Pituitary surgery is the first line treatment for CD, consisting in selective removal of the pituitary tumor, mainly performed by a transsphenoidal approach with microscopic or endoscopic techniques (Nieman *et al.*, 2015; Pivonello *et al.*, 2015). Currently, the historical transcranial approach is rarely used for selected patients with tumors of large size (Pivonello *et al.*, 2015). The overall mean (m) initial remission rate of pituitary surgery is 77.8%, ranging from 25% to 100%. Initial remission rate is lower for macrodenomas ($m = 62.3\%$; 30.8%–100%) than microdenomas ($m = 82.1\%$; 48.7%–100%). Persistence or recurrence of disease are common accounting for the high rate of long-term failure of pituitary surgery ($m = 31.7\%$; 0%–75%). Particularly, macroadenomas show a higher recurrence rate ($m = 18.8\%$; 0%–59%) than microadenomas ($m = 11.7\%$; 0%–36.4%). The recurrence risk is higher within the first 10 years, but it is still present even 30 years later (Mampalam *et al.*, 1988; Hofmann *et al.*, 2008; Lambert *et al.*, 2013; Jagannathan *et al.*, 2009; Invitti *et al.*, 1999; Patil *et al.*, 2008a; Cavagnini and Pecori Giraldi, 2001). Factors that might negatively influence pituitary surgery outcome include: male gender, tumor size (>2 cm), tumor with suprasellar extension or cavernous sinus invasion, undetected pituitary tumor at pre-surgical MRI or during surgical procedure, the absence of histological confirmation, the presence of peritumoral Crooke's cells and the inexpertise of surgeon (Pivonello *et al.*, 2015; Hammer *et al.*, 2004; Cannavo *et al.*, 2003; Wagenmakers *et al.*, 2013; Ciric *et al.*, 1997; Bigos *et al.*, 1980; Mampalam *et al.*, 1988; Invitti *et al.*, 1999; Jagannathan *et al.*, 2009). Particularly, when performed by skilled pituitary surgeons pituitary surgery has a low risk of complications, mainly including hypopituitarism and diabetes insipidus, occurring in 29.6% (0.9%–93.3%) and in 12.3% (0.9%–32.5%) of cases, respectively (Mampalam *et al.*, 1988; Pivonello *et al.*, 2015; Hofmann *et al.*, 2008; Cavagnini and Pecori Giraldi, 2001; Invitti *et al.*, 1999; Jagannathan *et al.*, 2009; Lambert *et al.*, 2013; Patil *et al.*, 2008a). Myocardial infarction, pneumonia infection and meningitis, are the main mortality causes, with a mean mortality rate of 0.6% (0%–7.1%) (Pivonello *et al.*, 2015).

Repeat pituitary surgery is one of the second line treatment options currently available for patients with persistent or recurrent CD after a first pituitary surgery. This approach is mainly suggested in patients with a clear evidence of a residual tumor at pituitary imaging (Pivonello *et al.*, 2015; Nieman *et al.*, 2015), although the remission rates (58%, 30%–87.5%) are lower and the recurrence rates ($m = 16.1\%$; 0%–60%) are higher than those of the first surgery (Pivonello *et al.*, 2015; Benveniste *et al.*, 2005; Hofmann *et al.*, 2008; Patil *et al.*, 2008b). Main negative predictive factors are residual tumor localization and size (Pivonello *et al.*, 2015; Benveniste *et al.*, 2005; Hofmann *et al.*, 2008; Patil *et al.*, 2008b). Hypopituitarism is the most common complication ($m = 38\%$; 9.1%–78.6%) (Pivonello *et al.*, 2015; Benveniste *et al.*, 2005; Hofmann *et al.*, 2008; Patil *et al.*, 2008b).

Pituitary radiotherapy is generally suggested as a second line option in case of pituitary surgery failure, especially with aggressive and/or invasive tumors, although it might rarely represent a first line approach, in patients without indication for surgery, with contraindications to surgery, and in patients who refuse surgery (Pivonello *et al.*, 2015; Nieman *et al.*, 2015). Currently, the pituitary radiotherapy is mainly used as third line option, in patients who are unresponsive or intolerant to medical treatment, or after a period of hypercortisolism control by medical therapy (Pivonello *et al.*, 2015). The historically used technique was conventional radiotherapy (CRT), which delivers ionizing radiation to the target tumor in small daily doses, over a period of 25–30 days. In terms of hypercortisolism control, the mean remission rate of CRT is 63.8% (19.6%–100%) (Pivonello *et al.*, 2015; Estrada *et al.*, 1997; Orth and Liddle, 1971; Minniti *et al.*, 2007; Tsang *et al.*, 1994). In terms of tumor growth control (growth arrest or tumor size reduction) the mean remission rate is 98.5% (53%–100%) (Pivonello *et al.*, 2015; Estrada *et al.*, 1997; Orth and

Liddle, 1971; Minniti *et al.*, 2007; Tsang *et al.*, 1994). Currently, the most commonly used technique is stereotactic radiotherapy (SRT), which provides the precise identification of tumor localization, with three spatial coordinates. SRT can be delivered as a fractionated treatment (stereotactic conformal radiotherapy) or as a single treatment (stereotactic radiosurgery) using a multi-headed cobalt unit (Gamma Knife), a linear accelerator system (LINAC), or a proton-beam system (Proton-beam) (Pivonello *et al.*, 2015). In terms of hypercortisolism control, the mean remission rate of SRT is 60.8% (10%–100%), with a mean recurrence rate of 12.3% (0%–100%) (Pivonello *et al.*, 2015; Estrada *et al.*, 1997; Orth and Liddle, 1971; Minniti *et al.*, 2007; Tsang *et al.*, 1994); whereas, in terms of tumor growth control, the mean remission rate is 90.9% (50%–100%) (Pivonello *et al.*, 2015; Estrada *et al.*, 1997; Orth and Liddle, 1971; Minniti *et al.*, 2007; Tsang *et al.*, 1994). Treatment response rates appear similar using the different SRT methods (Pivonello *et al.*, 2015). Potential predictors of SRT outcome include radiation dose and the use of medical treatments with a radioprotective effect. However, these predictors need further validation (Pivonello *et al.*, 2015).

The most frequent complication of radiotherapy is hypopituitarism, which ranges from 0% to 100% ($m = 39.3\%$) using CRT, from 0% to 66% ($m = 22.9\%$) using Gamma Knife, from 0% to 40% ($m = 17.\%$) using LINAC, and from 0% to 52% ($m = 26\%$) using proton-beam method (Pivonello *et al.*, 2015; Estrada *et al.*, 1997; Orth and Liddle, 1971; Minniti *et al.*, 2007; Tsang *et al.*, 1994). The incidence and severity of hormonal deficiencies increases over the time from the procedure (Pivonello *et al.*, 2015; Estrada *et al.*, 1997; Orth and Liddle, 1971; Minniti *et al.*, 2007; Tsang *et al.*, 1994). Other complications include cerebrovascular accidents, mainly reported after CRT (incidence of 4%, 11% and 21% after 5, 10 and 20 years, respectively), an higher incidence of secondary brain tumors, especially in patients who receive high radiation doses and CRT (Pivonello *et al.*, 2015; Estrada *et al.*, 1997; Orth and Liddle, 1971; Minniti *et al.*, 2007; Tsang *et al.*, 1994), and optic neuropathy, a specific complication of SRT (incidence of up to 11.1% of cases) (Pivonello *et al.*, 2015; Estrada *et al.*, 1997; Orth and Liddle, 1971; Minniti *et al.*, 2007; Tsang *et al.*, 1994).

Bilateral adrenalectomy is currently considered as a second or third line option, after failure of previous treatments and is reserved to a limited number of patients with a very severe CD. Very rarely bilateral adrenalectomy can be used as first line option to obtain an immediate hypercortisolism resolution (Nieman *et al.*, 2015). In CD patients, the most commonly used technique is the laparoscopic approach, which represents the gold standard, whereas the laparotomic approach is currently used only in case of contraindications for laparoscopic surgery (Pivonello *et al.*, 2015). The mean remission rate is 96.8% (78.9%–100%), with a mean persistence or recurrence rate of 1.7% (0%–12%), mainly due to adrenal rests (Pivonello *et al.*, 2015; Ernest and Ekman, 1972; Kelly *et al.*, 1983; Welbourn, 1985; Nagesser *et al.*, 2000; Chow *et al.*, 2008; Smith *et al.*, 2009; Ding *et al.*, 2010). The most important complication of bilateral adrenalectomy is the permanent adrenal insufficiency in all patients, which requires lifelong replacement treatment with GC and sometime also mineralocorticoids (Pivonello *et al.*, 2015). Another important complication ($m = 18.6\%$; 0%–34.6%) is the possible ACTH-secreting tumor progression (Nelson syndrome) due to the loss of the negative feedback exerted by GCs on ACTH-secreting cells (Pivonello *et al.*, 2015; Ernest and Ekman, 1972; Kelly *et al.*, 1983; Welbourn, 1985; Nagesser *et al.*, 2000; Chow *et al.*, 2008; Smith *et al.*, 2009; Ding *et al.*, 2010). Cardiovascular events, mainly myocardial infarction and secondary postoperative hemorrhages, are the main mortality causes, with a mean mortality rate of 1.8% (0%-–11.1%) (Pivonello *et al.*, 2015).

Medical treatment is gaining a more important role in different steps of the treatment algorithm particularly in patients with CD (Ferone *et al.*, 2014; Pivonello *et al.*, 2015). Currently, medical treatment plays a role in several situations: as preoperative treatment, in order to improve the clinical picture; as second line treatment after pituitary surgery, in patients with persistent or relapsed CD; before or after pituitary radiotherapy, to control hypercortisolism while awaiting for radiation effects and more recently as first line alternative treatment in case of contraindication to surgery or in case of patients refusal of surgery (Pivonello *et al.*, 2015). Available drugs can be divided in three main categories: (1) the pituitary-directed drugs; (2) the adrenal-directed drugs (steroidogenesis inhibitors); (3) the glucocorticoid receptor antagonist (Pivonello *et al.*, 2015).

Pituitary-directed drugs include two main compounds: the dopamine agonist, cabergoline, and the somatostatin analogue, pasireotide. Although they are effective only in a group of patients with CD, these compounds represent the ideal medical approach for CD management because they act directly on the cause of CD (Ferone *et al.*, 2014; Pivonello *et al.*, 2015).

Cabergoline is currently an off-label treatment for CD. This drug is an agonist of dopamine receptors type 2, which are often expressed in ACTH-secreting pituitary tumors (Pivonello *et al.*, 2015). In terms of hypercortisolism control, cabergoline (orally administered; dosages of 0.5–7 mg/week) has shown a mean remission rate of 32.7% (25%–40%) associated with a clinical improvement, particularly in hypertension and glucose metabolism, and with potential tumor shrinkage. However, a mean escape rate of 25% (18.2%–33.3%) has also been reported (Pivonello *et al.*, 2009, 2015; Vilar *et al.*, 2010; Barbot *et al.*, 2014; Lila *et al.*, 2010; Godbout *et al.*, 2010; Ferriere *et al.*, 2017). Cabergoline is very well tolerated with rare adverse events reported, including hypotension and severe asthenia ($m = 14\%$; 10%–20%), dizziness and nausea ($m = 16.5\%$; 5%–25%) (Godbout *et al.*, 2010; Pivonello *et al.*, 2009; Vilar *et al.*, 2010; Ferriere *et al.*, 2017). The increased risk of cardiac valve diseases, reported using cabergoline at the higher doses for neurological disorders, seems to be less important at the dosage used for CD (Pivonello *et al.*, 2009; Vilar *et al.*, 2010; Barbot *et al.*, 2014; Lila *et al.*, 2010; Godbout *et al.*, 2010). Because the limited experience with cabergoline in CD, further investigation are still required to define the role of this compound in CD management.

Pasireotide is the first medical therapy officially approved for the treatment of adult CD patients, which experienced a failure of pituitary surgery, or are not candidates for pituitary surgery and require medical therapeutic intervention. This compound is a recently developed multi-ligand somatostatin analogue with high affinity for somatostatin receptor type 5, which is highly expressed in ACTH-secreting pituitary tumors (Pivonello *et al.*, 2015). Pasireotide (s.c. administered twice daily; dosage of 300–900 μg), has shown remission rates, in terms of hypercortisolism control, ranging from 17% to 22.2% in the short-term

follow-up (shorter or equal 12 months), and reaching 68.8% of cases in the long-term follow-up (up to 5 years) (Boscaro *et al.*, 2009; Colao *et al.*, 2012; Schopohl *et al.*, 2015; Petersenn *et al.*, 2017; Trementino *et al.*, 2016). Pasireotide is generally well tolerated and it has also been associated with a clinical improvement (facial rubor, bruising, supraclavicular and dorsal fat pads, waist circumference, weight, body mass index, blood pressure, total and LDL-cholesterol levels, depression and QoL) and a reduction of pituitary tumor volume (in patients at 12-months follow-up; $m = 73.2\%$; 46.3%–100%) (Pivonello *et al.*, 2014, 2015; Simeoli *et al.*, 2015; Colao *et al.*, 2012). The most frequently reported significant adverse events include hyperglycemia-related events (72.8%), diarrhea (58%), nausea (52%), cholelithiasis-related events (30%), mild transient elevations in liver enzyme levels (29%), headache (28%), abdominal pain (24%), fatigue (19%) and asthenia (11%), hypocortisolism-related events (8%) and prolongation of the corrected QTc interval (2%) (Colao *et al.*, 2012). During treatment, glycemia need to be carefully monitored, and when appropriate an antidiabetic therapy should be initiated to maintain glycemic control (Colao *et al.*, 2014).

Pasireotide long acting release (LAR), a new formulation with monthly administration at a dosage of 10–30 mg, has been recently investigated and it seems to be an efficacious treatment option for some patients with CD (Lacroix *et al.*, 2018).

Adrenal-directed drugs include several compounds that reduce cortisol production by inhibiting different enzymes involved in steroidogenesis (steroidogenesis inhibitors). Among these compounds ketoconazole, metyrapone and mitotane are detailed in this chapter, but few other compounds (aminoglutethimide and etomidate) have been historically used with evidence of effects in subgroups of patients (i.e., etomidate in patients with conditions of emergency) and two new compounds (osilodrostat and levoketoconazole) are currently under investigation. These drugs can be used not only for CD, but also for other forms of endogenous CS (Pivonello *et al.*, 2015).

Ketoconazole, officially approved for the treatment of patients older than 12 years, suffering from CS, is an imidazole derivative, initially used as antifungal drug (Loose *et al.*, 1983; Feldman, 1986; Sonino, 1987). Apart from adrenal blocking effects, some preclinical studies suggest that ketoconazole might also have direct effects on corticotroph tumor cells in patients with CD (Feelders *et al.*, 2010b; Jimenez Reina *et al.*, 1989). Ketoconazole (orally administered; twice/thrice daily; dosage of 200–1200 mg), has shown a mean remission rate of 68.4% (44.7%–92.9%), although a mean escape rate of 14.4 (7.1%–22.7%) has been reported (Pivonello *et al.*, 2015; Sonino *et al.*, 1991; Moncet *et al.*, 2007; Castinetti *et al.*, 2008; van den Bosch *et al.*, 2014; Castinetti *et al.*, 2014; Espinosa-de-Los-Monteros *et al.*, 2017). This treatment has also been associated with clinical improvement particularly in body weight, hirsutism, myopathy and muscle weakness, bone status, psychiatric symptoms, glucose metabolism and blood pressure (Sonino *et al.*, 1991; Moncet *et al.*, 2007; Castinetti *et al.*, 2008; van den Bosch *et al.*, 2014; Castinetti *et al.*, 2014). The most severe and frequent adverse event related to ketoconazole is hepatotoxicity (2.6%–18.7%) which requires a careful monitoring of liver enzymes, particularly within the first month of treatment, although fatal hepatitis have been only rarely reported (Sonino *et al.*, 1991; Moncet *et al.*, 2007; Castinetti *et al.*, 2008; van den Bosch *et al.*, 2014; Castinetti *et al.*, 2014; Duarte *et al.*, 1984; Pivonello *et al.*, 2015). Additional adverse events include gastrointestinal disturbances, skin rash, adrenal insufficiency, pruritus, fatigue, headache, and gynecomastia (Sonino *et al.*, 1991; Moncet *et al.*, 2007; Castinetti *et al.*, 2008; van den Bosch *et al.*, 2014; Castinetti *et al.*, 2014). Ketoconazole can inhibit gonadal testosterone synthesis, resulting in hypogonadism, for this reason it should not be preferred in men (Pivonello *et al.*, 2015).

Metyrapone, officially approved for treatment of patients suffering from CS, is a pyridine derivative (Chart *et al.*, 1958; Liddle *et al.*, 1958; Carballeira *et al.*, 1976; Gower, 1974). Metyrapone (orally administered four to six times daily; dosage of 500-–6000 mg) has shown a mean remission rate of 71% (45.4%–100%), in terms of hypercortisolism control, although a mean escape rate of 7.8% (0%–18.7%) has been reported (Jeffcoate *et al.*, 1977; Thoren *et al.*, 1985; Verhelst *et al.*, 1991; Valassi *et al.*, 2012; van den Bosch *et al.*, 2014; Pivonello *et al.*, 2015). This treatment has also been associated with clinical improvement particularly in facial plethora, round face, muscle weakness, psychiatric symptoms, glucose metabolism and blood pressure (Jeffcoate *et al.*, 1977; Thoren *et al.*, 1985; Verhelst *et al.*, 1991; Valassi *et al.*, 2012; Igaz *et al.*, 2008). The most frequent adverse events are hyperandrogenism in women (4.5%–71.4%), together with hypertension (48.4%) and hypokalemia (6.7%–13.6%) (Jeffcoate *et al.*, 1977; van den Bosch *et al.*, 2014; Thoren *et al.*, 1985; Verhelst *et al.*, 1991; Valassi *et al.*, 2012; Igaz *et al.*, 2008; Chart *et al.*, 1958; Liddle *et al.*, 1958; Carballeira *et al.*, 1976; Gower, 1974; Pivonello *et al.*, 2015). These adverse events are related to the accumulation of androgens and cortisol or aldosterone precursors stimulated by the ACTH increase, which is consequent to the reduction of cortisol feedback on pituitary. Because of the potential increase of androgens, this drug should not be preferred in women (Feelders *et al.*, 2010b; Igaz *et al.*, 2008). Less frequently reported adverse events include dizziness, headache, arthralgia, myalgia, fatigue, gastrointestinal disturbances, adrenal insufficiency and skin rash (Jeffcoate *et al.*, 1977; Thoren *et al.*, 1985; Verhelst *et al.*, 1991; Valassi *et al.*, 2012; van den Bosch *et al.*, 2014; Feelders *et al.*, 2010b).

Mitotane officially approved for treatment of patients suffering from adrenocortical carcinoma, has been occasionally used in CD treatment. Mitotane, a dyphenilmethane derivative, inhibits different enzymes involved in adrenal steroidogenesis and shows a direct adrenolytic effect (Vilar and Tullner, 1959; Young *et al.*, 1973). Mitotane (orally administered, three daily; dosage of 1–12 g/day), has shown a mean remission rate of 86.9% (71.6%–100%), in terms of hypercortisolism control, without escape phenomenon (Orth and Liddle, 1971; Luton *et al.*, 1979; Schteingart *et al.*, 1980; Baudry *et al.*, 2012; Pivonello *et al.*, 2015). However, this compound has many interactions with other drugs (mainly through the activation of CYP3A4) and is associated with important adverse events, mainly including gastrointestinal disturbances, lipid disorders, neurological manifestations, gynecomastia, liver enzymes increase, leukopenia, skin rash, hypersialorrhea and chloasma (Orth and Liddle, 1971; Luton *et al.*, 1979; Schteingart *et al.*, 1980; Baudry *et al.*, 2012; Pivonello *et al.*, 2015). Therefore, mitotane plasma concentrations should be monitored, and maintained between 8.5 and 18 mg/L. Additionally, to avoid adrenal insufficiency, hydrocortisone should be co-

administered at dosage higher than those used for other causes of hypocortisolism (Baudry *et al.*, 2012; Luton *et al.*, 1979; Pivonello *et al.*, 2015).

The only *glucocorticoid receptor antagonist* currently developed is mifepristone, officially approved in USA for the treatment of patients suffering from CS associated with diabetes mellitus or impairment of glucose tolerance. This compound acts by blocking central and peripheral GR, and consequently antagonizing cortisol receptor binding. This effect determines a rise in plasma ACTH and serum cortisol levels, making the measurement of these hormones inadequate to monitor the treatment efficacy (Jung-Testas and Baulieu, 1983; Bertagna *et al.*, 1984). For this reason, treatment efficacy can only be evaluated by monitoring clinical parameters (Morgan and Laufgraben, 2013). Mifepristone (orally administered, once daily; dosage of 300–1200 mg), has shown an efficacy rate up to 87%, in terms of clinical picture improvement, including decrease in body weight, waist circumference and body fat, and increase in insulin sensitivity (Sitruk-Ware and Spitz, 2003; Castinetti *et al.*, 2009; Fleseriu *et al.*, 2012). The most important adverse events include endometrial thickening (38.5%), due to the antagonism of mifepristone on progesterone and androgen receptors, hypokalemia (25%–34%) and hypertension (24%–25%), both due to the effect of hypercortisolism on MR. Additional common adverse events include gastrointestinal disturbances, fatigue, headache, arthralgia, peripheral edema, adrenal insufficiency and dizziness (Castinetti *et al.*, 2009; Fleseriu *et al.*, 2012; Castinetti *et al.*, 2012; Castinetti *et al.*, 2010; Fleseriu *et al.*, 2013; Pivonello *et al.*, 2015).

Combined treatment aims at improving the hypercortisolism control and at reducing the risk of adverse events by administrating lower doses of compounds than those typically used in monotherapy (Pivonello *et al.*, 2015). Among treatment schedules reported, the combination of ketoconazole, metyrapone and mitotane, showed a rapid hypercortisolism control in all severe ACTH-dependent CS patients studied, associated with a rapid clinical improvement (Kamenicky *et al.*, 2011). The reported adverse effects were hypokalemia (100%), nausea and vomiting (63.7%), acute adrenal insufficiency (36.4%), dizziness and confusion (9.1%), and increases in liver enzymes (18.2%–81.8%) (Kamenicky *et al.*, 2011). Association of drugs acting at adrenal and pituitary levels, have also shown interesting results (Vilar *et al.*, 2010; Feelders *et al.*, 2010a; Barbot *et al.*, 2014). Combination of cabergoline and ketoconazole has shown remission rates, in terms of hypercortisolism control, ranging from 75% to 79%, associated with good tolerability (Vilar *et al.*, 2010; Barbot *et al.*, 2014). Stepwise combination approach using pasireotide, cabergoline and ketoconazole has reported remission rates up to 88%, in terms of hypercortisolism control, with potential positive effects on tumor mass, and it has been associated with a good safety profile (Feelders *et al.*, 2010a). These results are encouraging but further studies are needed to define the role of combined treatment in the management of CD patients (Pivonello *et al.*, 2015).

Conclusions

ACTH pituitary tumors cause the most frequent form of endogenous hypercortisolism named CD, a chronic and severe endocrine disease associated with an increased morbidity and mortality. The diagnosis of CD is a multistep process, still challenging, and requiring several tests and procedures adequately performed only in highly specialized centers.

The main treatment approaches for CD include pituitary surgery, which usually represents the first-line treatment, and repeat pituitary surgery, pituitary radiotherapy, adrenal surgery and medical treatment, which usually represent second-line approaches.

Medical treatment is gaining a more important role in different steps of the treatment algorithm and is represented by three cathegories of drugs: the pituitary-directed drugs; the adrenal-directed drugs (steroidogenesis inhibitors) and the glucocorticoid receptor antagonist. These drugs alone, or sometimes in combination, can help to control hypercortisolism or antagonize the hypercortisolism effects and seem to positively affect the morbidity of CD patients, but further experience are still required to optimize their use in the management of CD.

TSH-Secreting Pituitary Adenomas☆

Olympia Koulouri and Mark Gurnell, University of Cambridge, Cambridge, United Kingdom and National Institute for Health Research Cambridge Biomedical Research Centre, Cambridge, United Kingdom

Glossary

Hyperthyroidism Clinical disorder resulting from increased production and/or secretion of thyroid hormones from the thyroid gland.

Neoplastic inappropriate secretion of thyrotropin (TSH) Secondary or central hyperthyroidism due to a TSH-secreting pituitary tumor.

Nonneoplastic inappropriate secretion of thyrotropin Secondary hyperthyroidism due to a disorder of thyroid hormone transport, metabolism or action (e.g., syndrome of resistance to thyroid hormone (RTH)).

Primary hyperthyroidism Hyperthyroidism due to a primary disorder originating within the thyroid gland.

Secondary hyperthyroidism Hyperthyroidism due to stimulation of the thyroid gland by thyrotropin secreted from the anterior pituitary gland.

Introduction

Thyrotropin (TSH)-secreting pituitary adenomas have traditionally been considered rare tumors, accounting for approximately 1%–2% of all pituitary adenomas based on historical surgical and pathological series (Beck-Peccoz *et al.*, 2009). Central hyperthyroidism secondary to a TSH-secreting pituitary adenoma is sometimes referred to as neoplastic inappropriate secretion of TSH (thereby differentiating it from nonneoplastic inappropriate TSH secretion, as is observed in the syndrome of resistance to thyroid hormone (RTH, caused by mutations in *THRB*, encoding the β isoform of the thyroid hormone receptor)). Following the first case report in 1960, fewer than 300 cases had been described by the mid-1990s; however, in the last two decades TSH-secreting pituitary adenomas have been recognized with increasing frequency. Several factors likely account for this, including the development of ultrasensitive and specific TSH assays, the routine measurement of free thyroid hormone and TSH levels when screening for suspected thyroid dysfunction, and improvements in (coupled with more widespread use of) pituitary imaging. Analysis of data from a national Swedish registry covering the interval 1990–2010 revealed an approximate fivefold rise in the incidence of the condition (Ónnestam *et al.*, 2013).

Earlier recognition of the disorder offers the prospect of reducing the delay between the onset of hyperthyroidism and treatment (with the potential to reduce complications such as atrial fibrillation), and may increase the percentage of patients with surgically-remediable adenomas, while helping to avoid an inappropriate thyroid ablative procedure. On the other hand, the identification of an increasing number of TSH-secreting microadenomas raises new diagnostic challenges (e.g., when there are equivocal biochemical abnormalities, and magnetic resonance imaging (MRI) is unremarkable). The utility of long-acting somatostatin analogues as an alternative to the surgical treatment of these pituitary tumors is also increasingly recognized.

Pathogenesis and Pathology

The etiology of TSH-secreting pituitary tumors (which are monoclonal in nature) is still largely unknown. Previous studies have examined expression of the Gsp oncogene, and screened for mutations in the ras oncogene, and mutations or deletions in the Rb or p53 genes, but have proved largely uninformative in terms of causation. The pituitary-specific transcription factor (Pit-1) is overexpressed in TSH-secreting pituitary adenomas, and Pit-1 might play a role in cell proliferation as well as heterogeneous hormone expression in such adenomas. TSH-secreting pituitary adenomas have also rarely been observed in the context of multiple endocrine neoplasia type I and familial isolated pituitary adenoma (due to an aryl hydrocarbon receptor-interacting protein (AIP) mutation) (Burgess *et al.*, 1994; Hernández-Ramírez *et al.*, 2015).

TSH-secreting pituitary adenomas are heterogeneous with possible hormonal cosecretion (e.g., growth hormone, prolactin, gonadotrophins), suggesting that these tumors might arise from primordial stem cells with multidirectional differentiation potential. On the other hand, TSH-secreting macroadenomas are often accompanied by unbalanced hypersecretion of α-subunit,

☆*Change History*: March 2018. Olympia Koulouri and Mark Gurnell updated Abstract, Introduction, Pathogenesis and pathology, Clinical presentation, Hormonal evaluation, Differential diagnosis, Pituitary imaging, Treatment, Conclusion and Table 1, and added Figs. 1 and 2.

This article is an update of Philippe Caron, Pituitary Adenomas, TSH-Secreting, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 624–628.

and double-immunostaining studies have suggested the existence of two different types of cells: one secreting α-subunit alone and another cosecreting α-subunit and β-TSH.

TSH-secreting pituitary adenomas are benign, and only two cases of a malignant tumor, one with brain metastases and another with widespread metastases to lung, liver, and bone, have been reported (Brown *et al.*, 2006; Mixson *et al.*, 1993). These tumors are more fibrotic than other pituitary tumors, which has been linked to the secretion of basic fibroblast growth factor by the adenoma cells (Ezzat *et al.*, 1995). Such fibrosis may make surgical resection more challenging and explain relatively poorer surgical results in patients with macro-/invasive adenomas.

TSH-secreting pituitary adenomas constitutively secrete TSH and exhibit a defect in negative feedback regulation of TSH by thyroid hormones. High thyroid hormone concentrations in the face of a "normal" TSH level may be explained, at least in part, by an increased bioactivity of neoplasm-derived TSH. A somatic mutation of *THRB* (encoding TRβ), as well as aberrant expression of a TRβ4 isoform, have been proposed as potential mechanisms for the defective regulation of TSH by triiodothyronine (T3) (Tagami *et al.*, 2011; Ando *et al.*, 2001).

Thyrotropin-releasing hormone (TRH) receptors are present on the majority of tumor cells. However, the attenuated/absent response of TSH and α-subunit to TRH in the majority of patients with TSH-secreting pituitary adenomas suggests that the TRH receptor signaling pathway is impaired/nonfunctional in these tumors. Several studies have revealed high concentrations of different subtypes of somatostatin receptors on TSH-secreting adenomas, explaining the in vivo response to somatostatin analogue administration. Dopamine D2 receptors have been detected in TSH-secreting tumors, but the effect of long-term bromocriptine therapy is limited due to incomplete suppression of inappropriate TSH secretion. Finally, estrogen receptors have been found on TSH-secreting tumors and, at least in theory, could predispose to growth of these tumors during a hyperestrogenic state such as pregnancy.

Clinical Presentation

Clinical manifestations of central hyperthyroidism secondary to a TSH-secreting pituitary adenoma are similar to those found in the other forms of hyperthyroidism such as Graves' disease, multinodular goiter, and toxic nodular goiter, but without disease-specific (e.g., autoimmune Graves') manifestations. However, in many instances the clinical features are milder, with some patients appearing relatively asymptomatic (although following successful treatment these patients may report an improvement in their wellbeing, coinciding with resolution of previously unrecognized clinical symptoms). TSH-secreting pituitary adenomas can occur at any age and affect both genders (without a female predominance in the majority of series). Clinical features of hyperthyroidism may be progressive (although some patients report little change over time intervals as long as a decade), and the mean latency between onset of hyperthyroidism and correct diagnosis is four years. A wide spectrum of clinical presentations, ranging from mild to moderate, and even severe thyrotoxicosis with atrial fibrillation and cardiac failure, are observed in such patients. Goiter and/or thyroid nodules may be present and are likely due to sustained TSH stimulation of thyroid follicular cells over many years. The cooccurrence of differentiated thyroid carcinoma has been reported in a small number of cases. Historically, symptoms due to compression of surrounding nervous structures, such as visual field defects (80%) and headaches (20%), prevailed over those due to hyperthyroidism. However, this is no longer the case, as many patients present at an earlier stage and the incidence of microadenomas is also on the rise. Unilateral exophthalmos due to orbital invasion by the pituitary tumor is very rare, but must be distinguished from asymmetric exophthalmos of Graves' disease. In mixed secreting tumors, clinical findings are dependent on the nature of the hormone cosecreted (e.g., acromegaly features, amenorrhea and/or galactorrhea). In macroadenomas, concomitant hypopituitarism (e.g., hypogonadism, hypoadrenalism) may be present. TSH-secreting pituitary adenomas have been reported in pregnant women, in patients with multiple endocrine neoplasia type I, and in atypical McCune–Albright syndrome (Burgess *et al.*, 1994; Caron and Gerbaud, 1996; Gessl *et al.*, 1994).

Hormonal Evaluation

TSH-secreting pituitary adenomas are now more readily diagnosed following the introduction of ultrasensitive assays for TSH. The classical biochemical signature is one of a detectable or elevated TSH concentration in the face of biochemical hyperthyroidism (with increased free thyroxine (FT4) and triiodothyronine (FT3)). Once potential confounding intercurrent illness and medications (e.g., heparin, amiodarone) have been ruled out, and assay interference excluded, a diagnosis of hyperthyroidism with inappropriate secretion of TSH (IST) is made (Gurnell *et al.*, 2011). The next task is to differentiate neoplastic (TSH-secreting pituitary adenoma) and nonneoplastic (TRβ RTH) causes (see differential diagnosis below).

Classically, an increased plasma α-subunit level and increased α-subunit/TSH molar ratio were considered important diagnostic markers, but recent findings indicate that the α-subunit level is frequently normal in patients with TSH-secreting pituitary microadenomas. Some studies have reported a relationship between hypersecretion of other pituitary hormones and tumor volume; for example, hyperprolactinemia and/or elevated growth hormone and insulin-like growth factor-1 (IGF-1) concentrations are observed more commonly in the context of macroadenomas. In many patients with TSH-secreting pituitary adenomas, dynamic testing reveals a reduced or absent response of TSH during the TRH test, impaired negative feedback of thyroid hormone

Table 1 Distinguishing between TSH-secreting pituitary adenoma and TRβ resistance to thyroid hormone (TRβ RTH)

	TSH-secreting adenomas	*Resistance to thyroid hormone*
Family history	Usually absent	Possible
Increased free thyroid hormone	Yes	Yes
Normal or high TSH	Yes	Yes
Circadian TSH secretion	Absent	Preserved
SHBG	Increased	Normal
α-subunit level	Increased/normal	Normal
α-subunit/TSH molar ratio	Increased/normal	Normal
Response to TRH test	Absent/attenuated	Preserved
Response to T3 test	Absent	Present*
Hormonal cosecretion	+	−
MRI	Adenoma	Normal
Genetic analysis	−	+

Key: MRI, magnetic resonance imaging; SHBG, sex hormone-binding globulin; T3, triiodothyronine; TRH, thyrotropin releasing hormone; TSH, thyroid stimulating hormone; * signifies that TSH suppression following exogenous T3 may not be complete.

on TSH secretion (which forms the basis of the T3 suppression test), and a marked decrease in TSH levels after treatment with somatostatin analogues (see below).

Differential Diagnosis

Elevated total thyroid hormone (TT4, TT3) levels, with inappropriately normal or elevated TSH, may be observed when thyroid hormone binding capacity is increased (e.g., during pregnancy when thyroxine binding globulin (TBG) levels are raised, or in individuals with familial dysalbuminemic hyperthyroxinemia (FDH), where point mutations in the *ALB* gene increase albumin's affinity for thyroid hormone). FDH may also perturb commonly used FT4 ($\pm$FT3) assays to yield falsely elevated levels. Close liaison with the laboratory is therefore required to exclude these and other conditions (e.g., heterophilic antibodies or anti-iodothyronine antibodies) which are capable of producing false positive TSH or FT4 ($\pm$ FT3) assay readouts. In addition, careful consideration must be given to other conditions and medications (e.g., heparin, amiodarone) that may be associated with a blood profile suggestive of central hyperthyroidism.

Once genuine hyperthyroxinemia and nonsuppressed TSH have been confirmed, the main challenge is to distinguish a TSH-secreting pituitary adenoma and resistance to thyroid hormone (*THRB*) syndrome. Age, sex distribution, TSH and free thyroid hormone levels do not differ significantly between the two conditions. However, the diagnosis of a TSH-secreting pituitary adenoma is more likely when: serum α-subunit is raised (with a high α-subunit/TSH molar ratio); serum sex hormone-binding globulin (SHBG) is increased; the TSH response to TRH is attenuated/absent; TSH fails to suppress after oral administration of liothyronine (L-T3); treatment with depot somatostatin analogue (minimum of 2–3 injections) leads to a sustained reduction in free thyroid hormone levels; and in the absence of a family history of similar abnormal thyroid function tests (**Table 1**).

In contrast, patients with TRβ RTH exhibit resistance to thyroid hormone action in tissues predominantly expressing the TRβ isoform (principally the hypothalamus, pituitary, liver and kidney). Accordingly, the set point of the hypothalamic-pituitary-thyroid axis is altered (due to central resistance), but retains the ability to respond to stimuli such as TRH and T3. SHBG is also typically normal (reflecting hepatic resistance), while only a transient reduction in thyroid hormone levels is observed during depot somatostatin analogue therapy (**Table 1**).

The diagnosis of central hyperthyroidism secondary to a TSH-secreting pituitary adenoma is likely when there is an obvious pituitary lesion on magnetic resonance imaging (MRI) and genetic analysis has excluded a mutation in the *THRB* gene (**Table 1**). However, clinicians should be alert to the fact that around 10%–15% of patients with apparent TRβ RTH do not harbor a readily identifiable mutation in *THRB*, and it is also possible for a patient with TRβ RTH to have a pituitary incidentaloma. In addition, in a significant proportion of TSH-secreting pituitary microadenomas, a lesion cannot be readily visualized on pituitary MRI (see below). Finally, several cases of coexisting autoimmune thyroid disease (both Graves' and Hashimoto's thyroiditis) have been reported with coexistent RTH or a TSH-secreting pituitary adenoma (Arai *et al.*, 2017; Kamoun *et al.*, 2014; Losa *et al.*, 2006).

Pituitary Imaging

The presence of a pituitary microadenoma in a patient with inappropriate secretion of TSH, although strongly suggestive, is not diagnostic of a TSH-secreting pituitary tumor given that pituitary incidentalomas are found on MRI in $\sim$10% of normal individuals. In contrast, incidental macroadenomas are much less commonly encountered. In patients with TSH-secreting pituitary adenomas there is no correlation between serum TSH levels and tumor size. In older case series, patients commonly presented

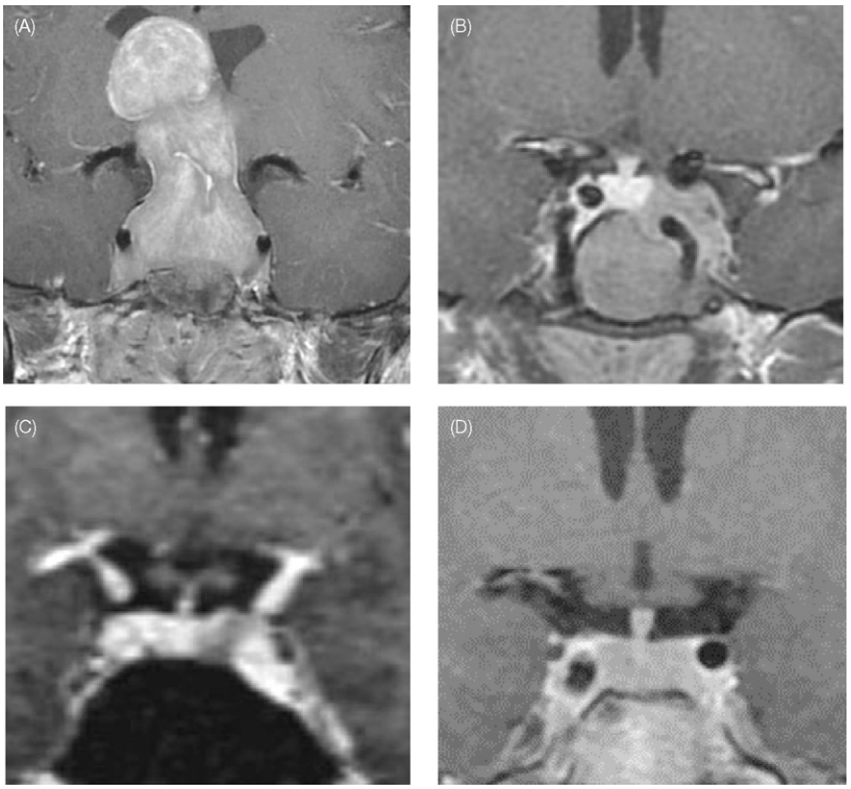

Fig. 1 *Spectrum of TSH-secreting pituitary adenomas.* (A) Giant adenoma. (B) Macroadenoma with cavernous sinus and sphenoid extension. (C) Left-sided microadenoma. (D) No visualized adenoma.

with macroadenomas with suprasellar and sphenoidal extension, whereas in more recent series microadenomas feature much more frequently. Indeed, it is now clear that thyrotropinomas exhibit a spectrum ranging from large invasive (even giant) tumors through to microadenomas that cannot be readily visualized using conventional MR sequences (analogous to some Cushing's microadenomas) (**Fig. 1**). For the latter, various approaches have been tried to aid localization of the tumor (including inferior petrosal sinus sampling with TRH stimulation) and octreotide scintigraphy. However, the most promising approach appears to be functional imaging with ^{11}C-methionine PET-CT coregistered with volumetric MRI, which may aid precise localization of the tumor, especially when performed pre-and postsomatostatin analogue therapy (**Fig. 2**) (Koulouri *et al.*, 2016).

Treatment

In patients with TSH-secreting pituitary adenomas, the goal of therapy is to restore euthyroidism and to eliminate the symptoms of mass effect in patients with large tumors. Early diagnosis and correct treatment of these rare tumors helps prevent complications, such as visual abnormalities due to compression of the optic chiasm and hypopituitarism, and may also improve surgical cure rates.

The success of treatment depends on the criteria used. It has been suggested that an early test of cure might be an undetectable TSH concentration seven days after surgery (when the normal thyrotrophs remain suppressed as a consequence of prolonged exposure to raised circulating thyroid hormone levels). However, many patients are now treated with somatostatin analogues prior to surgery, often with rapid normalization of hyperthyroidism, which may therefore allow recovery of normal thyrotroph function prior to theater. Normalization of dynamic tests (e.g., TRH test, T3 suppression test) might therefore represent a better (later) test of cure. In any case, long-term follow-up is necessary to detect relapse and recurrence.

Transsphenoidal surgery remains the treatment of choice in many patients with TSH-secreting pituitary adenomas. Historically, pituitary surgery alone has been reported to result in normalization of thyroid hormone secretion and resolution of the pituitary mass in approximately 50% of patients, achieve normalization of thyroid parameters despite incomplete tissue removal in approximately 25% of patients, and is unsuccessful in nearly 30% of cases. However, an increase in the surgical cure rate has been reported in more recent series, probably reflecting improved surgical techniques and earlier diagnosis.

