen, Denmark

Grigoris Effraimidis
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Urs Eiholzer
Paediatric Endocrine Center Zurich (PEZZ), Zurich, Switzerland

Graeme Eisenhofer
Technical University Dresden, Dresden, Germany

Jean-Marie Ekoe
CHUM University of Montreal, Montreal, QC, Canada

Mustapha El Lakis
National Cancer Institute, Bethesda, MD, United States

Sébastien Elis
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Rossella Elisei
University of Pisa, Pisa, Italy

Gregory R. Emkey
Pennsylvania Regional Center for Arthritis & Osteoporosis Research, Wyomissing, PA, United States

Klaus Engelke
University of Erlangen-Nürnberg, Erlangen, Germany

T. Erbas
Hacettepe University, Ankara, Turkey

Copenhagen University Hospital, Copenhagen, Denmark

Ulrich Knigge
ENETS NET Center of Excellence (CoE), Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Christian A. Koch
Technical University of Dresden, Dresden, Germany; and Medicover MVZ Oldenburg, Oldenburg, Germany

X. Kodji
King's College London, London, United Kingdom

Kamila Kolanska
Sorbonne University, Paris, France

Efstratios M. Kolibianakis
Aristotle University of Thessaloniki, Thessaloniki, Greece

Anne-Sophie C.A.M. Koning
Leiden University Medical Center, Leiden, The Netherlands

George Kontogeorgos
``George Gennimatas'' General Hospital of Athens, Athens, Greece; National and Kapodistrian University of Athens, Athens, Greece; and University of Toronto, Toronto, ON, Canada

John J. Kopchick
Ohio University, Athens, OH, United States

Márta Korbonits
Queen Mary University of London, London, United Kingdom

Olympia Koulouri
University of Cambridge, Cambridge, United Kingdom; and National Institute for Health Research Cambridge Biomedical Research Centre, Cambridge, United Kingdom

Stavroula Kousteni
Columbia University, New York, NY, United States

Jolanta Krajewska
Maria Sklodowska-Curie Memorial Institute-Cancer Center, Gliwice, Poland

Csilla Krausz
University of Florence, Florence, Italy

Berit Kriström
Umeå University, Umeå, Sweden

Helen Kroening
University of Sheffield, Sheffield, United Kingdom

Abraham A Kroon
Maastricht University Medical Center, Maastricht, The Netherlands

Heiko Krude
Charité–Medicine University, Berlin, Germany; and Institute of Experimental Pediatric Endocrinology, Berlin, Germany

George A. Kuchel
University of Connecticut Health Center, Farmington, CT, United States

Alexandra Kulle
Christian-Albrechts University of Kiel (CAU), Kiel, Germany; and University Hospital of Schleswig-Holstein (UKSH), Kiel, Germany

Ioannis Kyrou
Harokopio University, Athens, Greece; Aston University, Birmingham, United Kingdom; University of Warwick, Coventry, United Kingdom; and University Hospitals Coventry and Warwickshire NHS Trust, Coventry, United Kingdom

André Lacroix
Endocrine Division and Research Center, Centre hospitalier de l'Université de Montréal (CHUM), Montreal, QC, Canada

Svetlana Lajic
Karolinska Institute at Karolinska University Hospital, Stockholm, Sweden

Elizabeth M. Lamos
University of Maryland School of Medicine, Baltimore, MD, United States

Fabio Lanfranco
University of Turin, Turin, Italy

Bente L. Langdahl
Aarhus University Hospital, Aarhus, Denmark

Seppo W. Langer
ENETS NET CoE, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

A. Lania
University of Milan, Milan, Italy

E. Laspa
University Hospital of Ioannina, Ioannina, Greece

Guido Lastra
University of Missouri, Columbia, MO, United States

Ana Claudia Latronico
University of São Paulo, São Paulo, Brazil

Vincent Laudet
Sorbonne University, Banyuls-sur-Mer, France

S. Lauhon
University of Michigan, Ann Arbor, MI, United States

Michaël R. Laurent
University Hospitals Leuven, Leuven, Belgium

Fabio Lauria
National Research Council of Italy, Avellino, Italy

John H. Lazarus
Institute of Molecular and Experimental Medicine, Cardiff University, Cardiff, United Kingdom; and University Hospital of Wales, Cardiff, United Kingdom

Albert Lecube
University Hospital Arnau de Vilanova, Lleida, Spain; Obesity, Diabetes and Metabolism Research Group (ODIM), Lleida Biomedical Research Institute (IRBLleida), Lleida, Spain; and University of Lleida, Lleida, Spain

Benjamin Z. Leder
Harvard Medical School, Boston, MA, United States

E.C.-H. Lee
University of Connecticut, Storrs, CT, United States

Peter Lee
Penn State Hershey Medical Center, Hershey, PA, United States

Christoph Lees
Queen Charlotte's and Chelsea Hospital, London, United Kingdom; and Imperial College London, London, United Kingdom

Pierre J. Lefèbvre
University of Liège, Liège, Belgium

Lisa-Marie Legault
University of Montreal, Montreal, QC, Canada

Jacques W.M. Lenders
Radboud University Medical Center, Nijmegen, The Netherlands; and Technical University Dresden, Dresden, Germany

Livia Lenzini
University of Padua, Padua, Italy

A.M. Leung
Division of Endocrinology, UCLA David Geffen School of Medicine, Los Angeles, CA United States

Stafford Lightman
University of Bristol, Bristol, United Kingdom

Padiporn Limumpornpetch
University of Leeds, Leeds, United Kingdom; and Prince of Songkla University, Songkhla, Thailand

M. Link
University of Utah, Salt Lake City, UT

Benjamin A. Lipsky
University of Washington, Seattle, WA, United States; and Veterans Affairs Puget Sound Health Care System, Seattle, WA, United States

Saúl Lira-Albarran
National Institute of Medical Sciences and Nutrition SZ (INCMNSZ), Mexico City, Mexico

Kirstie Lithgow
University of Calgary, Calgary, AB, Canada

Peter Y. Liu
Clinical and Translation Science Institute, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, CA, United States

Sarantis Livadas
University of Athens, Athens, Greece

Clare H. Llewellyn
University College London, London, United Kingdom

V. Llorente-Cortés
Cardiovascular Research Center, CSIC-ICCC Hospital Santa Creu I Sant Pau, Barcelona, Spain

Jay S. Loeffler
Massachusetts General and Harvard Medical School, Boston, MA, United States

Marc Lombès
University Paris-Sud, University of Paris-Saclay, Le Kremlin-Bicêtre, France; and Bicêtre Hospital, Le Kremlin Bicêtre, France

Lindsey A. Loomba-Albrecht
University of California Davis, Davis, CA, United States

Miguel López
CIBER Fisiopatología Obesidad y Nutrición, Carlos III Health Institute, Madrid, Spain; and University of Santiago de Compostela (USC), Santiago de Compostela, Spain

Carolina López-Cano
University Hospital Arnau de Vilanova, Lleida, Spain; Obesity, Diabetes and Metabolism Research Group (ODIM), Lleida Biomedical Research Institute (IRBLleida), Lleida, Spain; and University of Lleida, Lleida, Spain

Isabel Losano
University of Turin, Turin, Italy

David A. Lovejoy
University of Toronto, Toronto, ON, Canada

María Lozano-Madrid
Carlos III Health Institute, Madrid, Spain; and University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Gertrud Lund
CINVESTAV Irapuato Unit, Irapuato, Gto, Mexico

Elena Lundberg
Umeå University, Umeå, Sweden

Aldons J. Lusis
University of California Los Angeles, Los Angeles, CA, United States

Lorenza Macrina
IRCCS San Raffaele Scientific Institute, Milan, Italy

Filippo Maffezzoni
University of Brescia, Brescia, Italy

Mario Maggi
University of Florence, Florence, Italy; and Istituto Nazionale Biostrutture e Biosistemi, Rome, Italy

M. Maghnie
University of Genova, Genova, Italy

Amita Mahajan
University of Calgary, Calgary, AB, Canada

Eamonn R. Maher
Cambridge Biomedical Campus, Cambridge, United Kingdom

Virginie Maillard
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Katharina M. Main
University of Copenhagen, Copenhagen, Denmark

Gabriel M. Makhlouf
Virginia Commonwealth University, Richmond, VA, United States

Konstantinos Makris
KAT General Hospital, Athens, Greece; and University of Athens, Athens, Greece

Willy J. Malaisse
Free University of Brussels, Brussels, Belgium

J. Maletkovic
UCLA School of Medicine, Los Angeles, CA, United States

Federico Mallo Ferrer
Biomedical Research Center (CINBIO), University of Vigo, Vigo, Spain

Núria Mallorquí-Bagué
Carlos III Health Institute, Madrid, Spain; and University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Meera Mallya
Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom

Giuseppe Mancia
University of Milan-Bicocca, Monza, Italy

Jacqueline Mandelbaum
Tenon Hospital, Paris, France; and Pierre and Marie Curie University, Paris, France

Massimo Mannelli
University of Florence, Florence, Italy

Franco Mantero
University of Padua, Padua, Italy

Paolo Manunta
University Vita-Salute San Raffaele, Milan, Italy

Claudio Marcocci
University of Pisa, Pisa, Italy; and University Hospital of Pisa, Pisa, Italy

Roxana Marino
Hospital de Pediatría Garrahan, Buenos Aires, Argentina

Gabriel V. Markov
Sorbonne University, Banyuls-sur-Mer, France

Laura Marroquí
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Gary R. Marshall
University of Pittsburgh School of Medicine, Pittsburgh, PA, United States

Ritzén E. Martin
Karolinska Institute, Stockholm, Sweden

Laetitia Martinerie
University Paris-Sud, University of Paris-Saclay, Le Kremlin-Bicêtre, France; Service d'Endocrinologie Pédiatrique, Hôpital Robert Debré, Paris, France; and Paris Diderot University, Paris, France

Antoine Martinez
CNRS, INSERM, Clermont Auvergne University, Clermont-Ferrand, France

Daniel B. Martinez-Arguelles
McGill University, Montreal, QC, Canada

Sergio Martinez-Hervas
University of Valencia, Valencia, Spain; and CIBERDEM-Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders, ISCIII, Madrid, Spain

Enio Martino
University of Pisa, Pisa, Italy

Katia Maruca
IRCCS San Raffaele Scientific Institute, Milan, Italy

George Mastorakos
National and Kapodistrian University of Athens, Aretaieion Hospital, Athens, Greece

Yuji Matsuzawa
Sumitomo Hospital, Osaka, Japan

Gherardo Mazziotti
Carlo Poma Hospital, Mantova, Italy

Eugene V. McCloskey
MRC Arthritis Research UK Centre for Integrated Research in Musculoskeletal Aging, Metabolic Bone Center, Northern General Hospital, Sheffield, United Kingdom; University of Sheffield, Sheffield, United Kingdom; and University of Sheffield Medical School, Sheffield, United Kingdom

Timothy McClure
Lefrak Center for Robotic Surgery, Weill Cornell Medicine, New York, NY, United States

Ken McElreavey
Institut Pasteur, Paris, France

Bruce S. McEwen
Rockefeller University, New York, NY, United States

Serge McGraw
University of Montreal, Montreal, QC, Canada

Christian Meier
University Hospital Basel, Basel, Switzerland

Onno C. Meijer
Leiden University Medical Center, Leiden, The Netherlands

Berenice B. Mendonca
University of São Paulo, São Paulo, Brazil

Gabriele Mertes
Mülheim, Germany

Gemma Mestre-Bach
University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Boyd E. Metzger
Northwestern University Feinberg School of Medicine, Chicago, IL, United States

Ralph G. Meyer
Utah State University, Logan, UT, United States

Heino F.L. Meyer-Bahlburg
New York State Psychiatric Institute, New York, NY, United States; and College of Physicians & Surgeons of Columbia University, New York, NY, United States

Mirella L. Meyer-Ficca
Utah State University, Logan, UT, United States

Dragan Micic
University of Belgrade, Belgrade, Serbia

Jesús E. Millán Núñez-Cortes
Gregorio Marañon University General Hospital, Madrid, Spain; and Complutense University of Madrid, Madrid, Spain

Joaquín J. Millán Pérez
Complutense University of Madrid, Madrid, Spain

Paul D. Miller
University of Colorado Health Sciences Center, Denver, CO, United States

Geltrude Mingrone
Catholic University, Rome, Italy; and Guy's Campus, King's College London, London, United Kingdom

Katrina M. Mirabito Colafella
Erasmus MC, Rotterdam, The Netherlands; and Monash University, Melbourne, VIC, Australia

Alexander D. Miras
Imperial College London, London, United Kingdom

Philippe Monget
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Danielle Monniaux
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Silvia Monticone
University of Turin, Turin, Italy

Rebecca J. Moon
Southampton Children's Hospital, Southampton, United Kingdom

Stefano Mora
IRCCS San Raffaele Scientific Institute, Milan, Italy

G. Morana
University of Genoa, Genoa, Italy

Rachel C. Morgan
Indiana University School of Medicine, Indianapolis, IN, United States

Alberto Morganti
Centro Fisiologia Clinica e Ipertensione, Policlinico Hospital, Milan, Italy; and University of Milan, Milan, Italy

Luigi Mori
University of Brescia, Brescia, Italy

A. Ross Morton
Queen's University, Kingston, ON, Canada

Howard A. Morris
University of South Australia, Adelaide, SA, Australia

Giovanna Motta
University of Turin, Turin, Italy

Pierre Mouriquand
Hôpital Mère-Enfant – Claude-Bernard University, Lyon, France

Miguel Muñoz
Virgen del Rocío University Hospital, Sevilla, Spain

Maria Teresa Muñoz
University Hospital Niño Jesús, Institute of Investigation La Princesa, Madrid, Spain; and Center for Biomedical Research in Network on the Pathophysiology of Obesity and Nutrition (CIBEROBN), Carlos III Health Institute, Madrid, Spain

Araceli Muñoz-Garach
Virgen de la Victoria Universitary Hospital (IBIMA), Malaga, Spain

Maria Lorenza Muiesan
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Dick Mul
Diabeter, Center for Pediatric and Adolescent Diabetes Care and Research, Rotterdam, The Netherlands

Manfred J. Müller
University of Kiel, Kiel, Germany

Beat Müller
Medical University Clinic, Kantonsspital Aarau, Aarau, Switzerland; and University Hospital Basel, Basel, Switzerland

Paolo Mulatero
University of Turin, Turin, Italy

Tayane Muniz Fighera
Federal University of Rio Grande do Sul, Porto Alegre, Brazil

K.S. Murthy
Virginia Commonwealth University, Richmond, VA, United States

Marina Muzza
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Angel Nadal
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Y. Nagayama
Nagasaki University, Nagasaki, Japan

Bimota Nambam
Louisiana State University, Shreveport, LA, United States

Ruta Navardauskaite
Lithuanian University of Health Sciences, Kaunas, Lithuania

M.-L. Névoret
Impeto Medical, San Diego, CA, United States

Markella Nezi
National and Kapodistrian University of Athens, Aretaieion Hospital, Athens, Greece

Brian T. Nguyen
Keck School of Medicine of University of Southern California, Los Angeles, CA, United States; and Los Angeles Biomedical Research Institute and Harbor-UCLA Medical Center, Torrance, CA, United States

Atossas Niakan
University of Tennessee Health Science Center, Memphis, TN, United States

Nicolas C. Nicolaides
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Claus H. Nielsen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Henriette S. Nielsen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Lynnette K. Nieman
National Institutes of Health (NIH), Bethesda, MD, United States

Sarah M Nikkel
University of British Columbia, Vancouver, BC, Canada

Charlotte M. Niznik
Northwestern University Feinberg School of Medicine, Chicago, IL, United States

James D. Nobles
Leeds Beckett University, Leeds, United Kingdom

Pavel Nockel
National Cancer Institute, Bethesda, MD, United States

Ruben Nogueiras
CIMUS, USC, IDIS, Santiago de Compostela, Spain; and Carlos III Health Institute, Madrid, Spain

Ruben Nogueiras
CIBER Fisiopatología Obesidad y Nutrición, Carlos III Health Institute, Madrid, Spain; and University of Santiago de Compostela (USC), Santiago de Compostela, Spain

Anna Nordenström
Karolinska Institute at Karolinska University Hospital, Stockholm, Sweden

M. Nowak
Medical University of Lublin, Lublin, Poland

Tsuneo Ogawa
University of Ottawa, Ottawa, ON, Canada

Onyebuchi Okosieme
Cardiff University, Cardiff, United Kingdom

Wilma Oostdijk
Leiden University Medical Center, Leiden, The Netherlands

Jacques Orgiazzi
Lyon 1-Claude Bernard University, Lyon, France

Andrés E. Ortiz-Flores
University Hospital Ramón y Cajal, Madrid, Spain; University of Alcalá, Madrid, Spain; Ramón y Cajal Institute for Health Research IRYCIS, Madrid, Spain; and Biomedical Research Network Center in Diabetes and Related Metabolic Diseases CIBERDEM, Madrid, Spain

Nantia Othonos
University of Oxford, Oxford, United Kingdom

Susan M. Ott
University of Washington, Seattle, WA, United States

Karel Pacak
University of Connecticut Health Center, Farmington, CT, United States; and National Institutes of Health, Bethesda, MD, United States

Stephanie T. Page
University of Washington, Seattle, WA, United States

Uberto Pagotto
Alma Mater Studiorum University of Bologna, Bologna, Italy

Anna Paini
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Stefano Palomba
Grande Ospedale Metropolitano of Reggio Calabria, Reggio Calabria, Italy

George Paltoglou
Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom

Alessandra Panarotto
University of Brescia, Brescia, Italy

Amit V. Pandey
University of Bern, Bern, Switzerland

Vassilios Papadopoulos
University of Southern California, Los Angeles, CA, United States

Ralph Papas
University of Balamand, Beirut, Lebanon

Theodora Pappa
National and Kapodistrian University, Athens, Greece

Anne-Simone Parent
University of Liège, Liège, Belgium; and CHU de Liège, Chênée, Belgium

Gabriele Parenti
Endocrine Unit, Careggi Hospital, Florence, Italy

Ralf Paschke
University of Calgary, Calgary, AB, Canada

Leena Patel
The University of Manchester, Manchester, United Kingdom; and Royal Manchester Children's Hospital, Manchester University Hospitals NHS Trust, Manchester Academic Health Science Centre, Manchester, United Kingdom

Heather B. Patisaul
North Carolina State University, Raleigh, NC, United States

G. Patti
University of Genova, Genova, Italy

Michael A. Patton
St Georges University of London, London, United Kingdom

L.J. Pelliniemi
University of Turku, Turku, Finland

Bas Penders
Maastricht University, Maastricht, The Netherlands

Alberto M. Pereira
Leiden University Medical Center, Leiden, The Netherlands

Paola Perotti
University of Turin, Turin, Italy

Luca Persani
University of Milan, Milan, Italy

Luca Persani
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Panagiota Pervanidou
National and Kapodistrian University of Athens Medical School, Athens, Greece

Felice Petraglia
University of Florence, Careggi University Hospital, Florence, Italy

Cindy Pham
Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, CA, United States

Eliana Piantanida
University of Insubria, Varese, Italy

Jean-Yves Picard
Pierre and Marie Curie University, Paris, France

Marie-Eve Piché
Quebec Heart and Lung Institute, Quebec City, QC, Canada; Laval University, Quebec City, QC, Canada;

and Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom

Axelle Pintiaux
Free University of Brussels (ULB), Brussels, Belgium

University Hospital Erlangen, Erlangen, Germany

Stephan Zipfel
Medical University Hospital Tübingen, Tübingen, Germany

PREFACE

The first Edition of the *Encyclopedia of Endocrine Diseases* was published in 2004. Because of the enormous development in the field it was found important to produce a completely revised and updated Second Edition of the Encyclopedia. The new Edition is a must-have one-stop reference covering every aspect of the physiological background, pathogenesis, clinical diagnostics, and therapeutic aspects of the wide array of endocrine and related metabolic diseases.

The functional balance of the body (homeostasis) is maintained by two regulatory circuits, i.e., the nervous and the endocrine systems. Among the most complex constructs in the body, the endocrine system comprises a group of glands that secrete hormones directly into the bloodstream, where they reach their specific receptors in other parts of the body, evoking specific intracellular signaling pathways leading to their biological effect. Many classically non-endocrine organs (e.g., the heart) have also turned out to have endocrine functions. The endocrine system maintains and regulates the body's homeostasis by using hormones to control metabolism, temperature, biological cycles, internal fluid volume, reproduction, growth, body composition, and development. The system is a marvel when functioning optimally, i.e., maintaining the body homeostasis. Unfortunately, there is a myriad of ways these processes, actions, and functions can go awry, resulting in various endocrine and metabolic diseases, which form the over-arching theme of the Encyclopedia.

The Encyclopedia is not meant as a primer on the subject of endocrinology, but instead intended to provide a comprehensive reference work on the extensive spectrum of diseases and disorders that can occur within the endocrine and metabolic system. The updated version of this groundbreaking encyclopedia is especially timely, as it covers the dramatic discoveries in the field of endocrinology and metabolism over the past 10 years, particularly with respect to novel diagnostic techniques and treatment approaches. In particular, there have been tremendous advancements in our understanding of the molecular basis of endocrine and metabolic diseases (mutations, epigenetics, signaling), as well as pathogenesis and therapy of the common forms of these diseases (e.g., diabetes, obesity, and endocrine malignancies).

The Encyclopedia offers a unique source of up-to-date information for the physicians and basic scientists working in the field. It is an essential resource for every clinician diagnosing and treating endocrine patients. The Encyclopedia also offers the prime source of information for students of medicine and science around the world, as well as basic research workers in academia, the pharma industry, and in other areas in need of information on endocrinology and metabolism. It also offers useful information for the lay public about normal and abnormal functions of hormones.

The Encyclopedia is intended to serve as a useful and comprehensive source of information spanning the many and varied aspects of the endocrine and metabolic system. The chapters have been written to be accessible to both clinical and nonclinical readers. The articles have been formatted in similar fashion and each is intended as a stand-alone presentation. Each article begins with a glossary list defining key terms that may be unfamiliar to the reader and are important for understanding the article. The body of the article begins with a brief introduction to the subject under discussion, bold headings lead the reader through the text, and figures and tables explain and illuminate most articles. The main text is followed by referenced citations to provide the reader with access to additional information on the topic, and cross-references lead the reader to related entries in the encyclopedia. The relatively short stand-alone articles have allowed us to recruit the best experts available for each topic.

Unlike the first Edition, where the articles were arranged in alphabetical order, the 2nd Edition is arranged in organ-based thematic order, where each organ-based group of diseases is presented as cluster of articles in the first four volumes. The fifth volume is a stand-alone compilation of all articles on pediatric endocrinology. The thematic organization gives the reader a better general view of the coverage of articles on a specific endocrine organ or disease type.

The Second Edition of the Encyclopedia builds of the first edition. Nevertheless, to bring a major reference work with such a broad scope from initial conception to final publication involved a great deal of planning and organization, together with the efforts of innumerable individuals. The authors of the first edition were invited to update their earlier texts. If this was not possible, the Section Editors invited another expert in the topic either to update the previous text or to write a de novo text; the latter happened in most of these cases. Hence, the Second Edition contains to a large extent totally new information, or at least the fluency of all texts has been scrutinized. Furthermore, all manuscripts have undergone peer-review arranged by the Section Editors.

Assembling a large volume of articles with the purpose to cover all essential topics of endocrine diseases posed multiple challenges. Coverage was a significant problem: on one hand some redundancy of the topics was almost impossible to avoid in places while, on the other, there were inevitable gaps. Some of these arose from late cancellations; others from oversights on our part. We can only promise to fill these gaps in future editions. We also note that as can be expected for a large multi-author compilation the individual articles do differ in detail and approach. We considered it more important to allow our experts substantial latitude in deciding how to present their topics than to apply rigid guidelines.

Most of the editing work of the Encyclopedia has been carried out by a highly competent board of 16 Section Editors, each of them internationally renowned experts in their respective field within clinical endocrinology. First, the broadest possible list of topics was compiled, aiming at the best possible coverage. Throughout the editorial process, the Section Editors supervised their subject area of expertise, recommended and corresponded with fellow editors and article contributors, reviewed the manuscripts, and continuously helped to refine the final list of topics. This has made the task of the Editor in Chief easy, mainly entailing the supervision of smooth progress of the project.

The Section Editors and their fields deserve being listed here: *Jean-Jacques Body* (Belgium, bone endocrinology), *Felipe F. Casanueva* (Spain, metabolism and obesity), *Richard N. Clayton* (United Kingdom, pituitary gland), *Jean-Louis Chiasson* (Canada, diabetes), *Sophie Christin-Maitre* (France, female reproduction), *Wouter W. de Herder* (The Netherlands, neuroendocrinology), *Ulla Feldt-Rasmussen* (Denmark, thyroid gland), *Ieuan Hughes* (United Kingdom, pediatric endocrinology), *Gregory Kaltsas*, Greece, and *Martin O. Weickert*, United Kingdom, (gastrointestinal hormones), *Jean-Marc Kaufman* (Belgium, endocrinology of aging), *André Lacroix* (Canada, adrenal cortex), *Franco Mantero* (Italy, adrenal medulla and endocrine hypertension), *Jorma Toppari* (Finland, endocrine disruptors), *Jacquetta Trasler* (Canada, endocrine epigenetics) and *Christina Wang* (United Kingdom, male reproduction).

The Elsevier editorial staff, *Will Smaldon*, *Laura Escalante Santos*, and *Kate Miklaszewska-Gorczyca*, have been of enormous help to the editors at every step during this long project. I admire the professionalism of everyone and am deeply indebted to all for their dedication and hard work to make the Encyclopedia the leading reference book of clinical endocrinology.

The authors of the individual chapters, more than 450 in total, were specifically selected by the Section Editors to represent the best available knowledge on the topic available. They all should be thanked for their dedication and the excellent quality of their contributions.

Ilpo T. Huhtaniemi
Editor in Chief

VOLUME 1 – General Principles of Hormone Production and Action, Diabetes, Lipid Metabolism and Atherosclerosis, Obesity, Gastrointestinal Hormones, Multi-Organ Endocrine Diseases, Endocrinology of Aging, and Endocrine toxicology and EDCs

General Principles of Hormone Production and Action

History of Endocrinology *Wouter W de Herder* 1
Statistics in Endocrinology: Meta-Analysis Advantages and Pitfalls *Olaf M Dekkers* 11
Evolution of Hormonal Mechanisms *Vincent Laudet and Gabriel V Markov* 16
General Principles of Endocrine Genetics *Constantin Polychronakos* 23
Endocrine Epigenetics, Epigenetic Profiling and Biomarker Identification *Virginie Bertrand-Lehouillier, Lisa-Marie Legault, and Serge McGraw* 31
Protein and Peptide Hormone Synthesis *Johannes Hofland and Frank H de Jong* 36
Protein and Peptide Hormone Action *Frank H de Jong and Johannes Hofland* 43
Roles of Plasma Binding Proteins in Modulation of Hormone Action and Metabolism *Geoffrey L Hammond, Lesley A Hill, and Phillip W Round* 51
Dynamic Endocrine Rhythms *Thomas J Upton and Stafford Lightman* 61
Growth Factors *Uxía Fernandez, Luisa M Seoane, and Ruben Nogueiras* 69

Diabetes

Normal Glucose Physiology *Mazen Alsahli and John E Gerich* 72
Glucose Metabolism and Hormonal Regulation *Keith Tornheim* 87
Insulin Secretion: Functional Biochemical Aspects *Willy J Malaisse* 95
Insulin Action; Post-Receptor Mechanisms *Ashok K Srivastava, Preeti Bajpai, and Ashish Jain* 100
Diagnosis and Classification of Diabetes Mellitus *Jean-Marie Ekoé* 105
Type 1 Diabetes *Bimota Nambam, William Winter, and Desmond Schatz* 110
Type 2 Diabetes *Susan L Samson and Alan J Garber* 116
Diabetes Mellitus and Pregnancy *Emily D Szmuilowicz, Charlotte M Niznik, and Boyd E Metzger* 122
Diabetes Mellitus; Diagnosis and Treatment in the Elderly *Odilia I Bermudez* 133

Carbohydrate Metabolism: Diabetes Mellitus, Genomic Aberrations *RK Semple* 141
Lifestyle Diabetes Prevention *Ahmad Alkhatib and Jaakko Tuomilehto* 148
Hyperglycemic Hyperosmolar State *J Maletkovic and A Drexler* 160
Hypoglycemia *Darleen A Sandoval, Elizabeth M Lamos, Lisa Younk, Maka S Hedrington, and Stephen N Davis* 163
Glycation- and/or Polyol Pathway-Inducing Complications *Naila Rabbani and Paul J Thornalley* 170
Hypertension and Diabetes *Atossas Niakan and William C Cushman* 180
Dyslipidemia in Diabetes *Savitha Subramanian and Alan Chait* 186
Ocular Manifestations Associated With Diabetes *S Lauhon, MS Stem, and PE Fort* 199
Kidney Disease in Diabetes *Stephanie Toth-Manikowski and Mohamed G Atta* 202
Diabetic Nerve Disease; Neuropathy *Jean-Marie Ekoe* 207
Neurological Disease and Diabetes, Autonomic *Aaron I Vinik, Tomris Erbas, M-L Névoret, and C Casellini* 210
Foot Disease in Diabetes *Jean-Marie Ekoé, Benjamin A Lipsky, and David G Armstrong* 216
Cardiovascular Disease in Diabetes *Marie-Eve Piché and Paul Poirier* 219
Treatment: Alpha Glucosidase Inhibitors *Markolf Hanefeld and Gabriele Mertes* 238
Insulin Pumps and Artificial Pancreas *Nadine Taleb, Véronique Gingras, and Rémi Rabasa-Lhoret* 245
Transplantation: Pancreatic and Islet Cells *Anissa Gamble, Antonio Bruni, and AM James Shapiro* 259
Hypoglycemic State, Nondiabetic *Pierre J Lefèbvre and André J Scheen* 270

Lipid Metabolism and Atherosclerosis

Classification of Hyperlipidemias and Dyslipidemias *Jesús E Millán Núñez-Cortes and Joaquín J Millán Pérez* 275
Atherosclerosis *Jesus A Araujo and Aldons J Lusis* 282
Atherogenesis *L Badimon and V Llorente-Cortés* 289
Epigenetics, the Vascular Wall, and Atherosclerosis *Gertrud Lund and Silvio Zaina* 303
Primary Mixed Dyslipidemias *Rafael Carmena* 314
Hypercholesterolemia *Sergio Martinez-Hervas and Juan F Ascaso* 320
Low HDL and High HDL Syndromes *Shizuya Yamashita and Yuji Matsuzawa* 327
Hypertriglyceridemias and Their Treatment *José T Real* 340

Obesity

Genetic Basis of Obesity *Dolores Corella and Oscar Coltell* 346
Gut Microbiota; Its Importance in Obesity *Araceli Muñoz-Garach, Isabel M Cornejo-Pareja, and Francisco J Tinahones* 353
Regulation of Food Intake *Albert Lecube and Carolina López-Cano* 363
Adipose Tissue *Xabier Unamuno, Gema Frühbeck, and Victoria Catalán* 370
Comorbidities of Obesity *Vettor Roberto and Di Vincenzo Angelo* 385
Hypothalamic Control of Food Intake and Energy Homeostasis *Luisa M Seoane, Miguel López, and Ruben Nogueiras* 393

Gastrointestinal Hormones and Their Regulation of Food Intake *Luca Busetto, Marco Rossato, and Roberto Vettor* 398

Body Composition *Manfred J Müller, Corinna Geisler, and Anja Bosy-Westphal* 406

Obesity and Food Addiction *Fernando Fernández-Aranda, Trevor Steward, Gemma Mestre-Bach, Susana Jiménez-Murcia, and Ashley Gearhardt* 414

Leptin *Rachel C Morgan and Robert V Considine* 420

Lifestyle and Nutrition *Dragan Micic and Snezana Polovina* 428

Physical Activity and Exercise *Federico Mallo Ferrer* 436

Treatment of Obesity with Bariatric Surgery *Maitane Izaguirre, Gema Frühbeck, and Victoria Catalán* 442

Metabolic Surgery; Indications and Outcomes *Lidia Castagneto-Gissey, James Casella-Mariolo, and Geltrude Mingrone* 459

Treatment: New Drugs *Silvia Garelli, Nicola Salituro, Giulia M Pontesilli, Luigi Ricciardiello, Valentina Vicennati, and Uberto Pagotto* 464

Binge-Eating, Bulimia, and Other Eating Disorders *Zaida Agüera, Núria Mallorquí-Bagué, María Lozano-Madrid, Andreas Stengel, Stephan Zipfel, and Fernando Fernández-Aranda* 473

Lipodystrophy *Marta Giralt, Francesc Villarroya, and David Araújo-Vilar* 482

Gastrointestinal Hormones

GI Hormone Development (Families and Phylogeny) *Anders H Johnsen* 496

GI Tract: General Anatomy (Cells) *George Kontogeorgos* 501

GI Hormones Outside the Gut: Central and Peripheral Nervous Systems *Graham J Dockray* 515

GI Tract: General Pathology of Neuroendocrine Growths *Guido Rindi, Frediano Inzani, and Enrico Solcia* 520

Gastrin *Graham J Dockray* 525

Cholecystokinin (CCK) *Nori Geary* 529

Pancreatic Polypeptide (PP) *Dana K Andersen and F Charles Brunicardi* 534

Peptide YY (PYY) *Peter Holzer and Aitak Farzi* 546

Glucagon and Glucagon-Like Peptides *Daniel M Kemp and Joel F Habener* 555

Glucagon Like Peptide 2 (GLP-2) *Georgios K Dimitriadis and Alexander D Miras* 561

Enterochromaffin-Like Cells *Apostolos V Tsolakis* 565

Substance P *Miguel Muñoz and Rafael Coveñas* 571

Gastrointestinal Hormones in Cancer *Inbal Uri, Kristallenia Alexandraki, and Simona Grozinsky-Glasberg* 579

Somatostatin Receptor Expression in Gastrointestinal Tumors *Eleftherios Chatzellis and Gregory Kaltsas* 587

Gastrointestinal Neuroendocrine Tumor Syndromes (GI NETS) *Robert T Jensen* 597

Gastrinomas *Robert T Jensen* 617

Pancreatic Islet Cell Tumors *Ulrich Knigge, Mikkel Andreassen, Birgitte Federspiel, Carsten Palnæs Hansen, Andreas Kjær, and Seppo W Langer* 626

Peptide Neurotransmitters and Smooth Muscle in the Gut *JR Grider, KS Murthy, and GM Makhlouf* 635

Multi-Organ Endocrine Diseases

Pituitary Tumors Associated With Multiple Endocrine Neoplasia Syndromes *Liliya Rostomyan, Adrian F Daly, and Albert Beckers* 642

Endocrinology of Aging

Aging and Longevity of Human Populations *Diana van Heemst* 648

Animal Models for Aging *EC-H Lee, B Rogina, L Haynes, and GA Kuchel* 653

Oxidative Stress and Aging *Arthur K Balin and RG Allen* 659

Immunology and Aging *Victor Appay* 664

Premature Aging Syndromes *Fabio Coppedè* 669

Hormonal Circadian Rhythms and Sleep in Aging *Georges Copinschi and Anne Caufriez* 675

Circadian Clock, Epigenetic Regulators (Sirtuins), and Metabolism *Mirella L Meyer-Ficca and Ralph G Meyer* 690

Somatotropic Axis in Human Aging *Sabrina Chiloiro, Antonio Bianchi, Antonella Giampietro, and Laura De Marinis* 700

Abnormalities in Water Homeostasis in the Elderly *Laura E Cowen and Joseph G Verbalis* 708

Body Weight, Body Composition, and Aging *Odessa R Addison and Alice S Ryan* 713

Lipid Disorders in the Elderly *Wilbert Aronow* 719

Gonadotropins and Testicular Function in Aging *Fiona Yuen, Peter Y Liu, Ronald Swerdloff, and Christina Wang* 723

Hypogonadism and Testosterone Therapy in Elderly Men *Bu B Yeap* 729

Sexual Function in Aging Men *Giulia Rastrelli, Giovanni Corona, and Mario Maggi* 739

Osteoporosis in the Oldest Old *Evelien Gielen* 748

Aging and the Thyroid Gland *Leonidas H Duntas* 758

Endocrine toxicology and EDCs

Introduction to Endocrine Toxicology and Endocrine Disruption *Jorma Toppari* 762

Toxic Effects of Common Environmental Pollutants in Pancreatic β-Cells and the Onset of Diabetes Mellitus *Paloma Alonso-Magdalena, Eva Tudurí, Laura Marroquí, Ivan Quesada, Robert M Sargis, and Angel Nadal* 764

Endocrine Disruptors and Obesity *Sigal A Willner and Bruce Blumberg* 776

Endocrine Disruptors and Thyroid Function *Josef Köhrle* 787

Neuroendocrine Disruption of Reproduction *Julie Fudvoye, Jean-Pierre Bourguignon, and Anne-Simone Parent* 793

Association of Endocrine Disrupting Chemicals With Male Reproductive Health *Helena E Virtanen, Katharina M Main, and Jorma Toppari* 802

Endocrine Disrupting Chemicals and Behavior *Sheryl E Arambula and Heather B Patisaul* 812

VOLUME 2 – Neuroendocrinology, Pituitary Gland and Diseases, Female Reproduction, and Male Reproduction

Neuroendocrinology

Corticotropin-Releasing Hormone (CRH) *Nicolas C Nicolaides and George P Chrousos* 1

Neurotensin *Arthur Shulkes* 10

Carcinoid Syndrome *Marina Tsoli and Gregory Kaltsas* 13

Catecholamines *Graeme Eisenhofer and Jacques WM Lenders* 21

Pineal Tumors *María-José Barahona and Susan M Webb* 25

Vasopressin *Aoife Garrahy and Christopher J Thompson* 29

Effects of Steroid Hormones on Brain *Anne-Sophie CAM Koning, Russell D Romeo, Bruce S McEwen, and Onno C Meijer* 36

Memory and Epigenetics: Role of Estrogen *Jennifer J Tuscher, Ashley M Fortress, and Karyn M Frick* 42

VIPoma, Glucagonoma, and Somatostatinoma *Wouter T Zandee and Wouter W de Herder* 52

Insulinoma *Wouter T Zandee and Wouter W de Herder* 58

Melatonin *J Arendt* 63

Overview of Neurotransmitters *Floyd E Bloom* 75

Pituitary Gland and Diseases

Anatomy of Hypothalamus *Béla Halász* 81

Pituitary Gland Anatomy and Embryology *Béla Halász* 90

Hypothalamic Disease *Sylvia L Asa and Shereen Ezzat* 97

Diabetes Insipidus *Gary L Robertson* 107

Growth Hormone (GH) *Rikke Hjortebjerg, Gerhard Baumann, and John J Kopchick* 116

Natural and Synthetic Growth Hormone Secretagogues *Giovanna Motta, Stefano Allasia, Marco Zavattaro, Ezio Ghigo, and Fabio Lanfranco* 127

Luteinizing Hormone (LH) *Livio Casarini, Daniele Santi, Gary R Marshall, and Manuela Simoni* 142

Follicle-Stimulating Hormone (FSH) *Daniele Santi, Livio Casarini, Gary R Marshall, and Manuela Simoni* 149

Prolactin: Regulation of Secretion and Action *Filippo Maffezzoni, Gherardo Mazziotti, and Andrea Giustina* 157

Molecular Pathogenesis of Pituitary Tumors *Shereen Ezzat and Sylvia L Asa* 165

Classification of Pituitary Neuroendocrine Tumors (PitNets) *Jacqueline Trouillas, Alexandre Vasiljevic, Emmanuel Jouanneau, and Gérald Raverot* 176

Genetic Causes of Familial Pituitary Tumors *Maria Manuel Costa and Márta Korbonits* 185

Clinical Features of Acromegaly *I Ilie and M Korbonits* 212

Diagnosis of Acromegaly *I Ilie and M Korbonits* 223

Therapy for Acromegaly *Philippe Chanson* 230

ACTH-Secreting Pituitary Tumors *Rosario Pivonello, Maria Cristina De Martino, Davide Iacuaniello, Chiara Simeoli, and Annamaria Colao* 248

TSH-Secreting Pituitary Adenomas *Olympia Koulouri and Mark Gurnell* 261

Surgery for Pituitary Tumors *Pamela Jones and Brooke Swearingen* 267

Clinical Features, Diagnosis, and Management of Nonfunctioning Tumors of Pituitary *Athanasios Fountas and Niki Karavitaki* 271

Surgical Treatment of Nonfunctioning Pituitary Tumors *Michael Buchfelder and Yining Zhao* 281

Pituitary Radiotherapy *Frederic Castinetti and Thierry Brue* 289

Diagnosis and Clinical Management of Aggressive Pituitary Tumors *Gerald Raverot, Emmanuel Jouanneau, and Jacqueline Trouillas* 294

Hypopituitarism, Causes, Diagnosis, Management and Mortality *Athanasios Fountas and Niki Karavitaki* 301

Diagnosis of Prolactinoma and Causes of Hyperprolactinemia *James Ahlquist* 314

Prolactinomas: Clinical Manifestations and Therapy *Anna Scholz and Dafydd Aled Rees* 319

Hypophysitis *Federica Guaraldi, Olivera Casar-Borota, and Marie-Lise Jaffrain-Rea* 325

Radiology of the Pituitary *Jane Evanson* 339

Hyponatraemia *Aoife Garrahy and Christopher J Thompson* 349

Pituitary Disorders Following Traumatic Brain Injury *Anne Marie Hannon and Christopher J Thompson* 365

Female Reproduction

Folliculogenesis *Danielle Monniaux, Véronique Cadoret, Frédérique Clément, Rozenn Dalbies-Tran, Sébastien Elis, Stéphane Fabre, Virginie Maillard, Philippe Monget, and Svetlana Uzbekova* 377

Human Menstrual Cycle *Sophie Christin-Maitre* 399

Implantation *Lechosław T Putowski and M Nowak* 404

Pregnancy Endocrinology *Stefano Palomba and Jessica Daolio* 408

Placental Epigenetics and Outcomes in Children *Patricia Fauque* 418

Endocrinology of Delivery *Silvia Vannuccini and Felice Petraglia* 425

Premenstrual Syndrome (PMS) *M Link* 432

Amenorrhea *Sophie Christin-Maitre* 436

Congenital Hypogonadotropic Hypogonadism in Females *Jacques Young* 439

Functional Hypothalamic Amenorrhea *Sarah L Berga* 444

Polycystic Ovary Syndrome *Stephen Franks* 451

Polycystic Ovary Syndrome: Implications for Cardiovascular, Endometrial, and Breast Disease *HF Escobar-Morreale* 456

Ovarian Androgen-Producing Tumors *Michael DiMattina and Callum Potts* 458

Sport and Menses *Angelica Lindén Hirschberg* 461

Primary Ovarian Insufficiency *Luca Persani* 471

Adult Care of Turner Syndrome *Claus H Gravholt, Mette Viuff, Kirstine Stochholm, and Niels H Andersen* 482

Initial Evaluation of the Infertile Couple *Jean-Marie Antoine and Jacqueline Mandelbaum* 490

Endometriosis *Alain Audebert* 498

Epigenetics of Endometriosis *Daniel Vaiman* 506

Uterine Fibroids and Infertility *Jacques Donnez, Olivier Donnez, Pablo Arriagada, and Marie-Madeleine Dolmans* 513

Environmental Factors and Female Reproduction *Patrick Fénichel and Charlotte Rougier* 525

Miscarriages *Hervé Fernandez and Perrine Capmas* 538

Obesity and Reproduction *Andrés E Ortiz-Flores and Héctor F Escobar-Morreale* 543

Developmental Epigenetics and the Contribution of Parental Diet to Offspring Outcomes *Oliver J Rando and Rebecca A Simmons* 553

Anti-Müllerian Hormone (AMH) in Adults *Agathe Dumont, Geoffroy Robin, Sophie Catteau-Jonard, and Didier Dewailly* 556

Ovarian Stimulation with Clomiphene Citrate *J Gianfortoni* 567

Ovulation Induction With Gonadotropins *Aude Bruyneel, Ralph Papas, and Anne Delbaere* 570

Ovarian Hyperstimulation Syndrome *Basil C Tarlatzis, Julia K Bosdou, and Efstratios M Kolibianakis* 581

Fertility and Pregnancy in Patients With 21-Hydroxylase Deficiency *Virginie Grouthier, Carine Courtillot, Jérôme Dulon, Philippe Touraine, and Anne Bachelot* 588

In Vitro Fertilization (IVF) *Renato Fanchin* 595

Ovarian Failure Treatment Strategies: Egg Donation *Pedro N Barri* 599

Fertility Preservation in Women *Julie Benard, Alexandra Benoit, Charlotte Sonigo, and Michael Grynberg* 603

Female Hormonal Contraception *Genevieve Plu-Bureau* 615

Progesterone Receptor Modulators: Current Applications and Perspectives *Kamila Kolanska, Axelle Pintiaux, Philippe Bouchard, Emile Daraï, and Nathalie Chabbert-Buffet* 622

Diagnosis of Menopause *Tommaso Simoncini, Marta Caretto, Andrea Giannini, and Andrea R Genazzani* 628

Menopausal Treatment *Anne Gompel* 634

Hormonal Treatment of Breast Cancer *Stéphanie Bécourt and Marc Espié* 646

Hormonal Treatment of Male to Female Transgender *Alessandra D Fisher and Louis Gooren* 656

Male Reproduction

Testes Embryology: Cellular Molecular Changes *T Svingen and LJ Pelliniemi* 664

Spermatogonial Physiology and Regulation of the Niche *Stefan Schlatt and Swati Sharma* 670

Male Germ Cell Differentiation *My-Thanh Beedle and Michael D Griswold* 678

Endocrine Control of Spermatogenesis *TM Plant, S Ramaswamy, and Karel De Gendt* 684

Gonadotropin-Releasing Hormone (GnRH) Development and Actions *Margaret E Wierman* 692

Genes and Gene Defects Affecting Gonadal Development and Sex Determination *Dagmar Wilhelm and Stefan Bagheri-Fam* 695

Mutations of the Gonadotropin-Releasing Hormone Receptor Gene *Alfredo Ulloa-Aguirre, Teresa Zariñán, and Saúl Lira-Albarran* 704

Androgen Biosynthesis and Gene Defects *Adina F Turcu and Richard J Auchus* 713

Reproductive and Nonreproductive Actions of Testosterone *Shalender Bhasin and Ravi Jasuja* 721

Hormone Replacement Therapy in Men *Cindy Pham, Christina Wang, and Ronald S Swerdloff* 735

Male Hormonal Contraception *Brian T Nguyen, Ronald S Swerdloff, Frederick CW Wu, and Christina Wang* 741
Estrogen and the Male *Agnė Kadusauskienė and Jonas Čeponis* 751
Gynecomastia *Glenn D Braunstein* 763
Male Sexual Dysfunction *Amarnath Rambhatla and Jacob Rajfer* 767
Androgens and Benign Prostatic Hyperplasia *Maritza Farrant and Stephanie T Page* 775
Prostate Cancer *Timothy McClure, Spyridon P Basourakos, Jaspreet S Sandhu, Peter N Schlegel, and James J Colt* 784
Insulin-Like Peptide 3 (INSL3) *Ravinder Anand-Ivell and Richard Ivell* 793
Epididymis *Maria Christina W Avellar and Barry T Hinton* 807
Fertility in Men With Spermatogenesis Abnormalities *Katherine Rotker and Mark Sigman* 814
Genetics of Male Infertility *Csilla Krausz and Francesca Cioppi* 821
Testicular Tumors *Ewa Rajpert-De Meyts* 831
Male Oncoinfertility *Bernard Robaire and Peter T Chan* 840

VOLUME 3 – Adrenal Glands and Hypertension

Adrenal Glands and Hypertension

Adrenal Cortex; Physiology *Fady Hannah-Shmouni and Christian A Koch* 1
Adrenal Cortex; Development *Typhanie Dumontet and Antoine Martinez* 8
Corticotropin-Releasing Hormone Peptide Family *David W Hogg, Mia Husic, and David A Lovejoy* 16
Regulation of POMC and ACTH Secretion *Dongyun Zhang and Anthony P Heaney* 27
ACTH, Melanocortin Receptors, and MRAP Accessory Proteins *Robert M Dores* 38
Adrenocorticotropic Hormone (ACTH): Physiology and Its Involvement in Pathophysiology *George Mastorakos and Athanasios Antoniou-Tsigkos* 48
Adrenal Steroidogenesis *Daniel B Martinez-Arguelles and Vassilios Papadopoulos* 56
Overview of Glucocorticoids *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 64
Stress and Endocrine Physiology *Nicolas C Nicolaides, Panagiota Pervanidou, and George P Chrousos* 72
Hypothalamic–Pituitary–Adrenal Suppression *Nicolas C Nicolaides and George P Chrousos* 83
Glucocorticoid Metabolism and Activation *Nantia Othonos and Jeremy Tomlinson* 90
Glucocorticoid Receptor *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 104
Glucocorticoids and Immunity *Karen E Chapman* 112
Corticotropin-Releasing Hormone and Inflammation *Markella Nezi, Evangelia Zapanti, and George Mastorakos* 121
Adrenal Insufficiency: Etiology and Diagnosis *Nicolas C Nicolaides and Evangelia Charmandari* 131
Primary Adrenal Hypoplasia and ACTH Resistance Syndromes *Ioannis Kyrou and Constantine Tsigos* 139
Impact of Glucocorticoid Receptor Polymorphisms on Glucocorticoid Action *Mesut Savas and Elisabeth FC van Rossum* 147

Glucocorticoid Resistance Syndromes and States *Nicolas C Nicolaides and George P Chrousos* 157

X-Linked Adrenoleukodystrophy/Adrenomyeloneuropathy *William B Rizzo* 166

Steroid Replacement in Adrenal Insufficiency *Joanne C Blair, Miguel Debono, and Richard Ross* 172

Management of Adult Patients With Congenital Adrenal Hyperplasia Due to 21-Hydroxylase Deficiency *Virginie Grouthier, Jérôme Dulon, Anne Bachelot, and Philippe Touraine* 185

Cushing Syndrome; Screening and Differential Diagnosis *André Lacroix and Lynnette K Nieman* 193

Molecular Genetics of Cushing Disease *Martin Reincke, Marily Theodoropoulou, and Adriana Albani* 205

Pituitary Surgery for Cushing Disease *Pamela Jones and Brooke Swearingen* 215

Evaluation and Follow-Up of Patients With Cushing Disease After Pituitary Surgery *Amandine Ferriere, Claire Cordroch, and Antoine Tabarin* 223

Medical Therapy of Hypercortisolism *Richard A Feelders* 232

Radiation Therapy in Patients With Cushing Disease *Nicholas A Tritos, Jay S Loeffler, and Beverly MK Biller* 237

Bilateral Adrenalectomy for Cushing Disease *Frederic Castinetti* 243

Cushing Syndrome—Unilateral Adrenal Adenoma *Guido Di Dalmazi* 249

Somatic β-Catenin Gene Mutations and WNT Signaling in Adrenal Tumors *Isabelle Bourdeau* 259

Adrenocortical Tumors and *gsp* Mutations *Maria Candida Barisson Villares Fragoso, Isadora Pontes Cavalcante, Leonardo Tadeu Araujo, Helaine Laiz Silva Charchar, Ingrid Quevedo Wanichi, Vania Balderrama, Amanda Meneses Ferreira, and Beatriz Marinho de Paula Mariani* 266

PPNAD, Carney Complex, and Other Micronodular Adrenal Hyperplasia *Stéphanie Espiard and Jérôme Bertherat* 271

Genetics of Familial Forms of Cortisol-Secreting Adrenal Tumors and Hyperplasias *Ludivine Drougat and Constantine A Stratakis* 283

Primary Bilateral Macronodular Adrenal Hyperplasia *André Lacroix* 293

Adrenal Incidentalomas *Massimo Terzolo, Soraya Puglisi, and Giuseppe Reimondo* 303

Adrenocortical Carcinoma: Diagnosis and Therapy *Massimo Terzolo, Soraya Puglisi, Paola Perotti, Mélanie Claps, Elisa Roca, and Alfredo Berruti* 308

Adrenocortical Carcinoma: Genetics and Molecular Markers *Anne Jouinot and Guillaume Assié* 317

Adrenal Surgery *Pavel Nockel, Mustapha El Lakis, and Electron Kebebew* 323

Long-Term Complications of Hypercortisolism *Rosario Pivonello, Davide Iacuaniello, Chiara Simeoli, Maria Cristina De Martino, and Annamaria Colao* 341

Effects of Glucocorticoids on the Brain *Alberto M Pereira, Susan M Webb, and Onno C Meijer* 360

Hypertension; Overview *Morton P Printz and Rebecca L Jaworski* 369

Neurogenic Hypertension *Gino Seravalle, Guido Grassi, and Giuseppe Mancia* 381

Renal Hypertension *Daniele Cusi* 383

Endocrine Hypertension *Inga Harbuz-Miller, Ryan Woodman, and Guido Lastra* 390

Resistant Hypertension *Robert M Carey* 402

Hypertension and Target Organ Damage *Maria Lorenza Muiesan, Anna Paini, Claudia Agabiti Rosei, Fabio Bertacchini, Carlo Aggiusti, Carolina De Ciuceis Damiano Rizzoni, and Massimo Salvetti* 406

Stroke *PCAJ Vroomen and GA Donnan* 415

Normetanephrine and Metanephrine *Jacques WM Lenders and Graeme Eisenhofer* 420

Adrenergic Mechanisms *Peter W de Leeuw and Abraham A Kroon* 425

Novel Insights in β-Adrenergic Receptor Signaling *Guido Iaccarino and Daniela Sorriento* 432

Baroreceptor Responses *AF Sved, EM Stricker, and SD Stocker* 440

Antiadrenergic Agents *Enrico Agabiti-Rosei* 443

Pheochromocytoma and Paraganglioma Syndromes *Vitaly Kantorovich and Karel Pacak* 449

Pheochromocytoma/Paraganglioma: Diagnosis and Treatment *Maurizio Castellano, Mara Giacchè, Luigi Mori, Alessandra Panarotto, and Carlo Cappelli* 455

Malignant Pheochromocytoma *Massimo Mannelli, Gabriele Parenti, Letizia Canu, Giuseppina De Filpo, and Elena Rapizzi* 460

Pheochromocytoma/Paraganglioma: Management, Genetics, and Follow-up *Anne-Paule Gimenez-Roqueplo and Laurence Amar* 469

Renin and Prorenin *Alberto Morganti* 478

Angiotensinogen and Angiotensins *Massimo Volpe and Speranza Rubattu* 483

Kininases *Randal A Skidgel, Ervin G Erdös, and Peter A Deddish* 490

Tissue Ace–Angiotensin–AT_1 Receptor Axis and Repair in the Heart *Yao Sun and Karl T Weber* 497

Hypertension and the Renin–Angiotensin–Aldosterone System *Elena Kaschina, Ulrike M Steckelings, and Thomas Unger* 505

Hyperreninemia *Pierre-François Plouin, Laurence Amar, and Michel Azizi* 511

Renal Vein Renin Measurement as a Diagnostic Tool *Gian Paolo Rossi* 516

Interference With the Renin–Angiotensin System (RAS): Classical Inhibitors and Novel Approaches *Katrina M Mirabito Colafella, Estrellita Uijl, and AH Jan Danser* 523

Aldosterone; Synthesis and Metabolism *John W Honour* 531

Aldosterone; Action and Function *Peter J Fuller and Morag J Young* 540

Aldosterone Receptors *Say Viengchareun, Marc Lombès, and Laetitia Martinerie* 546

Regulation of Potassium Homeostasis *Paola Russo, Fabio Lauria, and Alfonso Siani* 552

Salt-Sensitivity of Blood Pressure *Pasquale Strazzullo, Ferruccio Galletti, and Lanfranco D'Elia* 558

Endogenous Ouabain *Paolo Manunta and Marco Simonini* 564

Atrial Natriuretic Factor and the Family of Natriuretic Peptides *Tsuneo Ogawa and Adolfo J de Bold* 569

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Pathophysiology *John W Funder* 581

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Clinical Aspects *Ellen Marie Freel* 586

Primary Aldosteronism; Epidemiology and Screening *Michael Stowasser* 598

Primary Aldosteronism; Diagnosis and Treatment *Franco Mantero and Maria Verena Cicala* 607

Adrenal Venous Sampling for Primary Aldosteronism *Gian Paolo Rossi* 613

Genetics of Familial Hyperaldosteronism *Silvia Monticone, Martina Tetti, Isabel Losano, Franco Veglio, and Paolo Mulatero* 623

Aldosterone-Producing Adenomas; Genetics *Livia Lenzini, Sofia Zanin, and Gian Paolo Rossi* 631

Apparent Mineralocorticoid Excess *Padiporn Limumpornpetch and Paul M Stewart* 638

Licorice and 11β-Hydroxysteroid Dehydrogenase *Decio Armanini and Chiara Sabbadin* 644

Liddle Syndrome *Ermanno Rossi and Giovanni Maria Rossi* 652

Secondary Hyperaldosteronism *Aleksander Prejbisz and Andrzej Januszewicz* 664

Aldosteronism in Congestive Heart Failure *Yenal I Harper, Oluwaseun A Akinseye, Salem A Salem, Muhammad Shahreyar, and Karl T Weber* 668
Mineralocorticoid Receptor Antagonists *John W Funder* 674
Diuretics *Claudio Ferri and Rita Del Pinto* 681
Calcium Channel Blockers *Stefano Taddei and Rosa Maria Bruno* 689
Pseudohypoaldosteronism Type 1 *Fabio L Fernandes-Rosa* 696
Hyporeninemic Hypoaldosteronism *Shrey Purohit, Dalila B Corry, and Michael L Tuck* 703
Bartter and Gitelman Syndromes *Lorenzo A Calò and Verdiana Ravarotto* 714
Angiogenesis *Lindsay S Cooley and Andreas Bikfalvi* 722

VOLUME 4 – Calcium and Bone, and Thyroid Gland

Calcium and Bone

Bone Cells: Osteoblast/Osteoclast/Osteocyte *Nadia Rucci and Anna Teti* 1
Bone Remodeling *Susan M Ott* 10
Bone Structure and Biomechanics *Fjola Johannesdottir and Mary L Bouxsein* 19
Bone and Bone Marrow; Interactions *Delphine Spruyt, Céline Gillet, and Joanne Rasschaert* 31
Bone Muscle Interactions and Exercise *Jenny E Gunton* 40
Bone as an Endocrine Organ *Gerard Karsenty and Stavroula Kousteni* 47
Calcium Homeostasis in Humans *Roger Bouillon* 52
Calcium-Sensing Receptor *Giuseppe Vezzoli, Teresa Arcidiacono, Lorenza Macrina, Katia Maruca, and Stefano Mora* 58
Phosphate Metabolism, Hyperphosphatemia, and Hypophosphatemia *Seiji Fukumoto* 68
Vitamin D *Ian R Reid* 75
Nutrition and Bone *Peter Burckhardt* 82
Bone Development During Childhood and Adolescence: Peak Bone Mass *Jean De Schepper* 89
Bone Mass Measurement *Paul D Miller and Pierre JM Bergmann* 94
X-Ray Based Imaging Methods to Assess Bone Quality *Klaus Engelke* 102
Bone Turnover Markers *Etienne Cavalier, Richard Eastell, Niklas Rye Jørgensen, Konstantinos Makris, Samuel Vasikaran, and Howard A Morris* 116
Primary Hyperparathyroidism *Claudio Marcocci and Filomena Cetani* 128
Parathyroid Cancer *D Fink and Elizabeth Shane* 139
Parathyroid Surgery *EF Garner and H Chen* 151
Hypercalcemia: Other Causes than Primary Hyperparathyroidism *René Rizzoli* 160
Parathyroid Hormone Related Protein (PTHrP) *Archana Kamalakar, Charity L Washam, and Larry J Suva* 168
Physiology of Calcitonin and Its Therapeutic Uses *Sunil J Wimalawansa* 178
Hypoparathyroidism and Other Causes of Hypocalcemia *Bart L Clarke* 192
Calcitonin Gene-Related Peptide (CGRP) *AA Aubdool, X Kodji, and SD Brain* 204

Epidemiology of Fractures *Nicholas R Fuggle, Elaine M Dennison, and Cyrus Cooper* 213
Pathogenesis of Osteoporosis *Emma O Billington and Ian R Reid* 222
Role of Estrogens and Androgens in Osteoporosis *Michaël R Laurent* 233
Osteoporosis in Premenopausal Women *Serge Rozenberg* 246
Secondary Osteoporosis *Gregory R Emkey* 253
Osteoporosis; Prevention and Ca–Vitamin D Treatment *Bo Abrahamsen* 270
Osteoporosis Treatment: Bone-Forming Agents *Bente L Langdahl* 275
Osteoporosis Treatment: Sequential and Combination Therapy *Benjamin Z Leder and Joy N Tsai* 281
Osteoporosis: Treatment Gaps and Health Economics *Nicholas CW Harvey, Eugene V McCloskey, René Rizzoli, John A Kanis, Cyrus Cooper, and Jean-Yves Reginster* 288
Cancer Treatment-Induced Bone Loss (CTIBL) *Catarina Abreu, Maria R Dionísio, Joana C Silva, and Luís Costa* 296
Bone Metastases; Basic Aspects *Margaux Bernard, Paola Di Mauro, Caroline Reynaud, Chantal Diaz-Latoud, and Philippe Clézardin* 304
Bone Metastases; Clinical Aspects *Steven Wood, Azeez Salawu, Helen Kroening, Stella D'Oronzo, and Janet Brown* 310
Bone Metastases; Medical Treatment *Robert Coleman* 320
Multiple Myeloma Bone Disease *Evangelos Terpos and Maria Gavriatopoulou* 329
Diabetes and Bone *Peter Vestergaard* 341
Paget Disease of Bone *Stuart H Ralston* 350
Heterotopic Ossification and Calcification *Chen Kan, Na Ding, and Lixin Kan* 356
Kidney Stones *S Dizon, EA Iliescu, and A Ross Morton* 365
Pseudohypoparathyroid States *A Tsatsoulis, A Fountas, and E Laspa* 372

Thyroid Gland

Thyroid Gland: Anatomy and Physiology *Salvatore Benvenga, Giovanni Tuccari, Antonio Ieni, and Roberto Vita* 382
Thyroid Gland Development, Molecular Biology *Marina Muzza and Laura Fugazzola* 391
Hypothalamus–Pituitary–Thyroid Axis *Marco Bonomi, Biagio Cangiano, and Luca Persani* 398
Thyroid-Stimulating Hormone (TSH; Thyroptopin) *Leonidas H Duntas* 403
TSH Function and Secretion *Susan R Rose and Janet S Chuang* 408
TSH (Thyrotropin) Receptor *Yuji Nagayama* 416
Thyroid Hormone Metabolism *Josef Köhrle* 420
Sodium/Iodide Symporter (NIS) *Nancy Carrasco and Rachel R Kaspari* 429
Thyroid Peroxidase *Salvatore Benvenga and Roberto Vita* 433
Thyroglobulin *Marina Muzza and Laura Fugazzola* 439
Serum Thyroid Hormone-Binding Proteins *Luigi Bartalena and Eliana Piantanida* 442
Thyroid Hormone Receptors *Claire Briet, Frédéric Illouz, and Patrice Rodien* 448
Thyroid Hormone Action *Yui Watanabe and Roy E Weiss* 452
Resistance to Thyroid Hormone *Gisah Amaral de Carvalho, Tayane Muniz Fighera, and Roy E Weiss* 463

TSH-Producing Adenomas and Resistance to Thyroid Hormones *P Beck-Peccoz, L Persani, and A Lania* 473
Thyroid Function Tests *ER Christ and Albert G Burger* 477
Epidemiology of Thyroid Disease *Mark PJ Vanderpump* 486
Genetic Factors in Thyroid Disease *Marina Muzza and Laura Fugazzola* 496
Environmental Goitrogens *Veena Agrawal, Sana A Ghaznavi, and Ralf Paschke* 506
Iodine Deficiency *Peter Taylor, Onyebuchi Okosieme, Lakdasa Premawardhana, and John H Lazarus* 512
Nontoxic Goiter *Sana Ghaznavi, Kirstie Lithgow, Veena Agrawal, and Ralf Paschke* 524
Thyroid Nodule *Laszlo Hegedüs* 529
Thyroid and Irradiation *Barbara Jarzab, Daria Handkiewicz-Junak, and Jolanta Krajewska* 539
Thyroid Imaging *Luca Giovanella, Giorgio Treglia, and Pierpaolo Trimboli* 545
Thyroid Fine Needle Aspiration Cytology *Ivana Kholová and Camilla Schalin-Jäntti* 565
Thyroid Carcinoma *Rossella Elisei* 573
Medullary Thyroid Carcinoma *Maria Alevizaki, Katerina Saltiki, and Theodora Pappa* 586
Causes of Hypothyroidism *Ulla Feldt-Rasmussen, Marianne Klose, and Åse Krogh Rasmussen* 600
Diagnosis of Hypothyroidism *Ulla Feldt-Rasmussen, Marianne Klose, and Åse Krogh Rasmussen* 604
Central Hypothyroidism *Luca Persani and Marco Bonomi* 608
Hashimoto's Thyroiditis *Grigoris Effraimidis and Ulla Feldt-Rasmussen* 613
Systemic Manifestations of Hypothyroidism *Massimo Tonacchera and Luca Chiovato* 616
Treatment of Hypothyroidism *Bernadette Biondi* 624
Myxedema Coma *Leonard Wartofsky* 627
Hypothyroidism, Subclinical *Bettina F Winzeler, Mirjam Christ-Crain, Beat Müller, and Christian Meier* 630
Thyroid Autoimmunity *Ulla Feldt-Rasmussen, Sofie Bliddal, and Claus H Nielsen* 636
Thyrotoxicosis; Overview of Causes *Claudio Marcocci and Roberto Rocchi* 651
Thyrotoxicosis; Diagnosis *Claudio Marcocci and Roberto Rocchi* 657
Thyrotoxicosis; Systemic Manifestations *Claudio Marcocci and Filomena Cetani* 665
Thyrotoxicosis; Treatment *Claudio Marcocci and Filomena Cetani* 673
Subclinical Hyperthyroidism *Bernadette Biondi* 680
Antithyroid Drugs *Jacques Orgiazzi* 683
Radioactive Iodine *Barbara Jarzab and Jolanta Krajewska* 688
Thyrotoxicosis Factitia *Fausto Bogazzi and Enio Martino* 693
Thyrotoxic Storm *Leonard Wartofsky* 695
Graves' Disease *Irene Campi and Mario Salvi* 698
Hyperthyroidism in Graves' Disease *Danila Covelli and Mario Salvi* 702
Pretibial Myxedema *Guia Vannucchi and Mario Salvi* 707
Graves' Orbitopathy *Mario Salvi* 711
Smoking and the Thyroid *Luigi Bartalena and Maria L Tanda* 719

Toxic Adenoma *Kirstie Lithgow, Sana A Ghaznavi, Alexandra Stephenson, Amita Mahajan, and Ralf Paschke* 723
Toxic Multinodular Goiter *Amita Mahajan, Sana A Ghaznavi, Kirstie Lithgow, and Ralf Paschke* 730
Thyroiditis, Infectious and Subacute *Grigoris Effraimidis and Ulla Feldt-Rasmussen* 737
Postpartum Thyroid Dysfunction *Lakdasa DKE Premawardhana and John H Lazarus* 746
Thyroid and Infertility *Sofie Bliddal, Henriette S Nielsen, and Ulla Feldt-Rasmussen* 752
Thyroid Disease and Pregnancy *AM Leung and Jerome M Hershman* 762
Thyroid Disorders in the Elderly *Vafa Tabatabaie and Martin I Surks* 768
Drug Effects and Thyroid Function *Ulla Feldt-Rasmussen and Åse K Rasmussen* 772
Lithium *John H Lazarus* 780
Amiodarone and Thyroid *Fausto Bogazzi and Enio Martino* 782
Thyroid Disease and Bone *Bente L Langdahl* 787
Thyroid Function and Depression *Martin B Jørgensen and Ulla Feldt-Rasmussen* 792
Measuring Impact of Benign Thyroid Diseases on Quality of Life *Torquil Watt* 802

VOLUME 5 – Pediatric Endocrinology

Pediatric Endocrinology

Control and Monitoring of Fetal Growth *Tomas Prior and Christoph Lees* 1
Physiology of Growth Hormone in Fetus and Child *Vijayarangan G Kannian and Fiona J Ryan* 10
Infant, Childhood, and Adolescent Auxology *Gary Butler* 19
Body Proportions *Willem JM Gerver, Bas Penders, and Ralph Brecheisen* 31
Genetic and Hormonal Control of Growth *George Paltoglou, Harshini Katugampola, and Mehul T Dattani* 38
Abnormal Growth: Small for Gestational Age *Kathryn Beardsall, Meera Mallya, and Ajay Thankamony* 55
Growth Hormone Deficiency in Children *Berit Kriström and Elena Lundberg* 66
Growth Hormone Insensitivity *Martin O Savage, Sumana Chatterjee, Vivian Hwa, and Helen L Storr* 81
Tall Stature *Sabine E Hannema and Lars Sävendahl* 94
Growth in Childhood Chronic Conditions *Kung-Ting Kao, Syed Faisal Ahmed, and Sze Choong Wong* 102
Normal Puberty: Somatic Characteristics *Dipesalema Joel and Ieuan Hughes* 118
Genetic and Epigenetic Control of Puberty *Ana Claudia Latronico and Leticia F Silveira* 126
Hormonal Control of Puberty *Lindsey A Loomba-Albrecht and Dennis M Styne* 137
Secular Changes in Puberty *Camilla Eckert-Lind, Alexander S Busch, Elvira V Bräuner, and Anders Juul* 144
Delayed Puberty; Male *Alan D Rogol* 153
Delayed Puberty and Hypogonadism; Female *Sasha Howard and Leo Dunkel* 157

Gonadotropin-Dependent Precocious Puberty; Female and Male *Dick Mul, Wilma Oostdijk, and Stenvert LS Drop* 166

Gonadotrophin-Independent Precocious Puberty; Female and Male *Stenvert LS Drop and Hedi L Claahsen van de Grinten* 175

Organ-Specific Pediatric Endocrine Disorders, Pituitary: Craniopharyngioma *Timothy Shao Ern Tan, John Paul Kilday, and Leena Patel* 186

Hamartoma, Pituitary *G Patti, G Morana, N Di Iorgi, and M Maghnie* 196

Anorexia Nervosa *Maria Teresa Muñoz, Monserrat Graell, and Jesús Argente* 205

Endocrine Late Effects in Childhood Cancer Survivors *Wassim Chemaitilly and Laurie E Cohen* 216

Disturbances of Sodium and Water. Diabetes Insipidus in Children *Rasa Verkauskiene and Ruta Navardauskaite* 235

Obesity, Childhood, and Adolescence *Wieland Kiess* 247

Appetite and Weight *Clare H Llewellyn and Alison Fildes* 260

Management of Obesity in Children and Adolescents: Lifestyle and Exercise Options *James D Nobles and Paul J Gately* 269

Congenital Hypothyroidism: Screening, Early Management, and Outcome *Tim Cheetham* 280

Genetic Causes of Congenital Hypothyroidism *Nadia Schoenmakers* 291

Congenital Hypothyroidism: A Historical Perspective on Cognitive Outcome *Heiko Krude* 308

Hyperthyroidism, Childhood and Adolescence *Scott A Rivkees* 312

Thyroid Tumors in Children *Ari J Wassner* 322

Physiology of Fetal and Neonatal Calcium Metabolism *Jeremy Allgrove* 330

Rickets and Osteomalacia *Suma Uday and Wolfgang Högler* 334

Osteogenesis Imperfecta *Nick Bishop* 350

Hypercalcemia *Justin H Davies and Rebecca J Moon* 361

A Review of Skeletal Dysplasias for the Pediatric Endocrinologist *Sarah M Nikkel and Leanne Ward* 373

Premature Adrenarche *Antonis Voutetakis, Catherine Dacou-Voutetakis, Maria Dracopoulou, and Sarantis Livadas* 380

21-Hydroxylase Deficiency: Clinical and Biochemical Aspects *Anna Nordenström and Svetlana Lajic* 388

Prenatal Diagnosis and Treatment of Congenital Adrenal Hyperplasia *Svetlana Lajic and Anna Nordenström* 401

Steroidogenic Factor 1 (SF-1; NR5A1) *Ken McElreavey and Anu Bashamboo* 410

11β-Hydroxylase Deficiency *Krupali Bulsari and Henrik Falhammar* 416

Human P450 Oxidoreductase Deficiency *Christa E Flück and Amit V Pandey* 426

Pediatric Cushing Disease *Ingrid CE Wilkinson, Martin O Savage, and Helen L Storr* 439

Genetic Control of Fetal Sex Development *Rajini Sreenivasan, Brittany Croft, and Andrew Sinclair* 449

Hormonal Control of Fetal Sex Development *Nadine Hornig, Alexandra Kulle, and Paul-Martin Holterhus* 463

Classification and Presentation of Disorders of Sexual Development (DSD) *Kanthi Bangalore Krishna, Selma F Witchel, Christopher Houk, and Peter Lee* 471

Androgen Biosynthetic Defects: 17β-Hydroxysteroid Dehydrogenadse Type 3 and 5α-Reductase Type 2 Deficiencies *Nathalia L Gomes, Rafael L Batista, and Berenice B Mendonca* 481

Androgen Insensitivity Syndrome (AIS): Complete AIS (CAIS) *Jarmo Jääskeläinen* 487

Androgen Insensitivity: Partial AIS *Rieko Tadokoro-Cuccaro and Ieuan A Hughes* 496

Anti-Müllerian Hormone Deficiency and Resistance *Rodolfo A Rey, Jean-Yves Picard, Nathalie di Clemente, Richard L Cate, and Nathalie Josso* 501

Hypospadiac Genital Tubercle (GT) *Maguelonne Pons, Daniela-Brindusa Gorduza, and Pierre Mouriquand* 513

Undescended Testes *Ritzén E Martin* 521

Human Aromatase Deficiency *Gabriela Guercio, Nora Saraco, Mariana Costanzo, Roxana Marino, and Alicia Belgorosky* 527

Turner Syndrome *Theo CJ Sas, Janielle AEM van Alfen-van der Velden, and Sabine MPF de Muinck Keizer-Schrama* 545

Klinefelter Syndrome *Shanlee M Davis and Judith L Ross* 556

45,X/46,XY Gonadal Dysgenesis, 46,XX/46,XY Chimerism (and Variants), and 46,XX Testicular and Ovotesticular DSD *Martine Cools* 563

Intersexuality: Gender Assignment and Psychosocial Care *Heino FL Meyer-Bahlburg* 570

Ethical and Legal Aspects of DSD/Intersex *Jens M Scherpe and Jameson Garland* 581

Neonatal Diabetes Mellitus *Abdelhadi Habeb and Asma Deeb* 591

Congenital Hyperinsulinism *Indraneel Banerjee, Maria Salomon Estebanez, Karen E Cosgrove, and Mark J Dunne* 602

Beckwith–Wiedemann Spectrum *Eamonn R Maher* 618

McCune–Albright Syndrome *Erica A Eugster* 629

Noonan Syndrome *Michael A Patton and Alistair P Patton* 635

Prader–Willi Syndrome *Urs Eiholzer, Claudia Katschnig, and Annik Hauri-Hohl* 639

Glossary

Adrenocorticotropic hormone or corticotropin (ACTH) ACTH is synthesized from proopiomelanocortin, a 241-amino acid precursor. Usually, ACTH is derived from the pituitary gland to stimulate the adrenal glands through the melanocortin-2 receptor. ACTH is rarely produced ectopically from neuroendocrine tumors (i.e., in ectopic Cushing syndrome), or in the adrenal glands, as seen in primary bilateral macronodular adrenocortical hyperplasia.

Corticotropin-releasing hormone (CRH) CRH is a hypothalamic 41-amino acid peptide that usually stimulates the pituitary gland to release ACTH.

Hypothalamic–pituitary–adrenal (HPA) axis Hypothalamic-releasing factors including CRH are influenced by central nervous system afferents. For instance, stress can trigger CRH release. The main peptide secreted by corticotroph cells when POMC is activated by CRH is ACTH, which subsequently stimulates the adrenal glands to produce and release steroids, including cortisol. Cortisol, on the other hand, can inhibit further release of CRH and ACTH through a tightly regulated negative feedback loop.

Steroids These members of a large family of compounds that are derived from the cyclopentanoperhydrophenanthrene ring structure that consists of three cyclohexane rings and one cyclopentane ring and are produced by the adrenal glands. The nomenclature denotes rings by a letter and the individual carbon atoms by a number. Gonane is the unsaturated 17'carbon ring structure. Estranes are steroids with 18 carbons (C18 steroids) by adding a methyl group at C13. Androstane is a C19 steroid with two methyl groups. Pregnane is a C21 steroid with methyl and ethyl groups.

Introduction

In 1563, Bartholomeo Eustachius, a famous Italian anatomist and artist, was credited for the first full description of the anatomy of the adrenal glands (Miller, 2013a,b). Subsequently in 1849, Thomas Addison, a renowned 19th-century English physician and scientist, described the central physiologic role of the adrenal glands (Miller, 2013a,b). In the 21st century, our growing understanding of adrenal zonation, genetics, and steroidogenesis has improved our understanding of the pathophysiologic states of the adrenal glands (Xing *et al.*, 2015).

The adrenal glands are divided into two major anatomic areas, cortex and medulla. The adrenal cortex is composed of three zones; glomerulosa (ZG), fasciculate (ZF), and reticularis (ZR). The largest zone in humans is the ZF, where glucocorticoids including cortisol are produced (Xing *et al.*, 2015). In general, extracellular volume status is influenced by aldosterone, the hormone of ZG. Adrenal androgens such as dehydroepiandrosterone (DHEA) are primarily produced by the ZR, which begins to grow at approximately age 4, shortly before adrenarche (Xing *et al.*, 2015).

Corticotropin (ACTH), produced from the pituitary gland, is the principal stimulator for cortisol and/or adrenal androgen production (and to a minor extent, aldosterone) (Margioris and Tsatsanis, 2000). Corticotropin is released under stress and other stimuli through hypothalamic corticotropin-releasing hormone (CRH) secretion. Like CRH, arginine-vasopressin (AVP), a hypothalamic hormone, stimulates the pituitary release of ACTH. A tightly regulated feedback loop exists between the hypothalamus (H), pituitary (P), and adrenal glands (A), known as the HPA axis. High peripheral cortisol levels inhibit further release of CRH and corticotropin. Hypothalamic CRH and pituitary corticotropin are suppressed in various conditions (e.g., in conditions of supraphysiologic exogenous glucocorticoid administration), with subsequent atrophy of the adrenal glands due to the lack of corticotropin. The adrenal medulla forms postnatally and exerts effects on the adrenal cortex and vice versa. Adrenomedullary chromaffin cells are intermingled with the adrenal cortex, facilitating interaction between the two layers.

Fetal Adrenal Gland Development

The fetal adrenal cortex plays a critical role in regulating intrauterine homeostasis and the maturation of fetal organ systems that are necessary for extrauterine life. The important mediators for these functions are steroid hormones from the fetal adrenal glands.

☆*Change History*: December 2017. Christian A. Koch and Fady Hannah-Shmouni updated the text and references to this entire chapter, added table 1A and figures 1 and 2.

This article is an update of Christian A. Koch, Adrenal Cortex, Physiology, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 68–74.

Throughout gestation and postnatally, the fetal adrenal glands undergo morphological and functional changes during its transformation to the adult adrenal gland (Ishimoto *et al.*, 2011; Merke *et al.*, 2006).

Following the formation of the adrenal cortex at the fourth week of human embryonic development, a blastema of undifferentiated cells of mesodermal origin forms from either the medial part of the urogenital ridge or mesoderm (**Fig. 1**) (Xing *et al.*, 2015; Merke *et al.*, 2006). The adrenogonadal primordium cells undergo proliferation and invasion of the underlying mesenchyme that is dependent on the interplay between the transcriptional factors steroidogenic factor 1 (SF1) and DAX1 that ultimately separates from the gonads by day 33 post conception (Xing *et al.*, 2015; Beuschlein *et al.*, 2002; Hammer *et al.*, 1999). Further mesodermal cell proliferation, under the control of fetal corticotropin, forms the first evidence for zonation: a definitive zone (DZ) and a fetal zone (FZ) that arise from the celomic epithelium, while the transitional zone (TZ) originates from the mesonephron and arises from the region of Bowman's capsule. Thus, the progenitor cells of the adrenal cortex stem from a cell lineage that also leads to steroid-secreting cells of the gonads. The FZ consists of large eosinophilic steroid-secreting cells that express high levels of steroid 17α-hydroxylase (CYP17) and DZ consists of cells that do not express CYP17 (Scheys, 2011). The TZ is composed of cells similar to those of the zona fasciculata of the adult adrenal glands (Scheys, 2011).

Several endocrine, paracrine, and autocrine factors influence the steroidogenesis of the fetal adrenal cortex. Between the 8th and 12th embryonic week, sinusoidal vascularization of the glands forms the framework for the zonation of the adult cortex (Scheys, 2011). At gestational week 8, chromaffin cells enter the rudimentary adrenal glands and cluster as discrete islands until day 8 postnatally, before they form a rudimentary adrenal medulla. Cortisol is produced from the rapidly growing FZ at about the 6th week of development, reaching a peak between the 8th and 9th week (Scheys, 2011). Gradually, aldosterone and cortisol are made by DZ and TZ cells, respectively, whereas the FZ, which represents 85% of the cortical volume, produces large amounts of DHEA and DHEA sulfate (DHEAS), that ultimately support estrogen production through the fetal-placental unit. Placental estrogen supports the fetal adrenal glands to synthesize cortisol (Sidiropoulou *et al.*, 2000). By the 9th week, progenitor populations of the adult adrenal cortex encapsulate the adrenal glands, expressing *Nr5a1* and *Gli1*. Migrating neural crest cells forms the adrenal medulla and intermingles with cortical cells of the FZ, attaining a maximum adrenal size by the 4th month. Thereafter, the gradual receding of FZ, and expansion of DZ and TZ, gives rise to the adult ZG and ZF, respectively (Scheys, 2011). After birth, FZ involutes and the corticomedullary junction separates between steroid hormone-producing and catecholamine-secreting cells. A transition zone of primarily fibrous tissue separates the FZ from the remaining gland. By the end of the second year of life, the first evidence of an anatomically distinct ZR appears; however, steroidogenic activity of this zone is not present until the age of 5 years, concomitant with the onset of adrenarche (Nakamura *et al.*, 2009). The adult adrenal cortex likely reaches maturity as early as 8 years of age to as late as after mid-puberty (Nakamura *et al.*, 2009).

Growth Factors

During the first trimester of pregnancy, human chorionic gonadotropin (HCG) regulates the growth of the fetal adrenal glands. Corticotropin is critical for growth, steroidogenesis, and differentiation of the fetal adrenal glands (Scheys, 2011). Corticotropin becomes the main growth factor after the 5th month of gestation. Corticotropin deficiency leads to increased apoptosis and subsequent atrophy of the adrenal glands, whereas corticotropin excess (e.g., in Cushing syndrome or congenital adrenal hyperplasia) can cause hyperplasia of the adrenal glands. In addition to HCG, corticotropin, and its receptor ACTHR, local growth factors are important for steroidogenesis, growth, and development of the adrenal gland. Insulin-like growth factors 1 and 2 (IGF-1 and IGF-2), their receptors, and binding proteins are all expressed in the fetal adrenal glands. IGF-1 amplifies the effect of corticotropin on the adrenal and enhances adrenal steroidogenesis by increasing the activities of 17α, 21-, and 11β-hydroxylase (Scheys, 2011). Similarly, IGF-2 promotes the action of corticotropin. In addition, IGF-2 helps the fetal adrenal to synthesize cortisol and androgen by regulating the enzymes p450scc, p450c17, and 3β-hydroxysteroid dehydrogenase (Scheys, 2011).

Basic fibroblast growth factor is a mitogenic protein and is more effective (stimulating proliferation) on adrenal cells of the DZ than those of the fetal zone. This may lead to hypertrophy of the fetal adrenal glands. EGF and EGFR play an important role in ACTH secretion from the pituitary gland. The TGF-β family of growth factors, including activin, inhibin, and TGF-β_1, are paracrine/autocrine regulators of growth and steroidogenesis in the fetal adrenal cortex. Activin increases corticotropin-stimulated cortisol production but not DHEAS production in fetal zone cells. In the adult adrenal cortex, activin has no effect on growth or steroidogenesis. In fact, activin may lead to apoptosis and involution of the fetal adrenal cortex postnatally. TGF-β_1 appears to decrease fetal and definitive zone cell proliferation and steroidogenesis.

Nuclear Receptors

The proliferation and invasion of adrenogonadal primordium cells are dependent on the interplay between the transcriptional factors SF1, DAX1 and estrogen receptor (ER) (Hanley *et al.*, 2006; Lin *et al.*, 2006). These factors belong to the nuclear receptor superfamily. Members of this family are transcription factors that are important for regulating expression of genes involved in cellular growth control and differentiation. SF-1 is classified as an orphan receptor because its ligand is unknown. The human cDNA sequence of SF-1 is highly homologous ($>95\%$) to murine and bovine sequences. Human adrenal cortex, ovaries, testes, and spleen show high SF-1 mRNA expression. In human placenta, SF-1 is not or only minimally expressed. SF-1 plays an essential role in the organogenesis of the fetal adrenal glands and also in regulating genes that code for steroidogenic enzymes (Hanley *et al.*, 2006). SF-1 stimulates the promoter activities of genes encoding steroidogenic acute regulatory (StAR) protein, the scavenger receptor-type class BI (SR-BI), and the corticotropin receptor. StAR protein is critical in the translocation process of cholesterol from the outer to the inner mitochondrial membrane. In contrast to the adult adrenal glands, the fetal adrenal glands uses low-density lipoprotein (LDL) rather than high-density lipoprotein (HDL) cholesterol as the main source for steroid biosynthesis (Miller, 2013a,b). It appears that SR-BI binds to LDL with high affinity. SF-1 influences the constitutive activity of the human corticotropin receptor gene promoter and regulates steroid hydroxylase enzymes (Miller, 2013a,b). In addition, SF-1 regulates the genes coding for the β-subunit of luteinizing hormone, the α-subunit of the glycoprotein hormones, gonadotropin-releasing hormone receptor, prolactin receptor, oxytocin, Mullerian inhibiting substance, and aromatase (Hammer *et al.*, 1999). Furthermore, SF-1 interacts with other proteins and cofactors.

DAX1 is an orphan nuclear receptor that is highly expressed in the fetal and adult adrenal glands, gonads, ventromedial hypothalamus (VMH), testes, ovaries and the pituitary gonadotropes (Hanley *et al.*, 2006). Together with SF-1, they may coregulate steroidogenesis as well as adrenal and gonadal organogenesis. DAX-1 can block steroidogenesis by inhibiting the activity of StAR and the expression of p450scc and 3β-hydroxysteroid dehydrogenase (Margioris and Tsatsanis, 2000). Estrogens are important in cell differentiation, growth, and function of various tissues. Estrogen receptors are members of the steroid receptor superfamily and mediate the action of estrogens. ERβ is highly expressed in the fetal adrenal gland, in contrast to ERα.

Mice that are knockouts (KO) for Sf1 have complete absence of the adrenal glands, whereas mice KO for Dax1 have developmental adrenal gland defects without adrenal insufficiency (AI) (Scheys, 2011; Miller, 2013a,b). In humans, X-linked DAX1 (mutations in *NR0B1*) defects cause the most common human form of congenital adrenal insufficiency (Lin *et al.*, 2006). These patients are usually 46,XY phenotypic boys and may have hypogonadotropic hypogonadism and a family history of male-only congenital adrenal insufficiency. Additionally, gene deletions at Xp21/22, where the DAX-1 gene is located, may lead to glycerol kinase deficiency, hypogonadotropic hypogonadism, and/or Duchenne's muscular atrophy. Humans with heterozygous *SF1* (coded by the *NR5A1* gene) mutations have adrenal insufficiency and gonadal abnormalities (Zanaria *et al.*, 1994). More recently, patients with isolated adrenal insufficiency and heterozygous *NR5A1* mutations have been described. SF1 gene mutations were also found in patients who also had isolated 46,XY gonadal dysgenesis and have been rarely identified in patients with congenital adrenal insufficiency without evidence of gonadal defects.

Adult Adrenal Cortex

Steroid Biosynthesis and Regulation of Cortisol Production

The normal adult human adrenal glands weighs approximately 5 g. Ninety percent of this weight is contributed by the adrenal cortex, which is composed of three zones (from outside to inside): the ZG, ZF, and the ZR. The adrenal medulla forms postnatally

and is composed of chromaffin cells, some of which may still be intermingled and spread within the adrenal cortex. The adult adrenal cortex produces glucocorticoids, mineralocorticoids, and adrenal androgens (**Fig. 2** and **Table 1**) (Hammer *et al.*, 1999; Miller, 2013a,b). The blood flow in the adrenal glands is centripetal (from outside to inside), which exposes the inner zones and the adrenal medulla to increasing concentrations of adrenal steroids. High cortisol levels in the medulla are needed to induce enzymes for epinephrine biosynthesis. In fact, patients with congenital adrenal hyperplasia have a compromised development and function of the adrenomedullary system due to cortisol deficiency.

Seventy-five percent of the adrenal glands weight is due to the ZF, the largest zone and the one that synthesizes glucocorticoids. The ZF and ZR also produce DHEA and DHEAS, whereas cortisol is primarily produced in the ZF. In contrast to the ZF, the ZR is small and not very involved in adrenal androgen production until adrenarche. The precursor for glucocorticoid production is cholesterol, which is initially converted to pregnenolone in the adrenal cortex. Steroids are derived from the cyclopentanoperhydrophenanthrene four-ring hydrocarbon nucleus, a relatively inert structure. Depending on the presence of several enzymes in the respective adrenal cortex zone, several steroid hormones can then be synthesized. Cytochromes P450 are categorized into two classes: type 1 enzymes that reside in the mitochondria and type 2 enzymes located at the smooth endoplasmic reticulum (**Table 1**) (Miller *et al.*, 2011).

The secretion and synthesis of cortisol are regulated by the hypothalamic–pituitary–adrenal (HPA) axis. Certain stimuli including stress lead to the release of CRH in the hypothalamus. CRH then stimulates corticotropin release from the pituitary gland (**Fig. 3**). Corticotropin binds to corticotropin receptors located on adrenocortical cells and stimulates the release of cortisol through cyclic adenosine monophosphate (cAMP). Cortisol leads to an increase in energy-providing compounds, including glucose, free fatty acids, and free amino acids. As mentioned previously, corticotropin is also growth promoting on the adrenal cortex; that is, continuous stimulation by corticotropin may lead to adrenal hypertrophy, whereas a lack of corticotropin may lead to adrenal atrophy. The HPA axis is very sensitive to exogenous and chronic glucocorticoid exposure, which can easily lead to

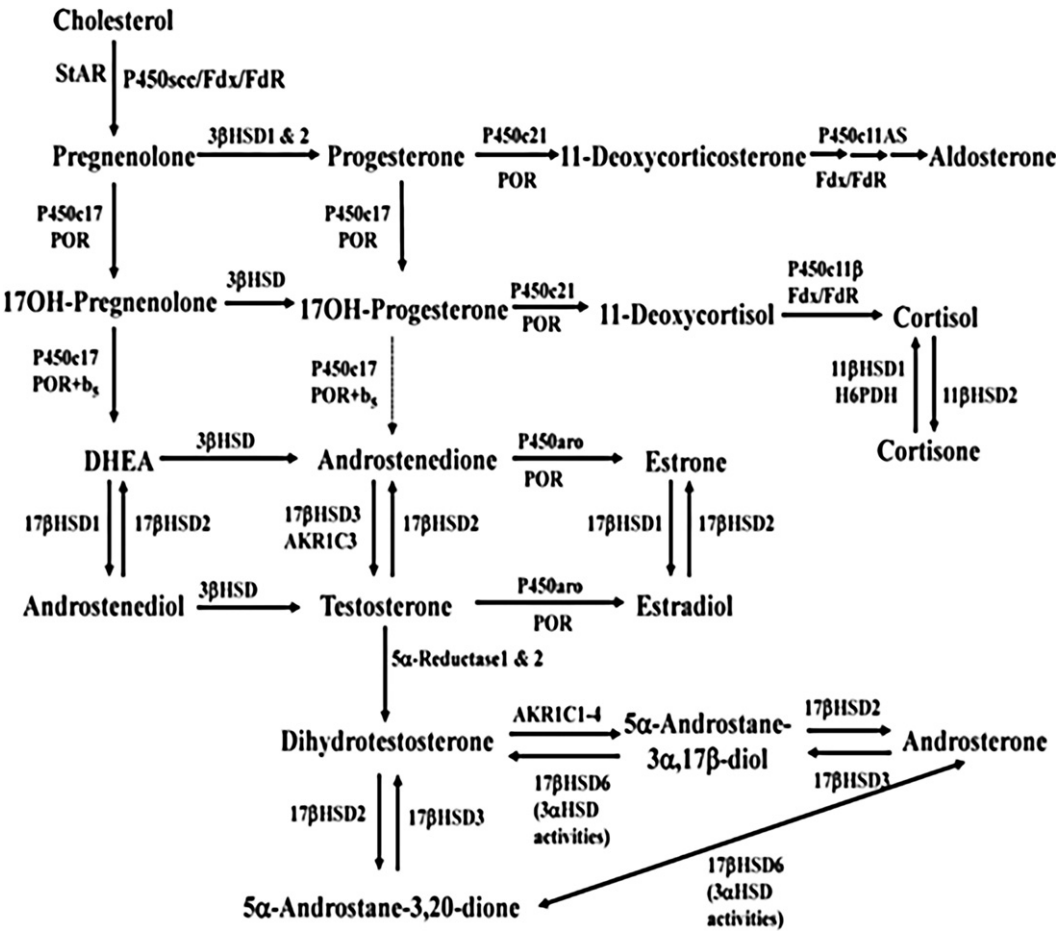

Fig. 2 Adrenal steroidogenesis. In brief, desmolase converts cholesterol to pregnenolone, 3β-OH-steroid dehydrogenase I/II convert pregnenolone to progesterone, 17-OH-pregnenolone converts progesterone to 17-OH-progesterone, P450c11 converts deoxycorticosterone to 18-OH-corticosterone and 11-deoxycortisol to cortisol, etc. Not all intermediate steroids, pathways, and enzymes are shown. corticotropin suppression through a negative feedback loop on CRH, and ACTH in corticotroph cells. In normal individuals who are not working in (night) shifts, there is a diurnal variation of cortisol production, with serum cortisol being highest in the morning and lowest at midnight. In patients with Cushing syndrome (hypercortisolism), these normal physiologic circuits are

disturbed. Prolonged (7–48 h) increases in corticotropin leads to an increased synthesis of all the steroidogenic enzymes, especially P450scc, as well as an increased uptake of cholesterol from the circulation (Hanley *et al.*, 2006; Miller *et al.*, 2011). Chronic lack of corticotropin (e.g., through exogenous glucocorticoid administration) leads to adrenal atrophy. Therefore, the exogenous glucocorticoid has to be tapered to allow the pituitary and adrenal glands to recover in order to synthesize normal levels of cortisol on its own. Depending on the level of suppression, this may take weeks or months.

Biosynthesis and Regulation of Aldosterone Production

Aldosterone, the major human mineralocorticoid, is produced in the ZG of the adrenal cortex. Its secretion is stimulated mainly by potassium, angiotensin II (and III) through the renin–angiotensin–aldosterone system and, to a lesser extent, by corticotropin. Chronic infusion of corticotropin stimulates aldosterone secretion for only 24 h. Less potent stimulators of aldosterone secretion are endothelin and serotonin. Also, increases in potassium concentrations stimulate aldosterone production (Hattangady *et al.*, 2012). An increase in serum potassium of 0.1 mmoL/L can elevate plasma aldosterone by 35%. On the other hand, a decrease in serum potassium of 0.3 mmoL/L can reduce plasma aldosterone by 46%. Aldosterone promotes potassium excretion, sodium reabsorption and fluid retention, thereby increasing the extracellular fluid volume. However, after a few days of extracellular fluid expansion by increased aldosterone levels, the individual will be protected from continuous expansion through a so-called "escape" mechanism that denotes attaining a new equilibrium of sodium balance and the formation of a new steady state (Hattangady *et al.*, 2012).

Target tissues of aldosterone, including kidney (distal tubules and cortical collecting ducts), colon, and salivary glands, have mineralocorticoid receptors that bind aldosterone. In the distal nephron, cortisol is a potent agonist at the mineralocorticoid receptor. Among inhibitors of aldosterone secretion are atrial natriuretic peptide (ANP) and dopamine (Hattangady *et al.*, 2012). ANP strongly inhibits stimulated (e.g., low sodium intake) aldosterone secretion, with much less effect on basal (e.g., normal or high sodium intake) activity. Chronic sodium restriction leads to increased activity of aldosterone synthase and a higher content of this enzyme in the ZG. The first steps of aldosterone biosynthesis are identical to those of cortisol biosynthesis (**Fig. 2**). The synthesis of cortisol, however, depends on 17α-hydroxylation of pregnenolone by 17α-hydroxylase (P450c17), which is exclusively expressed in the ZF (Hanley *et al.*, 2006; Miller *et al.*, 2011). On the other hand, aldosterone synthase is normally expressed only in the ZG.

Regulation of Adrenal Androgen Production

At approximately 4 years of age, in both sexes the ZR forms and continues to grow until the mid-20's. After age 40, this zone gradually regresses. Corticotropin and prolactin stimulate adrenal androgen secretion in the fetal adrenal zone (Sidiropoulou *et al.*, 2000). Postnatally, the ZR responds to corticotropin, as exemplified in congenital adrenal hyperplasia in which corticotropin and androgen hypersecretion can occur. During infancy, only small amounts of androgens are secreted, and it is unknown how adrenarche, the time point at which a slight amount of pubic hair develops, is regulated. Seventy percent of circulating testosterone in women with normal menstrual cycles derives from the conversion of adrenal DHEA. The principal androgens secreted by the adrenals are DHEA, DHEAS, androstenedione, and (minimally) testosterone (Nakamura *et al.*, 2009). DHEAS per se has only weak androgenic effects. Peripheral conversion of the aforementioned precursors leads to more potent androgens, such as testosterone and dihydrotestosterone. Major conversion sites include the hair follicles, sebaceous glands, external genitalia, and prostate. Peripheral adipose tissue can convert androgens into estrogens by the highly active enzymes aromatase and 17-ketosteroid reductase. Glucocorticoids stimulate aromatase. Inactivation or degradation of androgens and their metabolites occur at different sites, including the liver and kidneys. Exogenous adrenal androgen administration can suppress gonadotropin secretion. Excess endogenous androgen production can be caused by several conditions, including congenital adrenal hyperplasia, polycystic ovary syndrome and adrenal tumors.

Impact of the Sympathoadrenal System on the Regulation of Adrenocortical Function

Adrenocortical steroid hormones influence the differentiation and hormone production of adrenal chromaffin cells. On the other hand, the sympathoadrenomedullary system modulates diurnal variations of steroidogenesis in the adrenal cortex. The adrenal cortex is innervated by neurons originating in cell bodies within the adrenal medulla and by nerves that have cell bodies outside the adrenal, reaching the cortex via blood vessels. Adrenal chromaffin cells contain many neuropeptides that regulate adrenocortical steroid production in many species. Adrenomedullary cells are found throughout the adrenal cortex, which facilitates the paracrine action of their products. Another avenue for adrenomedullary secretory products reaching the adrenal cortex is the lymphatics.

Conclusion

The adrenal cortex fulfills important and essential functions throughout a persons lifespan. Prenatally, the fetal adrenal cortex is large and consists of the fetal zone, which produces large amounts of DHEAS, a hormone that serves as a precursor for other

androgens. DHEAS is used by the placenta to synthesize estriol and to regulate intrauterine homeostasis as well as maturation of fetal organ systems that are necessary for life after birth. Cortisol and aldosterone, both vital for homeostatic functions, are produced in the adrenal cortex and play important physiological functions in various tissues. Postnatally, the adrenal cortex becomes a three zoned structure with the ZF being the largest zone. All three zones gradually regress during a life span and their dysfunction could lead to serious illness.

Glossary

Adrenarche The gonadotropin-independent increase in adrenal androgen production marked by the rise in plasma DHEAS occurring at around 6–9 years of age. Adrenarche corresponds to the emergence of zona reticularis at the corticomedullary junction.

Embryogenesis Differentiation of the fertilized ovum during the period of most rapid development, that is, after the long axis appears until all major structures are represented.

Nuclear receptor Ligand-inducible transcription factor that specifically regulates the expression of target genes involved in metabolism, development, and reproduction.

Pregnancy or gestation The condition of having a developing embryo or fetus in the body. Duration of pregnancy is 266 days in women, 184 days in baboons, 165 days in rhesus monkeys, 145–150 days in sheep, 21 days in rats, and 18.5 days in mice.

Steroid hormones Lipophilic molecules, having a C_{17} ring as the basis of their chemical structure, that freely cross the cell membrane and interact with nuclear receptors.

Transcription factor Protein that directly affects the initiation of transcription of specific genes.

Maturation of the hypothalamic–pituitary–adrenal axis, which is characterized by increased activity during late gestation, is essential for the development of the fetus and plays a critical role in preparing for its transition to extrauterine life. The fetal adrenal cortex synthesizes and secretes androgens, glucocorticoids, and mineralocorticoids. In primates, androgens are necessary for placental conversion to estradiol, a hormone that is crucial for the maintenance of pregnancy, the maturation of the fetal and maternal tissues, and immunosuppression, leading to implantation of the placenta and the fetus. Glucocorticoids are essential for the maturation of brain, lung, liver, gut, kidney, and the adrenal itself. In some species, a surge in fetal glucocorticoid secretion has been suggested as being integral to the cascade of events leading to the onset of parturition. However, premature or abnormal exposure of fetuses or newborns to high levels of glucocorticoids leads, through a programming mechanism, to an increased prevalence of metabolic and cardiovascular disease. This article details both morphological and functional aspects of adrenal cortex development and zonation in humans and rodents. In particular, the role of nuclear receptors and transcription factors in the regulation of adrenocortical organogenesis and steroidogenesis is examined.

Embryogenesis, Development and Growth

Fig. 1 depicts the major milestones of adrenal cortex development in human and mouse.

In Humans

Human adrenal development begins at approximately the 4th week of gestation (28–30 dpc) and continues into adult life. Adrenocortical and gonadal cells derive from a single cell lineage that originates in the celomic epithelium in the notch between the primitive urogenital ridge and the dorsal mesentery, marked by the expression of steroidogenic factor 1 (SF-1, NR5A1) and forming the adrenogonadal primordium (AGP). Five landmark phases have been described:

Condensation of the celomic epithelium forms the AGP (3–4 weeks of gestation).

Proliferation and migration of celomic epithelial cells (weeks 4–6) that stream medially and cranially, accumulating at the cranial end of the mesonephros, forming the adrenal blastema that progressively separates from the mesenchyme and becomes fully encapsulated by a fibrous layer by 52 dpc.

Morphological differentiation of fetal adrenal cortical cells into two distinct zones (weeks 8–10): the fetal zone and the definitive zone. The fetal zone is an inner cluster of large, eosinophilic cells and represents the largest part (80%–90%) of the adrenal cortex. The definitive zone is a thin outer band of small basophilic cells, densely packed, showing structural characteristics of proliferative cells that appear to function as a reservoir of progenitor cells that may populate the remainder of the gland. A third zone, located between the fetal and definitive zones, has been called the transitional zone. By week 30 of gestation, the definitive and transitional zones resemble

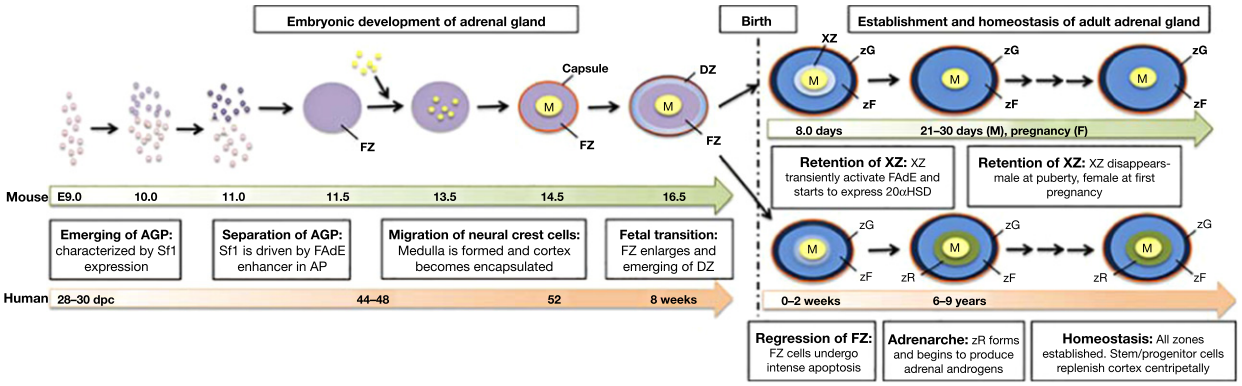

Fig. 1 Developmental and zonation of the adrenal gland. FZ: fetal zone. DZ: definitive zone. XZ: remnant of fetal zone (X-zone). zG: zona Glomerulosa. zF: zona Fasciculata. zR: zona Reticularis. Adapted from Xing, Y., Lerario, A.M., Rainey, W., Hammer, G.D. (2015). Development of adrenal cortex zonation. *Endocrinology and Metabolism Clinics of North America* **44**(*2*): 243–274. DOI: 10.1016/j.ecl.2015.02.001.

the adult zona glomerulosa and the zona fasciculata, respectively. A period of rapid growth begins at approximately week 10 and continues to term. The fetal zone grows by hypertrophy and limited proliferation, whereas growth in the definitive zone occurs mainly by hyperplasia. Several lines of morphological evidence indicate that the human fetal adrenal gland is a dynamic organ, in which proliferating cells located at the periphery migrate, differentiate, and finally undergo senescence in the central part of the gland.

Decline and disappearance of the fetal zone (first 3 postnatal months); by this period, the primate adrenal cortex remodeling involves apoptosis of the fetal zone with a corresponding decrease in adrenal androgen levels and expansion of the preexisting zona glomerulosa and zona fasciculata. Following the involution of the fetal zone, chromaffin elements, derived from the fetal ectoderm, begin to cluster around the central vein. The medulla acquires an adult-like pattern by 12–18 months.

At 6–8 years of age in girls and 7–9 years in boys, emergence of the zona reticularis at the corticomedullary junction, heralds the onset of adrenarche and the return of adrenal androgen production, including DHEA/DHEAS and androstenedione.

Stabilization of the adult zonal pattern (10–20 years of age) with the individualization and homeostatic maintenance of the three distinct cell layers: the outer zona glomerulosa, the central zona fasciculata, and the inner zona reticularis.

In Rodents

In mice, the adrenal gland starts to individualize from the AGP on E11. On E12.5, the cortical cells forming the fetal zone are found intermingled with adrenal medulla sympathoblasts migrating from the neural crest. Encapsulation of the mouse fetal zone by mesenchymal cells from the intermediate mesoderm is achieved by E14.5. Following encapsulation, a second population of cells emerges at the periphery of fetal zone that forms the definitive zone or future adult cortex.

By contrast to humans, the fetal zone in mice does not seem to support any specific steroid hormone production and the individualization of adult adrenocortical layers, zonae glomerulosa and fasciculata, from the definitive zone is completed by birth. Finally, the mouse adrenal cortex does not undergo zona reticularis differentiation but possesses a transient developmental zone between the zona fasciculata and the adrenal medulla, the X-zone. The X-zone becomes histologically distinct at 8–14 dpc and enlarges until 21 dpc, then regresses at sexual maturity in males and during first pregnancy in females. Although its function remains yet unknown, lineage tracing studies clearly identified X-zone as being a remnant of the mouse fetal zone.

Ontogeny of Steroid Biosynthesis

The adrenals synthesize several classes of steroids: androgens, glucocorticoids, and mineralocorticoids. The major human adrenal steroidogenic pathways are summarized in **Fig. 2** Schematically, the process of adrenal steroidogenesis has two major components. The first is quantitative; that is, it regulates how much steroid can be made at a given moment. The second is qualitative; that is, it regulates which particular steroid is made.

First step: Conversion of cholesterol to pregnenolone. This step involves the delivery of the substrate cholesterol to the inner mitochondrial membrane, driven by steroid acute regulatory protein (StAR), and the conversion of cholesterol to pregnenolone, catalyzed by P450 steroid chain cleavage (P450ssc), adrenodoxin, and adrenodoxin reductase.

Second step: Transformation of pregnenolone to active hormones. The coordinate regulation of several enzymes will direct the transformation of pregnenolone toward a given class of steroid hormone—androgens, glucocorticoids, and mineralocorticoids. During adrenal cortex development, the synthesis of these various steroids is not temporally coordinated, is zone-dependent, and is species-specific. **Table 1** summarizes the localization and relative expression of the enzymes involved in fetal adrenal steroid biosynthesis.

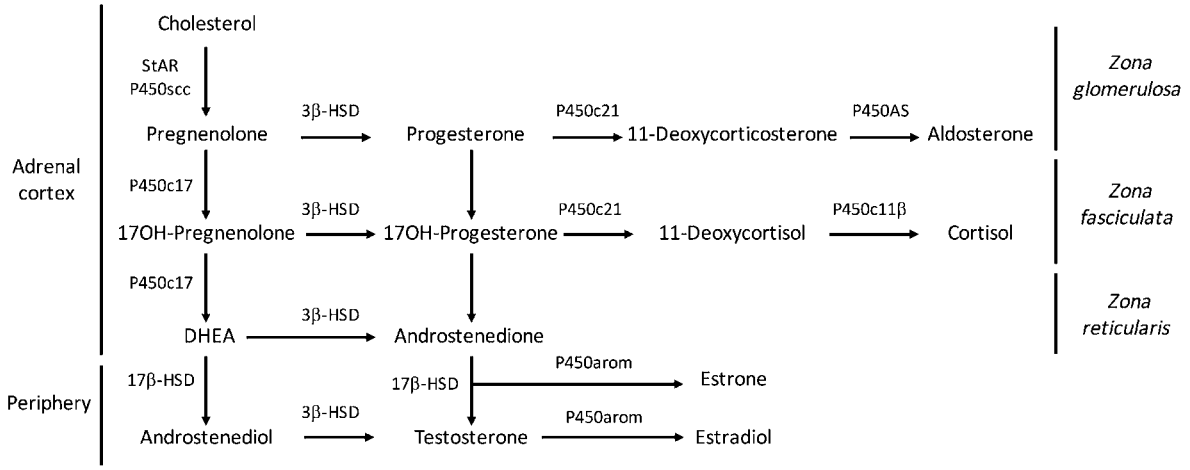

Fig. 2 Schematic view of human adult adrenal and peripheral steroidogenic pathways. StAR, steroid acute regulatory protein; P450ssc, side-chain cleavage enzyme; P450c17, enzyme complex having 17α-hydrolase and 17,20-lyase activities; 17β-HSD, 17β-hydroxysteroid dehydrogenase; 3β-HSD, 3β-hydroxysteroid dehydrogenase; P450c21, 21-hydroxylase; P450c11AS, aldosterone synthase (contains 11β-hydroxylase, 18-hydroxylase, and 18β-hydroxysteroid dehydrogenase activities); P450c11β, 11β-hydroxylase; P450arom, aromatase.

Androgens

The conversion of cholesterol to pregnenolone is mature in the fetal zone during early pregnancy in humans. High levels of 17α-hydroxylase/17,20-lyase (P450c17) and of its allosteric regulator cytochrome *b*5 (CYB5) favoring lyase activity are present in the fetal zone very early (as soon as 44 days postconception) together with low levels of 3β-HSD. As a consequence, the fetal zone produces dihydroepiandrosterone (DHEA), the bulk of which appears to be secreted as a 3-sulfoconjugate DHEA sulfate (DHEAS) that is formed by the action of DHEA sulfotransferase and the cofactor 3′-phosphoadenosine 5′-phosphosulfonate. DHEAS is used by the placenta for conversion to estrogens. By term, the fetal zone produces approximately 200 mg DHEA per day.

Due to the dramatic postnatal involution of fetal zone, androgen production virtually ceases in the first few months of life and remains very low until the emergence of zona reticularis that marks adrenarche onset. Biochemical adrenarche is defined by the reincrease in circulating adrenal androgen levels leading to serum DHEAS concentrations $\geq$40 µg/dL. This leads to axillary and pubic hair development, adult-like body odor, oily hair and possibly brain maturation.

In rodents, the postnatal adrenals do not express P450c17, do not develop a functional zona reticularis and, thus, do not synthesize DHEA. Interestingly, a functional reticularis-like zone (expressing P450c17, high CYB5, and low 3β-HSD) producing adrenal androgens, can be forced to differentiate in a genetic mouse model where adult cortical cells renewal has been stimulated by constitutive activation of PKA signaling (Dumontet et al., 2018). Thus, the onset of adrenarche seems to depend on the combined effect of PKA and cell turnover that will dictate organ size. The possibility that such a mechanism also occurs in humans to induce adrenarche, remains to be explored.

Glucocorticoids

In Humans

Assays of steroids in cord blood have suggested that human fetus can synthesize cortisol as early as the 10th week of gestation. This hypothesis is supported by clinical and biological observations in patients with congenital adrenal hyperplasia (CAH) caused by deficiency of 21-hydroxylase (P450c21), 3β-hydroxysteroid dehydrogenase (3β-HSD), or 11β-hydrolase (P450c11β). Patients with this disorder have impaired glucocorticoid production with a compensatory increase in pituitary adrenocorticotropic hormone (ACTH) secretion and subsequent stimulation of DHEA synthesis. Interestingly, female infants with CAH have ambiguous external genital development, indicating that, in unaffected female fetuses, cortisol is synthesized by the adrenal by the time of external genital differentiation, a process that is sensitive to androgens and begins at approximately week 10. These observations do not necessarily indicate that the week 10 fetal adrenal is able to synthesize cortisol de novo from cholesterol. Although StAR and P450ssc immunoreactivities are expressed in the cytoplasm of human fetal adrenocortical parenchymal cells of the transitional zone as soon as week 14, in early gestation the fetal adrenal can synthesize cortisol using placental progesterone as substrate, since high levels of progesterone are present in the fetal circulation. P450c21 and P450c11β immunoreactivities have been detected in the transitional zone of human fetal adrenals as soon as weeks 13–14 and P450c17mRNA is present in the transitional zone of week 22 human fetal adrenal. This is consistent with the observation that progesterone infusion into human fetuses between weeks 16 and 18 results in cortisol synthesis. As a consequence, the key enzyme for the production of cortisol de novo from cholesterol during early gestation is 3β-HSD. It has been reported that 3β-HSD immunoreactivity and mRNA could not be detected in human adrenals before weeks 22–24, suggesting that the transitional zone of human fetus adrenals is able to synthesize de novo cortisol beginning at week 24. Similarly, in nonhuman primates, 3β-HSD mRNA is undetectable during early gestation, starts to increase at midgestation, and is further stimulated at late gestation. 3β-HSD protein expression in the transitional zone of adrenals from fetal rhesus monkeys follows a comparable developmental pattern.

In Rodents

Adult mouse and rat adrenal cortex, which lack P450c17, produce mainly corticosterone. P450ssc and adrenodoxin are expressed at midgestation in the rodent adrenal cortex (E15–E16). 3β-HSD mRNA and protein have been detected in the fetal rat adrenal as early as E16; their labeling in zona fasciculata is at a higher level than in the zona glomerulosa at E18. P450c21 and P450c11β immunoreactivity and mRNA are present in the fetal rat adrenal at E18. P450c17mRNA and activity are detectable in the adrenals of mouse fetuses at E12.5, increase in abundance from E12.5 to E14.5, and are then lost between E16.5 and E18.5, suggesting that the fetal mouse adrenal is able to synthesize cortisol during late gestation. Although the ontogeny of StAR expression in the rodent embryonic adrenal remains to be elucidated, it is known that fetal rat adrenals synthesize and secrete corticosterone as early as E13. The corticosterone contents of the fetal rat adrenal are high from E16 to E20 and plasma corticosterone concentrations rise progressively from E16 to E19. This phenomenon occurs following activation of pituitary ACTH and the hypothalamic neuropeptides that control ACTH synthesis and secretion.

During the first 10 days after birth, there is a marked decrease in adrenal corticosterone contents and both basal and stress-induced circulating corticosterone levels. This period has been called the "stress hyporesponsive period" (SHRP). These low-circulating glucocorticoid levels are believed to be essential for normal brain and behavioral development. A decrease in the steroidogenic capacity of the newborn adrenal cortex may account, at least in part, for the SHRP. It has been demonstrated that StAR mRNA and protein are highly expressed in the adrenals at birth, decrease subsequently until P14, and increase thereafter. The level of expression of P450ssc is comparable to that of P1 in adults. At birth, adrenal 3β-HSD activity is low at P1, increases at P10, and remains stable until adulthood. P450c21 activity is low (approximately half of the adult values) on P1 and P10. P450c11β immunoreactivity has been detected in the adrenals of newborn rats and did not change during neonatal development. In P7 rats, P450c11β mRNA is present at high levels only in the zonae fasciculata and reticularis.

Mineralocorticoids

In Humans

Regarding the ontogeny of aldosterone secretion, assays of steroids in cord blood have suggested that human fetus can synthesize aldosterone as early as weeks 16–20. However, in vitro experiments have demonstrated that at midgestation human fetal adrenal tissues do not produce detectable levels of aldosterone, under basal or stimulated conditions. The primary steps in aldosterone synthesis, that is, those driven by StAR, P450ssc, 3β-HSD, and p450c21, are mature in the definitive zone in human fetal adrenals at the end of the midgestation period. However, in human fetal adrenals obtained from second-trimester abortuses, aldosterone synthase (P450c11AS) immunoreactivity is absent in the definitive zone and P450c11AS mRNA is weakly detectable in the whole cortical zone. Similarly, P450c11AS immunoreactivity is absent in the definitive zone of fetal rhesus monkey adrenal until near term. Activation of the late gestation fetal rhesus monkey HPA axis (obtained after treatment with metyrapone, a compound that

inhibits P450c11β) was able to induce P450c11AS expression. Taken together, these data indicate that in the primate fetal adrenal gland the definitive zone has the capacity to synthesize aldosterone, but not until term.

In Rodents

In rats, P450c11AS immunoreactivity is detected in E16 adrenals, in small clusters of cells, dispersed throughout the gland. By E18–E19, the number of P450c11AS-labeled cells increases and these cells become localized in the outer cortex. P1 adrenals have a pattern of P450c11AS staining comparable to that of the adult gland. In P7, rats, P450c11AS mRNA is confined to the subcapsular zona glomerulosa. Aldosterone content in fetal adrenal homogenates increases between E17 and P1 and remains stable thereafter.

Role of Nuclear Receptors and Transcription Factors

The complex cascade of the development and differentiation of the adrenal cortex, from the formation of the urogenital ridge to the zonation of the fetal adrenal, involves several nuclear receptors and transcription factors (**Table 2**).

Table 2 Transcription factors and nuclear receptors involved in adrenal differentiation and steroidogenesis

Transcription factor or nuclear receptor	*First detected on*	*Phenotype of total or conditional[a] mouse KO*	*Genes that are regulated in adrenal cells*

Wt1, Sf-1, and Dax-1

Several transcription factors, such as Wt1 (Wilm's tumor suppressor gene 1), steroidogenic factor-1 (Sf-1), dosage-sensitive sex-reversal adrenal hypoplasia congenita critical region on the X chromosome, gene 1 (Dax-1), Pre-B-cell transcription factor 1 (Pbx1), and CBP/p300-interacting transactivator, with Glu/Asp-rich C terminal domain, 2 (Cited2) play major roles in the development of the adrenal primordium, its functional zonation, and the regulation of fetal adrenal steroidogenic capacities.

Wt-1

Wt1, which encodes a protein having many characteristics of a transcription factor, is crucial for the development of the urogenital ridge. Wt1 is developmentally one of the earliest known genes that specifies kidney, gonadal, and adrenal cell lineages. Mice fetuses knocked out for Wt1 and rescued with a YAC (yeast artificial chromosome) construct spanning the Wt1 locus have adrenal-like structures that are greatly reduced in size and express lower levels of P450ssc mRNA than wild-type mice.

Sf-1

Sf-1, also called Ad4BP or NR5A1, belongs to the orphan receptor class of nuclear receptors. It has been proposed that Sf-1 acts through recruitment of cofactors, including both coactivators (CREB-binding protein, Wt-1, and nuclear receptor coactivator 1) and corepressors (nuclear receptor corepressor, DEAD/H box polypeptide 20, COP9 constitutive photomorphogenic subunit 2, nuclear receptor-interacting protein 1, and Dax-1). In mouse, Sf-1mRNA was detected in the adrenal primordium from E9.5. From E14–E14.5 onward, Sf-1mRNA is restricted to the steroidogenic cells in the cortex. In humans, Sf-1 was expressed as early as E33 in the presumptive adrenal primordium. Newborn Sf-1 knockout mice are devoid of adrenals and die from adrenocortical insufficiency shortly after birth. However, Sf-1 heterozygous mice (*Sf-1*$^{+/-}$) are viable but show adrenal disorganization (reduced adrenal size and hypoplastic zona fasciculata and adrenal medulla), altered adrenal gene expression (increased StAR mRNA and decreased ACTH receptor mRNA), and impaired basal and stress-induced glucocorticoid secretion. Studies of Sf-1 gene mutations in humans demonstrated that Sf-1 regulates adrenal development in a dose-dependent manner. A number of studies have demonstrated that Sf-1 acts a global regulator of the proteins involved in adrenal steroidogenesis (StAR, P450ssc, 3β-HSD, P450c21, P450c11AS, P45011β, and P450c17). In addition, Sf-1 regulates adrenal ACTH sensitivity through a cell-specific modulation of both constitutive and cyclic AMP-induced expression of the ACTH receptor gene. Moreover, Sf-1 post-translational modification by sumoylation also affects its functional capacity that, in turn, alters adrenal development. Indeed, a genetically engineered mouse expressing an unsumoylatable Sf-1 mutant, develops perturbation of cell-fate specification in adrenal cortex characterized by ectopic localization of gonadal cells and persistence of the X-zone (Lee et al., 2011). Sf-1 sumoylation sites mapping at Lysine 119 and 194 are conserved between species but until now no mutation have been described in humans.

Dax-1

Dax-1 is an orphan nuclear receptor that regulates both adrenal development and functional zonation. Mutations in the Dax-1 gene are responsible for X-linked adrenal hypoplasia congenita, an inherited disorder in humans that is characterized by hypoplasia of the fetal adrenal glands with absence of the definitive zone and persistence of the fetal zone. Dax-1 has been postulated to bind to hairpin loops of the StAR promoter and/or to function as an RNA-binding protein. In mouse, it has been shown that Dax-1 is colocalized with Sf-1 in the developing adrenal and that Sf-1 expression precedes or coincides with expression of Dax-1, suggesting that these two molecules could cooperate in regulating adrenal development. In vitro, Dax-1 inhibited Sf-1-induced stimulation of transcription of the adrenal promoter of StAR, P450c17, Dax-1 itself, possibly through interactions with Sf-1, and transcriptional corepressors such as NcoR and Alien, whereas Sf-1 stimulated expression of the Dax-1 promoter. In vivo, male mice with a single Dax-1-deleted allele (Dax-1$^{-/y}$) have normal zona glomerulosa, but the zona fasciculata is less well developed and shows decreased staining for 3β-HSD and delayed X-zone regression. Dax-1$^{-/y}$ animals have increased stress-induced corticosterone secretion and enhanced adrenal responsiveness to exogenous ACTH stimulation, most probably following increased adrenal P450c21 and ACTH receptor expression. Dax-1$^{-/y}$ animals have normal expression of Sf-1 and expression of Dax-1 is maintained in Sf-1$^{+/-}$ mice. The absence of Dax-1 partially reverses adrenal growth defects in Sf-1$^{+/-}$ mice. However, the precise mechanisms governing the interplay between Sf-1 and Dax-1 in regulating adrenal development and steroidogenesis are not well known. Interestingly, sumoylation of Sf-1 increases its physical interaction with the corepressor Dax-1, resulting in the complete inactivation of the fetal zone-restricted Sf-1 enhancer FAdE which ultimately leads, by a yet unexplained mechanism, to postnatal regression of the fetal remnant cortex, the X-zone (Xing et al., 2017). These data are therefore reminiscent to the converging phenotype—partial retention of the X-zone—shared by Dax-1$^{-/y}$ and sumoylation-deficient Sf-1 mice. In human fetuses, Dax-1 is expressed in the adrenal primordium as early as E33. Between W15 and 21 Dax-1 immunoreactivity has been found mainly in the nucleus in the outer definitive zone and in the cytoplasm in the fetal zone, while the density of Dax-1 positive cells decreased from the internal to the external portion of the gland.

Pbx1

Pbx1, an homeodomain protein, is expressed as soon as E10 in the mouse adrenal primordium. Embryos of *Pbx1*$^{-/-}$ mice lack the adrenal glands. This was linked to a decrease in Sf-1 expression, while that of Wt1 was unaffected. Adult Pbx1 haploinsufficient mice have lighter adrenals together with a reduced level of proliferation and of IGF-I receptor. In addition, it has been demonstrated that Pbx1 stimulates ACTH receptor expression, synergistically with Sf-1. Pbx1 was detected in 7 week gestation human fetal adrenal extracts.

Cited2

Cited2 was first detected in the mouse adrenogonadal primordium at E10, with high levels of expression in the adrenal cortical cells at E13.5 and later. *Cited2*$^{-/-}$ embryos showed a lack of expression of Sf-1 in the adrenal primordium at E10.5 and of Dax-1 and Wnt-4 at later stages, resulting in a lack of adrenal development. Embryos heterozygous for Cited2 and Wt1 have strongly reduced adrenal size at E13.5 with decreased Sf-1 mRNA. Cited2 was detected in 7 week gestation human fetal adrenal extracts.

Other Transcription Factors and Signaling Pathways

Rspo/Wnt/β-Catenin

Wnt (wingless-related mouse mammary tumor virus integration) 4, a member of the Wnt family of developmentally regulated signaling molecules, is involved in the development of the adrenal, kidney, pituitary gland, female reproductive system, and mammary gland. Wnt canonical signaling pathway is transduced to the nucleus by β-catenin. Wnt4 is expressed next to the anterior site of the mouse mesonephros on E11.5 and in the developing adrenal cortex from E12.5 onward. Adrenals of Wnt4 knockout mice are morphologically comparable to those of wild-type animals. However, Wnt4 knockout animals have impaired zona glomerulosa differentiation together with reduced adrenal P450c21 and P450 aldosterone synthase mRNA concentrations and decreased aldosterone production. All the above-mentioned observations strongly suggest that Wnt4 and possibly β-catenin are involved in the establishment of the zonated function of the adrenal. Indeed, β-catenin ablation in Sf-1 expressing cells leads, depending of the amount of affected cells, to adrenocortical aplasia that ranges from definitive zone failure in embryos to progressive cortex thinning in aging animals. Similarly, R-spondin 3 (Rspo3), a signal molecule secreted by capsular cells that modulates β-catenin activity in the underlying steroidogenic compartment, is essential to imprint glomerulosa identity and to maintain organ growth by ensuring replenishment of adult cortex (Vidal et al., 2016). Thus, β-catenin activation (at least responding to Wnt4 and Rspo3 signals) is required for definitive zone emergence during development, proper maintenance of adrenocortical progenitor cells in postnatal cortex and glomerulosa zonation. Moreover, Wnt and PKA signaling pathways play essential and complementary roles in functional zonation of the adrenal cortex (Drelon et al., 2016). Gain- and loss-of-function mouse models show that the Rspo3/Wnt4/β-catenin pathway is a driver of glomerulosa identity, a repressor of fasciculata identity and has tumorigenic activity when constitutively activated. Reciprocally, constitutive activation of cAMP/PKA signaling inhibits glomerulosa fate, triggers fasciculata identity, and counteracts β-catenin-induced adrenocortical tumorigenesis.

Sonic Hedgehog

Hedgehog family proteins are secreted molecules that act upon target cells by binding to multiprotein receptor complexes. Both sonic hedgehog (Shh)-expressing cells and Shh-responsive cells are detected in the mouse embryonic adrenal cortex at E12.5 at the periphery of the gland. In adults, Shh produced by partially differentiated cortical cells acts on non-cortical cells of the overlying capsule. Shh mutants adrenals have a thinner capsule and a disproportionately reduced cortex that is well differentiated with appropriate zonation. Thus it appears that Shh signal is important for capsule and cortex growth, but does not regulate cortical differentiation or zonation. This hypothesis is consistent with the observation that corticosterone levels in Shh mutants are normal at birth but strongly reduced in adult animals.

GATA Proteins

GATA proteins are transcription factors that bind to the consensus sequence (A/T)GATA(A/G) in the promoter and enhancer regions of their target genes. GATA-4 is present in human adrenocortical carcinoma and in a transgenic mouse model developing adrenocortical tumors. GATA-4 and GATA-6 are detectable from E14 and week 19 onward in the mouse and human adrenal cortex, respectively. After birth, GATA-4 expression decreases, whereas GATA-6 continues to be expressed. Studies in chimeric mouse embryos demonstrated that GATA-4 is not essential for early adrenocortical differentiation. In contrast, GATA-6 conditional gene deletion in the adrenal cortex (in Sf-1 expressing cells) leads to severe adrenal insufficiency with a deficit in both zona glomerulosa and fasciculata cells, complete absence of the X-zone and ectopic differentiation of gonadal-like steroidogenic cells (Tevosian et al., 2015). These data indiquate that GATA-6 is essential for adrenocortical cells maintenance in developing and postnatal glands and repression of gonadal fate but its loss does not completely preclude adrenocortical formation and

steroidogenesis since active steroidogenic cells expressing the master regulator Sf-1 remain in the hypoplastic glands and sustain viability.

Corticotropin-Releasing Hormone Peptide Family☆

David W Hogg, Mia Husic, and David A Lovejoy, University of Toronto, Toronto, ON, Canada

Glossary

Corticotropes Cells of the anterior lobe of the pituitary gland, which produce adrenocorticotropic hormone and respond to corticotropin-releasing-hormone.

G protein-coupled receptor (GPCR) A polypeptide receptor with seven transmembrane domains. Ligand binding occurs on the extracellular side of the plasma membrane and results in stimulation of G proteins which modulate intracellular signal transduction pathways.

Homeostasis In an organism, homeostasis is any process that acts to actively regulate/maintain a physiological variable within an acceptable range necessary for survival. Examples include the regulation of body temperature, fluid balance, pH, and blood glucose.

Hypothalamic–pituitary–adrenal axis (HPA) axis A major neuroendocrine system involving the hypothalamus, the pituitary gland, and the adrenal glands. The HPA axis functions as the central stress response system by coordinating central nervous system and endocrine responses to physiological or psychological stress.

Homology In biology, the term homolog indicates shared ancestry between a pair of genes or structures in different taxa. Homologous sequences are orthologous if the genes in different species have evolved from a common gene by speciation. Homologous sequences are paralogous if the genes are related by duplication within the genome of a single species. Orthologs tend to retain the same function in the course of evolution, whereas paralogs evolve new functions, even if these are related to the original one.

Limbic system A collection of brain structures, including the hippocampus, hypothalamus, amygdala, and prefrontal cortex, that support various functions including emotion, behaviour, motivation, long-term memory, and olfaction. Afferent neural pathways connecting structures of the limbic system to the paraventricular nucleus of the hypothalamus activate CRH neurons and play an important role in modulating the HPA axis and the stress response.

Corticotropin-Releasing Hormone: Driver of the HPA/I Stress Axis

Biological or physiological stress is commonly defined as any event, whether perceived or real, that can disturb the homeostatic state of an organism. The concept of stress was originally developed by Hans Selye (1907–1982) and described in his treatise, "Stress" (Selye, 1950). It was in this work that he defines the "General Adaptation Syndrome" which describes the physiological response to a stressor (e.g., disease, infection, or injury), and involves modulation of both the nervous and endocrine systems. Whereas Selye's work focused mainly on the chronic aspects of stress, it was Walter Cannon (1871 to 1945) and his studies on epinephrine (adrenaline) that outlined the short-term elements of stress and coined the term "fight or flight response." Together, the work performed by these researchers established the foundation of the stress-associated aspects of the sympathetic nervous system. Psychological responses associated with perceived threats arising from environmental novelty, social interaction, and challenge can also induce stress. The contribution of the psychological aspects of stress was later introduced by Robert Sapolsky, leading to our modern definition of the stress response (Sapolsky, 1994).

In vertebrates, maintenance of homeostasis in response to a stressor includes a multifaceted response involving the endocrine, nervous, and immune systems (Chrousos and Gold, 1992; Carrasco and Van de Kar, 2003; Haddad *et al.*, 2002). The primary mediator of the stress response is the hypothalamus–pituitary–adrenal/inter-renal (HPA/I) axis. During periods of stress, the physiological function of the HPA/I axis is to divert energy production to where it is needed most. Typically, this involves increasing sympathetic nervous system activity necessary for defense and survival (e.g., increased cardiovascular activity, respiratory rate, and intermediate metabolism), and reducing maintenance activities associated with the parasympathetic nervous system (e.g., feeding, growth, and development) (Smith and Vale, 2006). The principle anatomical structures that mediate the stress response are the paraventricular nucleus (PVN) of the hypothalamus, the anterior lobe of the pituitary gland, and the adrenal gland. In response to a challenge, corticotropin-releasing hormone (CRH) is secreted from parvocellular neuroendocrine cells of the PVN into the hypophyseal portal system, the primary blood supply of the anterior pituitary gland. CRH stimulates corticotropes in the anterior pituitary gland to secrete adrenocorticotropic hormone (ACTH) into the bloodstream. In addition to CRH, a number of other factors that modulate ACTH release are also secreted in response to a stress challenge (e.g., arginine vasopressin). The primary target of circulating ACTH is the adrenal cortex, where cells in the zona fasciculata layer are stimulated to synthesize and

secrete glucocorticoids. Glucocorticoids, such as cortisol in humans (corticosterone in rats, birds, and reptiles), are the downstream effectors of the HPA/I axis and regulate physiological changes throughout the body, primarily through an enhancement of energy metabolism. The HPA/I axis is a negative feedback cycle in which circulating glucocorticoids act back on the hypothalamus and pituitary to suppress CRH and ACTH production (**Fig. 1**).

The evolutionary development of the HPA/I axis in vertebrates has had a major impact on their physiology. It integrated the neural actions of CRH with the glucocorticoid-synthesizing tissues of the periphery by linking a large and mobility-constrained neuropeptide (CRH) with small lipophilic hormones (glucocorticoids) that could traverse all tissues. This interaction allowed the organism's stress-response metabolism to be placed under the control of a single neuropeptide. Additionally, CRH is controlled by both sensory and associative inputs, allowing the HPA/I axis to act as a key stress-perceiving and integrating unit. As a result, the evolution of the HPA/I axis allowed organisms to anticipate a future stressor and to mount a metabolically integrated response to the stimulus.

Discovery of the CRH Family of Peptides

CRH was first isolated from purified sheep hypothalami by Wylie Vale (1941–2012) and colleagues in 1981. It was determined to be 41 amino acid residues in length and capable of stimulating ACTH secretion from cultured anterior pituitary cells (Vale *et al.*, 1982). The discovery of CRH occurred following decades of previous research that suggested the existence of a peptide hormone capable of regulating the release of ACTH from the pituitary gland in vertebrates. Indeed, the concept of "releasing factors" produced in the brain that can regulate pituitary hormone activity can be traced as far back as the early 20th century (see Lovejoy, 2005 for discussion). Together, this lead to the proposal by Harris (1948) that there is a physiological system in which chemical factors from the hypothalamus are released into the hypophyseal portal blood vessels to stimulate the release of pituitary hormones. This gave rise to a further postulation that each pituitary hormone was controlled by a single hypothalamic releasing factor. Attempts to purify the putative ACTH-releasing factor were first independently described by Schally and Saffran (1955) and Guillemin and Rosenberg (1955); however, its low concentration in tissues made it difficult to attain sufficient amounts to solve its structure.

Prior to solving the structure of CRH multiple other studies reported CRH-like peptides in non-mammalian species. In Montecucchi *et al.* (1979) and associates identified the structure of sauvagine (SVG), a 40-amino acid peptide isolated from the skin of a neotropical leaf frog (*Phyllomedusa sauvagei*). The ability of SVG to induce the release of ACTH from the pituitary gland led

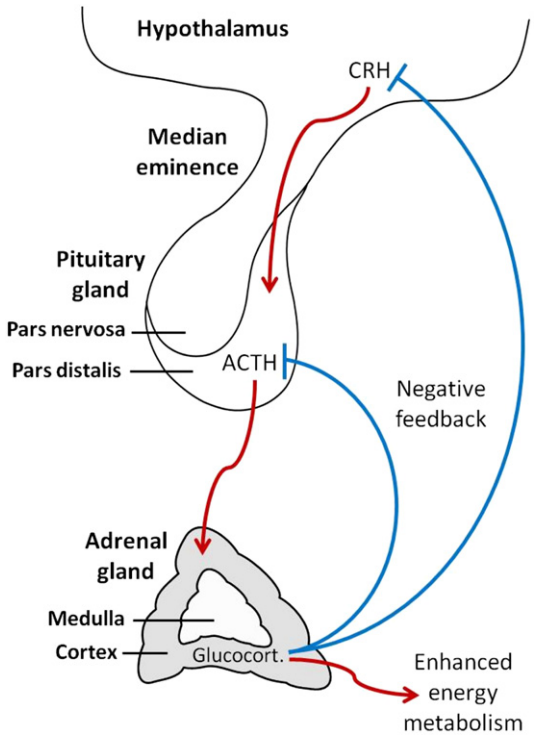

Fig. 1 Mammalian hypothalamic–pituitary–adrenal axis. In mammals, CRH is secreted from the hypothalamus to the median eminence, where it travels via the hypophyseal portal system into the pars distalis of the pituitary gland. In the pituitary gland, CRH stimulates the release of ACTH into the bloodstream. ACTH then acts in the cortex of the adrenal gland to induce production and secretion of glucocorticoids (Glucocort.), which enable enhanced energy metabolism under stress conditions and negatively feedback on CRH and ACTH to reduce their production and release.

to the speculation that SVG was structurally related to the elusive ACTH-releasing factor (Erspamer and Melchiorri, 1980). Following the discovery of CRH, Lederis and colleagues isolated a 41-amino acid peptide from the neurosecretory organ (urophysis) of the white sucker fish (*Catostomus commersoni*) with sequence similarity to CRH (Lederis *et al.*, 1982). They named this neuropeptide urotensin-I (UI; termed "urocortin" (Ucn) in mammals), after its tissue of origin. Both SVG and UI were found to stimulate ACTH release from the rat pituitary gland, although their pharmacological profiles differed from that of CRH (see Lovejoy and Balment, 1999; Lovejoy, 2009 for reviews).

These studies indicated that CRH-like peptides were found in a variety of vertebrate species; however, how they were functionally and genomically related remained unclear at the time. In 1989, the structure of the first insect CRH-like peptide, diuretic hormone (DH), was reported by Kataoka *et al.*, and since then, many CRH-related peptides have been reported in insects (Coast, 1996, 1998; Lovejoy and Jahan, 2006; Cardoso *et al.*, 2014). These additional sequences allowed Vale and his colleagues to determine the structures of two additional CRH-like peptides, which they termed urocortin 2 (Ucn2) and urocortin 3 (Ucn3) (Reyes *et al.*, 2001; Lewis *et al.*, 2001). Simultaneously, Hsu and Hsueh (2001) reported the structure of the same peptides, which they called "stresscopin" and "stresscopin-related peptide." Since these publications, numerous homologous structures have been identified in vertebrates demonstrating that these peptides were physiologically essential to the survival of early vertebrates and, therefore, retained in the genome throughout vertebrate evolution (Cardoso *et al.*, 2014; Endsin *et al.*, 2017).