Medical treatment is an alternative option to pituitary surgery in patients with TSH-secreting pituitary tumors. Dopamine agonists are an effective treatment in true mixed TSH/prolactin-secreting pituitary adenomas, whereas success is limited when bromocriptine is used in patients with pure TSH-secreting pituitary adenomas. In contrast, depot somatostatin analogues

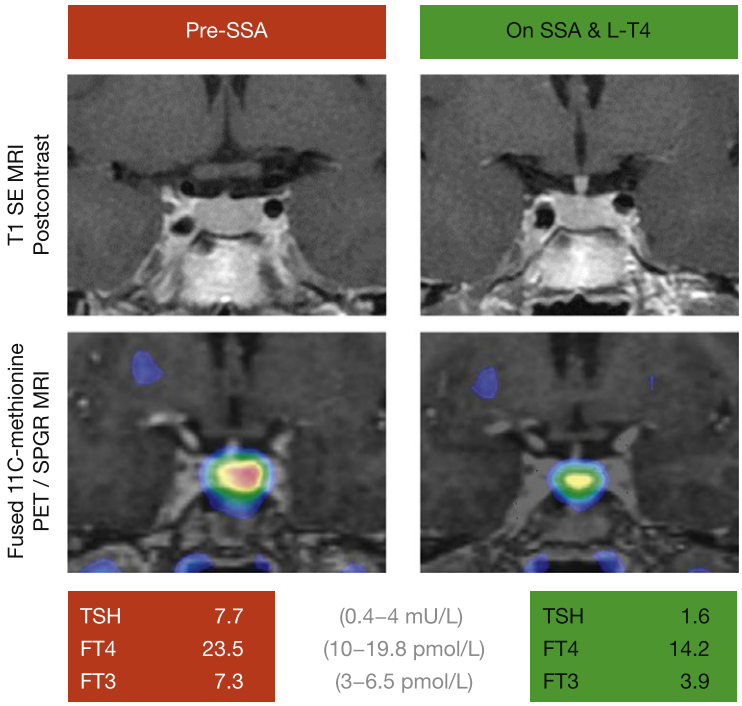

Fig. 2 *Confirmation of the site of a microadenoma using functional PET imaging.* Spin echo (SE) MRI and ^{11}C-methionine PET coregistered with spoiled gradient recalled acquisition (SPGR) MRI before (left panels) and after (right panels) treatment with somatostatin analogue (SSA) in a patient with a suspected microTSHoma. Coregistered ^{11}C-methionine PET/SPGR MRI reveals asymmetric tracer uptake with maximum intensity on the left side of the gland. Treatment with SSA leads to extinction of tracer uptake from this area, leaving only physiological (central) tracer uptake by the normal pituitary gland. Transsphenoidal surgery and histological analysis confirmed a left-sided TSH secreting microadenoma.

(octreotide LAR or lanreotide ATG) suppress TSH secretion in more than 90% of TSH-secreting pituitary adenomas, and normalize thyroid hormone levels in approximately 75%–90% of patients. However, significant shrinkage of the adenoma is only observed in approximately 50% of cases, and total resolution of a macroadenoma with maintenance of long term cure in response to somatostatin analogue therapy has been reported in only a single case (Fliers *et al.*, 2012). As a general rule, the effects of somatostatin analogues are reversible, with the need for long-term administration, with possible tachyphylaxis requiring increasing doses of the drug to maintain good control of the disease in up to 10% of cases, and with true resistance in a small number of patients. The second generation somatostatin receptor ligand pasireotide may offer an alternative for treatment resistant cases, although experience to date is limited to a single patient in whom it was not clear whether there was true resistance to first line SSA therapy (van Eersel *et al.*, 2017). Somatostatin analogues remain expensive and may be associated with side effects such as cholelithiasis and carbohydrate intolerance. Accordingly, although some patients and their clinicians might elect to pursue long-term primary SSA therapy, for many patients these remain an important bridge to surgery (allowing anesthesia to proceed safely) and as adjunctive therapy when surgery is unable to achieve full remission, or while awaiting the beneficial effects of radiotherapy.

It is appropriate to briefly mention conventional antithyroid drug (ATD) therapy, which may be used for a short duration in preparation for surgery. However, concerns remain that longer term use may predispose to tumor expansion (Nelson's-like phenomenon), and for that reason permanent thyroid ablation is also generally best-avoided, although may occasionally be indicated in those with recalcitrant arrhythmias or cardiac failure.

Conventional radiotherapy and stereotactic radiosurgery have also been employed in the management of TSH-secreting pituitary tumors, especially when surgery and/or medical therapy has proved unsuccessful. However, the number of reported cases, especially using modern radiotherapy techniques, remains relatively small. As with other pituitary tumor subtypes, and taking into consideration the long time period necessary for the full effect to be realized and the well-known late side effects (e.g., hypopituitarism, impaired cognitive function, second tumor), radiotherapy is now generally reserved for the small number of cases in whom combination surgery and medical therapy is unable to achieve satisfactory biochemical and/or tumor control.

Conclusion

TSH-secreting pituitary adenomas are a rare cause of hyperthyroidism. The main prognostic factors of these adenomas are size and invasiveness of the tumors, duration of symptoms, and intensity of hyperthyroidism. Early recognition of central hyperthyroidism, and localization of the causative lesion should now be readily achieved in most cases, reflecting the availability of ultrasensitive

TSH assays and improvements in pituitary imaging. Reflecting this, the spectrum of disease and approach to the treatment of these rare pituitary tumors has changed significantly during the past decade. Patients typically present with mild or moderate symptoms and signs of hyperthyroidism, hormonal evaluation shows increased free thyroid hormone concentrations with detectable serum TSH levels, and MRI increasingly identifies patients with micro- rather than macro-adenomas. Transsphenoidal surgery remains the treatment of choice, although depot somatostatin analogue therapy is now established as a key component in the management pathway: either pre- and, in selected cases, postsurgery or sometimes as long-term primary medical therapy.

Surgery for Pituitary Tumors☆

Pamela Jones and Brooke Swearingen, Massachusetts General Hospital, Boston, MA, United States

Glossary

Acromegaly A chronic disease marked by the progressive enlargement of the hands, feet, face, head, and thorax due to abnormally high secretion of growth hormone secreted by the anterior lobe of the pituitary gland.

Adenomas Various benign epithelial tumors in which the cells form glandlike structures or develop from the glandular epithelium.

Amenorrhea The absence or abnormal stoppage of menstruation.

Cushing's disease ACTH dependent hypercortisolemia caused by excess ACTH secretion from a pituitary adenoma.

Galactorrhea An excessive flow of milk or a persistent secretion of milk, irrespective of breastfeeding.

Sella turcica A shallow depression, located in the superior surface of the body of the sphenoid bone, that contains the pituitary gland.

Introduction

Surgery for pituitary adenomas has evolved over 120 years. Largely performed via the transsphenoidal route, this procedure carries an acceptably low mortality and morbidity rate. Surgical excision is considered first-line treatment for most secretory pituitary tumors (causing acromegaly and Cushing's disease), except for prolactinomas, where surgery is usually reserved for cases of medication-resistant tumors. Surgery for non-functioning tumors is strongly indicated for symptoms of mass effect, especially visual loss due to pressure on the optic apparatus, and may be recommended when tumors are >1 cm (macroadenomas), are growing, or are causing pituitary insufficiency. Long-term outcomes for these tumors are favorable, although medical management following surgery may be required for biochemical control of acromegaly and Cushing's disease (CD) and radiation treatment of tumors may sometimes be necessary for growth control and/or biochemical remission as well.

History

Since the late 1800s, surgery has been a mainstay of treatment for pituitary disease, when Sir Victor Horsley performed the first craniotomy for treatment of a patient with acromegaly. Surgeons quickly realized that the proximity of the sella turcica (translated as "Turkish saddle") to the sphenoid sinus provided a relatively noninvasive approach to the pituitary and began to devise alternative routes. In 1907, Hermann Schloffer developed an approach through the sphenoid sinus via a lateral rhinotomy incision, while A. E. Halstead and Oskar Hirsch approached sublabially and transnasally, respectively. Harvey Cushing modified Halstead's approach and performed more than 1000 transsphenoidal procedures in the early 1900s (Schmidt *et al.*, 2012; Liu *et al.*, 2001). His careful clinical observations led to significant advances in the field, especially in his description of the syndrome of cortisol excess that bears his name. Difficulties with visualization and orientation were overcome by the introduction of the operating microscope by Cushing's pupil Dott and the intraoperative use of the lateral fluoroscope by G. Guiot in the 1950s. With J. Hardy's microscopic excision of the first microadenoma in 1962, transsphenoidal surgery entered the modern era.

Surgical Anatomy and Approach

The pituitary is enclosed in a bony cavity, the sella turcica, at the base of the skull. It is bounded inferiorly and anteriorly by the sphenoid sinus, laterally by the cavernous sinuses, posteriorly by the dorsum sella, and superiorly by the diaphragm sella, which is in close proximity to the suprasellar cistern, optic nerves, and chiasm above. There are multiple variants on the transsphenoidal approach to this region. These include sublabial or transnasal approaches, either submucosally along the nasal septum or directly endonasally through the face of the sphenoid sinus at the level of the sphenoid ostia. The endonasal approach can be performed with a microscope or an endoscope. It is critical to maintain awareness of the midline, since lateral deviations can lead to unintentional encroachment on the carotid or optic canals, with potentially severe complications. Intraoperative navigation or intraoperative imaging, as traditionally performed with lateral fluoroscopy, will ensure the correct trajectory in the sagittal plane

☆*Change History*: February 2018. Brooke Swearingen has updated the text throughout the article.

This article is an update of Brooke Swearingen, Pituitary Tumors, Surgery, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 687–689.

and avoid inadvertent penetrations through the skull base. The sella can be markedly expanded, as is seen with large macroadenomas, or can be completely normal, as is seen with the tiny microadenomas of Cushing's disease. The sella is opened with a drill and the tumor is removed using an array of ring curettes. Suprasellar tumors can often be delivered into the operative field and removed, whereas cavernous sinus invasion usually results in an incomplete resection. The tumor bed is then packed with fat, muscle, or fascia lata, to avoid a cerebrospinal fluid (CSF) leak. Nasal packing may be required for a short period of time, but the procedure is usually well-tolerated with minimal morbidity.

Modern Advances

Technological advancements have improved preoperative diagnosis, both radiographically and endocrinologically, have aided intraoperative orientation, and have improved intraoperative visualization.

Imaging

The major advance in surgical planning over the past 50 years has been the introduction of sophisticated radiographic imaging techniques. Computerized tomography was introduced in the early 1980s, followed by magnetic resonance imaging (MRI) shortly thereafter. Current MRI scans will delineate all but the smallest microadenomas and demonstrate their proximity to surrounding structures. MRI scanners have been incorporated into the operating room environment and can provide near-real-time MRI for both intraoperative orientation and determination of the adequacy of resection. Whether this expensive technology leads to improvements in patient care and outcome remains to be shown.

Surgical Techniques

Advances in surgical techniques have aided both intraoperative orientation and visualization. Navigational devices which correlate intraoperative localization with preoperative imaging may offer some benefits when the traditional anatomical landmarks have been destroyed, as in cases of recurrent tumors. Improved lateral visualization with a wider field of view is offered by the use of the endoscope, though traditional operative microscopy offers better optics, depth of field, and binocular vision.

Surgical Results

Secretory Tumors

Cushing's disease

Transsphenoidal surgery remains the primary mode of treatment for Cushing's disease, with cure rates approaching 90% in experienced hands (Valassi *et al.*, 2010; Aranda *et al.*, 2015). After surgical cure, patients will demonstrate profound hypoadrenalism for some months postoperatively and require cortisol replacement during this time. Tumors may recur at a rate of at least 10% at 5 years; reoperation for tumor recurrence is less successful (Shimon *et al.*, 2002; Nakane *et al.*, 1987; Prevedello *et al.*, 2008). Here, adjuvant therapy, including radiosurgery, adrenalectomy, or medical therapy, may play a role. Since MRI is able to detect microadenomas in this disease in at best 60% of cases, accurate endocrine diagnosis, including inferior petrosal sinus catheterization, is necessary (Jagannathan *et al.*, 2009; Ciric *et al.*, 2012; Hall *et al.*, 1994).

Acromegaly

Patients with acromegaly tend to present with larger, more invasive tumors, and transsphenoidal surgery is less successful in achieving cure. The remission rate is 50%–60% in the typical macroadenomas, whereas the remission rate may approach 90% in the less common microadenomas (Sun *et al.*, 2014). Newer medical treatments are available, including the use of somatostatin analogues and growth hormone receptor antagonists, are useful in controlling growth hormone levels in those patients not surgically cured. Aggressive multimodality therapy (e.g., surgery combined with medical treatment and possibly radiotherapy) is sometimes necessary to control the increased mortality risk associated with the disease. The role of medical pretreatment, or primary medical therapy for acromegaly, remains unclear, but has been suggested for those patients who are not optimal surgical candidates or who have a low chance of surgical cure (Fougner *et al.*, 2014).

Prolactinomas

Women who present with amenorrhea–galactorrhea, mild elevations in prolactin level, and microadenomas on MRI scanning are usually best treated with dopamine agonist therapy. Surgery, though effective in approximately 90% of patients with microadenomas (Babey *et al.*, 2011), is usually reserved for those patients who are unable to tolerate or who fail to respond to medical treatment. With newer, better-tolerated dopamine agonists (cabergoline), patients only rarely require surgical treatment. Men with

prolactinomas tend to present with either impotence or visual abnormalities and their tumors are more likely to be large and invasive. Dopamine agonist therapy remains effective in these cases, with surgery reserved for those cases that fail to respond. Even patients with bitemporal field defects will often respond dramatically after a few weeks of treatment with a dopamine agonist. It must be remembered that mild elevations in prolactin (less than $\approx$200 ng/mL) may have causes other than prolactin-secreting tumors (e.g., pregnancy, medication effects). A large tumor with a mild increase in prolactin level may represent the so-called "stalk effect" from compression of the pituitary stalk and normal gland, resulting in blockade of intrinsic dopamine inhibition and an elevated prolactin level. This tumor is unlikely to be a prolactinoma and may well require surgical removal. Dopamine agonist therapy in these cases may well normalize the prolactin level, but will do nothing to shrink the tumor.

Nonfunctioning tumors

The term "nonsecreting" may well be a misnomer in these cases, as many of these tumors secrete inactive hormone fragments, especially the α-subunit. Because of their endocrine inactivity, they can become large and invasive before being detected. They usually present with signs of mass effect, either with visual abnormalities, especially the classic bitemporal field defect of chiasm compression, or with endocrine abnormalities from destruction of the remaining gland. Surgery is required to decompress the optic apparatus and approximately 70% of patients will regain some degree of visual loss. Decompression of the remaining gland results in improvements in hormone function in approximately 30%–50% of these patients. A small amount of residual tumor may be followed with serial MRIs, whereas an extensive amount of residual should be treated with radiotherapy. An incidentally found nonfunctioning tumor (the "incidentaloma") has been reported in up to 10% of MRI studies (Sivakumar *et al.*, 2011). Microadenomas (<1 cm) can usually be followed with serial MRI; macroadenomas (>1 cm) often merit resection, though some can be followed for a time with MRI to determine the rate of growth before recommending surgery.

Complications

Transsphenoidal surgery in experienced hands carries a low risk of serious complications. New hormone insufficiency may occur in 5%–10% of cases, although this may be considerably greater in cases of Cushing's disease, in which extensive exploration of the gland is sometimes required to find a tiny microadenoma. The incidence of permanent diabetes insipidus is approximately 1%–2%. Serious complications are unlikely. Carotid artery injury occurs at a rate of approximately 0.1%, whereas permanent postoperative visual decline occurs at a rate of approximately 0.5%. Postoperative CSF rhinorrhea is seen in approximately 1%–2% of cases and may lead to meningitis if untreated. Approximately 5% of patients report persistent sinus disease postoperatively (Murad *et al.*, 2010; Ciric *et al.*, 1997).

Conclusion

Transsphenoidal surgery remains the therapy of choice for nonfunctioning adenomas, especially in cases of optic chiasm compression or hormonal insufficiency. Secretory tumors, except for prolactinomas, require surgical therapy in most cases, although new medical treatments and radiosurgery may provide useful adjuncts.

Clinical Features, Diagnosis, and Management of Nonfunctioning Tumors of Pituitary

Athanasios Fountas and Niki Karavitaki, Institute of Metabolism and Systems Research, College of Medical and Dental Sciences, University of Birmingham, Birmingham, United Kingdom and Centre for Endocrinology, Diabetes and Metabolism, Birmingham Health Partners, Birmingham, United Kingdom

Introduction

Pituitary tumors constitute 10%–15% of all intracranial neoplasms with an increasing prevalence over the last 20 years due to various factors (advances in imaging techniques and hormonal measurements, increased awareness of the medical community, more frequent use, and easier access to imaging facilities). Numerous types of neoplasms can be found in the sellar/parasellar region, including both benign and malignant tumors.

Patients with sellar/parasellar tumors can present with manifestations of mass effects to surrounding structures or can be discovered on imaging performed for an unrelated reason. Treatment depends on the diagnosis and includes surgery, radiotherapy (RT), chemotherapy, or combination of these.

Nonfunctioning Pituitary Adenomas

Nonfunctioning pituitary adenomas (NFPAs) are histologically benign neoplasms that constitute the majority of nonfunctioning pituitary tumors, and on the basis of maximum diameter on imaging, are classified into microadenomas (<1 cm) and macroadenomas (≥ 1 cm).

Epidemiology

The prevalence of NFPAs is difficult to be reliably assessed given that many patients do not experience any symptoms and remain undiagnosed. According to recent epidemiological studies, their prevalence is 22–41 per 100,000 inhabitants, with an annual incidence of 1–1.8 new cases per 100,000 inhabitants per year (Agustsson *et al.*, 2015; Tjörnstrand *et al.*, 2014; Gruppetta *et al.*, 2013; Fernandez *et al.*, 2010; Raappana *et al.*, 2010). NFPAs comprise 28%–43% of all pituitary adenomas and they are the second most frequent type after prolactinomas, although one study reported that NFPAs were the most common pituitary adenomas with a percentage of 54% (Tjörnstrand *et al.*, 2014). They are mainly diagnosed between the fifth and sixth decade of life, 70%–80% of them are macroadenomas on presentation, and their incidence increases with age.

Pathogenesis

NFPAs are monoclonal in origin and their pathogenesis remains unknown: genetic and epigenetic changes that result in cell cycle dysregulation, signaling defects, or loss of tumor suppressor factors have been proposed as possible underlying mechanisms (Melmed, 2011). Although the majority of NFPAs are sporadic, rare cases related to hereditary syndromes have been reported. Familial isolated pituitary adenomas and multiple endocrine neoplasia type 1 and type 4 are the most recognized syndromes associated with NFPA (Thakker, 2014; Beckers *et al.*, 2013).

Clinical Features and Diagnosis

The absence of clinical manifestations due to hormonal hypersecretion translates into delays in the diagnosis of NFPAs and patients usually present with symptoms due to local mass effects. These depend on the size of the tumor and its anatomical position and extensions. Headaches, caused by dura stretching and increased intracranial pressure, are the most common reported presenting manifestation of NFPAs (Rogers *et al.*, 2014). In case of suprasellar extension with compression of the anterior visual pathways (optic nerves, chiasm, and tracts), neuro-ophthalmological symptoms can present, mainly bitemporal hemianopia, although unilateral or even central visual loss can be present (Newman *et al.*, 2016). If the pressure on the optic chiasm is prolonged, optic atrophy and decreased visual acuity can be evident. Lateral expansion of the NFPA and invasion of the cavernous sinus can lead to ocular nerve palsies (particularly III, IV, and VI cranial nerves), resulting in ptosis, ophthalmoplegia, and diplopia. Erosion of the sellar floor and extension of the adenoma to the sphenoid sinus may cause cerebrospinal fluid (CSF) rhinorrhea and meningitis. Finally, in rare cases, pituitary apoplexy due to hemorrhage or infarction of an adenoma can be the first presentation of a NFPA, characterized by severe headache, sudden onset of visual disturbance, ophthalmoplegia, meningism, and impaired consciousness (Capatina *et al.*, 2015).

Patients with NFPA can also complain about manifestations attributed to hypopituitarism such as fatigue, decreased libido, impotence, and menstrual disturbances (Greenman and Stern, 2009). Anterior pituitary dysfunction is generally present in most patients with macroNFPA, with growth hormone (GH) deficiency being the most common deficit, followed by gonadotropins, and lastly thyrotropin-stimulating hormone (TSH) and adrenocorticotropic hormone (ACTH) deficiencies. Prolactin levels can be increased due to interruption of the inhibitory effect of dopamine on prolactin release or can be decreased indicating severe pituitary damage.

Magnetic resonance imaging (MRI) is the preferred imaging modality, used not only for the differential diagnosis of a pituitary adenoma from other sellar/parasellar masses but also for identifying expansion of the adenoma to the optic chiasm, anterior cerebral vessels, and cavernous sinuses (Buchfelder and Schlaffer, 2014). The diagnosis of NFPA is established by pathological examination demonstrating the presence of adenomatous cells; on immunohistochemistry, the majority of them stain for pituitary hormones. About 70% of NFPAs stain for gonadotropins or their subunits, followed by null-cell adenomas, that are negative on immunohistochemistry for any pituitary transcription factor and adenohypophyseal hormone; the remaining are either silent adenomas (corticotropinomas, prolactinomas, thyrotropinomas, and somatotropinomas) or stain for multiple hormones (Mete and Lopes, 2017; Neto *et al.*, 2016).

Treatment

Treatment of patients with NFPA includes monitoring, surgery, and RT. A "watch and wait" policy can be adopted in cases of NFPAs without neuro-ophthalmological symptoms that do not compress the optic chiasm. Macroadenomas are at higher risk of enlargement compared with microadenomas and regular imaging surveillance is recommended, initially yearly and less frequent thereafter. Monitoring for new pituitary dysfunction or for visual deterioration is also advised (Fernández-Balsells *et al.*, 2011; Freda *et al.*, 2011).

Pituitary surgery, especially via the transsphenoidal route, is the treatment of choice in NFPAs with neuro-ophthalmological manifestations and/or compression of the optic pathways, as well as in cases of pituitary apoplexy with severe visual acuity and visual field impairment or deterioration of visual or neurological signs. The aim of surgical treatment is to improve or resolve the mass effects on adjacent structures, especially the optic pathways, and the preservation of the normal pituitary tissue (Capatina *et al.*, 2015; Dekkers *et al.*, 2008).

RT, conventional or stereotactic, is mainly used as adjuvant treatment postoperatively in selective cases, aiming to reduce the risk of tumor enlargement, or in case of tumor recurrence (Molitch, 2017). Consideration of irradiation adverse sequelae, particularly hypopituitarism, needs to be taken into account (Loeffler and Shih, 2011).

Finally, no medical therapy is currently approved for the treatment of NFPAs; dopamine agonists and somatostatin analogs are potential options but their place in the management algorithm remains to be established (Greenman, 2017). Temozolomide is also used in the treatment of aggressive NFPAs that show continuous growth despite surgery and irradiation (Halevy and Whitelaw, 2017).

Rathke's Cleft Cysts

Rathke's cleft cysts (RCCs) are benign, sellar, and/or suprasellar cystic lesions originating from the remnants of Rathke's pouch. They are the most common type of sellar mass after pituitary adenomas (Famini *et al.*, 2011).

Epidemiology

The prevalence of RCCs is uncertain, considering that most of them are asymptomatic and escape diagnosis. However, they are detected more frequent nowadays as the quality of brain imaging has improved and its use is more extensive in clinical practice. RCCs are mainly discovered during adulthood and a female preponderance has been described, although this is probably attributed to their earlier detection in women due to menstrual irregularities (Trifanescu *et al.*, 2012).

Clinical Features and Diagnosis

RCCs are found incidentally when they have a small size but become clinical apparent when they are large enough to cause mass effects to adjacent structures or when they rupture. Headaches are the most prevalent manifestation of RCCs and are not correlated with the size or the location of the cyst (Nishioka *et al.*, 2006). Visual field defects and impairment of visual acuity are also evident in most symptomatic cases. Anterior pituitary hormone deficiencies affecting all axes and hyperprolactinemia are commonly found in patients with RCCs and in contrast to NFPAs, diabetes insipidus can be also present. In rare cases, apoplexy can be the first presentation of a RCC, characterized by manifestations similar of pituitary apoplexy. Rupture of the cyst leading to aseptic meningitis due to leakage of cystic contents on the subarachnoid space is also rare (Larkin *et al.*, 2014).

On MRI, RCCs often appear as well-circumscribed, spherical or ovoid lesions, located between the anterior and posterior pituitary gland in the region of the pars intermedia (Trifanescu *et al.*, 2012). The intensity of the signal of the cyst depends on its

contents. A cyst filled with clear, CSF-like fluid appears hypointense on T1- and hyperintense on T2-weighted images, whereas a cyst containing thick mucoid material made up of cholesterol and protein is hyperintense on T1- and isointense on T2-weighted imaging (Han *et al.*, 2014). In addition, an intracystic nodule with high signal intensity on T1-weighted images and low signal intensity on T2-weighted images can also be demonstrated.

Treatment

The natural history of RCCs is not known and the percentage of nonoperated cysts that grow during follow-up varies between studies. Cases of spontaneous involution or decrease of the size of cysts under monitoring has also been described (Amhaz *et al.*, 2010; Sanno *et al.*, 2003). However, given that RCCs are slowly growing, surveillance seems to be the most appropriate management for patients with small and asymptomatic cysts.

Surgical therapy, aiming to complete drainage of the cyst and removal of a proportion of the capsule as safely as possible, avoiding damage to the posterior pituitary and pituitary stalk, is recommended in symptomatic patients and is performed mainly with a transsphenoidal approach (Zada, 2011). Craniotomy may be required in complex cases of giant or purely suprasellar RCCs or when transsphenoidal surgery is contraindicated. Cyst decompression results in improvement or resolution of headaches and visual disturbances in the majority of the patients, while the recovery of pituitary function varies.

Relapse of the RCCs is possible after surgery and in a recent meta-analysis a recurrence rate of 12.5% was reported (Mendelson *et al.*, 2014). Although there is no consensus on the optimal therapeutic approach in recurrent RCCs, asymptomatic cases are usually followed up with imaging surveillance, while repeat surgery is performed in the symptomatic ones. RT has also been used in a small number of recurrent cases (Mukherjee *et al.*, 1997).

Craniopharyngiomas

Craniopharyngiomas are benign (World Health Organization grade I) epithelial tumors arising along the path of the craniopharyngeal duct. These tumors can be aggressive, infiltrating the parasellar structures and resulting in significant morbidity and mortality. The majority of them have a suprasellar component whereas the purely intrasellar ones represent the least common type (Müller, 2014).

Epidemiology

Craniopharyngiomas are rare tumors with an overall incidence of 1.34 cases per million persons per year in all ages and 1.44 cases among children; approximately 70% of them are diagnosed during adulthood (Zacharia *et al.*, 2012; Nielsen *et al.*, 2011). They can be detected at any age with peak incidence rates demonstrated in children between 5 and 14 years old and adults between 50 and 74 years old (Bunin *et al.*, 1998). No sex predisposition has been described.

Pathology

Histologically, there are two primary subtypes, the adamantinomatous and the papillary, but mixed or transitional forms have also been described (Prieto and Pascual, 2013). The adamantinomatous is the most common and is mainly detected in children and young patients, in contrast to the papillary one which is almost predominantly found in adults. Macroscopically, adamantinomatous craniopharyngiomas have cystic and/or solid components and calcifications (especially in children), while papillary tumors are mainly solid or mixed with cystic and solid parts with rare calcifications; they are also differences in the cystic contents between the two types (Karavitaki *et al.*, 2006). Although craniopharyngiomas are considered benign tumors, there are reports of malignant transformation in the literature (Sofela *et al.*, 2014).

Clinical Features and Diagnosis

The clinical manifestations of craniopharyngiomas are mainly due to pressure effects of the tumor to the adjacent structures including the optic pathways, the parenchyma of the brain, major blood vessels, and the hypothalamic-pituitary axis. Symptoms of increased intracranial pressure (headaches, nausea, vomiting, and papilledema; mainly in children), visual impairment (mostly bitemporal hemianopia), endocrine defects (growth failure, sexual immaturity in children; hypogonadism in adults), and cranial nerve palsies (also mainly found in children) are the most frequent features (Karavitaki *et al.*, 2005). In the majority of cases, anterior pituitary function is compromised at the time of diagnosis, while diabetes insipidus is present in 17%–27% of the patients (Müller, 2014).

MRI with contrast enhancement is valuable for the detection of craniopharyngiomas and for the differential diagnosis from other sellar/parasellar masses, mainly including RCC and other cysts (epidermoid, dermoid, arachnoid), pituitary adenomas, hamartomas, gliomas, intracranial germinomas, and other inflammatory/infiltrative diseases. The signal intensity of

craniopharyngioma on MRI is highly variable and depends on the proportion of the solid and cystic components, the content of the cysts, and the presence of calcifications, which are ideally detected with the use of computed tomography (CT).

Treatment

Surgery combined or not with adjuvant RT is the mainstay of treatment. The extent of the resection depends on many factors, including the location, the consistency, the shape and size of the tumor, its infiltration to adjacent neurovascular structures, as well as on the surgeon's preference and experience (Karavitaki, 2014). Complete resection may be attempted in craniopharyngiomas that do not expand to surrounding brain areas and can be safely removed without damage of the hypothalamus and the optic pathways (Müller, 2014). On the other hand, a hypothalamus-sparing subtotal resection of the tumor may be performed in cases of craniopharyngiomas that invade the hypothalamus (Elowe-Gruau *et al.*, 2013).

The transsphenoidal surgical route is mainly preferred for smaller intrasellar-infradiaphragmatic tumors, while craniotomy through a number of different approaches is used for all other cases (Buchfelder *et al.*, 2013). When large cystic components are present in the neoplasm, fluid aspiration facilitates the removal of the solid portion of the tumor and provides relief of the obstructive symptoms.

RT plays an important role in the management of patients with craniopharyngiomas for controlling tumor growth. It is usually offered postoperatively in cases of subtotal resection of the neoplasm or in tumor recurrence, which is common in patients with craniopharyngioma particularly after partial resection (Kortmann, 2011). However, in cystic tumors treated with RT, there is a risk of enlargement during the radiotherapy which may necessitate further intervention.

Given that the majority of the craniopharyngiomas is comprised of a cystic component, intracavitary instillation of beta-emitting radioisotopes or antineoplastic agents (bleomycin, interferon-a) has been used as alternative treatment (Julow, 2013; Steinbok and Hukin, 2010). A potential benefit of systemic chemotherapy in craniopharyngiomas has also been investigated in a very small number of patients.

Long-Term Morbidity and Mortality

Craniopharyngiomas are related with significant morbidity due to the damage of critical structures by the primary and/or recurrent tumor and/or to the adverse effects of the therapeutic interventions. Pituitary hormone deficiencies are common at the time of diagnosis of craniopharyngioma and their recovery after the surgical removal of the neoplasm is rare; in addition, aggressive surgery leads to more frequent pituitary dysfunction. Compromised vision is evident in a significant number of patients treated by surgery (combined or not with RT) and is adversely affected by the presence of visual symptoms at diagnosis and by daily irradiation doses >2 Gy (Karavitaki *et al.*, 2006).

Hypothalamic damage may lead to devastating comorbidities including hyperphagia and uncontrollable obesity, imbalances in regulation of body temperature, of thirst, of heart rate, and blood pressure, behavioral changes, cognitive impairment, and disorders in the sleep pattern. Obesity is the most common morbidity and is caused by the disruption of the mechanisms that control satiety, hunger, and energy balance (Karavitaki, 2014). Finally, other long-term irradiation-attributed morbidities, such as vasculopathy or secondary brain tumors, have been proposed as rare consequences of RT in patients with craniopharyngioma, but the risk of developing these has not been as yet defined (Liu *et al.*, 2009; Rajan *et al.*, 1993).

The mortality rates of patients with craniopharyngioma have been reported to be 3–5 times higher than that of the general population (Müller, 2014). Deaths are mainly attributed to the tumor and/or its recurrences, the treatment interventions, the hypothalamic and pituitary dysfunction, and to cardio/cerebrovascular and respiratory diseases.

Meningiomas

Meningiomas are the most common intracranial tumors and originate from the meningothelial cells of the arachnoid. They are slowly growing neoplasms which can arise from the dura at any site, including sellar/parasellar region. In imaging series, meningiomas account for 15% of nonadenomatous sellar masses (Famini *et al.*, 2011). According to World Health Organization, they are classified as benign (grade I), which constitute the majority of menigiomas, atypical (grade II), and malignant (grade III), which are the least common type.

Their clinical manifestations are attributed to compression of adjacent structures. Visual deterioration is the most common symptom, with varying types of field defects depending on the location of the tumor, followed by headaches. Pituitary dysfunction with mild hyperprolactinemia can also be evident. The diagnosis is facilitated by the characteristics of meningiomas on imaging. The typical MRI signal intensity consists of isointensity to slight hypointensity relative to gray matter on the T1-weighted sequences and a homogeneous, intense contrast enhancement (Watts *et al.*, 2014). However, there can be areas of necrosis or calcification (best demonstrated with CT) that do not enhance. The presence of a linear, enhancing dural tail, extending away from the neoplasm, is useful to distinguish meningiomas from other parasellar masses (Raoa *et al.*, 2008).

Surgery is the treatment of choice for symptomatic or growing meningiomas, while asymptomatic tumors can be managed conservatively with active surveillance (Oya *et al.*, 2011). The aim of surgical treatment is total excision of the tumor, although

many of them cannot be totally removed due to encasement of vital vascular or neural structures. In addition, given that meningiomas are high vascular neoplasms, major bleeding can occur during surgery (Kwancharoen *et al.*, 2013). RT can be used as primary treatment in patients with inoperable meningiomas, as adjuvant therapy in order to slow tumor growth after incomplete resection of grade I tumors or after complete removal of grade II and III neoplasms and as salvage therapy for recurrent and progressive disease (Rogers *et al.*, 2015).

Germcell Tumors

Intracranial germcell tumors (GCTs) represent a rare and heterogeneous group of neoplasms, primarily affecting children, adolescents, and young adults (<20 years old) and mostly males. They are mainly midline tumors, usually arising in the pineal gland, followed by the neurohypophyseal/suprasellar region but they can also be found in other intracranial sites (McCarthy *et al.*, 2012). Although the majority of patients have an isolated mass in either the pineal or the neurohypophyseal region, in some cases synchronous lesions in both locations may be found (Aizer *et al.*, 2013).

Primary central nervous system GCTs share histologic and genetic similarities to extracranial GCTs, and based on histology, they are classified as germinomas, which account for 2/3 of the cases, and nongerminomatous GCTs, which include embryonal carcinoma, yolk sac tumors, choriocarcinoma, teratoma, and mixed GCT with more than one type of histology (Echevarría *et al.*, 2008). GCTs may secrete the tumor markers alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (β-hCG) in the serum and/or CSF; high levels of AFP are found in yolk sac tumors, while β-hCG is very much increased in choriocarcinomas and mildly raised in germinomas which contain syncytiotrophoblastic elements (Bromberg *et al.*, 2013). Increased levels of one or both tumor markers can also be seen in mixed GCTs and immature teratomas.

The clinical presentation varies based on the location and size of the tumor. The majority of patients with suprasellar tumors presents with hypothalamic-pituitary dysfunction and visual disturbances, caused by compression or invasion of the optic chiasm. Endocrine manifestations include diabetes insipidus (the commonest sign which may precede all other abnormalities), followed by anterior pituitary hormone deficits and precocious puberty, especially in males due to increased β-hCG levels (Jorsal and Rørth, 2012). It should be also noted that the presence of the endocrinopathies often appear prior to radiological findings rendering the diagnosis of the tumor delayed (Sethi *et al.*, 2013).

MRI is the best imaging modality for intracranial GCTs. Suprasellar germinomas usually appear as ill-defined contrast enhancing masses, with similar or slightly low signal intensity on T1-weighted images and being isointense to slightly hyperintense on T2-weighted sequence (Wang *et al.*, 2010). On the other hand, teratomas appear as heterogeneous masses, due to their contents (fatty tissue, cystic components, and calcifications); they are also enhanced after gadolinium administration, except for the cystic areas.

The diagnosis of intracranial GCTs depends on clinical manifestations, tumor markers, neuroimaging characteristics, and/or histology. In patients with consistent radiological findings and increased serum and/or CSF AFP and β-hCG levels (above nationally defined thresholds), surgical biopsy is not required and the diagnosis can be based on the tumor markers (Murray *et al.*, 2015). Biopsy for an intracranial GCT diagnosis should be performed in patients who are marker-negative, regardless of imaging findings.

Treatment depends on the type of GCT. Pure germinomas are radiosensitive and can be treated with RT alone or a combination of lower dose RT and chemotherapy (Fu *et al.*, 2017). Patients with malignant nongerminomatous GCTs have a worse prognosis compared to those with pure germinomas and should receive a combination of chemotherapy and RT, to maximize their chance of cure; if metastatic disease is present, craniospinal RT should be performed (Murray *et al.*, 2015). Finally, radical surgical resection, where feasible, is the treatment of choice for intracranial mature and immature teratomas without malignant transformation.

Chordomas

Chordomas are rare tumors that are derived from embryonic remnants of the notochord. Their cranial sites include mostly the clivus region. They are slow-growing neoplasms that are locally destructive and may metastasize. Their symptoms depend on the direction of tumor growth and they more commonly manifest with headaches and asymmetric visual disturbances (mainly diplopia) (Kaltsas *et al.*, 2008). Pituitary dysfunction, although uncommon, may be present, as well as neck pain and nasopharyngeal obstruction in large tumors.

MRI reveals an invasive lesion in the clivus which enhances after contrast administration and is heterogeneously hyperintense on T2-weighted images (Rennert and Doerfler, 2007). A honeycomb appearance of the tumor after gadolinium injection can also be revealed due to low T1 signal areas within the neoplasm (Doucet *et al.*, 1997). Osteolytic bony erosion of the scull base and calcifications inside the tumor, which are common in chordomas, are better demonstrated with CT. In some cases, the normal pituitary gland can be distinguished from the tumor, which is helpful for the differential diagnosis of chordomas from other pituitary masses.

Treatment includes a maximal safe surgical resection of the tumor, leading to symptomatic improvement of the patient, although a complete removal of the neoplasm is usually not possible due to locally aggressive growth pattern of chordomas.

Considering the difficulty in achieving gross total resection of the tumor and its high recurrence rate, postoperative RT is important for local tumor control (Fernandez-Miranda *et al.*, 2014). However, issues regarding the type of adjuvant RT and the timing of the treatment (in all patients after surgery or only in those with residual or recurrent disease) remain unresolved.

Pituitary Malignancies

Primary pituitary malignancies are extremely rare and comprise pituitary carcinomas, primary lymphoma, and melanoma. On the other hand, metastatic involvement of the pituitary gland, although uncommon, has been increasingly reported during the past decades.

Pituitary Carcinoma

Pituitary carcinomas are tumors of adenohypophyseal origin demonstrating metastatic spread by either craniospinal dissemination or systemic metastases (Mete and Lopes, 2017). They are extremely rare, accounting for only 0.1% of all pituitary tumors, and most of them are hormonally active; prolactin-secreting tumors are the most frequent, followed by ACTH-secreting ones (Heaney, 2011). They tend to metastasize mainly hematogenous and through the lymphatic system rather than via craniospinal spread and are associated with a poor prognosis that depends on the extent of the metastatic disease (Heaney, 2014).

Pituitary tumors that will ultimately become carcinomas can follow different courses; they can be aggressive and unresponsive to treatment from their initial diagnosis, progressing rapidly to carcinoma, or they can remain stable, responsive to standard therapy and progress to carcinomas after a long period. No single morphological feature is able to predict pituitary tumor behavior but Ki-67 $\geq$3%, p53 positivity and a mitotic count $>$2 mitoses/10HPFs are frequently observed in aggressive pituitary tumors and carcinomas (Raverot *et al.*, 2017).

A multimodal approach is required in pituitary carcinomas including surgery, RT, chemotherapy, and medical therapy for the control of the biochemical secretion (in cases of functioning tumors) and tumor growth. Temozolomide can be used as the first-line chemotherapeutic treatment in pituitary carcinomas with documented progressive disease due to its reported effectiveness (Raverot *et al.*, 2017). Also, new potential targeted therapies are being studied such as mammalian target of rapamycin (mTOR), vascular endothelial growth factor (VEGF), and epidermal growth factor receptor 2 (EGFR2) inhibitors (Di Leva *et al.*, 2014).

Pituitary Lymphoma

Primary pituitary lymphoma defined as isolated involvement of the pituitary gland without evidence of systemic disease is extremely uncommon and can be found either in immunocompetent or in immunocompromised patients. They mostly affect patients in their 5th–6th decade of life, although adult cases from all age groups have been reported, and the majority of them are of B-cell origin (Tarabay *et al.*, 2016).

The clinical manifestations are those of expanding intracranial masses with headache, diplopia, visual field defects, and cranial nerve deficits; hypopituitarism is also a common finding (Giustina *et al.*, 2001). In addition, fever has been described in a small proportion of patients (Liu *et al.*, 2007). On imaging, primary pituitary lymphomas are usually contrast enhancing lesions, isointense on T1-MR images, and hypo- to isointense on T2-weighted sequences, and can demonstrate suprasellar extension, invasion of the sphenoid and cavernous sinuses, and pituitary stalk thickening (Tarabay *et al.*, 2016).

After the final diagnosis, which is established histologically, a differential diagnosis between primary and secondary intracranial pituitary lymphoma should be performed. Treatment is comprised of surgical resection of the tumor, RT, and chemotherapy.

Metastases

Although many kinds of malignancies can metastasize to the pituitary, breast, and lung cancers are the most common, followed by prostate and renal cancer (He *et al.*, 2015). Pituitary metastases occur mostly in patients with systemic dissemination but they can also be the first manifestation of an occult primary tumor or the only evident metastatic lesion (Komninos *et al.*, 2004).

The majority of pituitary metastases is asymptomatic and found incidentally. In symptomatic cases, the most common presenting manifestations are similar to those of pituitary macroadenomas, including headaches, visual field deficits, cranial nerve palsies, and anterior pituitary dysfunction but with higher prevalence (Al-Aridi *et al.*, 2014). Diabetes insipidus, however, which is absent in patients with pituitary adenomas, is a frequent finding in pituitary metastatic disease, given that the posterior pituitary is a preferred site for bloodborne metastatic spread due to its direct arterial supply from the hypophyseal arteries.

Imaging is not very helpful in the differential diagnosis of metastases from other pituitary masses, although some findings can be useful, including a dumbbell-shaped tumor (due to indentation by the diaphragma sella), invasion of the infundibular and bony erosion (He *et al.*, 2015; Komninos *et al.*, 2004). Although the diagnosis is ultimately confirmed by pathology, the possibility of pituitary metastasis is high in patients with a rapidly increasing sellar mass, sudden onset of diabetes insipidus and quick development of mass effect symptoms, especially in patients with a history of malignancy.

Treatment depends on the symptoms and the extent of systemic disease, as well as on the prognosis of the patient. The available management modalities include surgery, RT, and chemotherapy or a combination of them. In patients with metastatic mass effects causing visual impairment and diplopia or ophthalmoplegia, transsphenoidal surgery combined with postoperative radiotherapy may provide symptomatic relief and local disease control (Burkhardt *et al.*, 2016). However, resection of the pituitary metastases can be difficult due to their invasive, infiltrative, and vascular nature.

Gliomas and Pituicytomas

Gliomas in the sellar, parasellar, and suprasellar region may arise from the hypothalamus, the optic chiasm, nerve or tract, the brainstem, and the neurohypophysis or the pituitary stalk (pituicytoma). Optic pathway/hypothalamic gliomas are mainly diagnosed during childhood, with a significant proportion found in patients with neurofibromatosis type 1, and the majority is low-grade malignant tumors (Goodden *et al.*, 2014). On the other hand, pituicytomas are very rare intrasellar or suprasellar low-grade gliomas (about 100 cases in the literature) that originate from the neurohypophysis or infundibulum in adults (Wang *et al.*, 2016). Finally, brainstem gliomas, which generally affect young adults, can extend to the parasellar region (Hu *et al.*, 2016).

The clinical manifestations of gliomas depend on their location and they are the results of local tumor effects. The presenting features of pituicytomas include headaches, visual impairment, anterior pituitary hormone deficits, diabetes insipidus, and mild hyperprolactinemia due to pituitary stalk effect (El Hussein and Vincentelli, 2017). Patients with hypothalamic-optochiasmatic tumors can present with all the aforementioned manifestations, as well as hypothalamic dysfunction, obstructive hydrocephalus, and other signs of increased intracranial pressure (headaches, papilledema). Precocious puberty and diencephalic syndrome can also be found in children (Binning *et al.*, 2007).

Hypothalamic–optochiasmatic gliomas are suprasellar masses which may infiltrate the adjacent structures and on MRI they demonstrate high signal intensity on T2-weighted images. Larger tumors can be heterogeneous with both cystic and solid components, with the solid component showing a significant contrast enhancement. On the other hand, pituicytomas are generally well-defined, solid, round, or oval masses in the intrasellar and/or suprasellar region with the same MRI characteristics as hypothalamic-optochiasmatic gliomas (Yang *et al.*, 2016). The presence of a cystic component in pituicytomas is uncommon.

Complete tumor resection is the mainstay of treatment for symptomatic pituicytomas, although not possible most of the times due to their potential for infiltration and their high vascularization which can lead to extensive bleeding during the surgery limiting the extent of removal (Pirayesh Islamian *et al.*, 2012). RT has been used as adjuvant treatment in a minority of cases with residual disease but its efficiency has not been as yet established. Treatment of hypothalamic-optochiasmatic gliomas depends on the size, location, and presenting symptoms of the patients and can include observation, chemotherapy, RT, and surgery (Bornhorst *et al.*, 2016).

Gangliocytomas

Gangliocytomas are well-differentiated slow-growing neuroepithelial tumors composed by mature neurons that are very rarely discovered in the sellar region. The majority consists of mixed adenomatous and neuronal tissue and are usually found in association with a hormone secreting pituitary adenoma (in particular GH-secreting adenoma, followed by prolactin- and ACTH-secreting adenomas), although isolated sellar gangliocytomas have also been reported (Qiao *et al.*, 2014). Interestingly, the latter tumors can also demonstrate endocrine manifestations, especially hyperprolactinemia, acromegaly, and Cushing's.

The clinical presentation of gangliocytomas depends on their secreting activity and includes symptoms and signs due to pituitary hormone hypersecretion and/or local mass effects. Imaging reveals a sellar tumor that can extend to the suprasellar region or infiltrate the cavernous and sphenoid sinuses. Treatment is surgical and consists of the safe resection of the gangliocytoma, mainly via the transsphenoidal route. However, if hormonal resolution is not achieved with surgery (in cases of hormone secreting tumors), adjuvant medical treatment or RT may be needed (Cossu *et al.*, 2016).

Granular Cell Tumors

Granular cell tumors arising in the posterior lobe of pituitary or the stalk are rare entities and mostly affect adults in their 4th–5th decade of life and most frequently women (Covington *et al.*, 2011). They are purely suprasellar or intrasuprasellar lesions that can be asymptomatic and be discovered incidentally or present with visual impairment and headaches. Endocrine disturbances, mainly hyperprolactinemia, can also be evident, although hypopituitarism is uncommon; despite their location in the neurohypophysis and the infundibulum, diabetes insipidus is also rare (Ahmed *et al.*, 2017).

On MRI, granular cell tumors usually appear isointense to the brain on T1-weighted sequence and isointense to the white matter on T2-weighted images with a heterogeneous or homogeneous enhancement after gadolinium administration (Gagliardi *et al.*, 2016). In symptomatic cases, surgical resection of the tumor is the treatment of choice and the approach (transsphenoidal or transcranial) depends on the location of the lesion. The use of RT must be individualized, considering that this treatment modality has not shown clear benefits in cases which it has been used till now (Ahmed *et al.*, 2017).

Hypothalamic Hamartomas

Hypothalamic hamartomas are rare, congenital, benign mass lesions, composed of abnormally distributed but cytologically normal neurons and glia and are mostly found in children and adolescents (Coons *et al.*, 2007). They arise from the floor of the third ventricle, the tuber cinereum, or the mammillary bodies and they mainly present with epileptic syndromes, behavioral and cognitive impairment, psychiatric disorders and, from an endocrine point of view, isosexual central precocious puberty. A strong association between the clinical manifestations of the hypothalamic hamartomas and their connection to normal hypothalamic and surrounding tissues has been recognized (Mittal *et al.*, 2013).

High-resolution MRI scans reveal a hypo- to isointense mass on T1-weighted images, that is hyperintense on T2-weighted sequence and do not enhance following administration of contrast. Surgical treatment is usually required for the treatment of epilepsy associated with hypothalamic hamartomas, for halting the progressive decline in neurocognitive function and improving the coexisting behavioral and psychiatric syndrome. On the other hand, central precocious puberty is treated medically with GnRH-agonist therapy (Harrison *et al.*, 2017). Other methods of treatment, including stereotactic radiosurgery, brachytherapy, and radiofrequency ablation, can also be used in specific cases.

Cysts

Apart from RCCs, which constitute the majority of the cystic lesions found in the sellar/suprasellar region, other congenital cysts can also be rarely discovered in the same anatomical area, including arachnoid, epidermoid, and dermoid lesions. Arachnoid cysts arise from a splitting of the arachnoid membrane which fills with CSF, while epidermoid and dermoid cysts are of ectodermal origin, containing keratin and cholesterol, derived from desquamated epithelial cells; dermoid cysts contain epidermal appendages as well, such as hair follicles, sweat glands, and sebaceous glands (Lynch *et al.*, 2014).

Symptoms usually develop when the cysts are large enough to cause compression of the adjacent brain parenchyma or the cranial neurovascular elements. Headaches and visual disturbances are the most commonly presenting manifestations, while pituitary dysfunction is less frequently observed. Spontaneous rupture of a dermoid (mainly) or a epidermoid cyst (in rare cases) can cause aseptic chemical meningitis; there are also reports for these two types of cystic lesions describing a clinical presentation mimicking pituitary apoplexy (Tuna *et al.*, 2008; El-Bahy *et al.*, 2006).

On imaging, arachnoid cysts are pure cystic lesions with clear defined borders, no contrast enhancement or calcifications, and with a typical CSF-like signal behavior. Epidermoid cysts are usually isointense or slightly hyperintense to CSF on both T1- and T2-MR images, although lesions with high protein content can show reversed signal intensity. They generally do not enhance after contrast administration, although some minimal rim enhancement can occur, and calcification may be present (Osborn and Preece, 2006). High signal intensity on diffusion-weighted images is helpful for the differential diagnosis of epidermoid cysts from arachnoid ones (Hakyemez *et al.*, 2005). Finally, dermoid cysts are hyperintense on T1-weighted images due to the lipid content and they have heterogeneous signal intensity on T2-weighted sequence due to their mixed composition; they do not show contrast enhancement and foci of calcification can also be evident (Warakaulle and Anslow, 2003).

Sellar/parasellar cystic lesions not causing manifestations do not require treatment and can be followed up, while surgical treatment is preferred in symptomatic cases. In arachnoid cysts, the operative aims include the evacuation of the cystic fluid, the safe excision of all or part of the cyst membranes, and the enlargement of the communication of the lesion with the suprasellar CSF spaces (Dubuisson *et al.*, 2007). On the other hand, in epidermoid and dermoid cysts, a gross-total resection is desirable but not feasible many times, given that these tumors can often be adhesive to vital vascular and nervous structures lesions and the cyst capsule and contents cannot be dissected without significant morbidity (Zada *et al.*, 2010). Intraoperatively, the removal of the contents of the cysts should be performed with caution in order to avoid a spillage of fluid that can cause chemical meningitis.

Surgical Treatment of Nonfunctioning Pituitary Tumors

Michael Buchfelder and Yining Zhao, University Hospital Erlangen, Erlangen, Germany

Abbreviations

3D	3-Dimensional
BMI	Body mass index
CT	Computerized tomography
CSF	Cerebrospinal fluid
ERS	Extensive resection surgery
HSS	Hypothalamus-sparing surgery
MRI	Magnetic resonance imaging
NFPA	Nonfunctioning pituitary adenoma
RCC	Rathke's cleft cyst

Glossary

Adenomas A type of benign epithelial tumors of glandular origin, glandular characteristics, or both, which can grow from glandular organs, such as the pituitary gland and others.

Craniopharyngioma Squamous epithelium tumors develope from residual cells of Rathke's pouch, which often arises from the anterior superior margin of the pituitary. It does not undergo malignant degeneration but has a tendency to recur.

Endoscope In contrast to the microscope, endoscopy usually has a long and thin body that carries the camera and light source on the tip, which can be inserted into a cavity or organ and inspect the inside, providing an image via a digital screen.

Hypopituitarism The deficient (hypo) secretion of one or more of the hormones normally produced by the pituitary gland.

Hypothalamic syndromes Malfunctions of the hypothalamus, causing cachexia, disturbed sleep–wake rhythm, altered temperature regulation, the gain of weight, etc.

Non-functioning tumor or hormonally inactive tumor Neoplasm that does not produce excess hormones or just biologically inactive hormone fragments.

Operating microscope An optical microscope specifically designed to be used in a surgical setting is typically used to perform microsurgery.

Pituitary tumor Tumors which are located in the intra-, para-, or supra-sellar region, such as pituitary adenomas, craniopharyngiomas, and meningiomas.

Suprasellar region The region above the pituitary (the level of the chiasmatic cistern), below the third ventricle. It includes the suprasellar cisterns, the visual pathways, and the inferior hypothalamus.

Visual compromise Tumors in sellar region may compress the optic chiasm, thus causing deterioration of vision, such as bitemporal visual field defects and decreased visual acuity.

History

Pituitary surgery began with subtemporal craniotomy approaches to the sellar region performed by Horsley in 1887. Almost 20 years later, Schloffer and Von Eiselberg described a new nasal approach for pituitary surgery via the sphenoid sinus, which was thus called the transsphenoidal approach. Oscar Hirsch improved the technique further. He and Harvey Cushing, who had tremendous interest in pituitary physiology and pathophysiology, designed instruments for this operation. Cushing performed the subtemporal approach, first described the sublabial transsphenoidal approach, and later the "transfrontal" (i.e., subfrontal) approach for pituitary adenoma resection. However, he abandoned the transsphenoidal approach since with the transcranial approach, he had a lower recurrence rate and a better recovery of vision. For a while, only Dott and Guiot continued to practice the transsphenoidal approach. With the introduction of the image intensifier and the operating microscope by Jules Hardy, from 1965 on, the transsphenoidal approach experienced a renaissance and became the operative approach of choice for most of the sellar tumors. Large patient series documented its efficiency and safety. More recently, with the development of magnetic resonance imaging (MRI), the endoscope, and navigation technology, transsphenoidal surgery is considered to be the first choice operation for pituitary surgery. It is efficient and safe for most patients (Buchfelder and Schlaffer, 2009; Couldwell, 2004).

Indications of Surgery

Tumors that compress the visual pathways or neurovascular structures on MRI, and cause corresponding symptoms like deterioration of vision and diplopia, respectively, are considered absolute indications for surgery (Chanson *et al.*, 2015; Freda *et al.*, 2011; Marosi *et al.*, 2008). Tumors, which abut or compress the visual pathways, or neurovascular structures on MRI, without causing any corresponding symptoms, are also recommended to undergo surgical resection as primary treatment (Freda *et al.*,

2011; Marosi *et al.*, 2008). Patients with hypopituitarism in the endocrinological assessment should be considered for surgery (Chanson *et al.*, 2015; Freda *et al.*, 2011). When the tumors are close to the chiasm (<5 mm) but as yet without any contact, decisions can be made on an individual basis, particularly taking into account the age of the patients and their health status (Chanson *et al.*, 2015). However, the risk of apoplexy and a patient's desire for pregnancy in nonfunctioning pituitary adenomas (NFPAs) should be considered (Freda *et al.*, 2011). Patients without ophthalmological or endocrinological symptoms, but with other symptoms that are caused by the mass effect of the tumor, such as a persistent headache, may also be good candidates for elective surgery (Chanson *et al.*, 2015; Freda *et al.*, 2011; Marosi *et al.*, 2008). Tumors with documented size increase during follow-up imaging might be considered for surgery (Freda *et al.*, 2011). Incidental, asymptomatic tumors which are remote to the chiasm (≥5 mm) should rather undergo serial follow-up with MRI and endocrinological assessments, with or without ophthalmological testing (Chanson *et al.*, 2015; Freda *et al.*, 2011; Igarashi *et al.*, 1999; Marosi *et al.*, 2008). Other conditions including pituitary apoplexy, progression, or recurrence of residual tumors during the follow-up period should be managed according to the criteria mentioned above. In some situations, surgery may be needed to establish the diagnosis of an unknown lesion (Glezer *et al.*, 2008; Hadziahmetovic *et al.*, 2008; Huang and Castillo, 2005).

Preoperative Evaluation

Pituitary MRI with T1-weighted coronal and sagittal (with and without contrast enhancement) and T2-weighted axial sequences are the most valuable radiological studies, especially with high-field MRI. Computerized tomography (CT) may also provide some information. However, the MRI depicts any intracranial lesion with the highest soft tissue contrast and precisely shows its relationship to the adjacent anatomical structures. Sometimes, in consideration of preoperative evaluation, CT angiography or MR angiography is recommended to rule out aneurysms or other abnormal vascular conditions. An ophthalmological evaluation, in particular, perimetry and visual acuity testing, is required, at least, once there is impingement of the visual pathways on MRI. Of course, clinical and laboratory endocrinological evaluation is needed before surgery to exclude hormonally active adenomas and to assess pituitary function. Pre- and perioperative substitution therapy should be initiated in case of partial or total hypopituitarism. Clinical symptoms, such as diplopia, headache, and other cranial nerve functions, should be documented as well. These radiological, ophthalmological, and endocrinological evaluations are crucial for the optimal management of an individual lesion and the assessment of surgical outcome (Buchfelder and Schlaffer, 2009). Additional testing might be required for the differential diagnosis.

Differential Diagnosis

Pituitary adenomas, craniopharyngiomas, supra- and parasellar meningiomas, and various cystic lesions are frequent space-occupying lesions in the sellar region. Secreting pituitary adenomas can be easily identified by measuring hormones. Thus, the entire differential diagnosis of space-occupying lesions within the sellar region is related to nonfunctioning tumors.

Non-Functioning Pituitary Adenomas

In adults, an adenoma is by far the most common pituitary lesion. Nonfunctioning adenomas are rare in childhood. The tumors usually present as macroadenomas (>10 mm diameter). Only a minority are incidentally found as microadenomas (<10 mm diameter). The classical manifestations are visual compromise and hypopituitarism. Loss of vision may be gradual (with gradual tumor growth) or sudden (apoplexy). Characteristically, the mass lesion sits in the sella turcica and expands from there (Buchfelder and Schlaffer, 2009).

Craniopharyngiomas

They are common pituitary tumors in children, but also occur even in aged adults. Craniopharyngiomas tend to arise from the anterior superior margin of the pituitary, the infundibulum, and from the third ventricle. Many craniopharyngiomas have cystic and solid components, as well as calcifications in imaging. Some craniopharyngiomas might leak cystic component and thus present with aseptic meningitis. Clinically, patients may present with visual compromise (optic chiasm compression), hypothalamic syndromes (compression on hypothalamus), hypopituitarism (compression on the pituitary gland), and symptoms due to hydrocephalus (when the tumor occludes the foramina of Monro). Intraoperatively, the normal pituitary gland is usually found to be compressed at the sellar floor level, and the "machine-oil" cyst fluid contains cholesterol crystals. Once the diagnosis of craniopharyngioma is suspected, most surgeons would recommend an operation (Karavitaki *et al.*, 2006).

Supra- and Parasellar Meningiomas

Patients with meningiomas in the sellar region usually present with progressive visual loss due to optic nerve or chiasm compression. Characteristic features in imaging are a wide dural attachment at the planum sphenoidale in suprasellar meningiomas

and a narrowing of the carotid artery in parasellar meningiomas. The mass of the lesion homogenously enhances in postcontrast T1-weighted sequences on MRI and the major portion of the lesion is usually not located within the sella turcica. They can also cause hormonal deficiencies as the tumor impinges on normal pituitary gland and stalk, however, much less frequent than pituitary adenomas or craniopharyngiomas. Symptomatic meningiomas and those with signs of compression in imaging should undergo surgery. Asymptomatic patients without neurovascular compression in imaging are recommended to undergo serial follow-up. Patients who are not suitable candidates for surgery can be considered for radiotherapy (Marosi *et al.*, 2008).

Cystic Lesions

Rathke's cleft cyst (RCC) is thought to derive from remnants of Rathke's pouch. It appears as low-density cystic lesions in the CT and low signal intensity in the MRI. RCC is radiologically differentiated from craniopharyngioma by the presence of only a cyst without solid components or calcification. It can cause visual compromise and/or hypopituitarism just as with craniopharyngioma. Intraoperatively, the cyst content resembles motor oil. The differentiation from craniopharyngioma is essentially based on the histology of the cyst membrane (Huang and Castillo, 2005).

Colloid cysts are the macromanifestations of "pars intermedia's" cysts, which are frequently found in minute size. They do not at all enhance in either CT or MRI, and are located between the anterior and posterior lobe of the pituitary. As intrasellar space-occupying lesions, they might cause disturbances of pituitary function. They are ideal targets for selective resection because they lack membranes (Nomikos *et al.*, 1999).

Rare Parasellar Tumors

Hypophysitis refers to inflammation of the pituitary gland, with a sellar mass lesion in the MRI. It presents mostly with headaches, followed by visual disturbances. Nontumorous hyperprolactinemia is a common feature in hypophysitis. Patients who are considered to have hypophysitis should have a histologic confirmation via a biopsy. When the patients suffer from cranial nerve deficits and severe headache, pituitary surgery can be an option as active treatment, and partial resection is preferred over gross total resection. It is a matter of debate whether corticosteroids should be used for primary treatment (Glezer *et al.*, 2008; Gutenberg *et al.*, 2006).

Germinomas are the most common subtype of central nervous system germ cell tumors that can mimic craniopharyngiomas and other nonfunctioning tumors when located within the sellar region, frequently causing diabetes insipidus and severe hypopituitarism. The MRI shows contrast-enhanced lesion with unclear boundaries, mostly in young patients. Patients with germinomas may develop spinal metastasis. Therefore, a spinal MRI could assist in the diagnosis. There are tumor markers like alpha-fetoprotein, β-human chorionic gonadotrophin and placental alkaline phosphatase, which can be assessed in the serum and cerebrospinal fluid (CSF). The diagnosis is confirmed by biopsy. Radiotherapy is usually curative because of the high radiosensitivity (Hadziahmetovic *et al.*, 2008).

Chordoma is a semimalignant tumor that arises from the clivus. It presents with symptoms of mass effect, like other nonfunctioning tumors, such as headaches, visual deterioration, diplopia, and hormonal changes. Characteristically, the clivus is distended in postcontrast MRI, and shows heterogeneous enhancement and frequently also brain stem compression. Surgical treatment usually results in incomplete resection and requires postoperative irradiation (Glezer *et al.*, 2008).

Moreover, there are other neoplastic, inflammatory, and vascular rare space-occupying sellar and parasellar lesions that are even less frequent (Glezer *et al.*, 2008; Huang and Castillo, 2005; Petrakakis *et al.*, 2016).

Surgical Anatomy

The pituitary gland sits in the sella turcica, which lies almost in the center of the head. The sella turcica is a bony cavity in the skull base. Bone thus forms the anterior and posterior walls and the floor of the pituitary fossa. The cavernous sinuses are the lateral walls. The roof of the sella is called diaphragm sella. It has a small opening for pituitary stalk just enough wide for it to pass through. The dura from the frontal basis splits into two layers that hug the pituitary gland. Anteriorly and inferiorly to the pituitary fossa is the sphenoid sinus, and superiorly of the pituitary gland is the suprasellar region with the optic pathways, blood vessels (anterior cerebral artery and anterior communicating artery). As the nonfunctioning tumor grows, it will increasingly compress and distort the normal pituitary gland and thus gradually cause hypopituitarism. Subsequently, the tumor is likely to cause enlargement of the sellar fossa and expand laterally and inferiorly, to finally reach and compress surrounding neurovascular structures resulting in cranial nerve palsy (compression on cranial nerves III, IV, V, and VI which run through the cavernous sinuses), and deterioration of vision (compression on optic chiasm or optic nerves).

In order to reach the sellar region and remove the tumors, a passage to this region has to be dissected either from inferiorly, that is, through all the bony structures of the sphenoid sinus and sellar floor (transsphenoidal approaches), or from superiorly via a craniotomy (transcranial approaches) along the skull base or through the ventricles to reach the sellar region (Buchfelder and Schlaffer, 2009; Couldwell, 2004).

Operative Approaches

Transsphenoidal Approach

Transsphenoidal surgery is to date the main procedure for pituitary tumor resection since it suits most of the cases. There are many variants of the transnasal approach, such as a submucosal dissection along the nasal septum or a direct endonasal access by cutting the mucosa only at the surface of the sphenoid sinus. A sublabial submucosal approach is another popular approach to reach the sphenoid sinus, which provides a perfect visualization of the entire sella when compared with the direct transnasal approach. 95% of pituitary adenomas can be operated via this approach. The patient is positioned supine, with the head slightly extended. A septal mucosal incision in the right nostril (based on the surgeon's dominant hand) is made after submucosal injection of diluted adrenaline to expose the nasal cartilage. The septal mucosa is detached from the cartilaginous and osseous septum by creating a submucosal pouch, which finally exposes the crest of the sphenoid bone. The perpendicular plate of the vomer is pushed aside and partially removed. A speculum is introduced to maintain the corridor open and to allow microscopic visualization of the sphenoid sinus. The septations are resected to expose the sellar floor, and the mucosa of the sphenoid sinus is removed (Buchfelder and Schlaffer, 2009). The C-arm or neuronavigation can be used to confirm the location. The sellar floor is removed exposing the dura. Then a "cross" incision or square window is made in the dura and tumor is removed with different microsurgical instruments. Tumors with soft consistency or fluid components can be easily removed with suction. Tumors with firm texture or attachment to surrounding structures need to be dissected gently piece by piece or "en bloc." The goal is to achieve total resection or maximal safe resection. The normal pituitary should be identified and preserved during surgery, which gives the name "selective adenomectomy" to the procedure. During the surgery, the descent of the arachnoid is evidence of decompression, but occasionally tumor may hide between the arachnoidal folds. An elevation of intracranial pressure (ICP) by using ventilation with positive end-expiratory pressure (PEEP) or compression of the jugular veins may help to make the residual tumor descend, but also increases the risk of CSF leak.

Many different modifications of the transsphenoidal approach are described and both microscope and endoscope are potential visualization aids in this approach (Couldwell, 2004). The classical endonasal transsphenoidal approach can be extended by additionally drilling parts of clivus or anterior fossa for the resection of large pituitary tumors (Di Maio *et al.*, 2011). Extreme variants, mostly supported by the endoscopic technique, are opening of the frontal base with posterior ethmoidectomy, wide sphenoidotomy, removal of large parts of the sphenoid, and drilling of the clivus, laterally only limited by the optic canal. With the extended approaches, the risk of postoperative CSF leaks is high.

When the tumor has been extracted as much as possible, the sellar floor must be reconstructed. This can be accomplished by gelfoam, fat, fascia lata, or bone fragments. The nasal septum and mucosa are repositioned and the mucosal incision is sutured. Many authors recommend the introduction of nasal tamponades into both nostrils. Modifications might not require tamponades. In case of CSF leak, an autologous graft with fascia lata or fat and harvested bone has been used to close the defects of the skull base. Fibrin glue is often used as an adhesive (Buchfelder and Schlaffer, 2009).

In craniopharyngioma or meningioma and in many of the rare tumors in the sellar region, the adenohypophysis might be the first structure to be seen after dura opening. A dissection of the adenohypophysis in the anterior–posterior dimension or even a partial resection of the gland might be needed to expose the tumor. The tumors are usually quite firm and need to be gradually dissected. The optic chiasm, the optic nerve and tract, the pituitary stalk, the anterior communicating artery, and the hypothalamus are important structures that should be detached cautiously because any mechanical damage could cause postoperative complications (Buchfelder and Schlaffer, 2009; Couldwell, 2004).

Transcranial Approach

Although the transsphenoidal approach is sufficient for many cases, transcranial approaches offer better access when there is only minimal enlargement of the sella but extensive suprasellar extension, or if the tumor has a larger extrasellar than intrasellar portion. For fibrous tumors like meningiomas in this region or recurrent tumor following transsphenoidal resections, transcranial approaches are occasionally more suitable. However, the disadvantage of transcranial microsurgery is the direct brain exposure, retraction, and the inconvenience that surgeons have to sharply dissect the tumor from the optic nerve and cerebral arteries, which exposes these to the threat of damage.

Usually, a frontolateral or frontotemporal (pterional) craniotomy is performed with a curvilinear skin incision behind the hairline. The skin flap is retracted and a small craniotomy is performed, placed maximally near the skull base. A dura flap is retracted to expose and dissect the Sylvian fissure and to release CSF to slacken the brain. It is suitable for tumors that also have a significant lateral extension. A subfrontal approach provides access to both optic nerves and does not require the dissection of the Sylvian fissure. The view, however, is pretty much restricted to the midline. Self-retaining retractors are used to maintain a corridor of access to the sella and visual pathways. The tumor is resected piece by piece through this corridor. For tumors that extend significantly into the third ventricle or have a large retrosellar component, a trans-lamina terminalis approach could be considered with bifrontal skin incision and a midline craniotomy. This approach is most frequently used for craniopharyngioma, which may extend into the third ventricle. The olfactory nerves need to be gently dissected. For complex tumors, one approach may not be sufficient. Thus, a transsphenoidal approach followed by a transcranial approach is sometimes preferred in two stages to resect such tumors (Buchfelder and Schlaffer, 2009; Couldwell, 2004).

Surgical Results

The goals of surgery for nonfunctioning tumors in the sellar region include the elimination of mass effect, normalization and preservation of endocrinological functions, and ideally total resection. The extent of resection is normally evaluated with pre- and postoperative MRI and used as a measure of surgical results. Pre- and postoperative ophthalmological and endocrinological functions should also be appreciated as surgical results.

Nonfunctioning Pituitary Adenomas

For all tumors, utmost resection should be attempted. However, many NFPAs are usually already large at the time of diagnosis. Over the years of progression, para- and suprasellar regions might be invaded. Invasion into the cavernous sinus and encasement of major arteries are factors that force surgeons to leave some tumor on purpose, which might be treated by irradiation. The evaluation of the extent of resection, the existence of a residual tumor, and the occurrence of recurrence are entirely based on MRI since there are no hormonal tumor markers. There is some controversy in the literature in consideration of the total resection and recurrence rates at 5 or 10 years postoperatively. One study reported that 23 out of 35 patients (66%) who underwent transsphenoidal surgery had residual tumor according to postoperative imaging (Marazuela *et al.*, 1994). Likewise, in another study, 34 out of 51 patients (67%) who underwent transsphenoidal surgery had tumor residuals (Soto-Ares *et al.*, 2002). In contrast, a large individual series reporting the results of 1140 patients with several types of pituitary adenomas who underwent primary transsphenoidal surgery demonstrated a total resection rate of 64.8% in patients with NFPA (Mortini *et al.*, 2005). In respect to long-term results, 98 out of 132 (74.2%) patients who were treated with transsphenoidal surgery had a total resection, and 73 of the 98 total resection patients were followed by serial pituitary imaging without irradiation therapy, showing a 90% recurrence-free survival at 5 years (Bradley *et al.*, 1994). A follow-up study of 65 of the 73 patients from the same cohort showed freedom from recurrence in 82% at 5 years and 56% at 10 years based on life table analysis of nonirradiated patients (Turner *et al.*, 1999). Another study described a 5-year recurrence-free rate of 84.8% and 10-year recurrence-free rate of 49.5% in nonirradiated patients (Park *et al.*, 2004), which was lower than that in the irradiated patients (in these, 5- and 10-year recurrence-free rates were both 97.7%).

Recovery of vision is probably the first sign of a successful decompression achieved through surgery. In a study with 2000 eyes, it was documented that a visual recovery occurred gradually after 3 months postoperatively, and peaked at 6 months to 1 year in patients who had giant adenomas with ophthalmological symptoms for >2 years (Dutta *et al.*, 2016). They reported a 93% improvement of vision at 1 year after pituitary tumor resection in both visual acuity and visual fields.

After removing the tumor and the decompression of the normal pituitary, endocrinological improvements were found in a variable degree of the individual axes. A study from Spain reported that all but one patient who had normal pituitary functions preoperatively retained their functions, while for the patients with preoperative abnormal pituitary function, 46% had improvements of variable degree and 54% had persistent deficits (Marazuela *et al.*, 1994). We previously reported improvement in endocrinological function in 49.7% of the patients who underwent transsphenoidal surgery, whereas 11.3% of the patients who underwent transcranial surgery had at least some recovery of pituitary function (Nomikos *et al.*, 2004).

The outcome is much more associated with tumor characteristics and surgical experience than with the visualization tool utilized for the resection. Moreover, asymptomatic patients with NFPA have better surgical results and the 5-year tumor recurrence rate was found much lower than that of symptomatic patients (Losa *et al.*, 2013). Moreover, patients who were younger at the time of surgery had a higher 5-year recurrence risk than older patients (Losa *et al.*, 2013; Reddy *et al.*, 2011).

Craniopharyngiomas

Craniopharyngiomas are benign tumors with a high tendency to recur, and local recurrences occur mostly within the first 3 years after complete resection. The main controversy in the management for craniopharyngioma is whether radical resection or subtotal resection followed by radiation therapy would be the better choice (Karavitaki *et al.*, 2006; Shi *et al.*, 2008). A realistic chance for tumor excision exists only during primary surgery. An attempt of radical resection is preferred by some neurosurgeons even if the sacrifice of the pituitary stalk and the need of postoperative substitution therapy are unavoidable sequelae. There are three major types of surgeries for craniopharyngioma: transcranial microsurgery, transsphenoidal microsurgery, and transsphenoidal endoscopic surgery. Unlike NFPA, craniopharyngiomas frequently have extra-sellar extensions and intense involvement with the surrounding neurovascular structures and the hypothalamus, and thus, an operation via a transcranial procedure is more frequent than via the transsphenoidal route. As a result, overall severe complications in craniopharyngiomas, such as postoperative visual defects, partial or complete hypopituitarism, hypothalamic dysfunctions, are higher than that in NFPA. Surgical results have been reported with variable outcomes in the literature, but with similar surgical indications and postoperative complications. Transsphenoidal approaches are documented with more efficiency in improving ophthalmological symptoms than transcranial approaches, but with a significantly higher risk of postoperative CSF leak. However, postoperative seizures and permanent diabetes insipidus rate are significantly more frequent than after transsphenoidal approaches. Transsphenoidal endoscopic and microscopic surgeries reveal a similar amount of resection and postoperative complications. The extended endoscopic endonasal approach is popular in some centers, but frequently there are difficulties in the reconstruction of the skull base. A study from China (Shi *et al.*,

2008) reported on an impressively high resection rate of craniopharyngioma using microscopic techniques. They extracted 97% of the tumors with a diameter of up to 6 cm. In recent years, another management strategy is proposed by an initiative from France (Elowe-Gruau *et al.*, 2013), who advocates hypothalamus-sparing surgery (HSS), a maximal resection sparing the optical and hypothalamic structures, for craniopharyngioma especially in children to decrease surgery-related postoperative hypothalamic dysfunctions and to provide a better postoperative quality of life. They reported an 18.5% complete resection rate by the first operation, and 37% of the patients required at least one additional intervention for tumor residuals or recurrences. In contrast, a 60% complete resection rate after the first extensive resection surgery (ERS) was observed (Elowe-Gruau *et al.*, 2013). Interestingly, the body mass index (BMI, indicates the risk of obesity) of patients with HSS was significantly lower after 6 and more months postoperatively than after ERS with no significant difference in the local recurrence rate, and patients who underwent HSS tended to have less postoperative endocrinological deficiencies (Elowe-Gruau *et al.*, 2013; Karavitaki *et al.*, 2006; Mortini *et al.*, 2013).

Complications of Surgery

Transsphenoidal surgery has a lower general risk of complications than transcranial surgery. Permanent diabetes insipidus is more frequent in transcranial approaches, for the direct dissection of the infundibulum. Transient diabetes insipidus usually occurs within 24 h after surgery and abates within several days. Damage to the normal gland might result in long-term hypopituitarism, which requires hormonal substitution therapy. Hypothalamic injury is feared after craniopharyngioma radical resection and results in an uncontrollable gain of weight and behavioral abnormalities. Other complications, such as loss of vision and carotid artery injury, are relatively rare (Mortini *et al.*, 2005). Modern technologies such as neuronavigation or application of the laser Doppler probe allow the surgeon to localize the carotid artery and avoid such injuries. Rhinological complications may cause persistent nasal discomfort after transnasal surgeries. Infection, meningitis, and subarachnoid hemorrhage are other rare but possible complications for both transsphenoidal and transcranial surgeries. Individual reports of selected patient series from experienced surgeons suggest extremely low cumulative complication rates in primary interventions (Mortini *et al.*, 2005). However multicenter studies reveal much higher, countrywide figures. In a recent multicenter analysis of 5886 patients who underwent microsurgical or endoscopic transsphenoidal surgery, the overall cumulative complication rate of transsphenoidal surgery was 40.0%. It was 35.3% with microscopic surgery and 45.8% with endoscopic surgery (Asemota *et al.*, 2017). The most common postoperative complications after transsphenoidal surgery were hypopituitarism (19.1%), particularly diabetes insipidus (16.9%), followed by fluid and electrolyte disorders (11.2%) and postoperative CSF leaks (10.4%). Multivariate regression analysis and propensity score matching showed that endoscopic surgery was more likely to cause diabetes insipidus and postoperative CSF leaks than microscopic surgery (Asemota *et al.*, 2017). Other medical complications, such as acute respiratory failure, deep vein thrombosis, pulmonary embolism, and mortality, were not significantly different in microscopic and endoscopic surgery. The overall complication rate of transsphenoidal surgery increased by 18.5% from 2010 to 2014, while neither the endoscopic-related complication rate nor the microscopic-related complication rate changed over this period. This increase in overall complication might be due to a better recording of complications (Asemota *et al.*, 2017). A convincing relationship between the surgeon's experience, the centers' caseload, and the cumulative complication rate was documented in an analysis based on insurance data in the United States (Barker *et al.*, 2003).

Follow-Up

Regular repeat radiological, ophthalmological, and endocrinological examinations are recommended for nonfunctioning pituitary tumors.

The first endocrinological and ophthalmological testing is usually performed 3–7 days after surgery, and the initial postoperative MRI 3 months after surgery, together with endocrinological and ophthalmological testing. Ophthalmological follow-up is repeated every 6 months until maximal improvement is achieved. The frequency of hormonal follow-up is adapted to the requirements (Chanson *et al.*, 2015). Further radiological follow-up intervals should be 1 year (Chanson *et al.*, 2015). For patients without postoperative residuals, they may be repeated at intervals of 5 years, then at 7, 10, and 15 years after surgery (Chanson *et al.*, 2015). One study reported alarmingly high relapse rates of 23.1%, 46.7%, and 67.9% at 5, 10, and 15 years respectively, and a significant increase in the regrowth rates in patients either with tumor remnants in the first postoperative imaging or a younger age at initial surgery (Reddy *et al.*, 2011). Thus, patients with postoperatively documented or suspected residual tumor should undergo a yearly follow-up MRI for at least 5 years, and then every 2 or 3 years (Chanson *et al.*, 2015). Ideally, life-long follow-up should be performed (Reddy *et al.*, 2011). Irradiation is recommended for those patients who harbor residual tumor to decrease the risk of recurrence (Park *et al.*, 2004). After irradiation, ophthalmological follow-up in yearly and hormonal follow-up in 6 monthly intervals should be continued (Chanson *et al.*, 2015). Symptomatic recurrences should be submitted to further surgical management or irradiation.

For asymptomatic adenomas that do not reach criteria for surgical resection, follow-up with pituitary MRI and endocrinological screening is recommended over many years (Chanson *et al.*, 2015; Freda *et al.*, 2011).

Modern Advances

New Technology

Endoscope

The development of the endoscope and its introduction into pituitary surgery provided surgeons with a closer view and better illumination in the deep-seated pituitary region. With an endoscope, the "eye" of the surgeon is virtually introduced close to the sellar floor or tumor cavity, whereas the lens of the microscope remains far outside and the surgeon's view is restricted by the straight beam of light. It is feasible for both transsphenoidal and transcranial approaches. Various angled lenses are available for endoscopes that allow the surgeons to have a more panoramic and lateral visualization. It can be combined with the microscope to compensate its visual limits, or the surgery can be conducted purely by using the endoscope. The advantages of endoscopic transsphenoidal surgery are avoidance of a septal dissection, a nasal speculum, and of postoperative tamponades, as well as better visualization. However, the insertion of the endoscope may take valuable space when micro instruments must be manipulated through the corridor (Buchfelder and Schlaffer, 2016b). Thus, some surgeons use both nasal cavities for this procedure and the endoscope will be held by an assistant. Most of the endoscopes do not offer three-dimensional (3D) views, and endoscopic surgery requires special training. Experience with endoscopic surgery is quite crucial because the surgical orientation is different from conventional microsurgery. Many series reported a longer duration of endoscopic surgery than microsurgery, the results of endoscopic surgery are comparable to conventional microsurgery (Mortini, 2014).

Intraoperative MRI

A surgical room with access to MRI allows the acquisition of MRI during a surgical procedure. Mostly, the surgery is interrupted and an MRI scan is performed when the surgeon estimates that he has achieved satisfactory tumor resection. This intraoperative MRI reveals the extent of tumor excision, and in case of a residual lesion, guides re-resection. Numerous data from different countries have shown that intraoperative MRI has the advantage of improving the extent of resection, and increase the proportion of complete excisions. This intraoperative feedback can certainly speed up the learning curve of young surgeons with little experience in this region. High-field MR systems (≥ 1.5 T) have a better resolution and allow a better depiction of the parasellar space in comparison to the low-field system (≤ 0.5 T). However, the measurement during a surgical procedure is time-consuming. Moreover, the tumor cavity can be filled with blood, fluid, and hemostasis material, and it is sometimes difficult to interpret the intraoperative situation (Buchfelder and Schlaffer, 2012, 2016a). Although 1.5 T and 3 T intraoperative systems are commonly available, the cost of the system restricts the general use of this technology. In addition, the interpretation of intraoperative imaging should always refer to surgical conditions, rather than simple radiological manifestation.

Neuronavigation

Neuronavigation utilizes preoperative MRI and/or CT to guide the surgery in a 3D anatomical orientation. This is extremely helpful in patients with incomplete or lacking pneumatization of the sphenoid sinus and during reoperations. The recognition of the midline is crucial in transsphenoidal surgery. A proper opening on the sellar floor avoids complications. Crucial structures are generated with computer software based on preoperative imaging, and the navigation system superimposes these contours into the real surgical field. Although it cannot directly depict tumor residuals like intraoperative MRI, it increases the comfort of the surgeon and the safety of the patient. No brain shift is expected at the level of the skull base. Thus, the location provided by the navigation system can be trusted, particularly during transsphenoidal surgery (Buchfelder and Schlaffer, 2016b).

Ultrasound and Doppler system

Pituitary adenomas are mostly hyperechoic masses in ultrasound images. Ram and coworkers described that ultrasound allowed visualizing the interface between tumor and normal pituitary gland and enabled depiction of small tumors (Ram *et al.*, 1999). However, the inconsistency of findings, the low resolution, and the prerequisite for specialized ultrasound skills made ultrasound less popular in the recent years. Doppler systems are commonly used to localize the carotid arteries at the level of the sellar floor (Buchfelder and Schlaffer, 2016b). They are extremely helpful in reducing the risk of damaging the carotid arteries, especially when the tumor infiltrates the cavernous sinus (Solheim *et al.*, 2010).

Conclusions

Transsphenoidal surgery to date is the established procedure of the first choice for pituitary tumor resection. Transcranial surgery has advantages in tumor with extensive extrasellar components. Endoscopic surgery is becoming more popular, but as yet no improved resection rate or reduction of complications has been documented when compared with microscopic surgery. Intraoperative MRI and navigation increase the safety of the procedure and the rate of maximal resections, especially in complicated cases. Serial imaging, endocrinological testing, and assessment of vision can be used to evaluate the surgical results, as well as to detect tumor recurrence. Residual and recurrent tumor can be either observed or treated with secondary surgery or irradiation, depending on the patient's condition.

Introduction

Various modalities can be employed in the treatment of patients with secreting or nonsecreting pituitary adenomas, including medical treatment, surgical intervention, or either radiotherapy or radiosurgery. Concerning these latter two modalities, it is however, sometimes difficult to distinguish between different patient profiles that may benefit from such treatments. The principles of radiotherapy and radiosurgery being different, it is valid to consider each of them individually rather than in opposition: their patient profile as a general rule is different and each modality has a place in the treatment of pituitary adenomas. The aim of this article is to clarify the respective indications for each modality, their advantages and disadvantages in terms of their antisecretory and antitumoral effects, as well as their patient tolerance, and to better define whether radiotherapy and radiosurgery maintain a place in therapeutic plans for pituitary adenomas in the 21st century.

The Different Modalities of Radiotherapy

The general principle of radiotherapy is the delivery of radiation in a concentrated manner to a defined zone, termed the target zone. There are several radiotherapy modalities available, which vary in the way that they deliver the radiation to the tissue or in the precision with which they strike the target zone. So-called conventional radiotherapy is in general delivered in fractionated doses from 160 to 200 centiGray (cGy), four to five times per week for a total duration of 5–6 weeks (giving a total dose of 45–50 Gy). This modality of radiotherapy has seen major improvements over the last 10 years including better techniques for visualization of the target or for immobilization of the head (Minniti *et al.*, 2009). The risk of side effects is correlated with the total radiation dose and the dose delivered by fraction. Fractionated radiotherapy can be delivered via a noninvasive, repositionable stereotactic frame to improve the precision of target definition: this is termed fractionated stereotactic radiotherapy, for which the total dose of radiation delivered is the same (in the order of 45–50 Gy). The aim of destroying the target zone is achieved due to the phenomenon of cellular DNA damage and repair. DNA damage that is induced by the procedure is repaired in healthy cells more so than in tumoral cells, this being possible due to the fractionation of the total dose. Classically, fractionated radiotherapy is contrasted with stereotactic radiosurgery, in which the total radiation dose is delivered in a single session using a stereotactic frame. One such modality is Gamma Knife (GK) radiosurgery in which gamma radiation is delivered by 201 sources of Cobalt-60 with an isodose 50 in the order of 20–30 Gy. Other modalities are possible using a linear accelerator (LINAC), which delivers photons. These intervention methods theoretically allow the target zone to be irradiated while sparing surrounding or peripheral healthy tissue. In contrast to radiotherapy, the goal here is focused on destruction of the target rather than the greater capacity for recovery in healthy cells compared to tumor cells. Lastly, the Cyberknife is a LINAC which allows stereotactic radiotherapy without a frame, thanks to a robotic arm and real-time analysis of information that means the target can be followed during movement. In each endocrine pathology, we will outline the principal published data in relation to the modality (radiotherapy, radiosurgery) by which radiation is delivered. As the majority of published studies on radiosurgery are based on GK surgery, we will limit our analysis to these data. It should be noted that studies on other modalities, though fewer, have reported similar values for efficacy and side effects to those for GK.