Expression of CRH and CRH-Like Peptides

In CRH expressing neurons, the CRH gene is first translated into a prepro-CRH peptide and is subsequently cleaved in the rough endoplasmic reticulum to generate a pro-CRH peptide (Itoi *et al.*, 1998; Perone *et al.*, 1998). The pro-CRH peptide is then processed within the trans-Golgi-network and secretory granules to generate the 41 amino acid mature CRH peptide (Itoi *et al.*, 1998; Perone *et al.*, 1998). CRH production is stimulated by a number of different signals including: neurotransmitters: norepineprine, epinephrine serotonin, histamine, and acetylcholine; neuropeptides: arginine vasopressin, angiotensin II, neuropeptide Y, cholecystokinin, activin, and enkephalin; the cytokines interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-α; and leptin (see Aguilera and Lui, 2012 for review). Transcriptional regulation of the CRH gene involves the cyclic AMP (cAMP)/protein kinase A (PKA)-dependent pathway leading to downstream recruitment of the phosphorylated cAMP response element binding protein (pCREB) by the cAMP response element (CRE) of the CRH promoter (Seasholtz *et al.*, 1988). In addition, CRH transcription requires cAMP-dependent translocation of the CREB co-activator, transducer of regulated CREB activity (TORC; see Aguilera and Lui, 2012 for review). Negative regulation of CRH production is primarily by glucocorticoids, but also by estrogens, and γ-aminobutyric acid (GABA) (Itoi *et al.*, 1998; Orth, 1992; Owens and Nemeroff, 1991; Stephanou *et al.*, 1997; Torpy and Chrousos, 1996). Secretion of CRH is also inhibited by dynorphin, substance P, somatostatin, and galanin (Itoi *et al.*, 1998).

CRH expressing neurons are dispersed throughout the CNS (**Fig. 2**A), with the highest concentration found in the PVN (Swanson *et al.*, 1983). Within the PVN there are three areas that have CRH expressing neurons which project to different parts of the brain. In the anterior and medial-dorsal PVN, axons of parvocellular CRH neurons project to hypophyseal portal capillaries and modulate the stress response. Magnocellular oxytocinergic neurons from the dorsolateral aspect of the PVN have axons that project to the posterior pituitary and release CRH into the peripheral circulation. CRH expressing neurons are also located in the dorsal, medial-ventral and lateral parvicellular areas of the PVN, and they project to the brainstem and spinal cord and regulate the sympathoadrenal system (see Aguilera and Lui, 2012 for review). CRH is also present in the limbic brain region as well as other structures involved in the stress response, including the bed nucleus of the stria terminalis, the central nucleus of the amygdala, locus coeruleus, cerebral cortex, cerebellum, and dorsal root neurons of the spinal cord (Makino *et al.*, 1995). Interestingly, limbic dysfunction and dysregulation of the HPA/I axis are common features of affective disorders, indicating that CRH neurons from these brain regions are involved in these disease states (Herman *et al.*, 2005). CRH expressing neurons are also located in other cells of neural origin including chromaffin cells of the adrenal medulla and sympathetic ganglia of the autonomic nervous system. Immune cells, skin, and cells in the gastrointestinal tract also express CRH (Aguilera and Lui, 2012).

In the mammalian brain, expression of Ucn is concentrated in the Edinger–Westphal nucleus (EW), which appears to be the only brain site where Ucn expression is conserved across species (Vasconcelos *et al.*, 2003). Ucn is also expressed in the lateral superior olivary and supraoptic nuclei, with lower expression levels in cranial nerves, spinal motoneurons and neurons in the forebrain (Bittencourt *et al.*, 1999; **Fig. 2**A). Projections from these neurons input into the PVN, cerebellum, brainstem, and spinal cord indicating that the Ucn system is involved in control of autonomic, endocrine, and sensorimotor functions. In rodents, Ucn2 mRNA expression is primarily in subcortical brain regions, with high expression in the paraventricular, supraoptic, and arcuate nuclei of the hypothalamus, and the locus coeruleus of the rostral pons. In addition, Ucn2 mRNA expression is localized to motor nuclei of the brainstem and the spinal ventral horn (Reyes *et al.*, 2001). Ucn3 expressing neurons are primarily located in the hypothalamus and amygdala, with some expression in the brainstem (Li *et al.*, 2002; **Fig. 2**A).

Evolution of CRH Family of Peptides

The ancestral peptide to the CRH family is not known; however, there is a growing body of evidence which provides clues to its origin. CRH and related peptides exist in a variety of vertebrate and invertebrate species, which indicates that the ancestral

peptide to the CRH family evolved early in animal evolution, likely between 400 and 500 million years ago. A possible progenitor to the CRH family is the evolutionarily ancient teneurin C-terminal associated peptide (TCAP) family which has structural similarities to CRH, as well as the closest known resemblance in terms of amino acid sequence (Lovejoy *et al.*, 2006; Lovejoy and De Lannoy, 2013). In addition, both CRH and TCAP bind and activate G protein-coupled receptors (GPCRs) to induce their physiological effects. The cognate receptor of the CRH family is the class B/Secretin-like receptor family of GCPRs that also includes glucagon, calcitonin, parathyroid hormone, vasoactive intestinal peptide, and growth hormone releasing hormone receptors. The TCAP and the protein they are derived from, the teneurins, bind to a member of the adhesion class of GPCRs, and play a role in regulation of energy metabolism. Evidence indicates that the secretin family of GPCRs evolved directly from the adhesion GPCRs (Schiöth *et al.*, 2010; Fredriksson *et al.*, 2003), providing an additional evolutionary link between these the CRH and TCAP peptides systems. Furthermore, the adhesion GPCR latrophilin 1 (ADGRL1), a cognate receptor for the teneurins (Silva *et al.*, 2011), was identified based on its ability to bind the black widow spider toxin,

α-latrotoxin, another peptide with structural similarity to the secretin family of peptides (Holz and Habener, 1998). Together this indicates that the earliest ancestor of CRH peptides may have evolved near the base of metazoan evolution and subsequently became essential in the regulation of energy metabolism.

In vertebrates, the CRH family of peptides is composed of four paralogous peptides with two distinct lineages; the CRH and UI (Ucn in mammals and SVG in frogs) lineage, and the Ucn2 and Ucn3 lineage. This agrees with Ohno's (1970) 2R hypothesis which proposes that there were two rounds of genomic duplications at the base of chordate evolution, resulting from a single CRH precursor gene inherited from a protochordate ancestor and leading to the four homologues found in most chordates (Lundin, 1993; Holland and Garcia-Fernandez, 1996). During the first duplication event in chordates, a CRH-like and a Ucn3 peptide were first formed, as evidenced by the presence of both CRH and UI in lampreys (Endsin *et al.*, 2017) and cartilaginous fish (Nock *et al.*, 2011) as well the absence of Ucn2 in lampreys. Then, during the second genome duplication event, the CRH-like peptide split into both CRH and UI (Lovejoy, 2009; Lovejoy and De Lannoy, 2013) while the Ucn3-like gene was unaffected. Subsequently, possibly just before the emergence of the cartilaginous fishes, the Ucn3-like gene split into Ucn2 and Ucn3 as known in extant species (Cardoso *et al.*, 2014; Endsin *et al.*, 2017). Prior to the appearance of the cartilaginous fishes the CRH gene also split into two forms as evidenced by two CRH genes in cartilaginous fish and some teleosts (Nock *et al.*, 2011; Hosono *et al.*, 2015).

Early metazoans had a less complex genome and physiology, and extracellular signaling systems were primarily associated with the coordination of energy metabolism to organismal survival with respect to feeding, digestion, diuresis, and defense. Indeed, in studies conducted primarily in insect models, where generally only a single CRH-like peptide (DH) is present, the earliest function of the peptide family is associated with diuresis and feeding (Kataoka *et al.*, 1989; Audsley *et al.*, 1997; Coast, 1998, 2007). Given the phylogenetic age of the CRH peptides, this is not surprising. Therefore, the formation of the CRH-like peptides in ancestral metazoans may have been selected and conserved through evolution because they acted to regulate cellular and organismal energy acquisition and production for defense against environmental stressors. This has come to be known as the organismal stress response that acts to protect the organism from external and internal environmental challenges.

Mechanisms of CRH Action: Receptors, Ligands and Signaling Pathways

In vertebrates, CRH binds to and activates two distinct receptor isoforms: the CRH receptor 1 (CRH_1) and CRH receptor 2 (CRH_2). It should be noted that the International Union of Basic and Clinical Pharmacology (IUPHAR) has promoted the use of the nomenclature corticotropin-releasing factor 1 (CRF_1) and CRF_2 (Hauger *et al.*, 2003). Both receptors are seven-transmembrane domain GPCRs that, upon ligand binding, activate intracellular signaling cascades. Pharmacological studies of CRH homologues have determined that receptor activation occurs through a two-part process: (1) the C-termini of the CRH family of ligands binds to the extracellular binding pocket of the CRH receptor, and (2) the N-termini interact with the other extracellular loops of the transmembrane domain to activate the intracellular signal cascade (Perrin and Vale, 2002; Grace *et al.*, 2004; Hoare *et al.*, 2004).

In 1993, Vale's team cloned the first CRH receptor, CRH_1, using an expression library from a human corticotropic tumor (Chen *et al.*, 1993). The receptor was reported to be a 415-amino acid protein with seven putative membrane-spanning domains. Further studies determined that the CRH_1 receptor has significant structural variability, differing from 415 to 446 residues depending on the species: human, (Chen *et al.*, 1993; Vita *et al.*, 1993), mouse (Vita *et al.*, 1993), rat (Chang *et al.*, 1993; Perrin *et al.*, 1993), chicken (Yu *et al.*, 1996), frog (Dautzenberg *et al.*, 1997), tree shrew (Palchaudhuri *et al.*, 1998), sheep (Myers *et al.*, 1998), and fish (Arai *et al.*, 2001; Pohl *et al.*, 2001). Binding and functional studies have determined that CRH_1 exhibits a distinct ligand-selective profile, having the highest binding affinity for CRH and Ucn, as well as the Ucn orthologues orthologues UI and SVG

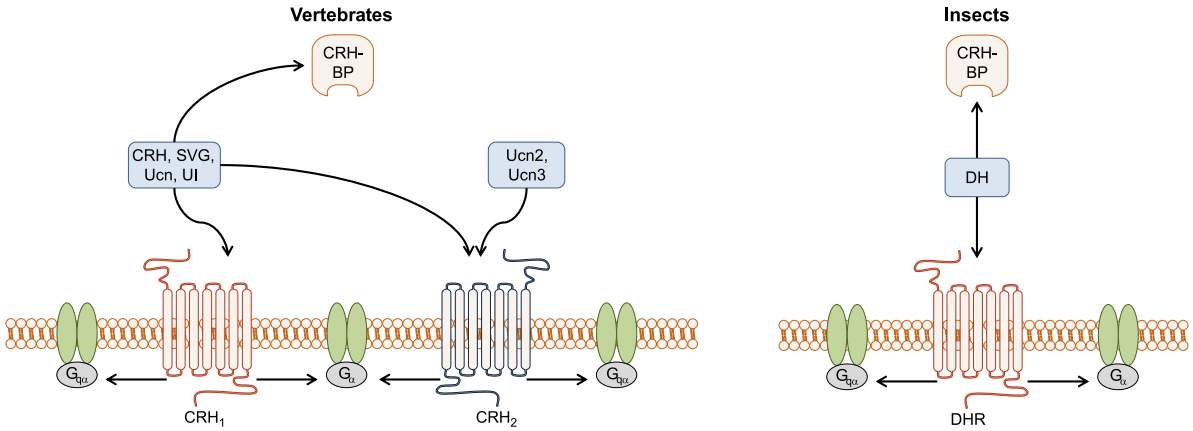

Fig. 3 Scheme of the molecular interaction among CRH ligands, receptors and the binding protein in chordates and insects. See text for discussion.

(Donaldson *et al.*, 1996; Dautzenberg *et al.*, 1997, 2001; Perrin *et al.*, 1999). It has little affinity for Ucn2 or Ucn3 (Hsu and Hsueh, 2001; Lewis *et al.*, 2001; Reyes *et al.*, 2001; **Fig. 3**).

Identification of CRH_2 was reported shortly after the discovery of CRH_1. The two receptors are encoded by different genes and orthologues of these two receptors are about 70%–80% identical to each other at the amino acid level (see Bonfiglio *et al.*, 2011; Lovejoy *et al.*, 2014 for reviews). Structural characterization of CRH_2 has been reported in the rat (Lovenberg *et al.*, 1995) mouse (Kishimoto *et al.*, 1995; Perrin *et al.*, 1995; Stenzel *et al.*, 1995), and human (Liaw *et al.*, 1996). It has a higher binding affinity for UI/Ucn-like peptides than for CRH, and binds to all vertebrate paralogues as well as several synthetic CRH peptide variants (Tellam *et al.*, 2002; Hauger *et al.*, 2006). A key reason for the difference in ligand specificity is that the two receptors exhibit significant differences in their ligand binding sites, having only about 47% sequence similarity (Grammatopoulos, 2012).

An additional component of the CRH system is the secreted CRH-binding protein (CRH-BP). First isolated from human blood plasma, CRH-BP is a 37-kDa N-linked glycoprotein that is structurally unrelated to the CRH receptors and exhibits a high degree of sequence similarity among species. CRH-BP binds both CRH and Ucn with high affinity, as well as other CRH orthologues (Behan *et al.*, 1989; Valverde *et al.*, 2001; Sutton *et al.*, 1995). Orthologues of CRH-BP have been identified in each of the major vertebrate classes, with the exception of Chondrichthyes (cartilaginous fish) and are well established in the insect lineages (Seasholtz *et al.*, 2002; Huising and Flik, 2005). This degree of conservation indicates that CRH-BP evolved early in the evolution of CRH/DH ligand–receptor systems and has become an integral part of the CRH and DH physiology. The role of the binding protein is unclear; however, CRH-BPs have comparable binding affinities to CRH receptors (Sutton *et al.*, 1995) indicating that one function might be to modulate the bioavailability of CRH-like peptides. Generally, the CRH-BP appears to act as a negative regulator of CRH activity (Stinnett *et al.*, 2015).

Similar to other class B/secretin-like GPCRs, CRH receptors have a highly glycosylated external domain and a long N-terminal domain (Attwood and Findlay, 1994; Harmar, 2001; Fredricksson *et al.*, 2003). The receptors in this family are commonly associated with functioning in the regulation of ion and nutrient transport and being involved in the cellular stress response (Harmar, 2001; Fredricksson *et al.*, 2003). The primary signal transduction pathway activated by CRH and the Ucns involve coupling of CRH receptors to the G_s (stimulatory) protein subunit, resulting in activation of the adenylate cyclase-PKA pathway (Chen *et al.*, 1993; Olianas *et al.*, 1995; Hauger *et al.*, 2006) which phosphorylates downstream cytosolic and nuclear targets. There is also substantial evidence of CRH-mediated activation of G_q proteins and other G proteins to stimulate inositol triphosphate (IP_3)- and Ca^{2+}-mediated signal transduction pathways (Hauger *et al.*, 2006; Gutknecht *et al.*, 2010), indicating a capacity for regulation of neuronal excitability and cell–cell communication. Furthermore, CRH receptors have been demonstrated to activate multiple G-alpha (Gα) subunits, including G_s, Go_o, $G_{q/11}$, $Gi_{1/2}$, and G_z (Grammatopoulos *et al.*, 2001).

In general, the action of CRH is associated with cellular and organismal homeostasis with respect to regulation of energy metabolism and the related diuretic requirements of an animal in response to physiological and environmental stress (Lovejoy, 2012; Janssen and Kozicz, 2013; Lovejoy and De Lannoy, 2013). Fundamentally, CRH and the CRH receptor system are associated with activation of the sympathetic arousal system (e.g., increased heart rate and glycogenolysis) and inhibition of the parasympathetic system (e.g., growth, feeding and digestion) in vertebrates. Both of the receptors are expressed in a variety of tissues depending on species and taxa, although a full profile is currently incomplete. CRH_1 is predominantly expressed in the central nervous system (CNS) with high expression in the cortex, cerebellum, hippocampus, amygdala, olfactory bulb, pituitary gland, and spinal cord (Potter *et al.*, 1994; Chalmers *et al.*, 1996; Palchaudhuri *et al.*, 1998; Van Pett *et al.*, 2000; **Fig. 2**B). Due to CRH_1 expression, CRH-mediated signaling also influences several neurotransmitter systems within the CNS, including glutamatergic neurons of cortex and hippocampus, GABAergic cells in the reticular thalamic nucleus, globus pallidus and septum, dopaminergic neurons of the substantia nigra pars compacta and ventral tegmental area, and serotonin-containing (5-HT) neurons of the dorsal and medial raphe nuclei (Refojo *et al.*, 2011). CRH_1 is also found at low levels in peripheral tissues, including the female reproductive tract (Nappi and Rivest, 1995; Kiapekou *et al.*, 2011; Wypior *et al.*, 2011), skin (Slominski *et al.*, 1995, 2001), adrenal gland (Willenberg *et al.*, 2005; Squillacioti *et al.*, 2011) and gastrointestinal (GI) tract (Chatzaki *et al.*, 2004).

CRH_2 is likewise found in many regions of the brain, however its expression is more limited compared to that of CRH_1 (Lovenberg *et al.*, 1995; Perrin *et al.*, 1995; Van Pett *et al.*, 2000). CRH_2 receptors are typically expressed in subcortical regions such as the ventromedial hypothalamus, dorsal raphe nuclei of the midbrain, nucleus of the solitary tract in the hindbrain and various hindbrain nuclei (Bittencourt *et al.*, 1999; **Fig. 2**B). Relative to CRH_1, CRH_2 has lower expression in the cortex; however, it is also found in regions that express CRH1 as well, such as the septal nuclei. In the periphery, CRH_2 is expressed in the heart (Kishimoto *et al.*, 1995; Lovenberg *et al.*, 1995; Perrin *et al.*, 1995; Stenzel *et al.*, 1995), lung (Lovenberg *et al.*, 1995), GI tract (Perrin *et al.*, 1995; Chatzaki *et al.*, 2004), skeletal muscle (Kishimoto *et al.*, 1995), male reproductive system (Perrin *et al.*, 1995), and adrenal gland (Müller *et al.*, 2001).

Dysfunction of the CRH System: Neuropathological Actions of CRH Peptides

The CRH system integrates autonomic and behavioral responses to stress through interactions primarily at the level of the CNS. Therefore, in vertebrates, CRH and Ucn induce organismal responses to stress and environmental novelty such as elevated physiological arousal, defense actions, decreased food intake and reduced reproductive activity. These responses are achieved by CRH_1-mediated activation of the HPA/I axis and sympathetic branches of the stress response. In contrast, CRH_2 has been associated with anxiolytic effects, thus Ucn2 and 3 have been considered anxiolytic peptides as they bind exclusively to this

receptor (Hauger *et al.*, 2006; Ohata and Shibasaki, 2004). Together, the actions of all four peptides and their receptors provide a balanced regulation of the stress response under most situations. Dysregulation of this balance is associated with several human neuropsychiatric conditions.

The CRH system has been implicated in particular with the onset of affective disorders. Affective disorders may be loosely defined as those conditions that affect the mood and well-being of patients. These conditions generally include major depression and anxiety, panic disorder, post-traumatic stress disorder, anorexia nervosa and possibly aspects of bipolar disorder. Conditions of chronic stress can result in hypersecretion of CRH causing the initially beneficial effects of CRH to induce anxiety- and depression-like behaviour (Landgraf, 2006). This is outlined in the CRH hypothesis of depression, which posits that stress-induced increases in secretion of CRH, activation of the HPA axis, and the resulting elevation in glucocorticoid levels are associated with mood and anxiety disorders. Patients with depression have a significantly higher number of CRH-expressing neurons, and higher CRH mRNA levels in neurons in the PVN compared to those without depression (Raadsheer *et al.*, 1994, 1995; Wang *et al.*, 2008). Furthermore, symptoms of depression, including decreased appetite, decreased sexual interest, disrupted sleep, and anxiety, can all be reproduced in experimental animals by the intracerebroventricular injection of CRH (Holsboer, 2001). Conversely, these symptoms can be reduced by CRH_1 receptor antagonists or inhibition of receptor expression. (Lu *et al.*, 2008a,b; Holsboer and Ising, 2008). Additionally, antidepressants have been found to decrease CRH synthesis and the upregulation of glucocorticoid receptor expression, making the HPA system more responsive to feedback inhibition by cortisol (Barden, 1996). CRH levels are also increased in the cerebrospinal fluid (CSF) of depressed patients (Nemeroff *et al.*, 1984), and treatment with antidepressants decreases CRH levels in both healthy volunteers and depressed patients (Heuser *et al.*, 1998).

CRH and the HPA axis are associated with addiction and are activated by drugs of abuse, including opioids, cocaine, alcohol, and nicotine. These drugs activate the HPA axis both when they are first taken and again during acute withdrawal. Repeated cycles of drug taking and withdrawal desensitize the HPA axis, but the consequent exposure to high levels of glucocorticoids can sensitize the CRH system in the amygdala (Imaki *et al.*, 1991; Makino *et al.*, 1994; Swanson and Simmons, 1989). Sensitization of CRH system in the amygdala leads to the withdrawal stress response associated with drug addiction (reviewed in Koob, 2010). Currently, CRH receptor antagonists are being evaluated for use in the clinical treatments of addiction (reviewed in Grammatopoulos and Chrousos, 2002; Zorrilla *et al.*, 2014).

Due to its influence over so many physiological systems, dysregulation of CRH signaling and the HPA axis has also been implicated in anorexia and bulimia nervosa (Laessle *et al.*, 1992; Licinio *et al.*, 1996; Birketvedt *et al.*, 2006, Bailer and Kaye, 2003; Casper, 2006), obesity (reviewed in Arora, 2006; Valassi *et al.*, 2008), insomnia and obstructive sleep apnea (reviewed in Buckley and Schatzberg, 2005), and neurodegenerative disorders such as Alzheimer's disease (Dautzenberg and Hauger, 2002; Dunn and Berridge, 1990; Nemeroff and Owens, 2002). The origin of these pathologies with respect to CRH over- or under-secretion is not understood but appears to involve both genetic and environmental factors that lead to changes in peptide, receptor and binding protein regulation, as well as changes in neurosynaptic regulation and the neurotransmitters that regulate the CRH system.

Summary

CRH is the principle neuropeptide responsible for activation of the organismal stress response in vertebrates. CRH had its evolutionary origins relatively early in the ancestry of animals, and its role became associated with the regulation of the HPA/I axis in the vertebrates. Along with its paralogous peptides, the Ucns, this family is essential for the regulation of the stress response. Dysregulation of this peptide family along with their cognate receptors and binding protein has been implicated in the development of some neuropsychiatric disorders and further elucidation of the physiological functions played by CRH will aid in the development of therapeutics for treating these diseases.

Regulation of POMC and ACTH Secretion

Dongyun Zhang and Anthony P Heaney, University of California Los Angeles, Los Angeles, CA, United States

Tissue Specific Expression of POMC

The pituitary gland comprises the posterior pituitary lobe (~ 1/3 of total gland) that stores and releases arginine vasopressin (AVP, also known as antidiuretic hormone ADH) and oxytocin. These hormones are synthesized in the hypothalamic neurosecretory cells of the paraventricular and supraoptic nucleii and travel downward along axon endings that project into the posterior pituitary lobe. When stimulated by secretagogues, AVP and oxytocin are released into the bloodstream, where they maintain water balance and regulate parturition and breast milk release respectively. The anterior pituitary comprises the remaining 2/3 of the pituitary and contains five distinct hormone-secreting cell types, namely corticotrophs, lactotrophs, somatotrophs, thyrotrophs and gonadotrophs (Nussey and Whitehead, 2001). POMC is predominantly expressed in corticotrophs and melanotrophs of the anterior and intermediate pituitary lobes, and in a few thousand neurons of the hypothalamus (Drouin, 2016). This distinct cell-restricted POMC gene expression is precisely controlled by spatiotemporal coordination of a set of signaling molecules and transcription factors during embryogenesis (Nudi *et al.*, 2005).

Pituitary Organogenesis

In vertebrates, the anterior and the intermediate pituitary lobes (the adenohypophysis) originate from the nonneural surface ectoderm, whereas the posterior pituitary lobe (neurohypophysis) develops from the anterior neural plate (**Fig. 1**A) (Suga *et al.*, 2011). In birds and mammals, the anterior pituitary primordium forms as an invagination of the stomodeal ectoderm (oral ectoderm) at the roof of the oral cavity, which develops initially into Rathke's pouch (**Fig. 1**B) (Zhu *et al.*, 2007). Simultaneously, a part of the adjacent ventral diencephalon, which originates from the neural plate and is destined to become the hypothalamus and the posterior lobe of pituitary, outgrows to form the infundibulum in close proximity to Rathke's pouch (**Fig. 1**B) (Zhu *et al.*, 2007). Thereafter, directed by local growth factors and morphogens, such as Sonic Hedgehog (SHH), Fibroblast Growth Factors (FGFs), Bone Morphogenetic Proteins (BMPs), and Wingless-Type MMTV Integration Site (WNTs) factors, Rathke's pouch thickens and elongates ventrally. The rapid proliferation inside the cranial region of Rathke's pouch gives rise to the progenitors of the hormone-secreting cell types, and together with emerging vascularized mesenchymal cells, the rostral region of Rathke's pouch develops into the anterior pituitary lobe, or the pars distalis. The dorsal part of Rathke's pouch remains less expanded and forms the intermediate pituitary lobe, or pars intermedia (Scully and Rosenfeld, 2002), and following this, Rathke's pouch degenerates to a rudimentary structure and separates from the ventral pharyngeal epithelium (Skowronska-Krawczyk *et al.*, 2016). The continuous outgrowth of the infundibulum leads to the development of the posterior lobe of the pituitary gland (**Fig. 1**C).

Several notochord-derived ectoderm signals are essential for head and pituitary development during early embryogenesis (Cleaver and Krieg, 2001). Surgical disruption of the notochord or deletion of the SHH gene, the major notochord secreted factor, results in malformation of midline structures, cyclopia, and absence of Rathke's pouch (Chiang *et al.*, 1996). Gli1 and Gli2 are the main downstream zinc finger transcription factors of the SHH pathway. Genetic deletion of both Gli1 and Gli2 results in a general defect of midline structures, including complete absence of the pituitary gland (Park *et al.*, 2000). Distinct from SHH's general effects on early embryogenesis, FGF8, and FGF10 have also been shown to play important roles in pituitary development. Deletion of FGF10 or FGF receptor 2 IIIb in mice causes anterior pituitary agenesis (Ohuchi *et al.*, 2000). Deletion of FGF8 is embryonic lethal, and overexpression of FGF8 under the control of αGSU regulatory element led to pituitary hyperplasia with dramatic expansion of the POMC-producing cell lineage accompanied by ectopic Lhx-3 induction (Treier *et al.*, 1998). Interestingly, BMP2 signaling appears to have an opposing action to FGF8 in Rathke's pouch. BMP2 induces expression of Isl-1, a LIM homeodomain transcription factor and αGSU, but suppresses ACTH expression (Ericson *et al.*, 1998). BMP4 signaling is critical for progression of pituitary development, and BMP4 overexpression leads to mild anterior pituitary hyperplasia (Ericson *et al.*, 1998). Notch and WNT signaling are part of an evolutionary conserved mechanism that regulates the maintenance of stem cell fate and differentiation. During early embryogenesis, transient Notch and WNT expression activate the downstream stem cell transcription factors, Hesx1 and β-catenin, which sequentially turn on the pituitary lineage specific transcription factors Prop1 and Pit1, leading to pituitary growth and differentiation into specific pituitary cell subtypes. Prolonged activation of Notch2 blocks terminal differentiation of pituitary cells, such as thyrotrophs and gonadotrophs (Raetzman *et al.*, 2006), emphasizing the role these signals play in both a temporal and spatial manner to direct distinct transcription factor-mediated specific cell lineages (**Fig. 1**D).

Regulators of POMC Lineage Commitment in Pituitary

POMC expressing corticotrophs are the first terminal differentiated lineage to appear in the developing anterior pituitary (E12.5 in the mouse). Several tissue specific transcription factors interact with upstream regulatory sequences of the POMC promoter to

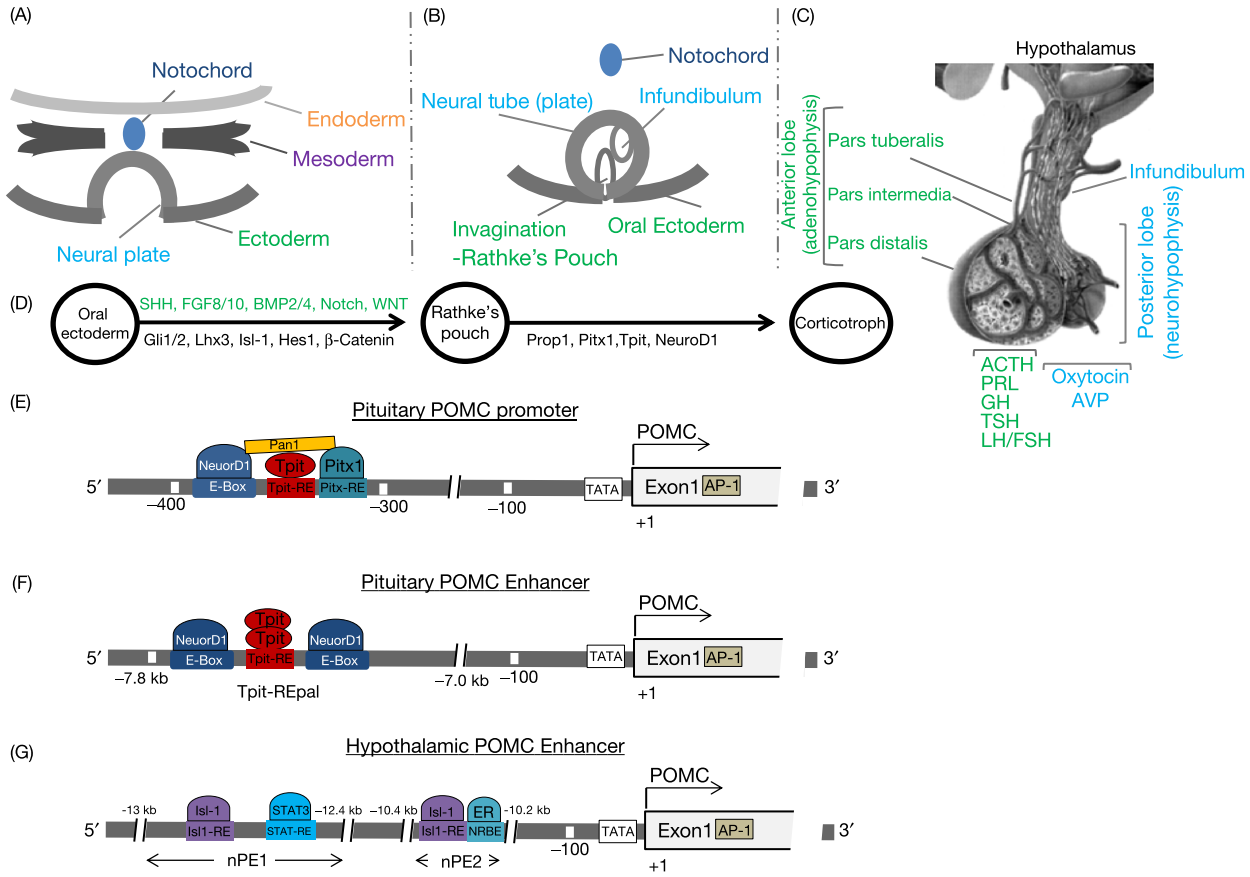

Fig. 1 Schematic of human POMC lineage origin during pituitary development. (A) The anterior and the posterior pituitary lobes originate from nonneural surface ectoderm and the anterior neural plate respectively. (B) The anterior pituitary primordium forms as an invagination of the stomodeal ectoderm at the roof of the oral cavity, which develops initially into Rathke's pouch. The primordium of the posterior lobe of pituitary originates from an outgrowth of the ventral diencephalon to become the infundibulum. precisely control the spatiotemporal programming of corticotroph cell commitment (Jeannotte *et al.*, 1987). For example, Pitx1, a pan-pituitary activator of transcription which belongs to the bicoid-type homeodomain subfamily, is expressed from E8 in the presumptive oral ectoderm when Rathke's pouch initially forms. Pitx1 binds the human POMC promoter at $-307/-299$ (transcription initiation site set as $+1$, **Fig. 1**E) and its interactions with adjacent other trans-elements, including Tpit-RE and *E*-box, are required for pituitary development (Lanctôt *et al.*, 1999). Tpit (also known as Tbx19), a T-box containing transcription factor, exhibits relatively low affinity for its response element (Tpit-RE, at $-318/-312$) on the human POMC promoter, but through a protein-protein interaction with Pitx1 which is already bound to Tpit-RE/Pitx-RE, Tpit is a potent activator of corticotroph POMC gene expression (**Fig. 1**E) (Liu *et al.*, 2001). In contrast to Pitx1 knockout, which only modestly affects POMC lineage development (Lanctôt *et al.*, 1999), Tpit knockout mice almost completely lack pituitary POMC-expressing cells (Budry *et al.*, 2011), and Tpit mutations in humans cause early onset isolated ACTH deficiency (Pulichino *et al.*, 2003). Tpit-RE/Pitx-RE is also bipartite with an *E*-box element located at $-370/-365$, which binds a basic helix-loop-helix (bHLH) transcription factor called NeuorD1 (also known as BETA2) (Lamolet *et al.*, 2004). The synergism of Tpit-RE/Pitx-RE and E-box$_{neuro}$ relies on direct protein interactions between Pitx1 and a NeuorD1 heterodimer partner Pan1. NeuroD1 is essential for specific binding to the E-box$_{neuro}$, and by anchoring to the POMC promoter, the tertiary complex (Tpit/Pitx1/NeuroD1) potentiates POMC transcription (**Fig. 1**E). An additional more responsive Tpit-RE palindrome site flanked by two E-box sites is located in a -7 kb enhancer region of pituitary POMC and binds a Tpit homodimer for activation at this site (**Fig. 1**F). Compared to the Tpit-RE in the proximal promoter, this enhancer is more selectively activated in pituitary corticotrophs compared to melanotrophs, and is independent of Pitx1 binding (**Fig. 1**F) (Langlais

et al., 2011). In summary, these composite regulatory elements coordinate with a variety of cell-specific and pituitary-specific transcription factors to confer corticotroph lineage-restricted POMC expression in the anterior pituitary.

Hypothalamic POMC Expression During Embryogenesis

In parallel, the hypothalamus develops from the adjacent neuroepithelium, and common early transcription factors, such as Hesx1, and local gradients of SHH, BMPs and FGFs, as well as tissue specific hormones generated at later developmental stages orchestrate programming of the pituitary anlagen and the hypothalamic sulcus (Zhu *et al.*, 2007). POMC expression in the ventral diencephalon of the developing hypothalamus is regulated by a −12 kb enhancer rather than the −480 bp proximal promoter involved in pituitary development. The LIM homeodomain transcription factor, Isl-1, binds to two target sequences called nPE1 and nPE2 on the POMC enhancer, and contributes to hypothalamic POMC lineage commitment (**Fig. 1**G) (Drouin, 2016). STAT response element (STAT-RE) and an estrogen receptor binding consensus (NRBE) have also been identified in the nPE1 and nPE2, and act as POMC neuron regulators in hypothalamus (**Fig. 1**G) (Bates *et al.*, 2003; de Souza *et al.*, 2011).

Regulation of POMC Synthesis

POMC Gene Structure

POMC belongs to an ancestral opioid/orphanin gene family, which plays an essential role in pain signaling and reward circuitry. This gene family encodes four prepropeptides, proenkephalin (PENK), prodynorphin (PDYN), pronociceptin/orphanin (PNOC), and POMC (Dores and Baron, 2011; Sundström *et al.*, 2010). They share three common sequence similarities: (a) a set of conserved six cysteine residues located at the N-terminus region (four Cys in POMC, **Fig. 2**A), (b) at least one core opioid (YGGF) or orphanin (FGGF) sequence in the C-terminus of the precursor protein (**Fig. 2**A) and (c) a single intron located between the signal peptide and the subsequent codons (the example of POMC is delineated in **Fig. 2**B). The human POMC gene is located on chromosome 2p23.3, spanning 7999 bp on the reverse strand. It contains three exons (354, 152, and 900 nt respectively) separated by two introns (3705 and 2888 nt respectively, **Fig. 2**B). The 5′-untranslated region (5′-UTR) of POMC mRNA includes the entire Exon 1 and the first 20 nt of the proximal region of Exon 2 (**Fig. 2**B). The remaining sequence of Exon 2 encodes a signal peptide and the first 18 aa of the POMC precursor. A large part of Exon 3 is translated to 223 aa of the POMC peptide and the 3′-UTR covers a 228 bp sequence of the 3′ end of Exon 3 (**Fig. 2**B). The N-terminal 26 aa-signal peptide of the precursor POMC protein is cleaved during maturation, and the remaining 241 aa region is further processed into several peptides in a tissue-specific manner (**Fig. 2**B). In the anterior pituitary lobe, POMC gives rise to several bioactive peptides, which include a 16 kDa N-POMC fragment (also known as Pro-γ-MSH), a joining peptide (JP), ACTH and beta-lipotropin (β-LPH, **Fig. 2**B). In the intermediate lobe of pituitary or hypothalamus, these peptides are further processed to gamma-melanocyte-stimulating hormone (γ-MSH), alpha-MSH (α-MSH), corticotropin-like intermediary peptide (CLIP), gamma-lipotropin (γ-LPH), beta-MSH (β-MSH) and beta-endorphin (β-END, **Fig. 2**B). Very low levels of POMC peptide and mRNA have also been identified in several extrapituitary sites, including the pancreas, stomach, appendix, kidney, testis, prostate, placenta, skin, adipose tissue, skeletal muscle, lymph nodes, brain, adrenal and lung. However the POMC transcript in these tissues is significantly shorter, containing approximately 800 nt derived from Exon 3 but lacking the N-terminus signal peptide for secretion (Clark, 2016). This finding indicates that tissue specific factors are involved in POMC transcriptional regulation.

The Effects of Hypothalamic Neural Peptides on Pituitary POMC

The spatial contiguity between the pituitary and hypothalamus is not only attributable to inter-dependent organogenesis, but involves close central-peripheral communication orchestrated by a plethora of neuropeptides through the portal circulation (Nieman and Loriaux, 1989). Hypothalamic-derived corticotrophin releasing hormone (CRH) and arginine vasopressin (AVP) are the most physiologically important stimuli of pituitary ACTH synthesis and secretion. CRH is a 41 aa peptide and its precursor is synthesized in the hypothalamic paraventricular nuclei neurons (PVN) that project to the external layer of the median eminence (ME). There, CRH is released into the hypophyseal portal system by which it reaches the anterior pituitary lobe (**Fig. 3**). CRH neurons also receive innervation from multiple brain regions, including the brainstem and limbic structures, coordinating neuroendocrine, autonomic and peripheral stimuli to transmit signals to the pituitary gland (Papadimitriou and Priftis, 2009). CRH actions on anterior pituitary corticotrophs exclusively rely on the seven transmembrane G protein-coupled CRH receptor-1 (CRH-R1). Upon ligand binding, CRH-R1 couples to G_s, the stimulatory heterotrimeric GTP binding protein that activates adenylate cyclase (AC). Increased cAMP levels and protein kinase A (PKA) activity subsequently induce ACTH synthesis and secretion (**Fig. 3**) (Mason *et al.*, 2002). CRH-mediated actions on POMC transcription are immediate, reaching their peak within 10–30 min, and do not require de novo protein synthesis, indicating these rapid CRH actions are mediated by changes in signaling cascades that alter protein modification or protein interaction. The orphan nuclear receptor Nur77 (also known as nerve growth factor-induced protein IB, NGFI-B) binds to either the POMC promoter Nur responsive element (Nur-RE, located at −397/−377) as a heterodimer with Nur-related 1 (Nurr1), and/or neuron-derived orphan receptor 1 (NOR-1). Nur77 also interacts with Nur factor binding responsive element (NBRE, located at −73/−52) as a homodimer following CRH stimulation. Nur77 undergoes a phosphorylation modification that recruits the steroid receptor co-activator (SRC) to enhance POMC transcription (**Fig. 3**) (Mason *et al.*, 2002). CRH treatment also increases Nur77 and c-Fos mRNA expression which bind

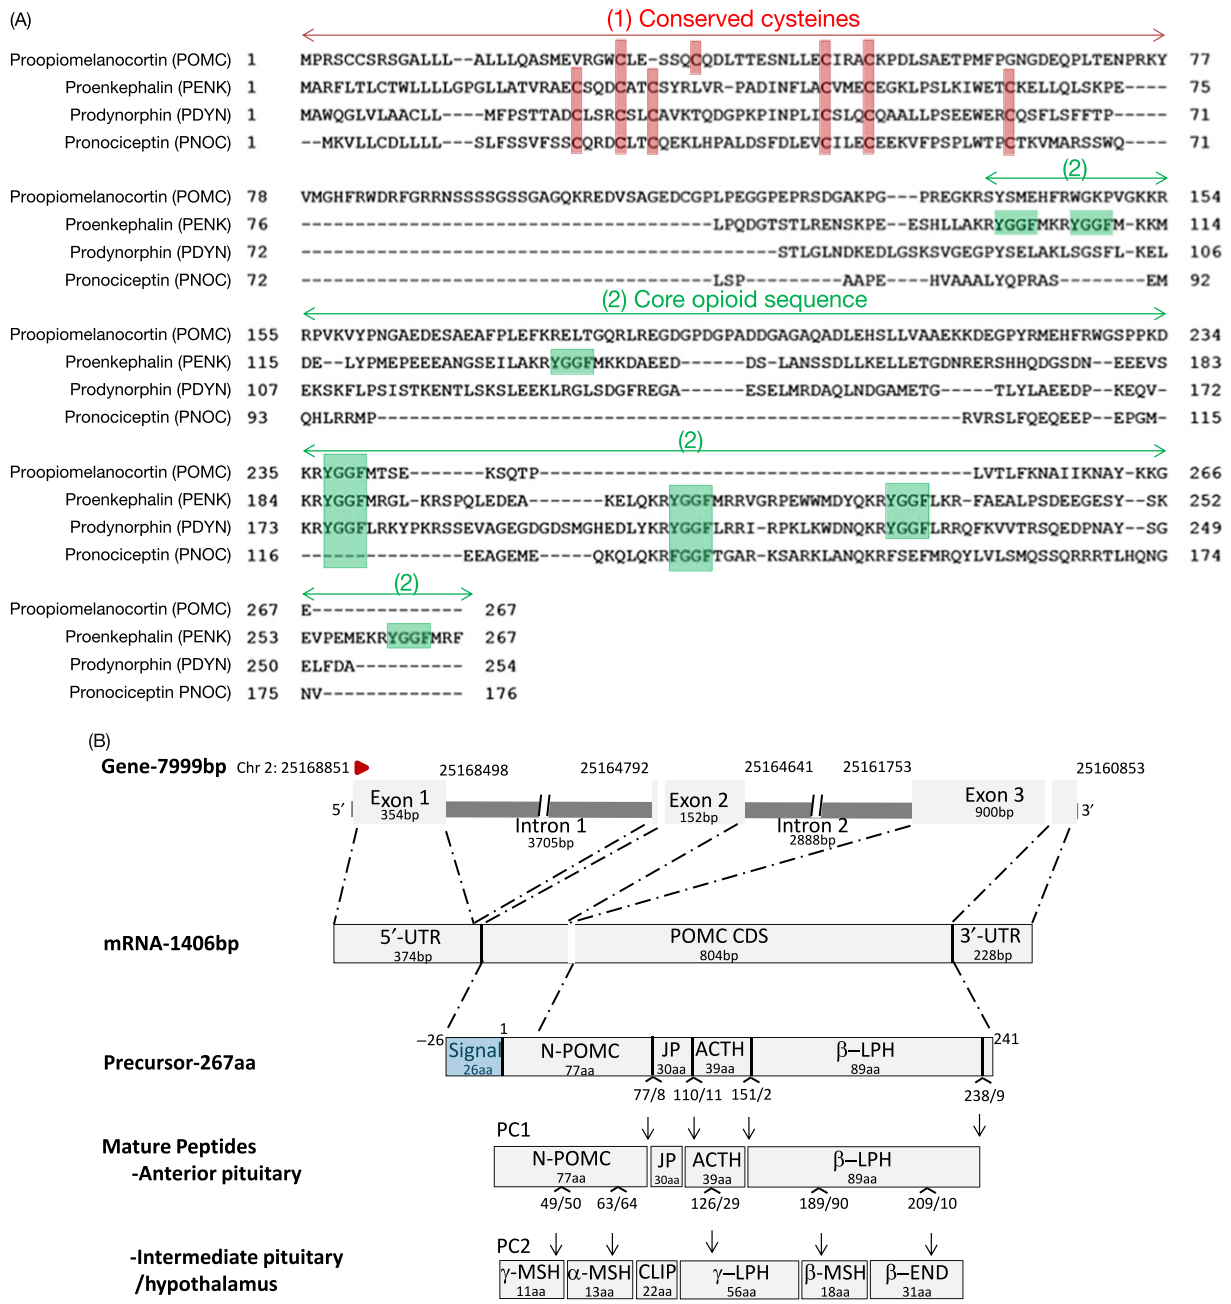

Fig. 2 Gene structure and the bioactive peptides derived from human proopiomelanocortin (POMC) gene. (A) Alignment of precursors for the human opioid gene family, including Proopiomelanocortin (POMC, NP_000930.1), Proenkephalin (PENK, NP_001129162.1), Prodynorphin (PDYN, NP_001177821.1), and Pronociceptin/proorphanin (PNOC, NP_006219.1) depicting their common sequence similarities: (1) Conserved cysteine residues (six Cys in PENK, PDYN, and PNOC; four Cys in POMC) at the N-terminus are highlighted in . (2) Core opioid sequences, including one YGGF core in POMC, seven YGGF cores in PENK, three YGGF cores in PDYN, and one FGGF core in PNOC, are highlighted in . (B) The human POMC gene is located on chromosome 2p23.3, spanning 7999 bp on the reverse strand. Its transcript contains three exons and two introns, and translates a precursor protein of 267 amino acids. The N-terminus 26 aa-signal peptide is cleaved during maturation, and the remaining region is further processed into several peptides in a tissue-specific manner. In the anterior pituitary, POMC gives rise to a 16 k N-POMC (also known as Pro-γ-MSH), joining peptide (JP), ACTH and beta-lipotropin (β-LPH). Whereas in the intermediate pituitary or hypothalamus, these peptides are further processed to generate gamma-melanocyte-stimulating hormone (γ-MSH), alpha-MSH (α-MSH), corticotropin-like intermediary peptide (CLIP), gamma-lipotropin (γ-LPH), beta-MSH (β-MSH) and beta-endorphin (β-END).

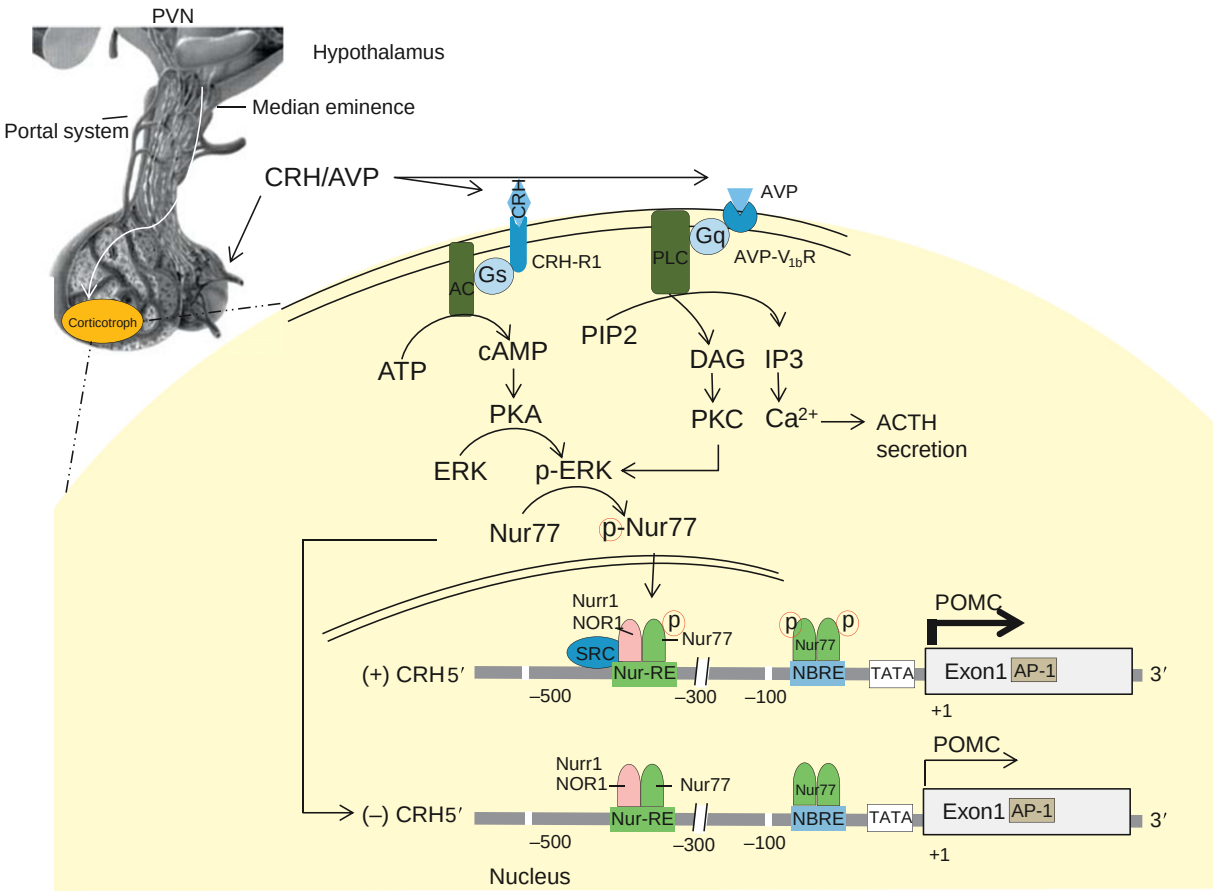

Fig. 3 Schematic summary of some of the key intracellular signaling pathways that regulate pituitary POMC transcription by the hypothalamic derived neural peptides CRH and AVP. By activating cognate receptors, hypothalamic corticotropin-releasing hormone (CRH) and arginine-vasopressin (AVP) simultaneously activate the protein kinase A (PKA) and protein kinase C (PKC) pathways which in turn phosphorylate Nurr77 to bind Nur-RE and NBRE to activate POMC transcription.

and activate a Nur-RE (− 397/ − 377) and an AP-1 site (+ 41/ + 47 in Exon 1) respectively on the POMC promoter. This is a more delayed CRH response and its occurrence in the intermediate pituitary lobe melanotrophs mediates amphibian camouflage.

AVP (also known as antidiuretic hormone, ADH) is a 9 aa peptide hormone, derived from a 164 aa glycosylated precursor protein, preprovasopressin (Aguilera and Rabadan-Diehl, 2000). Pro-AVP is synthesized in the paraventricular nucleus and supraoptic nuclei magnocellular neurons and travels downward through the infundibulum to the posterior pituitary lobe, where the processed AVP is released into peripheral circulation to regulate fluid homeostasis (Barakat *et al.*, 2006). AVP is also synthesized in the hypothalamic parvocellular neurons, from where AVP is transported to the median eminence (ME), and then travels through the hypophyseal portal system to the anterior pituitary (**Fig. 3**). Corticotrophic cells express AVP-V_{1b} receptor, whose activation synergizes with the CRH action to produce ACTH, but AVP by itself is a weak secretagogue (Castro, 1993). Ligand bound AVP-V_{1b} receptor couples to $G_{q/11}$ to stimulate phospholipase C (PLC), leading to hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3), two key intracellular messengers for protein kinase C (PKC) and Ca^{2+} channel activation which mediate ACTH synthesis and secretion (**Fig. 3**) (Christ-Crain and Fenske, 2016). Both the CRH and AVP receptors are subject to dynamic changes, such as receptor-uncoupling, internalization or down-regulation, which can lead to desensitization during repeated or prolonged CRH and/or AVP stimulation. Reversible, this alternating desensitization–resensitization represents a tier of adaptation to chronic stress at the pituitary level, integrating signals from variable CRH and AVP concentrations as well as adrenal derived steroid feedback under different degrees of stress (Aguilera and Rabadan-Diehl, 2000).

Adrenal Glucocorticoid Actions on POMC

Adrenal-derived glucocorticoids (GCs) are the major negative feedback mediators of pituitary, hypothalamic and central hippocampus-derived ACTH secretion (**Fig. 4**) (Papadimitriou and Priftis, 2009), whose acute inhibitory effects occur within minutes through blocking of ACTH secretion rather than synthesis. It is hypothesized that these actions are mediated by GC-induced

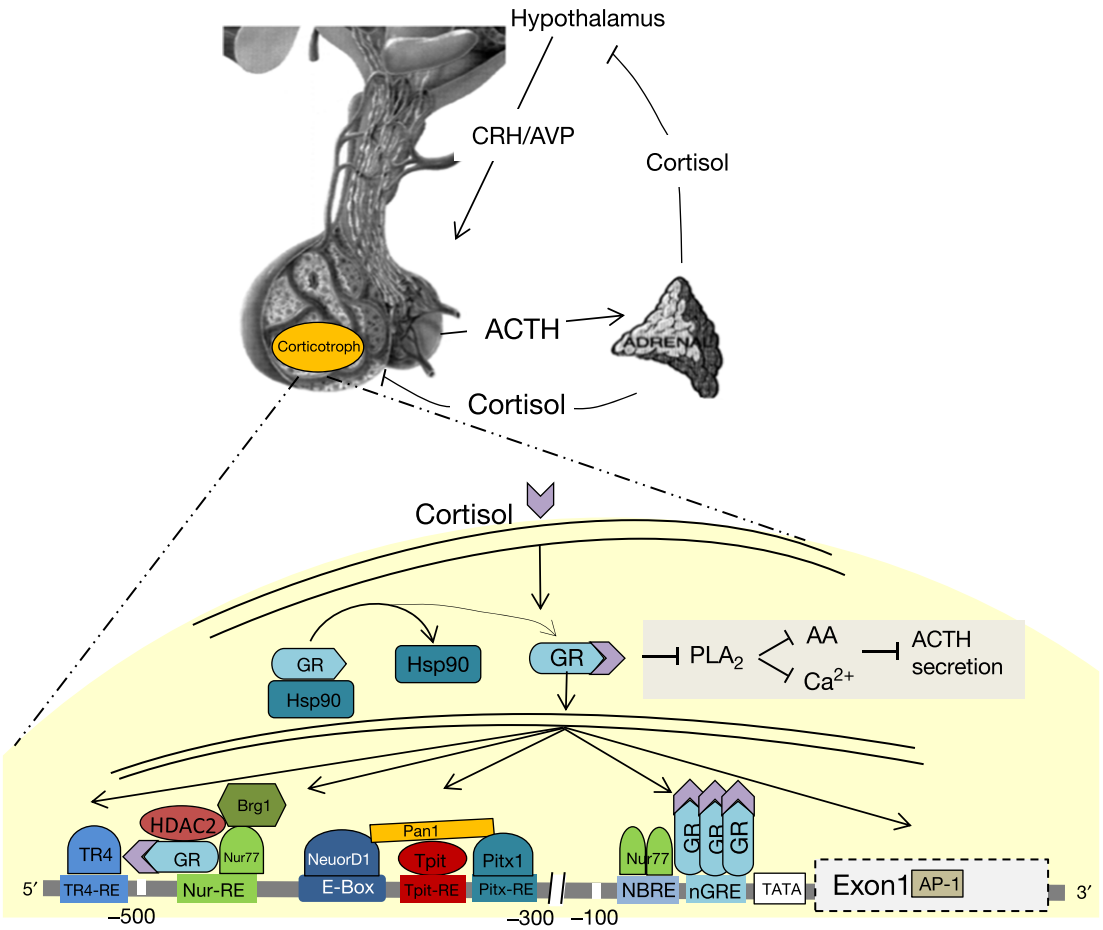

Fig. 4 Schematic diagram of the molecular mechanisms by which glucocorticoids and the glucocorticoid receptor (GR) mediate regulation of the POMC gene. Negative feedback regulation of the HPA axis is exerted by glucocorticoids both at the hypothalamic and pituitary level. It comprises acute inhibitory actions via inhibition of phospholipase A2 and slower inhibitory actions via the nGRE by steric interference of CRH-involved Nur factor binding. Target DNA regions (Nur-RE, NBRE, nGRE, TR4-RE) that modulate GR action on pituitary POMC transcription repression are represented.

inhibition of phospholipase A2 (PLA_2) activity and the resultant reduction in the generation of arachidonic acid (AA) and extracellular Ca^{2+} influx (**Fig. 4**) (Won and Orth, 1994). However, it is GC-mediated inhibition of pituitary ACTH synthesis that constitutes the most important aspect of physiological HPA axis autoregulation (Martini, 2004). Upon ligand binding, the glucocorticoid receptor (GR) undergoes a conformational change, disassociates from its cytoplasmic chaperone Hsp90, and translocates into the nucleus where it transrepresses POMC transcription by binding to the negative glucocorticoid response element (nGRE) as well as interacting with other transcription factors, coactivators and remodelers of the chromatin landscape (**Fig. 4**) (Drouin, 2016). Quite distinct from the inducing GRE which binds monomeric GR, the nGRE recruits three distinct moieties of the GR, and mutation of this GR DNA binding domain causes increased POMC transcription (Giraldi *et al.*, 2011). On the human POMC proximal promoter, the nGRE is located at $-69/-61$, overlapping with the Nur factor binding responsive element (NBRE), which is located at $-73/-52$. Therefore the three GR-ligand complexes sterically interfere with Nur factor binding to the NBRE and blunt CRH stimulated Nur-RE-mediated actions to increase POMC transcription and vice versa, leading to a reciprocally competitive "Yin-Yang" between the GC and CRH response (**Fig. 4**) (Giraldi *et al.*, 2011).

Brahma-related gene 1 (Brg1) is the ATPase component of the switch/sucrose nonfermentable (SWI/SNF) chromatin remodeling complex and stably resides on POMC promoter, contributing to POMC basal expression. In the presence of GCs, Brg1 stabilizes the GR-Nur77 interaction to interfere with Nur-RE activation, and also recruits histone deacetylate 2 (HDAC2), causing histone H4 deacetylation and promoter clearance to inhibit POMC transcription (**Fig. 4**) (Bilodeau *et al.*, 2006). Based on these observations, it has been proposed that reduced or mislocated Brg1 and HDAC2 may contribute to the GC resistance that is observed in Cushing's disease (Bilodeau *et al.*, 2006). In addition to directly regulating POMC transcription, Brg1 also functions as a negative cell cycle modulator through repression of Cyclin E (Roussel-Gervais *et al.*, 2010). More recently CABLES1 (Cdk5 and ABL enzyme substrate 1), which is rapidly upregulated following GC treatment, has been demonstrated to mediate the growth inhibitory effect of Dexamethasone (Roussel-Gervais *et al.*, 2016). Although pathogenic germline missense CABLES1 variants (2.2%, 4/181) are uncommon (Hernández-Ramírez *et al.*, 2017), CABLES1 is underexpressed in nearly half of corticotrope adenomas where it correlated strongly with low p27 expression (Roussel-Gervais *et al.*, 2016), suggesting there may be epigenetic

mechanisms reducing corticotroph tumor CABLES1 levels. The role, if any, of CABLES1-mediated POMC regulation is as yet unclear and additional cases from larger CD pedigrees would be beneficial to confirm the findings.

Intact Tpit-RE/Pitx-RE is also required for GC-mediated transrepression since competitive interaction between the coactivators SRCs and GR reduces Tpit-RE/Pitx-RE activation, which also needs SRC for activity (**Fig. 4**). A similar mechanism also operates for antagonism of AP-1 activity by ligand bound GR. Although no canonical cAMP responsive element (CRE) was identified in the human POMC promoter, a phorbol ester responsive element (TRE) located in Exon 1 ($+41/+47$) can be activated by Jun-Jun homodimer or a Jun-Fos heterodimer (**Fig. 4**) (Jenks, 2009). GCs interfere with TRE-mediated POMC activation through multiple mechanisms, including reducing CRH-induced AP-1 DNA binding, inhibiting the CRH-stimulated c-fos mRNA increase (Autelitano, 1994), and affecting upstream kinase (JNK) activation (González *et al.*, 2000). This partially underlies the anti-inflammatory and anti-tumor activities of glucocorticoids. Our own studies recently demonstrated that an orphan nuclear receptor called testicular receptor 4 (TR4, also known as NR2C2) positively regulates POMC gene transcription and ACTH secretion which is in part mediated by an interaction of TR4 with the GR to override GR repressive actions on POMC transcription (**Fig. 4**) (Du *et al.*, 2013; Zhang *et al.*, 2016a,b).

Regulation of POMC by Nuclear Receptors

Nuclear receptors are a large group of transcription factors that are involved in many fundamental biological processes, including development, differentiation, and homeostasis (Willson and Moore, 2002). In addition to Nur transcription factors, GR and TR4 as described above, several members of the thyroid hormone and retinoid X receptor subfamilies have been implicated in the regulation of pituitary ACTH synthesis and secretion (Hashimoto *et al.*, 2011; Heaney *et al.*, 2002; Matsumoto *et al.*, 2009; Páez-Pereda *et al.*, 2001; Saito-Hakoda *et al.*, 2015).

All-trans-retinoic acid (atRA) and 9-*cis* retinoic acid (9-*cis*-RA) are the most biologically potent retinoic acid isomers. However, they have short plasma half-lives (<1 h), and induce their own metabolism. In contrast, 13-*cis*-retinoic acid (13-*cis*-RA) has a half-life >13 h and cannot induce self-metabolism but is less biologically active (Labeur *et al.*, 2009). The retinoic acid receptor (RARα, RARβ, RARγ) and retinoid X receptor (RXRα, RXRβ, RXRγ) are the cogent nuclear receptors of the retinoic acids (Labeur *et al.*, 2009). In the absence of ligand, these retinoid receptors function as transrepressors by binding to specific retinoic-acid response element (RARE) on target genes and recruit nuclear co-repressors, such as nuclear receptor co-repressor (NCOR) and silencing mediator of RAR and thyroid hormone receptor (SMRT). On ligand binding, RARs release from their co-repressors and recruit transcriptional co-activators such as steroid receptor co-activator-1 (SRC-1) to regulate a diverse range of target genes (Labeur *et al.*, 2009). In support of this concept, the synthetic RARα/β agonist Am80 up-regulates POMC gene transcription by increasing NeuroD1 and Tpit expression (Uruno *et al.*, 2014). In apparent contradiction, it has been reported that retinoic acid inhibits cell proliferation and ACTH transcription in ACTH-secreting human pituitary and small cell lung cancer cells through inhibiting AP-1 and Nur77 (Páez-Pereda *et al.*, 2001). Interestingly, the RA actions were not seen in normal pituitary cells due to inhibition by the orphan receptor Chicken Ovalbumin Upstream Promoter-Transcription Factor I (COUP-TFI), which is reportedly absent in corticotroph tumors (Páez-Pereda *et al.*, 2001). Studies in dogs reported retinoic acid treatment led to tumor shrinkage and relief of hypercortisolism (Castillo *et al.*, 2006). Two recent prospective trials in patients with persistent or recurrent hypercortisolism after transsphenoidal surgery showed sustained normalization of 24 h urinary free cortisol in 25% of patients treated with 13-*cis* retinoic acid for between 6 and 12 months (Occhi *et al.*, 2014; Pecori Giraldi *et al.*, 2012; Vilar *et al.*, 2016).

In addition to homo- and heterodimerization between RAR and RXR, RXRs also heterodimerize with other nuclear receptors, and are activated by a wide spectrum of ligands (Evans and Mangelsdorf, 2014). When RXRs homodimerize or heterodimerize with peroxisome proliferator-activated receptors (PPARs), liver X receptor (LXR) and pregnane X receptor (PXR), the receptor complex responds to agonists of both RXR and the partner, and these heterodimers are so-called permissive heterodimers. Conversely, when RXR forms a heterodimer with RAR, vitamin D nuclear receptors (VDRs) and/or thyroid receptors (TRs), the complex can only be activated by the agonists of the partners but not that of RXRs, this group of heterodimers being called nonpermissive heterodimers (Saito-Hakoda *et al.*, 2015). These apparent contradictory actions of RAR activation to either stimulate or inhibit POMC transcription could be explained by involvement of an RXR homodimer or permissive heterodimer that mediates mixed RXR/RAR actions. A heterodimer of RXRα/LXRα has also been found to bind at an LXR-RE half site at $-73/-52$ region of the POMC proximal promoter (Matsumoto *et al.*, 2009), and the LXR agonist TO901317 positively regulates POMC transcription.

Our own studies demonstrated that activation of PPAR-γ, which was abundantly expressed in human corticotroph tumor, by the thiazolidinedione compound rosiglitazone inhibited ACTH secretion and growth of human and murine corticotroph tumor cells in vitro and in an in vivo xenograft corticotroph tumor animal model (Heaney *et al.*, 2002). Not dissimilar to RA, Rosiglitazone treatment in a small numbers of patients with Cushing's Disease reported normalized urinary free cortisol in $\sim$30% of treated patients (Ambrosi *et al.*, 2004; Giraldi *et al.*, 2006; Morcos *et al.*, 2007).

Regulation of POMC Processing

Intracellular Trafficking of POMC

The endoplasmic reticulum (ER) is an interconnected bilayer membrane system which manufactures, processes and transports a multitude of proteins and peptides. POMC is soluble and highly charged, and its N-terminal signal peptide directs the newly synthesized precursor

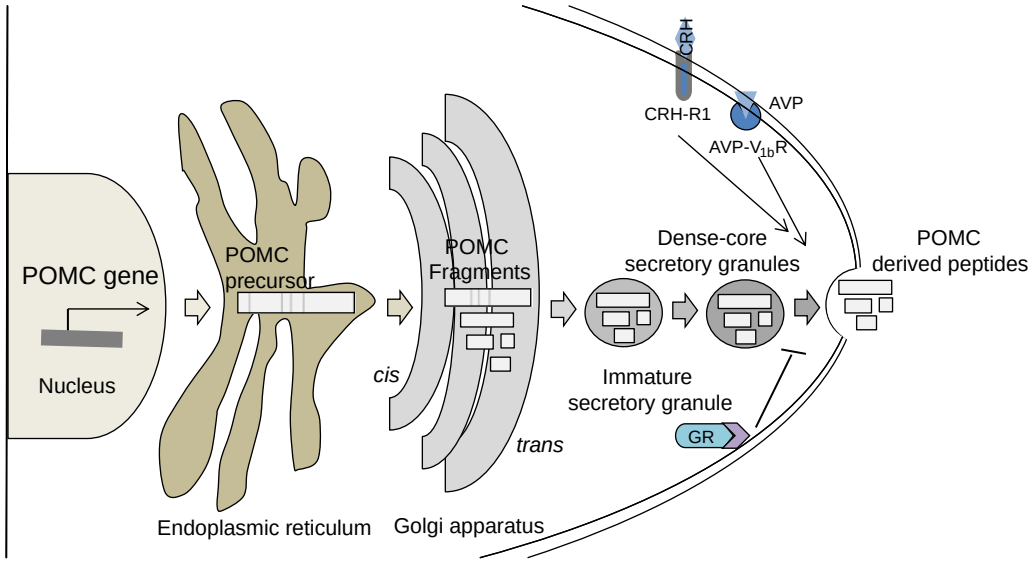

Fig. 5 The posttranslational processing and release of POMC and derived peptides. Schematic depiction of the multiple steps involved in POMC processing and transportation from its site of synthesis in the nucleus to the release of its processed peptides through the regulated secretory pathway.

into the ER lumen. After the POMC protein is properly folded in smooth ER, it enters the adjacent Golgi apparatus (GA), which comprises several membrane-covered cisternae (**Fig. 5**). The Golgi apparatus is polar in both structure and function, and the POMC protein enters the Golgi apparatus through the *cis* face (close to the nucleus and ER) and exits from the *trans* face toward the plasma membrane (**Fig. 5**). When budding off from the *trans* Golgi network (TGN), POMC is sorted into immature secretory granules (ISGs), which ultimately develop into large dense-core secretory granules (DCSGs) containing the processed products of POMC (**Fig. 5**). These are then delivered to the plasma membrane by a regulated secretory pathway to await a secretagogue signal.

Enzymatic Processing of POMC

The sequential processing of POMC involves a spectrum of enzymes, including endoproteases, exopeptidase, *N*-acetyl transferase and peptidyl amidating monoxygenase (Stevens and White, 2010). The initial processing of POMC occurs during transportation to the *trans* Golgi network by prohormone convertase 1 (PC1), which belongs to the subtilisin-like serine protease family (Cawley *et al.*, 2016). This family contains nine proprotein convertases, and PC1 and PC2 are mostly localized within immature and large dense-core secretory granules of neural and endocrine cells, and process most polypeptide prohormones within the regulated secretory pathway (Seidah and Prat, 2012). PC1 is most abundant in the anterior pituitary and similar to POMC, is synthesized in the endoplasmic reticulum as an inactive proprotein that undergoes maturation by initial autocatalytic cleavage followed by an N-terminal cleavage and a tertiary C-terminal truncation step as it transits from the *trans* Golgi network to the secretory vesicles (Chrétien and Mbikay, 2016). PC1 activity is inhibited by its own unprocessed peptide as well as an endogenous inhibitor called ProSAAS. The latter is a granin-like protein that is processed by PC1, but also binds to PC1 to inhibit its enzymatic activity in the early stages of the regulated secretory pathway (Stijnen *et al.*, 2016). PC1 cleaves POMC at dibasic residues, generating three peptide intermediates, namely a 16 kDa N-POMC (1–77), ACTH and β-LPH (**Fig. 2**B) (Chrétien and Mbikay, 2016). PC1 null mice have impaired ACTH production and compensatory accumulation of POMC mRNA, and a patient with mutated PC1 exhibited high levels of partially processed POMC intermediate products and a phenotype that included obesity, impaired glucose homeostasis and orange hair (Chrétien and Mbikay, 2016). PC2 is expressed in the neurointermediate lobe, but not in the anterior lobe, and processes POMC to γ-MSH, α-MSH, CLIP, γ-LPH, β-MSH and β-END (**Fig. 2**B). PC2 null mice lack α-MSH, and accumulate ACTH, ACTH-containing intermediate peptides, POMC, and β-END. These animals exhibit retarded growth and developmental defects due to improper processing of growth hormone and other prohormones, including insulin (Chrétien and Mbikay, 2016). PC2 has an endogenous chaperone, 7B2, that inhibits PC2 in both its unprocessed and processed forms (Stijnen *et al.*, 2016). Similar to PC2 knockout animals, 7B2 null mice develop spontaneous Cushing's disease due to excessive ACTH secretion. In addition to the PC family, several other enzymes process POMC, including Yapsin A, an aspartic protease that cleaves POMC at dibasic residues. Acidic ACTH-converting enzyme (AAVE), a tetrabasic residue-specific enzyme found in the intermediate lobe, is a calcium dependent serine protease that cleaves ACTH at the Arg 17-Arg18 residues to yield ACTH 1–17 and CLIP (Cawley *et al.*, 2016). As a penultimate step in POMC processing, aminopeptidases and carboxylpeptidase E (CPE) remove extending N- and C-terminal lysine and arginine residues from POMC products (Cawley *et al.*, 2016). Additionally, POMC fragments undergo cell specific posttranslational modifications, such as *N*-acetylation and amidation which modulate the stability and activity of the various POMC-derived peptides (Cawley *et al.*, 2016).