Three criteria need to be specified when evaluating a radiotherapy or radiosurgery treatment:

- Antisecretory efficacy, which needs to be defined in the absence of any other antisecretory treatment. This parameter needs to take into account the delay required for obtaining maximal efficacy: after therapy, hormone levels will progressively fall until they reach a plateau phase. This delay varies depending on the modality used and thus means that an efficient antisecretory treatment must be used in the interim. In studies published to date, this delay is often overestimated due to the lack of regular withdrawal of antisecretory treatment.
- Antitumoral efficacy, which consists of stabilization or reduction of tumor volume.
- Pituitary and extra-pituitary side effects, which are generally observed and in some cases appear several years after the procedure.

Antisecretory Efficacy

Conventional Radiotherapy

Overall, the results with conventional radiotherapy are similar regardless of the type of hypersecretion. However, the values for remission vary over time and depending on the study, either because of stricter criteria for remission or because of shorter or longer

periods of patient monitoring. Thus for acromegaly, the majority of studies published prior to 1997–2000 report totals for remission of 80%–100%, based solely on mean growth hormone (GH) levels, without taking into account IGF-1 levels. The first study to evaluate both parameters was published in 1997, and reported normalization in only 5% of cases. However, this study has been the subject of much criticism due to the small number of patients who had prolonged monitoring (mean of 5 years), the major variability between patients in terms of the radiation techniques used and variability in dose, and multicenter modalities of treatment (Barkan *et al.*, 1997). A single study that was published since found similar results with 10% of patients normalized during 10 years of follow-up (Cozzi *et al.*, 2001). The largest published study to date, on 884 patients, found 60% of patients in remission after a mean duration of monitoring of 10 years, in agreement with the majority of studies published since 1997 (remission showing a spread of values between 35% and 76% of cases with a mean follow-up of 10 years) (Jenkins *et al.*, 2006). No cases of later relapse were reported after conventional radiotherapy. Results are comparable in Cushing's disease (53%–82% rates of remission, depending on the study) (Losa *et al.*, 2010). It is much more difficult to show such data in the case of prolactinoma, since in this setting, radiotherapy is rarely considered a therapeutic option. The few published studies on the subject report comparable values for remission.

The principle limiting factor with conventional radiotherapy is the delay before obtaining maximal efficacy, in the order of 5–10 years, though some studies have reported a maximal antisecretory effect up to 20 years after radiotherapy. There is a progressive decrease in hormone levels until a plateau is reached. This delay in obtaining eventual remission means that effective antisecretory treatment is necessary during the intervening period. Equally, it explains that the principal predictive factor for remission is the initial hormone level: even very high initial levels can be controlled by radiotherapy, but after a consequently longer period of time.

Radiosurgery

In the case of radiosurgery, as for radiotherapy, antisecretory efficacy is generally comparable regardless of the type of hypersecretion, being approximately 50%. In acromegaly, published studies report antisecretory efficacy for GK surgery in 17%–100% of cases. As with radiotherapy, this high degree of variability can be explained in the main by the use of different remission criteria: for example in the case of acromegaly, more recent studies that have used strict remission criteria have reported figures for remission in the order of 40%–50% (Castinetti *et al.*, 2010; Lee *et al.*, 2014; Pollock *et al.*, 2008a; Ronchi *et al.*, 2009). In addition to the 50% with remission, around 20% of patients should be added who were uncontrolled prior to the procedure and are perfectly controlled by administration of antisecretory drugs after the procedure (the reduced hormone levels allowing control of the hypersecretion). The number of studies on Cushing's disease is smaller, probably due to the large number of relapses in patients in whom a residual mass is not seen by MRI, and thus lack a target for further radiosurgery: the number of remissions reported varies between 10% and 83% of cases (Castinetti *et al.*, 2009; Jagannathan *et al.*, 2007; Sheehan *et al.*, 2013b). However, the higher numbers for remission correspond to older studies, where evaluation of the target was by CT scan rather than MRI: the efficacy is increased since the target is defined more approximately, at the cost of panhypopituitarism in the majority of cases (radiosurgery being similar in this case to conventional radiotherapy). Recently, the first large international multicenter retrospective study on the outcome of patients treated by radiosurgery for Cushing's disease was reported: out of 278 patients, cumulative control of hypercortisolism was obtained in 80% at 10-year follow-up. Such results should however be toned down by the fact that 11% of these patients were controlled by medical treatments at last follow-up (while they were not before GKS), and that 18% recurrences were observed on a long-term basis (Mehta *et al.*, 2017). This means that GKS allowed cure in 50% of the 278 patients treated after a mean follow-up of 5 years. The time to obtain remission was shorter than usually expected, roughly a year (14.5 months). The total for remission after GK surgery for prolactinoma ranges from 15% to 100% of cases (Landolt and Lomax, 2000; Pouratian *et al.*, 2006). As for radiotherapy, the precise place for radiosurgery in this type of adenoma is probably fairly limited: the majority of studies reporting on small numbers of subjects. A single group has reported on their experience with a large cohort of 128 patients; however, the low efficacy reported in this study (15%) suggests that some indications for GK were poorly evaluated (Pan *et al.*, 2000).

The principal predictive factor is the preradiosurgery hormone level (Castinetti *et al.*, 2010). The main limitation of radiosurgery is, as for radiotherapy, the existence of a delay between the procedure and the plateau of antisecretory efficacy. This delay period is of the order of 18–36 months, and thus requires the use of drug treatment during this time to control hypersecretion. This also limits the use of GK surgery which cannot be used in the case of massive hypersecretion, which requires rapid, efficient treatment. This more rapid efficacy (compared to radiotherapy) is obviously counterbalanced by a reduced overall antisecretory efficacy (50 vs. 60%–80%). Therefore, the ideal profile of patients who could benefit from radiosurgery needs to be defined, the classical criteria being a target of small volume that is well defined and not highly secretory. However, somewhat surprisingly, the target volume and the dose delivered to the target have been inconsistently reported to be predictive factors. Contradictory data have been reported on administration of somatostatinergic and dopaminergic drugs having a radio-protective effect, when taken during radiosurgery. It was hypothesized that in reducing the proliferation rate of the adenoma these treatments may reduce the efficacy of the radiosurgery (Landolt *et al.*, 1998; Landolt and Lomax, 2000). Only two of seven major long-term follow-up studies reported a deleterious effect in subjects with acromegaly, and this effect has not been reported in any studies of prolactinoma (Castinetti *et al.*, 2010). Even if it seems improbable that such an effect exists, we feel that it may be useful to stop antisecretory treatments 1–3 months before radiosurgery with the aim of knowing initial hormone levels after withdrawal of treatment since

this constitutes a predictive factor for remission. Lastly, a crucial difference compared to radiotherapy is the possibility of late relapse, three studies have reported on cases of relapse in 10%–20% patients suffering from Cushing's disease, 12–60 months after radiosurgery efficacy (Castinetti *et al.*, 2009; Mehta *et al.*, 2017; Sheehan *et al.*, 2013b). Taking into consideration the plateau of efficacy that is reached very late, prolonged surveillance, including after remission, is justified by the possibility of late relapse. The explanation for this phenomenon is unclear, but needs to be compared with the possibility of relapse after surgery for Cushing's disease which can occur even where the neurosurgeon believes that they have completely excised the tumor.

Antitumor Efficacy

Antitumor efficacy is a crucial point in the case of residual nonsecretory adenomas, where the aim is to stabilize or indeed reduce the volume of residual tissue. Antitumoral efficacy is similar for all techniques. For radiosurgery, the theoretical dose for antitumoral control is lower than the dose necessary for antisecretory efficacy, thus exposing less healthy pituitary tissue to radiation toxicity. Stabilization or a reduction in tumor volume was observed in 70%–100% of cases. However, there are no detailed studies of tumor volume in patients monitored long term who were treated by radiotherapy or radiosurgery in the setting of nonsecreting pituitary adenomas. Given the very slow evolution of these adenomas, it is possible that some may increase in size despite treatment by radiotherapy or radiosurgery. One theory that is still under discussion is the possible eventual transformation of an adenoma that was treated several years before by radiotherapy, into a carcinoma. To date, there are no data that support this hypothesis and additionally the exact mechanisms by which an adenoma may transform into a carcinoma are not completely understood. The antitumoral effect is rapid, appearing in the first year after treatment by GK surgery (Chen *et al.*, 2013; Sheehan *et al.*, 2013a). A large follow-up study reported on the outcomes of 62 patients treated by GK after incomplete surgery on a nonsecretory adenoma, who were then monitored for more than 5 years. The tumoral volume decreased in 60% of cases and was stabilized in 37% of cases, while only two patients presented an increase in tumor volume despite the radiosurgery procedure (Pollock *et al.*, 2008b). In the short term, there is likely edema with inflammation postradiosurgery. MRI data from a short time after the procedure is lacking, but one study has reported a transient increase in volume immediately after the procedure, probably due to a transient edema.

Side Effects

All of the studies reporting side effects of radiotherapy are based on very long surveillance of patients who were treated using modalities of radiotherapy that have since been greatly modernized (Brummelman *et al.*, 2011). Therefore it is difficult to determine if these "classic" side effects are still present in patients that are currently treated with conformal radiotherapy (rather than conventional radiotherapy). There are numerous side effects of conventional radiotherapy and their risk increases proportionally with the time elapsed since the radiotherapy. These side effects include an increased risk of hypopituitarism (estimated at 25%–80% of treated patients), vascular effects, radiation-induced tumors, and cognitive problems. The cerebrovascular effects of conventional radiotherapy are well known, with an increased risk of stroke, $3\times$ greater compared to the general population, in patients who have undergone conventional radiotherapy of more than 50 Gy, and $1.7\times$ greater for those receiving doses of 45–50 Gy. This risk of stroke is also increased with the duration of hypopituitarism in these patients (Ayuk, 2012). The risk of radiation induced optic neuropathy is estimated to be around 5% in subjects treated with conventional radiotherapy. Lastly, in studies on conventional radiotherapy, the risk of radiation induced tumors has been estimated to be low (Burman *et al.*, 2017). However, these tumors can occur after a long delay, estimated at 7–24 years after conventional radiotherapy.

In the case of radiosurgery, side effects, in particular late side effects are difficult to evaluate since the majority of studies have had a mean follow-up of <5 years. A single study reported results from 20-year follow-up, but was based on CT scan and not on MRI imaging of the target (this poor definition of the target resulting in panhypopituitarism in the majority of patients) (Hoybye *et al.*, 2001). Current studies underline that the principal risk of radiosurgery is the occurrence of panhypopituitarism which affects around 20% of patients (Castinetti *et al.*, 2010; Marek *et al.*, 2011). This risk increases with (i) time elapsed since radiosurgery; (ii) radiosurgery subsequent to surgery or radiotherapy (possibly due to increased fragility of the tissue), and (iii) with dose. In general it is also correlated with efficacy (the studies showing the highest rates of remission also show the highest levels of hypopituitarism). As outlined earlier, the initial definition of the target is fundamentally important in diminishing the risk of side effects. Older studies have reported a high risk of optic neuropathy, with this risk being low if the distance between the target and the optic chiasm (>5 mm) and the dose at the optic chiasm (<8–10 Gy) are adhered to. A review described the occurrence of optic neuritis and cranial (oculomotor, trochlear, trigeminal) neuritis in around 1% of patients treated with GK surgery for pituitary adenoma, with half of these cases being regressive (Leavitt *et al.*, 2013). Lastly, intense headaches are classically reported in the 48 h after radiosurgery, with these generally being well controlled by administration of level 1 or 2 analgesics.

Other potential side effects (radiation-induced tumors, cognitive deficits, vascular abnormalities), are unlikely due to the improved definition of the procedure (more targeted), and have not been described to date in the treatment of pituitary adenoma (Muracciole and Regis, 2008). A review has described the occurrence of cerebral necrosis or inflammation (hypothalamic or temporal) in 13 cases out of 1567 patients, on average 1 year after radiosurgery (though six of these patients had prior treatment with conventional radiotherapy) (Brada *et al.*, 2004). However, as with radiotherapy, it is likely that these effects, if they occur, will

occur late. Therefore, studies with very long surveillance of patients need to be performed to definitively assess the safety of radiosurgery. Similarly, studies with very long surveillance of patients treated with conformal radiotherapy will be required to show if technical progress in radiotherapy results in a reduction in the number of complications, particularly extra-pituitary complications.

The Place of Radiotherapy and Radiosurgery in Treatment of Pituitary Adenoma

Are the principle reasons for which patients were treated by radiotherapy 20 years ago or by radiosurgery since the start of 2000, still the same? The last 20 years have seen the development of multiple antisecretory treatments for acromegaly, Cushing's disease, and prolactinoma. These treatments have shown variable degrees of efficacy (in the order of 30%–50% control for somatostatinergics and 60%–80% for GH receptor antagonists in acromegaly; in the order of 50% for the main anticortisol drugs in Cushing's disease; and around 80% for dopaminergics in the treatment of hyperprolactinemias) and have shown good patient tolerance. If the role of radiotherapy in treatment of prolactinoma has always seemed to be an accessory one (and more so since dopaminergic drugs are very efficient), this question remains current in acromegaly and Cushing's disease for at least two reasons: the first being that the number of patients controlled by antisecretory treatment is at best equivalent to that for radiosurgery, and at least 50% of patients treated with drugs are not controlled; the second is that radiotherapy or radiosurgery may result in cure of the pathology, whereas antisecretory treatments may control hypersecretion via a lifetime of treatment. In the current conditions of reducing the load on our health systems, it is valid to suggest radiotherapy or radiosurgery for those patients with a profile suitable to achieve the best outcome: small tumor volume (for radiosurgery), low level of hypersecretion and absence of risk of major side effects (for example sufficient distance from optic tracts, in the case of radiosurgery). If the model of surgery as first-line treatment remains logical for acromegaly and Cushing's disease, and antisecretory treatments remain crucial for treatment of patients where surgery is not possible or contraindicated, then radiotherapy and radiosurgery maintain a role in the treatment of secretory pituitary adenomas, particularly as new modalities of treatment will drastically reduce the risk of side effects, particularly extra-pituitary side effects. In this setting, even though indications are rare, we have reported efficacy of radiosurgery as first-line treatment (in cases of refusal or contraindication for surgery, intolerance of drug treatments). We have described treatment of 13 patients, who underwent first-line treatment with radiosurgery and were monitored for >60 months, who had values for remission that were comparable, being approximately 50%.

The discussion is different for treatment of nonsecretory adenomas, where no drug treatment is available. Here surgery remains the first-line treatment in the case of increased tumor volume. Radiotherapy or radiosurgery can be considered when there is persistence of and an increase in volume of residual tumor. Because of the rapid antitumoral efficacy of the procedure, and assuming a sufficient distance from the optic chiasm, these treatments can be considered after surgery without great urgency: studies with long follow-up report an increase in volume of residual tumor, postsurgery, in around 20% of cases. Systematic radiotherapy after incomplete surgery for a nonsecretory adenoma is no longer indicated except in cases where there is a large amount of residual tumor that is inaccessible for further surgery. One last point is the problem of occurrence of Nelson syndrome after bilateral adrenalectomy for Cushing's disease. The objective here is to limit possible expansion of the tumor rather than secretory level. Systematic radiotherapy was, for a long time, recommended in this case. More precise studies now allow better characterization of this phenomenon and the patients at risk so that radiotherapy no longer needs to be performed systematically in these patients. In all of these cases (nonsecretory adenomas, Nelson syndrome) surveillance by MRI is indispensable when deciding on the potential usefulness of radiotherapy or radiosurgery.

Perspectives and Conclusions

It is difficult to determine whether treatment for pituitary adenoma in the future will use radiotherapy and radiosurgery. Pharmacological advances may lead to the percentage of patients being controlled by a combination of surgery/drug treatments being close to 100% (compared to a value currently in the order of 80%). The lack of perfect treatments at the moment, however, means it is almost mandatory that some patients are treated with all available treatment modalities. Improvements in drug treatments will in any case go together with improvements in radiotherapy and radiosurgery techniques. Assuming equal efficacy, and conditional on a reduction in late side effects, economic criteria mean that the use of radiotherapy or radiosurgery will likely continue with a view of curing young patients and avoiding a lifetime of drug treatment. However, for young patients, more than any other age group, the safety of modern techniques of radiotherapy and radiosurgery needs to be formally demonstrated. Research to better characterize the theoretical risk of late side effects, particularly for radiosurgery, is currently ongoing.

Diagnosis and Clinical Management of Aggressive Pituitary Tumors

Gerald Raverot, Emmanuel Jouanneau, and Jacqueline Trouillas, Groupement Hospitalier Est, Bron, France

Introduction

Pituitary neuroendocrine tumors (PitNETs) are the most common intracranial neoplasms, affecting 1/1000 of the worldwide population (Daly *et al.*, 2007; Fernandez *et al.*, 2010). PitNETs are largely benign tumors. However, tumor growth occurred in about half of the nonoperated nonfunctioning PitNET macroadenomas followed up for a period of 5–10 years (Dekkers *et al.*, 2007; Karavitaki *et al.*, 2007). Recent evidence suggests that while metastasis is rare (Heaney, 2014), the benign status of PitNETs requires revision. Indeed, a small subset of pituitary tumors are defined as aggressive pituitary tumors, based on their resistance to medical treatment and multiple recurrences despite standard therapies combining surgical, medical, and radiation therapy treatment approaches. The identification of this group of aggressive pituitary tumors is of major clinical importance, as they are associated with an elevated morbidity and mortality despite the absence of metastasis (Lasolle *et al.*, 2017; Losa *et al.*, 2016). Pituitary carcinoma, defined by the presence of systemic metastasis, occurs in the setting of an initially aggressive pituitary tumor. Management of these tumors is based on optimizing conventional medical treatment, in combination with radiation therapy in some instances. Use of temozolomide resulted in a good response rate when conventional treatment (including chemotherapy in the case of pituitary carcinomas) had failed to control tumor growth (Lasolle *et al.*, 2017).

Clinical Markers of Aggressiveness

The WHO 2004 classification proposed the term "atypical" pituitary tumors following the identification of potential pathological prognostic markers. The term "atypical" tumor is not synonymous with "aggressive" tumor. It is a pathological term whose prognostic value has not been evaluated in a prospective study. As it is presented in a specific chapter, we will not discuss this pathological classification here. However, we would emphasize that a prognostic classification of PitNETs allowing early identification of aggressive pituitary tumors would be of great importance in personalizing therapeutic strategies (Raverot *et al.*, 2017; Trouillas *et al.*, 2013). In a recent prospective study, we demonstrated that around 10% of PitNETs were classified as having a high risk of recurrence or progression within three years based on the pathological classification (Raverot *et al.*, 2017).

The definition of an aggressive PitNET is based on clinical characteristics and behavior during the follow-up period. Aggressive PitNETs are usually large and radiologically confirmed invasive tumors with an unusually rapid growth rate, and/or clinically relevant tumor growth or recurrence, despite optimal standard therapies.

Tumor Size: Giant Tumors

Recent surgical studies (Dallapiazza *et al.*, 2015; Raverot *et al.*, 2017) demonstrate that tumor size does not significantly impact surgical outcomes thanks to the development of new surgical procedures. Transsphenoidal endoscopy allows large tumor resection and, in some instances, for example when combined with a transcranial approach for giant PitNETs with large suprasellar extensions, is able to remove almost all, if not all, of the tumor (**Fig. 1**). Moreover, giant prolactinomas, which are usually invasive, respond reasonably well to medical treatment (**Fig. 2**). As for all prolactinomas, dopamine agonists are the first-line treatment and result in rapid alleviation of neurologic symptoms in the majority of cases, and a significant reduction in tumor size and prolactin normalization in three-quarters of patients (Maiter and Delgrange, 2014).

Invasion

Parasellar invasion into the cavernous sinus structures is the most common reason for incomplete tumor removal. There is a good correlation between radiological and surgical (via endoscopic judgment) classification of the parasellar growth of tumors (Micko *et al.*, 2015). Cavernous sinus invasion is graded from grade 1 to 4, with grade 4 being encasement of the internal carotid artery (**Fig. 3**A). Grading of tumor growth into the cavernous sinus could potentially identify different outcomes. Invasion of the cavernous sinus is associated with a high risk of residual tumor and is predicative of future tumor progression or recurrence (Cortet-Rudelli *et al.*, 2015; Monsalves *et al.*, 2014). It is significantly associated with recurrence (HR: 2.98, 95%CI: 1.89–4.70) (Raverot *et al.*, 2017). Progression of postoperative residual tumors occurred in 30%–60% of patients compared to recurrence in 10% of patients in the absence of tumor remnants after a long follow-up period (Dallapiazza *et al.*, 2015; Tampourlou *et al.*, 2017). However, invasion alone is not a synonym for PitNET aggressiveness, and not all invasive PitNETs are associated with recurrence (Chatzellis *et al.*, 2015; Raverot *et al.*, 2017).

Sagittal T1 (A) and T2 coronal (B) MRI view before cabergoline treatment, sagittal T1 (C) and coronal T2 (D) demonstrating massive tumor shrinkage associated with rapid prolactin decrease after six months of cabergoline (0.25 µg/day) (E).

Growth Rate

Aggressive tumors recur more frequently and earlier. One study suggests that the preoperative growth rate is associated with age, suprasellar growth, and the presence of a cyst/hemorrhage (Monsalves *et al.*, 2014). This study calculated a preoperative tumor volume doubling time (VDT) of 1147 ± 870 days (range 60–3478 days). For patients with a residual tumor, there was no

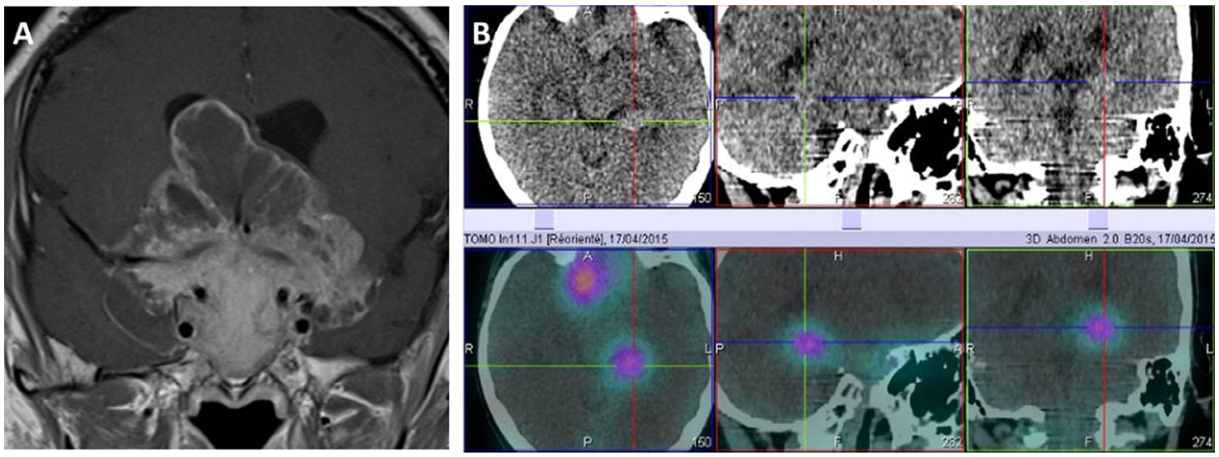

Fig. 3 A giant silent corticotroph tumor encompassing both cavernous sinuses, coronal T1 view after gadolinium (A). 111In-DTPA-octreotide scintigraphy imaging demonstrating high uptake in the sella and in brain metastatic deposits in the presence of a growth hormone-secreting pituitary carcinoma (B).

difference in the postoperative VDT compared to the preoperative (Monsalves *et al.*, 2014). However, the preoperative growth rate of PitNET is rarely known and is difficult to estimate in the absence of multiple MRI scans. In the absence of preoperative information on tumor growth, close postoperative follow-up is mandatory to identify PitNETs associated with rapid growth. Ratnasingam *et al.* suggest that the postoperative growth rate of nonfunctioning PitNETs in the first three years of imaging is the best marker to identify potentially aggressive tumors, and can be used to tailor long-term follow-up to optimize the use of health resources (Ratnasingam *et al.*, 2017). The progression rate of PitNETs is difficult to estimate, and growth kinetics can be described either by an exponential growth model or by a logistic model with initial exponential growth followed by deceleration of growth (Honegger *et al.*, 2008). Some PitNETs exhibit slow growth and necessitate a long observation time; others are more aggressive and invade the neighboring structures, thereby requiring rapid neurosurgical intervention to prevent long-term impairment on the visual field or pituitary deficiency. Moreover, recurrent tumors are more prone to regrowth during follow-up. A study of 90 patients with recurrent tumors determined a 5-year second regrowth rate of 35.3%; the probability of regrowth was influenced by the regrowth management approach (Tampourlou *et al.*, 2017).

Pituitary Carcinomas

Until recently, there has been limited data on pituitary carcinomas. A review from Dudziak *et al.* published in 2011 identified 132 cases without gender predilection. The mean age at diagnosis was 40 years, with a latency of 89 months between initial diagnosis and occurrence of distant metastasis. In this review, all pituitary carcinomas evolved from invasive macroadenoma, and, in most cases, had proliferative features. To our knowledge, there are no reports of de novo pituitary carcinomas revealed by the presence of metastasis at diagnosis.

Since 2006, >50 pituitary carcinomas have been reported in published case reports or in small and large studies of pituitary tumors treated with temozolomide, suggesting that pituitary carcinomas may be more common than initially thought. In patients with aggressive pituitary tumors, where site-specific symptoms occur (neck/back pain, neurological complaints), or where there are discordant biochemical and radiological findings, screening for metastatic disease is recommended. Appropriate structural (MRI or CT) and/or functional (FDG- and/or SSTR-PET) (**Fig. 3**B) imaging may be considered. Pituitary carcinomas disseminate via lymphatic, hematologic, and craniospinal spread, and range from a single lesion to widespread dissemination.

Lactotroph and corticotroph carcinomas are the most commonly encountered subtypes, representing 36% and 30%, respectively, of published cases (Dudziak *et al.*, 2011) and together representing around 80% of patients treated with temozolomide reported in the literature. These two subtypes seem more likely to behave aggressively. Lactotroph tumors are expected to be more frequently observed, as they represent the most common subtype in the general population. However, this is not the case for corticotroph tumors, which represent <15% of all pituitary tumors, and most of these are microadenomas. Special attention should be given to "silent" ACTH tumors, which are very common in corticotroph tumor population. "Silent" ACTH tumors are ACTH tumors without Cushing's disease. These tumors express ACTH or other peptide products of the pro-opiomelanocortin gene (*POMC*) (Trouillas *et al.*, 1984). Despite the absence of clinical and biochemical signs of hypercorticism, elevated plasma ACTH levels can resemble those found in cases of macroadenoma with Cushing's disease (Raverot *et al.*, 2010b), and a number of patients with "silent" ACTH tumors may present with clinical symptoms of Cushing's disease at some stage during disease evolution (Cooper and Melmed, 2012; Raverot *et al.*, 2010b). A phenotype change from a "silent" to a "secreting" tumor should be considered a marker of aggressiveness and a risk factor for malignancy (Bradley *et al.*, 2003; Jouanneau *et al.*, 2012). Indeed, most reported ACTH carcinomas were classified as "silent" ACTH tumors at diagnosis (Dudziak *et al.*, 2011; Heaney, 2011).

Resistance to Medical Treatment

A distinction should be made between resistance to treatment and an absence of secretion normalization. Moreover, a discrepancy between hormonal and tumor response has been noted in some instances. Numerous therapeutic options are available to control tumor secretion or the hormonal effect; however, few treatments are able to induce tumor shrinkage or control tumor growth.

In somatotroph PitNETs, treatment with somatostatin analogs is considered the cornerstone of currently available treatment options. First-generation somatostatin analogs (lanreotide, octreotide) act on the somatostatin receptor (sst), predominantly on sst2, and can normalize levels of insulin-like growth factor 1 (IGF1) and reduce growth hormone levels to <2.5 μg/L in about 20%–40% of cases (Caron *et al.*, 2014; Colao *et al.*, 2014), while second-generation analogs (pasireotide), acting on sst1–3 and particularly sst5, achieve biochemical control in 15%–20% of patients who had inadequate control with first-generation somatostatin analogs (Gadelha *et al.*, 2014). More importantly, treatment with somatostatin analogs achieves $\geq$20% tumor volume reduction in 70%–85% of patients, with the maximal decrease occurring within the first 6 months of treatment (Caron *et al.*, 2014; Colao *et al.*, 2016). Despite the absence of tumor shrinkage in a high proportion of patients during treatment with somatostatin analogs, an increase in tumor volume is rarely observed (1%–2% patients) (Freda *et al.*, 2005). Such tumor growth during somatostatin analog treatment is considered a sign of aggressiveness. In the presence of biochemical resistance without evident tumor reduction (volume increase or $<$20% volume reduction compared with baseline) or when tumor regrowth is observed, somatostatin analogs should not be continued and alternative therapies should be considered. Although dopamine is reported to normalize IGF1, its effect on tumor growth still requires evaluation (Kuhn and Chanson, 2017).

Cabergoline, a dopamine agonist, is the most effective and the best-tolerated drug for the treatment of lactotroph PitNETs (Colao and Savastano, 2011). For doses of cabergoline up to 3.5 mg/week, complete resistance, defined as a failure to normalize prolactin and a $<$50% decrease in size, occurs in $<$10% of these tumors (Delgrange *et al.*, 2009). In addition, higher doses of cabergoline (up to 11 mg/week) successfully treated patients in one study (Ono *et al.*, 2008).

Data on the antitumoral effect of pasireotide monotherapy on corticotroph PitNETs are very limited (Colao *et al.*, 2012). The rare thyrotroph PitNETs are well controlled by somatostatin analogs (Amlashi and Tritos, 2016). There is currently no treatment available for gonadotroph or immunonegative PitNETs (Raverot *et al.*, 2014).

Radiation Therapy

Fractionated radiation therapy, γ-knife radiosurgery, proton-beam radiosurgery, and linear accelerator radiosurgery should be discussed when surgery fails to cure a patient in cases of recurrent tumors or tumors with pathological markers of aggressiveness (Cortet-Rudelli *et al.*, 2015; Ding *et al.*, 2014). Most studies showed a significant improvement in the nonrecurrence rates at five years for functioning (Ding *et al.*, 2014) and nonfunctioning tumors following the use of radiation therapy; postoperative radiation therapy is the only factor that limits the risk of recurrence in recurrent tumors (Cortet-Rudelli *et al.*, 2015; Tampourlou *et al.*, 2017).

Radiation therapy, irrespective of the technique, is associated with an increased risk of hypopituitarism, radiation-induced cerebral tumors, and cognitive disorders, and may also increase vascular risk (Cortet-Rudelli *et al.*, 2015). Indications for radiation therapy should take account of risk factors for regrowth, patient age and history, and any hypopituitarism. In most cases, regular surveillance can be the first-line approach, with treatment postponed until the residual tumor progresses and/or becomes threatening. Postoperative adjuvant radiation therapy should be considered in the setting of a clinically relevant invasive tumor remnant with pathological markers (high Ki67/high mitosis count/p53-positive tumor). Radiation therapy is also recommended for patients with clinically relevant tumor growth despite surgery in nonfunctioning tumors, or despite surgery and standard medical treatment in functioning tumors. In these cases, the risk of hypopituitarism is not a major problem.

Chemotherapies

Systemic chemotherapy is indicated when conventional therapeutic modalities fail, or in the presence of metastasis confirming the diagnosis of pituitary carcinoma. Several therapeutic regimens have been used in the past (procarbazine-etoposide-lomustine; cyclo-hexyl-chloroethyl-nitrosourea; and lomustine-doxorubicin) (Kaltsas *et al.*, 1998), all resulting in occasional, sporadic, and short-lasting responses. None of them was able to control tumor progression or improve survival (Kaltsas *et al.*, 2005).

This paradigm fortunately changed after the first publication reporting the successful use of temozolomide (Fadul *et al.*, 2006; Lim *et al.*, 2006; Syro *et al.*, 2006), a second-generation alkylating agent routinely used for the treatment of glioblastomas (Stupp *et al.*, 2005). Temozolomide is an imidazotetrazine derivative that is rapidly converted at physiological pH to methyl-triazeno-imidazole-carboxamide, which is the active drug. It exerts its action by attaching a methyl group to the O6 position of guanine bases, causing a mispair with thymine bases, DNA damage, proliferation arrest, and cell death (apoptosis). Temozolomide can cross the blood–brain barrier, and its action is not cell cycle-specific. It therefore inhibits all stages of tumor cell growth, even in slow-growing tumors such as pituitary tumors.

Temozolomide is relatively well tolerated. The most common side effects are fatigue, nausea, vomiting, and hematologic effects (thrombocytopenia, rarely neutropenia). A dose reduction or delay in treatment cycles can allow the patient to continue treatment. The

preferred dosing regimen is 200 mg/m^2 daily for 5 days every 28 days. However, recent publications reported cases of temozolomide treatment given according to the Stupp protocol (Stupp *et al.*, 2005) that is used routinely in the treatment of glioblastomas—a daily dose of 75 mg/m^2 for 6 weeks in combination with radiation therapy, followed by 6–12 months of "standard regimens."

Following the initial publications on temozolomide, numerous case reports and studies on relatively large series (Bengtsson *et al.*, 2015; Lasolle *et al.*, 2017; Losa *et al.*, 2016; Raverot *et al.*, 2012) have been published. Limiting the literature review to publications, including at least three patients, a total of 149 patients have been reported on, all showing a similar response rate despite heterogeneity in the populations. The largest series reported partial or complete tumor regression in about 50% of patients at the end of treatment. Most tumors were corticotroph or lactotroph tumors.

To date there is no clearly identified predictive marker of responsiveness to temozolomide. The response rate is similar in aggressive pituitary tumors and carcinomas, but silent pituitary tumors appear to be associated with a worse prognosis. Concomitant radiation therapy, given according to the Stupp protocol, seems to be associated with a high rate of tumor response. However, the number of patients is too limited to be conclusive (Lasolle *et al.*, 2017).

Evidence of tumor shrinkage after three cycles, as evaluated by MRI, is the only undebatable prognostic marker of later response. Indeed, all responders showed tumor shrinkage after three cycles, while a delayed tumor response was never observed in the absence of an initial response. However, an initial response is not a guarantee of long-term tumor control. In some patients, tumor growth occurred during subsequent cycles, and, more frequently, tumor progression occurred after temozolomide cessation. After treatment ended, responders exhibited improved overall survival compared to nonresponders (44 months (42–infinity) (95% CI) vs. 16 months (9–25), with an estimated survival probability of 51.3% (32.4–70.3) at 3 years (Lasolle *et al.*, 2017)). Due to the limited data on long-term follow-up, the optimal duration of temozolomide treatment remains unclear. Remissions are rare, secondary resistance common (Bengtsson *et al.*, 2015; Campderá *et al.*, 2016; Lasolle *et al.*, 2017; Losa *et al.*, 2016; Raverot *et al.*, 2010a), and all new treatment attempts with temozolomide in cases of relapse failed (Campderá *et al.*, 2016; Lasolle *et al.*, 2017).

The expression of proteins implicated in DNA repair mechanisms has been studied to identify tumors more likely to be sensitive to temozolomide treatment. O^6-methylguanine-DNA methyltransferase (MGMT), a DNA repair enzyme that counteracts the effects of temozolomide by removing alkylating adducts from DNA, is the most frequently studied. There is debate regarding the results of these studies (Bengtsson *et al.*, 2015; Bush *et al.*, 2010; Lasolle *et al.*, 2017; Losa *et al.*, 2010; McCormack *et al.*, 2009; Raverot *et al.*, 2010a,b); however, it is now agreed that MGMT status should not be used to select patients for treatment with temozolomide, but that patients with high MGMT expression have a lower probability of tumor response. Studies on other DNA mismatch repair proteins (MLH1, MSH2, MSH6, and PMS2) are too limited to draw conclusions.

Alternative Therapies

Temozolomide treatment failed to control at least 50% of these tumors, and progression or recurrence after temozolomide cessation is common. Identification of therapeutic alternatives is therefore needed. Unfortunately, clinical experiences are uncommon. Only single case reports have demonstrated the efficacy of antivascular endothelial growth factor (anti-VEGF) therapy (bevacizumab 10 mg/kg every 2 weeks for 10 months) (Ortiz *et al.*, 2012), or tyrosine kinase inhibitor treatment (lapatinib 1250 mg daily for 6 months) (Cooper *et al.*, 2014). Despite encouraging preclinical data (Chanal *et al.*, 2016; Lee *et al.*, 2015), treatment with a mTOR inhibitor (everolimus 5 mg daily) does not seem effective in humans (Jouanneau *et al.*, 2012).

Conclusion

Aggressive PitNETs are not especially rare (10%), and cases of carcinoma are perhaps not as exceptional as once thought. These tumors, associated with poor prognosis and high morbidity, should be managed by an expert multidisciplinary team. Recent studies focusing on clinical, radiological, and pathological presentation allowed early identification of these tumors, which are associated with a high risk of recurrence and resistance to medical treatment. Better classification of these patients will improve stratification of the different treatment options, including radiation therapy. Moreover, more clinical evidence of the efficacy of temozolomide treatment in controlling tumor growth may change the prognosis for these patients. The upcoming publication of the European Society of Endocrinology clinical practice guidelines for the management of aggressive pituitary tumors and carcinomas will provide the tools for the treatment of these tumors. However, despite this progress, more studies, in particular international collaborative studies, are needed to decipher PitNET tumor behavior and to identify new treatment options for patients with tumors that are not controlled by temozolomide.

Hypopituitarism, Causes, Diagnosis, Management and Mortality☆

Athanasios Fountas and Niki Karavitaki, Institute of Metabolism and Systems Research, College of Medical and Dental Sciences, University of Birmingham, Birmingham, United Kingdom and Center for Endocrinology, Diabetes and Metabolism, Birmingham Health Partners, Birmingham, United Kingdom

Introduction

The pituitary gland together with the hypothalamus control many endocrine and metabolic functions essential for survival, growth, and reproduction. Hypopituitarism is caused by conditions that reduce or completely damage the pituitary function or interfere with the hypothalamic secretion of pituitary-releasing hormones, leading to complete or partial pituitary dysfunction (Schneider *et al.*, 2007).

Hypopituitarism is associated with significant morbidities, compromised quality of life and increased mortality, especially if it is not timely diagnosed and treated (Jasim *et al.*, 2017; Ehrnborg *et al.*, 2000). Given that many of the presenting manifestations of pituitary dysfunction are nonspecific, early diagnosis can be challenging.

Epidemiology

Accurate data on the prevalence of hypopituitarism are very limited. In a study including 146,000 adult inhabitants in northwestern Spain (Regal *et al.*, 2001) the prevalence of hypopituitarism was increased from 29.0 to 45.5 cases per 100,000 people between 1992 and 1999 with a mean annual incidence of 4.21 cases per 100,000 persons. However, these figures probably underestimate the actual incidence of this disorder. It should be also noted that with the advances in pediatric oncology, the number of patients diagnosed with hypopituitarism in childhood or later during monitoring in adult life is increasing.

Etiology

Hypopituitarism can be caused by a plethora of etiologies shown in **Table 1**.

Neoplastic Causes

Pituitary insufficiency can be caused by sellar and parasellar lesions. Pituitary tumors account for 10%–15% of all intracranial tumors (Terada *et al.*, 1995); and 90% of them are pituitary adenomas with a prevalence of 77.6 cases per 100,000 inhabitants in the United Kingdom (Fernandez *et al.*, 2010). Pituitary adenomas are defined as clinically functioning or nonfunctioning (depending on the presence of secretory activity that can cause clinical manifestations), and into microadenomas (<1 cm) and macroadenomas (≥ 1 cm) on the basis of maximum diameter on imaging. Prolactinomas are the most common functioning pituitary adenomas, followed by those causing acromegaly and Cushing's disease, with functioning gonadotropinomas and thyrotropinomas occurring only rarely.

Both functioning and nonfunctioning adenomas may result in hypopituitarism due to pressure effects to the normal gland (possible mechanisms include mass effect of the tumor on the vascular portal system, raised intrasellar pressure affecting portal circulation, and focal pituitary necrosis (Arafah *et al.*, 2000; Arafah, 1986)) or the effects of hormonal hypersecretion on other pituitary hormones. The typical sequence of hyposecretion starts with growth hormone (GH) deficiency, followed by loss of gonadotropins before progressing to loss of thyrotropin-stimulating hormone (TSH) and adrenocorticotropic hormone (ACTH) reserves. Mild hyperprolactinemia may be detected in nonprolactin secreting adenomas due to interruption of the inhibitory effect of dopamine from the hypothalamus on prolactin release. Pituitary adenomas do not present with vasopressin deficiency.

Parasellar masses related with hypopituitarism are craniopharyngiomas, gliomas, hamartomas, meningiomas, germinomas, chordomas and astrocytomas. Craniopharyngiomas account for up to 4% of all intracranial tumors and although are often thought to be childhood tumors, 50% of all of them present in patients over 16 years of age (Karavitaki *et al.*, 2006). They have the potential of aggressive behavior with increased morbidity and mortality compared with patients with other sellar/parasellar masses.

☆*Change History:* November 2017. A. Fountas and N. Karavitaki updated the whole text of the manuscript, added the mortality section, citations in the manuscript, as well as a reference section. In addition, they deleted the old Table 1; they updated the old Tables 2 and 3 (with the new Tables 1 and 2) and added a new table (Table 3). Finally, they deleted Figs. 1, 2 and 3, as well as the further reading section.

This chapter is an update of K.J. Bradley and J.A.H. Wass, Hypopituitarism, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 652–661.

Table 1 Causes of hypopituitarism

Neoplastic	Sellar and parasellar masses (e.g., pituitary adenomas, craniopharyngiomas, cysts, gliomas, meningiomas, chordomas, metastases)
Iatrogenic	Pituitary surgery
	Pituitary radiotherapy
Vascular	Pituitary apoplexy
	Sheehan syndrome
	Carotid artery aneurysm
	Subarachnoid hemorrhage
	Snake bite
Inflammatory/infiltrative	Hypophysitis
	Hemochromatosis
Infections	Bacterial
	Fungal
	Parasital
	Viral
	Tuberculosis
Traumatic	Head injury
Anatomic	Empty sella syndrome
Congenital	Genetic (*POU1F1, PROP1, HESX1, LHX3, LHX4, TPIT, SIX6, SOX2, SOX3, FGF8, PROKR2, ARNT2, GLI2, NFKB2, PAX6*)
	Developmental central nervous system defects
	Perinatal insults (traumatic delivery, birth asphyxia)
	Interrupted pituitary stalk
Medications	Opiates
	Somatostatin analogs
	CTLA4 and PD1 inhibitors
	Interferon-alpha
	Glucocorticoids
Idiopathic	

(*CTLA4: cytotoxic T-lymphocyte antigen 4/PD1: programmed cell death protein 1*).