Transport and Exocytosis of Secretory Granules

The N-terminus 26 aa signal peptide of the POMC precursor is predicted to act as a "sorting" peptide that binds to sorting receptors of the *trans* Golgi network, potentially carboxylpeptidase E and secretogranin III. Independent of its enzymatic activity, carboxylpeptidase E functions as a sorting receptor by adoption of a transmembrane orientation, interacting through its cytoplasmic tail with a complex of "motor" proteins, including dynactin, and the kinesins 2 and 3. It is proposed that POMC containing secretory granules anchor to and travel along microtubules aided by the high affinity of carboxylpeptidase E for its motor complex (Cawley *et al.*, 2016). Gamma-adductin is a newly defined binding partner of carboxylpeptidase E, and it is proposed that it partners with carboxylpeptidase E to facilitate budding off from the *trans* Golgi network through an interaction with peri-Glogi F-actins (Cawley *et al.*, 2016). Once the regulatory secretory granule vesicles containing POMC-derived peptides have transferred along the microtubule track to the actin cortex close to the plasma membrane, they are then tethered there and docked by the small guanosine triphosphatase (GTPase) Rab proteins and their effectors (Park and Loh, 2008). Rab3D in association with Rab3A, docks the POMC-derived peptides containing vesicles to the plasma membrane (Park and Loh, 2008). The SNARE complex then facilitates the fusion of the vesicles with the plasma membrane. Following an ACTH stimulus, Ca^{2+} influx occurs and activates the Ca^{2+} sensor synaptotagmin, which binds the SNARE complex and triggers membrane fusion and release of vesicular ACTH content (Park and Loh, 2008). Detailed characterization of trafficking and transportation of secretory vesicles is still poorly understood, and the exact molecular mechanisms involved may vary in a tissue and cell specific manner (Park and Loh, 2008).

Concluding Remarks

The human POMC gene and its orthologs are highly conserved across mammalian organisms. POMC first appeared in the vertebrate kingdom ~ 500 million years ago prior to the rise of jawless Agnatha. Since corticotrophin was first purified from pig pituitary extracts in 1950 (Payne *et al.*, 1950), our understanding of the biochemical characteristics and physiological activity of ACTH has vastly improved. However, many details of the physiopathological regulation of POMC remain unknown. For example, plasma ACTH and cortisol exhibits a distinct circadian rhythm in humans and higher mammals with an ~24 h cycle length, peaking between 5 and 8 am with its nadir at 11 pm-3 am (Dickmeis, 2009). Interestingly, this ACTH and cortisol oscillatory profile is disturbed in Cushing's disease's and in disrupted sleep-wake cycles or feeding intervals (Dickmeis, 2009). Further insights into the molecular mechanisms that regulate POMC synthesis and secretion, and its complex interplay with other target organs especially the adrenal cortex will advance our understanding of this fascinating area in endocrinology.

ACTH, Melanocortin Receptors, and MRAP Accessory Proteins☆

Robert M Dores, University of Denver, Denver, CO, United States

Nomenclature

1 R: first genome duplication event that occurred in the ancestral agnathan vertebrates.
2 R: second genome duplication event that occurred in the ancestral agnathan vertebrates.
3 R: genome duplication event that occurred in the ancestral ray-finned fishes.

Glossary

ACTH Adrenocorticotropin; polypeptide hormone derived from POMC.
αMSH Alpha-melanocyte stimulating hormone; polypeptide hormone derived from POMC.
βMSH, γMSH, δMSH Polypeptide hormones related to αMSH and derived from POMC.
Endoproteolytic cleavage site Amino acid motifs (i.e., KR, RR, RK, KKRR, RKRR) located within a polypeptide that serve as the cleavage site for either prohormone convertase 1 or 2.
Genome duplication event Complete duplication of an entire genome.
GPCR G protein-coupled receptor.
Local gene duplication Duplication of a gene within a chromosome.
MC1R Melanocortin-1 receptor.
MC2R Melanocortin-2 receptor.
MC3R Melanocortin-3 receptor.
MC4R Melanocortin-4 receptor.
MC5R Melanocortin-5 receptor.
Melanocortin peptide. A polypeptide with the HFRW Motif.
Melanocortin receptor A GPCR with a binding site for the HFRW motif of a melanocortin peptide.
MRAP1 Melanocortin-2 receptor accessory protein 1.
MRAP2 Melanocortin-2 receptor accessory protein 2.
Opioid/Orphanin A polypeptide chemical signal that has the N-terminal motif, YGGF, YGGL, or FGGF that can bind to either an opioid receptor or an orphanin receptor.
POMC Proopiomelanocortin; the common precursor for melanocortin peptides and the opioid peptide β-endorphin.

Introduction

ACTH is one of several melanocortin-related peptides that are derived from the common precursor protein, POMC (Nakanishi *et al.*, 1979). The *pomc* gene appears to have emerged early in the evolution of the chordates, and is a member of the opioid/orphanin gene family (Dores *et al.*, 2002). By the time the gnathostomes (jawed vertebrates) appeared in the fossil record, the organizational plan for the POMC common precursor protein was well established. In addition it is likely that all five melanocortin receptor genes, and the two accessory proteins, melanocortin receptor-2 accessory protein-1 (MRAP1) and melanocortin-2 accessory protein-2 (MRAP2), were also present in the genomes of the ancestral gnathostomes. Before considering the properties of melanocortin peptides, melanocortin receptors, and the MRAP-related accessory proteins, some comments about the transformations that have occurred in chordate genomes may be helpful.

Extant chordates (i.e., members of phylum Chordata) include protochordates such as the tunicates and lancets (*Amphioxus*, genus), the jawless fishes, such as hagfishes and lampreys, and the jawed vertebrates (gnathostomes) such as cartilaginous fishes, bony fishes (ray-finned and lobe-finned), amphibians, reptiles, birds, and mammals (Hedges, 2009). The features that unite all of these organisms include the presence of a dorsal nerve cord, pharyngeal gill slits, and a notochord at some point in development (Buchsbaum *et al.*, 1987). A feature that separates the various extant lineages of chordates is the number of genome duplication events a particular lineage has endured (Ohno *et al.*, 1968; Holland *et al.*, 1994; Lundin, 1993; Kuraku *et al.*, 2009). As shown in **Fig. 1**A, there is evidence that during the radiation of the ancestral jawless fishes two genome duplication events occurred. Hence, while there may have been a single gene in the ancestral protochordates for some trait, there could be, theoretically, four paralogous genes potentially located on separate chromosomes in the genome of the ancestral gnathostomes. During this period of genome expansion the possibility that some paralogous genes might undergo duplication events within a chromosome, or be moved to a different chromosome, or accumulate point mutations that resulted in a pseudogene cannot be dismissed. To add to

☆*Change History:* September, 2017. Robert M Dores expanded "Evolution of ACTH, α-MSH, and POMC" [2004; Volume 1: 30–34] to include a discussion of melanocortin receptors and melanocortin receptor accessory proteins.
This is an update of Robert M. Dores and Phillip B. Danielson, ACTH, alpha-MSH, and POMC, Evolution of, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 30–34.

 doi:10.1016/B978-0-12-801238-3.95733-7

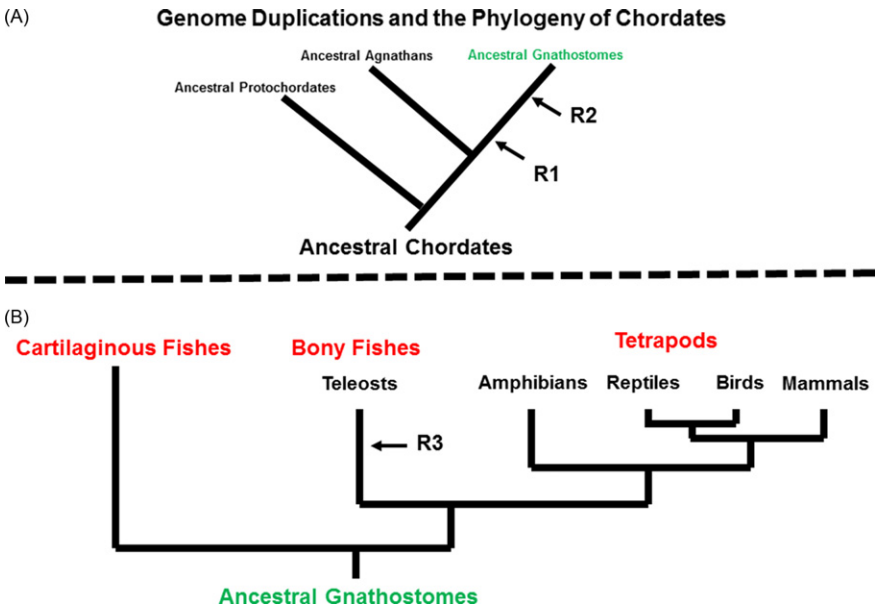

Fig. 1 Chordate phylogeny. (A) The ancestral chordates experienced two whole genome duplication events during the radiation of the ancestral agnathan vertebrates. (B) Within the radiation of the gnathostomes a third genome duplication event occurred in the ancestors to the teleosts. 1R—first genome duplication event; 2R—second genome duplication event; 3R—third genome duplication event.

this complexity, a third genome duplication event occurred at some point in the radiation of the ancestral ray-finned fishes, and as a result modern bony fishes (teleosts) are 3R (Meyer and Van de Peer, 2005).

The implications of chordate genome duplication events can be seen for the opioid/orphanin gene family. This gene family appears to have its origin in the ancestral protochordates, and the *pomc* gene appears to be the result of the 1R duplication event (Sundstrom *et al.*, 2010). However following the 2R event, it appears that a duplicate copy of the *pomc* gene was lost in the genomes of most nonteleost gnathostomes. The organization of gnathostome POMC will be discussed in Section "ACTH and POMC."

With respect to the melanocortin receptors, the current hypothesis is that this gene family arose in the ancestral protochordates (Vastermark and Schiöth, 2011). Hence, the presence of five paralogous melanocortin genes in most gnathostome genomes is consistent with two genome duplication events and one local gene duplication event. In support of this conclusion the *melanocortin-1 receptor* (*mc1R*) gene, the *melanocortin-2 receptor* (*mc2r*) gene, the *melanocortin-3 receptor* (*mc3r*) gene, and the *melanocortin-4 receptor* (*mc4r*) gene are located on separate chromosomes in most gnathostome genomes, and the *melanocortin-5 receptor* (*mc5r*) is usually found on the same chromosome as the *mc2r* gene (Schiöth *et al.*, 2003).

Currently, the *mrap1*gene and the *mrap2* gene have only been found on separate chromosomes of representative 2R organisms such as the extant gnathostomes (Dores, 2016). This observation would suggest that these paralogous genes arose after the 2R genome duplication event, and the ancestral *mrap* gene had its origin in a 1R ancestral jawless vertebrate lineage.

ACTH and POMC

When considering the organization plan for POMC in extant gnathostomes, mammalian POMC serves as a good model (**Fig. 2**A). All POMC orthologs have the sequence of the endogenous opioid peptide, β-endorphin, located at the C-terminal of the precursor. In addition, mammalian POMC orthologs have three melanocortin peptide sequences: an ACTH sequence as well as a γMSH and a βMSH sequence. Note that the sequence of αMSH is embedded in the sequence of ACTH. Each of the melanocortin peptides sequences has the melanocortin core motif, HFRW, and each sequence is flanked by a set of paired basic amino acids that serve as endoproteolytic cleavage sites (Chang *et al.*, 1980). The role of the HFRW motif will be discussed in Section "Melanocortin Receptors." In addition there is a tetrabasic amino acid motif in the ACTH sequence that allows for the generation of αMSH following endoproteolytic cleavage (Eipper and Mains, 1980).

One of the intriguing features of POMC is that this precursor protein can undergo cell specific endoproteolytic cleavage to yield different sets of end products (Seidah and Chrétien, 1999). For example in mammalian corticotropic cells of the anterior pituitary, POMC undergoes endoproteolytic cleavage to yield ACTH and β-endorphin as major end products. Whereas, in mammalian melanotropic cells of the intermediate pituitary, and in selected neurons in the central nervous system POMC undergoes endoproteolytic cleavage to yield the various MSH-sized peptides (i.e., αMSH, βMSH, γMSH), and β-endorphin as major end products (Eipper and Mains, 1980). The implications of this differential posttranslational processing of POMC will be discussed in Section

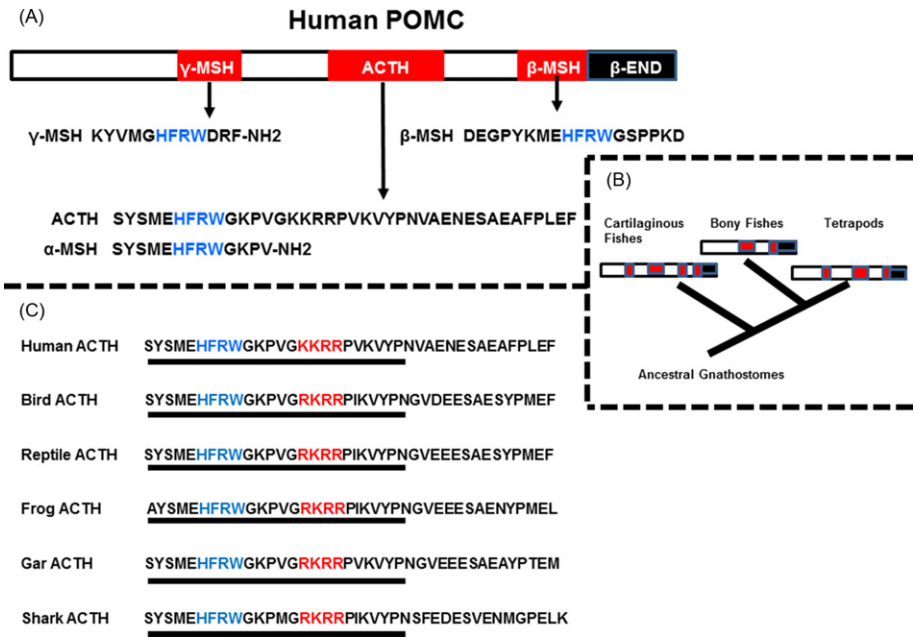

Fig. 2 POMC and ACTH. (A) The organizational plan for POMC is presented in schematic form. The relative positions of γMSH, ACTH, and βMSH within the precursor protein are highlighted in *red*. Below each melanocortin peptide position is the sequence of the human form of the peptide. Note that the HFRW motif in each peptide sequence is highlighted in *blue*. The relative position of the β-endorphin sequence is highlighted in *black*. (B) The phylogeny of cartilaginous fish POMC, Bony Fish POMC, and Tetrapod POMC is presented in this schematic representation. The location of the melanocortin sequences is shown in *red*, and the location of the β-endorphin sequence is shown in *black*. Note the organizational plan for the POMC sequences is very similar for these representative gnathostomes. (C) Comparison of Gnathostome ACTH Sequences. The amino acid sequences for representative gnathostome ACTH orthologs were aligned. The HFRW motif is highlighted in *blue* and the tetrabasic motif is highlighted in *red*. The location of ACTH(1–24) for each sequence is underlined with a *black line*. The following sequences were aligned: Chick (*Gallus gallus* NP_001026269); Alligator (*Alligator mississippiensis* NP_0012745535.1); Frog (*Xenopus tropicalis* NP_0011318.1); Gar (*Lepisosteus osseus* AAB03227.1); Dogfish (*Squalus acanthias* BAA 32606.1).

"Melanocortin Receptors." That said, the differential posttranslational processing of POMC observed in the pituitary of mammals is also seen in the pituitaries of cartilaginous fishes and nonmammalian bony vertebrates (Dores and Lecaude, 2005). In addition, as shown in **Fig. 2**B, the basic organization plan for POMC (i.e., multiple melanocortin peptide sequences and a single β-endorphin sequence) is found in cartilaginous fishes and the bony vertebrates. Subtle variations in this organizational plan are seen in cartilaginous fishes with the presence of an additional melanocortin sequence (δMSH), and in teleosts with the loss of the γMSH sequence (Vallarino *et al.*, 2012). Thus, it would be reasonable to assume that the POMC common precursor in the ancestral gnathostomes also had multiple melanocortin peptide sequences and a β-endorphin sequence, and that in the pituitary of the ancestral gnathostomes the enzymes for performing cell-specific differential posttranslational processing were in place.

Finally, as shown in **Fig. 3**C, gnathostome ACTH sequences have a number of interesting features. Earlier studies had shown that full bioactivity for ACTH only requires the first 24 amino acids of the peptide [ACTH(1–24); **Fig. 3**C, underlined] (Schwyzer, 1977). Within this domain of ACTH, there is 83% primary sequence identity for the ACTH orthologs presented in **Fig. 3**C. In addition, all of the ACTH sequences have the canonical HFRW motif highlighted in *blue*, and all of the ACTH sequences have a tetrabasic amino acid motif (KKRR or RKRR) highlighted in *red*. As noted, in cells of the intermediate pituitary and POMC neurons in the central nervous system, the tetrabasic motif serves as an endoproteolytic cleavage site that results in the generation of αMSH. Hence in these secretory cells ACTH(1–39) serves as a biosynthetic intermediate (Lowry *et al.*, 1977). However, when corticotropic cells of the anterior pituitary secrete ACTH(1–39), the tetrabasic amino acid motif plays an important role in the activation of melanocortin-2 receptors of bony vertebrates (see Section "Melanocortin Receptors"). These two functional roles for the tetrabasic motif of ACTH are quite unique, and it is difficult to identify another chemical signal with similar properties.

Melanocortin Receptors

The melanocortin receptors are G protein-coupled receptors (GPCR) that were initially characterized from mammals in the early 1990's (for review see Cone, 2006), and then later from several species of nonmammalian tetrapods, bony fishes, and a few cartilaginous fishes (Schiöth *et al.*, 2003). The melanocortin receptors are Class 1 (Rhodopsin-like) GPCRs that belong to Subfamily 13 (Attwood and Findlay, 1994). As shown in **Fig. 3**, these receptors have seven transmembrane domains, and when positioned on the plasma membrane, an N-terminal domain faces the extracellular space and a C-terminal domain faces the cytosol. These various domains differ in amino acid sequence to a sufficient degree such that five paralogous genes are clearly

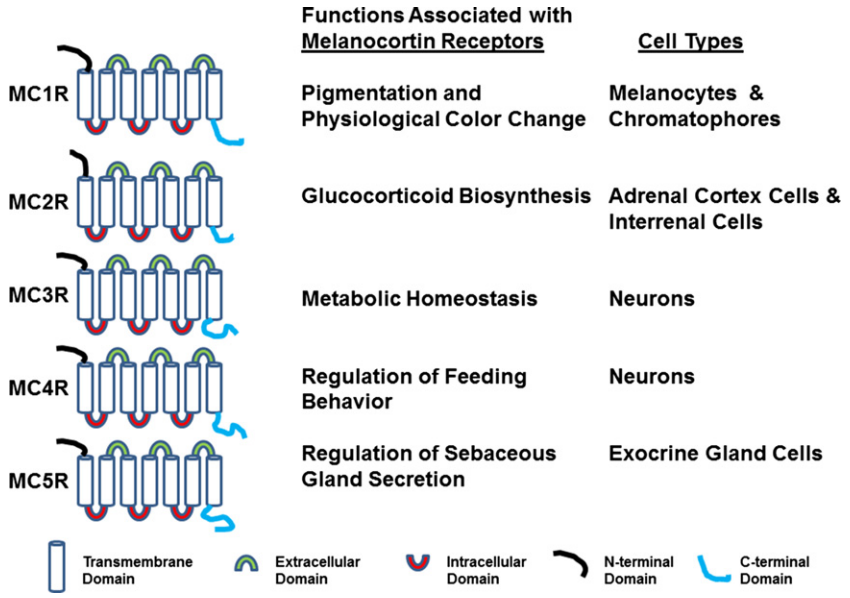

Fig. 3 Melanocortin receptors. This figure presents a schematic representation of the five melanocortin receptors. Some of the functions associated with each receptor are presented, and the cell types associated with these functions are also presented.

present in gnathostome genomes, but these receptors share a number of amino acid motifs which clearly define the melanocortin receptors as a distinct family within Class 1.

The functions that have been studied most extensively for these receptors are listed in **Fig. 3**. However, it is appreciated that members of this receptor family have additional functions and a broader tissue distribution than indicated in **Fig. 3** (Caruso *et al.*, 2014). In this regard, several studies indicate that MC1R can be found on the surface of melanocytes and melanophores, and these cells located in the integument play a role in the regulation of pigmentation in mammals, and physiological color change in several species of amphibians, reptiles, and teleosts, respectively (Cone, 2006; Bagnara *et al.*, 1968; Logan *et al.*, 2006). MC2R can be found on the surface of adrenal cortex cells (mammals, birds, and reptiles), and interrenal cells (amphibians and fishes), and the binding of ACTH to this receptor initiates glucocorticoid biosynthesis (Gallo-Payet and Bastista, 2014). MC3R and MC4R are found on neurons in the central nervous that are involved in the regulation of metabolism and feeding behavior (Abdel-Malek, 2001). In mammals and perhaps other gnathostomes, MC5R has been implicated in the regulation of sebaceous gland secretion (Thiboutot *et al.*, 2000). However, MC5R appears to also play a role in the immune system (Taylor *et al.*, 2006). An objective of this review is to comment on three issues related to melanocortin receptor pharmacology, which have physiological implications: (a) pharmacological features of MC1R, MC3R, MC4R, and MC5R orthologs in teleosts and tetrapods; (b) pharmacological properties of MC2R orthologs in teleosts and tetrapods; and (c) the pharmacological properties of melanocortin receptors in cartilaginous fishes.

Pharmacological Properties of Teleost and Tetrapod MC1R, MC3R, MC4R, and MC5R

From a pharmacological perspective, teleost and tetrapod MC1R, MC3R, MC4R, and MC5R orthologs appear to exhibit the ligand selectivity redundancy that can occur as a result of genome duplications events. There are now several studies which show that following the individual expression of these paralogous melanocortin receptors in various mammalian cell lines, activation of any of these receptors can be achieved following incubation with either ACTH- or MSH-related ligands (Gantz and Fong, 2003; Ling *et al.*, 2004; Dores *et al.*, 2014; Takahashi *et al.*, 2016). What are the implications of these observations from a physiological perspective? Consider that in an amphibian or reptile that utilizes melanophores for physiological color change, the simultaneous release of αMSH, βMSH, and γMSH from cells of the intermediate pituitary will stimulate activation of melanocortin-1 receptors on chromatophores to facilitate physiological color change. However, since these waves of MSH-sized ligands are released into the vascular system, melanocortin-5 receptors positioned on cells of various organs in the periphery could also be activated. While "side effects" are certainly possible when amphibians and reptiles release melanocortin peptides during a physiological color evident, documentation of these "side effects" has not been a focus of these types of studies.

This issue of "cross-talk" between melanocortin receptors in the periphery of gnathostomes may be more relevant following the release of ACTH from corticotropic cells of the anterior pituitary. While the intended target for ACTH when the Hypothalamus/Pituitary/Adrenal-Interrenal system is activated is the melanocortin-2 receptors located on either adrenal cortex cells or interrenal cells (see Section "Pharmacological Properties of Teleost and Tetrapod MC2R"), ACTH could also activate melanocortin-1 receptors and melanocortin-5 receptors located on various cell types in the periphery. For example, ACTH does effect melanin synthesis in mammalian melanocytes in the integument (Carlson *et al.*, 2007), and pigment granule movement within

chromatophores of amphibians (Burgers and Van Oordt, 1962). That said, the physiological effects of ACTH binding to melanocortin-5 receptors on organs in the periphery have received relatively little attention.

In the case of the melanocortin-3 receptor and the melanocortin-4 receptor, the focus shifts to the roles that these receptors play on neurons in the central nervous system. In these circuits presynaptic neurons express the *pomc* gene and following post-translational process of POMC, package MSH-sized end products in regulated secretory vesicles. At the synapse, either melanocortin-3 receptors or melanocortin-4 receptors are positioned on the dendrite of the postsynaptic neuron. In for example mammals, at the synapse αMSH, βMSH, and γMSH will be released in equimolar amounts by the presynaptic neuron thus concentrating the melanocortin signal at the synapse for interaction with the melanocortin receptors on the postsynaptic neuron. The implications for signaling from all three melanocortin peptides interacting with the receptor virtually simultaneously have not been evaluated. The common approach for studying the ligand selectivity of melanocortin-3 and melanocortin-4 receptors is to transiently express these receptors individually in a mammalian cell line, and then stimulate with a single melanocortin peptide.

That said, teleost and tetrapod MC1R, MC3R, MC4R, and MC5R paralogs can respond to ACTH or any of the MSH-sized ligands due to the fact that all melanocortin peptides have the HFRW motif, a motif required for activation of melanocortin receptors, and in these melanocortin receptor paralogs there is a common HFRW binding site. A schematic representation of the HFRW binding site for the human melanocortin-4 receptor is presented in **Fig. 4**A. Pogozheva *et al.* (2005) used a single alanine substitution paradigm to identify critical amino acid positions in human MC4R in transmembrane domains 2, 3, 6, and 7, which form an HFRW binding site near the surface of the receptor. These amino acid positions are rigorously conserved in human MC1R, MC3R, and MC5R (Pogozheva *et al.*, 2005), and these amino acids are also conserved in the MC1R, MC3R, MC4R, and MC5R paralogs of bird, amphibian, and bony fishes (Dores, 2009; Baron *et al.*, 2009). Hence, the presence of this HFRW binding site in teleost and tetrapod MC1R, MC3R, MC4R, and MC5R paralogs accounts for the generic ligand selectivity of these receptors for any melanocortin-related peptide.

Pharmacological Properties of Teleost and Tetrapod MC2R

By contrast, teleost and tetrapod melanocortin-2 receptor orthologs have more stringent ligand selectivity properties. The melanocortin 2 receptor is a critical component of the Hypothalamus/Pituitary/Adrenal axis is mammals, birds, and reptiles, and the

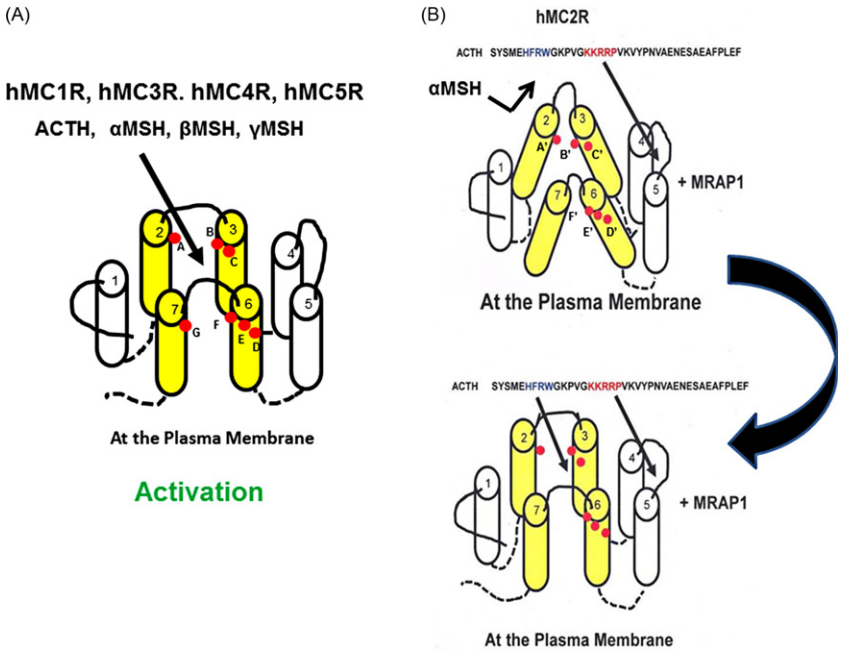

Fig. 4 Proposed mechanisms for activating melanocortin receptors. (A) Human MC4R is presented in a cartoon format, and the critical amino acid positions in the HFRW binding site are based on the work of Pogozheva *et al.* (2005). That study indicated that the following amino acid positions are involved in the αMSH binding event: (A) E^{100} in TM2, (B) D^{122} in TM3, (C) D^{126} in TM3, (D) F^{261} in TM6, (E) H^{264} in TM6, (F) L^{265} in TM6, and (G) L^{288} in TM7. These transmembrane domains form a shallow hydrophobic binding pocket on the extracellular space side of the receptor. The binding of αMSH at this pocket results in the activation of the G protein associated with human MC4R. (B) Human MC2R has six of the seven conserved amino acid position predicted for the HFRW binding site (i.e., A′, B′, C′, D′, E′, and F′). However, αMSH cannot bind to this receptor (Mountjoy et al., 1992). As a result, in this cartoon TM2, TM3, TM6, and TM7 are depicted in a confirmation in which the HFRW binding site is closed. Hence, the proposed mechanism for activation of human MC2R by ACTH(1–24) involves a two-step process. First the tetrabasic motif in ACTH(1–24) binds to a predicted site in the TM4/EC2/TM5 domain (Dores et al., 2016). In this proposed mechanism, binding at the TM4/EC2/TM5 domain would result in a conformation change in the receptor that would open the HFRW binding site, and activation of the G protein associated with human MC2R would occur after this second binding event.

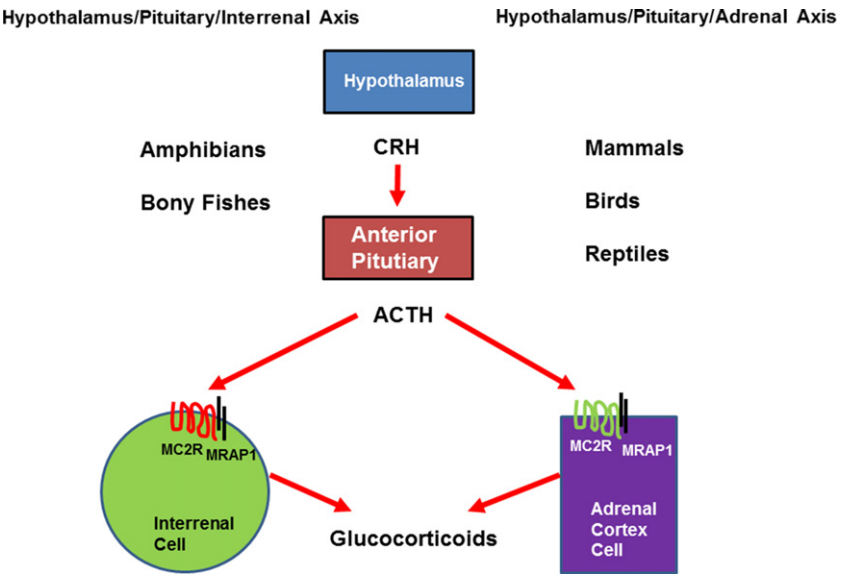

Fig. 5 Overview of the Hypothalamus/Pituitary/Adrenal-Interrenal axis. The Hypothalamus/Pituitary/Adrenal axis (HPA) and the Hypothalamus/Pituitary/Interrenal axis (HPI) follow a common pathway. Sensory information is evaluated by higher brain centers, and as a result, neurons in the hypothalamus release the neuropeptide CRH (corticotropin releasing hormone). CRH binds to receptors on corticotropic cells in the anterior pituitary and ACTH is released. For mammals, birds, and reptiles ACTH will bind to the melanocortin-2 receptor (MC2R) that is associated with the accessory protein, MRAP1 on adrenal cortex cells. This binding event initiates the synthesis and release of glucocorticoids. In amphibians and fishes, ACTH will bind to the melanocortin-2 receptor (MC2R) that is associated with the accessory protein, MRAP1 on interrenal cells to initiate the synthesis and release of glucocorticoids.

Hypothalamus/Pituitary/Interrenal axis of amphibians and bony fishes (**Fig. 5**). The primary objective of the HPA/HPI axis is to restore homeostasis for metabolic processes, the immune system, and behavior within an organism after a stress event through the release and action of glucocorticoids: steroid released from adrenal cortex cells or interrenal cells (Abdel-Malek, 2001).

As summarized by Schwyzer (1977), the "ACTH" receptor on mammalian adrenal cortex cells could be activated by ACTH, but not by αMSH. Mountjoy *et al.* (1992) renamed the human "ACTH" receptor, MC2R, and found that this melanocortin receptor paralog could only be activated by ACTH, but not by αMSH. Subsequent studies on bird, reptile, amphibian, and teleost MC2R orthologs have also showed that these MC2R orthologs could only be activated by ACTH, but not by αMSH (Agulleiro *et al.*, 2010; Davis *et al.*, 2013; Barlock *et al.*, 2014). The paradox in these observations is that six of the seven critical amino acid positions in human MC4R required for αMSH binding are present in human MC2R, and other tetrapod and teleost MC2R orthologs (**Fig. 4**B; Pogozheva *et al.*, 2005; Dores, 2009; Baron *et al.*, 2009). To reconcile these observations, the cartoon presented in **Fig. 4**B would propose that the HFRW binding site on teleost and tetrapod MC2R orthologs is closed prior to a binding event; hence αMSH is blocked from binding to the receptor. However, to account for ACTH's ability to active MC2R orthologs, Schwyzer (1977) proposed that the tetrabasic motif (i.e., $K^{15}K^{16}R^{17}R^{18}$) in human ACTH) binds to another site on the receptor. It is further proposed that this binding event causes a conformation change in the receptor to open the HFRW binding site, and this two-step process results in activation of the G Protein (**Fig. 4**B). Support for this hypothesis comes from alanine substitution experiments in the TM4/EC2/TM5 domain of human MC2R (Chen *et al.*, 2007; Dores *et al.*, 2016). Single alanine substitution at several positions in this domain either lowered or completely blocked activation of human MC2R following an ACTH stimulation event. Definitive binding studies to confirm that the TM4/EC2/TM5 domain in teleost and tetrapod MC2R orthologs is the tetrabasic motif binding site remain to be done. In addition, the caveat to the mechanism presented in **Fig. 4**B is that the MC2R ortholog must form a heterodimer with the accessory protein, MRAP1. Previous studies had shown that when MC2R orthologs were expressed alone in nonadrenal mammalian cell lines, the MC2R ortholog did not traffic to the plasma membrane (Rached *et al.*, 2005). Thus to understand the unique ligand selectivity properties of teleost and tetrapod MC2R orthologs, an understanding of the accessory proteins, MRAP1 and MRAP2, is needed. However, before getting into that discussion some comments on ligand selectivity properties of cartilaginous fish melanocortin receptors should be considered.

Pharmacological Properties of Melanocortin Receptors of Cartilaginous Fishes

As noted in **Fig. 1**B, early in the radiation of the ancestral gnathostomes, the ancestral cartilaginous fishes diverged from the ancestral bony fishes (Sallan and Coates, 2010). Since the ancestral gnathostomes most likely had all five melanocortin receptor genes, this gene family has been diverging in parallel in the cartilaginous fishes lineage and the bony vertebrate lineage with some interesting twists.

The ligand selectivity for various cartilaginous fish melanocortin receptors have been determined for the dogfish (*Squalus acanthias*) MC3R, MC4R, and MC5R (Ringholm *et al.*, 2003; Klovins *et al.*, 2004: Reinick *et al.*, 2012a); the elephant shark

(*Callorhinchus milii*) MC2R and MC3R (Reinick *et al.*, 2012b; Liang *et al.*, 2013); and the Japanese stingray (*Dasyatis akajei*) MC1R, MC2R, MC3R, MC4R, and MC5R (Takahashi *et al.*, 2016). For every cartilaginous fish melanocortin receptor paralog, even elephant shark MC2R and stingray MC2R, the paralog could be activated by either a cartilaginous fish ACTH or cartilaginous fish MSH-sized peptide (i.e., αMSH, Des-Acetyl-αMSH, βMSH, γMSH, or δMSH). In addition, the elephant shark and stingray MC2R orthologs did not require coexpression with an MRAP1 ortholog for functional express in Chinese Hamster Ovary Cells (Reinick *et al.*, 2012b; Takahashi *et al.*, 2016). The study on stingray MC2R is particularly interesting because this receptor, as well as stingray MC5R, is expressed in stingray interrenal cells. Cartilaginous fishes do have a Hypothalamus/Pituitary/Interrenal axis (Gelsleichter, 2004), hence at least for the stingray, the interrenal cells could theoretically be induced to produce glucocorticoids either through the action of ACTH- or the MSH-sized peptides.

While the ligand selectivity properties of cartilaginous fish MC1R, MC3R, MC4R, and MC5R paralogs are not surprising, the ligand selectivity properties of elephant shark MC2R and stingray MC2R are unexpected. Perhaps at this stage it would be appropriate to consider the radiation and properties of the accessory proteins, MRAP1 and MRAP2.

Melanocortin Receptor Accessory Proteins: MRAP1 and MRAP2

The inability to functionally express mammalian MC2R orthologs in nonadrenal mammalian cell lines (Rached *et al.*, 2005) was an enigma until the discovery of the accessory protein, MRAP (Metherell *et al.*, 2005). Not long after the discovery of MRAP, a paralog, MRAP2, was characterized (Chan *et al.*, 2009). For clarity MRAP will be referred to as MRAP1. In **Fig. 6** mouse MRAP1 and MRAP2 are used to illustrate the functional domains in teleost and tetrapod MRAP1 and MRAP2 paralogs. The first feature to note is that both MRAPs form a homodimer in which each monomer is oriented in an antiparallel manner. This orientation is referred to as reverse topology (Sebag and Hinkle, 2009). There is a critical amino acid motif in the N-terminal domain of MRAP1 and MRAP2 that is required for reverse topology (**Fig. 6**). In addition, in MRAP1 orthologs, but not in MRAP2 orthologs, there is another amino acid motif in the N-terminal domain referred to as the activation motif (**Fig. 6**). Alanine substitution in this region of the N-terminal of MRAP1 interferes with activation of teleost and tetrapod MC2R orthologs when the heterodimer forms (Sebag and Hinkle, 2009).

As shown in **Fig. 6**, since MRAP1 forms a homodimer with reverse topology, it was not apparent which activation motif (i.e., extracellular space side or cytosolic side) was making contact with teleost or tetrapod MC2R. However, recently Malik *et al.* (2015) found that the activation motif on the extracellular space side of MRAP1 makes contact with an extracellular domain on MC2R. At present the exact extracellular domain has not been identified. In addition, Sebag and Hinkle (2007) observed that the transmembrane domain of MRAP1 makes contact with a transmembrane domain on MC2R to facilitate trafficking of the receptor from the endoplasmic reticulum to the plasma membrane. Once again the exact transmembrane domain in MC2R interacting with MRAP1 has not been identified.

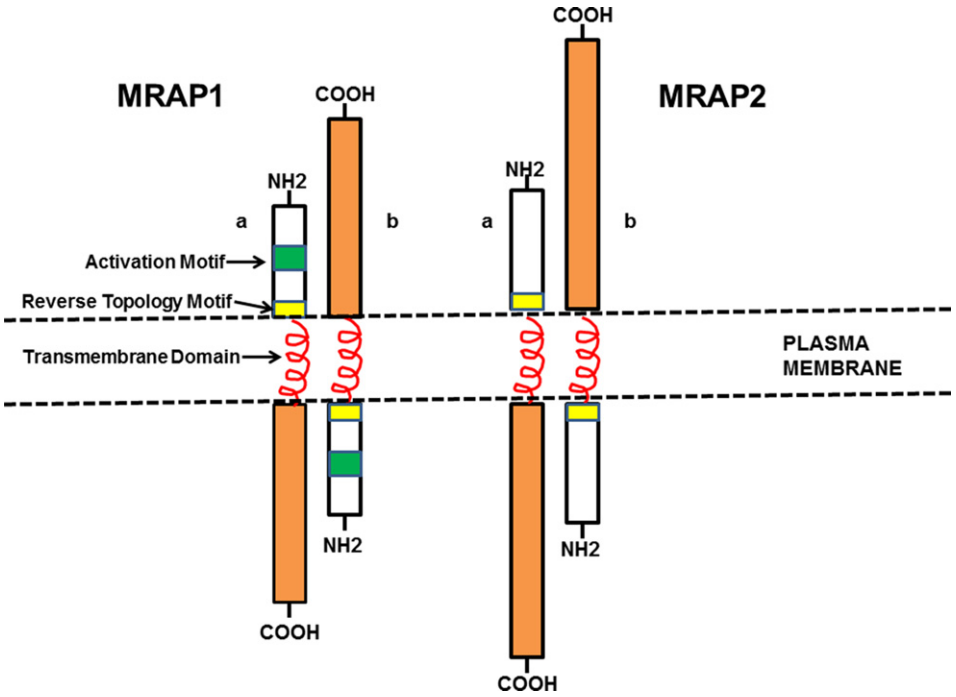

Fig. 6 MRAP1 and MRAP2. This figure provides a cartoon representation of MRAP1 and MRAP2. Mouse MRAP1 and MRAP2 were used as examples. Please note the images are not drawn to scale. Both MRAP1 and MRAP2 form a homodimer with reverse topology. For each homodimer the monomers are presented as (a) and (b). Each monomer has a single transmembrane domain. The C-terminal domain for each monomer is demarcated by an orange box (COOH). In the N-terminal (NH2) of each monomer an amino acid motif is present this is required for reverse topology (*yellow box*). Only in the N-terminal domain of MRAP1 monomer will you find an activation motif (*green box*).

As noted in Section "Introduction", the current hypothesis is that the ancestral *mrap* gene emerged prior to the 2R genome duplication event. As a result, the *mrap1* and *mrap2* genes were most likely present in the genome of the ancestral gnathostomes. Recently an MRAP1 ortholog was detected in the genome of the elephant shark. Thus, it is possible that other cartilaginous fishes also have an MRAP1 ortholog in their genomes. While the role that MRAP1 plays in the trafficking and activation of bony vertebrate MC2R orthologs is now very clear, the possible interaction between cartilaginous fish MRAP1 and cartilaginous fish MC2R orthologs remains to be determined.

Conclusions and Possibilities

When considering the coevolution of melanocortin peptides, melanocortin receptors, and melanocortin receptor accessory proteins it would appear that all three elements originated within phylum Chordata, but most likely not simultaneously. The ancestral *pomc* gene and the ancestral *melanocortin receptor* gene probably arose in a lineage of the protochordates on the line of evolution that gave rise to the jawless fishes. The ancestral *melanocortin receptor accessory protein* gene arose much later in a lineage of ancestral jawless fishes on a line of evolution which gave rise to the gnathostomes. The circumstances that linked the melanocortin peptides to the melanocortin receptors, or the sequence of events which led to the interaction between MRAP1 and the melanocortin-2 receptor, are unknown. However, there are features of this neuroendocrine network which played critical roles in forming these connections.

The interaction between melanocortin peptides and melanocortin receptors hinges on the HFRW motif in the melanocortin peptides, and the emergence of a binding site for this amino acid motif on melanocortin receptors. To retain this relationship, in gnathostomes there have been strong selection pressures to maintain, to a high degree, the primary sequence of the first 24 amino acids in ACTH. As a result of these selection pressures the primary sequence of αMSH is also highly conserved among gnathostomes. In addition, the high degree of primary sequence conservation in ACTH (1–24) helps to explain the unique ligand selectivity of bony vertebrate MC2R orthologs where both the HFRW motif and the tetrabasic amino acid motif (i.e., KKRR or RKRR) are essential for activation. Since the cartilaginous fish MC2R orthologs that have been studied can be activated by either ACTH or αMSH, the role that the tetrabasic amino acid motif in ACTH is playing most have emerged after the divergence of the ancestral cartilaginous fishes and the ancestral bony fishes. That said, the phylogeny of the melanocortin-2 receptor appears to be unique as compared to the other melanocortin receptors.

While most gnathostomes have retained all five paralogous melanocortin receptor genes, and each melanocortin receptor has an HFRW binding site, there is a very clear dichotomy between bony vertebrate melanocortin receptors. Whereas MC1R, MC3R, MC4R, and MC5R can all be activated by either ACTH- or MSH-sized ligands, MC2R can only be activated by ACTH. This dichotomy for ligand selectivity is not seen in the cartilaginous fish melanocortin receptors. Clearly something "happened" to MC2R following the divergence of the ancestral cartilaginous fishes and the ancestral bony fishes from their common ancestor. Vastermark and Schiöth (2011) have observed that gnathostome MC3R, MC4R, and MC5R paralogs have maintained a high degree (at least 65%) of primary sequence identity during the radiation of gnathostomes, which would explain the common ligand selectivity properties of these receptors in taxa as diverse as cartilaginous fishes and mammals. By contrast, during the radiation of the gnathostomes, MC2R orthologs have undergone extensive primary sequence variation. For example, stingray MC2R and human MC2R have only 37% primary sequence identity, and even among bony vertebrates the primary sequence identity between gar MC2R and human MC2R is only 55% (Dores, 2016). Given the important role that MC2R plays in the Hypothalamus/Pituitary/Adrenal-Interrenal axis, the degree of primary sequence variable among MC2R orthologs is counterintuitive.

Hence, in order to put the preceding observations into a physiological context, it is important to factor in the pivotal role that MRAP1 plays in the Hypothalamus/Pituitary/Adrenal-Interrenal axis. While the function that MRAP1 played in the interrenal cells of the ancestral gnathostomes is unknown, several studies on extant bony vertebrate MC2R orthologs indicate that the interaction between MRAP1 and MC2R not only makes it possible for MC2R to move from the endoplasmic reticulum to the plasma membrane, but also places MC2R into a unique conformation such that this receptor can only be activated by ACTH, but not by any of the MSH-sized melanocortin peptides (Metherell *et al.*, 2005; Hinkle and Sebag, 2009; Webb and Clark, 2010). The next issue that should be resolved for the bony vertebrate MC2R orthologs is to identify the sites on the receptor that make contact with the activation motif and the trafficking motif in MRAP1. With this information it should be possible to critically analyze the proposed MC2R activation mechanism presented in **Fig. 4**. In addition, since an MRAP1 ortholog has been detected in the genome of the elephant shark (Dores, 2016), studies are need to determine whether MRAP1 plays some supporting role in the activation cartilaginous fish MC2R orthologs.

Adrenocorticotropic Hormone (ACTH): Physiology and Its Involvement in Pathophysiology☆

George Mastorakos and Athanasios Antoniou-Tsigkos, National and Kapodistrian University of Athens, Athens, Greece

Glossary

Adrenocorticotropic hormone (ACTH) A 39 amino-acid peptide hormone (MW 45,000) that is part of the proopiomelanocortin precursor molecule. It controls the function of the adrenal cortex.

Proopiomelanocortin (POMC) A precursor molecule (MW 28,500) that, in the anterior lobe of the pituitary, is processed to adrenocorticotropic hormone and b-lipotropin and further processed to b-endorphin, an endogenous opioid peptide of 31 amino acids

Biochemistry

Adrenocorticotropic hormone (ACTH) is a 39-aminoacid peptide hormone (MW 45,000) that is part of the proopiomelanocortin (POMC) precursor molecule (MW 28,500). The PMOC gene is located on chromosome 2. Proopiomelanocortin is expressed in the brain, skin, and immune system and in the anterior and intermediate lobes of the pituitary gland. This gene undergoes extensive, tissue-specific, post-translational processing via cleavage by subtilisin-like enzymes known as prohormone convertases. There are eight potential cleavage sites within the polypeptide precursor and, depending on tissue type and the available convertases, processing may yield as many as ten biologically active peptides involved in diverse cellular functions. The encoded protein is synthesized mainly in corticotroph cells of the anterior pituitary where four cleavage sites are used (DiBlasio *et al.*, 1987). Specifically POMC is processed to ACTH and β-lipotropin (β-LPH), which is further processed to β-endorphin, an endogenous opioid peptide of 31 amino acids. (Fig.1). In the intermediate lobe, ACTH is processed to α-melanocyte-stimulating hormone (α-MSH) (ACTH 1–13) and CLIP (ACTH 18–39). In human corticotrophs, POMC is processed predominantly into N-terminal glycopeptide (1–76), joining peptide (JP 79–108), ACTH (112–150) and β-LPH (153–240). Much smaller amounts of α-MSH (112–124), CLIP (130–150), β-endorphin (210–240) and a truncated form of N-terminal glycopeptide (1–61), also known as "big" γ-MSH, are also present. There is no evidence of cleavage after arg (50) and therefore no evidence for the presence of γ-MSH (51–61) in the human pituitary. Whereas the production of distinct POMC peptide derivatives is clearly segregated between the anterior and intermediate lobes of the rodent pituitary evidence suggests that the strict dichotomy between corticotrope and melanotrope POMC processing doesn't extend to human pituitaries. Human POMC is also expressed in several brain sites outside the anterior pituitary predominantly in the arcuate nucleus of the anterior hypothalamus and the nucleus tractus solitarius of the caudal medulla where it generates a range of bioactive peptides, including ACTH, β-lipotropin, and γ-MSH. β-Lipotropin, a fragment with 91 amino acids, contains β-MSH (41–58), γ-LPH (1–58), and β-endorphin which is secreted in equimolar quantities with ACTH. The endogenous opioid peptides α-, β-, and γ- endorphin are derived from POMC and are composed of amino acids 61–76, 61–91, and 61–77, respectively, of β-LPH. In these extrapituitary locations POMC is expressed to a greater extent than in anterior pituitary. In the brain

☆*Change History:* September 2016. G Mastorakos and A Antoniou-Tsigkos added keywords, abstract, updated the text, and further reading.

This article is an update of George Mastorakos and Evangelia Zapanti, ACTH (Adrenocorticotropic Hormone), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 25-29.

 doi:10.1016/B978-0-12-801238-3.99422-4

ACTH (112–150) is cleaved to α-MSH (112–124) and CLIP (130–150) so that the amount of α-MSH (112–124) relative to ACTH is 300-fold higher in hypothalamus telencephalon and mesencephalon than it is in anterior pituitary (Bicknell, 2008).

The biological effects of POMC-derived peptides are diverse and are largely mediated through melanocortin (MC) receptors (R), five of which have been described. MC1R, MC2R, and MC5R have established roles in the pigmentation in the skin, adrenal steroidogenesis, and thermoregulation, respectively. However, the functional basis of the role of POMC in appetite and obesity is largely due to interactions between POMC-derived peptides in the brain and the neuroendocrine specific receptors, MC3R and MC4R (Smith and Funder, 1988; Whitfeld *et al.*, 1982).

In other tissues, including the hypothalamus, placenta, and epithelium, all cleavage sites may be used, giving rise to peptides with roles in pain and energy homeostasis, melanocyte stimulation, and immune modulation.

Pathology and Embryology

ACTH is synthesized within the corticotroph cells of the anterior pituitary lobe which represent 15–20% of adenohypophyseal cells. They are most numerous in the midsagittal region of the pituitary (median wedge) but also occur in the lateral wings of the gland. The embryological origin of corticotrophs is the intermediate lobe, but groups of cells migrate during development into regions of the anterior and posterior lobes (Grino *et al.*, 2001). Although the vast majority of ACTH is synthesized in anterior pituitary corticotrophs, it is also expressed in several non pituitary human tissues both within and outside the central nervous system (e.g. infundibular nucleus of the basal hypothalamus, substantia nigra, periventicular grey matter and hippocampus). In humans in addition to sellar pituitary there is a pharyngeal pituitary which is located in either the sphenoid sinus or within the sphenoid bone. It consists of pituitary-like tissue approximately 2–5 mm by 0.2 mm in size. It is connected to the sellar gland by trans-sphenoidal vessels. Only 1–2% of the cells in the pharyngeal pituitary contain immunoreactive ACTH in contrast to approximately 14% of the cells in the sellar pituitary (Favrod-Coune *et al.*, 1986).

Besides ACTH many other neuropeptides have been found to be co-localized in the corticotrophs (e.g. neurophysin, galanin, chromogranin A) although in most cases it is not clear whether this is due to binding or synthesis of the peptide within the cell. Histologically, corticotroph cells are polygonal medium sized to large sized, basophilic and strong PAS positive because of a carbohydrate moiety contained in POMC (Fig.2). In immunostained preparation corticotrophs show strong and diffuse cytoplasm ACTH staining consistent with the numerous secretory granules present at the ultrastructural level. Corticotrophs may also contain other POMC derivatives, including β-LPH, MSH, endorphin and enchepalin. Perinuclear bundles of cytokeratin filaments are also a characteristic feature of ACTH cells. Under conditions of glucocorticoid excess, either exogenous or endogenous, corticotrophs accumulate cytokeratin as a manifestation of Crooke's hyaline change (Puy and Ciocca, 1986; Doniach, 1985).

Measurement of ACTH

As regards assay methodology, comparison between competitive, single-antibody RIA and sandwich, two-site immunometric assays revealed that human plasma contains different ACTH species which can variably affect assay results. In most laboratories, RIA has been superseded by non-competitive radiometric or chemiluminescent assays but, even among the latter, some will yield up to 20% higher

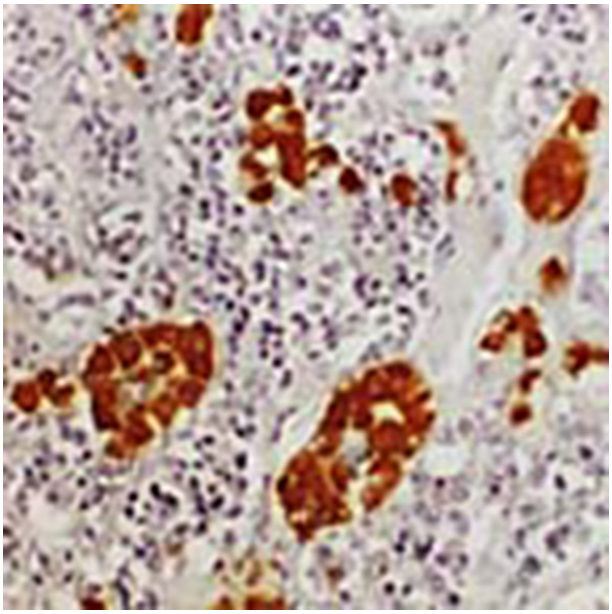

Fig. 2 Corticotroph cells in the anterior pituitary positively stained immunohistochemically with a basophilic staining.

measurements than others. In fact, although correlation between measurements was statistically sound, deviances in the lower assay range may prove clinically significant for certain situations (for example the differential diagnosis of Cushing syndrome). The basal morning concentration of ACTH ranges from 9 to 80 pg ml^{-1}. The episodic secretion of ACTH causes fluctuations in plasma ACTH and cortisol levels. ACTH secretion has a distinct diurnal rhythm, with peak levels in the early morning and the lowest levels at approximately midnight. The interpretation of ACTH values requires a simultaneous cortisol determination. Provided that adrenocortical function is intact, plasma cortisol measurements, from a practical viewpoint, are a reliable index of ACTH secretion (Giraldi and Alberto, 2015) The half-life of ACTH depends on the assay used for its measurement. Bioactive ACTH disappears from the circulation more rapidly (half-life of 3–9 min) than does immunoreactive ACTH (half-life of 7–12 min).

Physiology

Control of ACTH Secretion

The secretion of ACTH is controlled by an inherent diurnal rhythmicity; it is augmented by noxious stimuli that are neurally, hormonally, and biochemically mediated, which is termed stress (open-loop component), and is inhibited by glucocorticoids (closed-loop, negative feedback) (Miller and Tyrell, 1995). In normal circumstances, the daily secretion of ACTH and cortisol is episodic and variable (Jefcoate *et al.*, 1986; Krieger, 1979). The highest burst of activity is observed in the early morning hours. ACTH secretion is characterized by pulsatile release of ACTH from the corticotroph in a burst-like pattern with no interpulse secretion. Fifteen minute sampling reveals approximately 12 ACTH and cortisol pulses over a 24 h period, whereas more frequent 10 min sampling reveals a 40 ACTH pulses in 24 h. Blood ACTH rises by an average of 24 pg ml^{-1} per pulse. Spontaneous ACTH and cortisol pulses correlate highly. It should be stated also that the 24 h pattern of ACTH pulses, but not the cortisol pattern, differs between males and females (Veldhuis *et al.*, 2009).

Diurnal Rhythmicity

The basis of the diurnal rhythm is poorly understood. There is evidence for the involvement of at least three factors in the regulation of the diurnal rhythmicity of ACTH: (1) intrinsic rhythmicity of the secretion of the corticotropin-releasing factor (CRH) as well as vasopressin (AVP); (2) light–dark exposure; and (3) feeding times. Diurnal variation frequently disappears during periods of stress and depression and is also changed by conditions that affect cortisol metabolism (liver disease, chronic renal failure, alcoholism).

Intrinsic Rhythmicity of Hypothalamic CRH and AVP

Tests for the evaluation of the CRH secretion pattern have shown a diurnal intrinsic rhythmicity that persists even in hypophysectomized animals that are deprived of ACTH and glucocorticoid feedback. This hypothalamic rhythmicity appears to be neuronal but not hormonal. On the other hand, the presence of diurnal rhythmicity of ACTH in women during pregnancy when the increased circulating levels of placenta-derived CRH do not show a nychthemeral rhythm strongly suggests that hypothalamic AVP secretion plays a role in this diurnal regulation (Malee and Mellon, 1991). In addition although in situ hybridization studies show that there is a circadian rhythm in CRH expression in the suprachiasmatic nucleus, other reports do not confirm this. Moreover, the circadian rhythm persists despite a continuous infusion of CRH, suggesting that other factors are responsible for the modulation of ACTH pulses, most likely AVP: immunocytochemical studies show a circadian rhythm in AVP expression and transgenic knockout mice for CLOCK gene show a loss in the circadian rhythm in AVP RNA expression (6–10). The circadian CLOCK system consists of central and peripheral components, which are located respectively in the suprachiasmatic nucleus (SCN) of the hypothalamus and virtually all remaining organs and tissues. The SCN acts as a "master" CLOCK under the strong influence of light/dark input from the eyes, whereas the peripheral CLOCK behaves as a "slave", subjugated by the former through as yet unclear mechanisms. Both master and slave CLOCKs share almost the same transcriptional regulatory machinery with coordinated activation/inactivation of a set of transcription factors including the "circadian locomotor output cycle kaput" (Clock), its heterodimer partner "brain-muscle-arnt-like protein 1" (Bmal1). These transcription factors create a negative feedback transcriptional loop through mutual transcriptional activation and repression that ultimately maintains an approximately 24-h oscillation of their gene expression. Findings indicate that CLOCK/BMAL1 is a reverse-phase negative regulator of glucocorticoid action in target tissues, antagonizing the biologic actions of diurnally fluctuating circulating glucocorticoids and providing a local target tissue counter-regulatory feedback loop to the central clock influence on the HPA axis. As a result, tissue sensitivity to glucocorticoids is decreased in the morning (when circulating cortisol concentrations are elevated) and increased in the evening and early night (when cortisol concentrations reach their nadir). In addition to the predictably regular day/night changes in the environment, humans face frequent unforeseen short- and long-term influences, the "stressors". To adapt to these stressful stimuli, they possess another regulatory system, the hypothalamic-pituitary-adrenal (HPA) axis, (the "Stress System"). The circadian clock system and the HPA axis regulate the activity of one another through multilevel interactions to ultimately coordinate homeostasis against the day/night change and various unforeseen random internal and external stressors. Uncoupling of or dysfunction in either system alters internal homeostasis and causes pathologic changes virtually in all organs and tissues, including those responsible for

intermediary metabolism and immunity. Disrupted coupling of cortisol secretion and target tissue sensitivity to glucocorticoids may account for (i) the development of central obesity and the metabolic syndrome in chronically stressed individuals, whose HPA axis circadian rhythm is characterized by blunting of the evening decreases of circulating glucocorticoids, as a result of enhanced input of higher centers upon the hypothalamic paraventricular nucleus secretion of CRH and AVP; and (ii) the increased cardiometabolic risk and increased mortality of rotating shift workers or subjects exposed to frequent jet lag because of traveling across time zones. In addition, given that tissue sensitivity to glucocorticoids is increased in the evening, clinicians should avoid the administration of high doses of glucocorticoids for the treatment of adrenal insufficiency or congenital adrenal hyperplasia at night, because they increase the possibility of glucocorticoid-related side effects (Takahashi *et al.*, 2008; Nader *et al.*, 2009; Chrousos, 2009; Roozendaal *et al.*, 2009; Nicolaides *et al.*, 2014; Kino and Chrousos, 2011; Ko and Takahashi, 2006; Hastings *et al.*, 2007; Kalsbeek *et al.*, 2006).

Light–Dark Cycles

In parallel with cortisol, ACTH levels vary in an endogenous circadian rhythm, reaching a peak between 0600 and 0900 h, declining through the day, to a nadir between 2300 and 0200 h, and beginning to rise again at about 0200–0300 h (Veldhuis *et al.*, 1990) This rhythm usually appears after the first year of life but may not be established until the age of 8 years. Normal children between the ages of 1 year and 16 years do not differ from adults in ACTH, β-endorphin and cortisol responses to CRH, and the responses of boys do not differ from girls. Reversal of the normal asleep–awake patterns, as occurs when an individual moves to a distant time zone, is followed by a corresponding change in the diurnal pattern of ACTH secretion over the course of 2–3 weeks (Desir *et al.*, 1981).

Feeding Cycles

Cortisol is well known to rise after eating but not after parenteral feeding. This has been shown in studies to be provoked by two mechanisms: (i) by direct stimulation of the HPA axis; and (ii) via regeneration of cortisone to cortisol by stimulation of 11β-hydroxysteroid dehydrogenase type 1 (11βHSD1). There appear to be key differences not only between the effects of individual macronutrients, but also between the gut hormones which are released in response to enteral nutrients (Quigley and Yen, 1979; Follenius *et al.*, 1982; Stimson *et al.*, 2014).

Open-Loop Control (Stress)

The open-loop component of ACTH control may be initiated by noxious stimuli of various sorts, all of which represent types of physical or emotional stress, such as pain, fever, trauma, hypoglycemia, hypoxia, surgery, anxiety, and depression. All of these stimuli stimulate the secretion of ACTH via the release of CRH. Corticotropin-releasing hormone and AVP are probably the two major physiologic secretagogues of hypophyseal ACTH. Immunoreactive CRH is found in the human hypothalamus in the paraventricular, supraoptic, and infundibular nuclei and also in the human thalamus, cortex, cerebellum, and pons. However, most human CRH-secreting neurons are located in the anterior portion of the paraventricular nucleus and their nerve endings project to the external layer of the median eminence, where CRH is released into the portal hypophyseal circulation. Besides stimulating POMC transcription and ACTH biogenesis, CRH stimulates the release of ACTH, leading to a biphasic response with the fast release of a pre-synthesized pool of ACTH, and the slower and sustained release of newly synthesised ACTH (DeBold *et al.*, 1983). The same neuronal bodies in the paraventricular nucleus also produce AVP. These AVP neurons are probably the most important in vasopressin control of ACTH release, but the major site of vasopressin neurons is the supraoptic nucleus. These vasopressin neurons are usually of the magnocellular type and most of them project to the neural lobe.

There is strong evidence that both α- and β-adrenergic stimuli, cytokines, other hormones (angiotensin II, oxytocin), VIP, ANP, GH secretagogues (e.g. ghrelin, hexarelin, GHRH, GH releasing peptide2-) opiates, as well as the endocannabinoid system are involved in the regulation of ACTH secretion (Mesiano *et al.*, 1991). During infection, autoimmune processes, or trauma, a complex cascade of events ensues, characterized by fever, circulation of cytokines, and alterations in acute-phase proteins in plasma that are important to initiate, propagate, and terminate host defense mechanisms. In addition, it has been known for several decades that activation of the hypothalamic–pituitary–adrenal (HPA) axis occurs in parallel. It has become apparent that several mediators of inflammation play a major role in this phenomenon. Among all cytokines, three tumor necrosis factor (TNF), interleukin (IL)-1 and IL-6 are responsible for most of the stimulation of the HPA axis that is associated with the immune/inflammatory response (Chrousos, 1995; Mastorakos *et al.*, 1993). These three cytokines are produced at inflammatory sites and elsewhere in response to inflammation. Tumor necrosis factor, which has a tumoricidal activity and is responsible for cachexia, is the first to appear in the inflammatory cascade of the events and stimulates both IL-1 and IL-6; similarly, IL-1 stimulates both TNF and IL-6. In contrast, IL-6, which participates in a major fashion in the acute-phase reaction, inhibits the secretion of both of the other cytokines. All three inflammatory cytokines have been shown to activate the HPA axis, that is, ACTH secretion in vivo, alone or in synergy with one another. This effect can be blocked significantly with CRH neutralizing antibodies, glucocorticoids, and prostanoid synthesis inhibitors. When administered to humans, both IL-1 and TNF have significant toxicity, including fever, general malaise, and hypotension, at the doses needed to activate the HPA axis. In the past, it has been demonstrated that IL-6,

with its ability to inhibit the two other inflammatory cytokines and its modest toxicity in experimental animals, was a potent stimulator of the HPA axis in humans, causing an impressively marked and prolonged elevation of plasma ACTH and cortisol when administered either subcutaneously or intravenously. The elevations of ACTH and cortisol attained after stimulation with IL-6 were well above those observed with maximal stimulatory doses of CRH, suggesting that parvocellular AVP and other ACTH secretagogues were also stimulated by this cytokine. In a dose–response study, maximal levels of ACTH were seen at doses at which no peripheral AVP levels were increased. At higher doses, however, IL-6 stimulated peripheral elevations of AVP, indicating that this cytokine might also be able to activate magnocellular AVP secreting neurons. This suggested that IL-6 might be involved in the genesis of the syndrome of inappropriate secretion of antidiuretic hormone, which is observed in the course of infectious or inflammatory diseases or during trauma. It has been shown that IL-6, in patients suffering head trauma (an aseptic inflammatory state) and presenting with syndrome of inappropriate secretion of AVP, is quantitatively correlated with AVP. In addition to their hypothalamic effects, the inflammatory cytokines can apparently directly stimulate pituitary ACTH and adrenal cortisol secretion. This may be related to the chronicity of the elevation of the inflammatory cytokines or may be a dose related phenomenon. It is noteworthy that IL-1 and IL-6 are themselves produced in the anterior pituitary and adrenal glands, where they may have autocrine/paracrine effects (Mastorakos *et al.*, 1994; Gionis *et al.*, 2003; Crofford *et al.*, 1997).

Finally it should be stated that cells of the immune system produce CRH, ACTH and endorphins. Releasing hormones and cytokines interact to stimulate ACTH production from immune cells. A feedback loop exists between immune and neuroendocrine systems. Cytokines released by immune cells stimulate secretion of ACTH and glucocorticoids which are active against infection. Subsequently these hormones suppress synthesis of cytokines (Tanaka *et al.*, 1978).

Closed-Loop Feedback

The negative feedback control of ACTH secretion is mediated by cortisol, which exerts inhibitory effects on both the central nervous system and the pituitary. Negative feedback occurs via three mechanisms: (1) fast feedback, which is sensitive to changes in the levels of circulating cortisol, (2) intermediate feedback, and (3) slow feedback, which is sensitive to the absolute cortisol level. Increased concentrations of glucocorticoids accelerate the progression from fast to slow feedback. Fast feedback occurs within seconds to minutes and involves inhibition of CRH-stimulated ACTH and CRH release, not synthesis, and occurs during the period when plasma glucocorticoids are increasing. It doesn't involve protein synthesis and it appears there is some involvement of the endocannabinoid system (Di *et al.*, 2003). Cortisol given to patients at the start of surgery attenuates the surgery induced ACTH rise, and may be an example of fast feedback. Intermediate feedback is due to inhibition of ACTH release but not synthesis, and may be important after short duration of exposure to glucocorticoids or after non continuous, repeated exposure. It develops after 45–20 min, and maximal inhibition occurs 2–4 h after administration of one dose of glucocorticoid. Unlike ACTH, CRH synthesis as well as release may be affected by intermediate feedback. Slow feedback is most important after long exposure to a moderately high dose of glucocorticoid and is a function of the total dose of glucocorticoids, the glucocorticoid level achieved, and the amount of time since the steroid was given. It occurs after more than 24 h of exposure to glucocorticoids and can persist for days. POMC biosynthesis is inhibited leading to inhibition of basal and stimulated ACTH secretion, and intracellular ACTH decreases implying decreased synthesis. Cortisol modulates the responsiveness of the pituitary. The corticotroph is dependent on CRH stimulation to maintain ACTH secretion while glucocorticoids suppress CRH induced ACTH secretion in vivo and in vitro. On the other hand when endogenous cortisol levels are suppressed by metyrapone, basal ACTH and CRH-induced ACTH release is increased. Glucocorticoid inhibition of ACTH secretion from the corticotroph may recover more quickly than CRH secretion from the hypothalamus. Secondary adrenal insufficiency due to long term glucocorticoid therapy may in part be due to continued suppression of hypothalamic CRH secretion. Adrenalectomized patients on exogenous glucocorticoid therapy have a blunted ACTH response to CRH that normalizes after several CRH boluses, suggesting the lack of stimulation of the corticotroph by the CRH suppresses the ACTH response. On the other hand, corticotrophs of patients recovering from trans-sphenoidal surgery for Cushing's disease are profoundly unresponsive to CRH, which cannot be attributed solely to deficient CRH priming. Glucocorticoids decrease the hypothalamic content of CRH and AVP although the sensitivity of CRH and AVP transcription to glucocorticoid feedback is markedly different. Additionally there is evidence that ACTH can inhibit CRH synthesis, and β-endorphin levels, in patients with Addison's disease or hypopituitarism, but not in the context of normal human subjects, suggesting that ACTH inhibits CRH secretion.

Action of ACTH

The adrenal cortex is the principal target organ for ACTH. ACTH stimulates the synthesis and release of steroids by binding to high-affinity plasma membrane receptors of adrenocortical cells. The ACTH–receptor interaction then activates adenyl cyclase and therefore stimulates the production of intracellular cyclic AMP (cAMP). Once formed the cAMP activates a number of intracellular phosphoprotein kinases that mediate both acute and chronic effects on steroidogenesis.

Acute and Chronic Actions of ACTH

ACTH stimulates the synthesis and release of cortisol within 2–3 min by increasing free cholesterol formation as a consequence of increased cholesterol esterase activity and decreased cholesteryl ester synthetase activity. ACTH rapidly promotes the transport of

cholesterol across the mitochondrial membranes, facilitates the binding of cholesterol to the cytochrome P450scc, and facilitates the release of newly synthesized pregnenolone from the mitochondria. ACTH also stimulates the release of adrenal mineralocorticoids and androgens, as well as the release of various intermediate products. Chronic actions of ACTH are exerted on both adrenal architecture and steroidogenesis. ACTH chronically stimulates low-density lipoprotein (LDL) uptake and metabolism and the synthesis of the LDL receptor and of other factors, so it has tropic effects on all known early steps in steroidogenesis. Chronic effects of ACTH on steroidogenesis occur mainly by promoting the transcription of the genes that encode steroidogenic enzymes and other factors. ACTH increases the transcription of the genes for P450scc, P450c17, P450c21, and P450c11 and stimulates the accumulation of human P450scc mRNA and human P450scc activity. The exact mechanisms of ACTH stimulation of the side-chain cleavage enzyme P450scc remain to be elucidated. In addition to its prominent role in regulating steroidogenesis ACTH has profound trophic effects upon the adrenal. Its role in adrenocortical mitogenesis and hyperplasia is not well understood. ACTH at physiologic concentrations can promote the synthesis of insulin-like growth factor-2 (IGF-2) and also the synthesis of basic fibroblast growth factor and epidermal growth factor, which may act with IGF-2 to stimulate adrenal growth. As far as the presence of ACTH receptor outside the adrenal gland it should be noted that it is also expressed elsewhere in the body, specifically in the osteoblast, which is responsible for making new bone. It has been demonstrated that the response of bone forming cells to ACTH includes production of VEGF, as it does in the adrenal. This response might be important in maintaining osteoblast survival under some conditions (Zhong *et al.*, 2005; Zaidi *et al.*, 2010).

Aging of HPA Axis

Studies in humans and experimental animals have shown evidence that hyperactivity of the HPA axis contributes to neuronal and peripheral deterioration associated with aging. High basal levels of glucocorticoids and loss of circadian rhythm have been associated with greater cognitive decline at a given age. Aging is associated with high basal levels circulating corticosteroids, although there is not always a correlation between plasma ACTH and corticosteroids. In addition, there is also an alteration to the circadian rhythm of the HPA axis, as demonstrated by studies using a feeding-associated circadian rhythm paradigm. This suggests that the aged HPA axis appears to take longer to adjust to changes in circadian rhythm, but such adjustments do not 'stick' as well as compared to the younger HPA axis.

Extensive studies reveal that the effects of age on the HPA axis are modulated by obesity and sex and the type of stress activating the system.

Controversy exists regarding unstressed mean ACTH concentrations, which are reportedly unchanged across the age span of 20–100 years, decreased with age or increased with age. Comorbidities, assay nonuniformities and sampling inconsistencies may, in part, explain the discrepant reports. Similar uncertainty applies to plasma, urinary or salivary (free) cortisol concentrations in aging individuals. Intra-abdominal adipose tissue mass is a major confounder of ACTH and/or cortisol output with high intra-abdominal adipose tissue mass predicting increased sympathetic outflow, cortisol production and cortisol inactivation, and (in women) increased mean ACTH concentrations.

Aging is also associated with increase in expression of 11βHSD1 both in brain and peripheral tissues. Such changes could conceivably expose tissues to elevated levels of glucocorticoids and contribute to an aging process.

The effects of aging on CRH regulation and whether CRH influences the course of aging are still unclear. Studies have reported increased, unchanged or reduced hypothalamic CRH release and expression during aging (Swaab *et al.*, 2005; Ferrari and Magri, 2008; Aguilera, 2011; Kasckow *et al.*, 2001; Tizabi *et al.*, 1992; Lupien *et al.*, 1996; Linkowski *et al.*, 1993; Franz *et al.*, 2010; Cooper, 2008; Holmes *et al.*, 2010; Blichert-Toft and Hummer, 1977; Sherman *et al.*, 1985; Haus *et al.*, 1989; Purnell *et al.*, 2004; Van Cauter *et al.*, 1996; Andrew *et al.*, 1998; Roelfsema *et al.*, 2012).

Introduction

The adrenal gland is a multilayer endocrine organ that impacts the body's physiologic response to stress and immune system through the production of cortisol and water balance and systemic blood pressure via aldosterone. The adrenal gland does not store steroid hormones and the production kinetics of the steroid products vary depending on the stimuli. Cortisol is produced within seconds of hormonal or sympathetic signaling, while aldosterone exhibits a delayed and steady rise that is secondary to the complex renin–angiotensin–aldosterone activating system. The adrenals also produce dehydroepiandrosterone (DHEA) and its sulfonated form DHEA-S, which are the most abundant adrenal steroids, via the sulfotransferase SULT2A1. The adrenal gland is also responsible for a small percentage of the body's testosterone, which is derived from the precursor androstenedione.

The Gonadal and Adrenal Gland Share a Common Developmental Origin

Adrenal and gonadal biogenesis of steroid hormones can be traced to a common developmental origin in the intermediate mesoderm. Early in development, around the 4 week of gestation, the adrenogenital primordium gives rise to the bipotential gonad, a precursor of the testes and ovary (Hanley *et al.*, 2001). Soon after, a group of adrenal progenitors can be identified by their expression of the steroidogenic factor (SF)-1, an essential transcription factor driving the expression of the steroidogenic machinery (Hatano *et al.*, 1996). These cells develop from the dorsal aortal side of the adrenogenital primordium around the 8 week of gestation and expand into a large mass of cells referred to as the definitive zone (DF) (Hammer *et al.*, 2005). In humans, there is an additional layer of inner cells known as the fetal zone (FZ) that express CYP17A1 but lack 3β-hydroxysteroid dehydrogenase (3β-HSD) expression (Mesiano and Jaffe, 1997). Development of the definitive zone is followed by the migration of chromaffin cells, which are of neural crest origin, as well as by encapsulation. Soon after birth, the fetal adrenal gland undergoes cell zonation where chromaffin cells are compacted into a rudimentary medulla and the definitive zone starts to give rise to the outer zona glomerulosa (ZG), the zona fasciculata (ZF), and the inner zona reticularis (ZR). In rodents, there is a transient cell layer known as the X zone that develops between the ZF and ZR. These cells disappear when males reach puberty and after females undergo their first pregnancy (Holmes and Dickson, 1971).

Adrenal Gland Steroidogenesis is Initiated by G-Coupled Receptor Activation or Changes in Extracellular Potassium Levels

In the human adrenal gland, the tissue-specific expression of steroidogenic enzymes produces aldosterone in the ZG, cortisol in the ZF, as well as DHEA and DHEA-S. The cellular mechanisms that initiate steroid biosynthesis are specific to the adrenal cortex layer (**Fig. 1**). In the

 doi:10.1016/B978-0-12-801238-3.66177-9

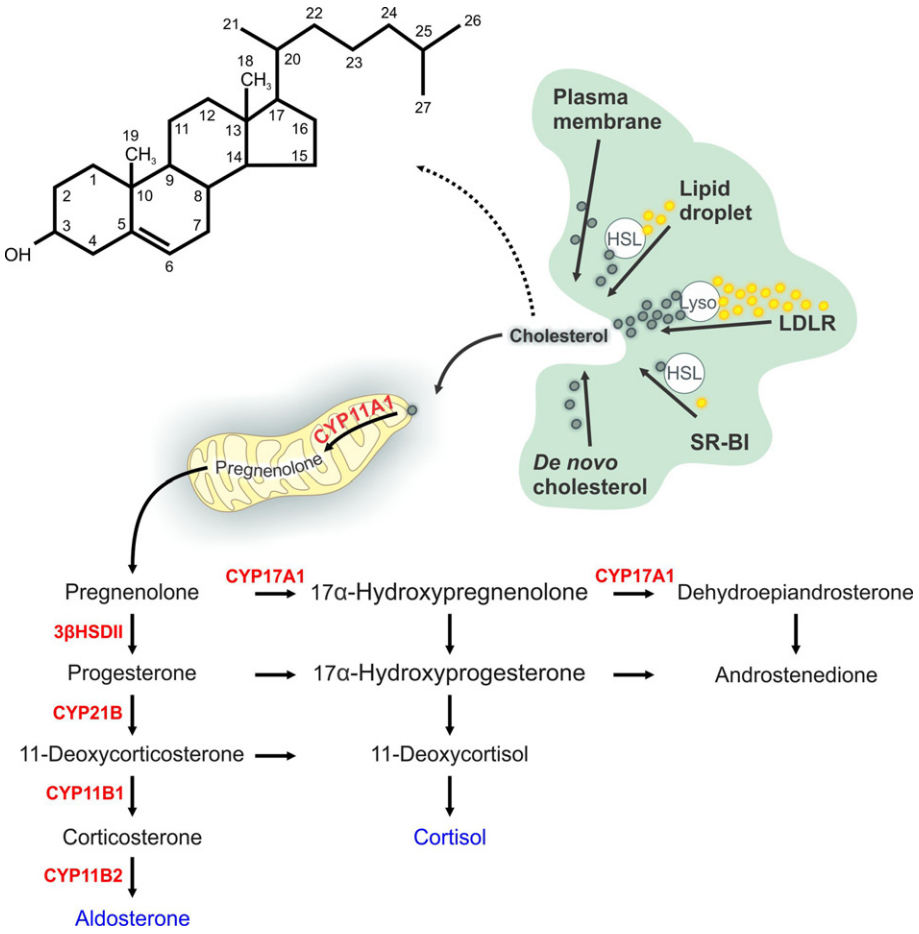

Fig. 1 The steroidogenic pathway. Cholesterol for steroidogenesis is harvested from extra- and intra-cellular sources. LDL-mediated import of cholesterol is the preferred source in humans. HDL (through the SR-BI pathway) and lipid droplets contain esterified cholesterol (*yellow*) that can be used in steroidogenesis after de-esterification (*green*) via hormone-sensitive lipase (HSL). Cholesterol is then imported to the inner mitochondria membrane where CYP11A1 cleaves the side chain of cholesterol. Thereafter, the tissue-specific expression of CYPs enzymes and 3β-HSDII result in the formation of aldosterone, cortisol, and dehydroepiandrosterone. The numbering of the carbons of cholesterol indicate the various reaction sites.

ZG, aldosterone production is stimulated by numerous molecules; however, angiotensin II, potassium, and adrenocorticotropic hormone (ACTH) have the most physiological relevance (Spat and Hunyady, 2004). The ZG expresses the angiotensin II type I receptor, which is part of the renin–angiotensin system that maintains blood pressure and water balance. The ZG also strongly expresses TWIK-related acid-sensitive potassium channels TASK1 and TASK3, two-pore domain potassium channels that detect changes in circulating potassium levels (Bandulik *et al.*, 2010). TASK1, which is also found in the ZF and ZR, appears to be involved in adrenal development since its deletion results in hyperaldosteronism and altered adrenal zonation (Heitzmann *et al.*, 2008). The ACTH receptor is expressed throughout the adrenal cortex and mediates the biosynthesis of glucocorticoids and androgens in the ZF and ZR (Gill, 1976). Ligand-mediated activation of these receptors and changes in extracellular potassium levels stimulate the release of second messengers that initiate cholesterol mobilization and prime the mitochondria for steroidogenesis.

Cholesterol is the Substrate for All Steroid Hormones

Steroid hormones are produced from the common building block, cholesterol (Payne and Hales, 2004). Cholesterol for steroid biosynthesis can be obtained from extracellular or intracellular sources or can be synthesized de novo. The preferred sources of cholesterol are tissue-specific; here we will focus on pathways preferred by the adrenal gland.

Extracellular cholesterol can be imported into the cell by the low-density lipoprotein (LDL) or scavenger receptor class BI (SR-BI) pathways (Kraemer, 2007). The LDL pathway internalizes lipoproteins containing apolipoprotein B or E and transports esterified cholesterol that is then hydrolyzed by liposomal acid lipase into unesterified cholesterol. The free cholesterol can then be used for steroidogenesis or re-esterified and stored in lipid droplets by acyl CoA:cholesterol acyltransferase encoded by the *ACAT1* gene. In humans, dietary cholesterol that is transported via LDL is the main source of cholesterol (Ikonen, 2006). This is contrary

to rodents where the SR-BI pathway mediates the uptake of high-density lipoprotein (HDL)-bound lipids (Connelly and Williams, 2003) and is the main source of cholesterol for adrenal steroid biosynthesis. Esterified cholesterol delivered by this pathway is de-esterified by the hydrolase action of the hormone-sensitive lipase (HSL) encoded by the *LIPE* gene (Kraemer and Shen, 2002). HSL is responsible for 90% of the cholesterol ester hydrolysis activity in the adrenal gland (Kraemer *et al.*, 2004). Lipid droplets also contain esterified cholesterol and require HSL function to provide free cholesterol to sustain steroidogenesis.

De novo cholesterol synthesis starts by combining acetyl CoA and acetoacetyl CoA precursors into 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) in a reaction catalyzed by HMG-CoA synthase. This is followed by the rate-limiting step in de novo cholesterol biosynthesis, the production of mevalonate catalyzed by the enzyme HMG-CoA reductase, which is the target of statin drugs (Lennernas and Fager, 1997). HMG-CoA reductase function is negatively regulated when LDL is in adequate supply and is stimulated by ACTH (Fluck and Miller, 2008). Although de novo cholesterol biosynthesis may help maintain adrenal gland steroidogenesis, studies have shown that lipoprotein-bound cholesterol is the primary source of cholesterol for normal adrenal steroidogenesis (Verschoor-Klootwyk *et al.*, 1982).

The Transport of Cholesterol Into the Mitochondria is the Rate-Limiting Step in Steroid Biosynthesis

The rate-limiting site of steroid biosynthesis occurs during the translocation of cholesterol into the mitochondria where pregnenolone is produced. Upon activation of the cellular mechanism for steroidogenesis, cholesterol transport to the mitochondria is aided by the steroidogenic acute regulatory protein (STAR), encoded as a 37 kDa preprotein by the *STARD1* gene located in Chromosome 8p11. Interestingly, dormant *Star* mRNA is transcribed soon after steroidogenic cell activation through the PKA and ERK kinase signaling pathways (Duarte *et al.*, 2014). STAR is directed into the mitochondria by a cellular targeting sequence, where it is cleaved into an inactive 30 kDa protein (Bose *et al.*, 2002). The presence of STAR is essential for adrenal steroidogenesis since mouse knockout studies and humans with STAR mutations exhibit an inability to produce sufficient levels of steroids (Baquedano *et al.*, 2013).

Other proteins involved in the translocation of cholesterol into the mitochondria are collectively found in a large multiprotein complex (Rone *et al.*, 2014). At the outer mitochondrial membrane (OMM), this complex is composed of the cytoplasmic proteins acyl-CoA binding domain 1 (ACBD1), ACBD3, STAR and cAMP-dependent protein kinase (PKA); the OMM proteins, translocator protein (TSPO) and voltage-dependent anion channel (VDAC); and CYP11A1 located in the inner mitochondria membrane (IMM) (Midzak and Papadopoulos, 2016). Moreover, cholesterol entry into the IMM is also helped by the formation of contact points between the OMM and IMM that increase the hydrophobic medium in which cholesterol travels. The presence in this bioactive complex of the IMM protein AAA+ ATPase domain 3 (ATAD3), which extends through the OMM to the endoplasmic reticulum, forming mitochondria-associated membrane bridges, supports the concept of a protein–protein interaction-mediated transfer of cholesterol across membranes to CYP11A1 in the IMM (Issop *et al.*, 2015). The presence of TSPO seems to be essential for ACTH-induced steroid production, since TSPO knockout studies, mutations in rodents and a human polymorphism impair the rate of adrenal steroid synthesis (Fan *et al.*, 2015; Owen *et al.*, 2017).

The Cytochrome P450s and the Hydroxysteroid Dehydrogenases Catalyze Formation of Steroid Hormones From Cholesterol

Adrenal steroid biosynthesis is carried out by two main families of enzymes, the cytochrome P450s (CYP) and the hydroxysteroid dehydrogenases (HSD). CYP enzymes are identified by their ability to absorb light in their reduced form at 450 nm and the presence of a heme prosthetic group that is critical in mediating the oxygenation of the target protein (Midzak and Papadopoulos, 2016). In humans, 5 out of the 57 genes coding for CYP enzymes play a role in adrenal steroid biosynthesis. CYP11A1, CYP11B1, and CYP11B2 are localized in the mitochondria, while CYP17A1 and CYP21A2 are found in the endoplasmic reticulum. The HSDs can be generally divided into dehydrogenases or reductases. These enzymes need cofactors: NAD+ is used by dehydrogenases to oxidize hydroxysteroids to ketosteroids, and the reductases use NADPH to catalyze the reverse reaction (Agarwal and Auchus, 2005). 3β-HSD, 17HSD3, and 17HSD1 are all involved in steroid biosynthesis. Interestingly, CYP enzymes are coded from a single gene, while the HSDs have many isoforms (gene splicing generates various enzyme versions) or isozymes (many genes code for the same enzyme) that modify their cellular distribution and affinity for cofactors and substrates (Payne and Hales, 2004). Together, the CYP and HSD enzymes cleave and modify cholesterol to yield more oxygenated and hydrophilic cholesterol derivatives that give rise to a group of highly versatile hormones (**Fig. 2**).

CYP11A1 Catalyzes the First Step in Steroid Hormone Formation

CYP11A1 is a 9-exon gene located on Chromosome 15q23 that codes for a highly conserved 56 kDa protein highly expressed in all the layers of the adrenal cortex. The amino terminus contains a 39 amino acid mitochondrial targeting sequence that positions the protein in the inner mitochondrial matrix, where it receives and cleaves the aliphatic side chain of newly translocated cholesterol. Cloning studies where CYP11A1 was directed to other cellular compartments revealed that both mitochondrial positioning and interaction with its microenvironment are essential for the enzyme to function (Black *et al.*, 1994). CYP11A1 is the only enzyme that can carry out this function and is commonly used as a marker to identify steroidogenic cells. CYP11A1 is the slowest enzyme

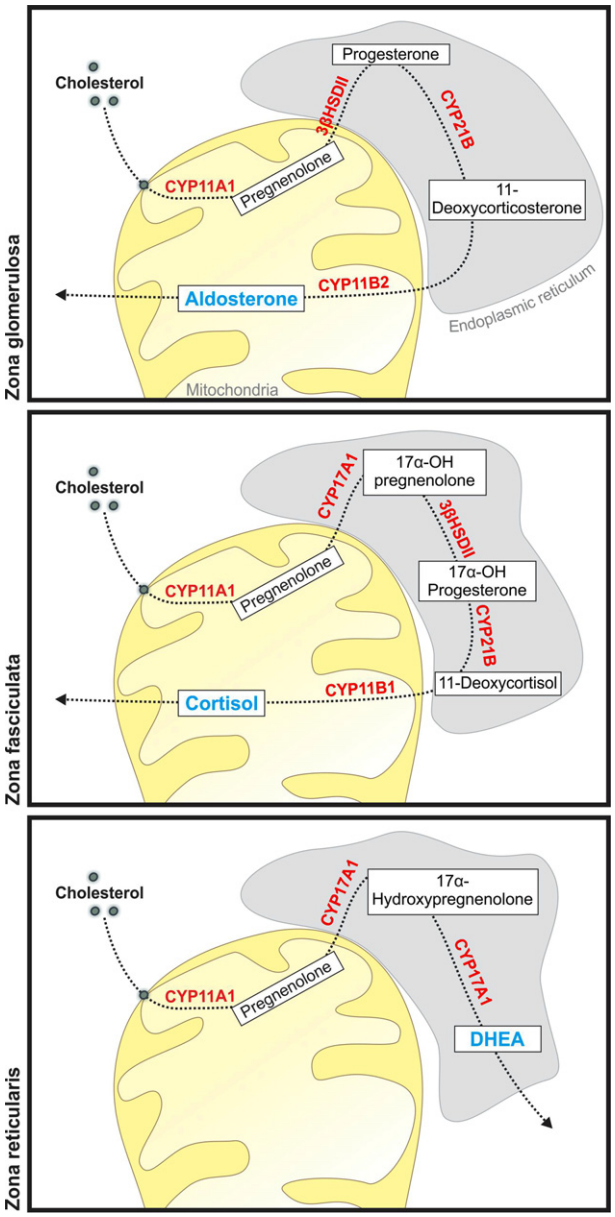

Fig. 2 Steroid production in human in the adrenal cortex. The figure depicts the enzymes, steroid intermediates, and end products at the zona glomerulosa, zona fasciculata, and zona reticularis. DHEA = dehydroepiandrosterone.

of the pathway, with each protein cleaving 6.2 molecules of cholesterol per minute (Kuwada *et al.*, 1991). The slow kinetics and the non-replaceable function of CYP11A1 make this the rate-limiting enzyme in steroidogenesis, and its protein levels have a direct correlation with steroidogenic activity of the cell.

CYP11A1 carries out three oxidation reactions, a C22 and C20 hydroxylation that yields 20,22 hydroxycholesterol followed by a cleavage between the hydroxylation sites, with each of the reactions needing an oxygen and a NADPH molecule. The transfer of electrons between NADPH and CYP11A1 is facilitated by ferredoxin reductase that harvests electrons from NADPH and passes them to ferredoxin, which in turn, shuttles electrons to the ferrous ion of CYP11A1. The resulting products are the C21 steroid pregnenolone and isocaproaldehyde. Isocaproaldehyde is a reactive molecule that is subsequently oxidized to isocaproic acid.

CYP17A1 is the Branching Point of the Adrenal Steroidogenic Pathway

CYP17A1 is on Chromosome 15q23 and codes a 57 kDa enzyme that catalyzes two oxidase reactions resulting in a hydroxylation and a cleavage (lyase activity). The zone-specific expression of CYP17A1 commits it to the production of cortisol, DHEA and

DHEAS in the ZF and ZR, while the absence of CYP17A1 in the ZG leads to aldosterone biosynthesis. Newly formed pregnenolone can either be metabolized to progesterone by 3β-HSD (Δ^4 pathway) or to 17α-hydroxypregnenolone by CYP17A1 (Δ^5 pathway). In humans, the Δ^5 pathway is preferred, while rodents follow the Δ^4 pathway, since they lack adrenal CYP17A1 expression. The species-specific absence of CYP17A1 expression means that rodents produce corticosterone instead of cortisol as their main corticosteroid and lack DHEA and DHEA-S biosynthesis.

CYP17A1 can use pregnenolone or progesterone as a substrate. In the Δ^5 pathway, pregnenolone is first hydroxylated at C17 yielding 17α-hydroxypregnenolone, followed by a cleavage reaction between C17 and C20 that results in C19 DHEA and acetaldehyde. In the Δ^4 pathway, progesterone is converted to 17α-hydroxyprogesterone, and in a follow up lyase reaction, C19 androstenedione is generated, with each reaction consuming oxygen and an NADPH molecule. While the Δ^4 pathway yields C19 androstenedione, it is not a significant source of androgens, since the Δ^5 pathway is more efficient in humans.

CYP17A1 is localized in the endoplasmic reticulum and needs flavoprotein P450 oxidoreductase (POR) to carry out its function. POR is a flavoprotein that moves two electrons from NADPH to CYP17A1. Moreover, the lyase activity of CYP17A1 is promoted by the allosteric cofactor cytochrome *b*5, which is positioned between POR and CYP17A1, and the phosphorylation of CYP17A1 serine residues (Auchus *et al.*, 1998).

3β-Hydroxysteroid Dehydrogenase

3β-HSDII is a 42 kDa protein expressed in the adrenal cortex, ovary, and testes and catalyzes the formation of progesterone from pregnenolone. In addition, 3β-HSDII can take 17α-hydroxypregnenolone and dehydroepiandrosterone from the Δ^5 pathway and convert them to 17α-hydroxyprogesterone and androstenedione, respectively, as previously discussed.

Several isoforms of 3β-HSD exist resulting in variations in tissue protein expression, activity, and affinity for substrates and cofactors. In the human, *HSD3B2* is a four-exon gene located on Chromosome 1p13.1 and expresses 3β-HSD type II in the adrenal cortex. It is important to note that the numeric nomenclature between humans and rodents is not indicative of an orthologue gene, and thus, the orthologue gene in the mouse for human *HSD3B2* is *Hsd3b1*, which codes for 3β-HSDI (Payne and Hales, 2004).

3β-HSDII carries out its reaction in a two-step process. First, the dehydrogenation of 3β-hydroxysteroid uses NAD^+ to generate a 3-keto intermediate and NADH. This is followed by the isomerization of the Δ^5-3-ketosteroid to form Δ^4-3-ketosteroid, where the reduced NADH propels the reaction forward.

Expression of 3β-HSDII in the fetal adrenal gland was reported to start after week 23 of gestation with expression mostly in the transitional zone and the definitive zone (Narasaka *et al.*, 2001). The lack of expression of 3β-HSDII correlates with the inability of fetal cells to produce glucocorticoids or mineralocorticoids during early gestation.

CYP21

CYP21B is a 10-exon gene found on Chromosome 6p21.3 and codes for a 56 kDa protein that is highly expressed in the ZG and ZF. *CYP21A*, which has high homology with *CYP21B*, is also expressed in humans but various deletions and insertions prevent the synthesis of a mature protein (Rodrigues *et al.*, 1987). The mouse has similar duplicated genes but, unlike the human, *Cyp21a* is the gene that expresses a mature protein (Parker *et al.*, 1986).

CYP21 places a hydroxyl group at carbon 21 of progesterone and 17α-hydroxyprogesterone to produce 11-deoxycorticosterone and 11-deoxycortisol, respectively. This reaction consumes oxygen and NADPH. Of clinical interest, most of the congenital adrenal hyperplasia cases are related to defects in CYP21 (Fluck and Miller, 2008).

CYP11B1 and CYP11B2 are Highly Homologous But Carry Independent Reactions

CYP11B1 is located on Chromosome 8q21 and produces a 50 kDa protein expressed mainly in the ZF and ZR. CYP11B1 carries out the 11β-hydroxylation of C11 of 11-deoxycorticosterone and 11-deoxycortisol to synthesize corticosterone and cortisol, respectively.

CYP11B2, aldosterone synthase, is located adjacent to *CYP11B1* on Chromosome 8q21-q22 and codes for a 48.5 kDa protein exclusively expressed in the ZG. This enzyme catalyzes three reactions, taking in 11-deoxycorticosterone and yielding aldosterone, with each of the reactions consuming oxygen, an NADPH molecule, and using the electron transport system (Payne and Hales, 2004). First, 11-deoxycoticosterone is 11β-hydroxylated to corticosterone, followed by a second hydroxylation at C18 to yield 18-hydroxycorticosterone. The third reaction oxidizes C18 resulting in aldosterone. It is important to note that CYP11B2 carries out this reaction only starting from 11-deoxycorticosterone, since studies have shown that corticosterone is not a substrate for this enzyme (Kawamoto *et al.*, 1992). This is reflected in the clinic where patients with CYP11B1 deficiencies produce aldosterone but not cortisol, while patients with CYP11B2 deficiencies, synthetize cortisol but lack aldosterone biosynthesis (Zhang *et al.*, 1995).

CYP11B1 and CYP11B2 use ferredoxin/ferredoxin reductase electron transport and consume oxygen and NADPH during each of the reactions catalyzed. Both enzymes share 95% identity and are directed to the inner mitochondria membrane by a targeting

sequence that is cleaved upon mitochondrial entry (White *et al.*, 1994). Moreover, expression levels of CYP11B1 are significantly higher than CYP11B2. Gene regulation of these enzymes are part of an endocrine feedback loop where ACTH increases CYP11B1 expression, and ATII and potassium levels stimulate CYP11B2 expression (Clyne *et al.*, 1997; Nanba *et al.*, 2015). Glucocorticoids, on the contrary, decrease CYP11B1 expression.

The SULT Enzymes Catalyze the Sulfation of Steroids

Steroid hormones can be sulfonated by the sulfotransferase (SULT) enzyme superfamily. These enzymes are all cytoplasmic, and SULT1A, SULT2A1, and SULT2B1 are known to sulfonate steroids. SULT2A1 is expressed in the adrenal gland and catalyzes the sulfonation of 3β-hydroxyl group of pregnenolone, 17α-hydroxypregnenolone, dehydroepiandrosterone, and androstenedione.

11β-Dehydrogenases are Expressed in Peripheral Tissues and Confer Steroid Selectivity

11β-HSD1 and 11β-HSD2 are two enzymes that depend on the presence of $NADP^+$ or NADPH to carry out their reductase or oxidase function. Both enzymes can catalyze the interconversion between cortisol and cortisone, a less active corticosteroid, with the different kinetics dictated by their affinity for the substrate. 11β-HSD1 has micromolar affinity while 11β-HSD2 has low nanomolar affinity for glucocorticoids (Takeyama *et al.*, 2000). This difference in substrate affinity results in inactivation of glucocorticoids in tissues that express 11β-HSD2 and the mineralocorticoid receptor (MR), which shares a similar affinity for glucocorticoids and mineralocorticoids, and thus, allows for selective binding of aldosterone and 11-deoxycorticosterone. The protective effect of 11β-HSD1 and 11β-HSD2 against glucocorticoids is also seen in the placenta and in fetal tissues, where both enzymes work to inactivate maternal glucocorticoids (Hirasawa *et al.*, 1999). In other tissues, like the liver, were selective MR activation is not desired, the 11β-HSD1 expression is thought to protect against excessive levels of glucocorticoids.

Other Steroidogenic Enzymes

While 17HSD3, 17HSD1, CYP19A1, and 5α-reductase do not play a role directly in adrenal steroid formation, they are involved in steroid biology. 17HSD3 is expressed in the testes and uses DHEA and androstenedione as a substrate to yield androstenediol and testosterone, respectively. CYP19A1, aromatase, is a 58 kDa protein that catalyzes the aromatization of testosterone into 17β-estradiol, which is the main steroid generated by the Leydig cells. Moreover, CYP19A1 can also convert androstenedione to estrone. 5α-Reductase increases the potency of testosterone several folds. This enzyme is expressed in peripheral tissues.

Mutations in Enzymes or Proteins Lead to Steroid Deficiency

Adrenal hyperplasia and lipoid adrenal hyperplasia are two histopathological findings in adrenal diseases arising from genetic errors in the enzymes or proteins involved in steroidogenesis. Congenital adrenal hyperplasia (CAH) groups together various recessive disorders that arise most commonly from steroidogenic enzyme mutations. The reduced enzymatic performance or, in some cases, enzyme inactivation halts the progression of steroid biosynthesis. Since steroidogenesis is tightly regulated, feedback loops triggered by the lack of end-products result in adrenal cortex overstimulation. This increased intracellular signaling is the root of the histopathological findings and is responsible for adrenal hypertrophy and lipid accumulation. Newborns show symptoms soon after birth, where the prompt diagnosis is critical to avoid possible life-threatening complications.

Mutations/deletions in the enzymes and proteins involved in steroidogenesis will have a wide gamut of outcomes depending on the severity of the modification. Moreover, the existence of a back door pathway and other CYPs that may metabolize intermediates to a certain degree may account for detectable levels of steroids even where there are inactivating mutations of enzymes (Auchus, 2004). In addition, steroidogenesis may also be affected by disorders that target the intracellular regulation and movement of cholesterol (Miller, 2017).

Steroidogenic Enzymes

The most frequent cause of CAH is a deficiency of CYP21 (90% of CAH) with an incidence of 1:14,000, followed by 11β-HSD (5% of CAH) with an incidence of $\sim$1:100,000 (Therrell *et al.*, 1998). The lack of CYP21 shunts steroidogenic biosynthesis away from the production of cortisol and aldosterone, which are exclusively produced in the adrenal cortex. The resulting decrease in cortisol triggers a feedback loop that increases the levels of ACTH, which results in the increase production of the androgen precursors DEHA, DHEAS, and androstenedione. Ultimately, the levels of testosterone, and the more potent DHT, increase and contribute to the pathology. In females, this condition is suspected by signs of virilization at birth, while the diagnosis in males maybe delayed until the onset of additional symptoms originating from the loss of cortisol and aldosterone (Hanley and Arlt, 2006). In severe

cases where the levels of aldosterone and corticosterone are below those needed to sustain physiological function, the newborn will exhibit signs and symptoms of salt-wasting accompanied by vomiting, lethargy, and failure to thrive perinatally. Various degrees of symptomatology can be observed in the clinic that correlates with the impact on enzyme kinetics by the mutation (Fluck and Miller, 2008).

CYP11A1 is the first and most common enzyme in all the steroidogenic pathways and any gene mutations lead to congenital adrenal insufficiency. In these patients, ACTH and renin activity are highly elevated, while the levels of adrenal-made steroids are decreased. Clinical findings depend on the severity of the mutations but may include sex reversal in males, severe adrenal failure at birth, or late-onset adrenal failure. While the decrease in adrenal steroid levels were maybe comparable to CAH, adrenal enlargement or lipoid histopathology are not part of the disease (Kim *et al.*, 2008).

Mutations of *CYP11B2* lead to congenital corticosterone methyl oxidase deficiency (CMO). As discussed, CYP11B2 catalyzes three consecutive reactions where the precursor deoxycorticosterone is metabolized to corticosterone, 18-hydroxycorticosterone, and aldosterone. Depending on the *CYP11B2* mutation site, catalytic activity may stop at corticosterone (CMO I) or 18-hydroxycorticosterone (CMO II) (Ulick *et al.*, 1992).

STAR

STAR is thought to bind cholesterol and to facilitate intracellular cholesterol transport (Miller, 2007). Human mutations in *STAR* are associated with lipoid adrenal hyperplasia and various degrees of steroid deficiency (Miller, 2017). Mouse KO models showed viable litters that later died from adrenocortical insufficiency and had adrenal lipid deposits. Interestingly, comparable lipid deposits were less in testes and not observed in the ovary, indicating that STAR may play a preferential role in adrenal steroidogenesis.

TSPO

TSPO is an 18 kDa high-affinity cholesterol- and drug-binding protein located in the outer mitochondria membrane (Papadopoulos *et al.*, 2006). TSPO is part of a protein complex that aids in the translocation of cholesterol into the mitochondria to initiate steroidogenesis. TSPO is the target of various drugs that modulate the import of cholesterol and thus formation of steroids and neurosteroids developed for the treatment of neuropsychiatric and neurological diseases. Changes in the drug binding affinity have been reported in patients with the rs6971 polymorphism (Owen *et al.*, 2012). *TSPO* deletion mutations in rat and its corresponding rs6971 polymorphism in humans alters ACTH-induced plasma corticosteroid concentrations (Owen *et al.*, 2017).

Overview of Glucocorticoids☆

Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos, National and Kapodistrian University of Athens, Athens, Greece and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Abbreviation

3β-HSD	3β-hydroxysteroid dehydrogenase
ACTH	Adrenocorticotropic hormone
AP-1	Activator protein-1
AVP	Arginine vasopressin
CBG	Corticosteroid-binding globulin
CpG	Cytosine-guanine dinucleotides
CRH	Corticotropin-releasing hormone
CYP	Cytochrome P450
DBD	DNA-binding domain
DHEA	Dehydroepiandrosterone
DOC	Deoxycorticosterone
hGR	Human glucocorticoid receptor
HPA axis	Hypothalamic-pituitary-adrenal axis
HSP	Heat shock proteins
LBD	Ligand-binding domain
LDL	Low-density lipoprotein
MAPK	Mitogen-activated protein kinase
NF-κB	Nuclear factor-κB
PI_3K	Phosphatidylinositol 3-kinase
STATs	Signal transducers and activators of transcription

Glossary

Addison disease An endocrine disorder caused by destruction of the adrenal cortex and characterized by a deficiency in aldosterone, cortisol, and sex hormones.

Cushing syndrome An endocrine disorder caused by excessive production of cortisol.

Cholesterol The major fatty steroid alcohol of all vertebrate cells, especially animal fat, blood, liver, nerve tissue, and brain tissue.

Diurnal or circadian pattern Displaying a daily cycle.

Steroidogenesis The biosynthesis or production of steroids through enzymatic pathways.

Introduction

Glucocorticoids are steroid hormones produced by the adrenal glands and secreted into the systemic circulation in an ultradian, circadian and stress-related fashion (Nicolaides *et al.*, 2014, 2017). These molecules regulate a variety of biologic processes, including proliferation, differentiation and programmed cell death (apoptosis), and exert profound influences on many physiologic functions by virtue of their diverse roles in growth, development, and maintenance of basal and stress-related homeostasis (Charmandari *et al.*, 2005). Accumulating evidence suggests that glucocorticoids may alter the methylation status of many cytosine-guanine dinucleotides (CpG) located in the promoter regions of several genes. These glucocorticoid-induced epigenetic alterations are mediated through changes in the expression and/or activity of enzymes involved in the methylation/demethylation process (Zannas and Chrousos, 2017).

Pathways of Steroid Biosynthesis

The adrenal cortex consists of three anatomical zones: the outer *zona glomerulosa*, the intermediate *zona fasciculata*, and the inner *zona reticularis*. The *zona glomerulosa* is responsible for the production of aldosterone, the *zona fasciculata* is responsible for the production of cortisol, and the *zona reticularis* is responsible for the production of adrenal androgens. The adrenal medulla is functionally related to the sympathetic nervous system and secretes epinephrine and norepinephrine both under basal conditions and in response to stress (Stewart, 2003; Miller, 2005).

The glucocorticoid cortisol and the mineralocorticoid aldosterone are synthesized by the adrenal cortex under the control of regulatory systems that largely function independently. All steroid hormones produced by the adrenal cortex are derived from cholesterol. Low-density lipoprotein (LDL)-cholesterol is the major source of cholesterol utilized in adrenal steroidogenesis. Proteolytic and lipolytic enzymes act on LDL to release cholesterol esters for storage in lipid droplets in the adrenal cells (Simpson and Waterman, 1995). In order for the adrenal cortex to synthesize active steroid hormones, a number of changes are required in

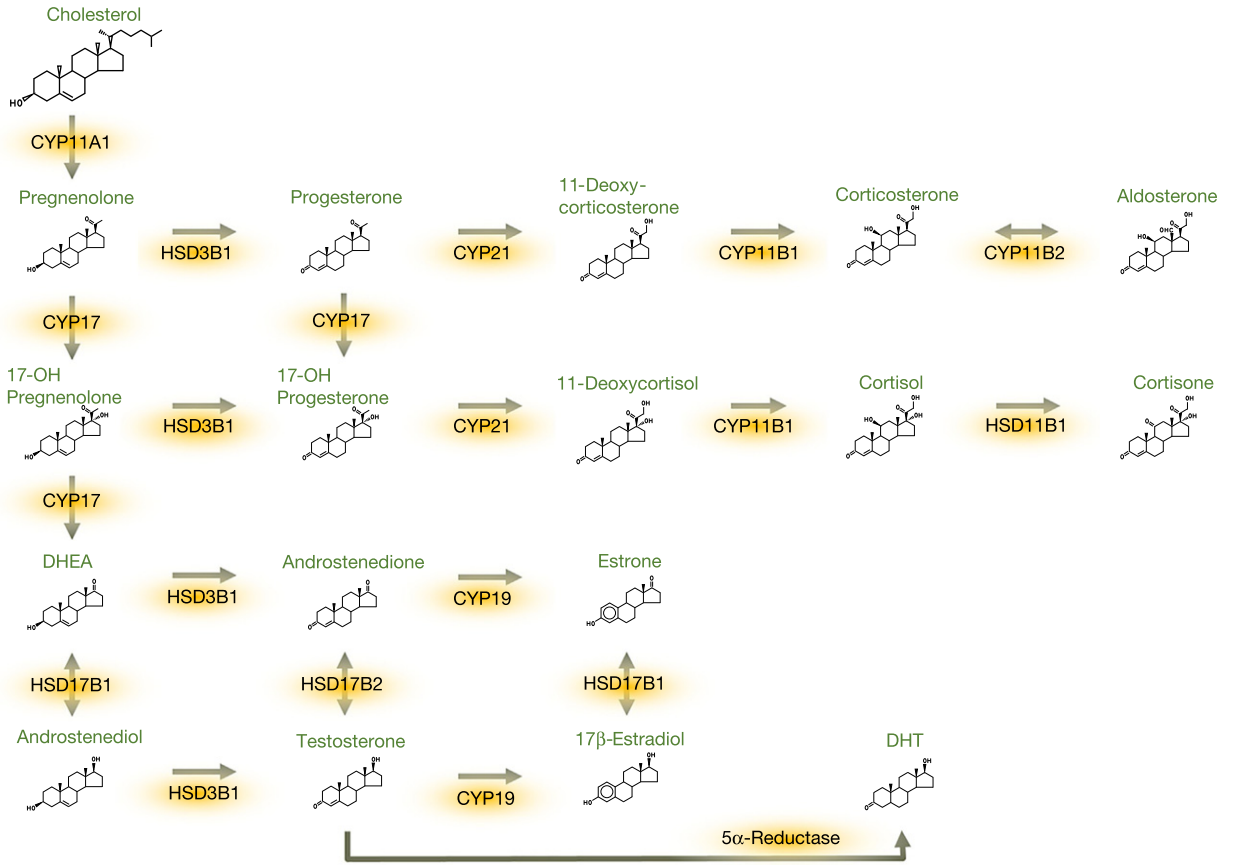

Fig. 1 Schematic representation of adrenal steroidogenesis.

the structure of cholesterol. Several of these reactions are catalyzed by the steroid hydroxylases, which are members of a superfamily of genes known collectively as cytochrome P450 (CYP). Adrenal steroidogenesis follows three distinct routes, which reflect the zonal differences in terms of function and regulation (**Fig. 1**).

The rate-limiting step in steroid biosynthesis is importation of cholesterol from cellular stores to the matrix side of the mitochondrial inner membrane, where the cholesterol side-chain cleavage system is located. This is controlled by the steroidogenic acute regulatory protein, the synthesis of which is increased by trophic stimuli, such as adrenocorticotropic hormone (ACTH) (Simpson and Waterman, 1995; Stocco and Clark, 1996; Arakane *et al.*, 1998). The first enzymatic step in steroid biosynthesis common to all steroidogenic pathways takes place in the mitochondrion and leads to the cleavage of six carbon atoms from the side chain of cholesterol, converting this C-27 compound to the C-21 steroid pregnenolone. This reaction is known as cholesterol side-chain cleavage and is catalyzed by the cytochrome P450 enzyme CYP11A (P450scc, cholesterol desmolase, side-chain cleavage enzyme), which is an integral protein of the inner mitochondrial membrane (Nebert *et al.*, 1991). Pregnenolone, the common precursor for all other steroids, then passes by diffusion from the mitochondrion to the endoplasmic reticulum, where it undergoes further metabolism by several other enzymes.

To synthesize mineralocorticoids in the *zona glomerulosa*, 3β-hydroxysteroid dehydrogenase (3β-HSD) in the endoplasmic reticulum and mitochondria converts pregnenolone to progesterone (Cherradi *et al.*, 1997). The latter is 21-hydroxylated in the endoplasmic reticulum by CYP21 (P450c21, 21-hydroxylase) to produce deoxycorticosterone (DOC). Aldosterone, the most potent 17-deoxysteroid with mineralocorticoid activity, is produced by 11β-hydroxylation of DOC to corticosterone, followed by 18-hydroxylation and 18-oxidation of corticosterone (**Fig. 1**). The final three steps in aldosterone synthesis are accomplished by a single mitochondrial P450 enzyme, CYP11B2 (P450aldo, aldosterone synthase) (White *et al.*, 1994).

To produce cortisol, CYP17 (P450c17, 17α-hydroxylase/17,20-lyase) in the endoplasmic reticulum of the *zona fasciculata* and *zona reticularis* converts pregnenolone to 17α-hydroxypregnenolone (Yanase *et al.*, 1991). 3β-HSD in the *zona fasciculata* utilizes 17α-hydroxypregnenolone as a substrate, producing 17α-hydroxyprogesterone. The latter is 21-hydroxylated by CYP21 to form 11-deoxycortisol, which is further converted to cortisol by CYP11B1 (P450c11, 11β-hydroxylase) in the mitochondria.

In the *zona reticularis* of the adrenal cortex and in the gonads, the 17,20-lyase activity of CYP17 converts 17α-hydroxypregnenolone to dehydroepiandrosterone (DHEA), a C-19 steroid and sex steroid precursor. DHEA is further converted by 3β-HSD to androstenedione. In the gonads, androstenedione is reduced by 17β-hydroxysteroid dehydrogenase (Penning, 1997). In pubertal ovaries, aromatase (CYP19, P450c19) can convert androstenedione and testosterone to estrone and estradiol, respectively

(Simpson *et al.*, 1994). Testosterone may be further metabolized to dihydrotestosterone by steroid 5α-reductase in androgen target tissues (Wilson *et al.*, 1993).

Regulation of Cortisol Secretion

Plasma glucocorticoid concentrations are regulated in ways that reflect the varying physiologic needs for the hormones under basal conditions and in response to stress. Cortisol secretion is primarily regulated by ACTH, a 39-amino-acid peptide released by the anterior pituitary (Stewart, 2003; Miller, 2005; Simpson and Waterman, 1995). ACTH is synthesized as part of a higher molecular weight precursor peptide, proopiomelanocortin. ACTH is secreted in regular pulses of variable amplitude over 24 h, with peak concentrations attained in the early morning hours (4:00–8:00 AM), thus forming the basis of the circadian pattern of cortisol secretion (Wallace *et al.*, 1991). The acute action of ACTH is to increase the flux of cholesterol through the steroidogenic pathway, resulting in the rapid production of steroids. ACTH also influences the remaining steps of steroidogenesis as well as the uptake of cholesterol from plasma lipoproteins, thus ensuring a continuous supply of cholesterol to the mitochondria to meet the demands of activated pregnenolone biosynthesis. It also maintains the size of the adrenal glands, stimulates melanocytes, and results in hyperpigmentation when secreted in excess.

Corticotropin-releasing hormone (CRH) is the principal hypothalamic factor that stimulates, synergistically with the arginine vasopressin (AVP), the pituitary production of ACTH (Itoi *et al.*, 1998). Both peptides are produced in the paraventricular nuclei of the hypothalamus, but are also found in other parts of the central nervous system as well as in noncentral locations (Habib *et al.*, 2001). CRH and AVP are secreted in a pulsatile fashion that results in the episodic secretion of ACTH and the circadian variation of cortisol secretion. The magnitude of cortisol response to each ACTH burst remains relatively constant; it is therefore the number of secretory periods, rather than the magnitude of each pulse of CRH/AVP or ACTH, that determines the total daily cortisol secretion. Although CRH increases the amount of ACTH secreted from each responsive corticotroph, vasopressin appears to increase the number of CRH-responsive corticotrophs. In addition to ACTH, other factors may play an important role in the regulation of the adrenal cortex (Ehrhart-Bornstein *et al.*, 1998; Bornstein and Chrousos, 1999).

Cortisol is the primary negative regulator of basal hypothalamic-pituitary-adrenal (HPA) axis activity through negative feedback on ACTH and CRH secretion (Keller-Wood and Dallman, 1984). The negative feedback effects of cortisol are exerted at the level of both the hypothalamus and the pituitary and are mediated by type II corticosteroid receptors. Whether and to what extent direct glucocorticoid feedback on the adrenal cortex itself regulates cortisol synthesis is not clear (Reincke *et al.*, 1998).

Secretion and Metabolism

In normal subjects, the secretion of glucocorticoids follows a diurnal pattern, with peak concentrations observed between 6:00 and 8:00 AM and the lowest concentrations observed at approximately 12:00 AM (Krieger *et al.*, 1971). The cortisol production rate is approximately 12 mg/m^2/day (Esteban and Yergey, 1990). More than 90% of circulating cortisol, and to a lesser extent aldosterone, is bound tightly to corticosteroid-binding globulin (CBG) or transcortin (Brien, 1981). The remaining (10%) of the circulating cortisol is free or loosely bound to albumin. The free and albumin-bound fractions of cortisol represent the biologically active form of the hormone. When plasma cortisol concentrations exceed 20 μg/dL, CBG becomes fully saturated and most of the excess cortisol is biologically active. CBG is synthesized in the liver. Estrogens, thyroid hormones, pregnancy, and oral contraceptives are associated with increased CBG concentrations (Brien, 1981; Mataradze *et al.*, 1992; Stolk *et al.*, 1996), whereas hypercortisolism, hepatic disease, or renal disease results in decreased CBG concentrations. In the presence of an intact HPA axis, alterations in CBG concentrations are likely not to affect circulating free cortisol concentrations.

The primary site of cortisol metabolism in humans is the liver, and a number of cytosolic and microsomal enzymes, including cytochrome P450, 5α/5β-reductase, 3α/3β-oxidoreductase, and 11β-hydroxysteroid dehydrogenase, play an important role in the hepatic metabolism of cortisol (Gower, 1984; Iyer *et al.*, 1990; Draper and Stewart, 2005). The major routes of hepatic metabolism involve A-ring and side-chain reduction followed by conjugation with glucuronic acid and sulfate (Abel *et al.*, 1992). The inactive glucuronide and sulfate metabolites are excreted by the kidneys, whereas less than 1% of cortisol is excreted unchanged in the urine. The metabolic clearance of cortisol, therefore, is influenced primarily by factors altering hepatic clearance and to a much lesser degree by factors affecting renal excretion.

Mechanisms of Glucocorticoid Action

At the cellular level, the actions of glucocorticoids are mediated by an intracellular receptor protein, the glucocorticoid receptor, which functions as a hormone-activated transcription factor that regulates the expression of glucocorticoid target genes (Nicolaides *et al.*, 2010). The human glucocorticoid receptor (hGR) is encoded by the *NR3C1* gene, which is located on chromosome 5 and consists of 10 exons; exon 1 contains non-coding DNA regions, whereas exons 2-9α/9β are transcribed and translated into the four functional domains of the receptor: the immunogenic or N-terminal domain, the DNA-binding domain (DBD), the hinge region, and the ligand-binding domain (LBD) (Ramamoorthy and Cidlowski, 2016). The alternative use of exon 9α or 9β produces the

two main hGR isoforms, the hGRα and the hGRβ. In addition, the eight alternative translation initiation sites generate eight distinct receptor isoforms for hGRα and, possibly, for hGRβ (Lu and Cidlowski, 2005; Chrousos and Kino, 2005).

At the cellular and molecular level, the hGRα resides primarily in the cytoplasm and forms a multiprotein complex that consists of heat shock proteins (HSP90, HSP70) and immunophillins (FKBP51 and FKBP52). Upon ligand binding, the receptor undergoes conformational alterations that result in the dissociation of hGRα from the multiprotein complex and subsequent translocation to the nucleus (Chrousos and Kino, 2005). In the nucleus, the ligand-bound hGRα forms homo- or hetero-dimers, which bind onto specific DNA sequences located in regulatory regions of glucocorticoid responsive genes, influencing the transcription of the latter in a positive or negative fashion. In addition to hGRα-mediated induction or repression of target genes, the activated receptor may interact with other transcription factors, including signal transducers and activators of transcription (STATs), the activator protein-1 (AP-1), and the nuclear factor-κB (NF-κB), thereby altering their transcriptional activity (Barnes and Karin, 1997; Karin and Chang, 2001; Didonato *et al.*, 1996).

Glucocorticoids may also induce some effects within a short time frame. These effects occur in cells lacking nucleus, and are not sensitive to transcription/translation inhibitors (Groeneweg *et al.*, 2012). Although the molecular mechanisms underlying the nongenomic glucocorticoid effects have not been elucidated yet, provocative studies have revealed an important role of a membrane-bound GR that activates the mitogen-activated protein kinase (MAPK) and/or the phosphatidylinositol 3-kinase (PI_3K) pathways (Samarasinghe *et al.*, 2012). Further to nongenomic effects, glucocorticoids exert mitochondrial actions through a locally expressed hGR (Psarra and Sekeris, 2011). Interestingly, synthetic glucocorticoids are used for the treatment of several hematologic malignancies, because they cause apoptosis in malignant cells, an effect that occurs in mitochondria (Lee *et al.*, 2013).

Treatment With Glucocorticoids

Natural and synthetic glucocorticoids can be used for both endocrine and nonendocrine disorders. In clinical practice, glucocorticoids are used to establish the diagnosis and cause of Cushing syndrome and in the treatment of adrenal insufficiency and congenital adrenal hyperplasia. Glucocorticoids are also given in pharmacologic doses to treat patients with inflammatory, allergic, or immunologic disorders (Stewart, 2003; Miller, 2005; Simpson and Waterman, 1995). Chronic therapy has many side effects, ranging from suppression of the HPA axis and Cushing syndrome to infections and changes in mental status. Factors that influence both the therapeutic and adverse effects of glucocorticoids include the pharmacokinetic properties of the glucocorticoid, daily dosage, timing of doses during the day, individual differences in steroid metabolism, and the duration of treatment.

Glucocorticoid Replacement Therapy

In deficiency states, physiologic replacement is best achieved with a combination of hydrocortisone and the mineralocorticoid fludrocortisone; hydrocortisone alone does not usually provide sufficient mineralocorticoid activity for complete replacement. In Addison's disease or following adrenalectomy, hydrocortisone at 10–15 mg/m^2 daily by mouth is usually required. This is given in two doses, the larger in the morning and the smaller in the evening, mimicking the normal diurnal rhythm of cortisol secretion. The optimum daily dose is determined on the basis of clinical response (Charmandari *et al.*, 2010). Glucocorticoid therapy is supplemented by fludrocortisone 50–300 μg daily. In acute adrenocortical insufficiency, hydrocortisone is given intravenously (preferably as sodium succinate) at doses of 100 mg every 6–8 h in 0.9% sodium chloride intravenous infusion. In hypopituitarism, glucocorticoids should be given as in adrenocortical insufficiency, but since the production of aldosterone is regulated by the renin–angiotensin system, a mineralocorticoid is not usually required. Additional replacement therapy with levothyroxine and sex hormones should be given as indicated by the pattern of hormone deficiency (Charmandari *et al.*, 2010).

Glucocorticoid Therapy

In comparing the relative potencies of corticosteroids in terms of their anti-inflammatory (glucocorticoid) effects, it should be borne in mind that high glucocorticoid activity in itself is of no advantage unless it is accompanied by relatively low mineralocorticoid activity (Charmandari *et al.*, 2010). The mineralocorticoid activity of fludrocortisone is so high that its anti-inflammatory activity is of no clinical relevance. The equivalent anti-inflammatory doses of corticosteroids are shown in **Table 1**.

The relatively high mineralocorticoid activity of cortisone and hydrocortisone and the resulting fluid retention make them unsuitable for disease suppression on a long-term basis. However, they can be used for adrenal replacement therapy; hydrocortisone is preferred because cortisone requires conversion to hydrocortisone in the liver. Hydrocortisone is used on a short-term basis by intravenous injection for the emergency management of some conditions. The relatively moderate anti-inflammatory potency of hydrocortisone also makes it a useful topical corticosteroid for the management of inflammatory skin conditions because side effects (both topical and systemic) are less marked; cortisone is not active topically (Charmandari *et al.*, 2010).

Prednisolone has predominantly glucocorticoid activity and is the corticosteroid most commonly used by mouth for long-term disease suppression (Charmandari *et al.*, 2010). Betamethasone and dexamethasone have very high glucocorticoid activity but insignificant mineralocorticoid activity. This makes them particularly suitable for high-dose therapy in conditions where fluid

Table 1 Equivalent anti-inflammatory doses of corticosteroids

Prednisolone	5 mg
≡ Betamethasone	750 μg
≡ Cortisone acetate	25 mg
≡ Deflazacort	6 mg
≡ Dexamethasone	750 μg
≡ Hydrocortisone	20 mg
≡ Methylprednisolone	4 mg
≡ Triamcinolone	4 mg

Note: This table takes no account of mineralocorticoid effects, nor does it take account of variations in duration of action.
Reprinted from the British Medical Association and the Royal Pharmaceutical Society of Great Britain (2002). British National Formulary No: 44. Chapter 6, pp. 348–351. London: Pharmaceutical Press.

retention would be a disadvantage. Betamethasone and dexamethasone also have a long duration of action and this, coupled with their lack of mineralocorticoid action, makes them particularly suitable for conditions that require suppression of ACTH secretion (e.g., congenital adrenal hyperplasia). Some esters of betamethasone and beclometasone (beclomethasone) exert a considerably more marked topical effect (e.g., on the skin or the lungs) than when given by mouth; use is made of this to obtain topical effects while minimizing systemic side effects (e.g. for skin applications and asthma inhalations) (Charmandari *et al.*, 2010). Deflazacort is derived from prednisolone and has high glucocorticoid activity (Charmandari *et al.*, 2010).

Side Effects of Glucocorticoids

Overdosage or prolonged use may exaggerate some of the normal physiologic actions of corticosteroids, leading to mineralocorticoid and glucocorticoid side effects. Mineralocorticoid side effects include hypertension, sodium and water retention, and potassium loss. They are most marked with fludrocortisone, but are significant with cortisone, hydrocortisone, corticotropin, and tetracosactide (tetracosactrin). Mineralocorticoid actions are negligible with the high-potency glucocorticoids betamethasone and dexamethasone and occur only slightly with methylprednisolone, prednisolone, and triamcinolone (Charmandari *et al.*, 2010). Glucocorticoid side effects include diabetes and osteoporosis, avascular necrosis of the femoral head, mental disturbances (a serious paranoid state or depression with risk of suicide may be induced, particularly in patients with a history of mental disorder), euphoria, and muscle wasting (proximal myopathy) (**Table 2**). Corticosteroid therapy is also weakly linked with peptic ulceration. High doses of corticosteroids may cause Cushing syndrome, which is usually reversible on withdrawal of treatment, but this must always be gradually tapered to avoid symptoms of acute adrenal insufficiency. In children, administration of corticosteroids may result in suppression of growth. Other complications include increased susceptibility to infection, poor wound healing, and activation of latent granulomatous infections (Charmandari *et al.*, 2010).

Adrenal Suppression

During prolonged therapy with corticosteroids, adrenal atrophy develops and may persist for years after stopping. Abrupt withdrawal after a prolonged period may lead to acute adrenal insufficiency, hypotension, or death. Withdrawal may also be associated with fever, myalgia, arthralgia, rhinitis, conjunctivitis, painful itchy skin nodules, and weight loss (Charmandari *et al.*, 2010).

To compensate for a diminished adrenocortical response caused by prolonged corticosteroid treatment, any significant intercurrent illness, trauma, or surgical procedure requires a temporary increase in corticosteroid dose or, if already stopped, a temporary reintroduction of corticosteroid treatment. Anesthetists must therefore know whether a patient is taking or has been taking a corticosteroid, to avoid a precipitous fall in blood pressure during anesthesia or in the immediate postoperative period. A suitable regimen for corticosteroid replacement, in patients who have taken more than 10 mg prednisolone daily (or equivalent) within 3 months of surgery, is as follows:

- Minor surgery under general anesthesia—usual oral corticosteroid dose on the morning of surgery or hydrocortisone 25–50 mg (usually sodium succinate) intravenously at induction; the usual oral corticosteroid dose is recommenced after surgery.
- Moderate or major surgery—usual oral corticosteroid dose on the morning of surgery and hydrocortisone 25–50 mg intravenously at induction, followed by hydrocortisone 25–50 mg three times a day by intravenous injection for 24 h after moderate surgery or for 48–72 h after major surgery; the usual preoperative oral corticosteroid dose is recommenced on stopping hydrocortisone injections.

Patients on long-term corticosteroid treatment should carry a Steroid Treatment Card, which gives guidance on minimizing risk and provides details of prescriber, drug, dosage and duration of treatment (Charmandari *et al.*, 2010).

Table 2 Effects of Chronic Pharmacologic Use of Glucocorticoids

Endocrine and metabolic
Suppression of HPA axis (adrenal suppression)
Growth failure in children
Carbohydrate intolerance
Hyperinsulinism
Insulin resistance
Abnormal glucose tolerance test
Diabetes mellitus
Cushingoid features
Moon facies, facial plethora
Generalized and truncal obesity
Supraclavicular fat collection
Posterior cervical fat deposition (buffalo hump)
Glucocorticoid-induced acne
Thin and fragile skin, violaceous striae
Impotence, menstrual disorders
Decreased thyroid-stimulating hormone and triiodothyronine
Hypokalemia, metabolic alkalosis
Gastrointestinal
Gastric irritation, peptic ulcer
Acute pancreatitis (rare)
Fatty infiltration of liver (hepatomegaly) (rare)
Hematopoietic
Leukocytosis
Neutrophilia
Increased influx from bone marrow and decreased migration from blood vessels
Monocytopenia
Lymphopenia
Migration from blood vessels to lymphoid tissue
Eosinopenia
Immunologic
Suppression of delayed hypersensitivity
Inhibition of leukocyte and tissue macrophage migration
Inhibition of cytokine secretion/action
Suppression of the primary antigen response
Musculoskeletal
Osteoporosis, spontaneous fractures
Aseptic necrosis of femoral and humoral heads and other bones
Myopathy
Ophthalmologic
Posterior subcapsular cataracts (more common in children)
Elevated intraocular pressure/glaucoma
Neuropsychiatric
Sleep disturbances, insomnia
Euphoria, depression, mania, psychosis
Pseudo-tumor cerebri (benign increase of intracranial pressure)
Cardiovascular
Hypertension
Congestive heart failure in predisposed patients

Infections

Prolonged courses of corticosteroids increase susceptibility to infections and severity of infections; clinical presentation of infections may also be atypical. Serious infections, for example, septicemia and tuberculosis, may reach an advanced stage before being recognized and amebiasis or strongyloidiasis may be activated or exacerbated (they should be excluded before corticosteroid treatment is initiated in those at risk or with suggestive symptoms). Fungal or viral ocular infections may also be exacerbated (Charmandari *et al.*, 2010).

Chickenpox

Unless they have had chickenpox, patients receiving oral or parenteral corticosteroids for purposes other than replacement should be regarded as being at risk of severe chickenpox. Passive immunization with varicella-zoster immunoglobulin is needed for

exposed nonimmune patients receiving systemic corticosteroids or for those who have used them within the previous 3 months; varicella-zoster immunoglobulin should preferably be given within 3 days of exposure and no later than 10 days. Confirmed chickenpox warrants specialist care and urgent treatment. Corticosteroids should not be stopped and dosage may need to be increased. Topical, inhaled, or rectal corticosteroids are less likely to be associated with an increased risk of severe chickenpox (Charmandari *et al.*, 2010).

Measles

Patients taking corticosteroids should be advised to take particular care to avoid exposure to measles and to seek immediate medical advice if exposure occurs. Prophylaxis with intramuscular normal immunoglobulin may be needed (Charmandari *et al.*, 2010).

Administration of Corticosteroids

Whenever possible, local treatment with creams, intra-articular injections, inhalations, eye drops, or enemas should be used in preference to systemic treatment. The suppressive action of a corticosteroid on cortisol secretion is lowest when it is given as a single dose in the morning. In an attempt to reduce HPA axis suppression further, the total dose for 2 days can sometimes be taken as a single dose on alternate days; alternate-day administration has not been very successful in the management of asthma. HPA axis suppression can also be reduced by means of intermittent therapy with short courses. In some conditions, it may be possible to reduce the dose of corticosteroid by adding a small dose of an immunosuppressive drug (Charmandari *et al.*, 2010).

Dosage of corticosteroids varies widely in different diseases and in different patients. If the use of a corticosteroid can save or prolong life, high doses may need to be given, because the complications of therapy are likely to be less serious than the effects of the disease itself. When long-term corticosteroid therapy is used in some chronic diseases, the adverse effects of treatment may become greater than the disabilities caused by the disease. To minimize side effects, the maintenance dose should be kept as low as possible (Charmandari *et al.*, 2010).

Withdrawal of Corticosteroids

A gradual withdrawal of systemic corticosteroids should be considered in those subjects whose disease is unlikely to relapse and who have: (1) recently received repeated courses (particularly if taken for longer than 3 weeks); (2) taken a short course within 1 year of stopping long-term therapy; (3) other possible causes of adrenal suppression; (4) received more than 40 mg daily prednisolone (or equivalent); (5) been given repeat doses in the evening; or (6) received treatment for more than 3 weeks (Charmandari *et al.*, 2010).

Systemic corticosteroids may be stopped abruptly in those whose disease is unlikely to relapse and who have received treatment for 2 weeks or less and who are not included in the patient groups described above. During corticosteroid withdrawal, the dose may be reduced rapidly to physiological doses (equivalent to prednisolone at 5 mg daily) and then reduced more slowly. Assessment of the disease may be needed during withdrawal to ensure that relapse does not occur (Charmandari *et al.*, 2010).

George P Chrousos, National and Kapodistrian University of Athens Medical School, Athens, Greece and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Nomenclature

ACTH	Adrenocorticotropic hormone
AVP	Arginine-vasopressin
BMAL1	Brain–muscle Arnt-like protein 1
Chrono	ChIP-derived repressor of network oscillator
CLOCK	Circadian locomotor output cycle kaput
CRH	Corticotropin-releasing hormone
CRY	Cryptochromes
HPA axis	Hypothalamic–pituitary–adrenal axis
IL-6	Interleukin-6
LC	Locus caeruleus
PER	Periods
PTSD	Posttraumatic stress disorder
SCN	Suprachiasmatic nucleus

Glossary

Autonomic nervous system The part of the nervous system that controls involuntary actions, including the smooth muscles, cardiac muscle, and glands. It is composed of the sympathetic and parasympathetic nervous systems.
Glucocorticoids Any of a group of adrenocortical steroid hormones whose metabolic effects include stimulation of gluconeogenesis, increased catabolism of proteins, and mobilization of free fatty acids; they are also potent inhibitors of the inflammatory reaction.
HPA axis The hypothalamic–pituitary–adrenal axis.

Introduction

Stress is defined as a state of disharmony or threatened homeostasis (Chrousos, 2009). The concepts of stress and homeostasis can be traced back to ancient Greek history; however, the integration of these notions with related physiologic and pathophysiologic mechanisms and their association with health and disease are much more recent (Nicolaides *et al.*, 2015).

This article focuses on the cellular and molecular infrastructure of the physiologic and behavioral adaptive responses to stress and defines the pathophysiologic effects of the dysregulation of the stress response, which may result in vulnerability to several disease entities, such as anxiety, depression, chronic inflammatory processes, and cardiovascular disease.

Physiology of the Stress Response

Life exists by maintaining a complex dynamic equilibrium, or homeostasis, that is constantly challenged by intrinsic or extrinsic adverse forces, the stressors (Chrousos and Gold, 1992; Chrousos, 2009). Under favorable conditions, individuals can be invested in vegetative and pleasurable functions that enhance their emotional and intellectual growth and development and the survival of their species, such as food intake and sex. In contrast, activation of the stress response during threatening situations that are beyond the control of the individual can be associated with dysphoria and eventually emotional or somatic disease (Chrousos, 2009; Nicolaides *et al.*, 2015).

When faced with excessive stress, whether physical or emotional, a subject's adaptive responses attain a relatively stereotypic nonspecific nature, referred to by Hans Selye as "the general adaptation syndrome" (Selye, 1936a, b). The adaptive responses have some specificity toward the stressor that generates them, which, however, is progressively lost as the severity of the stressor increases. During stress, attention is enhanced and the brain focuses on the perceived threat. Cardiac output and respiration are accelerated, catabolism is increased, and blood flow is redirected to provide the highest perfusion and fuel to the aroused brain, heart, and muscles (Chrousos, 1998).

☆*Change History:* January 2018. NC Nicolaides, P Pervanidou and GP Chrousos added Abstract, Keywords, Nomenclature, the section "HPA Axis-Clock System Interactions" and updated the reference section. NC Nicolaides prepared the figures.

This article is an update of George P. Chrousos, Stress and Endocrine Physiology, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 325-332.

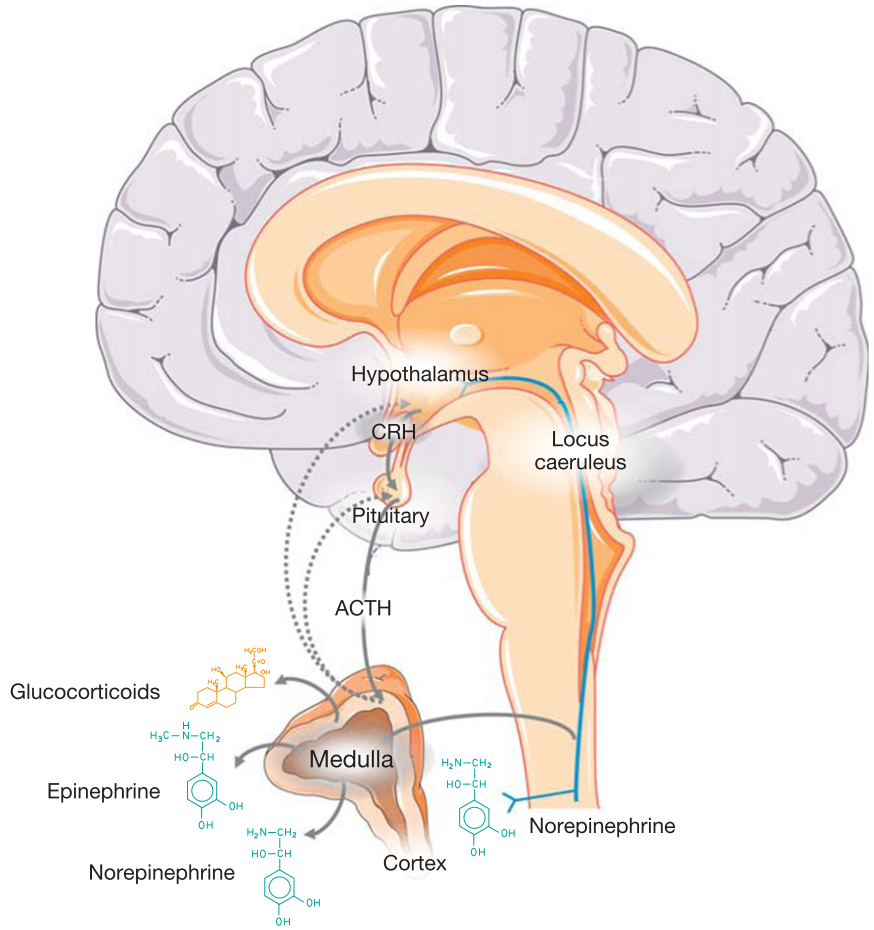

Fig. 1 The stress system consists of the HPA axis and the locus caeruleus/autonomic nervous system. *Solid lines* indicate stimulation; *dashed lines* indicate inhibition. *CRH*: corticotropin-releasing hormone; *ACTH*: adrenocorticotropic hormone. Modified from Chrousos, G.P., 1995. The hypothalamic-pituitary-adrenal axis and immune-mediated inflammation. New England Journal of Medicine 332, 1351–1362.