Rathke's cleft cysts are benign sellar and/or suprasellar lesions constituting the majority of the cystic lesions in this area. They arise from remnants of Rathke's pouch with a varying size and content (Fountas and Karavitaki, 2017). Other less common cystic lesions include arachnoid, epidermoid and dermoid cysts. Finally, primary malignancies of the sella are extremely rare and they comprise of pituitary carcinomas, primary lymphoma and melanoma. On the other hand, metastatic deposits at the pituitary do occur, usually arising from malignancies of the lung, breast, kidney and prostate (He *et al.*, 2015).

Iatrogenic Causes

Hypopituitarism is often the result of pituitary surgery (transsphenoidal or transcranial) and its frequency depends on the tumor size, invasion on the surrounding structures, as well as the skills and experience of the surgeon. In addition, cranial irradiation for various reasons (head and neck tumors, pituitary masses, brain tumors, prophylactic radiotherapy in children with leukemia, total body irradiation for various malignancies) is a causative factor for pituitary insufficiency. The risk of hypopituitarism is time- and dose-dependent with the deficits presenting with a typical manner (Pekic and Popovic, 2017). Deficiency of GH axis is the most common first manifestation, followed by the gonadotropin axis; ACTH and TSH deficiencies are the least frequent whilst diabetes insipidus (DI) does not occur as a consequence of radiation treatment (Fernandez *et al.*, 2009). The effects of radiotherapy may take many years to manifest fully; consequently, it is vital that irradiated patients at risk require regular assessment (usually at yearly intervals). The impact of new radiation techniques (e.g., protom beam) on the hypothalamo-pituitary function remains to be elucidated.

Vascular Causes

Pituitary apoplexy is the most frequent vascular cause of hypopituitarism and is attributed to damage of the pituitary gland due to infarction or hemorrhage, usually in the background of a pituitary adenoma. Its clinical features include acute, severe headache, accompanied by nausea and vomiting, reduced visual acuity and visual field defects, and ocular palsies (Capatina *et al.*, 2015a). However, hemorrhage in a pituitary adenoma may lack the typical acute clinical manifestations and be evident only on imaging.

Postpartum ischaemic pituitary necrosis (Sheehan syndrome), remains an important cause of hypopituitarism in developing countries, but is relatively rare in the western countries due to the advances in obstetric care (Karaca *et al.*, 2016). Another known vascular etiology of pituitary insufficiency is subarachnoid hemorrhage with variable frequencies reported among published studies (Robba *et al.*, 2016; Kronvall *et al.*, 2015; Gardner *et al.*, 2013). Carotid artery aneurysm is also a rare cause mainly due to

mass effect on the hypothalamus and the pituitary gland (Hanak *et al.*, 2012). Finally, cases of pituitary insufficiency after snake bite have been described (Golay *et al.*, 2014).

Inflammatory/Infiltrative Conditions

Primary hypophysitis is an inflammatory disease that can affect both lobes of the pituitary, as well as the stalk and can be divided in four different types: lymphocytic hypophysitis, mainly reported in women during or after parturition, granulomatous, xanthomatous and IgG-4-related (in patients with IgG-4-related disease). The clinical features are similar to those of pituitary adenomas, comprising local mass effects (headache, visual deterioration) and anterior hypopituitarism. However, in contrast to the patients harboring pituitary adenomas, DI can be present when the posterior lobe or the stalk are involved (Caturegli *et al.*, 2005).

Granulomatous conditions, such as sarcoidosis, Langerhans cell histiocytosis and granulomatosis with polyangiitis (previously known as Wegener's granulomatosis) can also cause anterior hypopituitarism and DI. Moreover, hereditary and secondary hemochromatosis can affect pituitary function, especially hypogonadotropic hypogonadism by iron deposits in the gland (Lewis *et al.*, 2009).

Infections

Pituitary infections, although rare, need to be considered in the differential diagnosis of hypopituitarism. They can be primary in origin, secondary due to hematogenous spread (especially in patients with immunoinsufficiency) or by direct dissemination of infection in adjacent sites, and iatrogenic after pituitary surgery. Pathogens responsible for these infections are bacteria (including mycobacterius tuberculosis), viruses, parasites and fungi. Pituitary abscess can also develop with magnetic resonance imaging (MRI) usually revealing a sellar cystic or partially cystic mass, with an enhanced rim following gadolinium administration (Wang *et al.*, 2014).

Traumatic Causes

Traumatic brain injury (TBI) is another recognized cause of pituitary insufficiency. The prevalence widely varies between different studies and depends on the methods and criteria used for the diagnosis of hypopituitarism (Kokshoorn *et al.*, 2010). A recent review reported prevalence of pituitary deficiency in TBI patients at the chronic phase (at least 3 months after the injury) of 15% when confirmatory tests were used after the initial abnormal testing (Tanriverdi *et al.*, 2015). GH deficiency is the most common deficit, followed by ACTH, gonadotropins and TSH deficiency. DI can also occur, especially in the acute phase of the injury (Capatina *et al.*, 2015b). Whether the severity of TBI is a predictor of hypopituitarism in these patients remains a matter of debate (Tan *et al.*, 2017).

Anatomic Malformations

Empty sella syndrome may be associated with variable clinical conditions ranging from normal pituitary function to hypopituitarism. It may be congenital secondary to arachnoid herniation through a diaphragmatic defect or acquired postsurgery, postradiotherapy, or postpituitary infarction (De Marinis *et al.*, 2005). Imaging reveals an enlarged empty pituitary fossa.

Congenital Causes

Congenital hypopituitarism can be attributed to many underlying causes, particularly genetic ones. Pituitary development requires interplay between pituitary transcription factors and signaling pathways; mutations of the genes coding for these transcription factors result in pituitary developmental anomalies and hypopituitarism (Castinetti *et al.*, 2016). These mutations are often associated with extrapituitary defects, mainly affecting craniofacial/midline development, including septo-optic dysplasia and holoprosencephaly (McCabe and Dattani, 2014).

Pituitary insufficiency may present in the neonatal period, in childhood or young adulthood and can be associated with single or multiple pituitary hormone deficiencies (Kelberman *et al.*, 2009). Many genes have been identified as responsible for hypopituitarism including *POU1F1*, *PROP1*, *HESX1*, *LHX3*, *LHX4*, *TPIT*, *SIX6*, *SOX2*, *SOX3*, *FGF8*, *PROKR2*, *ARNT2*, *GLI2*, *NFKB2*, *PAX6*, *KAL* and *KISS1R*. Each of these gene mutations is related with a different clinical phenotype, and appropriate genetic testing should be performed accordingly.

Pituitary stalk interruption syndrome also results to congenital hypopituitarism, ranging from isolated GH deficiency to combined pituitary hormone deficiencies, and belongs to the spectrum of midline abnormalities. It is characterized by the presence of a thin or absent pituitary stalk, commonly associated with an absent or hypoplastic anterior pituitary lobe and/or an ectopic posterior lobe (Reynaud *et al.*, 2011). The underlying mechanism is not known. However, mutations of genes involved in pituitary development have been found in some patients indicating a possible genetic background (Bar *et al.*, 2015). Finally, congenital hypopituitarism can be also caused by perinatal insults, such as birth asphyxia or traumatic delivery (Webb and Dattani, 2011).

Table 2 Main clinical manifestations and laboratory findings of hypopituitarism

Hormone deficiency	*Clinical features*
Growth hormone	Fatigue and weakness Reduced muscle strength and exercise capacity Impaired psychological well-being Reduced lean body mass and increased visceral adiposity Decreased bone mass density Increased cardiovascular risk Impaired sleep quality Dyslipidemia
Luteinizing hormone and follicle-stimulating hormone	Women ● Oligomenorrhea/amenorrhea ● Vaginal dryness, dyspareunia ● Breast atrophy Men ● Erectile dysfunction ● Testicular atrophy ● Diminished facial and body hair ● Fine facial wrinkles ● Gynecomastia ● Anemia (normocytic, normochromic) Both sexes ● Loss of libido ● Hot flushes ● Infertility ● Fatigue and weakness ● Reduced muscle strength and exercise capacity ● Impaired sleep quality ● Impaired psychological well-being ● Decreased bone mass density
Adrenocorticotropic hormone	Fatigue and weakness Reduced exercise capacity Impaired psychological well-being Anorexia Nausea and vomiting Weight loss Orthostatic hypotension Diarrhea Cognitive impairment Pallor Impaired cardiac function Oligomenorrhea/amenorrhea Decreased hair in armpits and pubic area (women) Decreased libido (women) Hypoglycemia Hyponatremia Anemia (normocytic, normochromic) Eosinophilia and lymphocytosis
Thyroid-stimulating hormone	Fatigue and weakness Reduced muscle strength and exercise capacity Impaired psychological well-being Weight gain Cold intolerance Constipation Dry skin and hair Cognitive impairment Hyporeflexia Oligomenorrhea/amenorrhea Bradycardia, impaired cardiac function and increased cardiovascular risk

(*Continued*)

Table 2 Continued

Hormone deficiency	*Clinical features*
	Hypertension
	Dyspnea
	Impaired sleep quality
	Insulin resistance
	Dyslipidemia
	Anemia (mainly normocytic, rarely macrocytic)
Prolactin	Failure of lactation
Vasopressin	Polydipsia
	Polyuria
	Nocturia
	Hypernatremia

Medications

Hypopituitarism can be caused by a variety of drugs. Opioid-induced changes in pituitary function are common, leading to hypogonadotropic hypogonadism, by decreasing the secretion of gonadotropin-releasing hormone (GnRH) and limiting the production of the luteinizing hormone, and to central hypoadrenalism, by reducing the secretion of corticotropin releasing hormone (CRH) and the pituitary responsiveness to it (Brennan, 2013). It is also well known that somatostatin and its analogs inhibit GH secretion acting directly on the somatotrophs and indirectly by antagonizing the production of growth hormone-releasing hormone (GHRH), as well as by inhibiting the secretion of ghrelin (Tannenbaum *et al.*, 2003). In addition, these agents inhibit the production of TSH and the stimulation of its secretion by the thyrotropin-releasing hormone (TRH) (Siler *et al.*, 1974). Immune checkpoint inhibitors are recently developed drugs that have proved effective for the treatment of a variety of malignancies, especially melanoma and lung cancer. Ipilimumab is the most known agent of this category followed by pembrolizumab and nivolumab. Use of these inhibitors has been related with multiple endocrinopathies, including hypophysitis. Although, the precise mechanism for this is not known, there are many proposed pathways that may lead to the development of hypophysitis including an autoimmune process targeting unidentified pituitary antigens and a direct binding of ipilimumab to the pituitary cells (Faje, 2016). In addition, there are reports in the literature of interferon-induced hypopituitarism (Concha *et al.*, 2003). Finally, suppression of the hypothalamus-pituitary-adrenal (HPA) axis is a common side effect of prolonged exogenous glucocorticoid administration (Crowley *et al.*, 2014).

Symptoms and Signs Related to Hypopituitarism

Clinical features of hypopituitarism (**Table 2**) depend on many factors, including the severity and the number of hormonal deficiencies and the underlying pathology that leads to pituitary failure. If the cause of hypopituitarism is a pituitary mass, apart from the manifestations of the pituitary hormone deficits, tumor effects (headache, visual impairment) will probably be also evident. Also, the rapidity of onset of hypopituitarism affects its clinical presentation. In cases of acute pituitary deficiency, such as pituitary apoplexy, central hypoadrenalism can be life threatening if not diagnosed and treated timely. However, most patients exhibit a slow and progressive loss of pituitary function with relatively mild and often nonspecific clinical symptoms.

Diagnosis

The diagnosis of hypopituitarism is established on appropriate hormonal investigations (**Table 3**). For the interpretation of the results, the limitations of the currently used assays, their sensitivity and specificity, as well as situations where interference is expected (drugs, disorders affecting binding globulins) need to be taken into account.

In any patient with suspected pituitary or hypothalamic pathology, imaging of the area, ideally with MRI scanning is mandatory. Additional investigations will be dictated by the imaging findings and the suspected etiology of hypopituitarism. Diagnosis is based on the measurement of the basal levels of the anterior pituitary and the target organ hormones, as well as on dynamic testing. The confirmation of hypotonic polyuria combined with exclusion of hypokalaemia or hypercalcaemia and a water deprivation test are valuable tools for the diagnosis of diabetes insipidus related to vasopressin deficiency (**Table 3**).

Table 3 Diagnosis of pituitary hormone deficits

GH deficiency

- GH stimulation testing is mandatory (exceptions: patients with clinical features of GHD and deficiencies in at least three other pituitary hormones, young adults with GHD and multiple hormone deficiency due to structural lesions or genetic disease with low IGF-1 levels after discontinuation of GH therapy for at least 1 month)
- One stimulation test is sufficient and prior to testing all other pituitary hormones must have been replaced adequately
- Insulin tolerance test: gold standard, GHD if peak GH levels $\leq$3–5 μg/L
- GHRH and arginine stimulation test: well tolerated, does not cause hypoglycemia; cut-off GH levels are BMI-dependent
- Glucagon stimulation test: GHD if peak GH levels $<$3 μg/L
- Normal IGF-1 levels do not exclude the diagnosis

FSH/LH deficiency

Men

- Low morning serum testosterone levels (measured before 10:00 h) in conjunction with low or normal gonadotropins
- Second measurement of testosterone with the same assay when initial levels in the mildly hypogonadal range
- Measurement of free or bioavailable testosterone in cases with alterations of SHBG or albumin concentration or when testosterone concentrations close to the lower limit of normal

Women

- Postmenopausal: Absence of high levels of gonadotropins
- Premenopausal: Low serum estradiol levels along with low or normal gonadotropins in the presence of oligomenorrhea or amenorrhea; other causes of oligomenorrhea or amenorrhea should be excluded particularly when dysfunction of other pituitary axes is not evident

ACTH deficiency

- Serum cortisol levels at 08:00–09:00 h $<$ 3 μg/dL (in the absence of glucocorticoid therapy) are indicative of adrenal insufficiency
- If morning cortisol values are 3–15 μg/dL, dynamic test is required
- Interpretation of cortisol values should be done with caution when alterations of cortisol-binding globulin levels are expected
- Inappropriately low or normal ACTH levels in the presence of low morning cortisol concentrations ($<$3 μg/dL) suggest ACTH deficiency
- Insulin tolerance test: adequate cortisol reserve if cortisol levels $>$18.1 μg/dL
- Standard dose short Synacthen test: easier to perform, less invasive, serum cortisol $>$18.1 μg/dL at 30 or 60 min excludes hypoadrenalism, false negative results in patients with recent onset ACTH deficiency
- Glucagon stimulation test: alternative to insulin tolerance test, associated with false-positive results

Central hypothyroidism

- Low free thyroxine concentrations in conjunction with low, normal, or mildly elevated TSH in the setting of pituitary disease
- Absence of nonthyroidal illness syndrome
- Milder cases, characterized by free thyroxine levels still within the normal range, can remain undiagnosed

Central diabetes insipidus

- Hypotonic polyuria ($>$50 mL/kg of body weight/24 h) must be evident and other causes of polyuria should be excluded (e.g., diabetes mellitus)
- Initiation of glucocorticoid replacement therapy unmasks diabetes insipidus
- Urine osmolality of $<$600 mOsm/kg together with serum osmolality of $>$295 mOsm/kg (in the absence of glycosuria) confirms the diagnosis
- In less clear-cut cases or when the differential diagnosis from nephrogenic diabetes insipidus or primary polydipsia is required, a formal water deprivation test is helpful

(*GH*: growth hormone/*GHD*: growth hormone deficiency/*IGF-1*: insulin-like growth factor 1/*GHRH*: growth hormone-releasing hormone, *BMI*: body mass index/*FSH*: follicle-stimulating hormone/*LH*: luteinizing hormone, *SHBG*: sex hormone binding globulin/*ACTH*: adrenocorticotropic hormone/*TSH*: thyroid-stimulating hormone).

Assessing Growth Hormone Reserve

GH is secreted in a pulsatile fashion with peaks at night during sleep and in response to stress, exercise and other factors (Muller *et al.*, 1999). Therefore, random blood GH measurements are of no diagnostic value. In addition, measurements of insulin-like growth factor 1 (IGF-1) concentrations, which is released in response to GH secretion and mediates many of the GH actions, are useful but not sufficient enough to establish the diagnosis of GH deficiency (GHD). IGF-1 levels in the blood are also affected by a number of other parameters (age, gender, oral estrogen therapy, prolactin levels, severity of GHD) (Mukherjee and Shalet, 2009). For the aforementioned reasons provocative tests that stimulate GH release are needed for the diagnosis of GHD.

Insulin tolerance test (ITT) is still regarded as the gold standard for assessing GHD with GH levels $>$3–5 μg/L indicating normal GH reserve (Fleseriu *et al.*, 2016). However, ITT is associated with risks in patients with a history of epilepsy, cardiovascular disease, as well as in the elderly. In these cases, the GHRH + arginine stimulation test can be used which is generally well tolerated without provoking hypoglycemia and with similar with the ITT sensitivity and specificity (Aimaretti *et al.*, 1998). The cut-off levels for the diagnosis of GHD using this test are body mass index (BMI)-dependent and they are divided in three main categories: for

BMI <25 kg/m^2, peak GH <11 μg/L, for BMI 25–30 kg/m^2, peak GH <8 μg/L and for BMI >30 kg/m^2, peak GH <4 μg/L (Ho, 2007). However, GHRH is no longer available in many countries including the United States. Furthermore, it should not be used in patients with suspected GHD of hypothalamic origin (e.g., after irradiation) due to high rate of false negative results (Darzy *et al.*, 2003). When an ITT is contraindicated and GHRH is not available, the glucagon stimulation test is the alternative method, with GH levels <3 μg/L confirming GHD (Gómez *et al.*, 2002). Other tests such as clonidine, L-DOPA, and arginine alone are not useful in adults.

One stimulation test is sufficient for the diagnosis of adult GHD and all other pituitary hormone deficits should have been replaced adequately before it is performed. Furthermore, a number of factors (including age, gender, BMI, exercise and uncontrolled diabetes mellitus) may affect the results of these tests and need to be kept into account when interpreting their results (Molitch *et al.*, 2011). It has been also proposed that in patients with clinical features of GHD and deficiencies in at least three other pituitary axes, provocative testing is not required (Fleseriu *et al.*, 2016). In addition, in children with GHD and multiple hormone deficits due to structural lesions or a genetic condition, a stimulation test is not necessary in adulthood: low IGF-1 levels after discontinuation of GH therapy for at least 1 month is sufficient proof of persistent GHD (Molitch *et al.*, 2011). On the other hand, young adults that received GH therapy during childhood due to short stature (not attributed to structural lesions or genetic conditions) should be retested for GHD, as many of them show normal GH reserve in adulthood.

Assessing the Pituitary–Gonadal Axis

The diagnosis of patients with central (secondary) hypogonadism is based on the measurement of basal levels of gonadotropins and their sex steroids (testosterone and estradiol), combined with menstrual history in females. GnRH stimulation test has no use in the diagnosis of hypogonadism in adult patients (Cheer and Trainer, 2014).

Men

Low morning serum testosterone levels in conjunction with low or normal gonadotropins confirm the diagnosis of central hypogonadism in males. Testosterone demonstrates a circadian secretion rhythm with higher levels in the morning necessitating blood sampling between 8 and 10 am (Brambilla *et al.*, 2009). A second measurement of testosterone should be performed using the same assay when the initial value is in the mildly hypogonadal range (Bhasin *et al.*, 2010). Normal ranges for testosterone concentration vary among laboratories and assays and clinicians need to rely on reference ranges established in their laboratory.

In addition, most of the circulating testosterone is bound to sex hormone binding globulin (SHBG) and to albumin, with only the free hormone being biologically active. In cases where alterations of SHBG or albumin concentration are expected or when total testosterone concentrations are close to the lower limit of the normal range, measurement of free or bioavailable testosterone should be considered, especially if an accurate and reliable method is available (Silveira and Latronico, 2013). Finally, many conditions can cause hypogonadotropic hypogonadism including illness, eating disorders, extensive exercise, drugs (glucocorticoids, opiates, marihuana, alcohol or anabolic steroids abuse) and hyperprolactinemia (Rahnema *et al.*, 2014; Kalyani *et al.*, 2007).

Women

In postmenopausal women, central hypogonadism is defined by the absence of the high levels of gonadotropins. In premenopausal women though, the diagnosis requires a combination of menstrual irregularities (oligomenorrhea or amenorrhea) attributed to anovulation and relevant hormonal findings. The latter include low serum estradiol and low or normal gonadotropins (which in case of oligomenorrhea, need to be measured during the follicular phase of the menstrual cycle (2nd-5th day)). Also, other causes of oligomenorrhea or amenorrhea should be excluded (pregnancy, hyperandrogenism, thyroid disease, drugs) (Fleseriu *et al.*, 2016).

Assessing the Hypothalamic–Pituitary–Adrenal Axis

Cortisol secretion follows a circadian rhythm reaching its peak levels in the morning after awakening. Due to this reason, measurement of serum cortisol concentration should be performed between 08:00–09:00 am. Cortisol levels <3 μg/dL are sufficient to diagnose adrenal insufficiency, whereas levels >15 μg/dL usually exclude the diagnosis (Fleseriu *et al.*, 2016). Patients with morning values between these limits warrant further investigation. Inappropriately low or normal ACTH levels in the presence of low morning cortisol concentrations (<3 μg/dL) suggest ACTH deficiency.

The majority of circulating cortisol is bound to cortisol-binding globulin (CBG) and serum cortisol measurements are, therefore, affected by changes in CBG concentrations. Conditions that increase (oral estrogen therapy, pregnancy, mitotane) or decrease CBG (genetic diseases, nephrotic syndrome, cirrhosis, inflammation) need to be kept in mind when interpreting total cortisol levels in patients with suspected hypopituitarism (Bae and Kratzsch, 2015).

The main tests for assessing ACTH reserve are the ITT and the short Synacthen test (SST). In patients already on glucocorticoid treatment, discontinuation of hydrocortisone for 24-h (or longer for synthetic glucocorticoids) is required. As for GHD, ITT is the gold standard for the assessment of ACTH reserve with peak serum cortisol >18.1 μg/dL considered to be adequate response for most assays. Adequate hypoglycemia (serum blood glucose <40 mg/dL) should be accomplished in order for valid results to be obtained (Crowley *et al.*, 2014).

The SST it the most common test in diagnosing adrenal insufficiency. Patients with primary or secondary hypoadrenalism do not reach cortisol levels >18.1 μg/dL 30 or 60 min following parenteral administration of 250 μg of synthetic ACTH. The SST is easier to perform and less invasive than ITT but is not of value in patients with recent onset of ACTH deficiency (immediately post-surgery or pituitary apoplexy). In these cases, it can lead to false negative results as it takes approximately 6 weeks for the adrenals to lose responsiveness to the stimulatory effect of ACTH. Given the widely accepted safety profile of the SST, most endocrinologists reserve the ITT for patients with borderline results on SST or for cases where simultaneous assessment of GH reserve is required. The low-dose SST, using 1 μg of synthetic ACTH instead of the supraphysiological 250 μg dose, has become increasingly popular during recent years. However, a recent meta-analysis has not confirmed superiority in its diagnostic performance compared with the 250 μg test for the diagnosis of central hypoadrenalism (Ospina *et al.*, 2016).

Other tests include the glucagon stimulation test and the overnight metyrapone stimulation test. The glucagon test has the advantage, as does the ITT, of being able to assess ACTH and GH reserves simultaneously. Glucagon, however, is a weaker stimulus for ACTH secretion and, consequently, is more often associated with false-positive results (Garrahy and Agha, 2016). On the other hand, metyrapone stimulation test is based on the principle that decrease of serum cortisol concentrations (by blocking 11b–hydroxylase and thereby inhibiting conversion of 11-deoxycortisol to cortisol) will lead to increase of ACTH secretion. In subjects with normal HPA axis, the increased ACTH production leads to rising levels of 11-deoxycortisol, whilst in patients with central ACTH deficiency no increase in both hormones is evident. However, this test is rarely used in clinical practice nowadays.

Assessing the Pituitary-Thyroid Axis

Baseline assessment of TSH and free thyroxine is usually sufficient for the diagnosis of secondary (central) hypothyroidism. Measuring free thyroxine instead of total is essential, especially in cases where abnormalities of thyroid-hormone binding proteins are possible (pregnancy, drugs that affect thyroxin-binding globulin, inherited diseases) (Pappa *et al.*, 2015). Free thyroxine levels below the reference range together with a low, normal, or mildly elevated TSH in the presence of pituitary disease usually confirm the diagnosis (Garber *et al.*, 2012). However, with this definition, the milder defects of central hypothyroidism, characterized by free thyroxine levels still within the normal range, can remain undiagnosed (Persani, 2012).

The differential diagnosis of secondary hypothyroidism due to pituitary disease is mainly from nonthyroidal illness syndrome, associated with critical systemic illness; the latter can also induce central hypothyroidism by suppression of TRH production and inhibition of TSH release (Warner and Beckett, 2010). The TRH test (assessment of TSH response to administration of intravenous TRH) has not any clinical use in the diagnosis of central hypothyroidism and has been practically abandoned.

Posterior Pituitary Assessment

The establishment of the diagnosis of DI relies on the confirmation of hypotonic polyuria (>50 mL/kg of body weight/24 h). Other causes of polyuria, even those related with osmotic diuresis (e.g., diabetes mellitus), need to be excluded. It should also be kept in mind that in concomitant ACTH deficiency, glucocorticoid replacement therapy may unmask DI, as lack of cortisol compromises free water clearance.

Paired plasma and urine osmolalities and accurate estimation of fluid balance may be sufficient for the diagnosis; urine osmolality of <600 mOsm/kg together with serum osmolality of >295 mOsm/kg (in the absence of glycosuria) confirms the diagnosis (Cheer and Trainer, 2014). However, in less clear-cut cases, or when the differential diagnosis from nephrogenic diabetes insipidus or primary polydipsia is required, a formal water deprivation test is helpful.

Treatment

Management of hypopituitarism includes appropriate hormone replacement therapy combined with addressing the underlying cause of pituitary dysfunction. Hormonal replacement should be optimized and monitored regularly aiming to avoid suboptimal treatment or the risks associated with over-replacement.

GH Deficiency

GH replacement is administered as a daily subcutaneous injection at a starting dose of 0.2–0.4 mg daily for patients aged below 60 years and 0.1–0.2 mg daily for older ones (Fleseriu *et al.*, 2016). Females usually need higher doses, especially if they are on oral estogens (Johannsson and Bengtsson, 1998). The dose is titrated up gradually guided by clinical and biochemical parameters. IGF-1 is the currently used marker and the aim is achievement of levels within age-adjusted reference range (Molitch *et al.*, 2011). It has been suggested that GH replacement in GHD adults is associated with improvement in mood, lipid metabolism, bone mineral density, exercise tolerance, quality of life, increase in lean body mass and reduction in fat mass (Reed *et al.*, 2013).

Side effects of treatment are arthralgias, myalgias, fluid retention, peripheral edema, carpal tunnel syndrome and sleep disturbances. Also, given that GH reduces insulin sensitivity, GH therapy has been implicated with the development of diabetes, although the relevant published data are conflicting (Weber *et al.*, 2017; Luger *et al.*, 2012). The safety profile in

terms of developing new cancers of GH treatment on appropriate replacement doses appears reassuring in surveillance studies (Fleseriu *et al.*, 2016). Finally, active malignancy is a contraindication for offering GH.

Gonadotropin Deficiency

In patients with central hypogonadism, fertility, sex steroid replacement therapy and careful induction of puberty (if the onset of the deficiency is in childhood or in cases of arrested pubertal progress) are the areas requiring focus.

Men

Androgen replacement in men is available as intramuscular testosterone injections (at intervals depending on the type of preparation used), oral tables, transdermal gels or patches, and subcutaneous implants, with different advantages and disadvantages (Aversa and Morgentaler, 2015). Contraindications for offering testosterone replacement are breast and metastatic prostate cancer, unevaluated prostate pathology, high levels of prostatic specific antigen (>4 ng/mL or >3 ng/mL in high risk individuals), hematocrit $>50\%$, severe lower urinary tract symptoms associated with benign prostatic hypertrophy and poorly controlled congestive heart failure (Bhasin *et al.*, 2010).

The monitoring of patients on testosterone therapy includes clinical response, measurement of serum testosterone levels in various times depending on the preparation used, as well as screening for possible side effects. When fertility is desired, testosterone therapy should be discontinued (it reduces spermatogenesis), and induction of spermatogenesis therapy with human chorionic gonadotropin and/or recombinant FSH is initiated (Anawalt, 2013).

Women

Any form of estrogen (mainly oral or transdermal) in combination with a cyclical progestagen (to avoid endometrial hyperplasia and risk of malignancy in women with intact uterus) or combined estrogen–progestogen preparations are suitable for sex steroid treatment in female patients with central hypogonadism. Unopposed estrogens are used for women who have undergone hysterectomy. The choice of the preparation offered relies on the risk of adverse effects, cost, patient convenience and preference. Estrogens should not be used in women with undiagnosed abnormal genital bleeding, known breast cancer or other estrogen-dependent malignancy or a history of these conditions, previous or active thromboembolic disease, liver disease and thrombophilic disorders (Stuenkel *et al.*, 2015).

Follow-up includes evaluating symptoms and potential side effects. Replacement is advised until the mean age of natural menopause and following this, decisions on continuing treatment should be individualized. Finally, induction of ovulation is achieved with established protocols using gonadotropins or pulsatile GnRH (Yasmin *et al.*, 2013).

ACTH Deficiency

A number of glucocorticoids are available for the treatment of hypoadrenalism. Hydrocortisone is the most commonly used; it is converted to cortisol in the body and can be easily measured in the serum. Alternatives include cortisone acetate or the synthetic glucocorticoids prednisolone, methylprednisolone and dexamethasone. Cortisone acetate is metabolized to cortisol by 11-hydroxysteroid dehydrogenase type 1 in the body. Due to the short half-life of hydrocortisone, two-three doses are required daily, whilst the synthetic glucocorticoids have a longer duration of action and can be administered once daily being a choice of treatment in patients with compliance issues. Dexamethasone is the least favorable option due to difficulties in dose titration and higher risk of side effects (Bornstein *et al.*, 2016). Patients with ACTH deficiency do not require mineralocorticoid supplementation as the renin–angiotensin–aldosterone pathway is intact.

Hydrocortisone in a total dosage of 15–20 mg/24 h divided into two or three doses is the most recommended approach, although patients with partial cortisol insufficiency may need lower doses. The highest dose should be given in the morning on waking and the second in the afternoon (two-dose regimen), or the second and third at lunchtime and in the late afternoon, respectively (three-dose regimen). Splitting of the dose aims to mimic the natural circadian rhythm of cortisol secretion. A newly marketed dual-release hydrocortisone preparation, comprising an immediate-release coating and an extended-release core, administered once daily, resembles the daily normal cortisol profile more closely than conventional hydrocortisone and has been associated with improvements of cardiometabolic factors (blood pressure, serum glucose and lipid levels, BMI) compared with the three-dose hydrocortisone regimen (Giordano *et al.*, 2016; Johannsson *et al.*, 2012). However, it cannot replace the physiological rise in early morning cortisol. Also, a new modified-release, multiparticulate, oral formulation of hydrocortisone is in clinical development; a two dose regimen (07:00 and 23:00 h) seems to provide a more physiological cortisol exposure, as well as an overnight rise in cortisol levels (Whitaker *et al.*, 2014).

Monitoring patients with hypoadrenalism is mainly comprised of clinical assessment for the presence of signs and symptoms of hypocortisolism or glucocorticoid excess. Cortisol day curves are useful when malabsorption or increased steroid metabolic clearance is suspected (Husebye *et al.*, 2014). Furthermore, compliance to treatment should be regularly checked, as well as a concomitant use of medications that may impair glucocorticoid metabolism, such as antiepileptics (Paragliola *et al.*, 2015). Close follow-up of patients with recent initiation of GH replacement is also important as GH inhibits 11β-hydroxysteroid

dehydrogenase type 1 that converts cortisone to cortisol (Stewart *et al.*, 2001). In these cases, adrenal insufficiency may be unmasked or in patients that are already ACTH deficient an increase of the hydrocortisone dose may be needed.

Patient education is vital in optimizing management and outcomes. Written information on sick day rules (adjustment of hydrocortisone dose in case of stress e.g., fever, infection requiring antibiotics), offering and educating on the emergency kit with the injectable hydrocortisone (aiming to avoid adrenal crisis, particularly in cases of vomiting or diarrhea), as well as some form of identification, such as a medic alert bracelet, to inform medical staff if they are found unconscious are vital points. In case of a surgical procedure or severe illness necessitating hospital admission, the cortisol requirements are increased and steroid cover is offered according to specific protocols (Allolio, 2015).

Finally, ACTH deficiency results in compromised secretion of adrenal androgen precursors (including dehydroepiandrosterone (DHEA) and androstenedione), which are a major source of androgens in women. Studies addressing the DHEA replacement in women with adrenal insufficiency have given conflicting results. A systematic review and meta-analysis suggested that the evidence regarding the use of DHEA in this group of women was not sufficient (Alkatib *et al.*, 2009). In addition, in the recent Endocrine Society guidelines on androgen therapy in women, the Taskforce recommended against the routine DHEA replacement in women with low androgen levels due to hypopituitarism (Wierman *et al.*, 2014).

TSH Deficiency

Levothyroxine is the treatment of choice for secondary hypothyroidism on an average adult replacement dose of 1.6 μg/kg/day (Slawik *et al.*, 2007). There is no evidence of beneficial use of triiodothyronine in these patients. Starting dose of levothyroxine and dose titration depends on age and comorbidities, with lower initiation doses and slower increments used in elderly and those with ischemic heart disease. Primary biochemical treatment goal is usually serum free thyroxine values in the upper half of the reference range (before the daily intake of levothyroxine) (Jonklaas *et al.*, 2014). In contrast to primary hypothyroidism, serum TSH is an unreliable indicator in patients with central hypothyroidism and has no value in the monitoring of replacement.

In cases of multiple pituitary hormone deficits, adequate steroid replacement should be initiated prior to commencing levothyroxine; otherwise, a potentially dangerous adrenal crisis may be precipitated. In addition, GH treatment increases the conversion of thyroxine to triiodothyronine (Jørgensen *et al.*, 1994). In these cases, monitoring of thyroid function is needed for the risk of developing central hypothyroidism or a decline in free thyroxine levels. Furthermore, women with secondary hypothyroidism and hypogonadism may require adjustment of their levothyroxine dose when alterations of estrogen levels are expected (e.g., change of estrogen formulation) due to the estrogen-induced increase of thyroid-binding globulin.

Vasopressin Deficiency

Desmopressin, a synthetic analogue of arginine vasopressin, is the replacement drug of choice. It is available in oral, intranasal, sublingual and parenteral forms and is generally administered between one and three times per day. Desmopressin should be started at bedtime to prevent nocturia and gradually titrated up during the day until polyuria is controlled. Monitoring serum urea and sodium, as well as monitoring of fluid balance are essential, particularly during the early stages and with dose adjustments.

In patients with central DI and intact thirst response, severe dehydration and hypernatremia are usually avoided because adequate fluid intake is maintained. In contrast, hyponatremia as a consequence of lack of free water excretion due to overtreatment with desmopressin is a potentially more serious complication. In order to avoid this side effect, a weekly phase of free diuresis is suggested in all patients by omitting a desmopressin dose (Fleseriu *et al.*, 2016). On the other hand, patients with adipsic DI are at risk of developing severe hypertonic hypernatremia. The management of these patients is challenging and includes a stable dose of desmopressin, a fixed amount of fluid intake (under normal circumstances), daily weighing and frequent monitoring of serum sodium levels (Cuesta *et al.*, 2017).

Mortality

Studies assessing the long-term mortality of patients with hypopituitarism have not given consistent results, mainly due to confounding factors, as selection bias, heterogeneity of population studied and variable treatment modalities. Furthermore, the etiology of the pituitary insufficiency is of major importance, as in a number of conditions like acromegaly, craniopharyngioma and Cushing's disease, mortality is affected by the original diagnosis and its management (Sherlock *et al.*, 2010). Despite these drawbacks, two recent meta-analyses suggest an increase premature mortality in adult patients with hypopituitarism (Jasim *et al.*, 2017; Pappachan *et al.*, 2015) with deaths mainly attributed to cardio/cerebrovascular causes, infections and malignancies.

Multiple predictive factors of increased mortality have been recognized: younger age at diagnosis, female gender, an underlying diagnosis of a craniopharyngioma, type of surgery, and prior radiotherapy treatment (Ntali *et al.*, 2016; Olsson *et al.*, 2015; Chang *et al.*, 2008; Tomlinson *et al.*, 2001; Nilsson *et al.*, 2000). In addition, the type of pituitary hormone deficit affects mortality. ACTH deficiency has been correlated with reduced survival, as well as hydrocortisone replacement dose of >20 mg/day, whilst no difference has been found between patients without secondary adrenal insufficiency and those receiving hydrocortisone dose

≤20 mg/day (Hammarstrand *et al.*, 2017; Zueger *et al.*, 2012). Finally, untreated gonadotropin deficiency has also been described as a risk factor of increased mortality (Tomlinson *et al.*, 2001).

Diagnosis of Prolactinoma and Causes of Hyperprolactinemia

James Ahlquist, Southend Hospital, Westcliff on Sea, United Kingdom

Introduction

Prolactin is a hormone which is secreted by the pituitary gland in mammals. It is well recognized as having a major role in mammalian reproduction.

Common in Clinical Practice

Hyperprolactinemia is a common problem in clinical endocrine practice. Hyperprolactinemia, a raised serum prolactin level, is typically associated with disorders of the reproductive system. It is important to understand the causes of hyperprolactinemia before making a diagnosis. With careful clinical and laboratory assessment the cause of hyperprolactinemia may be identified and appropriate treatment may be given.

Clinical Scenario

A 25 year old woman presented with secondary prolactinoma. She had had no menstruation for 4 months. A blood test showed serum prolactin was raised at 1112 mU/L. She had researched her condition and the blood test result, and wondered if she had a prolactin-secreting pituitary adenoma (prolactinoma).

Prolactin is secreted by the lactotroph cells of the anterior pituitary gland. The lactotrophs comprise up to 25% of the normal anterior pituitary gland. The key actions of prolactin in women are to promote lactation and to inhibit menstruation: this is an important physiological process after childbirth.

Human Prolactin: Key Facts

- Protein hormone
- Secreted by pituitary lactotroph cells
- Length: 199 amino acids
- Size: 23 kDa
- 82% homology with growth hormone
- Plasma half-life 20 min
- Normal serum prolactin levels:

<530 mU/L (<25 ng/mL) in women.
<420 mU/L (<20 ng/mL) in men.

Secretion of prolactin is regulated by a variety of endocrine factors, including estrogen, dopamine and thyrotropin releasing hormone (TRH). The high levels of estrogen found in pregnancy promote lactotroph hyperplasia and an increase in prolactin secretion; this is important in preparing the breast for lactation. Dopamine is secreted by the hypothalamus into the pituitary portal circulation, and inhibits prolactin secretion by the anterior pituitary gland; disruption of this circulation may interrupt the inhibition and lead to an increase in prolactin secretion and hyperprolactinemia. TRH is secreted by the hypothalamus and regulates the hypothalamic–pituitary–thyroid axis; primary hypothyroidism leads to an increase in TRH secretion, and this may result in hyperprolactinemia. Each of these three endocrine regulatory mechanisms is relevant in understanding the causes of hyperprolactinemia.

In clinical practice hyperprolactinemia most commonly presents in women of reproductive age. In women hyperprolactinemia typically causes amenorrhea (loss of menstruation) with estrogen deficiency. In some cases there is also galactorrhea (inappropriate lactation). In men hyperprolactinemia typically causes erectile dysfunction and loss of libido. In both women and men fertility is reduced.

Prolactinoma or Another Cause?

In common with other endocrine glands, the anterior pituitary gland may form a functioning adenoma, leading to autonomous secretion of a specific hormone. Prolactinoma, a benign adenoma secreting an excess of prolactin, is a common and well recognized cause of hyperprolactinemia. In clinical practice it is tempting to assume that a patient with hyperprolactinemia has a

 doi:10.1016/B978-0-12-801238-3.65190-5

prolactinoma. However, several other important causes of hyperprolactinemia must be considered before prolactinoma is diagnosed.

Physiological Causes

A raised serum prolactin is found in pregnancy and lactation. The degree of hyperprolactinemia is variable; there is no clear consensus on a normal reference range for serum prolactin in pregnancy and lactation. Physiological stress also leads to a rise in serum prolactin.

Clinical Case 1
A 17 year old woman was referred with secondary amenorrhea. She had had a normal menarche, and the menstrual cycle had been regular until 4 months earlier, when menstruation ceased. Initial investigations had shown serum prolactin 2560 mU/L, LH 1.8 U/L, FSH 1.6 U/L. She had mild weight gain and breast enlargement. She denied the possibility of pregnancy. On examination the uterus was enlarged. A urinary hCG pregnancy test was positive, and pregnancy was confirmed by ultrasound scan.

Pharmacological Causes

Many prescribed medications have been reported to cause hyperprolactinemia. The major causes of drug-induced hyperprolactinemia are the medications which act as dopamine antagonists: these include antiemetics (such as metoclopramide and domperidone) and antipsychotic agents (such as chlorpromazine and risperidone).

Clinical Case 2
A 34 year old woman with psychosis was treated with risperidone. She developed menstrual irregularity and galactorrhea. Serum prolactin was 1112 mU/L. There was no disturbance of vision. It was not clinically appropriate to stop treatment with risperidone. A pituitary MRI scan excluded the presence of a mass lesion. The hyperprolactinemia was attributed to the effects of risperidone acting as a dopamine antagonist.

Other Nonpituitary Medical Conditions

Primary hypothyroidism may cause hyperprolactinemia as a result of increased hypothalamic TRH production, which stimulates lactotrophs. In marked hypothyroidism there may be significant pituitary enlargement due to lactotroph and thyrotroph hyperplasia.

Chronic kidney disease is associated with hyperprolactinemia; this is partly due to reduced metabolic clearance of prolactin.

Clinical Case 3
A 42 year old woman was referred with menstrual irregularity. Investigations showed serum prolactin 1516 mU/L, creatinine 246 μmol/L. She was not aware of kidney disease. She had suffered recurrent urinary tract infections for many years. After further investigation she was found to have chronic kidney disease due to chronic pyelonephritis.

Polycystic ovary syndrome is a common reproductive disorder in women. It is characterized by menstrual irregularity and hyperandrogenism. Estrogen is generally abundant rather than deficient. Mild hyperprolactinemia is commonly seen in polycystic ovary syndrome: this may be due to the stimulatory effect of oestrogen on pituitary lactotrophs.

Clinical Case 4
A 19 year old woman presented with irregular menstruation. She had had oligomenorrhoea since menarche, with menstruation around every 3–4 months. She had mild hirsutism and acne. A blood test showed serum oestradiol 345 pmol/L, LH 10.8 mU/L, FSH 5.9 mU/L, prolactin 928 mU/L. Pelvic ultrasound revealed ovaries of polycystic appearance. Administration of an oral progestogen for 1 week led to a withdrawal bleed. The hyperprolactinemia was attributed to polycystic ovary syndrome.

Pitfalls in Measurement of Serum Prolactin

Laboratory assays of serum prolactin by immunoassay methods are generally reliable. However there are two important circumstances in which a serum prolactin level measured by immunoassay may be misleading.