The stress system consists of the hypothalamic–pituitary–adrenal (HPA) axis and the locus caeruleus/autonomic nervous system (**Fig. 1**). The central control stations of the stress system are located in the hypothalamus and the brainstem and include the parvocellular corticotropin-releasing hormone (CRH) and arginine-vasopressin (AVP) neurons of the paraventricular nuclei of the hypothalamus and the locus caeruleus (LC)-norepinephrine (NE) system (central sympathetic system). The hypothalamic–pituitary–adrenal (HPA) axis and the efferent sympathetic/adrenomedullary system represent the effector limbs, via which the brain influences all body organs during exposure to threatening stimuli (**Fig. 1**). The brain also differentially activates a subset of vagal and sacral parasympathetic efferents that mediate the gut responses to stress (Chrousos and Gold, 1992; Nicolaides *et al.*, 2015).

There are mutual interactions of the central stress stations with three higher brain control areas that influence affect and anticipatory phenomena (mesocortical/mesolimbic systems); the initiation, propagation, and termination of stress system activity (amygdala/hippocampus complex) and the setting of the pain sensation (arcuate nucleus) (**Fig. 2**). Several molecules and factors influence substantially the stress system activity (**Fig. 2**).

The Hypothalamic–Pituitary–Adrenal Axis

The hypothalamus controls the secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which, in turn, stimulates the secretion by the adrenal cortex of glucocorticoid hormones, mainly cortisol in humans (Tsigos and Chrousos, 1994; Chrousos, 2009). The principal hypothalamic stimulus to the pituitary–adrenal axis is CRH, a 41-amino-acid peptide first isolated in 1981 by Wylie Vale (Vale *et al.*, 1981). AVP is a potent synergistic factor with CRH in stimulating ACTH secretion; however, AVP has little ACTH secretagogue activity by itself (Gillies *et al.*, 1982; Antoni, 1993). Furthermore, it appears that there is a reciprocal positive interaction between CRH and AVP at the level of the hypothalamus, with each neuropeptide stimulating the secretion of the other (Rivier *et al.*, 1984).

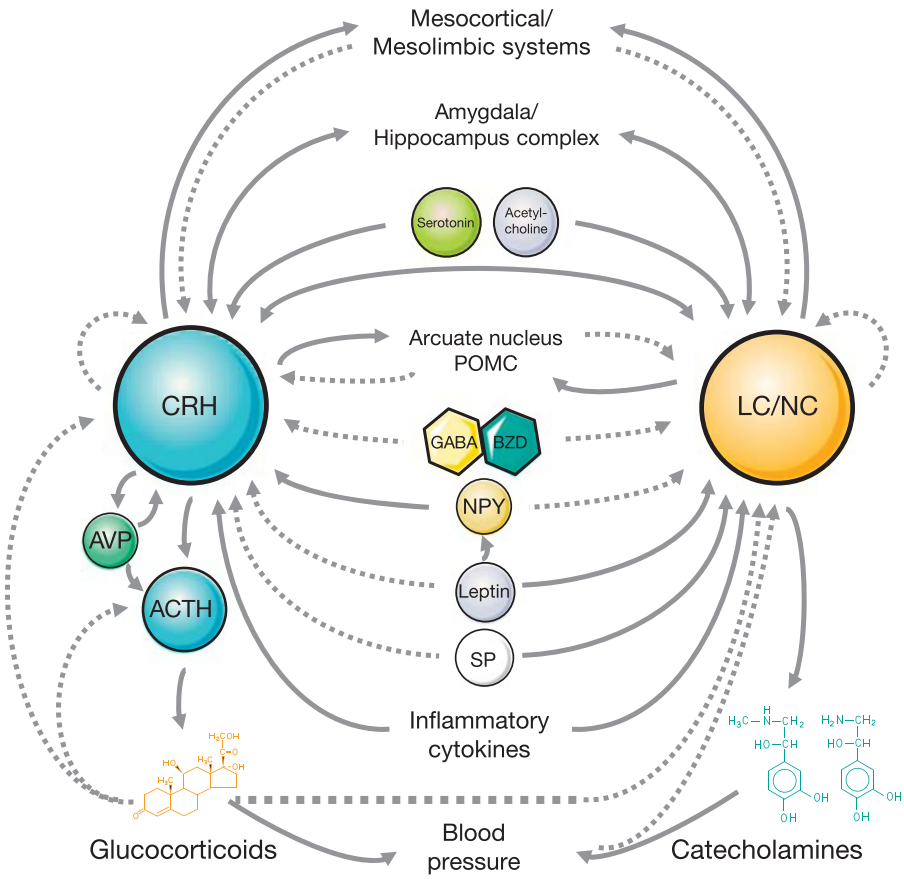

Fig. 2 A simplified schematic representation of the central and peripheral components of the stress system, their functional interrelations, and their relationships to other central systems involved in the stress response. The CRH–AVP neurons and central catecholaminergic neurons of the LC–NE system reciprocally innervate and activate one another. The HPA axis is controlled by several feedback loops that tend to normalize the time-integrated secretion of cortisol, yet glucocorticoids stimulate the fear centers in the amygdala. Activation of the HPA axis leads to suppression of the GH/insulin-like growth factor-I, luteinizing hormone/testosterone/estradiol, and TSH/triiodothyronine axes; activation of the sympathetic system increases interleukin-6 secretion. *Solid lines* indicate stimulation; *dashed lines* indicate inhibition. *BZD*, benzodiazepine; *GABA*, g-aminobutyric acid; *NPY*, neuropeptide Y; *SP*, substance P. Modified from Chrousos, G.P., Gold, P.W., 1992. The concepts of stress and stress system disorders. Overview of physical and behavioral homeostasis. Journal of the American Medical Association 267, 1244–1252.

In nonstressful situations, both CRH and AVP are secreted in the portal system in a circadian, pulsatile fashion, with a frequency of approximately two to three secretory episodes per hour (Engler *et al.*, 1989; Redekopp *et al.*, 1986). Under resting conditions, the amplitude of the CRH and AVP pulses increases in the early morning hours, resulting finally in ACTH and cortisol secretory bursts in the general circulation (Horrocks *et al.*, 1990). These diurnal variations are perturbed by changes in lighting, feeding schedules, and activity, are influenced by age, body mass index (BMI), and gender, and are disrupted by stress (Veldhuis *et al.*, 2011).

During acute stress, the amplitude and synchronization of the CRH and AVP pulsations in the hypophyseal portal system markedly increase, resulting in increases in ACTH and cortisol secretory episodes. Depending on the type of stress, other factors such as AVP of magnocellular neuron origin, angiotensin II, and various cytokines and lipid mediators of inflammation are secreted and act on hypothalamic, pituitary, or adrenal components of the HPA axis, potentiating its activity (Tsigos *et al.*, 2016).

Circulating ACTH is the key regulator of glucocorticoid secretion by the adrenal cortex and participates in aldosterone secretion by the *zona glomerulosa* (Aguilera, 1993). Other hormones or cytokines, either originating from the adrenal medulla or coming from the systemic circulation, as well as neuronal information from the autonomic innervation of the adrenal cortex may also participate in the regulation of cortisol secretion.

Glucocorticoids are the final effectors of the HPA axis and participate in the control of whole-body homeostasis and the organism's response to stress. They play a key regulatory role on the basal activity of the HPA axis and on the termination of the stress response by acting at extrahypothalamic centers, the hypothalamus, and the pituitary gland. The inhibitory glucocorticoid feedback on the ACTH secretory response acts to limit the duration of the total tissue exposure to glucocorticoids, thus minimizing the catabolic, antireproductive, and immunosuppressive effects of these hormones (Nicolaides *et al.*, 2015).

Glucocorticoids exert their effects through their ubiquitous cytoplasmic receptors (Chrousos and Kino, 2005). On ligand binding, the glucocorticoid receptors (GRs) translocate into the nucleus, where they interact as homodimers with specific

glucocorticoid-responsive elements within the DNA to activate appropriate hormone-responsive genes. The activated receptors also inhibit, through protein–protein interactions, other transcription factors, such as c-jun/c-fos, and nuclear factor κB, which are positive regulators of the transcription of several genes involved in the activation and growth of immune and other cells. Furthermore, glucocorticoids change the stability of mRNAs and hence the translation of several glucocorticoid-responsive proteins, as well as the electrical potential of neuronal cells (Nicolaides *et al.*, 2010).

Circulating glucocorticoids in humans have a circadian pattern of secretion, regulated by the suprachiasmatic nucleus (SCN) of the hypothalamus. The zenith of cortisol secretion is reached in the early morning and the nadir, at midnight, with the purpose of helping adjust the body's activities to the regular periodicity of day/night changes. CLOCK (the "circadian locomotor output cycle kaput") and its heterodimer partner BMAL1 (the "brain muscle ARNT-like protein-1") are essential in the formation of the circadian rhythm in man, participating in the physiological adjustment to daily activities, to the regular day/night changes and to unpredictable external or internal challenges (Nicolaides *et al.*, 2014, 2017).

The Autonomic Axes

The autonomic nervous system provides a rapidly responding mechanism to control a wide range of functions. Cardiovascular, respiratory, gastrointestinal, renal, endocrine, and other systems are regulated by the sympathetic nervous system or the parasympathetic system or both (Gilbey and Spyer, 1993). Interestingly, the parasympathetic system may assist sympathetic functions by withdrawing and can antagonize them by increasing its activity.

Sympathetic innervation of peripheral organs is derived from the efferent preganglionic fibers, whose cell bodies lie in the intermediolateral column of the spinal cord. These nerves synapse in the bilateral chains of sympathetic ganglia with postganglionic sympathetic neurons that richly innervate the smooth muscle of the vasculature, the heart, the skeletal muscles, the kidney, the gut, fat, and many other organs (Burnstock and Miller, 1989). The preganglionic neurons are cholinergic, whereas the postganglionic neurons are mostly noradrenergic. The sympathetic system also has a humoral contribution, providing most of the circulating epinephrine and some of the norepinephrine from the adrenal medulla. In addition to the classic neurotransmitters acetylcholine and norepinephrine, both sympathetic and parasympathetic subdivisions of the autonomic nervous system contain several subpopulations of target-selective and neurochemically coded neurons that express a variety of neuropeptides and, in some cases, ATP, nitric oxide, or lipid mediators of inflammation (Benarroch, 1994). Interestingly, CRH, neuropeptide Y, and somatostatin are colocalized in noradrenergic vasoconstrictive neurons. Transmission in sympathetic ganglia is also modulated by neuropeptides released from preganglionic fibers and short interneurons (e.g., enkephalin, neurotensin), as well as from primary afferent collaterals (e.g., substance P) (Elfvin *et al.*, 1993).

Regulation of the Stress Response

The orchestrated interplay of several neurotransmitter systems in the brain underlies the characteristic phenomenology of behavioral, endocrine, autonomic, and immune responses to stress. These transmitters include CRH, AVP, opioid peptides, dopamine, and norepinephrine (Tsigos *et al.*, 2016).

CRH–AVP

Shortly after its isolation, it became apparent that CRH was implicated in other components of the stress response, such as arousal and autonomic activity. Supportive evidence was derived from intracerebroventricular or selective brain administration of CRH in rodents and nonhuman primates, which precipitated several coordinated responses characteristic of stress (Dunn and Berridge, 1990). Moreover, administration of CRH peptide antagonists into selected areas of the brain suppresses many aspects of the stress response. Finally, CRH type 1 receptor knockout mice were shown to have a markedly deficient ability to mount an effective stress response.

CRH and CRH receptors were found in many sites in the brain outside of the hypothalamus, including parts of the limbic system and the central arousal sympathetic systems (LC–sympathetic systems) in the brainstem and spinal cord (Aguilera *et al.*, 1987; De Souza *et al.*, 1985). Stress is a potent general activator of CRH release from the hypothalamus and extra-hypothalamic sites. The mechanisms via which stress stimulates CRH neurons are unclear. Whether CRH or another transmitter (e.g., NE) is upstream in eliciting the neurocircuitry of stress remains to be determined.

CRH-binding sites are also found in various peripheral tissues, such as the adrenal medulla, heart, prostate, gut, liver, kidney, and testes (Tsigos *et al.*, 2016). CRH receptors belong to the G protein-coupled receptor superfamily and CRH binding stimulates the intracellular accumulation of cyclic AMP (Perrin and Vale, 1999). Two distinct CRH receptor subtypes, designated CRH-R1 and CRH-R2, have been characterized, encoded by distinct genes that are differentially expressed (Polymeropoulos *et al.*, 1995; Meyer *et al.*, 1997). CRH-R1 is the most abundant subtype found in the anterior pituitary and is also widely distributed in the brain, the adrenal gland, skin, gastrointestinal tract, ovary and testis (Chen *et al.*, 1993). CRH-R2 receptors are expressed mainly in the peripheral vasculature and the heart, as well as in subcortical structures in the brain (Lovenberg *et al.*, 1995).

Locus Caeruleus–NE System

The locus caeruleus and other noradrenergic cell groups of the medulla and pons are collectively known as the LC–NE system. Brain epinephrine serves globally as an alarm system that decreases neurovegetative functions, such as eating and sleeping, and that contributes to accompanying increases in autonomic and neuroendocrine responses to stress, including HPA axis activation. NE also activates the amygdala, the principal brain locus for fear-related behaviors, and enhances the long-term storage of aversively charged emotional memories in sites such as the hippocampus and striatum.

Reciprocal neural connections exist between the CRH and catecholaminergic neurons (LC–NE neurons) of the central stress system, with CRH and norepinephrine stimulating each other, the latter primarily through α_1-noradrenergic receptors (Valentino *et al.*, 1983; Calogero *et al.*, 1988a, b, c; Kiss and Aguilera, 1992). There is an ultra-short autoregulatory negative feedback loop on the CRH neurons exerted by CRH itself, just as there is a similar loop in the LC–NE neurons, by way of presynaptic CRH and α_2-noradrenergic receptors, respectively (Aghajanian and VanderMaelen, 1982; Calogero *et al.*, 1988a, b, c; Silverman *et al.*, 1989). There is also parallel regulation of both central components of the stress system by other stimulatory and inhibitory neuronal pathways. Several neurotransmitters, including serotonin and acetylcholine, excite CRH and the LC–NE neurons (Calogero *et al.*, 1990; Fuller, 1992). The negative feedback controls include glucocorticoids, γ-aminobutyric acid, corticotropin, and several opioid peptides, which inhibit both CRH and LC–NE neurons (Keller-Wood and Dallman, 1984; Calogero *et al.*, 1988a, b, c; Overton and Fisher, 1989).

Body Systems' Responses to Stress

HPA Axis–Immune System Interactions

It has been known for several decades that stress, whether inflammatory, traumatic, or psychological, is associated with concurrent activation of the HPA axis. In the early 1990s, it also became apparent that cytokines and other humoral mediators of inflammation are potent activators of the central stress response, constituting the afferent limb of a feedback loop through which the immune–inflammatory system and the CNS communicate (Reichlin, 1993; Chrousos, 1995).

All three inflammatory cytokines, tumor necrosis factor α, interleukin-1β (IL-β), and interleukin-6, can cause stimulation of the HPA axis alone or in synergy with one another (Bateman *et al.*, 1989; Akira *et al.*, 1990; Besedovsky and del Rey, 1992). There is evidence to suggest that IL-6, the main endocrine cytokine, plays the major role in the immune stimulation of the axis, especially in chronic inflammatory stress (Mastorakos *et al.*, 1993; Tsigos *et al.*, 1997; Rohleder, 2012).

Some of the activating effects of cytokines on the HPA axis may be exerted indirectly by stimulation of the central catecholaminergic pathways. Also, activation of peripheral nociceptive, somatosensory, and visceral afferent fibers would lead to stimulation of both the catecholaminergic and CRH neuronal systems via ascending spinal pathways (Tsigos *et al.*, 2016). Other inflammatory mediators, such as eicosanoids, platelet-activating factor, and serotonin, may also participate in the activation of the HPA axis, via autocrine/paracrine and/or endocrine effects (Bernardini *et al.*, 1989a, b).

Conversely, activation of the HPA axis has profound inhibitory effects on the inflammatory/immune response because virtually all the components of the immune response are inhibited by cortisol (Chrousos, 2000a, b; Charmandari *et al.*, 2004). Alterations of leukocyte traffic and function, decreases in production of cytokines and mediators of inflammation, and inhibition of the latter's effects on target tissues are among the main immunosuppressive effects of glucocorticoids (Chrousos, 2000a, b; Charmandari *et al.*, 2004).

The efferent sympathetic/adrenomedullary system apparently participates in a major fashion in the interactions of the HPA axis and the immune/inflammatory reaction by being reciprocally connected with the CRH system, by receiving and transmitting humoral and nervous immune signals from the periphery, by densely innervating both primary and secondary lymphoid organs, and by reaching all sites of inflammation via the postganglionic sympathetic neurons (Ottaway and Husband, 1992; Bellinger *et al.*, 1992). When activated during stress, the autonomic system exerts its own direct effects on immune organs, which can be immunosuppressive or both immunopotentiating and antiinflammatory (Hirano *et al.*, 1990; Rohleder, 2012). CRH secreted by postganglionic sympathetic neurons at inflammatory sites has proinflammatory properties (immune CRH) (Karalis *et al.*, 1991); one of its key actions is to degranulate mast cells (Theoharides *et al.*, 1998).

HPA Axis–Clock System Interactions

To adjust their activities to day/night cycles, all organisms have developed a highly sophisticated and conserved system, the circadian (from the Latin "circa diem" meaning "approximately a day") clock system, which generates internal rhythmicity according to light/dark information. This system consists of a central "master" clock located in the SCN of the hypothalamus and the peripheral "slave" clocks expressed in every tissue including the brain minus the SCN (Ko and Takahashi, 2006; Takahashi *et al.*, 2008; Nader *et al.*, 2010). The central clock communicates with peripheral clocks through unknown mechanisms, ultimately regulating many homeostatic systems (Kalsbeek *et al.*, 2006). At the molecular level, the circadian clock system creates a self-oscillating rhythm through transcriptional/translational loops, which are mediated by the heterodimer CLOCK/BMAL1 and

several negative transcription factors, including Periods (PER1, PER2 and PER3) and Cryptochromes (CRY1 and CRY2) (Kondratov *et al.*, 2006; Kiyohara *et al.*, 2006; Padmanabhan *et al.*, 2012).

Accumulating evidence suggests that there are molecular interrelations between the HPA axis and the circadian clock system. In addition to the above-discussed diurnal oscillation of circulating glucocorticoid concentrations, the central clock influences the adrenal cortex response to plasma ACTH via a multisynaptic neuronal pathway (Ishida *et al.*, 2005; Ulrich-Lai *et al.*, 2006). Moreover, in peripheral tissues, the circadian rhythm transcription factor CLOCK acetylates the GR and represses GR-induced transcriptional activity on glucocorticoid-responsive genes (Nader *et al.*, 2009). This Clock-mediated repression of GR transcriptional activity, oscillates in inverse phase to the HPA axis, acting as a target tissue counter regulatory mechanism to the diurnally fluctuating circulating glucocorticoids (Nader *et al.*, 2010; Kino and Chrousos, 2011a, b). Interestingly, a recently identified circadian CLOCK component and BMAL target gene, the *Gm129*, later termed as "Chrono" ("ChIP-derived repressor of network oscillator") was demonstrated to interact with the GR, providing a novel potential link between the circadian clock system and the HPA axis (Goriki *et al.*, 2014; Robinson, 2014).

On the other hand, glucocorticoids may reset the activity of peripheral clocks by phase-shifting the expression of several clock-related genes, including *Pers* (Yamamoto *et al.*, 2005). Indeed, glucocorticoids induce the expression of *Per1* and *Per2* genes, leading to a phase delay of the peripheral clocks, but not the SCN master clock (So *et al.*, 2009). Furthermore, glucocorticoids can regulate local oscillators, both in CNS and peripheral tissues, as demonstrated by rodent studies. Prolonged administration of prednisolone or adrenalectomy influence substantially the expression of a number of clock-related genes (Oster *et al.*, 2017). All these results indicate that there are many reciprocal interactions between the HPA axis and the circadian clock system (Nicolaides *et al.*, 2014; Nicolaides *et al.*, 2017).

HPA Axis–Other Endocrine Axes Interactions

Gonadal, growth and thyroid axes

The systems responsible for reproduction and growth are directly linked to the stress system and both are profoundly inhibited by various components of the HPA axis, the effector of the stress response. Either directly or through arcuate proopiomelanocortin (POMC) neuron β-endorphin, CRH suppresses the gonadotropin-releasing hormone (GnRH) neurons of the arcuate nucleus of the hypothalamus (Tsigos *et al.*, 2016). Glucocorticoids exert inhibitory effects at the levels of the GnRH neuron, the pituitary gonadotroph, and the gonads themselves and render target tissues of sex steroids resistant to these hormones (MacAdams *et al.*, 1986; Rivier *et al.*, 1986; Rabin *et al.*, 1990). Suppression of gonadal function caused by chronic HPA axis activation has been demonstrated in highly trained athletes of both sexes, in ballet dancers, and in individuals sustaining anorexia nervosa or starvation (Kyrou and Tsigos, 2008; Tsigos *et al.*, 2016). Moreover, during inflammatory stress, cytokines suppress reproductive function directly and indirectly by activating hypothalamic secretion of CRH- and POMC-derived peptides, as well as by peripheral elevations of glucocorticoids and inhibition of steroidogenesis at both the ovaries and the testes (Tsigos *et al.*, 1999).

The interaction between CRH and the gonadal axis appears to be bidirectional (Kyrou and Tsigos, 2008). Thus, the presence of estrogen-responsive elements has been demonstrated in the promoter area of the CRH gene, as well as direct stimulatory estrogen effects on CRH gene expression (Vamvakopoulos and Chrousos, 1993). This finding indicates that the CRH gene is a potentially important target of ovarian steroids and a potential mediator of gender-related differences in the stress response and HPA axis activity (Vamvakopoulos and Chrousos, 1994).

The growth axis is also inhibited at many levels during stress. Prolonged activation of the HPA axis with elevations in glucocorticoids leads to suppression of growth hormone (GH) secretion, inhibition of somatomedin C, and other growth hormone effects on their target tissues (Unterman and Phillips, 1985; Dieguez *et al.*, 1988; Burguera *et al.*, 1990). However, acute elevations of growth hormone concentration in plasma may occur at the onset of the stress response or after acute administration of glucocorticoids, presumably through stimulation of the GH gene by glucocorticoids through glucocorticoid-responsive elements in its promoter region (Casanueva *et al.*, 1990). In addition to the direct effects of glucocorticoids, CRH-induced stimulation in hypothalamic somatostatin secretion may also result in GH suppression, providing another potential mechanism for stress-related suppression of GH secretion (Rivier and Vale, 1985).

Similarly, activation of the HPA axis is associated with decreased production of thyroid-stimulating hormone (TSH) and inhibition of the conversion of the relatively inactive thyroxin to the more biologically active triiodothyronine in peripheral tissues (the "euthyroid sick" syndrome) (Duick and Wahner, 1979; Benker *et al.*, 1990; Roelfsema *et al.*, 2009). Both phenomena may be caused by the increased levels of glucocorticoids and may serve to conserve energy during stress. In the case of inflammatory stress, inhibition of TSH secretion may occur in part through the action of cytokines on both the hypothalamus and the pituitary (Torpy *et al.*, 1998).

Metabolism

Glucocorticoids directly inhibit pituitary growth hormone, gonadotropin, and thyrotropin secretion and make the target tissues of sex steroids and growth factors resistant to these hormones. Thus, glucocorticoids antagonize the beneficial actions of GH and sex steroids on fat tissue (lipolysis) and on muscle and bone anabolism (Chrousos, 2000a, b; Kyrou and Tsigos, 2007). Chronic activation of the stress system would be expected to increase visceral adiposity, decrease lean body (muscle and bone) mass, and suppress osteoblastic activity (Chrousos, 2000a, b; Kyrou and Tsigos, 2007; Pervanidou and Chrousos, 2012). Interestingly, the phenotype of central obesity and decreased lean body mass is shared by patients with Cushing syndrome and some patients with

the combined diagnosis of melancholic depression or chronic anxiety disorder and the metabolic syndrome (visceral adiposity, insulin resistance, dyslipidemia, hypertension) or "pseudo-Cushing syndrome."

Because increased hepatic gluconeogenesis is a characteristic feature of the stress response and because glucocorticoids induce insulin resistance, activation of the HPA axis may contribute to the poor control of diabetic patients during periods of emotional stress or concurrently with inflammatory and other diseases (Lloyd *et al.*, 1993).

Obese subjects with psychiatric manifestations ranging from those of melancholic depression to anxiety with perception of "uncontrollable" stress frequently have mild hypercortisolism, whereas carefully screened obese subjects without such manifestations are eucortisolemic (Pasquali *et al.*, 1993; Tamashiro *et al.*, 2011). The former may have stress-induced glucocorticoid-mediated visceral obesity and metabolic syndrome manifestations, which in the extreme may be called a pseudo-Cushing syndrome state that needs to be differentiated from frank Cushing syndrome. Stress-induced hypercortisolism and visceral obesity and their cardiovascular and other sequelae increase the all-cause mortality risk of affected subjects two- to threefold and curtail their life expectancy by several years (Tsigos *et al.*, 2016).

HPA Axis: Pathophysiology

Generally, the stress response with the resultant activation of the HPA axis is meant to be acute or at least of a limited duration. The time-limited nature of this process renders its accompanying antireproductive, antigrowth, catabolic, and immunosuppressive effects temporarily beneficial rather than damaging. In contrast, the chronicity of stress system activation would lead to the syndromal state that Selye described in 1936 (Selye, 1936a, b). Because CRH coordinates behavioral, neuroendocrine and autonomic adaptation during stressful situations, increased and prolonged production of CRH could explain the pathogenesis of the syndrome (Chrousos and Gold, 1992; Chrousos, 2009).

The prototypical example of chronic hyperactivation of the stress system (both the HPA axis and the LC–NE system) is manifested in melancholic depression, with dysphorichyperarousal and relative immunosuppression (Gold *et al.*, 1988a, b). Indeed, cortisol excretion is increased and the plasma ACTH response to exogenous CRH is decreased (Gold and Chrousos, 2002). Hypersecretion of CRH has been observed in depression and suggests that CRH may participate in the initiation or perpetuation of a vicious cycle. Owing to chronically hyperactive stress, patients with melancholic depression may sustain several severe somatic sequelae, such as osteoporosis, features of the metabolic syndrome, varying degrees of atherosclerosis, innate and T helper 1-directed immunosuppression, and certain infectious and neoplastic diseases. When not treated, these patients have a compromised life expectancy curtailed by 15–20 years after suicides are excluded (Gold and Chrousos, 2002).

In addition to melancholic depression, a spectrum of other conditions may be associated with increased and prolonged activation of the HPA axis (**Table 1**), including anorexia nervosa with or without malnutrition, obsessive–compulsive disorder, panic anxiety, chronic active alcoholism, alcohol and narcotic withdrawal, excessive exercising, poorly controlled diabetes mellitus, childhood sexual abuse, and hyperthyroidism (Tsigos *et al.*, 2016).

Another group of states is characterized by hypoactivation of the stress system, rather than sustained activation, in which chronically reduced secretion of CRH may result in pathological hypoarousal (**Table 1**). Patients with atypical, seasonal depression and chronic fatigue syndrome fall into this category (Demitrack *et al.*, 1991; Joseph-Vanderpool *et al.*, 1991). Similarly, patients with fibromyalgia have decreased urinary free-cortisol excretion and frequently complain of fatigue (Griep *et al.*, 1993). Hypothyroid patients also have clear evidence of CRH hyposecretion (Kamilaris *et al.*, 1987).

Table 1 States associated with hyperactivation or hypoactivation of the HPA axis

Increased HPA axis activity	*Decreased HPA axis activity*	*Disrupted HPA axis activity*
Severe chronic disease		
Melancholic depression	Atypical depression	Cushing syndrome
Anorexia nervosa	Seasonal depression	Glucocorticoid deficiency
Obsessive–compulsive disorder	Chronic fatigue syndrome	Glucocorticoid resistance
	Fibromyalgia	
Panic disorder	Hypothyroidism	
Chronic excessive exercise	Adrenal suppression	
Malnutrition	Postglucocorticoid therapy	
Diabetes mellitus	Poststress	
	Nicotine withdrawal	
	Postpartum	
Hyperthyroidism	Menopause	
Central obesity	Rheumatoid arthritis	
Childhood sexual abuse		
Pregnancy		

Modified from Chrousos, G. P. (1992). Regulation and dysregulation of the hypothalamic–pituitary–adrenal axis: The corticotropin releasing hormone perspective. *Endocrinology and Metabolism Clinics of North America* **21,** 833–858.

Withdrawal from smoking has been associated with decreased cortisol and catecholamine secretion (Elgerot, 1978; Puddey *et al.*, 1984). Decreased CRH secretion in the early period of nicotine abstinence could explain the increased appetite and weight gain frequently observed in these patients. In Cushing syndrome, the clinical picture of atypical depression, hyperphagia, weight gain, fatigue, and anergia is consistent with suppression of the CRH neuron by the associated hypercortisolism. The periods after cure of hypercortisolism or following cessation of chronic stress and the postpartum period are also associated with atypical depression, suppressed CRH secretion, and decreased HPA axis activity (Doherty *et al.*, 1990; Gomez *et al.*, 1993).

The pattern of centrally increased CRH secretion, together with decreased cortisol and increased catecholamines in the periphery, is typically represented in posttraumatic stress disorder (PTSD), a stress-related disorder than develops after exposure to traumatic life-events (Pervanidou and Chrousos, 2010). This unique neuroendocrine profile in PTSD suggests an increased cortisol signaling capacity, so that lower cortisol concentrations may suppress more efficiently the HPA axis, thus exerting increased negative feedback. This may lead to decreased exposure of the LC/NE system to the negative actions of cortisol, contributing to increased sympathetic activation. Mechanisms of down-regulation of pituitary CRH receptors secondary to elevated CRH and enhanced negative feedback inhibition of the pituitary to cortisol may also lead to lower peripheral cortisol concentrations in PTSD (Pervanidou and Chrousos, 2010). The important role of stress reactions and, consequently, stress biology in the pathophysiology of posttraumatic stress disorder (PTSD) has been highlighted in the last revision of the Diagnostic and Statistical Manual for Mental Disorders (DSM-5, 2013), where, PTSD is no more classified as an anxiety disorder, but moved into a new class, the "trauma and stressor-related disorders."

It is believed that an excessive HPA axis response to inflammatory stimuli would mimic the stress or hypercortisolemic state and would lead to increased susceptibility of the individual to a host of infectious agents or tumors as a result of T helper-1 suppression, but enhanced resistance to autoimmune/inflammatory disease (Sternberg *et al.*, 1992a,b). In contrast, a defective HPA axis response to such stimuli would reproduce the glucocorticoid-deficient state and would lead to relative resistance to infections and neoplastic disease, but increased susceptibility to autoimmune/inflammatory disease, such as Hashimoto's thyroiditis or rheumatoid arthritis. Thus, an increasing body of evidence suggests that patients with rheumatoid arthritis have a mild form of central hypocortisolism (Chikanza *et al.*, 1992a, b). Dysfunction of the HPA axis may actually play a role in the development or perpetuation of autoimmune disease, rather than being an epiphenomenon. The same rationale may explain the high incidence of autoimmune disease in the period after cure of hypercortisolism, as well as in glucocorticoid underreplaced adrenal insufficiency (Elenkov and Chrousos, 1999).

CRH Receptor as a Promising Therapeutic Target

Antalarmin, a novel CRH receptor type 1 antagonist, decreases the activity of the HPA axis and LC–NE system, suppresses neurogenic inflammation, and blocks CRH-induced skin mast cell degranulation, in addition to blocking the development and expression of conditioned fear and stress-induced colonic hyperfunction (Habib *et al.*, 2000). Chronic administration of antalarmin is not associated with glucocorticoid deficiency and permits HPA axis and LC–NE responses to severe stress (Wong *et al.*, 1999). These data suggest that such CRH antagonists may be useful in human pathologic states, such as melancholic depression and chronic anxiety, associated with chronic hyperactivity of the stress system, along with predictable behavioral, neuroendocrine, metabolic, and immune changes, based on the interrelations outlined above. Conversely, potentiators of CRH secretion and action are needed to treat atypical depression, postpartum depression, and the fibromyalgia/chronic fatigue syndromes, all characterized by low hypothalamic–pituitary–adrenal axis and LC–NE system activity, fatigue, depressive symptomatology, hyperalgesia, and increased immune/inflammatory responses to stimuli (Sajdyk and Gehlert, 2000; Lawrence *et al.*, 2002).

Glossary

ACTH (adrenocorticotropic hormone) A hormone synthesized and secreted by the anterior pituitary that is primarily responsible for the regulation of cortisol and adrenal androgen secretion.

Adrenal crisis A medical emergency in which the subject is affected by an extreme state of adrenal insufficiency, with symptoms resembling shock or coma; considered to be life-threatening and requiring immediate administration of fluids, electrolytes, glucose, and intravenous glucocorticoids. May occur in situations of extreme stress or after the abrupt cessation of a period of glucocorticoid therapy.

Cushing syndrome A metabolic disorder relating to the chronic oversecretion of adrenal glucocorticoids (mainly cortisol); may be associated with the long-term administration of pharmacological amounts of synthetic glucocorticoids. A condition first described by U.S. neurosurgeon Harvey Cushing in 1912.

HPA axis An anatomical complex consisting of the hypothalamus, the pituitary gland, and the adrenal cortex; ultimately controls the secretion of glucocorticoids from the adrenal cortex and thus plays a key role in various neuroendocrine, behavioral, autonomic, and immune responses to alterations in homeostasis.

Introduction

Glucocorticoids are produced by the cortices of the adrenal glands and secreted into the systemic circulation in a circadian fashion and in response to stressful stimuli (Nicolaides *et al.*, 2014, 2017). These steroid hormones play pivotal roles in the regulation of intermediary metabolism, maintenance of cardiovascular function, stimulation of behavior, and control of the immune inflammatory reaction (Charmandari *et al.*, 2005; Chrousos and Kino, 2005). The major endogenous glucocorticoid in humans is cortisol, the synthetic form of which has traditionally been called hydrocortisone. Cortisone, the 2-keto form of cortisol, was first used therapeutically in the management of rheumatoid arthritis by Hench and coworkers in 1949. Since then, a large number of synthetic compounds with glucocorticoid activity have been developed, and glucocorticoids (administered systemically or in a compartmental fashion) have been used in the therapy of a broad spectrum of nonendocrine and endocrine diseases (Liapi and Chrousos, 1992).

One of the adverse effects of long-term glucocorticoid therapy in supraphysiologic doses is suppression of the hypothalamic–pituitary–adrenal (HPA) axis, which can render the adrenal glands unable to generate sufficient cortisol if glucocorticoid treatment is abruptly stopped, and the patient may develop glucocorticoid deficiency manifestations. The true prevalence of adrenal suppression is not known since physicians usually discontinue high glucocorticoids gradually to allow recovery of the HPA axis (Chrousos *et al.*, 2009). Some of the risk factors for HPA axis suppression are clearly defined, whereas others are less certain (Christy, 1992; Krasner, 1999). Systemic glucocorticoid therapy is more likely to suppress the HPA axis than compartmentalized use of glucocorticoids, with the possible exception of intra-articular steroids. Systemic glucocorticoid potency is also known to correlate with risk for adrenal insufficiency. For this reason, if glucocorticoid dosage is to be reduced, it should be tapered slowly (Chrousos, 2007).

☆*Change History*: January 2018. NC Nicolaides and GP Chrousos added Abstract, Keywords, Nomenclature, and updated the sections "Physiology of the HPA Axis," "Pharmacology of Glucocorticoids," "Adrenal Suppression," "Predictors of Glucocorticoid-Induced HPA Axis Suppression," "Diagnostic Tests," "Glucocorticoid Withdrawal Syndrome," "Follow up," and the References section.

This article is an update of Maria Alexandra Magiakou and George P. Chrousos, Adrenal Suppression, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 81–89.

Physiology of the HPA Axis

The adrenal cortex consists of three anatomic zones: the outer *zona glomerulosa*, the intermediate *zona fasciculata*, and the inner *zona reticularis*. The *zona glomerulosa* is responsible for the production of aldosterone, the *zona fasciculata* for the production of cortisol, and the *zona reticularis* for the production of adrenal androgens (Prigent *et al.*, 2004). Adrenocorticotropic hormone (ACTH), synthesized and secreted by the corticotrophs of the anterior pituitary, is the primary regulator of cortisol and adrenal androgen secretion. Hypothalamic control of ACTH secretion is exerted primarily by corticotropin-releasing hormone (CRH), a 41-amino acid peptide produced by parvocellular neurons of the paraventricular nucleus and secreted into the hypophyseal portal system; Arginine vasopressin produced also by parvocellular neurons of the same nucleus and secreted in the hypophyseal portal system, as well as by magnocellular neurons, exerts a synergistic action on ACTH secretion (Rhen and Cidlowski, 2005).

There are several regulatory negative feedback loops that function to constrain the activity of the HPA axis. Prominent negative feedback loops are those exerted by glucocorticoids on CRH and ACTH secretion (Alves *et al.*, 2008). The adrenal cortisol secretion rate under basal conditions is 12–15 mg/m^2/day. In normal individuals, the highest plasma cortisol levels occur between 6:00 and 8:00 AM and the lowest at approximately midnight (Alves *et al.*, 2008). Cortisol secretion increases two- to fourfold under stress. Plasma cortisol concentrations are elevated during physical and/or emotional stress, including illness, trauma, surgery, and starvation.

In the systemic circulation, 75%–80% of the cortisol is bound to a transport protein, termed transcortin or cortisol binding globulin (CBG). A small percentage (6%) of cortisol circulates as a free hormone, and passes through the cytoplasmic membrane of glucocorticoid target cells (Alves *et al.*, 2008). Subsequently, cortisol binds to an intracellular receptor, the glucocorticoid receptor, which functions as a ligand-induced transcription factor (Nicolaides *et al.*, 2010). Upon cortisol binding, the receptor undergoes conformational changes, translocates to the nucleus, and binds as homo- or hetero-dimer onto specific DNA sequences, the glucocorticoid response elements (GREs), located in regulatory regions of target genes (Nicolaides *et al.*, 2010). Once bound to DNA, the activated receptor induces or suppresses the expression of glucocorticoid responsive genes. Alternatively, glucocorticoid receptor can modulate gene expression by interacting as a monomer with other important transcription factors, such as the activator protein-1 (AP-1), the nuclear factor-κB (NF-κB) and signal transducers and activators of transcription (STATs), providing the molecular basis of anti-growth, anti-inflammatory and immunosuppressant glucocorticoid effects (Barnes and Karin, 1997; Karin and Chang, 2001; Didonato *et al.*, 1996).

Pharmacology of Glucocorticoids

Since the introduction of glucocorticoids in the treatment of rheumatoid arthritis in 1949, intense efforts have been made by science and industry to maximize the beneficial effects and to minimize the side effects of these analogues. Thus, many synthetic compounds with glucocorticoid activity have been manufactured and tested. The pharmacologic differences among these chemicals result from structure alterations of their basic steroid nucleus and its side groups. These changes may affect the bioavailability of these compounds (including their gastrointestinal or parenteral absorption, plasma half-life, and metabolism in the liver, fat, or target tissues) and their abilities to interact with the glucocorticoid receptor and to modulate the transcription of glucocorticoid-responsive genes (Pousseau *et al.*, 1972). In addition, structural modifications diminish the natural cross-reactivity of glucocorticoids with the mineralocorticoid receptor, eliminating their undesirable salt-retaining activity. Other modifications increase glucocorticoids' water solubility for parenteral administration or decrease their water solubility to enhance topical potency (Liapi and Chrousos, 1992; Magiakou and Chrousos, 1996).

Synthetic glucocorticoids are classified into three groups depending on the duration of ACTH suppression that is induced by a standard dose equivalent to 50 mg of prednisone: short action analogues, including hydrocortisone, cortisone, deflazacort, which suppress ACTH for less than 36 h; intermediate action analogues, such as triamcinolone, prednisone, prednisolone, methylprednisolone, suppressing ACTH for approximately 48 h; and prolonged action analogues (e.g., dexamethasone, betamethasone) that suppress ACTH for more than 48 h (Alves *et al.*, 2008). **Table 1** shows the relative glucocorticoid and mineralocorticoid potencies of commonly used systemic glucocorticoids and their approximate plasma and biologic effect half-lives.

Therapeutic Indications

Glucocorticoids may be administered as replacement therapy in patients with primary or secondary adrenal insufficiency, as adrenal suppression therapy in congenital adrenal hyperplasia and glucocorticoid resistance (Magiakou and Chrousos, 1996), and as antiinflammatory or immunosuppressant therapy in a broad range of mostly nonendocrine disorders affecting many different systems (Boumpas *et al.*, 1993). Thus, glucocorticoids are used in endocrine, autoimmune, collagen, renal, gastrointestinal, respiratory, nervous, hematologic, and ophthalmic diseases and are used in the suppression of the host versus graft and graft versus host reaction in cases of organ transplantation. Neoplastic disorders of the lymphoid system, such as leukemia and lymphomas, are also treated with glucocorticoids, along with the appropriate chemotherapy (Rix *et al.*, 2005).

Acute administration of pharmacologic doses of glucocorticoids is necessary in a small number of nonendocrine diseases, such as malignant hyperthermia, and in patients with craniospinal trauma or brain tumors or in those who are undergoing major neurosurgical operations to decrease the temperature and prevent destruction of neural tissue from the local edema and

Table 1 Glucocorticoid equivalencies

	Equivalent dose (mg)	*Glucocorticoid potency*	*Mineralocorticoid potency*	*Plasma half-life (min)*	*Biologic half-life (h)*
Glucocorticoids					
Short acting					
Cortisol	20.0	1.0	2	90	8–12
Cortisone	25.0	0.8	2	80–118	8–12

inflammatory reaction, respectively. In addition, glucocorticoids have been used in the prevention of the respiratory distress syndrome in the premature neonate, when delivery is anticipated before week 34 of gestation. In this case, treatment of the pregnant woman with 12 mg of betamethasone, followed by 12 mg 18–24 h later, stimulates the production of pulmonary surfactant and the maturation of the fetal lungs (reviewed in Chrousos *et al.*, 2000).

Side Effects

Side effects occur only with supraphysiologic doses of glucocorticoids and not with proper replacement, which is equivalent to 12–15 mg of hydrocortisone/m^2 body surface area/day. Major complications are unlikely for short-term treatment (<2 weeks) with high doses of glucocorticoids, although sleep disturbances and gastric irritation are common complaints, and depression, mania, or psychosis may be infrequently precipitated. On the other hand, many side effects are associated with long-term daily administration of pharmacologic amounts of glucocorticoids (**Table 2**), including the development of varying degrees of Cushing syndrome manifestations during therapy and secondary adrenal insufficiency (adrenal suppression) after discontinuation of treatment. Growth retardation is one of the major side effects of long-term daily glucocorticoid therapy in children (Laue *et al.*, 1989).

Adrenal Suppression

Adrenal suppression is the most common form of tertiary adrenal insufficiency caused by abrupt withdrawal of chronic glucocorticoid administration (Lamberts *et al.*, 1997; Kaltsas and Alexandraki, 2015). This condition also occurs following correction of endogenous hypercortisolism. In adrenal suppression, the suprahypothalamic and hypothalamic nuclei of the HPA axis are incapable of rapidly recovering their normal function when glucocorticoid therapy is discontinued. In sufficiently severe cases of endogenous hypercortisolism, adrenal suppression occurs following removal of a cortisol-secreting adrenal tumor, or after removal of an ACTH-secreting pituitary adenoma, or a tumor secreting ACTH ectopically (Kaltsas and Alexandraki, 2015). The clinical manifestations of adrenal suppression include anorexia, abdominal pain, nausea, vomiting, myalgia, arthralgia, fever, weight loss, orthostatic hypotension, and circulatory collapse (Charmandari *et al.*, 2014). The main electrolytic disturbance that is present in pituitary-adrenal suppression is hyponatremia (Kaltsas and Alexandraki, 2015). Adrenal suppression can be partial or complete (Krasner, 1999). The true prevalence of adrenal suppression is unknown granted that physicians reduce high doses of glucocorticoids, gradually, thereby allowing the recovery of the HPA axis (Chrousos *et al.*, 2000).

Predictors of Glucocorticoid-Induced HPA Axis Suppression

Several predictors of glucocorticoid-induced HPA axis suppression have been discussed. The following are the most important:

1. Type of steroid used and glucocorticoid potency: Glucocorticoid potency (**Table 1**) correlates positively with risk for adrenal insufficiency. Thus, hydrocortisone and cortisone acetate are the least potent and, therefore, least suppressive agents. Prednisone, prednisolone, methylprednisolone, and triamcinolone are moderately suppressive, and dexamethasone suppresses ACTH the longest (Chrousos *et al.*, 2000).

Table 2 Effects of Long-Term Glucocorticoid Therapy

Endocrine and metabolic
Suppression of HPA axis (adrenal suppression)
Growth failure in children
Carbohydrate intolerance
Hyperinsulinemia
Insulin resistance
Abnormal glucose tolerance test
Diabetes mellitus
Cushingoid features
Moon facies, facial plethora
Generalized and truncal obesity
Supraclavicular fat collection
Posterior cervical fat deposition (buffalo hump)
Glucocorticoid-induced acne
Thin and fragile skin, violaceous striae
Impotence, menstrual disorders
Decreased thyroid-stimulating hormone, thyroxine and triiodothyronine
Hypokalemia, metabolic alkalosis
Gastrointestinal system
Gastric irritation, peptic ulcer
Acute pancreatitis (rare)
Fatty infiltration of liver (hepatomegaly) (rare)
Hemopoietic system
Leukocytosis
Neutrophilia
Increased influx from bone marrow and decreased migration from blood vessels
Monocytopenia
Lymphopenia
Migration from blood vessels to lymphoid tissue
Eosinopenia
Immune system
Suppression of delayed hypersensitivity
Inhibition of leukocyte and tissue macrophage migration
Inhibition of cytokine secretion or action
Suppression of the primary antigen response
Musculoskeletal system
Osteoporosis, spontaneous fractures
Aseptic necrosis of femoral and humoral heads and other bones
Myopathy
Ophthalmic
Posterior subcapsular cataracts (more common in children)
Elevated intraocular pressure or glaucoma
Neuropsychiatric disorders
Sleep disturbances, insomnia
Euphoria, depression, mania, psychosis
Cognitive and memory disturbances, dementia
Pseudotumor cerebri (benign increase of intracranial pressure)

Adapted from Laue, L., Kawai, S., Udelsman, R., *et al.* (1989). Glucocorticoid antagonists: Pharmacological attributes of the prototype antiglucocorticoid RU 486. In: Lichtenstein, L. M., Claman, H. & Oronsky, A. (eds.) Antiinflammatory steroid action: Basic and clinical aspects, pp 303–329. New York: Academic Press.

2. Systemic vs. compartmental therapy: Systemic glucocorticoid therapy, especially parenterally, is more likely to suppress the HPA axis than are intra-articular, inhalational, or topical glucocorticoids (Alves *et al.*, 2008; Mortimer *et al.*, 2006; Molimard *et al.*, 2008).
3. Daily therapy: There is evidence that patients are at lower risk for adrenal insufficiency if they can take glucocorticoids on alternate days from the outset or if they can convert to alternate-day therapy before the HPA axis is suppressed (Ackerman and Nolsn, 1968).
4. Once-a-day dosing in the morning or mimicking normal diurnal cortisol rhythms: Since evening doses of glucocorticoids tend to suppress the normal early morning surge of ACTH secretion, it is better, whenever possible, to treat patients with a single

morning dose. Once-a-day dosing is usually feasible for prednisone, triamcinolone, and dexamethasone. The short-acting hydrocortisone and cortisone acetate are usually given twice a day, at waking and at approximately 5 PM. To mimic normal diurnal cortisol rhythms, the morning dose is two-thirds and the afternoon dose is one-third of the total daily dose (Alves *et al.*, 2008; Nichols *et al.*, 1965).

5. Duration and cumulative dose of glucocorticoid treatment: Although traditionally the duration of glucocorticoid therapy and the cumulative dose of glucocorticoid received have been considered as predictive of the likelihood of HPA axis suppression, several studies suggest that they only roughly predict HPA axis suppression (Schlaghecke *et al.*, 1992; Henzen *et al.*, 2000). Adrenal insufficiency is extremely rare in patients treated for 1 week or less (Carella *et al.*, 1993).
6. Cushingoid features: Patients with clinical manifestations suggestive of Cushing syndrome are more likely to have a suppressed HPA axis (Alves *et al.*, 2008; Chrousos *et al.*, 2000).

Perhaps the best predictor of HPA axis suppression is the patient's current glucocorticoid dosage. A strong correlation has been found between prednisone maintenance doses >5 mg/day and a subnormal ACTH stimulation test result. From the practical point of view, patients who receive high doses of glucocorticoids (>20–30 mg hydrocortisone or equivalent per day) (**Table 1**) for more than 2 weeks and patients who have developed overt Cushingoid features are more likely to develop HPA axis suppression (Kaltsas and Alexandraki, 2015). Regarding the timing of drug administration, prednisolone in a dose of 5 mg given at night and 2.5 mg in the morning is more likely to cause HPA axis suppression compared to 2.5 mg at night and 5 mg in the morning (Kaltsas and Alexandraki, 2015). This is because the sensitivity of tissues to glucocorticoids increases in the evening hours (Charmandari *et al.*, 2011).

Acute Adrenal Crisis

Recovery of the HPA axis can take 12 months or longer. Abrupt cessation of glucocorticoid treatment or quick tapering can precipitate an acute glucocorticoid deficiency crisis. Clinical awareness is fundamental to recognize patients with this emergency condition. The main symptoms range from anorexia, fatigue, nausea, vomiting, dyspnea, fever, arthralgia, myalgia, and orthostatic hypotension to dizziness, fainting, and circulatory collapse (Charmandari *et al.*, 2014). Hypoglycemia is occasionally observed in children and very thin adults. The diagnosis is urgent and treatment should consist of immediate administration of fluids, electrolytes, glucose, and parenteral glucocorticoids (Charmandari *et al.*, 2014).

Diagnostic Tests

As previously mentioned, glucocorticoid treatment may not suppress the HPA axis at all, or it may cause central suppression and adrenal gland atrophy of varying degrees (Krasner, 1999). The insulin tolerance test and the metyrapone test have been employed in the diagnosis of adrenal suppression and are quite sensitive. However, the risks involved with both tests do not justify their use when a rapid ACTH stimulation test can distinguish clinically significant adrenal suppression (Chrousos *et al.*, 2000).

To evaluate the adequacy of HPA axis recovery, the rapid Synachten (or high-dose ACTH stimulation test) is most commonly used. An intravenous bolus of 250 μg of corticotropin 1–24 is administered, and cortisol is measured after 30 or 60 min or both. A plasma cortisol concentration $>$ 18–20 μg/dL at these times indicates adequate recovery of the HPA axis (Kamilaris and Chrousos, 1991). This test can also be done intramuscularly. However, if adrenal suppression is of recent onset, adrenals may still respond to 250 mcg of ACTH, because they may have not yet atrophied. In such cases, a modified Synachten test has been recommended in lieu of the standard test. Only 1 μg of corticotropin 1–24 is administered instead of 250 μg (Poon and Smith, 1996; Chrousos *et al.*, 2009). A number of studies have shown that the low-dose Synachten test may be a good test for the diagnosis of secondary/tertiary adrenal insufficiency, however, it is fraught with dosing problems in the clinical setting (reviewed in Magnotti and Shimshi, 2008).

The corticotropin-releasing hormone (CRH) test can be performed to distinguish between secondary and tertiary adrenal insufficiency in patients who receive glucocorticoids for prolonged periods (Gellner *et al.*, 1999). In both forms of adrenal insufficiency, cortisol concentrations are low at baseline and remain low following CRH administration (Kaltsas and Alexandraki, 2015). In secondary adrenal insufficiency, CRH administration results in a little or no ACTH response, whereas in the tertiary form there is a prolonged and exaggerated response of ACTH (Kaltsas and Alexandraki, 2015).

Weaning Patients From Glucocorticoid Therapy

Glucocorticoid withdrawal is indicated when the maximum therapeutic benefit has been achieved, or when inadequate therapeutic benefit has been obtained following an adequate therapeutic trial, or when significant side effects appear and become serious and uncontrollable, including diabetes mellitus, psychosis, severe hypertension and osteoporosis (Chrousos *et al.*, 2000). To avoid the occurrence of adrenal insufficiency, dose tapering is suggested as the best method of glucocorticoid withdrawal. Although there is no consensus on rapid or slow dose tapering of glucocorticoids, the common point is that glucocorticoid withdrawal should never

be abrupt (Alves *et al.*, 2008; Chrousos *et al.*, 2000). Patients receiving any glucocorticoid dose for less than 2 weeks are not likely to develop adrenal suppression and could be advised to discontinue glucocorticoid therapy without tapering, in the case tapering is not needed for the disease under treatment. There is only one possible exception to this, which is the patient who takes frequently "short" steroid courses, such as in asthma therapy (Chrousos *et al.*, 2000). In regimens longer than 2 weeks, the objective is to reduce rapidly the glucocorticoid dose to a physiologic level that is equivalent to 5 mg/day prednisolone. For example, this can be achieved by reducing 2.5 mg every week for a period of few weeks, and then by slower glucocorticoid withdrawal to permit full recovery of the HPA axis (Chrousos *et al.*, 2000).

Glucocorticoid Withdrawal Syndrome

Amatruda *et al.* first defined the steroid withdrawal syndrome as a symptom complex resembling true adrenal insufficiency, with nonspecific symptoms such as weakness, nausea, and arthralgias, occurring in patients who have completed a dosage reduction of glucocorticoid therapy and who respond normally to HPA axis testing (Amatruda *et al.*, 1960). Thus, following cessation of glucocorticoid therapy, patients may suffer from anorexia, myalgia, nausea, emesis, lethargy, headache, fever, skin desquamation, arthralgias, weight loss, and postural hypotension. In addition, they may experience exacerbation of a previously present autoimmune disease (e.g., rheumatoid arthritis, atopic dermatitis, and asthma) or develop a new autoimmune disease (e.g., Hashimoto's thyroiditis and Graves' disease).

The glucocorticoid withdrawal syndrome (GWS) might represent a withdrawal reaction caused by physical dependence on supraphysiologic glucocorticoid concentrations (Hochberg *et al.*, 2003). The pathogenetic mechanisms underlying GWS are not fully understood. Several neuroendocrine mediators and other factors, including vasopressin, CRH, POMC, cytokines and prostaglandins, have been considered as crucial molecules involved in GWS (Hochberg *et al.*, 2003). Interestingly, the syndrome is self-limited and may last approximately 10 months. Patients with GWS should be advised to have a temporary increase in glucocorticoid doses followed by slow tapering to a physiologic dose (Bhattacharyya *et al.*, 2005).

Follow-Up

All patients receiving glucocorticoids for long periods should be informed to increase glucocorticoid doses (supplementation equivalent to 100–150 mg of hydrocortisone) during exposure to major stressors, including surgical procedures, fractures, burns and severe systemic infections. They should also be advised to carry means of identification, such as medical alert bracelet (Kaltsas and Alexandraki, 2015).

Glucocorticoid Metabolism and Activation

Nantia Othonos and Jeremy Tomlinson, University of Oxford, Oxford, United Kingdom

Introduction

Corticosteroid hormones were first isolated and characterized in the 1930s by Kendall and Reichstein from the adrenal cortex (Mason *et al.*, 1936, 1937; Reichstein, 1936, 1937). In 1949, compound E (subsequently named cortisone) was synthesized and trialed in patients suffering from rheumatoid arthritis and rheumatic fever (Hench *et al.*, 1950). The extraordinary impact that this had in the successful treatment of these conditions lead to a surge of trials using cortisone as a treatment for nearly every disease. These trials lead to the discovery that cortisone was beneficial in adrenal deficiency disorders, inflammatory disorders, and malignancies such as lymphoma but was harmful in infective disease. Two years later, in 1951, compound F (cortisol) was synthesized and it soon became evident that this was the active compound providing some of the first evidence that glucocorticoids (GCs) undergo metabolism in vivo that can impact upon their activity (Hollander *et al.*, 1951). This prompted a new wave of studies investigating GC metabolism in rodents and in humans. Amelung *et al.* (1953) reported that cortisone was converted to cortisol in a number of rodent tissues, but this activity was highest in the liver (Amelung *et al.*, 1953).

This raised the important concept of prereceptor cortisol metabolism as a fundamental regulatory step in GC action. Cortisol, the predominant circulating GC in humans, is mainly bound (>90%) with high affinity to cortisol binding globulin and it is only the "free," unbound circulating cortisol that is available to enter cells. Once within the cell, cortisol can bind the cytosolic GC receptor (GR), translocate to the nucleus, and alter gene transcription. However, prereceptor GC metabolism means that prior to engaging with a relevant steroid hormone receptor, GCs can be metabolized to either enhance or limit their ability to bind and activate the GR.

Prereceptor GC metabolism occurs in many tissues throughout the body, but notably within the liver, kidney, adipose tissue, placenta, colon, and muscle. There are a variety of different enzyme systems that have been identified and they are summarized later (**Fig. 1**).

- 11β-Hydroxysteroid dehydrogenase type 1 and type 2 (11β-HSD1 and 2) interconvert active cortisol and inactive cortisone.
- A-ring reductases (5α-reductase types 1 and 2 (5αR1 and 5αR2) and 5β-reductase (5βR)) metabolize cortisol to 5α- or 5β-dihydrocortisol which is then subsequently metabolized to 5α-tetrahydrocortisol (allo-THF) and 5β-tetrahydrocortisol (THF), respectively, by 3α-hydroxysteroid dehydrogenase. Similarly, cortisone is converted to tetrahydrocortisone (THE). These metabolites are conjugated with glucuronic acid and excreted in the urine.
- 6β-Hydroxylase converts cortisol to 6β-hydroxycortisol and cortisone to 6β-hydroxycortisone.
- 20β-Oxoreductase reduces cortisol to 20β-dihydrocortisol and cortisone to 20β-dihydrocortisone.

11β-Hydroxysteroid Dehydrogenase-Type 1

11β-HSD1 is a bidirectional enzyme which acts as both an oxoreductase converting cortisone to cortisol and as a dehydrogenase inactivating cortisol to cortisone. However, in vivo, it acts mainly as an oxoreductase regenerating cortisol locally principally in metabolically active tissues such as liver, adipose tissue, and muscle (Tomlinson *et al.*, 2004). Within the cell, 11β-HSD1 is located in the endoplasmic reticulum (ER) membrane and its catalytic domain has a luminal orientation (Odermatt *et al.*, 1999). Its oxoreductase activity is critically dependent upon a tightly associated enzyme, hexose-6-phosphate dehydrogenase (H6PDH) that generates the cosubstrate, NADPH, to permit the reduction of cortisone to cortisol. It is the maintenance of the high intra-lumen NADPH/$NADP^+$ ratio which confers the directionality of 11β-HSD1 (Draper *et al.*, 2003). In the absence of H6PDH, 11β-HSD1 acts as dehydrogenase and oxidizes cortisol to cortisone. In humans, 11β-HSD1 is a 292 amino acid protein and is encoded by the gene HSD11B1 found on chromosome 1q32.2 (Tannin *et al.*, 1991).

11β-HSD1 is mainly not only expressed in hepatocytes, adipose stromal cells, gonads, and neuronal brain cells but can also be found in the cardiac myocytes and fibroblasts, spleen, lymph nodes, Peyer's patch, thymus, macrophages, osteoblasts, osteoclasts, corneal epithelium and endothelium, nonpigmented ciliary epithelial cells, surface epithelia and lamina propria, kidney cortex and medulla, pancreatic islets of Langerhans, skin fibroblasts, vascular smooth muscle, skeletal myoblasts and placental syncytiotrophoblast, chorion, and decidua (Tomlinson *et al.*, 2004). There are many factors that regulate its expression. GC, proinflammatory cytokines, peroxisome proliferator-activated receptor γ agonists, and CCAAT/enhancer-binding protein increase expression and activity. Conversely, growth hormone and liver X receptor agonists decrease its expression (Tomlinson *et al.*, 2004). Oestradiol reduces 11β-HSD1 expression in rat liver and kidney but testosterone has no effect (Gomez-Sanchez *et al.*, 2003).

Genetic Defects

Cortisone reductase deficiency and apparent cortisone reductase deficiency

There are two clinical phenotypes associated with impaired oxoreductase activity of 11β-HSD1 that arise as a result of specific genetic defects. Loss of function mutations in the HSD11B1 gene underpins "true" cortisone reductase deficiency (CRD) whereas

 doi:10.1016/B978-0-12-801238-3.64302-7

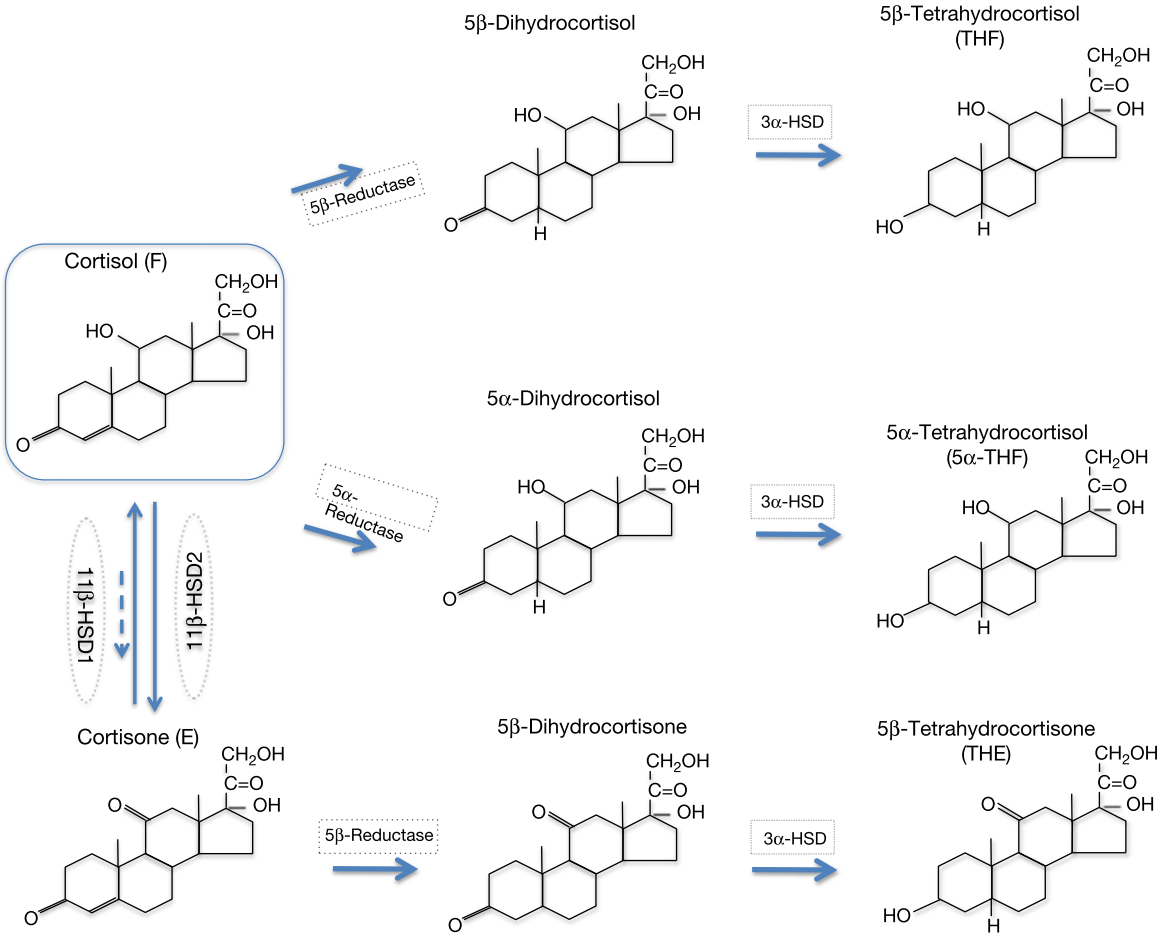

Fig. 1 Summary of cortisol metabolism: Cortisol is metabolized by the enzymes 5α-reductase (to 5α-dihydrocortisol) and 5β-reductase (to 5β-dihydrocortisol). 3α-Hydroxysteroid dehydrogenase (3α-HSD) further metabolizes 5α-dihydrocortisol to 5α-tetrahydrocortisol and 5β-dihydrocortisol to 5β-tetrahydrocortisol. Cortisol and cortisone are interconverted by the isozymes of 11β-hydroxysteroid dehydrogenase (11β-HSD). 11β-HSD2 inactivates cortisol to cortisone, while 11β-HSD1 predominantly reactivates cortisol from inactive cortisone. Cortisone is metabolized by 5β-reductase to 5β-dihydrocortisone, which is further metabolized by 3α-HSD to 5β-tetrahydrocortisone.

mutations in the H6PD gene cause "apparent" CRD (ACRD). ACRD is the more severe form of the condition as the loss of H6PDH activity instigates a decrease of the intralumen NADPH/$NADP^+$ ratio thus favoring the dehydrogenase activity of 11β-HSD1 where cortisol is inactivated to cortisone (Lavery *et al.*, 2008). The cortisol inactivation seen in ACRD induces a compensatory HPA axis activation and ACTH-mediated adrenal GC and androgen secretion. The activation of the HPA axis ensures that circulating cortisol levels are maintained and as a result these patients do not display features that would be indicative of cortisol deficiency. Clinically this condition presents with a phenotype that resembles polycystic ovary syndrome (PCOS) in adult females or as premature adrenarche in children. The urinary steroid profiles show extremely high cortisone with concomitantly low cortisol metabolites consistent with impairment of 11β-HSD1 activity. True CRD is a milder form of the condition; two cases have been reported presenting with premature adrenarche. As might be expected the urinary steroid profile shows a milder abnormality in comparison with ACRD reflecting that both the reductase and dehydrogenase activity of 11β-HSD1 are reduced (Lawson *et al.*, 2011; Lavery *et al.*, 2013). However, as in patients with ACRD there was secondary HPA axis activation and increased androgen secretion driving the clinical phenotype.

HSD11B1 and H6PDH polymorphisms

Several studies have been conducted to investigate possible links between single nucleotide polymorphisms (SNPs) of HSD11B1 and disease. Conditions such as PCOS, Alzheimer's disease, type 2 diabetes, and cardiovascular disease have been investigated but there is currently conflicting data on the association between HSD11B1 SNPs and these diseases (Gathercole *et al.*, 2013). Genetic variations in H6PDH have also been examined in the context of common diseases and associations with specific polymorphisms and multiple sclerosis, carotid intima-medial thickness, and atherosclerosis have been identified (Rahman *et al.*, 2011; Wellcome Trust Case Control *et al.*, 2007; Alcina *et al.*, 2010). Additionally, PCOS has been associated with the rs668832 H6PD SNP as reported in two small case-control studies (San Millan *et al.*, 2005; Martinez-Garcia *et al.*, 2012).

Tissue-Specific Impact of 11β-HSD1 Expression and Activity

Adipose tissue

11β-HSD1 is highly expressed in both white and brown adipose tissues and acts predominantly as an oxoreductase generating active GC cortisol. H6PDH and GRα receptors have been reported to be more highly expressed in omental adipose tissue compared to subcutaneous (SC) and therefore the impact of 11β-HSD1 activity may be more pronounced in this depot. Absolute expression levels of 11β-HSD1 are, however, similar in both omental and SC adipose tissue in humans (Veilleux *et al.*, 2009), but in mice, 11β-HSD1 is most highly expressed in SC adipose tissue (Morton *et al.*, 2004b).

GCs play an important role in adipocyte biology, promoting adipocyte differentiation, and 11β-HSD1 activity has been implicated in both the induction of adipogenesis and the maturation of adipocytes (Bujalska *et al.*, 2008). In addition, GCs promote fatty acid release through lipolysis. 11β-HSD1 inhibition and the consequent decrease in active GC availability decrease lipolysis both in vitro and in vivo (Gathercole *et al.*, 2011; Tomlinson *et al.*, 2007).

Rodent models have contributed significantly to our understanding of the role of 11β-HSD1 in adipose tissue. Perhaps the most important proof-of-concept observation as to the importance of 11β-HSD1 in adipose tissue was provided by Masuzaki *et al.* (2001) who overexpressed 11β-HSD1 in adipose tissue in mice under the aP2 promoter. These transgenic mice developed visceral obesity without changes in circulating GC levels. They did however report an increase in corticosterone (the active GC in rodents) in the portal vein, consistent with putative export of regenerated active GC from visceral adipose tissue. These mice developed many features of the metabolic syndrome including insulin resistance, dyslipidemia, and hypertension. Additionally, Morton *et al.* (2004a) have provided a detailed characterization of the 11β-HSD1 KO mouse model and reported that these animals have lower visceral adipocyte accumulation on high fat diet and resist the development of high fat diet induced insulin resistance and diabetes.