The hook effect

In patients with a large prolactinoma the serum prolactin level may be markedly elevated: serum prolactin may be $>10{,}000$ mU/L, and in some cases $>100{,}000$ mU/L. In some serum prolactin assays the extremely high level of serum prolactin exceeds the

linearity of the prolactin assay, causing failure of the assay performance: in this situation the prolactin assay result may be much lower than expected, such as around 1000–3000 mU/L. This assay result, in the context of radiological evidence of a large pituitary tumor, may lead to the erroneous diagnosis of a nonfunctioning pituitary adenoma with disconnection hyperprolactinemia (see below), and the diagnosis of large prolactinoma may be missed. This error can be prevented by reassay of the serum sample after dilution: the assay performance returns to linearity, revealing the very high serum prolactin level.

Macroprolactin

In some people serum prolactin exists in two distinct molecular forms, simple prolactin (23 kDa) and a high molecular mass form of prolactin, typically around 150 kDa. This larger form of prolactin is known as macroprolactin. Macroprolactin is usually formed by the association of simple prolactin with an IgG immunoglobulin; this form of prolactin has reduced metabolic clearance, leading to accumulation of prolactin and hyperprolactinemia. Macroprolactin is generally thought to have reduced or absent bioactivity: in people with hyperprolactinemia solely due to the presence of macroprolactin the raised serum prolactin level does not lead to amenorrhea, galactorrhea, reduced libido or hypogonadism. Laboratories can detect hyperprolactinemia by polyethylene glycol (PEG) precipitation, which removes higher molecular mass forms of prolactin, or by gel filtration chromatography. Clinicians need to know when macroprolactin is present, to avoid misinterpretation of a raised serum prolactin level; for this reason laboratories should routinely include a test for macroprolactin on all samples where a raised serum prolactin result indicates a new finding of hyperprolactinemia.

Clinical Case 5

An 18 year old woman presented with secondary amenorrhea. Her menstrual cycle was usually regular; she had missed one menstrual period, and had no galactorrhea. A urinary pregnancy test was negative, and a blood test showed serum prolactin 1812 mU/L, LH 3.8 U/L, FSH 4.1 U/L. On reassay of the serum after PEG precipitation the serum prolactin was 272 mU/L, indicating that the raised serum prolactin was due to the presence of macroprolactin. The menstrual cycle had returned to normal, and no further investigation was indicated.

Pituitary and Para-pituitary Causes

As noted above, prolactin secretion is inhibited by dopamine secreted by the hypothalamus into the hypothalamic–pituitary portal circulation. Interruption of this inhibition by disruption of the portal circulation may lead to hyperprolactinemia. A mass lesion in the pituitary gland or in the suprasellar space is an important cause of hyperprolactinemia. This phenomenon is sometimes referred to as stalk-compression hyperprolactinemia or disconnection hyperprolactinemia. The degree of hyperprolactinemia is usually modest, typically <2000 mU/L and rarely up to 5000 mU/L. The commonest cause is a nonfunctioning pituitary adenoma. Para-pituitary mass lesions causing hyperprolactinemia include craniopharyngioma and meningioma of the sphenoid wing. Disruption of the portal circulation, along with direct pressure on the anterior pituitary gland, may also lead to varying degrees of loss of pituitary function.

Clinical Case 6

A 53 year old man presented with erectile dysfunction and loss of libido. Blood tests showed serum testosterone 5.2 nmol/L, LH 1.2 U/L, FSH 2.5 U/L, prolactin 1712 mU/L. Anterior pituitary function was otherwise intact. A pituitary MRI scan revealed a large mass arising from an expanded pituitary fossa, extending into the suprasellar space and elevating the optic chiasm (see Fig. 1). He underwent pituitary surgery to protect his vision: on histological analysis the mass was a nonfunctioning pituitary adenoma.

Acromegaly is also a recognized cause of hyperprolactinemia. Acromegaly arises from autonomous secretion of growth hormone from an adenoma of the somatotroph cells of the pituitary gland. Somatotroph and lactotroph cells have a common origin, and in some cases of somatotroph adenoma there is cosecretion of growth hormone and prolactin. In acromegaly hyperprolactinemia may be due to cosecretion of growth hormone and prolactin by the adenoma, or alternatively the mass effect of the somatotroph adenoma inhibiting pituitary stalk function and leading to disconnection hyperprolactinemia.

Clinical Case 7

A 42 year old man was referred with loss of libido and erectile dysfunction. A blood test had shown serum testosterone 5.2 nmol/L, LH 1.8 U/L, FSH 2.1 U/L, prolactin 1119 mU/L. On examination he had coarse facial features, large hands and feet and prognathism. On further investigation he was found to have growth hormone excess due to acromegaly. He was treated for acromegaly, and the serum growth hormone and prolactin levels fell in response to treatment.

Prolactinoma

Prolactinoma is an important and clinically significant cause of hyperprolactinemia. Prolactinoma develops as a result of monoclonal proliferation of the lactotroph cell population. It causes autonomous secretion of prolactin, which leads to the

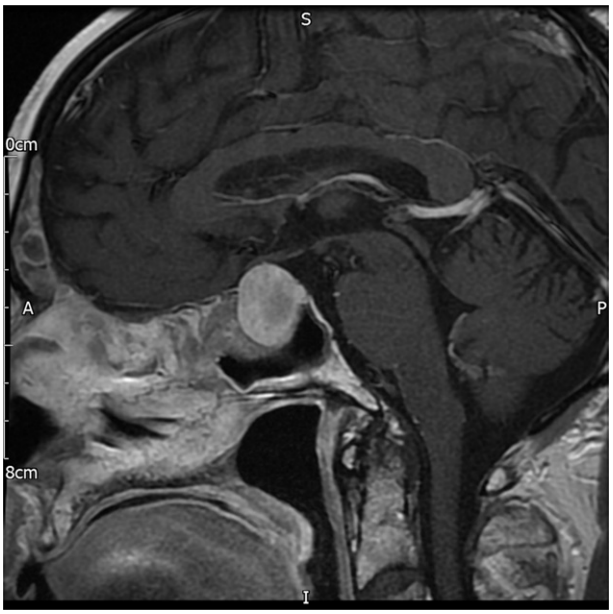

Fig. 1 MRI pituitary, sagittal view with contrast. Serum prolactin 1712 mU/L. The large smooth, round, high signal mass lesion arising from the pituitary fossa is larger than would be expected for a prolactinoma. The diagnosis is nonfunctioning pituitary adenoma with stalk-compression hyperprolactinemia.

hyperprolactinemia syndrome. In women of reproductive age the clinical manifestations are amenorrhea, sometimes galactorrhea, estrogen deficiency and loss of libido. In men the clinical manifestations are loss of libido and erectile dysfunction. As outlined above, it is important for other causes of hyperprolactinemia to be excluded before a diagnosis of prolactinoma is made.

In prolactinoma the degree of hyperprolactinemia is usually commensurate with the size of the adenoma. A large pituitary mass with mild hyperprolactinemia is usually due to a nonfunctioning adenoma rather than a prolactinoma. The diagnosis of prolactin-secreting pituitary adenoma is supported by finding a pituitary adenoma on MRI scan, of a size which is proportionate to the degree of hyperprolactinemia, and by a fall in serum prolactin and shrinkage of the adenoma after treatment with a dopamine agonist. In rare cases which are not responsive to dopamine agonist therapy the diagnosis of prolactinoma may be confirmed by surgical removal of the adenoma and immunohistological analysis showing adenoma with a predominance of cells which stain positively for prolactin.

Clinical Case 8

A 23 year old woman presented with secondary amenorrhea for 6 months. She had noticed mild galactorrhea. A urinary pregnancy test was negative. She was not taking any medication. There were no clinical features of androgen excess, hypothyroidism or acromegaly. The visual fields were full. Investigations revealed serum prolactin 1614 mU/L (with a similar result after PEG precipitation), oestradiol $<$70 pmol/L, LH 1.2 mU/L, FSH 1.5 mU/L, TSH 1.23 mU/L, fT4 12.1 pmol/L, creatinine 79 μmol/L. A pituitary microprolactinoma was seen on MRI pituitary scan (see Fig. 2). She was treated with a dopamine agonist, the serum prolactin level returned to normal, and menstruation was restored, supporting the diagnosis of prolactin-secreting pituitary microadenoma (microprolactinoma).

Summary

The clinical approach to assessing a patient with a raised serum prolactin level requires consideration of the several different causes of hyperprolactinemia. In each situation a disturbance in reproductive function may indicate the effect of the hyperprolactinemia. Prolactinoma is a common and well recognized cause of reproductive disturbance and hyperprolactinemia; however, several other causes of hyperprolactinemia should be considered before a diagnosis of prolactinoma is made.

Summary

Causes of hyperprolactinemia to be considered in diagnosis:

- Physiological
- Pharmacological

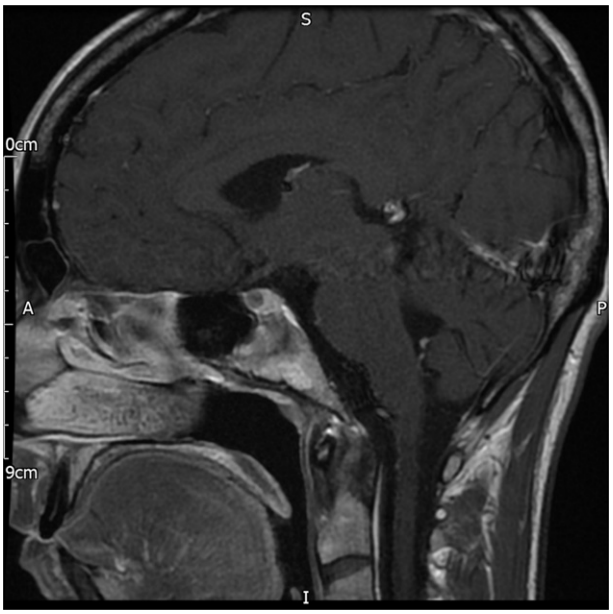

Fig. 2 MRI pituitary, sagittal view with contrast. Serum prolactin 1614 mU/L. The small low signal lesion within the pituitary gland is characteristic of a microprolactinoma.

- Nonpituitary disease
- Pitfalls in measurement
- Other pituitary and para-pituitary disease
- Prolactinoma

Further Considerations

It is generally recognized that the main physiological role of prolactin in women is in the regulation of reproduction. Its role in men is less clearly understood. It should be noted that prolactin is also secreted by tissues other than the anterior pituitary gland, and that there are prolactin receptors in a wide variety of tissues outside the reproductive system. Several functions for prolactin other than in reproduction have been recognized, including actions in the immune system and in relation to angiogenesis. Furthermore, prolactin is found in almost all vertebrates, including fish and birds, where its physiological role is clearly quite different. It should be remembered that our understanding of prolactin is incomplete, and that further research may reveal additional effects of hyperprolactinemia not generally recognized in current clinical practice.

Prolactinomas: Clinical Manifestations and Therapy

Anna Scholz, University Hospital of Wales, Cardiff, United Kingdom
Dafydd Aled Rees, University Hospital of Wales, Cardiff, United Kingdom and Cardiff University, Cardiff, United Kingdom

Glossary

Amenorrhea Lack of menstruation. Primary (never had menses) or secondary (loss of previously established menses).
Dopamine agonists Drugs that activate dopamine receptors.
Galactorrhea Discharge of milk from the breasts.
Hyperprolactinemia Raised levels of prolactin.
Oligomenorrhea Infrequent menses.
Prolactinoma A prolactin-producing pituitary adenoma.
Prolactin (PRL) Pituitary hormone whose physiological role is to cause lactation in women in the postpartum period.
Prolactinoma Prolactin-secreting pituitary adenoma.

Introduction

Prolactinomas are the commonest type of pituitary tumor, accounting for 40% of all pituitary adenomas. Symptoms and signs may arise from hyperprolactinemia per se and/or from local mass effects. Microadenomas (<10 mm in diameter), which predominate in women, are much commoner than macroadenomas (>10 mm in diameter), which have a more equal gender split. Local mass effects can cause symptoms in the latter, dependent on adenoma size and extension outside the sella.

Clinical Manifestations

Table 1 summarizes the commonest clinical findings on presentation.

Galactorrhea

Nonpuerperal galactorrhea describes any discharge of milk from the breasts, and may be spontaneous or expressible on stimulation. Lactation is considered inappropriate when it occurs outside pregnancy or if it persists for more than a year after completion of breast feeding. Galactorrhea is reported in 5%–10% of women with regular menses, nearly all of whom have normal prolactin

Table 1 Presenting symptoms at diagnosis according to tumor size and gender

	Women	*Men*
Macroprolactinoma		
Hypopituitarism	51%	59%
Visual field defects	37%	48%
Headache	69%	38%
Galactorrhea	75%	22%
Infertility	24%	19%
Menstrual disturbance	100%	–
Reduced libido	–	83%
Weight gain	94%	53%
Microprolactinoma		
Headache	31%	6%
Galactorrhea	43%	0%
Infertility	54%	19%
Menstrual disturbance	76%	–
Reduced libido	–	88%
Weight gain	59%	19%

Adapted from Colao, A., Sarno, A. D., Cappabianca, P., *et al.* (2003). Gender differences in the prevalence, clinical features and response to cabergoline in hyperprolactinemia. European Journal of Endocrinology 148(3), 325–331.

levels. In contrast, 75% of women will have hyperprolactinemia when galactorrhea coexists with oligo/amenorrhea. Galactorrhea is much less common in men (10%–20% of cases) but when present is almost pathognomonic of a prolactinoma.

Female Reproductive Function

Hyperprolactinemia affects reproductive function by a number of mechanisms. Hypogonadotropic hypogonadism is the best understood of these, whereby gonadotropin secretion is reduced as a consequence of suppressed gonadotropin-releasing hormone (GnRH) activity from upstream inhibition of hypothalamic kisspeptin-producing neurons. Other mechanisms include a direct inhibitory action of hyperprolactinemia on estrogen and progesterone production in the ovaries, and decreased estrogen production secondary to reduced ovarian aromatase activity from blockade of the stimulatory actions of FSH. As a consequence of these effects, hyperprolactinemia shortens the luteal phase, such that most women become anovulatory, with consequent oligo/amenorrhea and infertility. Menstrual disturbance was reported in 94% of >1400 patients undergoing transsphenoidal surgery for prolactinoma. This usually manifests as secondary oligo/amenorrhea although can present as primary amenorrhea if the adenoma develops prepubertally, at which age macro- lesions predominate.

Many patients with hyperprolactinemia present with infertility, which is inevitable when gonadotropins are suppressed. Most patients in this context have amenorrhea and galactorrhea but a small proportion do not. Dopamine agonist therapy may still be helpful in restoring fertility in such circumstances. Reduced libido may also be apparent, and usually improves when prolactin levels are normalized.

Male Reproductive Function

The mechanisms by which hyperprolactinemia results in hypogonadism in men are similar to those in women, and include reduced LH and FSH pulsatility. Testosterone concentrations, which are typically low or in the low-normal range, improve with correction of hyperprolactinemia provided there is no structural compromise of the pituitary gland. Reduced libido and erectile dysfunction are present in some 90% of patients with chronic hyperprolactinemia, although other hypogonadal symptoms such as reduced beard growth and loss of muscle strength are rare. Sperm count and function may be affected but this usually improves with restoration of normoprolactinemia.

Bone Mineral Density

Long-standing hypogonadism secondary to hyperprolactinemia can lead to osteoporosis in both men and women. Women with hyperprolactinemia, but normal menstruation, do not display a reduced bone mineral density (BMD). Bone mass improves in both sexes with correction of hyperprolactinemia and restoration of eugonadism.

Mass Effects

As with any macroadenoma, macroprolactinomas may induce symptoms through local mass effects. Macroprolactinomas are generally larger in men. Whilst delayed presentation may account for this in part, macroprolactinomas in men tend to be more invasive and resistant to dopamine agonist therapy, and display greater proliferative potential.

The risk of visual compromise increases with the extent of suprasellar extension. Visual field defects may range from classical bitemporal hemianopia (which is not always symmetrical) to smaller quadrantic defects or scotomas. Visual field loss is usually gradual and may go unnoticed by the patient. Lateral extension into the cavernous sinuses may lead to varying degrees of ophthalmoplegia and cavernous sinus syndrome as a result of entrapment of cranial nerves III, IV, V_1, V_2 and/or VI. Invasive tumors causing bony destruction in the skull floor can also cause cranial nerve entrapment, in addition to compression of other base-of-skull structures. Giant prolactinomas are rare, comprising $\sim$2%–3% of all prolactinomas and presenting most commonly in young to middle-aged men. Exact definitions vary, but common criteria are a diameter of >4 cm with significant extrasellar extension and markedly raised prolactin levels. Massive extrasellar extension in such tumors can cause hydrocephalus and temporal lobe epilepsy.

Moderate to severe headaches are most commonly reported by women with macroprolactinomas. Sudden onset of a severe headache, with or without visual compromise and reduced consciousness, should raise suspicion of pituitary apoplexy. This can rarely occur as the first presentation of a macroprolactinoma, but can also develop following initiation of dopamine agonist therapy. Dopamine agonists can also rarely induce a CSF leak as a result of significant tumor shrinkage.

Local mass effects can cause hypopituitarism, either due to direct compression of anterior pituitary cells or as a result of hypothalamic/pituitary stalk compression. The risk of hypopituitarism increases with tumor size, and the pattern of anterior pituitary loss follows that of other tumor types (GH > TSH > ACTH). In children, hypopituitarism may result in pubertal and growth delay. Rarely, clinical manifestations of prolactinomas can result from co-secretion of other hormones. Most commonly, this occurs in the context of Acromegaly, but has on occasion been reported with TSH or ACTH co-secretion.

Additional Features

Up to 5% of clinically diagnosed pituitary adenomas occur due to hereditary tumor syndromes. Prolactinomas are the most common, being found in approximately 40% of MEN-1 and FIPA (familial isolated pituitary adenoma) patients. Carney Complex patients can develop prolactinomas, but these usually also cosecrete GH.

Therapy

The goals of treatment are to restore gonadal and sexual function, to improve symptomatic well-being and, in macroprolactinomas, to reduce tumor size. All macroprolactinomas and most microprolactinomas require treatment. Specific indications for therapy include troublesome galactorrhea, infertility, neurological effects (especially visual field loss), hypogonadism, reduced BMD and delayed puberty. Women seeking fertility with normal menses and mild hyperprolactinemia may also benefit from treatment. Treatment may not be necessary in women with regular cycles and nontroublesome galactorrhea nor in postmenopausal women with microprolactinomas and nontroublesome galactorrhea. Regular surveillance with monitoring of prolactin levels is nevertheless important as an indicator of potential tumor expansion.

Medical Therapy

Dopamine agonists are the primary therapy for patients with prolactinomas. Whilst all dopamine agonists are effective, pergolide and quinagolide are much less commonly used than cabergoline and bromocriptine. A systematic review conducted by the Endocrine Society (Wang *et al.*, 2012) showed that dopamine agonists improve many important patient outcomes including normalization of prolactin levels (median 68%, range 40%–100%), resolution of galactorrhea (86%; 33%–100%), resolution of amenorrhea (78%; 40%–100%) and improvement of sexual function (67%; 6%–100%). In macroprolactinomas, a benefit on reduction in tumor size (62%; 20%–100%) and resolution of visual field defects (67%; 33%–100%) was also confirmed.

A number of studies have shown that cabergoline is more effective than bromocriptine in normalizing prolactin levels, restoring gonadal function and reducing tumor size, potentially due to a higher binding affinity for receptor binding sites. Cabergoline is also better tolerated and more convenient to administer; treatment adherence may therefore be better with cabergoline. For these reasons, cabergoline is generally preferred as first line therapy.

Cabergoline therapy is usually begun at a dose of 0.25–0.5 mg given once or twice weekly, with the dose increased monthly until normoprolactinemia is achieved. Doses in excess of 3 mg weekly are rarely needed. Postmenopausal women should be reassessed for the need for ongoing treatment as prolactin levels may normalize.

Bromocriptine is commenced at a dose of 0.625–1.25 mg daily which may be increased weekly to a typical maintenance dose of 2.5 mg twice or three times daily. Side-effects of nausea and postural hypotension are not uncommon but may be minimized by a gradual dose increment and taking tablets with a snack before bedtime.

Ergot-derived dopamine agonists (cabergoline, bromocriptine and pergolide) have been associated with an increased risk of cardiac valve fibrosis and regurgitation when used in high doses in patients with Parkinson's disease. In contrast, nearly all studies conducted in patients with prolactinomas have found no evidence of an increased risk of clinically significant valve disease, and no relationship of valvular abnormalities with cumulative dose exposure. Nevertheless it is prudent to keep the dose of dopamine agonist therapy at the lowest needed to control prolactin levels, and periodic echocardiography may still be needed in patients receiving high doses for prolonged periods of time.

Microprolactinomas

Dopamine agonist therapy is highly effective in restoring gonadal function and fertility in microprolactinomas. Tumor shrinkage is not a treatment goal because microprolactinomas by definition are confined to the sella and only 5%–10% will increase in size. Annual prolactin measurements and clinical review is often all that is required once normoprolactinemia is achieved. In some patients, gonadal function is restored even if prolactin levels are not normalized. Complete normalization of prolactin levels is therefore not always necessary and decisions on dose adjustment should be made based on clinical response as much as biochemical review. Estrogen replacement, most commonly given as the combined oral contraceptive pill, may be an alternative approach to dopamine agonist therapy in oligo/amenorrheic women with microprolactinomas not seeking pregnancy. Whilst studies have shown that estrogen therapy does not appear to be associated with an increase in tumor size, prolactin levels should be measured annually and an MRI repeated if these rise significantly. Many microprolactinomas shrink or even disappear in response to long-term therapy such that a trial of dopamine agonist withdrawal is recommended after 2 years of treatment in patients who no longer have a raised prolactin. Sustained normoprolactinemia is achieved in 20%–35% of patients under such circumstances.

Macroprolactinomas

Dopamine agonists will normalize prolactin levels and reduce tumor size in the majority of patients with macroprolactinomas. Tumor shrinkage usually occurs rapidly within a few weeks of starting therapy but may be delayed for a few months in some patients (**Fig. 1**). An MRI undertaken at 3 months following therapy commencement is helpful in confirming this response, with

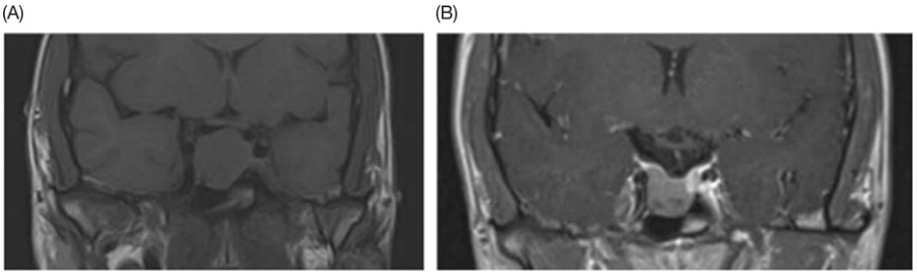

Fig. 1 MRI pituitary showing a macroprolactinoma (A) at diagnosis and (B) following 3-months of cabergoline therapy.

scanning intervals extended thereafter and guided by prolactin response. Similarly rapid improvements in visual function are usually evident, such that surgery is not required for patients with visual field defects in the absence of resistance or intolerance to dopamine agonist therapy. Hypopituitarism, especially growth hormone deficiency, may also recover hence it is important to consider retesting to confirm ongoing need for anterior pituitary hormone replacement. Treatment should aim to restore normoprolactinemia; once tumor shrinkage is achieved doses can be tapered gradually until the lowest dose which maintains a normal prolactin is reached. In contrast to microprolactinomas, cessation of dopamine agonist therapy is rarely followed by sustained remission. If a trial of drug withdrawal is to be considered in patients with significant tumor shrinkage and a normal prolactin, close follow-up is needed to look for recurrence of hyperprolactinemia and tumor reexpansion.

Resistant Prolactinomas

Whilst outcomes in response to dopamine agonists are usually excellent, some patients do not respond adequately. Intolerance to a dopamine agonist due to side-effects may be managed by switching to an alternative preparation or by undertaking transsphenoidal surgery. Dopamine agonist resistance should be distinguished from intolerance and may include a failure to restore normal prolactin levels in response to a maximally tolerated dose of dopamine agonist and a failure to achieve a significant ($>50\%$) reduction in tumor size. The molecular basis of dopamine agonist resistance varies and may include dopamine D2 receptor and postreceptor mechanisms. Cabergoline fails to restore normoprolactinemia in approximately 10% of microprolactinomas and 18% of macroprolactinomas. Men are also more likely to display resistance than women. Options for treatment include maximization of the dopamine agonist dose, switching to a different dopamine agonist and consideration of transsphenoidal surgery. The evidence for a benefit in switching dopamine agonist is greatest for changing bromocriptine to cabergoline. Up to 25% of patients are resistant to bromocriptine, 80% of whom will restore normal prolactin levels in response to cabergoline. Tumor shrinkage is also more profound with cabergoline.

Surgery

The success rates of transsphenoidal surgery, in common with all types of pituitary adenoma, are dependent on tumor size and skill of the surgeon. In specialized centers, normalization of prolactin levels occurs in about 75% of microprolactinomas but is significantly worse for macroprolactinomas, especially if there is cavernous sinus extension. A 20% recurrence rate of hyperprolactinemia is also reported. Transsphenoidal surgery is therefore usually reserved for patients showing dopamine agonist intolerance or resistance (including a failure of visual function to improve). Less commonly, surgery may be considered in cystic macroprolactinomas with neurological compromise (as these often fail to shrink in response to dopamine agonists), apoplexy with neurological signs and where patient preference is for surgery.

Radiotherapy

Radiotherapy is rarely required to treat prolactinomas, because medical therapy is so effective and the side-effects of radiotherapy are not inconsiderable (including hypopituitarism, increased risk of stroke and secondary brain tumors, and optic nerve damage). In practice, radiotherapy is therefore reserved for resistant tumors not cured by surgery, or for malignant prolactinomas. When used, radiotherapy restores normal prolactin levels in approximately one-third of patients and may stabilize tumor growth, albeit that it may take many years for maximum benefit.

Malignant Prolactinoma

Malignant prolactinomas are very rare and cannot be distinguished from adenomas on histological grounds. They are defined as malignant when metastatic disease develops elsewhere in the central nervous system or further afield. Only very few are malignant at presentation, and most arise on a background of a previously invasive macroprolactinoma that has already been treated with dopamine agonists, surgery and radiotherapy. Resistance to dopamine agonists is common and there is often a discordance

between tumor mass and prolactin levels. Treatment is particularly difficult. Whilst debulking surgery may be considered to reduce symptomatic local compression, outcomes from 'conventional' chemotherapy (e.g., vincristine, procarbazine, cisplatin, etoposide) are poor. However, although experience is limited to case series, the oral alkylating agent temozolomide appears to be effective in reducing prolactin levels and controlling tumor growth. Nevertheless, responses are not usually sustained and prognosis is usually poor.

Prolactinoma and Pregnancy

The management of hyperprolactinemia prior to and during pregnancy presents several challenges, including the effects of hyperprolactinemia on fertility, the safety of dopamine agonists in pregnancy, effects of pregnancy on tumor expansion, and lactation.

Dopamine agonists are highly effective in restoring a regular menstrual cycle and ovulation. Patients must thus be warned that restoration of fertility may occur rapidly, even before menses resume. Women not wishing to become pregnant should thus use appropriate methods of contraception. When pregnancy is desired in a woman with a macroprolactinoma, it is preferable to ensure that conception is planned once prolactin levels have normalized and tumor shrinkage has ensued, in order to reduce the risks of optic chiasmal compression with tumor expansion during pregnancy.

Both cabergoline and bromocriptine cross the placenta but to date no safety concerns have been raised with respect to fetal outcomes with either drug. In excess of 6000 pregnancies have been reported in women treated with bromocriptine, with no differences in congenital abnormalities, ectopic pregnancies or spontaneous abortions compared to the background population. Long-term follow-up studies have also been reassuring with respect to child neurodevelopmental outcomes. Although the experience with cabergoline use in pregnancy is much less, the data to date are also reassuring with respect to fetal outcomes. In contrast, quinagolide does appear to be associated with an increased risk of congenital malformations in the relatively small number of pregnancies reported, and its use in this setting is not recommended.

Although the safety data of both bromocriptine and cabergoline in pregnancy appear reassuring, the first trimester is the time when any drug-induced teratogenic effects are likely to be at their highest. It is thus appropriate for most women to be advised to stop these drugs as soon as they miss a menstrual period and pregnancy is confirmed.

Pregnancy is accompanied by an estrogen-stimulated expansion of the lactotroph population, such that prolactin levels increase 10-fold and pituitary volume twofold compared to prepregnancy values. This expected rise in prolactin during pregnancy, coupled with the observation that some prolactinomas can enlarge without a significant rise in prolactin, limits the diagnostic

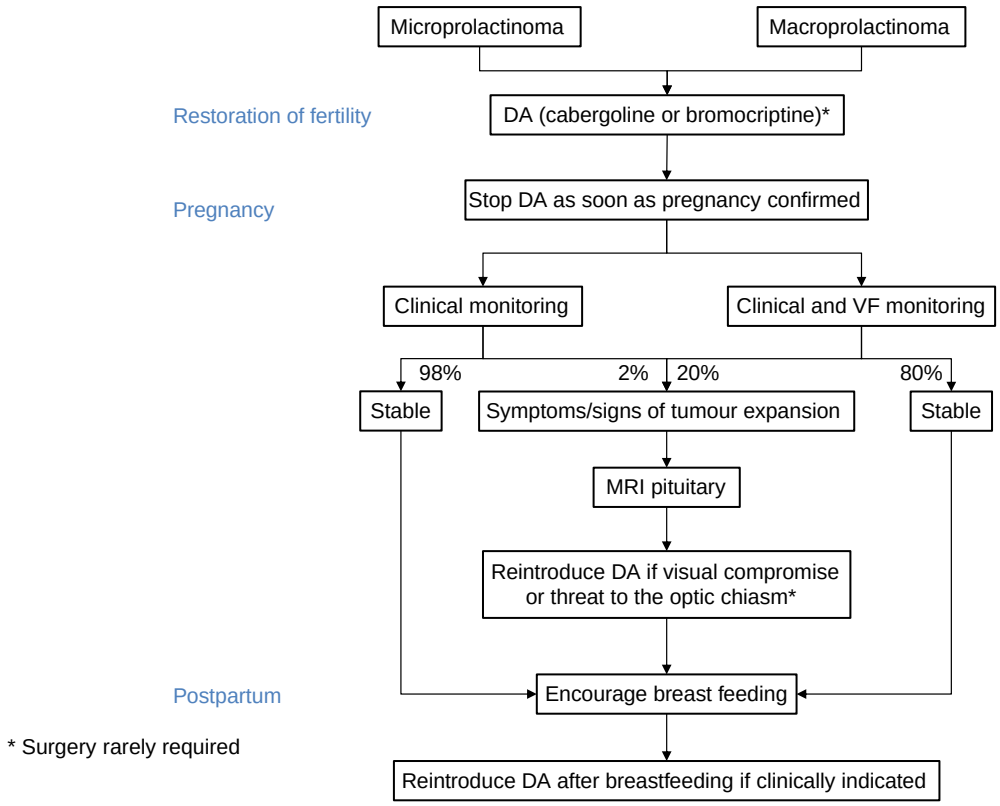

Fig. 2 Management algorithm for prolactinoma in pregnancy.

value of prolactin measurement as a marker of tumor enlargement in pregnancy. Serum prolactin should not therefore be measured during pregnancy.

The risk of clinically significant tumor expansion in pregnancy is dependent on tumor size and prior treatment. Only about 2.5% of microprolactinomas expand to an extent that symptoms ensue, such that clinical examination to include a bedside assessment of visual fields is all that is usually required in each trimester. Formal visual field assessment and MRI can then be reserved for those rare patients in whom there is clinical evidence of tumor growth. In contrast, the risk of symptomatic expansion in macroprolactinomas is 20%–30%, although this is reduced to 5% in patients who have previously been treated with surgery or radiotherapy. An individualized approach is needed in this setting dependent on the position of the macroprolactinoma with respect to the optic chiasm and its previous responsiveness to dopamine agonist therapy. Some clinicians might recommend debulking surgery before pregnancy in women with macroprolactinomas to reduce the risk of tumor expansion, but this runs the risk of inducing hypopituitarism and infertility, and is best reserved for patients who are intolerant or resistant to dopamine agonists. More common approaches include discontinuing the dopamine agonist once pregnancy is confirmed, with regular clinical surveillance and formal visual field testing, or continuing the dopamine agonist throughout pregnancy (recognizing that the safety data of dopamine agonists continued in this manner are still comparatively limited). MRI without gadolinium should be undertaken in women reporting worsened headaches and/or changes in their visual fields. In cases of confirmed tumor expansion, reintroduction of dopamine agonists is usually successful in reversing tumor enlargement, but transsphenoidal surgery or early delivery may rarely be required.

Women expressing a wish to breast feed their children should not be recommenced on dopamine agonists because the fall in prolactin levels will impair lactation. Breastfeeding need not be restricted since it does not cause an increase in prolactin levels nor are there data to suggest an increase in tumor size.

A flow chart outlining a potential approach to the management of prolactinoma during pregnancy is shown in **Fig. 2**.

Introduction

Hypophysitis is defined as the presence of any inflammatory process of the pituitary gland, that may involve the anterior lobe, the posterior lobe and/or the infundibulum. A rare localized or predominant involvement of the hypothalamus has been reported as "hypothalamitis." The etiopathogenesis of hypophysitis is complex (Caturegli *et al.*, 2005, 2008). Pituitary inflammatory infiltration was first recognized in Brissaud *et al.* (1908), while associated aspects (i.e., pituitary atrophy, concomitant extra-pituitary autoimmune (AI) disorders and the temporal association with pregnancy) were described in 1962 in an autopsy report of a young female who died of postsurgical adrenal crisis 14 months after delivery in a context of hypopituitarism (Goudie and Pinkerton, 1962). Soon after, the first experimental animal model of AI hypophysitis was reported (Levine, 1967), followed by the identification of autoantibodies against PRL-secreting pituitary cells (Bottazzo *et al.*, 1975). Then, the clinical, histological, and radiological features of different forms of hypophysitis have been progressively characterized (Carpinteri *et al.*, 2009; Guaraldi *et al.*, 2017).

Nowadays, the term "hypophysitis" encompasses a broad variety of primary and secondary inflammatory diseases, some of which are being increasingly recognized. In particular, in the last decade, hypophysitis has emerged as a frequent complication of anticancer immunotherapy, raising interest far outside the limited community of pituitary specialists. Hypophysitis in the setting of the systemic IgG4-related (IgG4-R) inflammatory syndrome or infective disorders in immunocompromised patients have also gained interest among physicians in different fields of internal medicine. As most of these disorders can be suspected according to the clinical context, the indications for diagnostic neurosurgery have decreased over time, but histopathological diagnosis remains a cornerstone in many cases. The clinical implications of hypopituitarism, in particular the risk of adrenal insufficiency, which is more common than in pituitary masses of noninflammatory origin, are relevant and should be promptly recognized and treated in order to prevent morbidity and mortality. Diabetes insipidus and mass effects are additional issues in affected patients.

This article presents a synthetic update on the physiopathology, clinical presentation, diagnosis, and treatment of the different forms of hypophysitis, in order to provide a useful tool for any practitioner who may need to recognize and manage this condition in clinical practice.

Pathogenesis and Natural History of Hypophysitis

Hypophysitis can be schematically classified according to three essential criteria: (1) the anatomical site of the inflammatory process: adenohypophysitis, infundibulum/neurohypophysitis, panhypophysitis (both adeno- and neuro-hypophysitis), and

infundibulum/hypothalamitis; (2) its etiology: primary hypophysitis, an intrinsic pituitary process, mostly of autoimmune origin, and secondary hypophysitis, which may be reactive to adjacent lesions (i.e., Rathke's cleft cysts), a part of systemic inflammatory or infectious diseases, or side effect of immunomodulatory therapies; (3) histopathology: lymphocytic (LYH), granulomatous (GrH), xanthomatous (XH), mixed forms (lympho- or xantho-granulomatous—LGrH or XGrH), and IgG4-R lymphoplasmacytic form. In clinical practice, overlap between the different anatomical localizations and/or underlying pathological conditions may occur and acute, subacute or chronic forms may be observed. We will use a transitional approach to link the pathogenic mechanisms to the clinical presentation and histological characterization of this heterogeneous condition.

Primary Hypophysitis

Primary hypophysitis is considered as a rare clinical entity. The estimated annual incidence is 1/9 million inhabitants (Caturegli *et al.*, 2005), accounting for 0.24%–0.88% of pituitary diseases and $<1\%$ of operated pituitary masses (Lee *et al.*, 2017). However, the real epidemiology remains uncertain due to the heterogeneity of criteria used for its definition and data collection.

Lymphocytic hypophysitis (LYH) is by far the most common form and is considered as an autoimmune (AI) disorder based on a series of findings: pituitary infiltration by inflammatory cells (typically T lymphocytes, occasionally organized in follicles, in combination with B lymphocytes and macrophages) (**Fig. 1**), the progressive replacement of glandular tissue by fibrotic tissue, the reproducibility of the disease in animal models, the common association with other autoimmune diseases or immunomodulatory treatments, the presence of antipituitary autoantibodies (APA) in most cases, and the frequent resolution of symptoms by immunosuppressive treatments (Caturegli *et al.*, 2005). LYH may be isolated or associated with additional AI disorders, in particular thyroiditis, including polyendocrine AI syndromes (Caturegli *et al.*, 2005; De Bellis *et al.*, 2008). It typically affects young patients (mean age 35 ± 13 years in females, 45 ± 13 years in males), women more than males (F:M ratio up to 6:1), especially in adenohypophysitis, which often occurs in the late pregnancy or within 6 months postpartum (Caturegli *et al.*, 2005). The association of hypophysitis with pregnancy could be due to the expression of common autoantigens expressed by pituitary and placenta tissues (i.e., α-enolase, CSH1–2), increased release of pituitary antigens and/or increased accessibility of pituitary to immune cells due to estrogen-driven pituitary enlargement and changes in blood flow, or unmasking of preexisting silent condition by pregnancy. Noteworthy, contrasting with other AI diseases, LYH is not transmitted from the mother to the fetus and does not appear to impair pregnancy outcome, fetus health or subsequent fertility, nor predispose to disease recurrence in subsequent pregnancies (Landek-Salgado *et al.*, 2010). LYH has been more recently reported in children (Kalra *et al.*, 2011). Pediatric LYH has no gender predominance, DI and GH deficiency are the leading symptoms and the diagnosis is usually delayed. The pituitary mass typically shrinks in some years, whereas hypopituitarism commonly persists, requiring long-term replacement therapy (Kalra *et al.*, 2011).

Idiopathic granulomatous hypophysitis (GrH) is the second most common form of primary hypophysitis but remains very rare, and it is still debated whether isolated GrH is a distinct physiopathological entity or may represent a late stage of LYH. In a systematic review of 82 cases of GrH reported in the literature (Hunn *et al.*, 2014), a female predominance was observed (72%) and the mean age at diagnosis was around 45 years. Mass effects were frequent and might include cranial nerve palsies. Multiple anterior pituitary insufficiency was common, ACTH deficiency being the most frequent ($>70\%$), whereas DI was present in about 25% of the cases. Importantly, attention should be paid to recognize secondary forms of GrH, which are more frequent and may

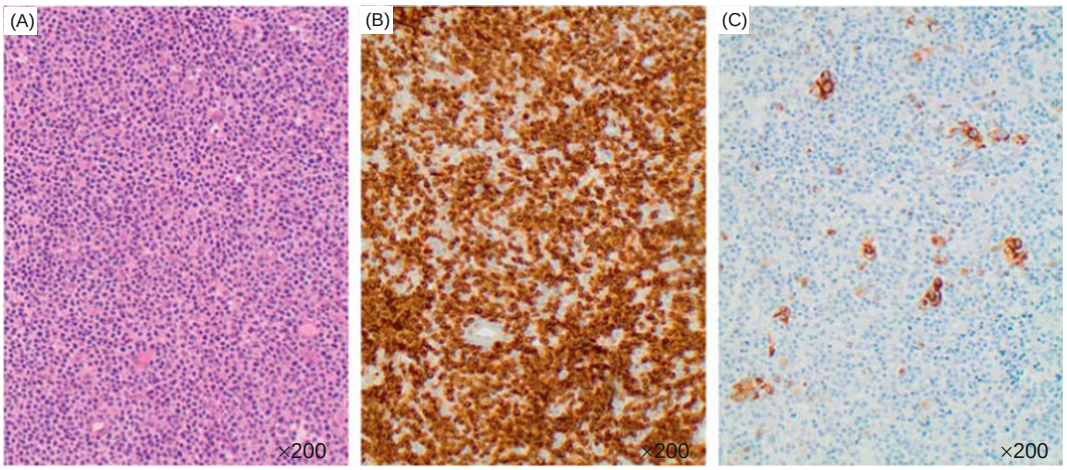

Fig. 1 Lymphocytic hypophysitis. The pituitary gland is intensively infiltrated by lymphocytes obscuring the normal architecture. (A) Hematoxylin-eosin; (B) Inflammatory cells are strongly expressing CD3 (T-cells); (C) Normal endocrine pituitary cells are visualized by anticytokeratin staining (Cam 5.2) By courtesy of Prof Jacqueline Trouillas, University of Lyon, France.

be associated to ruptured Rathke's cleft cyst (RCC), craniopharyngioma or microbial agents. Moreover, granulomatous involvement of pituitary gland may be part of a systemic, neoplastic or reactive granulomatous disorder (Carpinteri *et al.*, 2009).

Xanthomatous hypophysitis (XH) is the rarest histological type with less than 20 cases reported in the literature (Hanna *et al.*, 2015). Both XH and mixed XGrH are controversial as primary entities and probably represent spectrum of reactive changes related to other primary pituitary lesions, mainly RCC (Paulus *et al.*, 1999; Kleinschmidt-DeMasters *et al.*, 2017).

Finally, a pure necrotizing hypophysitis, characterized by an acute onset, has been reported, though it appears as an exceptional entity of unclear etiology (Gutenberg *et al.*, 2012). As such, its existence as a definite entity has been subsequently questioned.

IgG4-related hypophysitis (IgG4-RH) will be described with systemic diseases potentially involving pituitary gland.

Hypophysitis and Pituitary Gland Involvement In Systemic Diseases

The pituitary gland may be involved in a variety of rare inflammatory and/or neoplastic systemic diseases. As it may represent the first clinical manifestation, physicians should be aware of this eventuality in order to appropriately recognize and treat the systemic condition and endocrine deficiencies as appropriate.

Systemic granulomatous diseases such as sarcoidosis, granulomatosis with polyangiitis (Wegener's granulomatosis), Takayasu's disease and even Crohn's disease may rarely infiltrate the pituitary gland (Carpinteri *et al.*, 2009). Neurosarcoidosis with hypothalamic-pituitary involvement is the best characterized, with DI, hyperprolactinemia and hypogonadotropic hypogonadism being the most frequent symptoms, while hypothalamic manifestations are less common (Martin-Grace and Murialdo, 2015).