There is strong translational evidence to support the concept that 11β-HSD1 activity and expression are dysregulated in human obesity (Chapman *et al.*, 2013), while circulating GCs levels are unchanged in comparison with lean individuals (Travison *et al.*, 2007). In patients with simple obesity, 11β-HSD1 activity and expression are increased two- to threefold in SC adipose tissue often with a concomitant decrease in hepatic 11β-HSD1 activity (see later). However, in obese individuals with type 2 diabetes, the reduction in hepatic 11β-HSD1 activity is not observed and it has been postulated that this ongoing exposure to locally regenerated cortisol may fuel unchecked hepatic glucose output (Chapman *et al.*, 2013). There are fewer studies that have examined the impact of obesity on visceral 11β-HSD1 activity and expression and the data are more variable. Woods *et al.* (2015) reported a positive correlation between visceral adipose tissue 11β-HSD1 gene expression and BMI but not in SC adipose tissue. They did however report a reduction in HSD11B1 gene expression in SC adipose tissue following weight loss. On the other hand, 11β-HSD1 gene expression in hepatocytes was negatively correlated with BMI which is consistent with previous studies (Woods *et al.*, 2015). These findings are in accordance to the reports by Mlinar *et al.* (2011) and Michailidou *et al.* (2007) who reported that visceral adipose tissue HSD11B1 gene expression correlates with adiposity and adipocyte size. However, in contrast, Goedecke *et al.* (2006) reported that HSD11B1 gene expression in omental adipose tissue did not correlate with obesity and therefore there remain some discrepancies in the published literature.

Liver

11β-HSD1 is highly expressed in the liver and in humans it is mainly located centripetally and found in high levels around the central vein (Ricketts *et al.*, 1998b), and it acts exclusively as an oxoreductase (Jamieson *et al.*, 1995; Ricketts *et al.*, 1998a).

In global 11β-HSD1 KO mice, 11β-HSD1 deficiency has little effect on liver function in the fed state, but in the fasted state there is no rise in PPARα which is consistent with reduced GC action. On refeeding, there is an exaggerated increase in the expression of lipogenic enzymes and a parallel reduction in catabolic enzymes. Therefore, 11β-HSD1 deficiency causes a more favorable lipid profile and improved liver insulin sensitivity (Morton *et al.*, 2001). Mouse models with both liver-specific overexpression and deletion of 11β-HSD1 have also been generated. Overexpression of 11β-HSD1 in liver was achieved by using the apolipoprotein E promoter and these mice developed hypertension, dyslipidemia, and hypertriglyceridemia which lead to hepatic steatosis, but did not progress to steatohepatitis (Paterson *et al.*, 2004). They also became insulin resistant but were not obese. In mice with hepatic 11β-HSD1 deletion, there is no significant change in insulin sensitivity or hepatic or serum lipids. There was, however, an increase in adrenal size, despite circulating corticosterone levels being unchanged, suggestive of an increase in HPA axis activation (Lavery *et al.*, 2012).

As described earlier, in simple obesity, 11β-HSD1 activity in the liver is reduced (as reflected by the analysis of urinary steroid metabolites measured by gas chromatography, mass spectrometry, and the generation of cortisol from oral cortisone); however in patients who also have type 2 diabetes activity is unchanged (Stimson *et al.*, 2011). This is in accordance to the findings reported by Torrecilla *et al.* (2012) who reported that there was higher expression of GR, 11β-HSD1, H6PDH, and PEPCK in hepatocytes of obese patients with metabolic disease compared to obese patients (Torrecilla *et al.*, 2012). However, in the db/db diabetes murine model, 11β-HSD1 and GR expressions are both increased which is consistent with findings from human studies (Deary *et al.*, 2006).

Muscle

11β-HSD1 is present in skeletal muscle but at lower levels when compared to the liver (Whorwood *et al.*, 2001). In human muscle, 11β-HSD1 acts as an oxoreductase, but its role in metabolic disease remains controversial. Whorwood *et al.* (2001) reported that

11β-HSD1 levels did not correlate with adiposity in human muscle ex vivo but Abdallah *et al.* (2005) reported that there was an increased expression in myotubes from obese patients with type 2 diabetes. Similar findings were also shown in obese rodents with diabetes where there were increased levels of 11β-HSD1 mRNA and protein (Zhang *et al.*, 2009a). Morgan *et al.* (2009) showed that altering 11β-HSD1 activity can impact on insulin sensitivity in skeletal muscle in humans and rodent models (Morgan *et al.*, 2009). 11β-HSD1 inhibition in the hyperglycemic KK/Ta jcl mouse induced an increase in skeletal muscle insulin receptor substrate 1 and a decrease in expression of genes involved in lipid metabolism (Gathercole *et al.*, 2013).

More recently it has been postulated that 11β-HSD1 may be involved in age-related sarcopenia. 11β-HSD1 expression in skeletal muscle was increased with age in women and also associated with reduced grip strength, insulin resistance, and an adverse body composition profile (Hassan-Smith *et al.*, 2015).

Pancreatic islets of Langerhans

11β-HSD1 mRNA has been identified in rodent and human pancreatic islets but there has been controversy regarding its exact location with conflicting reports suggesting that it may be expressed in either α- (Swali *et al.*, 2008) or β-cells (Davani *et al.*, 2000).

The relationship between pancreatic 11β-HSD1 activity and metabolic disease has been investigated using several rodent models and increased 11β-HSD1 levels seem to be associated with β-cell failure (Davani *et al.*, 2000). However, the precise relationship between 11β-HSD1 expression and metabolic disease is not clear. In the global 11β-HSD1 KO mouse, there is impairment in the β-cell function, but with improved glucose tolerance (Turban *et al.*, 2012). In a diabetes-prone rodent model where 11β-HSD1 is overexpressed in the pancreas there is enhanced glucose-stimulated insulin secretion (Turban *et al.*, 2012). However, increases in 11β-HSD1 expression in the pancreatic islets of obese ob/ob mice (Ortsater *et al.*, 2005) and Zucker diabetic fatty fa/fa rats (Duplomb *et al.*, 2004) correlate with increasing hyperglycemia. This increase is reversed by troglitazone which inhibits hyperglycemia and hyperlipidemia. In normal mice, high-fat diet causes a compensatory increase in insulin secretion with upregulation of 11β-HSD1, whereas in severe obesity, very high islet 11β-HSD1 levels, and therefore GC regeneration, contribute to β-cell failure (Chapman *et al.*, 2013). In mouse strains that are susceptible to β-cell failure, high-fat diet causes a decrease in 11β-HSD1 expression whereas in mice that are not prone to metabolic disease there is some increase in 11β-HSD1 expression.

Cardiovascular disease

Both 11β-HSD1 and 11β-HSD2 are expressed in the vasculature (Walker *et al.*, 1991). 11β-HSD1 is mainly found in the vascular smooth muscle and is involved in angiogenesis and vascular remodeling (Walker *et al.*, 1991), whereas 11β-HSD2 is located in the endothelium (Hadoke *et al.*, 2001).

GCs inhibit angiogenesis and mice deficient in 11β-HSD1 exhibit increased angiogenesis particularly in cases of myocardial injury (Small *et al.*, 2005). 11β-HSD1 is also expressed in differentiated macrophages and 11β-HSD1 deficiency is associated with acute inflammation that exacerbates atherosclerosis. Hermanowski-Vosatka *et al.* (2005) reported that 11β-HSD1 inhibition reduces cholesterol levels in atherosclerosis-prone ApoE$^{-/-}$ mice. However, Lloyd *et al.* (2009) found that in atherosclerosis susceptible LDL receptor null mice, there was no effect. Therefore, 11β-HSD1's role in atherosclerosis remains controversial and has not been fully elucidated.

Nervous system

11β-HSD1 is expressed in the adult brain with highest expression in the hippocampus, cortex, cerebellum, and anterior pituitary. 11β-HSD2 is also located in the brain but it is expressed at considerably lower levels. 11β-HSD1 mainly acts as an oxoreductase but H6PDH is not frequently coexpressed with 11β-HSD1 in the brain (Gomez-Sanchez *et al.*, 2008). 11β-HSD1 is thought to be involved in cognition; the use of 11β-HSD inhibitors in elderly mice (Sooy *et al.*, 2010) and humans (Sandeep *et al.*, 2004) improves cognitive function. In a transgenic mouse model where 11β-HSD1 was overexpressed in the forebrain, there was evidence of cognitive impairment similar to that observed with aging (see later) (Holmes *et al.*, 2010).

11β-HSD1 is also involved in the regulation of aqueous humor production in the ocular ciliary epithelium and is thought to have a role in regulating aqueous humor production by increasing local cortisol generation (Rauz *et al.*, 2001). Rauz *et al.* (2003) reported that the nonspecific 11β-HSD inhibitor, carbenoxolone, decreased intraocular pressure in patients with ocular hypertension (Rauz *et al.*, 2003).

Dysregulation of 11β-HSD1 in the choroid plexus and arachnoid granulation tissue may be implicated in the development of idiopathic intracranial hypertension (IIH), which is known to be associated with GC excess and with simple obesity. Sinclair *et al.* (2010) reported that the largest fall in intracranial pressure in obese subjects with IIH was observed in those who had the largest decrease in global 11β-HSD1 activity associated with weight loss.

Aging

GC excess shares many phenotypic similarities with the aging phenotype including the development of central fat accumulation, hypertension, hyperlipidemia, insulin resistance, and sarcopenia. With increasing age, there is an increase in plasma cortisol concentrations, dampening of diurnal rhythm, and an increase in evening ACTH and consequent cortisol secretion (Van Cauter *et al.*, 1996). In addition, there is evidence to suggest increased tissue-specific cortisol regeneration through the activity of 11β-HSD1 and this may be an additional important contributory factor to local GC excess. The mechanisms underpinning this increased activity are not completely understood but higher levels of inflammatory cytokines, which upregulate 11β-HSD1, and lower levels of GH and IGF-1, which inhibit 11β-HSD1 activity, maybe important (Gathercole *et al.*, 2013).

Inflammation and immunity

GCs have an important role in modulating inflammatory and immune responses. Alteration of 11β-HSD1 expression and activity has been shown to have an important role in the modulation of the inflammatory response.

Many proinflammatory cytokines, including TNF-alpha and IL1-β, are potent upregulators of 11β-HSD1 activity and expression (Chapman *et al.*, 2013). In addition, IL-4 and IL-13 induce moderate 11β-HSD1 expression in monocytes (Thieringer *et al.*, 2001). 11β-HSD1 is induced during monocyte differentiation to macrophage (Thieringer *et al.*, 2001); lipopolysaccharide stimulates 11β-HSD1 expression in macrophages, which subsequently induces transformation to a proinflammatory M1 phenotype, and also in brain microglia (Martinez *et al.*, 2006; Gottfried-Blackmore *et al.*, 2010). In neutrophils, 11β-HSD1 expression is increased during inflammation, but absent during cellular apoptosis (Coutinho *et al.*, 2011). It is also expressed in mouse CD4 and CD8 positive lymphocytes, B cells, and dendritic cells (Freeman *et al.*, 2005).

11β-HSD1 KO mice have an impaired antiinflammatory response when challenged in models of joint inflammation, peritonitis, and lung inflammation; the inflammatory response was enhanced with a slower recovery rate (Coutinho *et al.*, 2012). In humans, 11β-HSD1 activity has been found to be augmented in rheumatoid arthritis (Hardy *et al.*, 2008) with increased expression in inflammatory bowel disease (Cooper *et al.*, 2011). Specifically, there is higher expression during acute exacerbation compared to remission suggesting that 11β-HSD1 has an active role in acute inflammation (Cooper *et al.*, 2011).

Bone and joint

11β-HSD1 is predominantly expressed in osteoblasts, while 11β-HSD2 is the only isoform found in osteosarcoma cells. Its activity in osteoblasts is induced by proinflammatory cytokines and GC (Cooper *et al.*, 2003). 11β-HSD1 KO mice do not exhibit any changes in bone mass, formation, or resorption (Justesen *et al.*, 2004). Sher *et al.* (2006) reported that in transgenic mice where 11β-HSD2 was overexpressed (with consequent increased local clearance of active GC) in osteoblasts there was a decrease in femoral cortical bone area and Weinstein *et al.* (2010) reported that 11β-HSD2 overexpression in osteoblasts and osteocytes of mice provided an age-related reduction in bone mass.

Using urinary steroid metabolites, Cooper *et al.* (2003) demonstrated that measurements of 11β-HSD1 activity were able to predict the fall in bone formation markers following a 7-day course of prednisolone therapy in healthy male volunteers. Therefore, this has the potential to be utilized in clinical practice, where 11β-HSD1 could predict an individual's susceptibility to GC-induced osteoporosis (Cooper *et al.*, 2003).

Skin and salivary glands

11β-HSD1 and 11β-HSD2 are both expressed in human and mouse skin (Tiganescu *et al.*, 2011; Vukelic *et al.*, 2011; Terao *et al.*, 2011). 11β-HSD1 acts as an oxoreductase and is expressed in the epidermis and dermis (Hennebert *et al.*, 2007) with high expression in keratinocytes (Terao *et al.*, 2011). 11β-HSD1 expression is increased with age and photodamage, and has been suggested to be a key mechanism in the atrophic, age-related skin changes (Tiganescu *et al.*, 2011). GCs are well recognized for their ability to inhibit wound healing. In rodent models, selective inhibition of 11β-HSD1 induced keratinocyte proliferation and enhanced cutaneous wound healing and prevented age-related skin changes (Hennebert *et al.*, 2007). The translation potential of selective 11β-HSD1 inhibitors to improve would healing in clinical studies is yet to be explored.

Selective 11β-HSD1 Inhibitors

Much of the data described earlier has led to the concept that decreasing tissue-specific GC exposure may have the potential to improve metabolic and also cognitive phenotype. On this background, highly potential selective (in that they inhibit 11β-HSD1, but not 11β-HSD2) 11β-HSD1 inhibitors have been developed.

The first selective compound was developed by Biovitrum (BVT2733) and reduced fasting blood glucose, insulin, and cholesterol levels in hyperglycemic rodent models (Barf *et al.*, 2002; Alberts *et al.*, 2002, 2003). Subsequently, many other compounds have been developed by pharmaceutical and biotech companies (including compounds A and 531) and have demonstrated potent metabolic benefits to reduce mesenteric fat mass, hepatic steatosis, improve insulin sensitivity, and reduce hepatic glucose production (Berthiaume *et al.*, 2007a,b; Edgerton *et al.*, 2010).

The first translational study in humans to examine the metabolic impact of these compounds used INCB013739 in patients with type 2 diabetes. After 2 weeks of administration, fasting blood glucose decreased, particularly in those patients with more pronounced hyperglycemia and there was also reduction in LDL cholesterol but no change in HDL cholesterol. In more prolonged 12-week studies in patients already taking metformin, there was modest weight loss and improvement in overall glycemic control as measured by a reduction in glycated hemoglobin (Rosenstock *et al.*, 2010). A further selective 11β-HSD1 inhibitor, MK0916, was trialed in patients with type 2 diabetes. This caused a modest reduction in weight and waist–hip ratio as well as an HbA1c reduction of 0.3% in the 6 mg group. However, there was no alteration in fasting plasma glucose, postprandial glucose or insulin levels. There was also increase in LDL and non-HDL cholesterol (Feig *et al.*, 2011). Other selective 11β-HSD1 inhibitors have been trialed and have mostly shown moderate effectiveness in improving glycemic control and blood pressure in patients with diabetes and metabolic disease (Gathercole *et al.*, 2013). The fact that these improvements were relatively modest (in comparison with other pharmaceutical therapies already available) has limited the subsequent development of this class of drug.

Importantly, in all studies where selective 11β-HSD1 inhibitors have been used and where they have been measured appropriately (including measurements of adrenal androgens and ACTH), there is secondary activation of the HPA axis as a consequence of the decreased cortisol half-life.

11β-HSD1 and GC Excess

There is emerging evidence to suggest that 11β-HSD1 may have a role to regulate the local availability of GCs in conditions of either endogenous or exogenous GC excess. In patients with Cushing's disease, 11β-HSD1 activity as measured by urinary steroid metabolite analysis is increased (Stewart *et al.*, 1995). However, patients have been described who have a functional deficit in 11β-HSD1 activity and it has been postulated that this inability to regenerate active GC within key target tissues may protect those individuals from the development of the classic Cushing's phenotype (Tomlinson *et al.*, 2002; Arai *et al.*, 2008), independent of their circulating GC levels. Similar observations have been made in rodent models with genetic deletion of 11β-HSD1 (Morgan *et al.*, 2014) and translational clinical studies using selective 11β-HSD1 inhibitors in this context are underway. This has potential implications not only for patients with Cushing syndrome but also for the large number of patients, perhaps up to 2%–3% of the population of the United Kingdom and United States, who take regular prescribed GC therapy and are vulnerable to their array of averse metabolic side effects.

11β-Hydroxysteroid Dehydrogenase-Type 2

11β-HSD2 is a unidirectional enzyme that acts solely as a dehydrogenase and is NAD^+ dependent. Its cDNA was first cloned from sheep kidney, followed by human, rat, rabbit, mouse, and other species (Chapman *et al.*, 2013). In humans, it is expressed by the gene HSD11B2 that is located on chromosome 16q22 (Agarwal *et al.*, 1995). Human 11β-HSD2 comprises of 405 amino acids with a molecular mass of about 44 kDa (Chapman *et al.*, 2013). Within cells, it is localized in the ER membrane, similar to 11β-HSD1, most likely via three transmembrane helices (Brown *et al.*, 1996).

11β-HSD2 is located mainly in mineralocorticoid-target tissues including kidney, colon, placenta, sweat, and salivary glands and it is also found in the exocrine pancreas and adrenal cortex. 11β-HSD2 expression does display some interspecies differences in that in humans, it can be found in testis but not in mice or rats (Chapman *et al.*, 2013). 11β-HSD2 appears to have an important role in developmental programming and it is widely expressed in the fetus and placenta (see later) (Chapman *et al.*, 2013).

Genetic Defects: Apparent Mineralocorticoid Excess

Apparent mineralocorticoid excess (AME) is caused by both homozygous and heterozygous mutations in the HSD11B2 gene. Clinical features of this condition consist of hypertension, plasma volume expansion, hypokalemic alkalosis, and a suppressed renin–angiotensin–aldosterone system (Stewart, 1999). This is caused by the absence or reduced activity of 11β-HSD2 in the kidney which consequently reduces the inactivation of cortisol to cortisone in the kidney allowing cortisol to bind and activate the mineralocorticoid receptor (MR) for which it shares the same affinity as the MR endogenous ligand, aldosterone. There are two types of AME; type I is congenital and is caused by a homozygous mutation of HSD11B2 which instigate full or partial loss of enzyme activity and is commonly found in consanguineous families. Type II normally develops in adolescence or early adulthood and is a milder form of the condition. It is also caused by homozygous mutation of the HSD11B2 gene (Palermo *et al.*, 2004).

In mice with a heterozygous HSD11B2 gene disruption, basal blood pressures are normal; however, blood pressure does rise on sodium loading. Interestingly, this effect is reduced by inhibiting the GR instead of the MR by mechanisms which are currently unknown (Bailey *et al.*, 2011). Defects in the HSD11B2 gene resulting in a prolonged cortisol half-life have been linked to the development of essential hypertension (Soro *et al.*, 1995; Walker *et al.*, 1993). With increasing age, there is a decline in 11β-HSD2 activity which is associated with an increase in blood pressure (Henschkowski *et al.*, 2008). HSD11B2 polymorphisms have been associated with hypertension in black men with renal failure but this finding has not been consistent in other studies (Watson *et al.*, 1996; White *et al.*, 2001). HSD11B2 polymorphisms have also been implicated with sodium-sensitive blood pressure changes in white men.

Acquired 11β-HSD2 deficiency through consumption of liquorice roots is well described. Liquorice roots contain *Glycyrrhizin* which is a potent competitive inhibitor of 11β-HSD2 in vivo. It therefore mimics a mild form of AME and patients present clinically with hypertension and hypokalemia and in some severe cases myopathy and cardiac arrhythmia (Palermo *et al.*, 2004). Flavonoid consumption, found in fruit such as grapefruit, also have an inhibitory effect on 11β-HSD2 which can also present in a similar way to excessive licorice consumption (Palermo *et al.*, 2004).

Kidney

As mentioned earlier, 11β-HSD2 is highly expressed in the kidney and specifically in the distal nephron and the cortical collecting duct cells in close proximity to the MR. Here it serves to deactivate cortisol into the inactive cortisone and thus prevent cortisol

from activating the MR (for which it shares the same affinity as its cognate ligand, aldosterone). The importance of 11β-HSD2 in the kidney was proved by Leckie *et al.* (1995) by transfecting distal nephron cells with MR and an MR reporter gene with or without 11β-HSD2. 11β-HSD2 coexpression was able to prevent GC activation of MR and this was reversed by carbenoxolone (a nonselective inhibitor of both 11β-HSD1 and 2) administration (Leckie *et al.*, 1995). Even though cortisol has a much higher affinity for binding to MR than to 11β-HSD2, 11β-HSD2 is still able to deactivate cortisol sufficiently to prevent it from activating the MR. It is not completely understood how this mechanism occurs but it has been suggested that cortisol may preferentially track through intracellular membranes such as the ER and be deactivated by 11β-HSD2 before reaching the cytosolic MR (Odermatt *et al.*, 1999).

Placenta

Total and free cortisol concentrations in the circulation rise during gestation and it is the presence of 11β-HSD2 in the placenta that offers a protective barrier to the fetus from maternal excess GC (through the inactivation of cortisol to cortisone). In humans and rats, placental 11β-HSD2 is found in the syncytiotrophoblast. Nacharaju *et al.* (2004) used the nonselective 11β-HSD inhibitor carbenoxolone to inhibit 11β-HSD2 activity in placental trophoblasts in vitro. This caused an increase in human chorionic gonadotropin secretion with rapid cytotrophoblast differentiation into syncytial trophoblasts, demonstrating the important functional role of 11β-HSD2 in placental development and function (Nacharaju *et al.*, 2004).

Placental 11β-HSD2 expression increases throughout gestation, but activity decreases in the last 2 weeks prior to delivery. This is in accordance with the fact that GCs are important in tissue and organ maturation; therefore 11β-HSD2 is widespread in the fetus prior to mid gestation but is subsequently downregulated to permit GC delivery. 11β-HSD2 activity in the placenta can impact upon fetal growth in humans. Human fetuses with homozygous or compound heterozygous mutations of HSD11B2 have lower birth weights (Dave-Sharma *et al.*, 1998; Kitanaka *et al.*, 1996; Mune *et al.*, 1995). This is in agreement with findings in 11β-HSD2 KO mice that also have decreased birth weights (Holmes *et al.*, 2006). In addition, women who consume large amounts of liquorice, a nonselective 11β-HSD inhibitor while pregnant, have shorter pregnancies and their off-spring have poorer cognitive function which is accompanied with hyperactivity of the HPA axis (Raikkonen *et al.*, 2009, 2010).

Lung

Both 11β-HSD enzymes are expressed in the human lung but specifically 11β-HSD1 is located in the alveoli and 11β-HSD2 in the bronchioles and trachea and vascular epithelium (Suzuki *et al.*, 1998). However, in adult rats, 11β-HSD1 is expressed mainly in the interstitial fibroblasts (Brereton *et al.*, 2001) and 11β-HSD2 is expressed at very low levels (Alikhani-Koopaei *et al.*, 2004).

In fetal lungs, in both humans and rodents, there is high expression of 11β-HSD2 in early to midgestation which is then subsequently downregulated (with 11β-HSD1 upregulation) in late gestation (Chapman *et al.*, 2013) to enhance local GC delivery which is vital for lung maturation.

Colon

11β-HSD1 and 11β-HSD2 are both expressed in the human colonic epithelium and lamina propria (Smith *et al.*, 1996; Whorwood *et al.*, 1994). In rodents, 11β-HSD1 is located in the lamina propria and 11β-HSD2 in the epithelial cells (Whorwood *et al.*, 1994). In humans with inflammatory bowel disease, 11β-HSD1 expression is increased and 11β-HSD2 is decreased (Zbankova *et al.*, 2007). This reciprocal regulation may be mediated by proinflammatory cytokines TNF-α and IL-1 (Kostadinova *et al.*, 2005). 11β-HSD2 inhibition has been reported to have an anticancer effect in colorectal adenocarcinoma. It has been postulated that this is due to the increased GC suppression of COX-2 and PGE_2 (Zhang *et al.*, 2009b).

Skin

In the skin, 11β-HSD2 is mainly located in the sweat glands as it is the main site in the skin that is a mineralocorticoid target (Smith *et al.*, 1996). 11β-HSD2 is also found in the parotid and submandibular salivary glands and thus salivary cortisol could potentially be used clinically as a biomarker of serum free cortisol (Smith *et al.*, 1996).

The A-Ring Reductases

Three different A-ring reductases have been identified and described. These include 5αR1, 5αR2, and 5βR (Russell and Wilson, 1994; Uemura *et al.*, 2008). They are a series of enzymes that have multiple roles to metabolize steroid hormones and bile acids. The 5α-reductases are keys enzymes in the metabolism of testosterone, cortisol, and progesterone (Russell and Wilson, 1994). They metabolize testosterone to 5α-dihydrotestosterone and reduce cortisol to 5α-dihydrocortisol, which is then metabolized further to 5α-tetrahydrocortisol by 3α-hydroxysteroid dehydrogenase. Therefore, 5α-reductases increase androgen but reduce GC availability making it an important regulator enzyme in the activity of steroid hormones. Similarly, 5βR clears cortisol to 5β-dihydrocortisol

(with further downstream conversion to 5β-tetrahydrocortisol), but is also a key regulatory step in the bile acid synthesis pathway. In contrast therefore to the regenerative, GC-enhancing activity of 11β-HSD1, the A-rung reductases clear cortisol and therefore limit GC action.

5α-Reductase Type 1 and Type 2

5αR1 is expressed by gene SRD5A1 which is located on chromosome 5p15.31 in the human genome. The enzyme consists of 259 amino acids and has a molecular weight of 29 kDa. It is found in the liver, nongenital skin, muscle, adipose tissue, and brain. Testosterone is the most well-recognized substrate for this enzyme, even though it has the highest affinity for progesterone. It is thought to be accountable for approximately a third of circulating dihydrotestosterone (Gisleskog *et al.*, 1998; Andersson and Russell, 1990; Normington and Russell, 1992). There are no known mutations of SRD5A1.

5αR2 is expressed by gene SRD5A2 which is located on chromosome 2p23.1 in humans. The enzyme consists of 254 amino acids and has a molecular weight of 28 kDa (Russell and Wilson, 1994). It is mainly expressed in the male reproductive tissues such as prostate, epididymis, and seminal vesicles (Russell and Wilson, 1994). A number of mutations and polymorphisms in SRD5A2 have been identified, some of which cause the clinical phenotype of 46XY disorder of sex development (Samtani *et al.*, 2010). Affected males lack virilization and have poor development of external genitalia due to reduction in the production of the potent androgen, dihydrotestosterone. Conversely, increased dihydrotestosterone production via 5αR2 has been associated with disorders such as polycystic ovarian syndrome, and breast and prostate cancers (Jakimiuk *et al.*, 1999; Labrie *et al.*, 1993).

Tissue Distribution and Function

Both 5αR1 and 5αR2 are expressed in human liver whereas in rodents, only 5αR1 is expressed. Therefore, 5αR1 function in the liver has been investigated using rodent models. 5αR1 KO male mice have a higher incidence of hepatosteatosis and consequently higher risk of liver fibrosis and scarring (Dowman *et al.*, 2013; Livingstone *et al.*, 2015). 5αR1 is also expressed in adipose tissue in both humans and rodents as well as in skeletal muscle (Upreti *et al.*, 2014). It is also found in vascular endothelium and smooth muscle and inhibition of 5αR causes endothelial damage and dysfunction (Campelo *et al.*, 2012). In the kidney, 5αR1 is expressed; however, 5αR2 and 5βR are absent (Quinkler *et al.*, 2003).

There is emerging evidence from translational studies to suggest that 5αR1 and 2 may have a role in the regulation of metabolic phenotype. In patients with and without PCOS, 5αR activity correlates with worsening metabolic phenotype (Blumenfeld *et al.*, 2016; Crowley *et al.*, 2014; Tomlinson *et al.*, 2008a,b; Tsilchorozidou *et al.*, 2003; Vassiliadi *et al.*, 2009). In addition, longitudinal data over a 5-year period suggest that baseline 5αR activity is able to predict the development of future adverse metabolic features including insulin resistance and dysglycemia (Crowley *et al.*, 2014). The precise molecular mechanisms underpinning these observations are currently unknown (Zyirek *et al.*, 1987; Perel *et al.*, 1986).

5α-Reductase Inhibition

5α-reductase inhibitors are traditionally used for their antiandrogen effects and they are commonly prescribed for conditions such as benign prostate hyperplasia and prostate cancer. A very small number of clinical studies have been undertaken in order to investigate their potential implication in steroid metabolism and metabolic phenotype. As mentioned previously, cross-sectional and longitudinal studies have shown that 5α-reductase activity is higher in the presence of high BMI and insulin resistance (Crowley *et al.*, 2014; Tomlinson *et al.*, 2008a,b). Hazlehurst *et al.* (2016) performed a clinical trial in 12 healthy male volunteers who were randomized to receive either a 3-week course of dutasteride (nonselective dual 5αR1 and 5αR2 inhibitor) or finasteride (5αR2 selective inhibitor). They reported that dual 5α-reductase inhibition using dutasteride was associated with increased hepatic lipid accumulation (Hazlehurst *et al.*, 2016). Similar results have also been published by Upreti *et al.* (2014) in which 46 men were randomized to take finasteride, dutasteride, or placebo for 3 months. They demonstrated that dual 5α-reductase inhibition increased insulin resistance and decreased skeletal muscle glucose disposal (Upreti *et al.*, 2014). Taken together, these studies provide some preliminary evidence to suggest that dutasteride may have an adverse impact on the metabolic phenotype, although additional studies are now warranted.

5β-Reductase

5βR is expressed in the liver and at lower levels in the testis (Charbonneau and The, 2001). It metabolizes cortisol and cortisone to 5β-dihydrocortisol and 5β-dihydrocortisone respectively, with conversion to their tetra-hydro metabolites by the activity of 3α-hydroxysteroid dehydrogenase. It also reduces testosterone to the inactive metabolite 5β-dihydrotestosterone. While it is a key protein in clearing GC, mineralocorticoids, and sex steroids, in addition, it is responsible for a key enzymatic step in the bile acid synthetic pathway. It is coded by the gene AKR1D1 which is found on chromosome 7q33 and it is made of 326 amino acids with a molecular weight of 37 kDa. Mutations in this gene cause bile acid deficiency and neonatal cholestatic liver disease which can lead to hepatic failure (Lemonde *et al.*, 2003) although spontaneous recovery into adult life is reported (Palermo *et al.*, 2008). As expected, these patients have a characteristic urinary steroid profile with a profound reduction on 5β-reduced steroids and a mild

Table 1 The impact of 11β-HSD1, 11β-HSD2, and 5αR1/2 on tissues

	11β-HSD1			*11β-HSD2*		*5αR1/2*	
Tissue	*Main enzymatic activity*	*Impact of increased activity/expression*	*Impact of decreased activity/expression*	*Main enzymatic activity*	*Impact of decreased activity/expression*	*Main enzymatic activity*	*Impact of decreased activity/expression*
Adipose	Oxoreductase (activates cortisol from cortisone)	Visceral obesity Increase in active GC in the portal vein Insulin resistance Dyslipidemia Hypertension (Masuzaki et al., 2001)	Decreased visceral obesity Decrease in insulin resistance following HFD (Morton et al., 2004a)				
Liver	Oxoreductase (activates cortisol from cortisone)	Hypertension Insulin resistance Dyslipidemia Hypertriglyceridemia Hepatic steatosis (Paterson et al., 2004)	No change in insulin sensitivity or hepatic or serum lipids Increase in HPA axis activation (Lavery et al., 2012)			Reduces cortisol to 5α-dihydrocortisol (metabolized to 5α-tetrahydrocortisol)	(5αR1) Higher incidence of hepatosteatosis (Dowman et al., 2013; Livingstone et al., 2015)
Muscle	Oxoreductase (activates cortisol from cortisone)	Insulin resistance (Hassan-Smith et al., 2015)	Insulin sensitivity (Morgan et al., 2009)				
Bone	Oxoreductase (activates cortisol from cortisone)		No changes in bone mass, formation or resorption (Justesen et al., 2004)				
Kidney				Dehydrogenase (deactivates cortisol to cortisone) in the distal nephron	Activation of MR by cortisol causing hypertension, hypokalemic alkalosis and suppression of renin–angiotensin–aldosterone system (Stewart, 1999; Palermo et al., 2004). Causes include mutations in the HSD11B2 gene and liquorice consumption		
Placenta				Dehydrogenase (deactivates cortisol to cortisone) in the syncytiotrophoblast		Decreased birth weights (Dave-Sharma et al., 1998; Kitanaka et al., 1996; Mune et al., 1995; Holmes et al., 2006)	

GC, glucocorticoid; *HFD*, high fat diet; *MR*, mineralocorticoid receptor; *AME*, apparent mineralocorticoid excess.

compensatory increase in 5α-reduced metabolites (Palermo *et al.*, 2008). The role of 5βR in the regulation of metabolic phenotype has not been explored.

Conclusion

GC metabolism and activation are important regulatory steps in determining GC action that are independent of circulating GC levels. Regeneration of the active GC cortisol, through the activity of 11β-HSD1 enhances GC action while conversely, 11β-HSD2 and the A-ring reductases clear cortisol and decrease steroid hormone receptor activation. Consequently, dysregulated expression of these enzymes leads to pathological phenotypes such as AME and ACRD. In common conditions, altered tissue-specific expression levels of these enzymes have been implicated in many disease processes, perhaps most notably metabolic disease including insulin resistance, obesity, and type 2 diabetes, but also, aging, cognitive decline, osteoporosis, glaucoma, skin damage, and wound healing (**Table 1**).

While the clinical impact of selective 11β-HSD1 inhibitors has been modest (perhaps too modest for them to be taken forward as standalone therapies in metabolic disease), there is now some evidence that they may have a role in preventing the adverse effects of prescribed steroids although relevant clinical data are yet to emerge (Morgan *et al.*, 2014).

Glucocorticoid Receptor☆

Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos, National and Kapodistrian University of Athens Medical School, Athens, Greece and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Nomenclature

AF	Activation function domain
AP-1	Activator protein-1
CBP	Cyclic AMP-responsive element-binding protein
CDK	Cyclin-dependent kinase
CLOCK	Circadian locomotor output cycle kaput
DBD	DNA-binding domain
DRIP	Vitamin D receptor-interacting protein
Gas5	Growth Arrest-Specific 5
GR	Glucocorticoid receptor
GREs	Glucocorticoid-response elements
GRIP1	Glucocorticoid receptor-interacting protein 1
hGRα	Human glucocorticoid receptor alpha
hGRβ	Human glucocorticoid receptor beta
HPA axis	Hypothalamic–pituitary–adrenal axis
HSP	Heat shock protein
LBD	Ligand-binding domain
MAPK	Mitogen-activated protein kinase
NF-κB	Nuclear factor-κB
NRB	Nuclear receptor-binding domain
NTD	Amino-terminal domain
p/CAF	p300/CBP-associated protein
PI3K	Phosphatidylinositol 3-kinase
SRC1	Steroid receptor coactivator 1
STATs	Signal transducers and activators of transcription
SUMO-1	Small ubiquitin-related modifier-1
TAFIIs	TBP-associated proteins
TBP	TATA-binding protein
TCR	T-cell receptor
TRAP	Thyroid hormone-associated protein complex

Glossary

Coactivator A protein transducing the transcriptional signal of the glucocorticoid receptor to the transcriptional initiation complex consisting of several general transcription factors and RNA polymerase II.

Glucocorticoid receptor-α and -β (GRα and GRβ) Two glucocorticoid receptor isoforms produced by alternative use of exon 9α and 9β.

Nuclear localization signal A specific protein sequence in the glucocorticoid receptor (GR), which mediates the nuclear translocation of the GR.

Protein–protein interaction A mechanism that transduces a signal from one protein to another protein by their direct association.

Introduction

Glucocorticoids regulate a variety of biologic processes and exert profound influences on many physiologic functions by virtue of their diverse roles in growth, development, and maintenance of basal and stress-related homeostasis (Nicolaides and Charmandari, 2017). At the cellular level, their actions are mediated by an intracellular receptor protein, the glucocorticoid receptor (GR), which functions as a hormone-activated transcription factor that regulates the expression of glucocorticoid target genes. The human (h) GR belongs to the superfamily of steroid/thyroid/retinoic acid receptor proteins that function as ligand-dependent transcription factors (Nicolaides *et al.*, 2010).

Structure of *NR3C1* Gene and hGR Protein

The *NR3C1* gene consists of 10 exons and is located on chromosome 5 (**Fig. 1**) (Chrousos and Kino, 2005). The alternative splicing of exon 9 generates two highly homologous receptor isoforms, termed α and β. These are identical through amino acid 727, but then diverge, with hGRα having an additional 50 amino acids and hGRβ having an additional, nonhomologous 15 amino acids. The molecular weights of these receptor isoforms are 97 and 94 kDa, respectively. The hGRα is ubiquitously expressed in almost all human tissues and cells, resides primarily in the cytoplasm, and represents the classical glucocorticoid receptor that functions as ligand-dependent transcription factor (Chrousos and Kino, 2005). The hGRβ is also ubiquitously

☆*Change History*: December 2017. NC Nicolaides, E Charmandari and GP Chrousos added Abstract, Keywords, Nomenclature, and updated the sections "Structure of *NR3C1* gene and hGR protein", "Molecular mechanisms of GR action", "Factors that modulate GR activity", "Glucocorticoid receptor beta", and the reference section. NC Nicolaides prepared new figures.

This chapter is an update from Evangelia Charmandari, Tomoshige Kino and George P. Chrousos, Glucocorticoid Receptor, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 229-234.

 doi:10.1016/B978-0-12-801238-3.95740-4

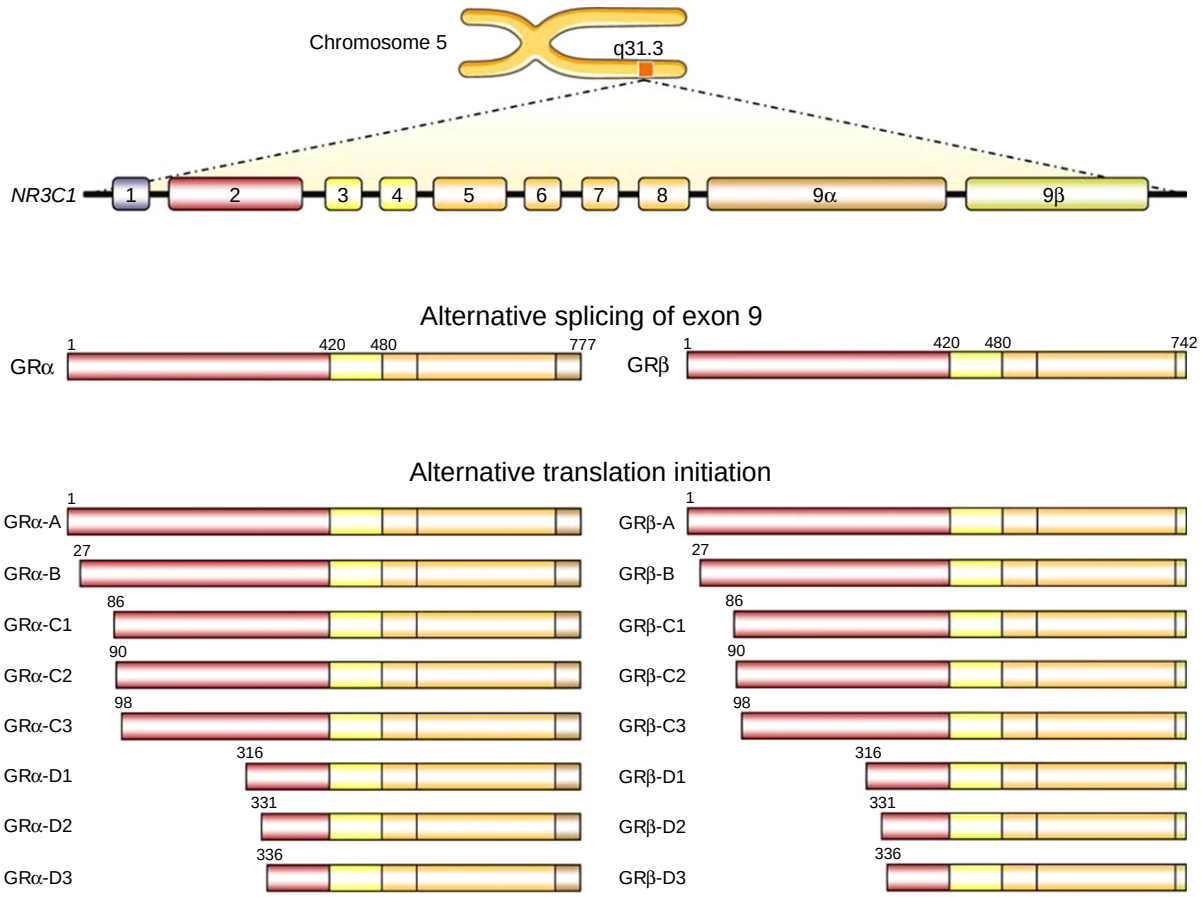

Fig. 1 The *NR3C1* gene is located in chromosome 5 and consists of 10 exons. Exon 1 is an untranslated region, exon 2 codes for the amino-terminal domain, exons 3 and 4 code for the DNA-binding domain, and exons 5–9 code for the hinge region and the ligand-binding domain. The *NR3C1* gene contains two terminal exons 9 (exon 9α and 9β), alternatively spliced to produce the hGRα and hGRβ isoforms. The alternative initiation of GRα mRNA translation may generate eight receptor isoforms (GRα-A, -B, -C1, -C2, -C3, -D1, -D2, and -D3). It is likely that the hGRβ mRNA might also be translated into eight distinct translational receptor isoforms.

expressed in tissues, usually at lower concentrations than hGRα, with the exception of epithelial cells and neutrophils. In contradistinction to hGRα, hGRβ interacts poorly with heat shock proteins (HSPs), resides primarily in the nucleus of cells independently of the presence of ligand, does not bind glucocorticoids or antiglucocorticoids, does not activate glucocorticoid-responsive genes, and can directly influence the transcription rate of a number of target genes (Kino *et al.*, 2009a).

The alternative initiation of GRα mRNA translation may give rise to eight distinct receptor isoforms, termed GRα-A, -B, -C1, -C2,-C3, -D1, -D2, and -D3 (**Fig. 1**) (Lu and Cidlowski, 2005). These isoforms have similar affinity to bind to glucocorticoids and similar capability to bind to GREs in the promoter regions of glucocorticoid-responsive genes (Ramamoorthy and Cidlowski, 2016). However, they have different transcription properties with less than 10% of target genes being commonly regulated by these receptor isoforms (Wu *et al.*, 2013). They also differ in terms of subcellular localization and tissue expression; for example GRα-D is primarily localized in the nucleus, and is expressed in the spleen and bladder. GRα-B and GRα-C reside in the cytoplasm and translocate to the nucleus following ligand binding. GRα-B is mostly expressed in thymus and colon, whereas GRα-C might be found in lung, pancreas and colon (Lu and Cidlowski, 2005). It is likely that the hGRβ mRNA is also translated into eight distinct translational receptor isoforms (**Fig. 1**).

The hGR protein is composed of a poorly conserved amino-terminal domain (NTD), a central, highly conserved DNA-binding domain (DBD), a hinge region, and a carboxyl-terminal, ligand-binding domain (LBD) (Nicolaides *et al.*, 2010). The NTD contains a major transactivation domain, termed activation function (AF)-1, which is located at amino acids 77–262 of hGR. The DBD spans over amino acids 420–480 and contains two zinc-finger motifs through which it binds to specific DNA sequences in the promoter region of target genes, the glucocorticoid-response elements. The hinge region is responsible for the structural flexibility of the receptor, and contains critical lysines that can be acetylated by the "circadian locomotor output cycle kaput" (CLOCK), a core transcription factor involved in the circadian oscillations of gene expression (Nader *et al.*, 2009). The LBD contains a second transactivation domain, AF-2, as well as sequences important for interaction with HSPs, nuclear translocation, and receptor dimerization. The LBD is composed of 12 helical structures and undergoes conformational changes following binding to the ligand.

Molecular Mechanisms of GR Action

Genomic GR Actions

Nucleocytoplasmic shuttling of GR

In the absence of ligand, the hGRα resides primarily in the cytoplasm of cells as part of a large multiprotein complex, which consists of the receptor polypeptide, heat shock proteins (HSP90, HSP70) and immunophillins (FKBP51 and FKBP52) (**Fig. 2**) (Grad and Picard, 2007). These molecules are thought to sequester hGRα in the cytoplasm of cells by maintaining the receptor in a conformation that masks or inactivates its nuclear localization signals (NLSs) (Pratt and Toft, 1997). Upon hormone binding, the receptor undergoes an allosteric change, which results in dissociation from HSPs and immunophillins, unmasking of the NLSs, and exposure of the ligand-binding pocket. In its new conformation, the activated, ligand-bound hGRα translocates into the nucleus, where it binds as homo- or hetero-dimer to glucocorticoid-response elements (GREs) located in the promoter region of target genes (**Fig. 2**) (Chrousos and Kino, 2005; Nicolaides *et al.*, 2010; Nicolaides and Charmandari, 2017). The hGRα then communicates with the basal transcription machinery and regulates the expression of glucocorticoid-responsive genes positively or negatively, depending on the GRE sequence and promoter context (**Fig. 3**). Following hGRα-mediated transcriptional activation or repression, the receptor dissociates from the ligand, and remains in the nucleus for hours or days. The hGRα is then exported from the nucleus to the cytoplasm, poised for a new round of ligand-induced activation (**Fig. 3**). Specific motifs in the DBD of the receptor and the calreticulin export pathway play fundamental role in the nuclear export of hGRα (Nicolaides *et al.*, 2010).

Mechanisms of transcriptional activation by GR

Following binding to GREs, which consist of two 6-nucleotide half sites separated by three nucleotides (GGAACAnnnTGTTCT), the activated hGRα enhances the expression of glucocorticoid-responsive genes by regulating the assembly of a transcriptional preinitiation complex at the promoter region of target genes (Beato, 1989). This is achieved by interaction of the liganded receptor with the basal transcription factors, a group of proteins composed of RNA polymerase II, TATA-binding protein (TBP), and a host of TBP-associated proteins (TAFIIs) (**Fig. 3**). The interaction between the activated receptor and the basal transcription factors is mediated by the coactivators, which are nucleoproteins with chromatin-remodeling activity and other enzymatic activities.

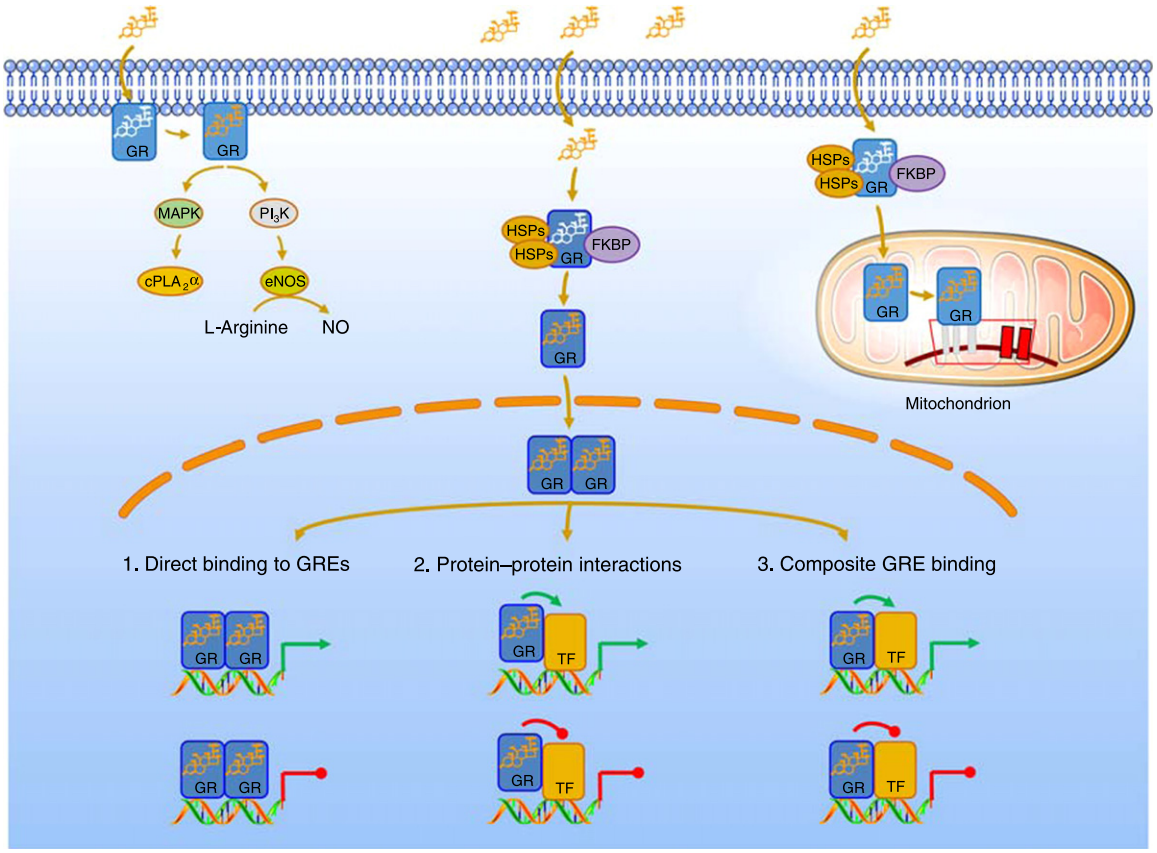

Fig. 2 Nongenomic, genomic and mitochondrial glucocorticoid signal transduction. cPLA2α: cytosolic phospholipase A2 alpha; eNOS: endothelial nitric oxide synthetase; FKBP: immunophillins; GR: glucocorticoid receptor; GREs: glucocorticoid response elements; HSP: heat shock proteins; MAPK: mitogen-activated protein kinases; NO: nitric oxide; PI3K: phosphatidylinositol 3-kinase; TF: transcription factor.

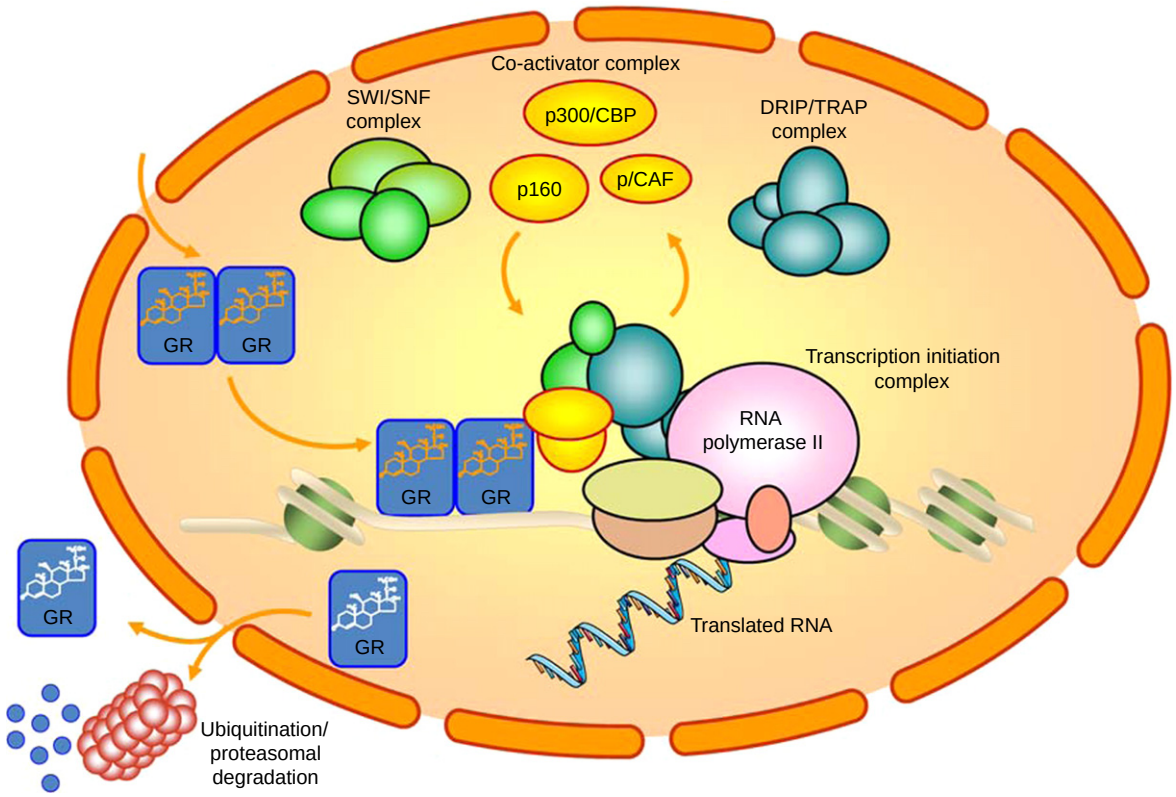

Fig. 3 Schematic representation of the interaction of the glucocorticoid receptor with coactivators and other chromatin modulators. GR: glucocorticoid receptor; p/CAF: p300/CBP-associated protein; CBP: cyclic AMP-responsive element-binding protein; DRIP: vitamin D receptor-interacting protein; SNF: sucrose nonfermenting; SWI: mating-type switching; TRAP: thyroid hormone receptor-associated protein.

Like other transcriptional activators, the hGRα uses its transcriptional activation domains AF-1 and AF-2 as surfaces to recruit chromatin remodeling factors and to interact with the coactivators that link enhancer-bound transcription factors to general transcription factors, thereby initiating transcription (Nicolaides *et al.*, 2010). At least two regions of hGRα possess intrinsic transcriptional activation functions: AF-2, which maps to the carboxyl terminus, is glucocorticoid-dependent, with ligand binding promoting the formation of a surface that permits protein–protein contacts between AF-2 and additional regulatory factors. In contrast, AF-1 is located at the amino terminus of the receptor, is glucocorticoid-independent, and can recruit both positive and negative regulatory factors that differentially regulate hGRα transcriptional enhancement (Nicolaides *et al.*, 2010).

Several families of nuclear hormone receptor coactivators have been described, including the p160 coactivators, such as the steroid receptor coactivator 1 (SRC1) and the glucocorticoid receptor-interacting protein 1 (GRIP1), the p300 and cyclic AMP-responsive element-binding protein (CBP) cointegrators, and the p300/CBP-associated protein (p/CAF) (Auboeuf *et al.*, 2002; McKenna *et al.*, 1999a,b; McKenna and O'Malley, 2002). The p160 coactivators are the first to be tethered to the promoter region of steroid target genes, thus playing a pivotal role in hGRα-mediated transactivation. These coactivators interact directly with both the AF-1 of hGRα through their carboxyl-terminal domain and the AF-2 of hGRα through multiple amphipathic LXXLL signature motifs, which are located in their nuclear receptor-binding domain (NRB) (Heery *et al.*, 1997). They also contain an additional binding site for hGRα, called auxiliary nuclear receptor-interacting domain, which is located between the NRB and the carboxyl-terminal AF-1-binding site. The p160 proteins have intrinsic histone acetyl-transferase activity, which disrupts the DNA nucleosomal interactions at these promoters, allowing the initiation of transcription. Other coactivators that interact with hGRα include the switching/sucrose nonfermenting (SWI/SNF) complex and the newly described chromatin remodeling complex, vitamin D receptor-interacting protein (DRIP)/thyroid hormone-associated protein (TRAP) complex (Heery *et al.*, 1997). The DRIP/TRAP complex interacts with both the AF-2 and AF-1 domains of hGRα via its components DRIP205 and DRIP150, respectively. Through coordinated interactions with AF-1 and AF-2, the coactivators enhance the transmission of signals from the DNA-bound hGRα to the transcriptional initiation machinery, loosen chromatin structure, and facilitate access and/or binding of other transcription factors and transcription initiation components to DNA, leading to full transcriptional activity of ligand-bound hGRα (Auboeuf *et al.*, 2002; McKenna *et al.*, 1999a,b; McKenna and O'Malley, 2002).

Mechanisms of transcriptional repression by GR

The activated hGRα can bind as dimers to negative GREs (nGREs) and suppress gene expression. These DNA elements have the consensus sequence CTCCn0-2GGAGA, which is different from the positive GRE in terms of nucleotide sequence and the number

of nucleotides between the half sites which can range from zero to two (Hudson *et al.*, 2013). Following binding to nGREs, the hGRα recruits corepressors, including NCoR1 and SMRT, and histone deacetylases, ultimately leading to repression of several target genes (Surjit *et al.*, 2011).

Interaction of GR with and actions via other transcription factors

In addition to binding to classic or negative GREs, the hGRα may regulate transcription by physically interacting with other transcription factors. Protein–protein interactions between hGRα and nuclear factor-κB (NF-κB), activator protein-1 (AP-1) and signal transducers and activators of transcription (STATs) result in negative or positive regulation of their responsive genes, mediating many of the antiinflammatory and immunosuppressive effects of glucocorticoids (Barnes and Karin, 1997; Karin and Chang, 2001; Didonato *et al.*, 1996). During this mode of protein–protein interactions, the activated hGRα interacts with the above-mentioned transcription factors without binding to DNA (**Fig. 2**) (Ramamoorthy and Cidlowski, 2016). In addition to tethering, the hGRα may bind to composite DNA elements, which consist of a GRE and a response element for a specific transcription factor, such as AP-1 or the STATs (**Fig. 2**) (Ramamoorthy and Cidlowski, 2016).

Nongenomic GR actions

Glucocorticoids exert some of their numerous effects in a short time frame. These rapid actions can occur in nonnucleated cells and do not require transcription/translation; therefore, they are termed as "nongenomic" and are thought to be mediated by membrane-bound GRs that alter the activity of many kinases, including the mitogen-activated protein kinase (MAPK) or the phosphatidylinositol 3-kinase (PI3K) (**Fig. 2**) (Groeneweg *et al.*, 2012). Some examples of nongenomic glucocorticoid actions are: (i) the immediate suppression of ACTH release from the pituitary gland by glucocorticoids (Hinz and Hirschelmann, 2000); (ii) the rapid increase of frequency of excitatory postsynaptic potentials in the hippocampus resulting in altered memory function upon acute exposure to glucocorticoids (Karst *et al.*, 2005); (iii) the glucocorticoid-induced vasorelaxation in patients with myocardial or brain ischemia (Hafezi-Moghadam *et al.*, 2002); and (iv) some immunosuppressive glucocorticoid effects through disruption of T-cell receptor (TCR) complex (Löwenberg *et al.*, 2006). The nature of the membrane GRs is under intense investigation (Nicolaides *et al.*, 2017).

Mitochondrial GR actions

Importantly, the GR has been detected in mitochondria, while GREs have been identified within the mitochondrial genome (**Fig. 2**) (Psarra and Sekeris, 2011). The mitochondrial gene expression is influenced directly by mitochondrial GR–GREs interactions, and, indirectly, by nuclear GR–GREs interactions leading to the expression of mitochondrial RNA-processing enzymes, nuclear respiratory factors or mitochondrial transcription factors (reviewed in Nicolaides and Charmandari, 2017).

Factors That Modulate GR Activity

Post-Translational Modifications of GR

Phosphorylation of GR

Following ligand binding, the hGRα is phosphorylated at serine residues, such as S113, S134, S141, S203, S211, S226, and S404 (Oakley and Cidlowski, 2011, 2013; Ramamoorthy and Cidlowski, 2016). The mitogen-activated protein kinase (MAPK) and the cyclin-dependent kinases (CDKs) phosphorylate hGR and modulate its transcriptional activity. MAPK suppresses the activity of hGR in yeast, whereas CDKs stimulate it. JNK, another mitogen-activated kinase, also phosphorylates hGR and suppresses its transcriptional activity. All these kinases phosphorylate hGRα at different sites, indicating that the function of the receptor may be also regulated by other signal transduction pathways through phosphorylation (Oakley and Cidlowski, 2011, 2013; Ramamoorthy and Cidlowski, 2016).

Ubiquitination of GR

Ubiquitination is a posttranslational modification characterized by the attachment of ubiquitin, a 76-amino-acid protein, to specific lysines, thereby marking proteins for proteasomal degradation. The hGRα undergoes ubiquitination at lysine 419, leading to receptor degradation by the 26S proteasome (Oakley and Cidlowski, 2011, 2013; Ramamoorthy and Cidlowski, 2016).

Sumoylation of GR

The addition of a small ubiquitin-related modifier-1 (SUMO-1) to lysine residues is referred to as "sumoylation." The hGRα is sumoylated at lysines 277, 293, and 703. Sumoylation at these residues results in receptor degradation and inhibition of its transcriptional activity in a promoter-specific fashion (Oakley and Cidlowski, 2011, 2013; Ramamoorthy and Cidlowski, 2016).

Acetylation of GR

Acetylation of hGRα occurs in multiple lysine residues at amino acid positions 492–495 (sequence KKTK) in the hinge region of the receptor. Interestingly, the circadian rhythm-generating transcription factor CLOCK acetylates hGRα at several lysines located in the hinge region. This CLOCK-mediated hGRα acetylation attenuates the binding of the GR to classic GREs, ultimately leading to repression of hGRα transcriptional activity (Nader *et al.*, 2009).

Chaperones and Cochaperones

The hGRα forms heterocomplexes with several heat shock proteins, including hsp90, hsp70, hsp56, and possibly hsp23, and the immunophillins FKBP51 and FKBP52, which may affect its transcriptional activity. The hsp90 and receptor-associating protein 46 regulate the transcriptional activity of hGR in a negative fashion (Grad and Picard, 2007).

MicroRNAs and Long Non-Coding RNAs

MicroRNAs are small non-coding RNAs, which are involved in numerous physiologic processes, including cell differentiation and proliferation. A number of microRNAs influence GR signaling, thereby altering tissue sensitivity to glucocorticoids (e.g., miR-433, miR-124, miR-18 etc.) (Wang *et al.*, 2017). Moreover, the "Growth Arrest-Specific 5" (Gas5) long non-coding RNA binds to the DBD of GRα and downregulates the expression of glucocorticoid target genes (Kino *et al.*, 2010). Interestingly, poor responders to glucocorticoids have increased Gas5 levels, indicating that Gas5 might be used as a biomarker of tissue sensitivity to synthetic glucocorticoids (Lucafo *et al.*, 2015).

GR Polymorphisms

A polymorphism is an inheritable genetic variant of a single locus (usually a single nucleotide variation), which can be found in at least 1% of the population. Polymorphisms in the *NR3C1* gene are associated with either glucocorticoid "resistance" or "hypersensitivity" phenotypes (Nicolaides *et al.*, 2010; Oakley and Cidlowski, 2011, 2013; Ramamoorthy and Cidlowski, 2016). Individuals harboring the ER22/23EK polymorphism, an arginine (R) to lysine (K) substitution at amino acid position 23 (R23K) located in exon 2, have a glucocorticoid resistant phenotype, and present with a healthier metabolic profile, better body composition and prolonged survival. On the other hand, carriers of the N363S or *Bcl1* polymorphisms exhibit a glucocorticoid hypersensitivity phenotype characterized by increased body mass index (BMI), insulin resistance and metabolic complications (Nicolaides *et al.*, 2010; Oakley and Cidlowski, 2011, 2013; Ramamoorthy and Cidlowski, 2016).

Natural GR Mutations

Mutations in the *NR3C1* gene may impair one or more of the molecular mechanisms of hGRα function, resulting in alterations in tissue sensitivity to glucocorticoids and the clinical phenotype of Chrousos syndrome (**Fig. 4**) (Nicolaides and Charmandari, 2017). Primary generalized familial or sporadic glucocorticoid resistance is a rare condition characterized by generalized, partial end-organ insensitivity to physiologic glucocorticoid concentrations. Patients have compensatory elevations in circulating adrenocorticotropic hormone and cortisol concentrations and resistance of the hypothalamic–pituitary–adrenal (HPA) axis to dexamethasone suppression, but no clinical evidence of overt hypo- or hypercortisolism. More than 22 sporadic cases with the condition have been reported (**Fig. 4**). Abnormalities of several hGRα characteristics, including cell concentrations, affinity for glucocorticoids, stability, and translocation into the nucleus, have been associated with this condition (Nicolaides and Charmandari, 2017).

In addition to *NR3C1* gene mutations causing Chrousos syndrome, only one mutation has been reported to be associated with primary generalized glucocorticoid hypersensitivity. The hGRαD401H was identified in a patient with obesity, dyslipidemia, and type 2 diabetes (**Fig. 4**) (Charmandari *et al.*, 2008).

Glucocorticoid Receptor Beta

The hGR*β* functions as a dominant-negative inhibitor of hGRα activity and inhibits hGRα-mediated transactivation of many target genes in a dose-dependent manner (Kino *et al.*, 2009b). The mechanism(s) underlying this inhibition has not been fully elucidated, but may involve competition between hGRα and hGR*β* for binding to GREs, formation of hGRα–hGR*β* heterodimers that are transcriptionally inactive, and/or titration or squelching of coactivators needed by hGRα for full transcriptional activity (Bamberger *et al.*, 1995; Charmandari *et al.*, 2005; Kelly *et al.*, 2008; Yudt *et al.*, 2003). The ability of hGR*β* to antagonize the function of hGRα suggests that hGR*β* may play a critical role in regulating target tissue sensitivity to glucocorticoids. Increased expression of hGR*β* has been documented in generalized and tissue-specific glucocorticoid resistance and leads to a reduction in the ability of hGRα to bind to GREs. Therefore, an imbalance in hGRα and hGR*β* expression may underlie the pathogenesis of several clinical conditions associated with glucocorticoid resistance, such as inflammatory diseases (rheumatoid arthritis, systemic

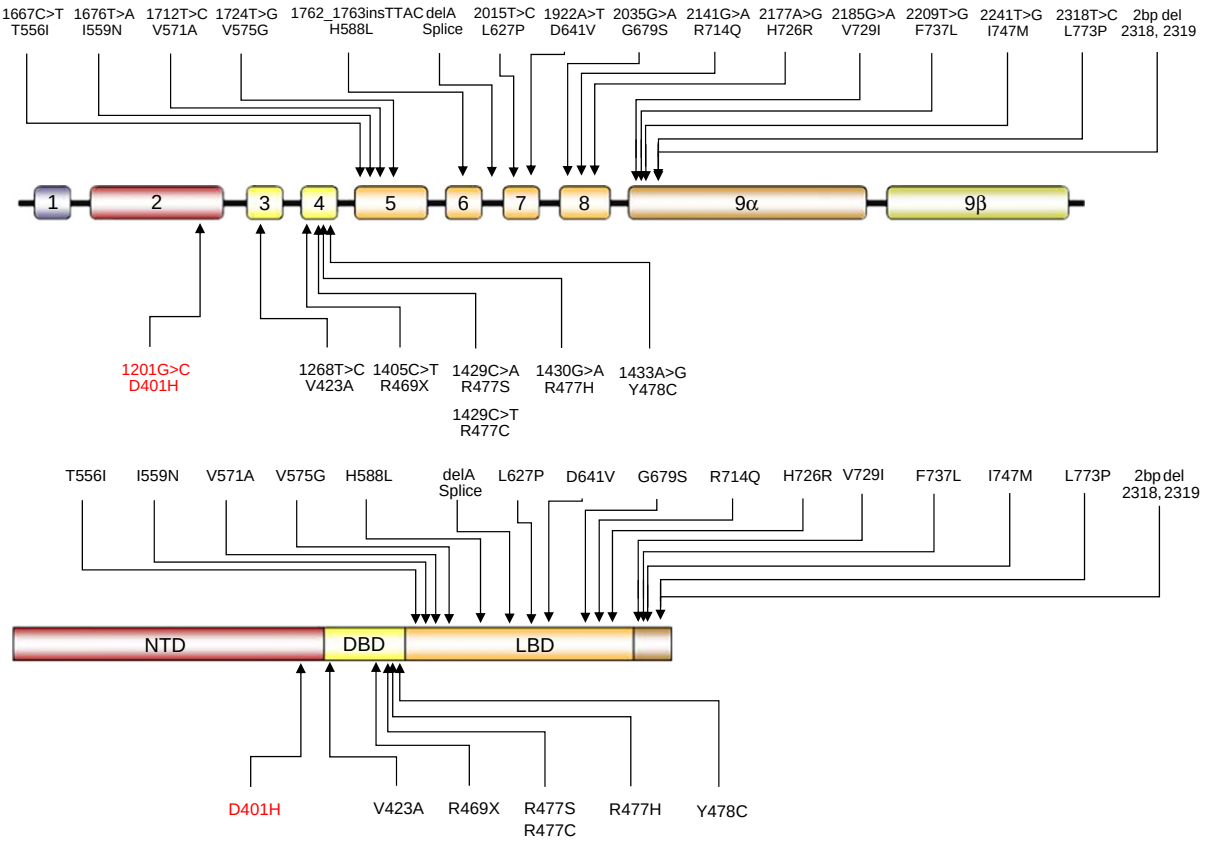

Fig. 4 Location of the known mutations of the *NR3C1* gene causing alterations in tissue sensitivity to glucocorticoids. Mutations indicated by dark color have been associated with primary generalized glucocorticoid resistance or Chrousos syndrome, while the D401H, which is indicated in *red* color, has been associated with primary generalized glucocorticoid hypersensitivity. DBD: DNA-binding domain; LBD: ligand-binding domain; NTD: amino-terminal domain.

lupus erythematosus, and ulcerative colitis), hematologic malignant disorders (acute lymphoblastic leukemia or chronic lymphocytic leukemia), and mood disorders (major depression, schizophrenia). In addition to its important role in inhibiting hGRα transcriptional activity, hGRβ might be involved in insulin signaling, gluconeogenesis, glioma formation and migration of bladder cancer cells (He *et al.*, 2015; Yin *et al.*, 2013; McBeth *et al.*, 2016).

Glucocorticoids and Immunity☆

Karen E Chapman, University of Edinburgh, Edinburgh, United Kingdom

Glossary

Autoimmune disease A disease that is caused when an individual produces an immune reaction against its own tissues.

Chemokines A subgroup of cytokines that guide cell movement towards a target location.

Cytokines A group of small proteins released from cells that are important in cell signaling and control of the immune system.