Langherhan's cell histiocytosis (LCH) and other histiocytic diseases. The classification of histiocytic disorders has been recently reviewed by the World Health Organization (WHO) (Pileri *et al.*, 2017). LCH, previously designated as histiocytosis X, is a clonal neoplastic proliferation of Langerhans-type cells that express CD1a, langerin and S100 protein, and shows Birbeck granules by ultrastructural examination (Weiss *et al.*, 2017). LCH may develop at any age but is more frequent in children. Most pediatric cases are diagnosed at the age of 1–5 years and adult cases in their 3rd–4th decade (Donadieu *et al.*, 2004a; Girschikofsky *et al.*, 2013). The severity of the disease depends on its localization and extension (bone, skin, central nervous system, lungs, liver, spleen, lymph nodes). Aggressive and potentially fatal disseminated forms are rare in adults. Hypothalamic-pituitary involvement is frequent (Donadieu *et al.*, 2004a; Girschikofsky *et al.*, 2013). DI is the most common endocrine symptom and may be the first manifestation of the disease, whereas hypopituitarism, which rarely occurs in the absence of DI, leads to progressive and permanent endocrine dysfunction. GH and gonadotroph deficiencies are the most frequent (40%–60%), and translate into impaired growth and delayed puberty in children (Donadieu *et al.*, 2004a). Hyperprolactinemia occurs mostly in adults. Hypothalamic symptoms may be present, including morbid obesity (Kaltsas *et al.*, 2000). Neurodegenerative radiological lesions are being increasingly recognized and may lead to neuropsychological disabilities (Fahrner *et al.*, 2012). Radiologically, an isolated thickening of the stalk or sellar/suprasellar masses can be found (Fahrner *et al.*, 2012; Girschikofsky *et al.*, 2013). Diagnostic criteria should possibly include at least a pathological proof of LCH (Girschikofsky *et al.*, 2013). Both Erdheim–Chester disease, a systemic, clonal proliferation of histiocytes and disseminated juvenile xanthogranuloma, a rare proliferation of xanthomatous histiocytes can affect the pituitary gland as isolated localization of the diseases or as a result of their dissemination to the central nervous system (CNS) (Brousse *et al.*, 2017a,b). Rosai–Dorfman disease, another histiocytic disorder, usually localizes to the skin, but may present as an intra/suprasellar lesion composed of a mixed inflammatory infiltrates composed of histiocytes, lymphocytes, and plasma cells (Paulus *et al.*, 2016). The differential diagnosis between primary (xantho)granulomatous hypophysitis and pituitary localization of systemic, frequently neoplastic, histiocytic disorders may be challenging and requires a multidisciplinary approach to avoid serious and potentially fatal consequences if these latter remain untreated, especially in the context of a CNS dissemination (Ferguson *et al.*, 2015).

IgG4-R hypophysitis was more recently characterized and appears as a rare disease characterized by fibrosis and lymphoplasmacytic proliferation including IgG4-reactive cells. Following its first description in van der Vliet and Perenboom (2004) and the first histological proof of this entity (Wong *et al.*, 2007), less than a hundred of cases were reported until 2015, many observations coming from Japan (Shikuma *et al.*, 2017). The typical localizations of the disease are retroperitoneum, pancreas, salivary glands, lymph node, lung, while isolated hypophysitis may not represent more than 10% of the cases. Men are more frequently affected, with a mean age at diagnosis around 67 and 56 years-old in men and in women, respectively (Shikuma *et al.*, 2017). Diagnostic criteria avoiding the need for a histological proof of the pituitary disease if sufficient additional elements are present have been proposed (Leporati *et al.*, 2011).

Cancer Immunotherapy and Hypophysitis

Immune checkpoints inhibitors aim to release constraints on immune cells and promote their antitumor activity. Not unexpectedly, immune-related adverse events (irAEs) often occur as side-effects and frequently involve endocrine glands (Bertrand *et al.*, 2015). Pituitary dysfunction is being increasingly recognized in cancer patients treated with a variety of monoclonal antibodies (mAbs) used as targeted therapies (Torino *et al.*, 2013). Hypophysitis is the most significant endocrine irAE induced by mAbs raised against CTLA-4 and may also be induced by anti-PD1 mAb (Faje, 2016; Boutros *et al.*, 2016; Joshi *et al.*, 2016). Ipilimumab (Ipi) and tremelimumab target CTLA4 whereas pembrolizumab and nivolumab target PD1. As Ipi and pembrolizumab/nivolumab were approved by FDA and EMA for the treatment of metastatic melanoma in 2011 and 2014/2015,

respectively, and their indications are extending to the treatment of additional malignancies, the number of patients treated with these molecules has dramatically increased in the last years. The pathogenesis and peculiarities of hypophysitis arising in this setting are being increasingly understood.

CTLA-4 is expressed on activated T-cells and negatively regulates their proliferation and activation. CTLA-4 is also expressed on endocrine pituitary cells and anti-CTLA-4 induced hypophysitis was reproduced in an experimental model whereas anti-TSH antibodies, followed in order by anti-FSH and anti-ACTH antibodies were also observed in humans and strongly associated with the subsequent development of hypophysitis (Iwama *et al.*, 2014). Yet, a single human pathological report of Ipi-induced hypophysitis is available as a postmortem observation showing evidence of type II and IV hypersensibility (Caturegli *et al.*, 2016). Faje (2016) recently summarized the results of three large longitudinal series of melanoma patients receiving Ipi (Faje *et al.*, 2014; Albarel *et al.*, 2015; Min *et al.*, 2015). Hypophysitis was recorded in 11.0%–17.2% of the cases, which is much higher than reported in oncological trials (0%–6.5%) (Barroso-Sousa *et al.*, 2018). Ipi-induced hypophysitis generally develops after 2–3 months of treatment, though delayed presentation may occur, with headache and hypopituitarism as leading symptoms, uncommon visual impairment, and exceptional DI (Faje, 2016). The dose effect (10 mg/kg vs. 3 mg/kg) remains uncertain. Overall, TSH, ACTH, FSH/LH, and GH deficits were reported in 96.3%, 85.7, 74.1%, and 28.6% of the patients, respectively (data on GH deficiency were partial but poorly relevant in this context), and hypoprolactinemia was more frequent than hyperprolactinemia (Faje, 2016). Of note, moderate pituitary enlargement was found to precede pituitary dysfunction and improve over time, explaining the absence of surgical indication and pathological reports. In addition, contrasting with frequent recovery of thyrotroph and gonadotroph functions, ACTH deficiency commonly persisted ($>80\%$) (Faje, 2016).

PD1 is expressed by activated T and B cells and its ligands PDL1 and PDL2 by antigen presenting cells (APC) and some tumor cells. Clinical experience with anti-PD1 is more recent but irAEs appear to be less frequent than reported with Ipi (Boutros *et al.*, 2016). This may reflect the differential role of CTLA4 and PD1, with a more restricted population of T cells affected by PD1 blockade, and is in agreement with the milder autoimmune phenotype of PD1–deficient mice as compared to CTLA-4-deficient mice (Boutros *et al.*, 2016). In a meta-analysis of nine randomized studies, the pooled risk of hypophysitis was estimated to 0.47% (Costa *et al.*, 2017). However, as delayed and even isolated ACTH deficiency is being reported on long-term treatment with nivolumab (Okano *et al.*, 2016; Kuru *et al.*, 2017; Takaya *et al.*, 2017), longitudinal follow-up studies are needed to better evaluate the prevalence of pituitary dysfunction and prevent acute adrenal failure.

Hypophysitis and Tumors of the Sellar Region

Hypophysitis may occur secondarily to a pathological process of nearby structures. Inflammation is frequently associated with RCC, which leakage, rupture or bleeding may promote xanthomatous or xanthogranulomatous reaction (Paulus *et al.*, 1999; Kleinschmidt-DeMasters *et al.*, 2017; Lee *et al.*, 2017). LH, XH or XGrH may also be observed in the proximity of a craniopharyngioma (Paulus *et al.*, 1999; Kleinschmidt-DeMasters *et al.*, 2017; Lee *et al.*, 2017). Germ cell tumors (GCT) are rare intracranial tumors mainly arising in the pineal and sellar regions (Duron *et al.*, 2018). Because of their rich lymphocytic infiltration, GCTs may be misdiagnosed as primary hypophysitis (Bettendorf *et al.*, 1999; Endo *et al.*, 2007; Ozbey *et al.*, 2006). Rarely, pituitary localization of lymphoma may present with a concomitant hypophysitis (Huang *et al.*, 2005). Slight lymphocytic infiltration or cholesterol clefts may occasionally be seen in pituitary adenomas (PA) (Lupi *et al.*, 2010; Yokoyama *et al.*, 1998), which should be distinguished from the true coexistence of primary hypophysitis and PA (Ballian *et al.*, 2007; Saeger *et al.*, 2007). Exceptionally, hypophysitis may coexist with meningioma, as in a case of a young pregnant woman with previously unrecognized sellar meningioma who developed lymphocytic hypophysitis. The meningioma, in combination with physiological lactotroph hyperplasia and additional pituitary enlargement due to the inflammatory changes by the end of pregnancy led to the critical increase of a sellar mass, requiring transsphenoidal debulking and surgical termination of pregnancy. (A consultation case, kindly provided by Dr. Pia Burman, University of Lund, Sweden) (**Fig. 2**).

Hypophysitis In Infective Conditions

Hypophysitis related to infectious agents still represents an important cause of transient or permanent hypopituitarism in tropical and developing countries. An increasing incidence can be expected worldwide due to migrations and a rising prevalence of predisposing conditions such as diabetes mellitus, immunosuppressive therapies and other immunocompromised conditions, including HIV infections (Harbeck *et al.*, 2011; Spinner *et al.*, 2013). Secondary abscesses in pituitary lesions such as RCC or PA, or following pituitary surgery, have also been reported (Awad *et al.*, 2014; Wang *et al.*, 2014; Yang *et al.*, 2017). Infectious agents can reach the sellar region via blood or by direct spreading from neighboring structures (brain, paranasal sinuses, cavernous sinus, and meninges). The most important forms of chronic bacterial infections of pituitary gland are granulomas associated with tuberculosis (Sharma *et al.*, 2000; Dhanwal *et al.*, 2010), less commonly syphilis (Bricaire *et al.*, 2015), which may also cause acute hypophysitis (Spinner *et al.*, 2013). Pituitary abscesses due to Gram-positive or Gram-negative bacteria are potentially life-threatening conditions which may affect patients at any age (Vates *et al.*, 2001; Altas *et al.*, 2013; Karagiannis *et al.*, 2016; Gao *et al.*, 2017). Infections by Hantaviruses are zoonoses spread by rodents causing hemorrhagic fever with renal syndrome, especially in Asia and America. The Puumala hantavirus (PUUV)—endemic in Nordic countries and other parts of Europe—causes a less severe systemic disease but may directly target the pituitary determining secondary hypophysitis and/or ischemia/necrosis

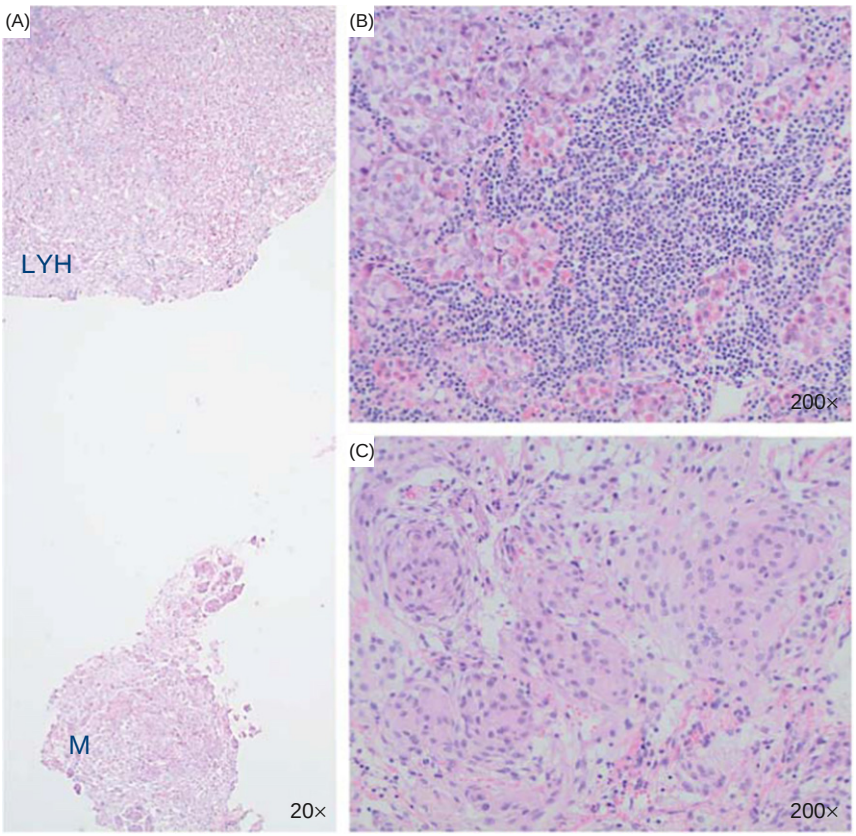

Fig. 2 Coexistence of a pregnancy-related lymphocytic hypophysitis (LYH) and a meningioma (M) (hematoxylin-eosin), (A) Both LYH and M are present in the same surgical specimen (provided by courtesy of Dr Pia Burman, see text), (B) LYH: the pituitary gland is infiltrated by lymphocytes; (C) The adjacent meningioma has a typical appearance and is devoided of lymphocytic infiltration.

leading to hypopituitarism (Hautala *et al.*, 2010; Partanen *et al.*, 2016; Pekic and Popovic, 2017). Aspergillus, Nocardia, Candida may occasionally cause fungal abscesses (Beatrice *et al.*, 2013; Hao *et al.*, 2008, Pekic and Popovic, 2017). Hypophysitis related to *Toxoplasma gondii* infection was recently reported in immunocompromised patients (Hamdeh *et al.*, 2015).

Headache is the most common symptom of pituitary infection (70%–90% in most series), whereas the prevalence of a suggestive subacute onset with fever and meningism may not exceed 25% (Karagiannis *et al.*, 2016). Rather, long-standing pseudo-tumoral symptoms may be present, implying that pituitary abscesses should be considered in the differential diagnosis of a pituitary mass, in particular if cystic. Endocrine dysfunction is frequent, due to variable degrees of destruction of the anterior pituitary (30%–85%), with a classical progressive hypopituitarism starting from GH and FSH/LH insufficiency, and DI in about half of the cases (Vates *et al.*, 2001; Karagiannis *et al.*, 2016; Gao *et al.*, 2017). Cavernous sinus thrombophlebitis may complicate the clinical outcome (Karagiannis *et al.*, 2016).

Diagnosis

Clinical Presentation of Hypophysitis

The clinical manifestations of hypophysitis are heterogeneous and nonpathognomonic, ranging from asymptomatic to severe clinical pictures, depending on the stage and evolution of the disease, its anatomic localization and extension. In its acute phase, adenohypophysitis may be revealed by mass effects due to rapid pituitary enlargement by the inflammatory process and associated edema, such as headache, visual disturbances (chiasmatic syndrome), and more rarely, nausea, vomiting, or diplopia secondary to III, IV, or VI cranial nerve palsies (cavernous sinus involvement), as well as hypopituitarism. Isolated pituitary deficiency may be present and limited to ACTH insufficiency, potentially leading to adrenal crisis. Variable degrees of menstrual abnormalities and hypogonadism are also frequent and may reflect primary impairment of gonadotroph cells or functional inhibition by hyperprolactinemia of unequivocal origin—impaired dopamine delivery to the anterior pituitary (pituitary stalk compression or infiltration), abnormal PRL release into the circulation due to massive cellular destruction, or PRL secretion by infiltrating immune cells (Caturegli *et al.*, 2005; Guaraldi *et al.*, 2017). Inability to lactate can also occur due to hypoprolactinemia in the context of hypopituitarism, mimicking Sheehan syndrome. DI typically occurs in the presence of neuro-infundibular localization of the

inflammatory process, though it may occur in adenohypophysitis, likely through an inhibition of the axonal transport of ADH due to swelling of the *pars tuberalis* (Caturegli *et al.*, 2005). Interestingly, the severity and rapidity of onset of hypopituitarism are poorly correlated with the degree of pituitary enlargement, suggesting the predominant role of immunomediated cell destruction over pituitary compression (Caturegli *et al.*, 2005). In the chronic phase of LYH, replacement of the functional gland by fibrosis and progressive atrophy lead to irreversible hypopituitarism, typically starting from ACTH, followed by FSH/LH, GH, TSH, and PRL secretion. Central DI may also persist as a permanent sequela. Of note, LYH may have a polyphasic course with remissions and relapses (Caturegli *et al.*, 2005). Rarely, hypophysitis manifest with mood disorders, alterations of hypothalamic functions (i.e., thermo-, weight and sleep regulation), epilepsy, or is asymptomatic and incidentally discovered (Guaraldi *et al.*, 2017).

Clinical Evaluation of a Patient With Suspect Hypophysitis

In clinical practice, hypophysitis often presents as a nonsecreting pituitary lesion revealed by mass effects, in particular headache, DI and/or various degrees of hypopituitarism. In the eventuality of surgery, the diagnosis relies on pathological examination, which remains the gold standard. In the absence of a pathological proof of the disease, the diagnosis may be challenging due to its heterogeneous, nonpathognomonic presentation and variations from acute to chronic forms (Caturegli *et al.*, 2005; Carpinteri *et al.*, 2009; Guaraldi *et al.*, 2017). The presence of predisposing factors has to be considered first. Then, a combination of clinical, radiological, and laboratory findings may be put together in order to reasonably approach the diagnosis. In the absence of a suggestive setting or in front of an atypical clinical presentation, the differential diagnosis with other nonsecreting pituitary masses requires specific multidisciplinary expertise and a surgical biopsy is generally indicated. Age and sex are not uniformly distributed among patients with hypophysitis and the clinical context may be highly suggestive, provided that differential diagnosis is appropriately thought. For example, primary LYH should be first considered in young women, especially in relation with pregnancy and/or in a context of autoimmunity, and in recent series the indications for diagnostic surgery have decreased (Honegger *et al.*, 2015; Kyriacou *et al.*, 2017; Wang *et al.*, 2017). Systemic LCH has a typically young onset whereas IgG4-R diseases generally occurs in elderly patients, and in both conditions additional localizations may be present and accessible for a diagnostic biopsy. The presence of fever, recent migration from tropical countries, immunosuppression may be suggestive of an infectious origin, which should be thought before any glucocorticoid trial is planned, since pituitary infections are potentially life-threatening conditions. Immunotherapy in cancer patients may induce transient hypophysitis as an irAE, which should not be confounded with pituitary metastasis, which may also induce DI, hypopituitarism and mass effects including cranial nerve palsies (Gilard *et al.*, 2016). Hypophysitis secondary to neighboring lesions should be considered, with special attention to GCTs masquerading as hypophysitis in children and young adults (Bettendorf *et al.*, 1999; Endo *et al.*, 2007; Ozbey *et al.*, 2006). Importantly, the spectrum of endocrine deficiencies varies according to the etiology and the typical order of progressive hypopituitarism in noninflammatory sellar masses such as PA (GH, followed by FSH/LH, and ACTH/TSH deficiencies) may be inverted and impaired ACTH secretion may be the earliest to occur, as in LYH or immunotherapy-related hypophysitis. Despite a variable prevalence according to the etiology of hypophysitis, DI is an important clinical argument against a PA.

Radiological Evaluation

Magnetic resonance imaging (*MRI*) is the gold standard method for the evaluation of sellar masses. Although no single radiological feature is specific of hypophysitis, a combination of criteria can be highly suggestive (Gutenberg *et al.*, 2009). These include symmetric and homogeneous enlargement of the pituitary gland; intense and homogeneous gadolinium enhancement, thickening of the pituitary stalk, disappearance of the posterior pituitary bright spot in T1 (usually accompanying DI), integrity of the sellar floor and, occasionally, hypothalamic infiltration. A radiological score, including patient gender, age and relation to pregnancy has been proposed to facilitate differential diagnosis between primary LYH and a PA, which is by far the most common pituitary mass (Gutenberg *et al.*, 2009). Similar aspects, including isolated pituitary stalk thickening, can also be found in GrH (Hunn *et al.*, 2014) and in secondary hypophysitis. Of note, intrasellar germinomas may be indistinguishable from a primary hypophysitis and attention should be paid to a potential pineal localization, since bifocal GCTs are not infrequent (Duron *et al.*, 2018). Peculiar MRI findings may be present in hypophysitis secondary to a RCC or a craniopharyngioma, and a thick peripheral enhancement surrounding a cystic lesion may be suggestive of a pituitary abscess (Gutenberg *et al.*, 2009; Guaraldi *et al.*, 2017). Subsequently, regression of the inflammatory process may be followed-up by MRI and secondary empty sella may be the late stage in hypophysitis of different etiologies (Gutenberg *et al.*, 2009; Guaraldi *et al.*, 2017). Whole brain MRI may reveal additional abnormalities in systemic diseases, especially in histiocytic disorders (Fahrner *et al.*, 2012), whereas hypothalamic-pituitary involvement may not be radiologically evident in neurosarcoidosis (Martin-Grace and Murialdo, 2015).

Additional imaging may include PET-^{18}FDG, since inflammatory lesions are typically associated with increased FDG uptake due to their high metabolic activity (Sher *et al.*, 2017; Wachsmann *et al.*, 2017). Combined PET-TC may be very useful in systemic diseases as it may help identifying additional lesions, some of them being more easily accessible to obtain a pathological diagnosis (Martin-Grace and Murialdo, 2015). Whole body PET-TC is also useful during follow-up and PET-MRI was recently proposed to minimize radiation in pediatric cases (Sher *et al.*, 2017). Of note, it is essential in cancer patients to distinguish between systemic localizations of irAE and metastatic lesions, as both may induce abnormal ^{18}FDG uptake (Wachsmann *et al.*, 2017).

Laboratory Evaluation

Diagnostic of primary hypophysitis

The identification of antipituitary autoantibodies (APA) contributes, but is not sufficient per se to diagnose AI hypophysitis, because of some important methodological and theoretical issues (Caturegli *et al.*, 2005, 2008; Ricciuti *et al.*, 2014). The role of APA in the pathogenesis of AI LYH and their clinical significance remains uncertain, since they have been identified in several conditions and no correlations have been detected between APA and disease severity or prognosis (Caturegli *et al.*, 2008; Guaraldi *et al.*, 2017). However, they may represent a useful tool in the presence of a suggestive clinical context. Indirect immunofluorescence (IIF) is currently considered the gold standard technique for APA evaluation (**Fig. 3**). Despite the low sensitivity and the subjective interpretation of results with respect to other immunological methods, IIF is characterized by a relatively low cost, rapidity and simplicity of application, and is useful when the target antigen is unknown, as in LYH. Indeed, although several antigenic pituitary targets have been postulated, including hormones (i.e., GH, chorionic somatomammotropin hormone 1 and 2, CSH 1–2; proopiomelanocortin, POMC), enzymes (i.e., α-enolase), enzymes (i.e., prohormone convertase PC 1/3 and 2; carboxypeptidase PC2 regulatory protein, 7B2), pituitary factors (i.e., PGSF 1a and 2), transcription factors (i.e., Tpit), cytosolic and nuclear proteins (i.e., rabphilin-3A, secretogranin II, chromosome 14 open reading frame 166, C14orf166; Tudor Domain Containing Protein 6, TDRD6), none of these appeared pathognomonic for the identification of primary hypophysitis, and, when injected in animal models, they were not able to induce the disease (Guaraldi *et al.*, 2017). An anti-Pit1 syndrome with combined GH, TSH, and PRL insufficiency (Yamamoto *et al.*, 2011) and antihypothalamic antibodies directed against AVP-secreting cells (De Bellis *et al.*, 2012) have also been identified. The reliability of pituitary IIF is limited by a high tissue background due to natural pituitary autofluorescence and nonspecific antigen-antibody binding, and there is no consensus yet regarding appropriate pituitary controls, tissue processing, and the interpretation of APA (Caturegli *et al.*, 2008; Ricciuti *et al.*, 2014). Such limits should be considered, and the determination of cut-off titers and attention to peculiar type of immunostaining may help improving the specificity of the results (Bellastella *et al.*, 2016; Guaraldi *et al.*, 2017).

An additional attractive tool is HLA haplotyping. Although the most frequently reported alleles were initially HLA-DR4 and DR5, HLA-DQ8 has been recently identified as the most reliable marker of AI LYH, being present in 87% versus 20% of the patients with AI versus non AI pituitary diseases; HLA-DR53 is also frequent but less specific than DQ8 (Heaney *et al.*, 2015). If these data are confirmed, HLA haplotyping could help differentiating AI LYH from other pituitary lesions.

Diagnosis of secondary hypophysitis

Systemic diseases can sometimes be suspected on the basis of circulating markers, though these may have an insufficient sensibility and specificity. Histologically proven IgG4-R lesions have been reported in the presence of normal circulating IgG4 and in a recent meta-analysis, the sensitivity and specificity of serum IgG4 measurement for the diagnosis of IgG4-R

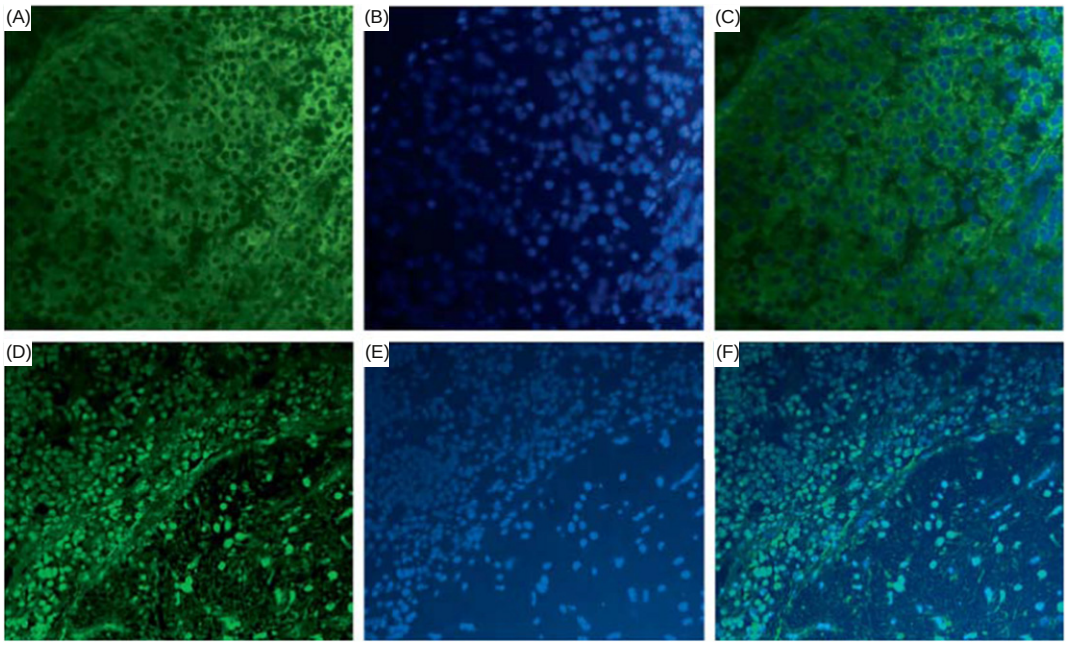

Fig. 3 Detection of antipituitary antibodies (APA) by indirect immunofluorescence (IIF), 20 × magnification. Double staining is based on the use of FITC-conjugated secondary antibodies (*green*, A and D), and DAPI counterstaining of cell nuclei (*blue*, B and E), with merged imaging (C and F). APA may have a cytosolic (A and C) or nuclear (D and F) pattern. On the lower panel (D—F), the anterior (top left) and posterior (bottom right) pituitary portions can be distinguished morphologically by cell distribution.

conditions were 87.2% and 82.6%, respectively (Hao *et al.*, 2016). Since they are rapidly normalized by glucocorticoid therapy, an early determination of IgG4 should be obtained. Elevated circulating ACE levels are found in a minority of patients with neurosarcoidosis and CSF analysis may be more sensitive, but not specific enough to make the diagnosis (Martin-Grace and Murialdo, 2015). Beta-human chorionic gonadotrophin (βHCG) and alpha-fetoprotein (AFP) are classical markers of germ cell tumors (GCTs). However, the majority of GCTs localized in the central nervous system are not accompanied by elevated serum values and CSF analysis should be performed in suspect cases (Endo *et al.*, 2007). A diagnostic biopsy may reveal the tumor even in the presence of normal CSF values (Ozbey *et al.*, 2006). Elevated white blood cell count may be present in patients with a pituitary abscess and a septic presentation, haemocultures and/or CSF biochemical and bacteriological analysis can be helpful, however the causal infective agent is difficult to identify and cultures of the pus removed from the cavity are often negative (Altas *et al.*, 2013; Vates *et al.*, 2001; Zhang *et al.*, 2012). Specialized infective work-up is advisable, especially in the case of atypical infections or granulomas of specific origin.

Pathological Diagnosis

Histopathological examination of surgical pituitary samples remains the gold standard in the diagnosis of hypophysitis, though it is not always available. Traditionally, the three main histological patterns of hypophysitis are lymphocytic, granulomatous, and xanthomatous (Sautner *et al.*, 1995; Caturegli *et al.*, 2005; Carpinteri *et al.*, 2009; Hanna *et al.*, 2015). Both primary and secondary hypophysitis can manifest as one of these histological patterns. Combinations, such as mixed Gr-LYH (Madsen and Karluk, 2000) and X-LYH (Gopal-Kothandapani *et al.*, 2015) have been reported. IgG4 hypophysitis has also been histologically characterized (Leporati *et al.*, 2011). In daily practice, the small size and fragmentation of pituitary surgical specimens may hamper the identification of the whole spectrum of inflammatory changes and/or a potential causative disease. Immunohistochemistry (IHC) may provide important additional clues. Finally, as similar aspects may be encountered in primary and secondary hypophysitis, multidisciplinary work-up may be essential to achieve a final etiological diagnosis.

Microscopic examination

In LYH the pituitary gland is richly infiltrated by polyclonal reactive lymphocytes and plasma cells surrounding the adenohypophysial cells (Beressi *et al.*, 1999) (**Fig. 1**). Occasionally, lymphoid follicles with germinal cents may form (Caturegli *et al.*, 2005). Fibrosis becomes a dominant feature in the later phase of LYH, making the histological diagnosis difficult. GrH is characterized by the presence of granulomas composed of epitheloid histiocytes and macrophages, including multinuclear giant cells, usually surrounded by a mixture of lymphocytes and plasma cells. Primary idiopathic GrH is very rare (Hunn *et al.*, 2014). Thus, secondary granulomatous process due to microbial agents or as a part of systemic granulomatous disorders should be considered (Carpinteri *et al.*, 2009), and specific staining for tuberculosis or fungal infections may be performed (Al-Haddad *et al.*, 2011). In XH, the rarest histological type, pituitary gland is infiltrated by foamy macrophages, also known as xanthomatous cells, with an admixture of T- and B-lymphocytes and plasma cells. Occasionally, XGrH has been reported, with a characteristic combination of epitheloid giant cell granulomas, xanthomatous cells surrounding cholesterol clefts and lymphoplasmacytic infiltration (Tashiro *et al.*, 2002; Burt *et al.*, 2003; Yokoyama *et al.*, 2004; Gopal-Kothandapani *et al.*, 2015). Causative primary pituitary lesions, such as ruptured RCC, may be recognized in XH and XGrH (Paulus *et al.*, 1999) (**Fig. 4**). Differential diagnosis between (X)GrH and a pituitary manifestation of systemic histiocytic disorders may require multidisciplinary expertise.

The histopathological characteristics of IgG4-RH were described in Wong *et al.* (2007) and an example is shown in (**Fig. 5**). Lymphoplasmacytic infiltration with a high proportion of IgG4-reactive plasma cells, storiform fibrosis and occasional obliterative phlebitis are common to all IgG4-R lesions, although organ-specific variations may occur (Deshpande *et al.*, 2012; Kamisawa *et al.*, 2015). Among the criteria reported by Leporati *et al.* for the diagnosis of IgG4-RH, criterion 1 consists of a histological proof of the disease and is therefore sufficient for the diagnosis. It is defined by fibrosis and lymphoplasmacytic infiltration with at least 10

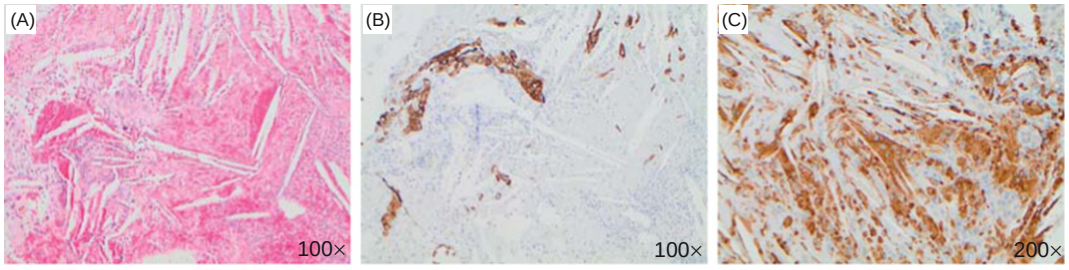

Fig. 4 Secondary xanthogranulomatous hypophysitis. Foamy histiocytes and multinuclear giant cells surround cholesterol crystals and bleeding resulting from a ruptured cyst. (A) Hematoxylin-eosin; (B) fragments of the epithelial cyst wall are identified by cytokeratin immunostaining (Cam5.2); (C) CD68 immunostaining is present in the foamy histiocytes and multinuclear giant cells.

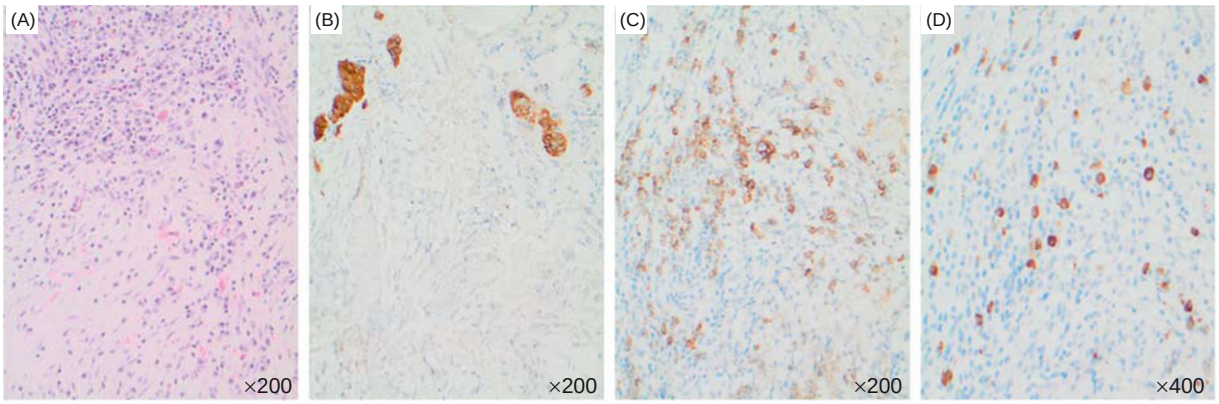

Fig. 5 IgG4-related hypophysitis. An abundant fibrosis is present with a mixed infiltration of lymphocytes, plasma cells, and eosinophils. (A) Hematoxylin-eosin; (B) Residual endocrine pituitary cells are identified by chromogranin A immunostaining; (C) A predominance of plasma cells among inflammatory cells is shown by CD138 immunostaining; (D) IgG4 immunostaining reveals IgG4 reactive cells.

IgG4 cells/HPF (high power field) (Leporati *et al.*, 2011). An IgG4 + /IgG + cells ratio above 40% is an additional criterion in other organs (Deshpande *et al.*, 2012). Of note, IgG4-positive cells have been observed in some localizations of granulomatosis with polyangiitis (GPA) (Wegener's), although its relationship to IgG4-RD is uncertain (Chang *et al.*, 2013; Bando *et al.*, 2015).

What can we expect from immunohistochemistry?

IHC is useful in the differential diagnosis of inflammatory pituitary lesions, especially in the presence of atypical pathological features and/or limited biopsy material. It may also help identifying normal pituitary endocrine cells in specimens with prominent inflammatory changes and/or fibrosis (**Figs.1**C and **5**B). In AI-LYH, inflammatory cell infiltrates are dominated by CD3 + T-cells (**Fig. 1**B), including CD8 + cytotoxic and CD4 + helper T-cells, whereas CD20 + B-cells, CD138 + plasma cells and CD68 + macrophages are less common. In GrH and XGrH, reactive epitheloid histiocytes and multinuclear giant cells are CD68 + (**Fig. 4**C), but do not stain for CD1a and Langerin, which are markers of LCH-type neoplastic histiocytes. More than 50% of LCH (Badalian-Very *et al.*, 2010; Sahm *et al.*, 2012) and Erdheim–Chester cases (Haroche *et al.* 2012) are related to a BRAF V600E mutation and immunopositive with a BRAF V600E monoclonal antibody. Since for unclear reasons normal corticotrophs and corticotroph adenomas may also show strong BRAF V600E immunolabeling in the absence of mutation (Mordes *et al.*, 2014), a BRAF V600E mutation gene analysis is advisable where a systemic histiocytic disorder is suspected. Another challenging issue may be the identification of GCTs, since the lymphocytic reaction may be largely predominant with a limited number of tumor germ cells. These latter can be identified by IHC panel of markers including PLAP, OCT3/4, CD117 (c-kit) for pure germinomas, and AFP, βHCG, cytokeratin AE1/AE3, and CD30 for other types of GCTs (Gao *et al.*, 2014). In IgG4-RH, IHC is used to identify and confirm the polyclonality of CD138 plasma cells and to quantify the population of IgG4 + cells (**Fig. 5**C and D).

Treatment

The wide clinical spectrum of hypophysitis in terms of etiology and symptoms accounts for the diversity of their management, which may range from follow-up to active medical or neurosurgical treatment—typically by a transsphenoidal (TS) route-, exceptionally radiotherapy. Due to its relative rarity, some guidelines are available as panel expert consensus rather than evidence-based. Indeed, no randomized trials are available to compare the outcome of surgical versus medical management where active treatment is thought necessary and the optimal treatment of primary hypophysitis is still a matter of debate. Improved knowledge of some secondary forms of hypophysitis has contributed to refine their diagnosis and management. Importantly, hypopituitarism should be actively treated in all cases, hormone replacement being mandatory in the presence of DI and/or secondary adrenal and thyroid deficiencies. Surgery may be considered for diagnostic or debulking purposes, upon multidisciplinary evaluation by a pituitary team. Microscopic or endoscopic TS is typically used where an intrasellar component of the lesion is present (Honegger *et al.*, 2015). More recently, extended TS and intraventricular endoscopic approaches (Jinguji *et al.*, 2013) and TS biopsy of the posterior lobe (Kinoshita *et al.*, 2017) have been proposed in alternative to transcranial surgery in the presence of lesions involving the stalk or the infundibular region.

Primary Hypophysitis

The decision to treat patients with a primary hypophysitis depends on the clinical symptoms and/or diagnostic challenges. In a nationwide retrospective survey conducted in Germany including 76 patients with primary hypophysitis (Honegger *et al.*, 2015), a wait-and-see option was elected in 40% of the cases, leading to spontaneous mass reduction in 46% and improvement of pituitary

dysfunction in 27% of the cases, whereas radiological progression and worsening of endocrine dysfunction were reported in 27% and 18%, respectively. The median time to disease progression was 1.2 years with wide variations. Active treatment included surgery and/or glucocorticoids (GC) and was generally elected in the most symptomatic cases, diagnostic surgery being performed in a minority of patients. Postoperative mass reduction was present in 68% of the cases, with early regrowth or later relapse leading to an overall recurrence rate of 25%. In contrast, GC induced a 97% rate of response, but recurrences occurred in 38% of the cases and side-effects in 63%. Despite a wide variability in the follow-up duration, this study provides relevant information on the natural course of primary hypophysitis and the potential limits of active treatment, supporting conservative management unless severe or progressive symptoms develop (Honegger *et al.*, 2015). The wait-and-see option was less frequently adopted in other recent studies, which tended to favor a medical versus surgical approach, since GC are effective on headache and may improve pituitary function (Kyriacou *et al.*, 2017; Wang *et al.*, 2017). However, there is no consensus on the optimal GC schedule in primary hypophysitis and a variety of protocols have been reported, ranging from high dose pulse therapy (up to 500 mg prednisone equivalent daily) (Kristof *et al.*, 1999; Honegger *et al.*, 2015) to continuous oral therapy (starting from 20 mg prednisone equivalent daily) (Honegger *et al.*, 2015; Wang *et al.*, 2017), with wide variations in the duration of treatment (from a few days to several weeks or months). In a former review of the literature, oral and i.v. GC were associated with pituitary mass reduction in 87% and 75% of the cases, respectively (Lupi *et al.*, 2011). Progressive tapering of the dose is always recommended. A slow tapering rate and a longer duration of treatment (>6 months) were recently associated with a lower rate of recurrences (Wang *et al.*, 2017). This should clearly be balanced with the long-term side effects of GC. Resistance to GC may occur in a minority of patients and surgery can be proposed as a second choice (Honegger *et al.*, 2015). Radiotherapy or other immunosuppressive therapies (mainly azathioprine) have been used in a minority of cases (Curtò *et al.*, 2010; Lupi *et al.*, 2011; Honegger *et al.*, 2015). An important long-term issue is potential endocrine sequelae. In the German survey, GC were associated with an equal rate of improvement or worsening of pituitary insufficiency (15% each), although worsening could accompany relapse (Honegger *et al.*, 2015). These results compare unfavorably with a previous review reporting an overall improvement of hypopituitarism and DI in 45% and 41% of medically treated cases, respectively (Lupi *et al.*, 2011), so this may reflect the treatment of the most symptomatic cases. Worsening of pituitary function appears to be more frequent after surgery (Honegger *et al.*, 2015).

Secondary Forms of Hypophysitis

The therapeutic options depend on the etiology of the disease. Systemic therapy, including chemotherapy, may be considered in LCH patients (Donadieu *et al.*, 2004a; Girschikofsky *et al.*, 2013), and if regression of the hypothalamic-pituitary lesions is seen in a significant proportion of patients, endocrine sequelea are the rule (Fahrner *et al.*, 2012). The first line treatment for IgG4-R conditions is GC, typically oral GC with a starting dose depending on disease severity; alternatively GC-sparing immunosuppressive drugs or rituximab, aiming at B-cell depletion, can be used (Kamisawa *et al.*, 2015). As extensive fibrosis is associated with poorer responses, early recognition of the disease is desirable (Kamisawa *et al.*, 2015). Rituximab was successfully used in recurring IgG4-RH (Gu *et al.*, 2017). Where a pituitary abscess is suspected, TS evacuation is highly recommended with antiseptic washing of the cavity and broad-spectrum antibiotherapy, keeping in mind that a transcranial approach, if strictly necessary, is endowed with a significant risk of cerebral spread of the infection (Zhang *et al.*, 2012; Gao *et al.*, 2017).