Extravasation The movement of leukocytes from capillaries into the tissues surrounding them.

Glucocorticoids Any of a group of adrenocortical steroid hormones whose metabolic effects include stimulation of gluconeogenesis, increased catabolism of proteins, and mobilization of free fatty acids; they are also potent inhibitors of the inflammatory response (allergic response).

Immune system The cells and tissues involved in recognizing and attacking foreign substances in the body.

Immunity A biological condition whereby a body is capable of resisting or overcoming an infection or diseases.

Immunosuppression The process of inhibiting a normal immune response with the use of drugs, biological agents, or chemical agents; commonly used in association with tissue transplantation or to control autoimmune diseases.

Studies carried out over the past 50 years have revealed the broad spectrum of actions of glucocorticoids on the immune system. Glucocorticoids shape almost all aspects of an immune response. Their antiinflammatory effects were recognized shortly after the discovery of glucocorticoids in the 1940s, and they remain a highly effective treatment for acute and chronic inflammation. The potent immunosuppressive effects of synthetic glucocorticoids also underpin their use in autoimmune disease and organ transplantation. This article discusses the mechanisms of glucocorticoid actions on immune cells and provides context to explain the immunosuppressive and anti-inflammatory actions of glucocorticoids.

Glucocorticoids: Receptors and Glucocorticoid Metabolism in Immune Cells

Much of what we know about glucocorticoid effects on the immune system has come from research using synthetic glucocorticoids such as dexamethasone, betamethasone and prednisolone. Synthetic glucocorticoids have greater potency and bioavailability than the physiological glucocorticoids, cortisol and corticosterone. Furthermore, whereas cortisol and corticosterone can bind to mineralocorticoid receptor (MR) as well as to glucocorticoid receptor (GR), most synthetic glucocorticoids preferentially activate GR, with little activity at MR. This is an important consideration when discussing the effects of glucocorticoids on the immune system (Coutinho and Chapman, 2011). Prolonged use of synthetic glucocorticoids suppresses endogenous cortisol/corticosterone production, potentially depriving MR of its ligand in those cells where it acts primarily as a high affinity glucocorticoid receptor. Both are expressed in immune cells: GR is present in most or possibly all immune cells, whereas MR distribution is more restricted (it is not expressed in the thymus for example) (McEwen *et al.*, 1997). The two receptors exert opposing effects in some instances. In macrophages, MR activation promotes a pro-inflammatory macrophage phenotype whereas GR activation generates an anti-inflammatory phenotype (Rickard and Young, 2009). A further complexity comes from glucocorticoid metabolism by the 11β-hydroxysteroid dehydrogenase (11β-HSD) enzymes (Chapman *et al.*, 2013b; Coutinho and Chapman, 2011). There are two 11β-hydroxysteroid dehydrogenase isozymes. The type 2 enzyme, 11β-HSD2, which converts cortisol to the intrinsically inert cortisone, is absent from immune cells in healthy adults. However, 11β-HSD1, which does the opposite, converting cortisone to cortisol, is present in many immune cells. Thus, by increasing intracellular cortisol/corticosterone levels in specific cells, 11β-HSD1 can contribute to GR and/or MR activation and help shape the immune response to infection or inflammation (Chapman *et al.*, 2013a). Prednisolone and prednisone are also interconverted by 11β-HSD, but dexamethasone is a poor substrate. Recent studies, particularly those in vivo in mice with genetic alterations in GR, MR or 11β-HSD1, are providing much needed information about the role of physiological glucocorticoids and their receptors in shaping immune responses (Cain and Cidlowski, 2017; Chapman *et al.*, 2013a). A detailed discussion of this is beyond the scope of this article, but the interested reader can learn more from the reviews referenced in the text.

Glucocorticoids Alter Leukocyte Distribution and Trafficking

Intravenous injection of glucocorticoids or acute cortisol release following stress rapidly and profoundly affects white blood cell (leukocyte) trafficking. Even the diurnal rhythm of glucocorticoid release impacts on blood lymphocyte numbers, with peak glucocorticoid levels corresponding with a diurnal trough in blood lymphocyte numbers and vice versa. Thus, endogenous glucocorticoids exert a tonic control over the immune system (McEwen *et al.*, 1997). The appropriate location of immune cells in different body compartments is vital for immune surveillance as well as for appropriate immune responses. Hence, glucocorticoid effects on immune cell trafficking between the blood, immune organs and other body compartments orchestrate immune responses, ensuring that immune cells are in the right location and ready to combat infection or inflammation. The redistribution of lymphocytes from blood to other body compartments (especially the bone marrow), the increased neutrophilia, and the profound depletion of monocytes, eosinophils and basophils result mainly from glucocorticoid-induced alterations in expression of adhesion molecules—selectins, integrins and members of the immunoglobulin superfamily—on leukocytes and endothelial cells (Besedovsky *et al.*, 2014; Guo *et al.*, 2017; McEwen *et al.*, 1997). These factors act passively, to modulate bone marrow release, peripheral tissue infiltration, and clearance of leukocytes by retaining (or extruding) leukocytes in specific compartments. As well as effects in uninfected or noninflamed conditions, during an ongoing infection or inflammatory response, glucocorticoids potently inhibit the infiltration of neutrophils, eosinophils and monocytes across the endothelium into sites of inflammation, effects that require new protein synthesis. This inhibition of leukocyte extravasation is critical for the anti-inflammatory effects of glucocorticoids and largely results from glucocorticoid inhibition of chemotaxis: glucocorticoids markedly suppress synthesis of a variety of chemokines including the neutrophil chemoattractants, IL-8 and other CXC (cysteine-X-cysteine) chemokines and the eosinophil chemoattractants —CC (cysteine–cysteine) chemokines, such as eotaxin, eotaxin 2, CCL-13/MCP (monocyte chemotactic protein)-4 and RANTES (regulated on activated normal T-cell expressed and secreted) (Franchimont, 2004).

The glucocorticoid-induced neutrophilia, familiar to most clinicians, results from three processes: an increase in neutrophil release from the bone marrow, inhibition of neutrophil extravasation and promotion of the survival of neutrophils (in contrast, glucocorticoids induce apoptosis of eosinophils) (Coutinho and Chapman, 2011; McEwen *et al.*, 1997). However, in the presence of severe hypoxia or pro-inflammatory mediators, glucocorticoids do not enhance neutrophil survival (Marwick *et al.*, 2013) suggesting that their effects are highly dependent on the microenvironment. Inhibition of neutrophil extravasation by glucocorticoids occurs through decreased expression of leukocyte adhesion molecules on endothelial cells, such as *E*-selectin/CD (cluster of differentiation)-62E, InterCellular Adhesion Molecule (ICAM)-1 and vascular cell adehsion molecule (VCAM)-1 (the latter, immunoglobulin superfamily members) and by reducing L-selectin/CD62L (important for neutrophil tethering and rolling along the endothelium) on the surface of neutrophils (Cain and Cidlowski, 2017; Franchimont, 2004; McEwen *et al.*, 1997). However, the immediate action of glucocorticoids on neutrophils is not related to a direct regulation of L-selectin on circulating neutrophils. Instead, glucocorticoids promote shedding of L-selectin from neutrophils, preventing their attachment to endothelial cells. Glucocorticoids also decrease the expression of L-selectin on bone marrow progenitors and on differentiating neutrophils that, then, reach the bloodstream with low L-selectin levels (Franchimont, 2004).

It is still unclear exactly how glucocorticoids increase bone marrow release of neutrophils. Mature neutrophils express CXCR4, the receptor for CXCL12/Stromal cell Derived Factor (SDF)-1α. CXCL12/SDF-1α is highly expressed in the bone marrow, where it retains neutrophils. Granulocyte colony-stimulating factor (G-CSF) indirectly down-regulates the CXCR4/SDF-1α chemokine axis as well as promoting the generation of neutrophils (Furze and Rankin, 2008). There appears to be a complex relationship between glucocorticoids and G-CSF, and G-CSF may be a target for glucocorticoid action (Root and Dale, 1999). During inflammation, chemokines released from the inflamed tissue are also important for recruiting and activating neutrophils and initiating extravasation. As mentioned above, glucocorticoids potently suppress chemokine synthesis. Importantly, whereas glucocorticoids decrease the expression of some chemokine receptors on neutrophils, eosinophils and other leukocytes, they enhance the expression of others, thus orchestrating the migration of specific leukocyte populations during an immune or inflammatory response.

In many immune cells (hematopoietic progenitor cells, specific T cell subsets, blood monocytes and eosinophils) but notably not neutrophils, CXCR4 expression is increased by glucocorticoids, causing these immune cells to be retained by SDF-1α in the bone marrow (Besedovsky *et al.*, 2014). The redirection of T cells and eosinophils to the bone marrow explains their disappearance from the circulation following glucocorticoid administration or stress. Glucocorticoids also prevent the influx of lymphocytes into draining lymph nodes, independently of the classical lymph node homing molecules, L-selectin and CCR7. This blockade of lymphocyte migration to certain lymph nodes may account for glucocorticoid suppression of some lymphocyte responses, for example, the production of antibody in response to antigen presenting cells in lymph nodes. This may also be an important mechanism in glucocorticoid suppression of acute relapse in multiple sclerosis: in an animal model of multiple sclerosis, glucocorticoids redirect T cell migration in a manner dependent upon the CXCR4/CXCL12 pathway, reducing T cell infiltration of the brain parenchyma (Schweingruber *et al.*, 2014).

The flow and movement of monocytes also seems tightly regulated by glucocorticoids via similar mechanisms, namely, through the repression of monocyte and endothelial adhesion molecules and the regulation of chemokines and their receptors.

Innate and Adaptive Immunity

Although the categorical distinctions between the innate and adaptive immune systems have become blurred over the last decade, they remain useful working concepts to understand the effects of glucocorticoids on immunity.

The innate immune response is critical for early defense following infection or injury. It is engaged following activation of pattern recognition receptors (PPRs) by pathogen-associated molecular patterns (PAMPs) or host-derived damage-associated molecular patterns (DAMPs). PPR activation triggers activation of pro-inflammatory pathways via the transcription factors NF-kB, AP-1, C/EBP and others leading to induction of genes encoding cytokines, chemokines, adhesion molecules and enzymes (Newton and Dixit, 2012). Adaptive immunity takes longer to establish. Immune memory is the hallmark of the adaptive immune system, lasting for many years and residing in antigen-specific T and B cells. The innate immune response has not traditionally been considered to provide immune memory. However, this view has been challenged in recent years with the discovery of memory lasting weeks to months in natural killer (NK), innate lymphoid cells (ILCs) and other innate immune cells. This recently described nonspecific type of immune memory occurs in response to foreign insult (e.g., infection or endotoxins) and has been termed "trained immunity" or "innate immune memory" (Netea *et al.*, 2016). Examples of this are the nonspecific protective effects against infections induced by vaccines against measles or tuberculosis. In experimental animals, a widely used model is the attenuated inflammatory response to high dose endotoxin (usually bacterial lipopolysaccharide; LPS) following several days "priming" with low dose LPS (Netea *et al.*, 2016).

The innate and adaptive immune systems can be divided into two types of cell-mediated effector immunity, categorized as type 1 and type 2. This nomenclature, which originally arose from the division of CD4+ T cell immune responses into those that promoted cell mediated (Th1) and humoral (Th2) immunity, has been extended more generally to cover other cell types, including cytotoxic (CD8+) T cells, ILCs and, importantly, macrophages: M1 being classically activated, pro-inflammatory and M2 being alternatively activated, or pro-repair (although in reality, macrophages can adopt a wide variety of phenotypes across a continuum from M1 to M2) (Lappin and Campbell, 2000). Type 1 and type 2 responses can be broadly classified by the cytokines associated with those responses. Thus, type 1 effector responses are pro-inflammatory, providing defense against microorganisms including bacteria and viruses as well as neoplasia, but they are also associated with autoimmune disease. These responses are strongly associated with Interferon (IFN)-γ, IL-12 and IL-18 and traditionally involve CD4+ Th1 (and more recently included, Th17) cells. Type 2 responses promote tissue repair/wound healing and provide defense against extracellular parasites, but are also important in driving allergic and fibrotic disorders. Type 2 responses are associated with IL-4, IL5, and IL-13 and traditionally involve CD4+ Th2 cells (Lappin and Campbell, 2000).

Glucocorticoids affect both the innate and adaptive immune systems. Generally speaking, they inhibit type 1 responses and promote a switch to type 2, thus altering the balance of an innate or adaptive immune response (del Rey and Besedovsky, 2000). Glucocorticoids prevent the overshoot of inflammatory responses under the control of the innate immune response. They also limit the adaptive immune response and prevent the expansion of immune cells with little or no affinity for the antigen that triggers an immune response. Glucocorticoid actions on immune cells, both in the innate and adaptive immune systems, include suppression or stimulation of numerous pathways involving pro-inflammatory or antiinflammatory mediators. They also alter immune cell phenotype and cellular differentiation programs to promote resolution of inflammation and adaption to future insult or infection. Many of these actions are described below, with reference to the cytokines and their receptors that may mediate these actions.

Glucocorticoid Effects on Innate Immune Responses

Endogenous glucocorticoids are vital to prevent the overshoot of an early innate immune response to infection. Adrenal insufficiency can be life-threatening in certain infections. Similarly, in animal models, adrenalectomy sensitizes mice or rats to the lethal effects of endotoxin, a powerful stimulatant of the HPA axis (Besedovsky and Del Rey, 2000; del Rey and Besedovsky, 2000). The stimulation of immune cells—by viral infection, endotoxin, or by neoplastic or damaged cells—triggers the release of IL-1 and other cytokines early during an immune response. These then activate the HPA axis, increasing glucocorticoid levels. Glucocorticoids subsequently prevent an excessive inflammatory reaction by suppressing the synthesis of numerous pro-inflammatory mediators, such as many cytokines (including IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-11, IL-12, IL-13, IL-16, IL-17, IFNγ and TNF-α), prostaglandins, leukotrienes, proteolytic enzymes, reactive oxygen species, and nitric oxide. At the same time, they exert direct actions on immune cells, shaping their function and indeed, the adaptive immune response (see below). In fact, the levels of glucocorticoid achieved during an immune response are enough to inhibit the response to another, unrelated, antigenic stimulus (Besedovsky and del Rey, 2000; del Rey and Besedovsky, 2000). This may be an important mechanism associated with, and that may contribute to, innate immune memory.

Monocytes/macrophages and dendritic cells are key targets of glucocorticoid actions. In mice, knockout of GR in macrophages and/or dendritic cells (DC) increases mortality in models of septic shock, associated with elevated levels of type 1 cytokines (IL-12, IL-1, TNF-α) (Bhattacharyya *et al.*, 2007; Kleiman *et al.*, 2012; Li *et al.*, 2015). This identifies macrophages/DC as the target for the protective effects of endogenous glucocorticoids in preventing the overshoot of the innate immune response. At the same time, glucocorticoids promote the resolution of inflammation by skewing macrophage polarization towards an M2-like (termed M2c) highly phagocytic phenotype, promoting the clearance of microorganisms, apoptotic cells and debris. M2c macrophages show

high expression of the hemoglobin scavenger receptor, CD163 as well as the protein S/Mer tyrosine kinase pathway, important for the engulfment and clearance of apoptotic cells (Martinez *et al.*, 2008). They secrete the antiinflammatory cytokines, IL-10 and transforming growth factor (TGF)-β, important in terminating an inflammatory response as well as inducing tolerance via the adaptive immune system (see below). In monocytes themselves, glucocorticoids induce an activated antiinflammatory state that resembles myeloid suppressor cells, with down-regulation of adhesion related proteins and increased migratory properties. It should be noted though, that many of the effects of glucocorticoids upon immune cells have been characterized in vitro. Given the high context dependence of glucocorticoid action, their effects upon immune cells in vivo are likely to depend upon the prevailing inflammatory and cellular microenvironment. Nevertheless, the suppression of pro-inflammatory cytokine synthesis by glucocorticoids has been clearly demonstrated both in vitro and in vivo. This is mediated by interference with the activity of the master pro-inflammatory transcription factors NF-kB and AP-1 (Cain and Cidlowski, 2017). Glucocorticoids also reduce pro-inflammatory cytokine levels via induction of tristetraprolin, which targets their mRNAs for degradation. Other antiinflammatory effects also involve gene activation by GR (Coutinho and Chapman, 2011). Glucocorticoids induce expression of IL-10, annexin A1, DUSP (DUal-Specificity Phosphatase)-1, GILZ (glucocorticoid-induced leucine zipper) and other proteins that promote the termination and resolution of inflammation. In genetically altered mice, the requirement for these anti-inflammatory proteins for dexamethasone-dependent effects during an inflammatory response depends upon the nature of the inflammation and the specific cell type in question. For example, glucocorticoids fail to suppress sterile peritonitis in mice lacking DUSP-1, demonstrating that DUSP-1 is required for the antiinflammatory effect of glucocorticoids effects in this model (Abraham *et al.*, 2006). In contrast, DUSP-1 knockout mice remain sensitive to the suppressive effects of glucocorticoids in mast cell-dependent anaphylaxis (Maier *et al.*, 2007). As well as the antiinflammatory mediators mentioned above, glucocorticoids also induce the receptors for a number of pro-inflammatory cytokines and chemokines (Cain and Cidlowski, 2017). This is likely to be a mechanism to increase the sensitivity of particular immune cells to these mediators to help these cells to resolve inflammation. Such mechanisms are important in shaping an ongoing immune response, with newly recruited cells differentiating within an altered inflammatory environment. Soluble or decoy receptors that inhibit the inflammatory process are also regulated by glucocorticoids, representing antiinflammatory mechanisms. For example, expression of the decoy receptor IL-1R2, which binds IL-1 without driving its signaling, is increased by glucocorticoids, though the cells responsible are unknown.

Under pro-inflammatory conditions some of the effects of glucocorticoids can be over-ridden, giving rise to apparent glucocorticoid resistance. One mechanism for this is via macrophage migration inhibitory factor (MIF) (Franchimont, 2004; Lerch *et al.*, 2014). MIF is secreted from the pituitary in response to endotoxin challenge or pro-inflammatory cytokines such as TNFα. This may account for the high MIF levels in serum that are associated with a range of chronic inflammatory diseases, including multiple sclerosis, rheumatoid arthritis, lupus and diabetes. MIF can override the antiinflammatory and immunosuppressive actions of glucocorticoids. MIF increases lethality, whereas genetic deletion or therapeutic neutralization confers protection against endotoxemia, acute distress respiratory syndrome, and septic shock. The finding that toll-like receptor (TLR) 4 expression is increased by MIF may explain why MIF-deficient mice are hyporesponsive to LPS. Thus, the notion that glucocorticoids enhance the secretion of a major pro-inflammatory cytokine that counteracts their effects represents a yin/yang mechanism of control of the acute-phase response or septic shock that may become dysregulated in chronic inflammation.

Lipid mediators, specific locally acting molecules derived from phospholipids and polyunsaturated fatty acids, initiate and perpetuate inflammation. Importantly though, certain lipid mediators actively promote resolution and tissue repair pathways. Glucocorticoids suppress the synthesis of eicosanoids, lipid mediators that include prostaglandins and leukotrienes. This is mediated by induction of annexin A1, which suppresses activity of phospholipase A2 thereby reducing the production of arachidonic acid, a key intermediate in eicosanoid biosynthesis (Franchimont, 2004). Glucocorticoids also reduce the generation of prostaglandins by suppressing inducible cyclooxygenase (COX/prostaglandin-endoperoxide synthase)-2, whilst having no effect on the constitutive COX-1 enzyme. Further down the pathway, the synthesis of PGE_2, a major inflammatory mediator, is reduced by glucocorticoid suppression of microsomal PGES (prostaglandin E synthase), an enzyme functionally coupled to COX-2. However, glucocorticoids do not affect cytosolic PGES, which is functionally coupled to COX-1. Thus, whilst glucocorticoids reduce production of prostaglandins and other lipid mediators during inflammation via some routes, synthesis continues via other routes. Glucocorticoids induce 5-lipooxygenase and 5-lipooxygenase-activating protein expression in monocytes and eosinophils, thus diverting arachidonic acid metabolism to leukotriene biosynthesis rather than prostaglandins. They also increase expression of the leukotriene B(4) receptor and activate the lipoxin A(4) receptor on human neutrophils, the latter mediated via annexin A1. This ability of glucocorticoids to suppress eicosanoid biosynthesis yet enhance other aspects of lipid signaling is reminiscent of their diverse effects on cytokines/chemokines and their receptors that redirect cell migration and behavior. Thus, glucocorticoids orchestrate lipid mediators to limit an inflammatory reaction and promote resolution, by altering their synthesis (suppressing or even, perhaps, inducing) and efficacy (cellular sensitivity via specific receptors). Nitric oxide is an important intra- and intercellular signaling molecule in shaping the innate and adaptive immune response, with potential for both detrimental and protective effects. Glucocorticoids suppress the cytokine induction of inducible nitric oxide synthase (iNOS/NOS2) expression, decreasing nitric oxide release by endothelial cells. This inhibition, mediated by the glucocorticoid second-messenger annexin A1, may prevent overshoot of an early endothelial cell-mediated inflammatory reaction (Franchimont, 2004). Glucocorticoids therefore play a vital role in shaping an immune response. The elevation in endogenous glucocorticoids following immune stress or trauma orchestrates the ongoing cellular, cytokine and lipid response to repair the damage caused by the initial injurious stimulus, leading to the resolution of an inflammatory response. The timing is crucial. The use of glucocorticoids in sepsis, for example, is highly controversial and too early (or too high) concentrations may suppress the immune response to sepsis, allowing persistence of the

bacterial infection. Similarly, the failure to engage appropriate resolution mechanisms or persistence of the injurious/infectious stimulus can lead to chronic inflammation. Glucocorticoids play a critical role in shaping the adaptive immune response to infection or other antigens and are important in the balance between immunity and tolerance.

Adaptive Immunity

On first encounter with a pathogen or an antigen, a primary immune response is elicited, depending on the nature of the microorganism or the antigen. Presentation of antigen complexed with MHC class I activates CD8+ cytotoxic T cells whereas antigen presentation with MHC class II activates CD4+ T cells. This leads to the generation of memory cells, highly specific for the inducing antigen, that in turn, mediate the secondary response if the same antigen is encountered subsequently. The cell-mediated response (which can be adoptively transferred by lymphoid cells but not by serum) results in the expansion of antigen-specific cytotoxic CD8+ T cells that kill infected, damaged or cancerous cells. The humoral response (which can be passively transferred by serum from immune individuals) is mediated by B cells and results in the production of high affinity, antigen specific antibodies to eliminate extracellular pathogens and parasites. CD4+ T cells are central to both cell-mediated and humoral immunity: they enhance and maintain CD8+ T cell responses and help B cells make antibody. As well as being important regulators of macrophage function, CD4+ T cells orchestrate immune responses to ensure the right balance between an appropriate magnitude and persistence of an immune response and prevention of autoimmunity.

A key cytokine that plays a pivotal role in the T cell response is IL-2, produced after antigen activation (Liao *et al.*, 2013). It promotes CD8+ T cell (and NK cell) cytotoxic activity and promotes CD4+ cell differentiation into Th1 and Th2 cells, whilst inhibiting differentiation of Th17 cells, the latter implicated in autoimmune and inflammatory disorders. IL-2 is essential for Treg development and maintenance, mediating tolerance and limiting inappropriate immune reactions. Glucocorticoid effects on IL-2 signaling are complex. They suppress IL-2 expression. This prevents excessive expansion and activation of naïve immune cells. On the other hand, glucocorticoids induce IL-2 receptors on activated T cells, amplifying the effect of IL-2 during clonal expansion. In a specific immune response, this suppresses immune cells with little or no affinity for an antigen and favors the clonal expansion of those with high affinity for an antigen (del Rey and Besedovsky, 2000).

Antigen Presentation and Adaptive Immune Response

Dendritic cells (DCs) represent the crucial interplay between innate and adaptive immunity. Following an encounter with microorganisms or antigen, immature tissue-resident DCs avidly capture, process and present antigens, maturing into immunostimulatory cells in the process. Activated DCs then rapidly migrate to draining lymph nodes where they activate T cells, triggering an adaptive immune response.

As they mature into professional antigen-presenting cells (APCs) during their migration, DCs express major histocompatibility complex (MHC) class II and costimulatory molecules to efficiently present the antigen to naive or memory T cells. Crosstalk between T cells and DCs through T-cell receptor(TCR)/MHC II-bound antigen, costimulatory molecules and cytokines allows the development of a T cell immune response and T cell expansion or deletion. When exposed to glucocorticoids during maturation, DCs differentiate into tolerogenic DCs in a manner at least partly dependent upon GILZ. Tolerogenic DCs resemble immature DCs in many respects: they are proficient in antigen uptake but have a poor ability to present antigens and elicit a T cell response (Coutinho and Chapman, 2011). Thus, glucocorticoids prevent MHC class II up-regulation and the expression of the costimulatory molecules, such as Cluster of Differentiation (CD)86 and to some extent CD80, CD40 and the ICAM-1/LFA-1 (intercellular adhesion molecule-1/lymphocyte function associated antigen-1) complex (Franchimont, 2004). Unlike immature DCs however, tolerogenic DCs induce the formation of T regulatory (Treg) cells. In contrast already terminally differentiated mature DCs exposed to glucocorticoids continue to express these molecules due to their relative glucocorticoid resistance. The timing of exposure to glucocorticoids thus appears to be essential during dendritic cell maturation.

The effects of glucocorticoids upon the terminal differentiation of DCs greatly impacts their cytokine secretion profile and their ability to modulate and shape the T cell immune response once it has flared up. The differentiation of $CD4^+$ T cells into T helper 1 (Th1) lymphocytes, which drive cellular immunity, or into Th2 lymphocytes, which drive humoral immunity, depends on the type of antigen encountered and the type of cytokines produced during antigen presentation. Interleukin-12 is a key link between innate and cellular immunity - it is required for CD4+ lymphocyte differentiation into Th1 cells and secretion of Th1 cytokines, such as IFN-γ and TNFα. Genetic disruption of IL-12 signaling in IL-$12^{-/-}$ and IL-$12R^{-/-}$ mice is associated with a defective Th1 immune response. In both mice and humans, the presence of glucocorticoids during the primary immune response is associated with reduced IL-12 production by macrophages or DCs, enhanced Th2 cytokine secretion and decreased Th1 cytokine secretion by $CD4^+$ lymphocytes on secondary stimulation. This effect can be reversed by the addition of exogenous IL-12 to glucocorticoid-treated APCs during the primary stimulation. Glucocorticoids therefore reduce the drive to a Th1 dominated response (Franchimont, 2004). Mice with selective knockout of GR in DCs are highly susceptible to LPS-induced sepsis because of a failure to suppress production of IL-12. Antibody neutralization of IL-12 in these mice prevents hypothermia and death, demonstrating the important role of glucocorticoid-mediated suppression of IL-12 in DCs. IL-12 neutralization also restores the ability of low-dose

LPS to tolerise these mice to subsequent challenge with high dose LPS (innate immune memory). Thus, glucocorticoids promote a DC phenotype that will ultimately generate a Th2 immune response and the secretion of Th2 cytokines.

As well as regulating the T cell response via their effects on DCs, glucocorticoids also exert direct effects on T cells.

Cellular Immune Response

Glucocorticoids affect both CD4+ and CD8+ T cells. Endogenous glucocorticoids attenuate acute graft versus host disease by suppressing the cytotoxic capacity of CD8+ T cells. Mice with specific knockout of GR in T cells develop severe acute graft versus host disease, which is not attenuated by therapeutic administration of glucocorticoids (Theiss-Suennemann *et al.*, 2014). As well as suppressing IL-12 secretion by monocytes/macrophages and DCs, glucocorticoids suppress IL-12Rβ1 and IL-12Rβ2 expression on T cells. They also interfere with IL-12 signaling in T cells by preventing phosphorylation of STAT (signal transducer and activator of transcription)-4 in response to IL-12. In turn, this reduces expression of interferon regulatory factor-1 and other STAT4-induced genes. STAT4-deficient mice are unable to elicit a Th1 immune response. STAT4 may be downstream of COX2: COX2 inhibition suppresses IL-12-induced T cell responses, associated with a block in STAT4 phosphorylation. Importantly, mice with a selective knockout of GR in T cells are unable to suppress COX-2 mediated lethal immune activation and show elevated levels of STAT4 phosphorylation (Brewer *et al.*, 2003). Both the lethal immune activation and the block in STAT4 phosphorylation are rescued by COX2 inhibition. Glucocorticoids also profoundly suppress secretion of the Th1 cytokines IFN-γ and TNFα, lessening NK and T cytotoxic effector functions. Such massive inhibition of the Th1 immune response by pharmacological glucocorticoids causes severe cellular immunodeficiency and impairs defense against intracellular and opportunistic infections.

Humoral Immune Response

Whereas glucocorticoids decrease the secretion of Th2 cytokines on first encounter with an antigen during primary stimulation, they promote Th2 differentiation during secondary stimulation. Independent of monocytes/macrophages and DCs, glucocorticoids prime naive T cells to Th2 commitment during a secondary immune response. The presence of glucocorticoids during primary stimulation promotes IL-10 secretion during secondary stimulation in both naive and memory T cells. Sequential contact with glucocorticoids during the primary and/or secondary immune response may thus influence the pattern of Th2 cytokines. This context-dependent action of glucocorticoids may explain some discrepancies reported in the literature on the regulation of Th2 cytokines by glucocorticoids. Similar to their effects on DCs, stimulation of CD4+ cells in the presence of glucocorticoid induces IL-10 secreting T regulatory (Treg) cells. Treg cells are immunosuppressive and repress the activation, cytokine production and proliferation of both CD4+ and CD8+ T cells. Treg cells themselves secrete high levels of IL-10. Their potent in vivo immunoregulatory properties are protective in experimental models of multiple sclerosis and other models of auto-immunity. The balance of CD4+ T cells between the related Th17 and Treg subsets is important in the pathogenesis of chronic inflammatory disease, including asthma. Glucocorticoids suppress the formation of Th17 cells by reducing production of Th17 promoting cytokines (particularly IL-6) by DCs and by repressing expression of ROR$\gamma\delta$ and STAT3, key transcription factors in Th17 cell differentiation. Thus, by shifting the balance from Th17 to Treg cells, glucocorticoids can help suppress chronic Th2 cell-mediated inflammatory disease. In mice, GR in T cells is needed for pharmacological suppression of Th1 and Th17 cell derived pro-inflammatory cytokines and suppression of antigen-induced arthritis. IL-17$^{-/-}$ mice (but not IFN$\gamma^{-/-}$ mice) are resistant to the therapeutic effects of glucocorticoids, suggesting Th17 cells (rather than Th1) are the likely target (Baschant *et al.*, 2011). The underlying mechanism remains unclear. However, glucocorticoids preferentially inhibit nonactivated lymphocytes but increase the expression of IL-2 receptors on activated lymphocytes. This increases the sensitivity of activated T cells to IL-2, thus preserving IL-2/IL-2R signaling in activated T cells whilst down-regulating it (via reduced IL-2 production) in naïve T cells (del Rey and Besedovsky, 2000). Given the vital roles for IL-2 signaling in clonal expansion as well as tolerance (IL-2 signaling is essential for Treg growth and survival), these effects of glucocorticoids on IL-2/IL-2R signaling may be important in the induction of Treg cells. They certainly contribute an important mechanism to shape T cell immune responses, limiting clonal expansion and ultimately contributing to down-regulation. Dysregulation of these regulatory circuits may contribute to auto-immune disease.

Thus, exposure to endogenous or exogenous glucocorticoids progressively shifts a cellular Th1 immune response to a humoral Th2 immune response. Several mechanisms are likely to be important in the ability of glucocorticoids to induce Th2 lymphocyte differentiation and the humoral immune response. The repression of IL-12 expression in APCs is likely to be one factor. Glucocorticoids also inhibit the transcription factor T-bet, the master regulator of Th1 differentiation (Cain and Cidlowski, 2017). Additionally, although glucocorticoids block IL-12-mediated STAT4 activation, they do not alter IL-4-induced STAT6 phosphorylation, essential for CD4+ Th2 development. These actions allow a Th2 immune response to develop whilst concomitantly suppressing a Th1 response.

The effects of glucocorticoids on B cells and antibody production have been less well studied. Nevertheless, similar to effects on T cells, glucocorticoids restrain B cell proliferation and the early steps in B cell development. GILZ may be at least partly responsible for the effects of glucocorticoids on B cell number: mice deficient in GILZ show exaggerated B cell proliferative responses. Like DCs and effector T cells, B cells become resistant to the inhibitory actions of glucocorticoids as they proceed through the different stages of differentiation and maturation. Surprisingly, the question of how these hormones influence B cell

receptor signaling compared to TCR signaling has not been explored, underscoring the paucity of information concerning glucocorticoid actions on B cells. Generally speaking, therapeutic glucocorticoid administration reduces immunoglobulin (Ig) concentrations. The number of activated B cells (secreting IgM, IgG and IgA) in the spleen inversely correlates with blood glucocorticoid levels (McEwen *et al.*, 1997). However, in vivo administration of glucocorticoids raises IgE serum levels in asthma or atopic patients. Glucocorticoids induce IgE isotype switching, acting synergistically with IL-4, the critical cytokine that induces Th2 differentiation and promotes B cell differentiation. Such IgE isotype switching is dependent on the CD40/CD40L complex since it is not observed in CD40L-deficient patients. In fact, glucocorticoids up-regulate CD40L expression on B cells and this may contribute to their synergistic actions on IgE isotype switching (Franchimont, 2004). Note, however, that the effects of endogenous glucocorticoids may differ from pharmacological treatment; adrenalectomy experiments in animals have shown that endogenous glucocorticoids help mount efficient immunization responses.

Allergy-Mediated Immune Response and Inflammation

The efficacy of glucocorticoids in the treatment of asthma and allergies despite their promotion of a humoral Th2 immune response and IgE secretion poses a paradox. Although glucocorticoids enhance IgE secretion, they strongly suppress allergic inflammation and chemokine-driven tissue infiltration of eosinophils. There may be several targets for the therapeutic benefit of glucocorticoids in these conditions, including mast cells and other innate immune cells. Glucocorticoids deplete tissue mast cells by decreasing expression of stem cell factor, the essential fibroblast-derived mast cell survival factor. Engagement of mast cell FcεRI by specific IgE triggers degranulation and release of preformed inflammatory mediators such as histamine, proteases, cytokines, and lipid mediators responsible for the early phase of type I hypersensitivity manifestations. Glucocorticoids suppress IgE receptor-mediated degranulation and release of inflammatory mediators from mast cells. They interfere with FcεRI signaling by disrupting raf-1/heat shock protein 90 and the subsequent activation of mitogen-activated phosphokinase and phospholipase A2 responsible for the de novo synthesis of arachidonic acid-derived metabolites (Franchimont, 2004). Glucocorticoids prevent the late phase of type 1 hypersensitivity characterized by mast cell activation with de novo synthesis of inflammatory mediators and secondary infiltration of Th2 cells, basophils, and eosinophils. Glucocorticoids also affect other innate immune cells to suppress allergic responses: studies in GR knockout mice suggest that macrophages and neutrophils are the target in contact allergy (Tuckermann *et al.*, 2007).

T Cell Development and Homeostasis

Though supra-pharmacologic doses of glucocorticoids induce T cell apoptosis, endogenous glucocorticoid action can induce T cell survival or apoptosis, depending on the differentiation stage, the degree of T cell activation and the timing of glucocorticoid exposure (before, during, or after activation). The effect of adrenalectomy in promoting thymocyte expansion in animal models is well known. The majority of thymocytes are immature double positive (CD4 + CD8 +) cells. These and some earlier stages in thymocyte differentiation are exquisitely sensitive to glucocorticoid-induced apoptosis. Indeed, the glucocorticoid-sensitivity of T cell progenitors to the pro-apoptotic effects of glucocorticoids is the reason glucocorticoids are the first line treatment in acute lymphoblastic leukemia and other blood cancers. Concomitant TCR signaling and glucocorticoid receptor (GR) signaling promote thymocyte survival, whereas either TCR signaling alone or glucocorticoid alone induces apoptosis (Ashwell *et al.*, 2000). In contrast, single positive (CD4 + or CD8 +) thymocytes are relatively resistant to the pro-apoptotic effects of glucocorticoids. Somewhat puzzlingly, thymic cellularity is normal in $GR^{-/-}$ mice. Studies in mice with T cell selective alteration of GR levels have produced conflicting results on thymic cellularity. Some insight into this paradox comes from animal studies showing that ACTH promotes thymocyte expansion when glucocorticoid levels are low, independently of the pro-apoptotic effects of glucocorticoids on thymocytes (Talaber *et al.*, 2015). The biological relevance of this remains unclear. Interestingly, glucocorticoids up-regulate IL-7Rα, thereby enhancing sensitivity to IL-7, a key cytokine for T cell development. IL-7 potently enhances both thymic-dependent thymocyte differentiation and thymic-independent antigen-dependent peripheral expansion of mature T cells, thereby restoring immunity in T cell-depleted mice. Conversely, deletion of IL-7Rα in mice and humans is associated with a lack of T cells. The positive regulation of IL-7Rα expression by glucocorticoids suggests their strong influence in the maintenance of peripheral T cell homeostasis (Franchimont, 2004).

Concluding Remarks

Glucocorticoid effects on the immune response are complex and depend upon many factors: type of glucocorticoid (synthetic or endogenous), cell type, differentiation and activation state, timing of glucocorticoid exposure and the cytokine milieu. Glucocorticoid effects can be immuno-suppressive or stimulatory and even, seemingly, both at the same time. The outcome of glucocorticoid action during an ongoing inflammatory response is different to that when glucocorticoid is administered prior to immune activation. If glucocorticoids are administered during the course of an immune response, they are less effective immunosuppressants than if administered prior to an immune response. This allows the early steps of an immune response (including

antigen presentation) to proceed, with activated cells resistant to the effects of glucocorticoids, without engaging more cells at later stages, preventing excessive expansion and activation of naïve immune cells.

Thus, glucocorticoids shape the immune response as it progresses, with different effects during the injury/infection and repair/resolution/immune memory phases. Maladaptation can contribute to auto-immune or chronic inflammatory disease. For example, in patients with rheumatoid arthritis, the HPA axis is hypo-reactive given the degree of inflammation and fails to control the auto-immunity and inflammation. Similar HPA axis hypo-reactivity to cytokine activation has been described in animal models of lupus or in susceptibility to experimental arthritis. The great advantage of the clinical use of glucocorticoids in Th1-inflammatory and Th1-autoimmune diseases is obvious because they restrain the inflammatory reaction, prevent tissue destruction, and block Th1-driven immune responses. The relative sparing of innate immunity and antibody responses may explain why glucocorticoids exhibit clinical benefit in certain bacterial infections such as in bacterial meningitis. However, these beneficial effects coexist with deleterious adverse effects. Because of their suppressive actions on Th1 immunity, they increase susceptibility to intracellular and opportunistic infections such as tuberculosis or viral infections. High levels of glucocorticoids may impair early macrophage and neutrophil responses by switching to the resolution phase of inflammation prematurely. The sum total of glucocorticoid action upon a particular immune response is therefore the balance of diverse effects on the many immune cells and inflammatory mediators that comprise a response. A greater understanding of the complexity of these interactions could be useful to enhance ex vivo therapies in auto-immune disease, organ transplants and cancer.

Introduction

The hypothalamic–pituitary–adrenal (HPA) axis is activated during stress and represents one of the major pathways through which the brain regulates the I/I response. Conversely, products of the I/I response influence brain function. In addition, immune cells produce a number of hormones and neuropeptides, such as corticotropin-releasing hormone (CRH) and α-melanocyte-stimulating hormone, which probably act locally as autacoids during both the early and late stages of the I/I process. This locally produced CRH, hereafter called "peripheral CRH," has been also implicated in other physiological functions, such as reproduction (Chrousos, 1995).

Central CRH and the HPA Axis-Peripheral CRH

Sauvagine, urotensin I, urocortin (UCN), and CRH belong to a family of peptides with similar activities. In humans the CRH and UCN genes are located on chromosomes 8 and 2, respectively. Initially, CRH is synthesized as a larger precursor molecule (spanning 191 amino acids in humans) from which it is cleaved at flanking basic amino acid pairs. CRH is a 41-amino-acid peptide and it shows significant interspecies homology at the amino terminal region (Rivier *et al.*, 1982; Vale *et al.*, 1983). CRH is synthesized by parvocellular neurons of the hypothalamic paraventricular nucleus (PVN) and is secreted—along with other adrenocorticotropic hormone (ACTH) secretagogues, such as arginine vasopressin (AVP), cholecystokinin, met-enkephalin, and dynorphin—into the hypophyseal portal blood via projecting axons to the median eminence. The plasma half-life of CRH in humans is 4 min. The secretion of CRH is regulated by inputs from higher centers integrating the effects of the circadian pacemaker, stress, and glucocorticoid negative feedback (acting at pituitary, hypothalamic, and higher levels, such as the hippocampus). There have not been noted any sex or age differences in plasma ACTH or cortisol responses to CRH (Pavlov *et al.*, 1986). However, the corresponding cortisol response is maximized late in the afternoon due to cortisol receptor change of affinity (Grino *et al.*, 1987). ACTH released by CRH leads to the secretion of cortisol and other adrenal steroids. Pituitary adenylate cyclase activating polypeptide (PACAP) increases CRH mRNA levels in the parvocellular region of the PVN of the hypothalamus, suggesting that this polypeptide is involved in the positive regulation of CRH gene expression. Interleukin (IL)-6, produced in the PVN stimulates CRH gene expression both directly and indirectly. Forskolin and PACAP stimulate IL-6 mRNA and protein levels in the hypothalamic cells. IL-6 may be important to sustain the activity of CRH and AVP genes. Estradiol may enhance the activation of CRH gene expression in response to stress (Kageyama and Suda, 2009; Navarra *et al.*, 1991; Vallieres and Rivest, 1999).

Most of the plasma CRH is apparently of nonhypothalamic origin since hypothalamic CRH is rapidly enzymatically decomposed at the pituitary level. Although the contribution of hypothalamic CRH to the total plasma CRH is small, in certain circumstances, such as insulin-induced hypoglycemia, hypothalamic CRH release leads to increments in plasma CRH concentration.

Peripheral CRH has been found in the adrenal medulla, the testes, the ovaries, the cardiovascular system, the gastrointestinal tract, the pancreas, the lung, the spinal cord, the myometrium, the endometrium, and the placenta (Grino *et al.*, 1987; Mastorakos *et al.*, 1996; Ferrari *et al.*, 1995; Petraglia *et al.*, 1992; Fabbri *et al.*, 1990; Baigent, 2001), as well as in diverse inflammatory sites (Mastorakos *et al.*, 1994a; Scopa *et al.*, 1994). Peripheral sensory afferent type C fibers and postganglionic sympathetic nerves also express CRH (Zhao and Karalis, 2002) and have been suggested as an additional source of the immune CRH (Chrousos, 1995). Another peripheral organ where CRH is locally produced is the skin where CRH receptor type 1 (CRH-R1) isoforms are expressed in keratinocytes (Zbytek *et al.*, 2004). Peripheral CRH has the same electrophoretic profile as hypophyseal CRH and the same expression pattern during acute inflammation, as the acute phase reactants, substance P (SP) and TNF, including their down-regulation by glucocorticoids (Karalis *et al.*, 1991). The epithelial cells of human and rodent endometrium produce CRH throughout the menstrual cycle, whereas the stroma needs to undergo decidualization in order to produce CRH. The placenta secretes CRH, leading to an increased maternal plasma CRH concentration during the third trimester of pregnancy. Only in humans, plasma CRH is bound to a high-affinity binding protein (37 kilodaltons) (CRH-BP), with a concomitant reduction in its bioactivity. This protein has been characterized and is expressed in the brain, the pituitary and the peripheral tissues (liver, kidney, spleen) (Guillemin, 2005).

Two types of G protein-coupled CRH receptors, types 1 and 2 (CRH-R1 and CRH-R2, respectively), with seven transmembrane domains each, have been described. They share an approximately 70% homology of their amino acid sequence but exhibit unique

This article is an update of George Mastorakos and Ioannis Ilias, Corticotropin-Releasing Hormone (CRH) and Inflammation, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 575–579.

pharmacologic profiles. They are differentially expressed and appear to mediate selective actions of CRH at different tissues. The affinity that CRH exhibits toward CRH-R1 is 10 times higher than toward CRH-R2 (Perrin and Vale, 1999). CRH-R1 is encoded by human chromosome 17q21 while CRH-R2 is encoded by human chromosome 7p14 (Mastorakos *et al.*, 1993a, 1994b; Vamvakopoulos and Sioutopoulou, 1994). Alternatively nine spliced isoforms α, β, c, d, e, f, g, h and v-1 have been identified for CRH-R1, whereas isoforms α, β, and γ, plus a stomach variant, have been identified for CRH-R2 (Catalano *et al.*, 2003; Johnson *et al.*, 2003; Pisarchik and Slominski, 2001).

CRH-R1α contains 415 amino acids. It mediates CRH and UCN 1 actions and is widely expressed throughout the body. Transcription of all 14 exons results in a CRH-R1 variant (CRH-R1β), a 444-amino acid heptathelial protein receptor with an extended first intracellular loop that exhibits impaired agonist binding and signaling properties. CRH-R1β can be regarded as a "pro-CRH-R1" receptor isoform without knowing its biological actions (Teli *et al.*, 2008). CRH-R1β is expressed in a tissue specific manner and is present at the anterior pituitary (Chen *et al.*, 1993), at reproductive tissues such as myometrium, endometrium and chorion trophoblast cells and mast cells but not in the placenta, adrenal and synovium (Merali *et al.*, 2008). Another CRH-R1 variant is CRH-R1d, containing 14 amino acids missing from the putative seventh transmembrane domain due to exon 13 deletion, a splicing event which is common in the other members of the B1 family of G protein-coupled receptors. In human embryonic kidneys the CRH R1d variant is mainly retained in the cytoplasm in contrast to CRH-R1α, although some cell membrane expression is evident, too. Membrane-expressed CRH-R1d contains an extracellular C terminus. A stomach variant has also been identified for CRH-R2 (Slominski *et al.*, 2001). CRH-R1 expression is highest in the cerebral cortex, striatum, amygdale and cerebellum. On the other hand, CRH-R2 is mostly present in subcortical structures such as the lateral septal nucleus, several nuclei of the hypothalamus and the choroid plexus (Chalmers *et al.*, 1996). CRH receptors mRNA and protein are also detectable in adipose tissue. CRH-R2 expression in fat tissue is comparable with its expression in heart, where the highest expression of CRH-R2 is detected. At the periphery, CRH-R2 is widely expressed in the gastrointestinal tract, the lung, skeletal muscle, arteries and the heart muscle. Indeed, peripherally injected CRH augments gastrointestinal motility, inhibits gastric secretion, lowers blood pressure and affects heart output and decreases inflammatory reactions. CRH-R2 is also expressed in the colon of patients with ulcerative colitis. CRH-R2 downregulation in distal/sigmoid biopsies of ulcerative colitis patients is indicative of change in CRH-R2 signaling associated with the process of inflammation (Chatzaki *et al.*, 2013). Increased serum CRH with decreased lesional skin CRH-R1 gene expression was observed in patients with psoriasis and atopic dermatitis, suggesting their involvement in stress-induced worsening of symptoms (Vasiliadi *et al.*, 2012). Substance P, another factor involved in inflammatory diseases, can stimulate mast cells and increase the expression of functional CRH-R1. CRH induces NK-1 gene expression, explaining CRH-R1 and NK-1 expression in lesional skin of psoriatic patients (Asadi *et al.*, 2012). CRH-R1 is also detected in the ovarian stroma and the theca and in the cumulus oophorus of the graafian follicle (Mastorakos *et al.*, 1993b; Asakura *et al.*, 1997). CRH-R1α is present on both epithelial and stromal cells of the human endometrium (Mastorakos *et al.*, 1996). CRH-R1/CRH-R2 ratio varies according to adipose tissue type. CRH-R1 expression is higher in subcutaneous than in visceral fat in contrast to CRH-R2 expression which is the opposite. Urocortin and stresscopin, ligands of the CRH-R, are also expressed in fat tissue, having metabolic and potent anorexic effects. CRH-R1 and CRH-R2 expression is downregulated by CRH in isolated adipocytes (Seres *et al.*, 2004).

CRH binds to type CRH-R1 of the anterior pituitary corticotrophs, resulting in adenyl cyclase activation and increased intracellular cyclic AMP (cAMP) concentration, cAMP-dependent protein kinase A activation, increased influx of extracellular calcium via L-type calcium channels, and the production of lipoxygenase metabolites of arachidonic acid. The net result is the secretion of ACTH and other proopiomelanocortin (POMC)-derived peptides within a few seconds, whereas increased POMC gene transcription and POMC biosynthesis ensue. The number of CRH-R in corticotroph cells may modulate the ACTH response.

It was shown that the CRH-induced activation of the NF-κB was mediated by two protein kinase systems, PKA and Protein Kinase C (PKC) (Rossant *et al.*, 1999; Sananbenesi *et al.*, 2003). CRH affects the PKC signaling pathway in the pituitary, Leydig cells, adrenals, placenta, immunocytes, myometrium and hippocampus. In human epidermoid cells, CRH induces the activity and the translocation of the conventional PKC isoenzymes (Kiang *et al.*, 1994). It is very interesting that UCN exerts its neuroprotective effect on cultured hippocampal neurons by the PKC pathway via activation of the CRH-R1 receptor (Pedersen *et al.*, 2002). Activation of the PKC pathway may modify the sensitivity to CRH since it affects the number of CRH-Rs (Dieterich and DeSouza, 1996; Dermitzaki *et al.*, 2005). CRH increases the concentration of cytosolic calcium ions in calcium rich and in calcium free media. As a result, the PKA signaling pathway mediates both effects of CRH while on the other hand the PKC signaling pathway mediates only the CRH-induced mobilization of calcium ions from intracellular stores, possibly via P-type calcium ion channel (Kuryshev *et al.*, 1995, 1996; Dermitzaki *et al.*, 2004). CRH-R1α and -R1β exhibit differential responses to PKC-induced phosphorylation. This might represent an important mechanism for functional regulation of CRH signaling in target cells. PKC activation increases internalization of CRH-R1β but not CRH-R1α in a β-arrestin-independent manner, although both CRH-R1 variants are susceptible to homologous desensitization and internalization following treatment with CRH (Marcovic *et al.*, 2006).

The I/I Response

The cellular components of the I/I response consist of circulating nonlymphoid leukocytes and local immune accessory cells. Nonlymphoid leukocytes include the monocytes/macrophages, neutrophils, basophils, and eosinophils. Local immune accessory cells include the endothelial cells, tissue fibroblasts, resident macrophages, and macrophage-related cells, such as Kupffer cells,

type A synovial-lining cells, as well as the basophil-related mast cells. Many substances secreted locally in the inflammatory area by the above-mentioned cells act as autocrine or paracrine regulators and/or mediators of the inflammatory response, as well as endocrine messengers between the inflammatory process and other systems such as the CNS, HPA axis, and peripheral nervous system. These substances include the vasoactive amines, histamine and serotonin, the kallikrein/kinin system, the Hageman factor and other clotting factors, the fibrinolytic system, several components of the complement system, and eosinophil and platelet activators. They also include cytokines (such as tumor necrosis factor α (TNF α), TNFβ, interferon-α, interferon-β, and interferon-γ), interleukin-1 (IL-1) through IL-4 (as well as their binding proteins and natural antagonists), many lipid and glucolipid products of triglyceride metabolism (such as several active products of arachidonic acid, including the endoperoxides, the thromboxanes, prostacyclin, and leukotrienes), and platelet-activating factor. In addition, active oxygen radicals, including nitric oxide and lysosomal constituents such as neutral proteases, participate in the inflammatory response.

The first step in the initiation of the I/I response is the activation of the innate immune system. This nonspecific response serves to locate the injurious agent, restrict the tissue damage and eliminate the harmful agent, initiate the adaptive immune system and determine the path that will be followed (cellular/humoral response). Subsequently, the adaptive immune system is activated by the innate immune responses. As lymphocytes arrive at the inflammatory area, antigen-presenting cells (APCs) such as plasmacytoid dentritic cells, interstitial and Langerhans dentritic cells and astrocytes present infectious agent antigens of macrophages to T cells. This is the ignition signal for the activation of the adaptive immunity, consisting of cellular (T4, T8, NK lymphocytes) and humoral (B lymphocytes, plasma cells, antibodies) immunity. CD4 helper T cells are the regulators of this antigen-specific response. These cells can be subdivided on the basis of cytokines produced in Th1 T cells which promote primarily the cellular/inflammatory immunity and Th2 cells which have a primary role in the regulation of humoral immunity. T-helper cells produce interleukin 17, a cytokine that acts as a potent mediator in delayed-type reactions by increasing chemokine production in various tissues to recruit monocytes and neutrophils to the site of inflammation. IL-17 is induced by IL-23 which results in destructive tissue damage in delayed-type reactions. IL-17 acts synergistically with TNF and IL-1.The balance between Th1 and Th2 is important for the homeostasis within the immune system. Glucocorticoids and catecholamines, the stress hormones, have a significant effect on this balance. Glucocorticoids suppress the production of IL-12 by monocytes/macrophages, the main inducer of Th-1 responses (Cao *et al.*, 2005; Elenkov *et al.*, 1996) and thus, they affect the Th-1/Th-2 balance leading to a Th-2 shift. In contrast to catecholamines, GCs also have a direct effect on Th-2 cells by upregulating their IL-4, IL-10 and IL-13 production (Elenkov *et al.*, 1996; Blotta *et al.*, 1997). On the other hand, the two major catecholamines, norepinephrine (NE) and epinephrine potently inhibit the production of IL-12 by APCs thus suppressing the development of Th1 type cells (Cao *et al.*, 2005; Ramierez *et al.*, 1996; Panina-Bordignon *et al.*, 1997).

CRH and the I/I Response

Hypothalamic (central) CRH has been considered to act indirectly in an antiinflammatory fashion, since the end product of the HPA axis' stimulation is cortisol, which has thoroughly studied antiinflammatory actions. Moreover, it is known that among the proinflammatory cytokines, IL-6 is a potent stimulator of the human HPA axis, and a secretagogue of magnocellular AVP (Mastorakos and Ilias, 2006). The administration of IL-6 subcutaneously provokes considerable elevations in plasma ACTH, cortisol, and AVP. It has been shown that IL-6 in head trauma (an aseptic inflammatory state) and a syndrome of inappropriate secretion of antidiuretic hormone is quantitatively correlated with AVP (Gionis *et al.*, 2003; Mastorakos *et al.*, 1993a, 1994c). The latter is also known to be a potent activator of the HPA axis.

However, disturbances in the HPA axis activity affect the I/I response. An excessive HPA response (e.g., a state of stress or relative hypercortisolemia) can increase susceptibility to infectious agents and tumorogenesis but enhance resistance to autoimmune or aseptic inflammatory diseases. On the other hand, a defective HPA axis response (e.g., relative glucocorticoid deficient state) diminishes susceptibility to infections and tumorogenesis but increases susceptibility to autoimmune or aseptic inflammatory diseases. Indeed, these suggestions have been ascertained in Fischer and Lewis rats, two highly inbred strains selected for their resistance (Fischer rats) or susceptibility (Lewis rats) to inflammatory disease. In Lewis rats hypothalamic CRH neurons respond poorly to all neurotransmitters and the overall HPA-axis response to stress is decreased (Chrousos, 1995). Moreover, CRH deficiency disrupts endogenous glucocorticoid production and enhances allergen-induced airway inflammation and lung mechanical dysfunction in CRH knock-out mice. Thus, inherited or acquired CRH deficiency could increase asthma severity in human subjects (Silverman *et al.*, 2004). Hypofunction of the HPA axis was also found in patients with Sjogren syndrome (Johnson *et al.*, 2000) and sarcoidosis (Porter *et al.*, 2003). Interestingly, high plasma levels of cortisol, CRH and ACTH that have been found in centenarians indicate an activation of the entire stress axis, likely counteracting the systemic inflammatory process occurring with age. This activation fits with the hypothesis that lifelong low-intensity stressors activate ancient, hormetic defense mechanisms, favoring healthy aging and longevity (Genedani *et al.*, 2008). On the other hand, the relative hypercortisolemia that accompanies aging has been suggested to result from an age-related HPA axis resilience.

Since CRH is the main stimulator of POMC production from the pituitary, and certain POMC products (like ACTH and β-endorphin) can directly affect the I/I response, it has been hypothesized that CRH itself might be directly involved with the I/I response. The putative role of CRH in the I/I response was further suggested by the presence of CRH-specific binding sites in human lymphocytes secreting POMC-derived peptides (ACTH and β-endorphin). By employing the rat air-pouch model of acute aseptic chemical inflammation, immunoreactive CRH (IrCRH) was localized in the inflammatory tissue by

immunohistochemistry. IrCRH was also found in the cytoplasm of immune accessory cells such as macrophages, endothelial cells surrounding vessels, and tissue fibroblasts. Immunoneutralization studies in vivo with a highly specific anti-CRH polyclonal antiserum resulted in a significant suppression of the inflammatory response, suggesting that peripheral CRH promotes inflammation. The decrease in inflammation by anti-CRH antiserum was similar to that caused by immunoneutralization of TNF (a well-known mediator of the I/I response that was used as a protocol). The effects of the combined administration of anti-CRH and anti-TNF were not additive, indicating that the two antisera might interfere with a common pathway of the inflammatory response. Furthermore, locally produced somatostatin mediates the glucocorticoid antiinflammatory effects at the inflammatory sites, whereas CRH levels at inflammatory sites are lowered in the presence of somatostatin analogues.

The mobility of this "immune" peripheral CRH is similar, as assessed by high-performance liquid chromatography, to that of r/hCRH 1–41 (the form produced by the rat and human hypothalamus as well as by the human placenta). The presence of CRH at peripheral inflammatory sites has also been demonstrated in other animal models of both acute and chronic inflammation. IrCRH was present in inflammatory cells of rat joint tissue with streptococcal cell wall- and adjuvant-induced arthritis. CRH mRNA was present in the inflamed synovial from arthritic rat joints that express specific CRH-binding sites. Furthermore, IrCRH was seen in the synovial-lining cell layers and blood vessels from joints of patients with rheumatoid arthritis (RA) and osteoarthritis, whereas high levels of CRH immunoreactivity were found in the synovial fluids of patients with RA (Crofford *et al.*, 1993). IrCRH was also found in immune accessory cells from uveitic retinas and corpora vitrea from Lewis rats with experimentally induced autoimmune uveitis (Mastorakos *et al.*, 1995a,b). Additionally, the local presence of CRH appears to be of pivotal importance in the process of experimental autoimmune uveoretinitis in rodents, since retinas from immunized B10.A mice treated with anti-CRH antibody showed significantly lower apoptosis and Fas and Fas ligand (FasL) expression than placebo-treated animals. Thus, CRH at inflammatory sites seems to be involved in the activation of the Fas/FasL system.

Whereas central CRH participates in the systemic endocrine inhibition of the I/I reaction, peripheral immune CRH may participate in autocrine/paracrine stimulation of inflammation. The mechanisms of the peripheral CRH-mediated component of the I/I response are still unclear, although these may be mediated by local POMC gene products with known proinflammatory activity and/or by inflammatory cytokines. Another possible source of peripheral immune CRH and other neuropeptides that are important in inflammation (such as substance P and SMS), other than the accessory immune cells, is the primary afferent (sensory) nerves as well as the sympathetic postganglionic neurons. CRH and substance P are depleted in the rat spinal cord and dorsal root ganglia in response to capsaicin, which is toxic to the sensory afferent fibers. Also, IrCRH is present in the intermediolateral sympathetic column as well as the ganglia of the sympathetic chain and, therefore, could contribute to the inflammatory process through the sympathetic postganglionic fibers. Thus, CRH is involved in opposing, and site-specific, pro- and antiinflammatory actions.

Regarding studies on models of septic inflammation, CRH-deficient mice had reduced ileal secretion, histological damage and inflammation in response to clostridium difficile (toxin A). In addition, the content of SP (a sensory neuropeptide with pivotal role in the mediation and amplification of toxin A-induced inflammatory signal) at the inflammatory sites is CRH-dependent. These results revealed the major proinflammatory role of CRH in the pathophysiology of toxin A-mediated inflammatory diarrhea and indicate a SP-linked pathway (Anton *et al.*, 2004). Recent findings support the idea that increased peripheral CRH mediates the enhanced visceral nociception in rats recovered from experimental colitis (La *et al.*, 2008).

Data exist showing that CRH enhances the expression of nitric oxide synthase (NOS III) to promote NO production from CRH-R1α expressing cells. These results confirm a role for CRH-R-mediated responses in regulating vascular changes associated with chronic synovitis (Ralph *et al.*, 2007). Corticotropin-releasing hormone acting through both receptors induces a significant increase of reactive oxygen species (ROS) content, catalase activity and superoxide dismutase activity, accompanied by a simultaneous significant decrease of endothelial NO activity and NO levels as well as a significant increase in nitrotyrosine (peroxynitrite) levels (Gougoura *et al.*, 2010). These data indicate that CRH may act as a regulator of proinflammatory mechanisms inducing adaptation of endothelial cell function to local oxidative stress (Gougoura *et al.*, 2010).

Interestingly, CRH-deficient mice are resistant to experimental autoimmune encephalomyelitis (Karalis *et al.*, 1991). This effect of peripheral CRH is independent of its ability to increase corticosterone production, because adrenalectomized wild-type mice had similar disease course and severity as control mice. Thus, it seems that peripheral CRH exerts a proinflammatory effect in experimental autoimmune encephalomyelitis with a selective increase in Th1-type responses indicating a novel contribution of peripheral CRH to the regulation of Th1-mediated inflammation. These findings might have implications for the treatment of Th1-mediated diseases such as multiple sclerosis (MS), a demyelinating autoimmune disease characterized by inflammation of the central nervous system (Benou *et al.*, 2005). Substantial evidence indicates that stress can precipitate or worsen symptoms of inflammation in multiple sclerosis (MS). However, the exact mechanism of how stress affects MS is not well understood. Karagkouni *et al.*, proposed that neuropeptides secreted under stress, such as CRH and neurotensin, activate microglia and mast cells to release inflammatory molecules, leading to maturation and activation of T17 autoimmune cells, disruption of the blood–brain barrier and T cell entry into the central nervous system, thus promoting brain inflammation and contributing to MS pathology. Reduction of stress and inhibition of these processes by selected flavonoids could provide novel therapeutic approaches (Karagkouni *et al.*, 2013).

Peripheral CRH exerts proinflammatory effects, possibly through mast cell activation. Acute psychological stress induces CRH-dependent mast cell degranulation. In a similar way CRH causes mast cell degranulation in human skin, releasing great amounts of histamine, which appears to be the principal mediator of the vasodilatory effects of CRH in human skin (Wright Ian, 2003). In addition, CRH is synthesized and secreted by human mast cells acting in autocrine and paracrine fashion, especially in allergic

inflammatory disorders exacerbated by stress (Kempuraj *et al.*, 2004). Finally, CRH can induce secretion of VEGF selectively (Mann-Chandler *et al.*, 2005).

Stress participates and worsens not only asthma and atopic dermatitis but also acute coronary syndromes (ACSs) which are associated with coronary inflammation. Activation of coronary mast cells by stress through CRH and other neuropeptides, contributes to coronary inflammation and coronary artery disease. Therefore, inhibition of cardia mast cells may be a novel treatment approach (Alevizos *et al.*, 2014).

Periodontal disease involves inflammation of the gingival tissues, caused by microbial pathogens. Recent research suggests that emotional stress worsens periodontal disease. Papathanasiou *et al.*, proposed that stress-induced CRH secretion stimulates gingival mast cells and other neuropeptides and cytokines as well to secrete proinflammatory molecules that contribute to periodontal pathology. Stress reduction and/or mast cell inhibition may provide additional therapeutic approaches (Papathanasiou *et al.*, 2013).

Septic shock is associated with decreased ACTH synthesis in humans and in rats, which is not compensated by its two natural secretagogues, AVP and CRH. Polito *et al.*, suggested that one underlying mechanism might be increased expression of iNOS in hypothalamic parvocellular neurons (Polito *et al.*, 2011). In septic patients during cardiovascular deregulation, increased levels of POMC derivatives have been found. Majetec *et al.*, found that after CRH administration, heart rate, cardiac index and stroke index increased and the systemic vascular resistance index decreased. Moreover, a positive correlation between ACTH concentration and stroke index as well as an inverse correlation between α-melanocyte stimulating hormone (αMSH) concentration and systemic vascular resistance index was observed. Corticotropin releasing hormone and ACTH may have opposite effects on the blood pressure. Therefore, POMC derivatives seem to have influences on patients hemodynamics during sepsis (Matejec *et al.*, 2011). In patients with septic shock, the upregulation of mHLA-DR expression after CRH infusion is independent of POMC derivatives release. From the positive correlation between plasma concentration of αMSH and mHLA-DR expression they concluded that in this group of patients, the downregulation of mHLA-DR expression is accompanied by the loss of αMSH release by monocytes into the cardiovascular compartment (Matejec *et al.*, 2013).

It has been shown previously that CRH induces NF-κB DNA-binding activity in mouse and human leukocytes. Karalis *et al.*, demonstrated that in the human monocytic P-1 cells, CRH activates the PI3K/Akt and ERK1/2 pathways. CRH-R2 mediates these CRH effects as suggested by their abolishment following treatment with the specific CRH-R2 antagonist, astressin 2B. The CRH-mediated PI3K/Akt activation induces cell survival as suggested by the stimulation of the antiapoptotic factor Bcl-2. ERK1/2 activation results in upregulation of IL-8 expression, an effect inhibited by the CRH-induced activation of PI3K/Akt. These studies demonstrate novel effects of CRH in human monocytes mediated by the activation of PI3K/Akt and they reveal pathway-specific effects of the CRH/CRH-R2 system in chemokine activation and cell survival which is important for the development of new therapeutic agents for inflammatory diseases (Chandras *et al.*, 2009).

CRH in the I/I Phenomena of the Female Reproductive System

Physiological phenomena taking place in the female reproductive tract (such as decidualization and luteolysis) bear characteristics of an aseptic inflammation (Nepomnaschy *et al.*, 2007; Vrekoussis *et al.*, 2010). In addition, pregnancy has been explored from the immunological point of view since it can be considered a semiallograft situation.

CRH and CRH-R have been localized in the ovary in rat and in the ovary, endometrium, myometrium, and placenta in human (Kalantaridou *et al.*, 2003). Further tentative actions of CRH on the female reproductive system have been suggested. Corticotropin releasing hormone R1 receptors are detected in the ovarian stroma and the theca and in the cumulus oophorus of the graafian follicle (Mastorakos *et al.*, 1993b; Asakura *et al.*, 1997). Granulosa cells are devoid of the expression of CRH and CRH-R1 genes and peptides (Asakura *et al.*, 1997). CRH was shown to have an inhibitory effect on ovarian steroidogenesis, mediated through CRH and interleukin-1 receptors, and possibly linked to the processes of follicular atresia and luteolysis. Corticotropin releasing hormone exerts an inhibitory effect on estrogen and progesterone production in human granulosa-lutein cells isolated from the follicular fluid upon oocyte retrieval (Calogero *et al.*, 1996; Ghizzoni *et al.*, 1997; Erden *et al.*, 1998). CRH inhibited LH-stimulated DHEA and androstenedione production in isolated follicular theca cells (Muramatsu *et al.*, 2001). The addition of CRH has an inhibitory effect on in vitro fertilized oocytes, resulting from cultured preantral follicles at all stages of preimplantation embryo development (Dinopoulou *et al.*, 2013). In addition, the presence of CRH in the culture medium inhibits steroidogenesis by preantral mouse follicles cultured in vitro (Dinopoulou *et al.*, 2013). Corticotropin releasing hormone, UCN and CRHR gene expression is higher during the regression of the human corpus luteum than in the earlier stages of the luteal phase (Muramatsu *et al.*, 2001).

Epithelial cells of the human endometrium and differentiated stoma cells also express the CRH gene (Mastorakos *et al.*, 1996; Makrigiannakis *et al.*, 1995a, b). In addition, CRH-R1 is present in both epithelial and stroma cells of human endometrium and myometrium (Di Blasio *et al.*, 1997; Grammatopoulos and Hillhouse, 1998; Grammatopoulos *et al.*, 1999). Endometrial CRH participates in the regulation of intrauterine inflammatory processes such as stroma decidualization, blastocyst implantation and early maternal tolerance (Gravanis *et al.*, 2002). The progesterone-induced decidualization is modulated by locally produced inflammatory factors. Epithelial and stoma CRH affects decidualization of stoma cells by regulating local modulators, that is, prostanoids (PGE2) and cytokines (IL-1 and IL-6). The net effect of its actions is the fine-tuning of the decidualizing effect of progesterone (Zoumakis *et al.*, 2000). Endometriosis is considered as an aseptic inflammatory disease, characterized by the

presence of ectopic endometrium-like tissue. Corticotropin-releasing hormone-R1β and -R2α are expressed in endometriotic sites and they are more strongly expressed in eutopic endometrium of women with endometriosis compared to healthy women endometrium at the mRNA and protein level (Vergetaki *et al.*, 2013). Corticotropin-releasing hormone, UCN, CRH-R1 and -R2 mRNAs and proteins are also more highly expressed in ectopic rather than eutopic endometrium in women with endometriosis. These findings indicate that CRH and UCN might play an immunoregulatory role in endometriotic sites by affecting reproductive functions such as decidualization and implantation in women with endometriosis (Vergetaki *et al.*, 2013).

Locally produced embryonic and endometrial CRH plays a role in both the aseptic inflammatory process of implantation and the antirejection process that protects the fetus from the maternal immune system. Placental trophoblasts express both CRH-R1 and -R2 (Gao *et al.*, 2008). The syncytiocytotrophoblasts of the placenta and the fetal membranes express the CRH -R1α, -R1c, -R1d and -R2β subtypes (Karteris *et al.*, 1998). By contrast to the hypothalamic CRH system, the production of placental CRH is positively regulated by both fetal and maternal GCs (Karalis *et al.*, 1996). Placental CRH production is also modified by estrogen, progesterone and NO which are inhibitory and by a range of neuropeptides which are stimulatory (Smith, 2007). CRH increases estrogen biosynthesis in cultured human placental cells (You *et al.*, 2006).