Hormone Replacement Therapy

Hormone replacement should be managed by an endocrinologist and is mandatory for DI and secondary adrenal and thyroid deficiencies, whereas gonadal replacement may be indicated according to the context. Recent clinical guidelines from the Endocrine Society are available for the diagnosis and treatment of adult hypopituitarism (Fleseriu *et al.*, 2016). As ACTH deficiency may occur first in hypophysitis, appropriate treatment with hydrocortisone should be started promptly and instructions for the prevention of adrenal crisis should be provided. Of note, treatment of adrenal insufficiency may unmask partial DI, whereas treatment of thyroid insufficiency may unmask adrenal insufficiency (Fleseriu *et al.*, 2016). Secondary adrenal insufficiency should also be thought when antiinflammatory corticoid therapy is withdrawn. An emergency card/bracelet/necklace is useful in patients with ACTH deficiency and DI for any situation in which they are unable to refer about their medical conditions. There is little experience with GH replacement therapy in patients with hypophysitis, though it may be considered where documented GH deficiency persists as an endocrine sequela. The diagnosis relies on diagnostic testing with age-related parameters and adjustment for BMI in adults (Corneli *et al.*, 2005, 2007; Fleseriu *et al.*, 2016; Grimberg *et al.*, 2016) and GH replacement may require adjustment of other replacement therapies (Fleseriu *et al.*, 2016). No adverse effect of GH replacement on the course of the disease was reported in pediatric LCH (Donadieu *et al.*, 2004b).

Conclusion

With the identification of new entities such as IgGR-4R diseases and the increasing use of immune checkpoint inhibitors, the epidemiology of hypophysitis has significantly changed over the past 15 years and this heterogeneous disease is gaining interest among the medical community, extending well beyond the specialized pituitary teams. The frequent clinical complexity of patients

affected by hypophysitis should encourage multidisciplinary collaboration to ensure appropriate diagnosis and treatment of this condition. The optimal treatment of endocrine deficiencies, including appropriate prevention of adrenal crisis and long-term management of endocrine sequelea, should be best managed by an endocrinologist, and endocrinologists should collaborate with internists/oncologists for the appropriate management of systemic/oncological diseases. Despite increasing knowledge of the different forms of hypophysitis has reduced the indications for diagnostic surgery, pathology remains the gold standard for the definitive diagnosis. Thus, evaluation by a multidisciplinary pituitary team should best define the need for a pathological specimen and evaluate the best surgical approach. In the future, new markers may improve the diagnostic of some entities, for example, the development of reliable panels of APA. Therapeutic neurosurgery may be indicated in the most symptomatic cases, such as visual fields defects, or if a peculiar etiological setting (e.g., a pituitary abscess or associated tumor) is suspected. Alternatively, GC may be proposed. In all cases, the diagnostic challenge and the choice of active treatment should be discussed with the patient.

Acknowledgments

The authors met at the European multidisciplinary post-graduate course on PItuitary Tumours (EUROPIT) in Annecy, November 2016.

Radiology of the Pituitary

Jane Evanson, Barts Health NHS Trust, London, United Kingdom

Anatomy and Embryology

The pituitary gland sits within the sella turcica which is a cup shaped depression in the sphenoid bone. The sphenoid air sinus lies below and anterior to the sella turcica (**Fig. 1**). Lying above the pituitary gland is a CSF space, the suprasellar system, which contains the optic chiasm (**Fig. 1**A and B). The lateral walls of the pituitary fossa are formed by the cavernous sinuses (**Fig. 1**B) which contain the internal carotid arteries as well as the 3rd, 4th, and 6th cranial nerves as well as the 1st and 2nd divisions of the 5th cranial nerve. The pituitary gland is connected via the pituitary stalk to the hypothalamus which is a thin plate of tissue making up the floor of the anterior part of the 3rd ventricle (**Fig. 1**A and C).

The appearance and size of the pituitary gland changes during life. At birth it is typically globular in shape and shows high signal on T1 weighted images (Dietrich *et al.*, 1995). By approximately 6 weeks of age this high signal has diminished and the anterior pituitary tissue has a similar signal to brain tissue. The posterior pituitary tissue, however, retains a bright signal on T1 weighted sequences. This so-called "posterior pituitary bright spot" is a normal appearance thought to be due to the high neurophysin content (**Fig. 1**).

The size of the pituitary gland varies with age and sex. On average it is between 3 and 8 mm in height but is generally larger in females than males. The height increases during adolescence due to normal physiological hypertrophy (Tsunoda *et al.*, 1997). There is also a slight increase in size seen during the sixth decade in females. The most striking physiological changes are seen during pregnancy when the gland progressively enlarges reaching a maximal height immediately after birth when it may reach 10 mm in height (Dinc *et al.*, 1998).

Embryologically, the anterior and posterior pituitary lobes are distinct. The anterior lobe forms from an invagination of the oral ectoderm known as Rathke's Pouch. The posterior pituitary forms from a protrusion of the neural ectoderm of the diencephalon. Between the anterior and posterior lobes lies an intermediate lobe which is vestigial and known as the pars intermedia. This is a potential site for small nonfunctional Rathke's cysts (**Fig. 2**).

MR Imaging

MR is the imaging of choice for the pituitary gland. Thin sections (2 mm or 3 mm) targeted to the ptituitary fossa and performed in both the sagittal and coronal planes are needed. T1 weighted sequences before and after intravenous contrast are the main-stay of pituitary imaging (**Fig. 1**A–C) (Steiner *et al.*, 1989). Coronal T2 weighted sequences can also give added information (cystic change or tumor consistency) but are less sensitive overall in the detection of adenomas (Heck *et al.*, 2012). CT does not provide such excellent soft tissue resolution as MR but can be a very useful investigation if MR is contraindicated or if it is important to identify the presence of calcification (e.g., if a craniopharyngioma is suspected). Dedicated CT study should be performed utilizing no more than 1 mm slice thickness in the axial plane and then reconstructed in the sagittal and coronal planes.

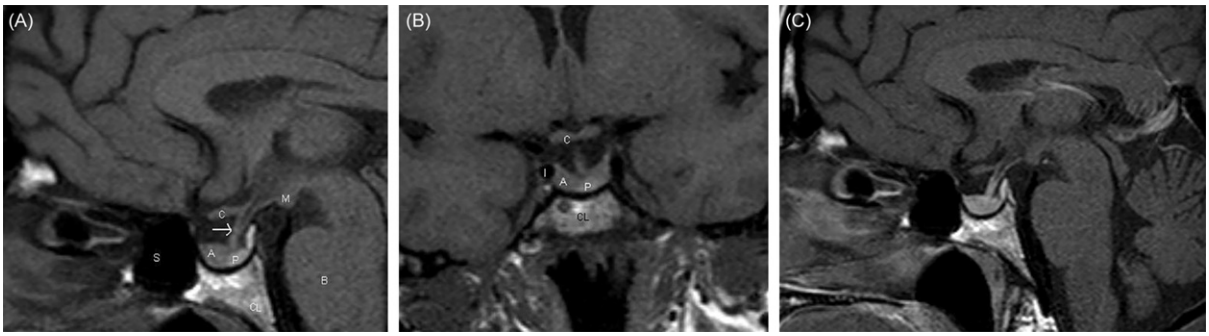

Fig. 1 (A) Sagittal T1W unenhanced images of the pituitary fossa demonstrate normal anatomy. The anterior pituitary tissue, A, is visible within the sella and the posterior pituitary bright spot, P, is evident behind it. The stalk (*arrow*) is well seen with a small cleft of CSF visible within it superiorly—the infundibular recess of the third ventricle. The optic chiasm, C, and mamillary bodies, M, are seen in the suprasellar region. *B*, Brainstem; *S*, sphenoid air sinus; *CL*, clivus. (B) Coronal T1W unenhanced images of the pituitary fossa. The anterior pituitary gland, A, is within the fossa. The posterior pituitary bright spot is visible centrally, P. The stalk is seen extending up into the suprasellar region. The optic chiasm, C, is visible. The cavernous segments of the carotids arteries, I, are seen within the cavernous sinuses, which form the lateral boundaries of the pituitary fossa. (C) Sagittal T1W enhanced image of the pituitary. The pituitary tissue has enhanced, as has the pituitary stalk.

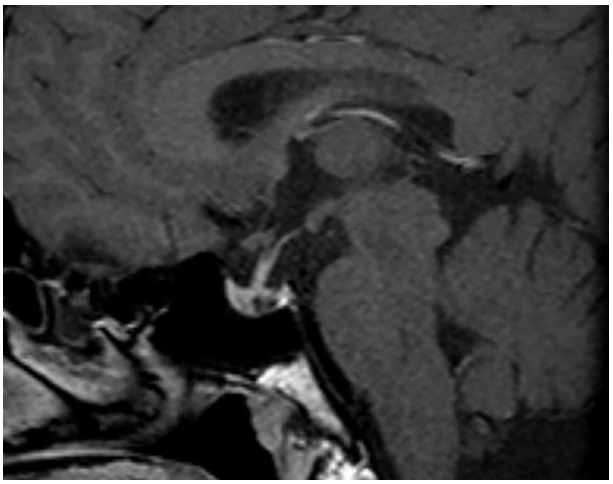

Fig. 2 Sagittal T1W enhanced image demonstrating a small Rathke's cyst. This is seen to lie just below the insertion of the pituitary stalk and centrally within the gland. Although it is possible that a small cystic adenoma could have these appearances, this is a very typical location for a Rathke's cyst arising in the pars intermedia.

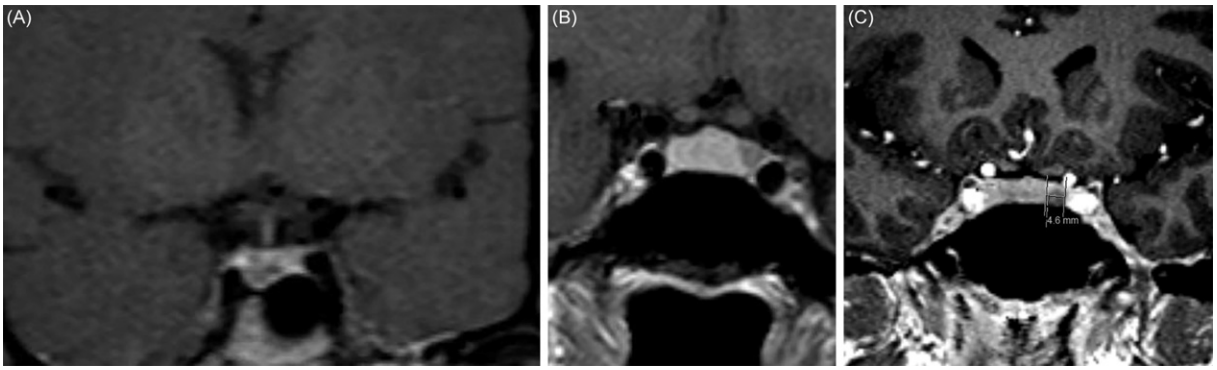

Fig. 3 (A–C) Coronal T1W after contrast images of microadenoma in three different cases. (A) Dynamic acquisition with a central lesion, (B) standard postcontrast with a small left far lateral lesion, and (C) a volumetric acquisition with a left lateral lesion.

There can be some benefit in performing the postcontrast MR sequences in a dynamic fashion (within the first 60 s) after contrast injection. This can maximize the conspicuity of adenomas which typically enhance less than the normal highly vascular pituitary tissue, and this differential enhancement is sometimes best appreciated within the first arterial phase of the contrast injection (**Fig. 3**A) (Kucharczyk *et al.*, 1994). However in the majority of cases lesions are adequately demonstrated on a standard acquisition after contrast (**Fig. 3**B) (Kucharczyk *et al.*, 1994).

Use of a postcontrast volumetric T1 weighted acquisition allows for higher resolution images with slice thickness around 1 mm and may improve the sensitivity for small microadenomas (Patronas *et al.*, 2003) and is therefore particularly useful in the investigation of Cushing's disease, when it should be used routinely (**Fig. 3**C).

Pituitary Adenomas

Pituitary adenomas are by far the most common mass lesion seen in the sella and parasellar region. They are slow growing benign neoplasms arising from the anterior pituitary tissue; radiologically they are simply classified by size: lesions smaller than 10 mm transversely are termed microadenomas and those greater than 10 mm are macroadenomas.

Pituitary Macroadenomas

Pituitary macroadenomas can extend superiorly into the suprasellar cistern (**Fig. 4**A and B) and impinge on the optic apparatus to produce visual field abnormalities (typically a bitemporal hemianopia). Pituitary macroadenomas with a large suprasellar com-

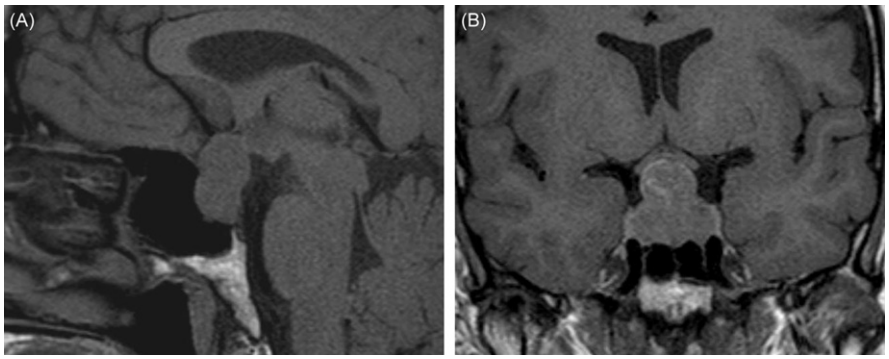

Fig. 4 (A) and (B) Sagittal and coronal T1W enhanced images of a macroadenoma. The sella is enlarged and the macroadenoma is seen to extend upwards into the suprasellar cistern with the optic chiasm stretched and deformed over the surface of the macroadenoma. (C) Coronal T1W enhanced image shows diffuse enhancement of the macroadenoma, no normal pituitary issue can now be identified. The optic chiasm is easily identified; it does not enhance and is seen to be stretched over the superior aspect of the adenoma.

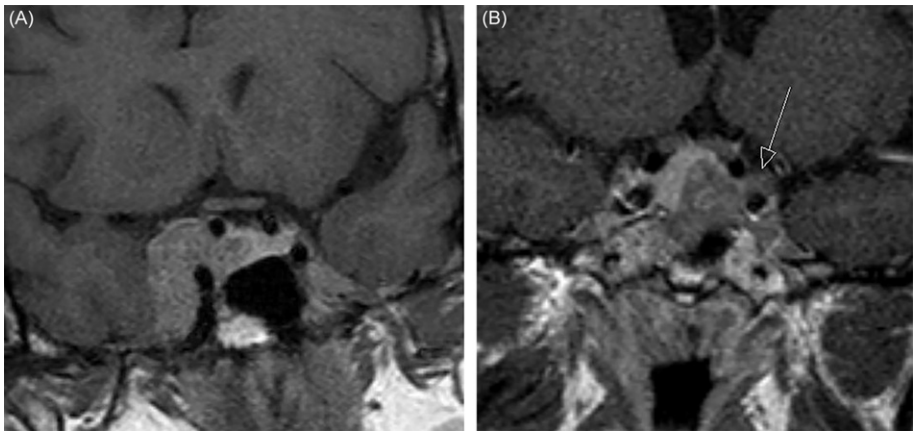

Fig. 5 (A) Coronal enhanced T1W images shows a large Rt sided pituitary adenoma that has invaded laterally into the Rt cavernous sinus. A significant component of the tumor lies lateral to the cavernous carotid artery and must therefore be within the cavernous sinus. (B) Coronal enhanced T1W images show a left sided lesion that has extended into the superior compartment of the left cavernous sinus and is seen to extend beyond the lateral border of the left cavernous carotid artery.

ponent characteristically show the appearance of "waisting" (**Fig. 4**B) as they pass through the opening in a sheet of dura—the diaphragma sellae.

Lateral growth of a macroadenoma is initially seen to cause deformity of the cavernous sinus; however, adenomas can invade into the cavernous sinus (**Fig. 5**A and B). If adenoma tissue extends beyond the lateral border of the cavernous internal carotid artery (**Fig. 5**A and B) then it is more likely that there is tumor directly within the cavernous sinus (Knosp *et al.*, 1993) although this remains a contentious issue. Recent studies suggest that the rate of direct invasion as identified at endoscopic surgery may be lower than previously thought using MR criteria (Micko *et al.*, 2015).

Occasionally macroadenomas will show very extensive involvement of the central skull base (**Fig. 6**) and, exceptionally, can extend out into the infratemporal fossa. Significant skull base involvement is associated with an increased risk of CSF leak after treatment (surgery or medical).

Macroadenomas may be heterogeneous in their MR signal characteristics and areas of cystic change and focal areas of hemorrhage are not infrequently identified. A significant hemorrhage with necrosis in an adenoma can produce the syndrome of *pituitary apoplexy*; sudden onset of headache often associated with visual disturbance and 3rd, 4th, or 6th cranial nerve palsies. The MRI shows an enlarged sella containing a macroadenoma with areas of high T1 signal representing the hemorrhage (**Fig. 7**A and B). Often there is suprasellar extension and lateral involvement of the cavernous sinus.

Pituitary microadenomas are confined within the sella and can be identified within the normal pituitary gland as an area of lower T1 signal than the normal pituitary tissue and reduced enhancement (**Fig. 3**C) (Kucharczyk *et al.*, 1986). Local remodeling of the floor of the sella and remodeling of the dorsum are also useful features. Although there may be displacement of the pituitary stalk by a lesion this is not a very reliable indicator (Ahmadi *et al.*, 1990).

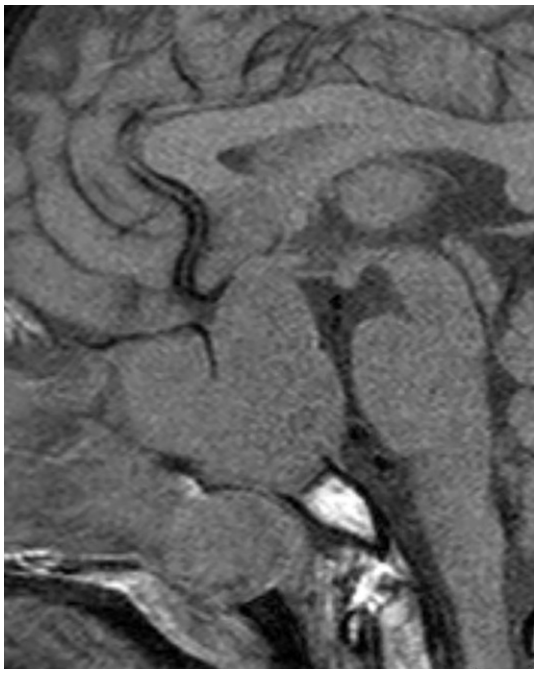

Fig. 6 Sagittal T1W unenhanced image shows an invasive macroadenoma which has involved much of the central skull base. It has invaded the sphenoid air sinus which can no longer be identified and has also extended down the clivus and into the nasopharynx. There is suprasellar extension with elevation of the optic chiasm.

After pituitary surgery it takes around 3–4 months for the postoperative changes within the sella to regress to allow for assessment of the true volume of residual pituitary tissue (Kremer *et al.*, 2002).

Rathke's Cleft Cysts

These benign, nonfunctioning cysts arise from remnants of squamous epithelium from Rathke's cleft. They typically arise close to the insertion of the stalk (**Fig. 2**). They are a common incidental finding reported in up to 11% of pituitary glands at autopsy (Teramoto *et al.*, 1994) and are found at all ages. On imaging they may appear proteinaceous, reflected as a hyperintense signal on T1 weighted sequence. It is not uncommon for these cysts to lie in the suprasellar region on the surface of the gland where they are usually found immediately anterior to the pituitary stalk (**Fig. 8**A and B). If they are of significant size then it may be hard to distinguish a Rathke's cyst from a cystic craniopharyngioma. However the wall of a Rathke's cyst shows no more than minimal enhancement, there are no solid enhancing areas and no calcification, which are all typical features of a craniopharyngioma.

Granular Cell Tumors

Granular cell tumors are rare lesions most typically seen in the suprasellar region. They arise from the neurohypophysis and/or the pituitary stalk. They have also been known as pituicytomas, infundibulomas, or choristomas (Cohen-Gadol *et al.*, 2003). Histologically they appear to arise from the pituicyte which is the main posterior pituitary cell. These are seen as well-defined suprasellar masses related to the pituitary stalk with homogenous enhancement (**Fig. 9**) (Cohen-Gadol *et al.*, 2003). Despite their intimate relationship to the pituitary stalk diabetes insipidus is not usually present although other endocrine disturbance may be present and these lesions may even be asymptomatic. If they have reached significant size they may be associated with visual disturbance or headache. They are benign and slow growing with a low recurrence rate after surgery.

Hypophysitis

Hypophysitis is an inflammatory lesion of the pituitary gland which is usually idiopathic rather than secondary to a known infection or systemic disease. Although the underlying cause of hypophysitis is not known, three distinct histopathological conditions are recognized; lymphocytic hypophysitis, granulomatous hypophysitis, and the very rare xanthomatous hypophysitis

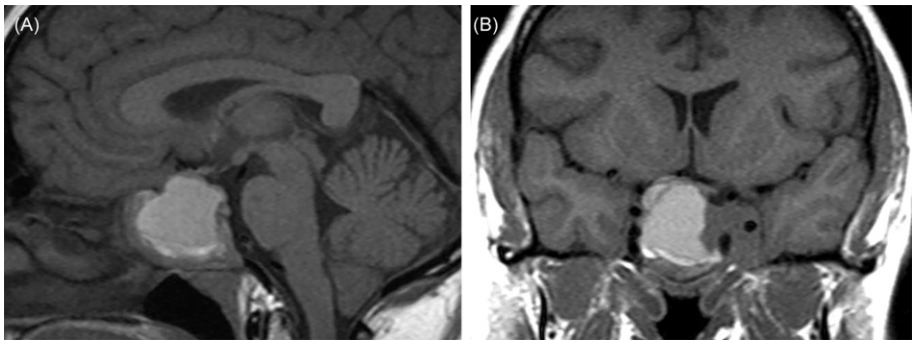

Fig. 7 Sagittal (A) and coronal (B) T1W noncontrast images showing hemorrhage into an existing pituitary macroadenoma. The area of high T1 signal represents the recent hemorrhage. There is a component of the tumor extending into the left cavernous sinus which does not show hemorrhage. The suprasellar extension is compressing the chiasm particularly on the right side.

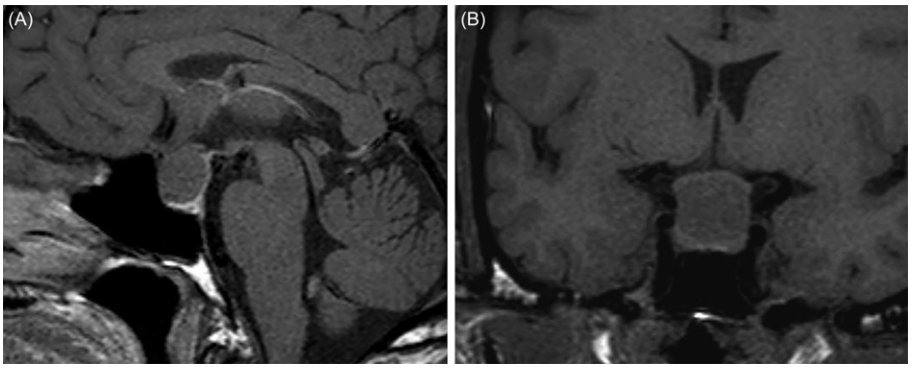

Fig. 8 Sagittal enhanced (A) T1W and coronal unenhanced (B) T1W images of a large Rathke's cyst. The cyst is seen to be sitting on the superior aspect of the pituitary tissue which appears flattened within the sella. The optic chiasm is stretched over the surface of the cyst. After contrast the cyst does not show enhancement. (A) The cyst shows higher signal than the CSF indicating that it has a higher protein content.

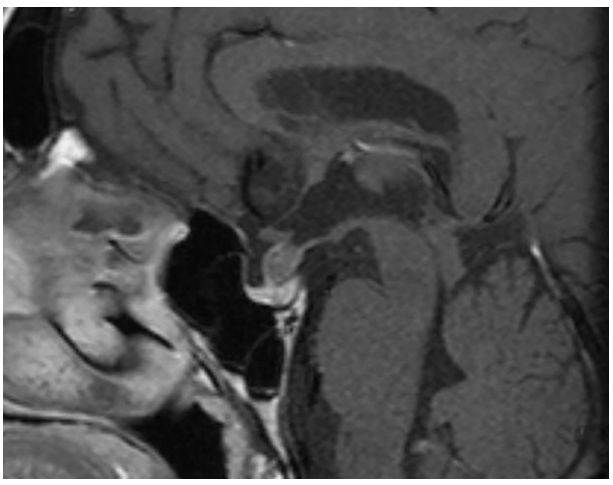

Fig. 9 Sagittal enhanced T1W image shows a well-defined enhancing mass within the pituitary stalk. The pituitary gland is normal, as is the hypothalamus. This was a granular cell tumor.

(Gutenberg *et al.*, 2006). Lymphocytic and granulomatous hypophysitis have similar indistinguishable MR imaging features; enlargement of the gland producing the appearance of a sellar mass lesion with involvement of the stalk (**Fig. 10**A and B). The gland may appear heterogeneous after contrast and there may be distortion of the chiasm if the suprasellar component is sizeable, although that is uncommon. Lymphocytic hypophysitis is the most common form occurring more often in females and classically presenting at the end of pregnancy or in the postpartum period with endocrine dysfunction (Gutenberg *et al.*, 2006). There may

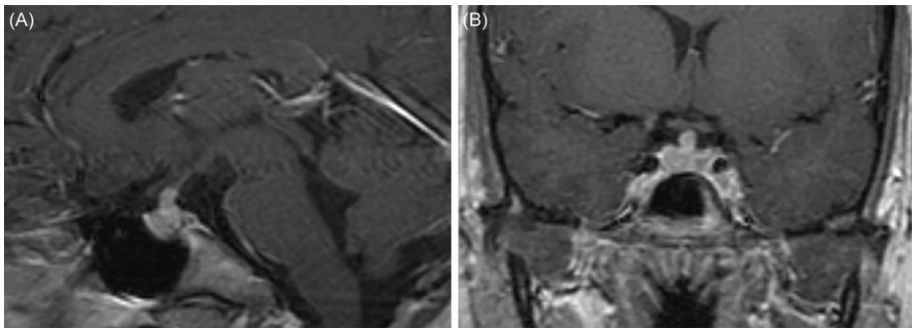

Fig. 10 Sagittal (A) and coronal (B) T1W enhanced images of lymphocytic hypophysitis. There is slight enlargement and heterogeneity of the gland with thickening of the lower part of the stalk. The fossa is not enlarged.

Fig. 11 Sagittal enhanced T1W image of neurohypophysitis. The stalk is thickened in its lower and mid portions, the pituitary gland is normal.

also be diabetes insipidus which may correlate with loss of the posterior pituitary bright spot, this is a helpful distinguishing feature from a pituitary adenoma.

Granulomatous hypophysitis is less common and is found equally in males and females. MR appearances are the same as those described for lymphocytic hypophysitis (Gutenberg *et al.*, 2006).

A variant of this condition is the so-called lymphocytic infundibulo-neurohypophysitis where the inflammatory process selectively involves the pituitary stalk and the posterior pituitary tissue and imaging reflects that—showing enlargement of only the posterior gland and stalk (Abe, 2008). Diabetes insipidus is the dominant clinical feature (**Fig. 11**).

All forms of hypophysitis can ultimately result in hypopituitarism with a small volume pituitary gland on imaging.

Newly described forms of hypophysitis are the rare IgG4 plasma cell hypophysitis (Hsing *et al.*, 2013) and hypophysitis caused by anticytotoxic T-lymphocyte antigen 4 antibody therapy for cancer.

Ipilimumab-related hypophysitis is now well recognized in up to 11% of patients (Faje *et al.*, 2014). MR often shows a diffuse enlargement of the gland (more rarely the stalk) which variably regresses after discontinuation of treatment (**Fig. 12**). Pituitary function may not recover despite imaging normalization (Faje *et al.*, 2014).

The Empty Sella

An empty sella contains only CSF without any visible pituitary tissue (anterior or posterior). The pituitary stalk will be visible and typically extends down to the floor of the sella (**Fig. 13**). An empty sella may be the result of previously documented pituitary/

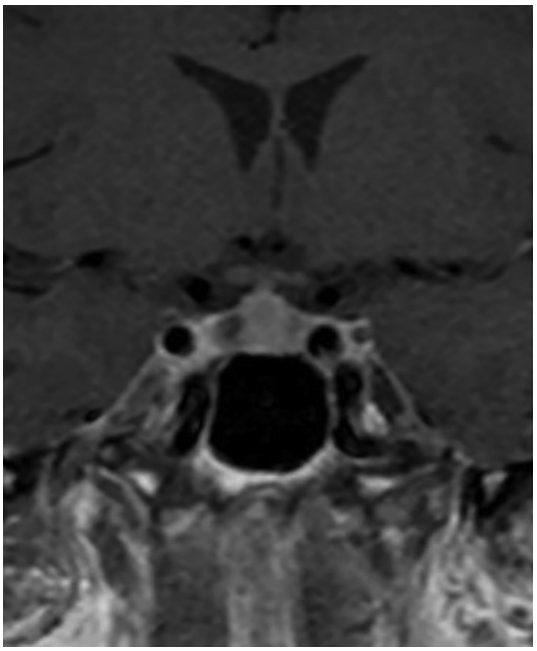

Fig. 12 Coronal T1W enhanced image of drug-induced hypophysitis. The gland is bulky and the enhancement is heterogenous.

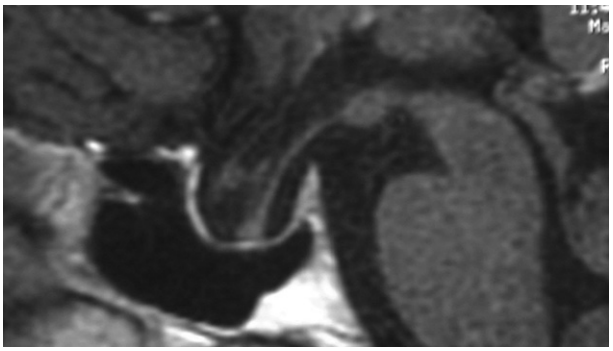

Fig. 13 Sagittal enhanced T1W images show an empty sella. No pituitary tissue is visible and the stalk extends down to the floor of the sella. The optic chiasm has prolapsed inferiorly; a not uncommon appearance after a large mass has been removed.

hypothalamic pathology or treatment (e.g., surgery, radiotherapy, hypophysitis, Sheehan syndrome, or pituitary apoplexy). However, it may also be discovered incidentally during MR scanning or in the course of investigating a new endocrine problem, then referred to as a "primary empty sella" (Del Monte *et al.*, 2006). A partially empty sella implies that some residual pituitary tissue can still be seen along the floor of the fossa. In the cases of a primary empty sella it is thought that a defect in the diaphragma sella (the sheet of dura over the surface of the sella through which the stalk passes) has allowed increased communication with the pulsatile CSF in the subarachnoid space. The primary empty sella is commoner in women and has been associated with idiopathic intracranial hypertension (IIH) obesity, visual disturbance, and spontaneous CSF leaks. Endocrine problems may be seen in up to 25% of cases with a primary empty sella (Del Monte *et al.*, 2006), the majority within this group being specifically investigated for a suspected endocrine abnormality. However, a small proportion of patients found to have an empty sella unexpectedly may have endocrine abnormalities on detailed testing.

Congenital Pituitary Abnormalities

Congenital hypopituitarism can manifest as isolated growth hormone deficiency (IGHD) or combined pituitary hormone deficiency (CPHD), which can be related to anatomical abnormalities of the hypothalamic/pituitary structures on MR imaging. Mutations associated with pituitary transcription factors (e.g., PROP1) can be associated with congenital hypopituitarism although most are sporadic (Mehta *et al.*, 2009). Imaging features include an ectopic location to the posterior pituitary which is seen to be

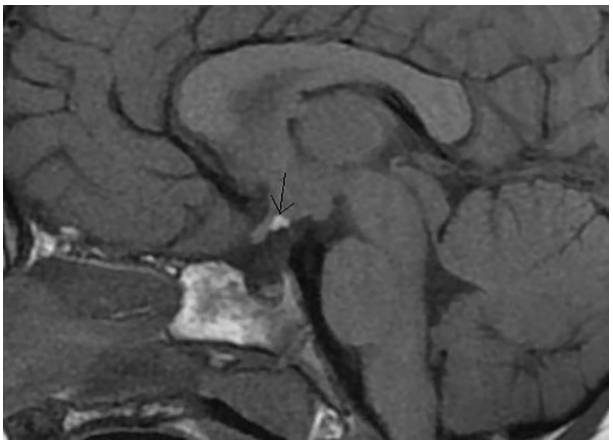

Fig. 14 Sagittal T1W unenhanced image. This demonstrates a small pituitary fossa containing a reduced volume of anterior pituitary tissue. The stalk is absent and the posterior pituitary bright spot (*arrow*) is lying in an ectopic location within the hypothalamus. The corpus callosum appears normal.

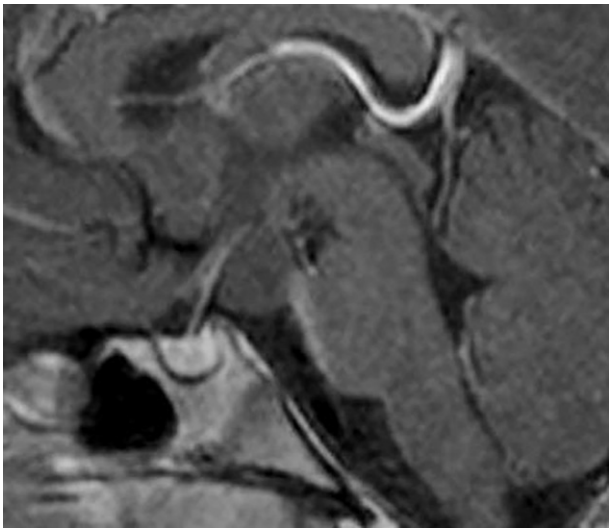

Fig. 15 Sagittal T1W enhanced image of a hypothalamic hamartoma. There is a nonenhancing mass visible arising from the undersurface of the hypothalamus and lying behind the pituitary stalk.

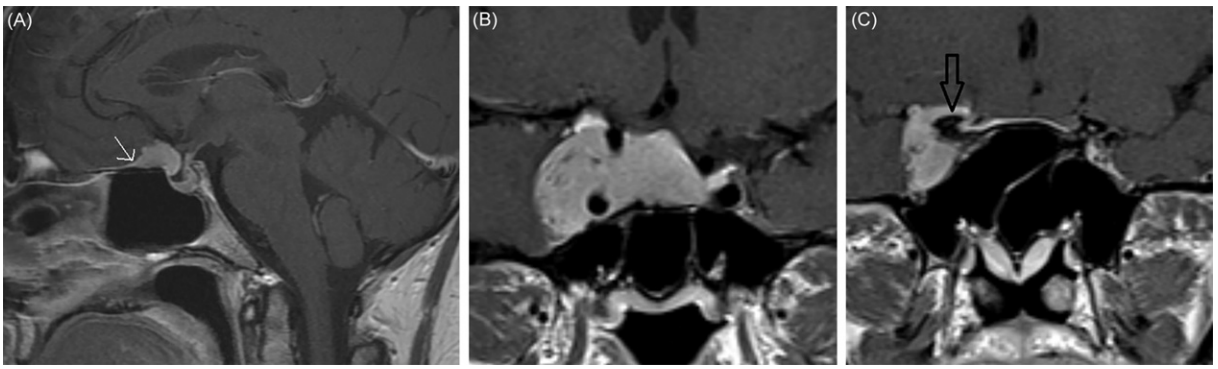

Fig. 16 (A) Sagittal enhanced T1W images show a meningioma arising from the floor of the anterior cranial fossa and extending into the pituitary fossa, lying anterior to the stalk, but separate from the pituitary tissue. There is a dural tail of enhancement extending forward (*arrowed*). (B) and (C) Coronal enhanced T1W image shows a large Rt sided meningioma involving the Rt cavernous sinus and filling most of the sella. This could be a large macroadenoma but (C) shows a more anterior image demonstrating the associated bony hyperostosis of the Rt anterior clinoid process (*arrowed*) confirming that this is a meningioma.

undescended and is visible as a high T1 signal area in the region of the median eminence (Fig. 14). There may be absence of the pituitary stalk and/or hypoplasia of the anterior pituitary tissue and a small pituitary fossa. Other congenital abnormalities of midline structures may be associated with these hypothalamic/pituitary features; optic nerve hypoplasia, absence of the septum pellucidum, and corpus callosum abnormalities (Mehta *et al.*, 2009). CPHD is more often associated with callosal and stalk abnormalities than the milder forms of hypopituitarism such as IGHD (Mehta *et al.*, 2009).

Hypothalamic Hamartomas

These are benign developmental mass lesions that arise in the tuber cinereum of the hypothalamus and can be associated with central precocious puberty, gelastic (laughing) seizures, and sometimes developmental delay. The lesions are easily identified on MR imaging as they have a distinctive appearance as an almost pedunculated rounded mass hanging from the hypothalamus. They are of similar signal to the gray matter of the cerebral cortex and do not show enhancement after contrast injection (Fig. 15). Histologically, they are composed of well differentiated neurones and glial cells. They are sometimes approached surgically if the epilepsy is proving refractory to treatment.

Stalk and Suprasellar Abnormalities

Pathological processes that primarily involve the pituitary stalk and suprasellar structures, rather than the pituitary gland itself, have a wide differential diagnosis. The commoner neoplastic processes include meningiomas, craniopharyngiomas, and germinomas. Meningiomas are benign tumors that can arise from any dural surface around the sella and features such as a dural tail, bony hyperostosis, calcification, and carotid artery constriction are useful distinguishing radiological features (Kaltsas *et al.*, 2008) (Fig. 16A–C). Craniopharyngiomas characteristically have both proteinaceous cystic and enhancing solid components with calcification and CT may be helpful to identify the calcification. Germinomas manifest as solid, noncalcified enhancing masses involving the upper part of the stalk/hypothalamus (Fig. 17A and B) and an associated pineal mass or ependymal enhancement indicates more extensive disease (Packer *et al.*, 2000).

Metastatic disease from systemic malignancy can also involve the stalk and sellar region, the typical clinical manifestation of diabetes insipidus may prompt pituitary imaging.

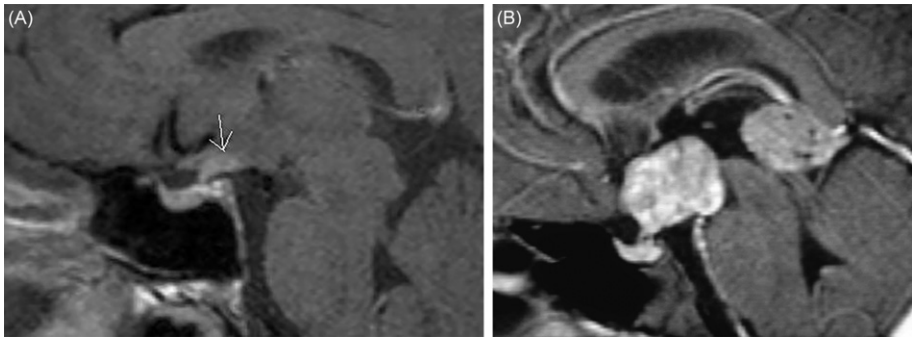

Fig. 17 Sagittal T1W enhanced images show a small germinoma (A) with thickening of the hypothalamus (*arrowed*) and a large suprasellar germinoma (B) with a synchronous pineal lesion.

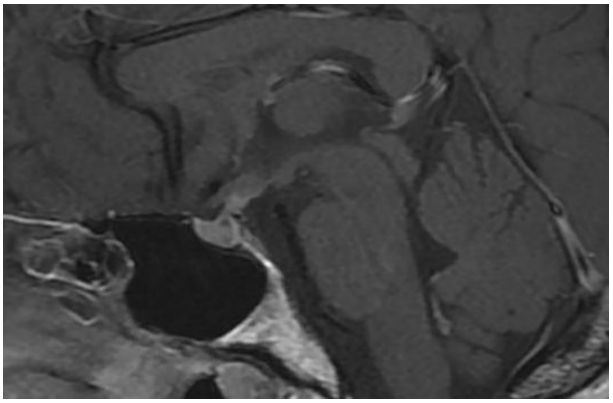

Fig. 18 Sagittal T1W image of Langerhans cell histiocytosis—visible only as thickening of the upper stalk and hypothalamus.

Processes such as sarcoidosis (Lexa and Grossman, 1994) and Langerhans cell histiocytosis can involve the pituitary stalk. Widespread basal leptomeningeal enhancement is one typical manifestation of neurosarcoidosis. Langerhans cell histiocytosis may show just isolated stalk thickening but the presence of extra cranial involvement should aid diagnosis (D'Ambrosio *et al.*, 2008) (**Fig. 18**).

Hyponatraemia

Aoife Garrahy and Christopher J Thompson, Beaumont Hospital/RCSI Medical School, Dublin, Ireland

Introduction

Hyponatraemia is the commonest electrolyte disturbance encountered in clinical practice. Estimates vary according to study populations (Sturdik *et al.*, 2014; Frenkel *et al.*, 2010; Funk *et al.*, 2010), but an overall view would suggest a figure of 15%–30% of hospitalized patients (Upadhyay *et al.*, 2006), with community rates of 2%–10% (Miller *et al.*, 1996; Liamis *et al.*, 2013; Gisby *et al.*, 2016; Mohan *et al.*, 2013). Hyponatraemia is habitually underinvestigated and undertreated in routine clinical practice (Greenberg *et al.*, 2015). However, the explosion of interest in hyponatraemia over the last 10 years has led to the publication of data which indicates that there is substantial morbidity, mortality and prolonged hospital stay in patients whose hospital admission is complicated by hyponatraemia (Corona *et al.*, 2013; Zilberberg *et al.*, 2008). Although mild hyponatraemia may be asymptomatic, subtle cognitive effects, which result in poor attention, predispose to unsteady gait (Renneboog *et al.*, 2006), leading to increased falls (Fehlberg *et al.*, 2017), and increased fracture rate (Kinsella *et al.*, 2010) are well recognized. The increase in fracture rate may reflect the association with osteoporosis, which animal studies suggest is directly related to hyponatraemia (Verbalis *et al.*, 2010).

In addition to excess morbidity, almost every published study has shown that mortality is increased in hyponatraemia (Corona *et al.*, 2013; Sturdik *et al.*, 2014; Waikar *et al.*, 2009), though there is still a debate regarding the causality of hyponatraemia, with some authors suggesting that hyponatraemia is only a marker of severity of the underlying disease (Chawla *et al.*, 2011). Severe hyponatraemia (plasma sodium [pNa] <125 mmol/L) is a medical emergency and can lead to seizures, coma, and death.

Hyponatraemia can complicate a diverse variety of pathologies with different pathophysiological mechanisms. Volume status of the patient and duration of hyponatraemia determine the treatment approach. Elucidating the underlying cause of hyponatraemia requires meticulous clinical examination to establish extracellular volume status as well as ancillary biochemistry including spot urine analysis for sodium and osmolality. Failure to do so can lead to inappropriate treatment which may lower plasma sodium concentration [pNa] further. On the other hand, over-zealous correction of chronic hyponatraemia can result in permanent neurological damage.

In this article, we will discuss the prevalence of hyponatraemia in hospital and in the community, explore the literature on the morbidity and mortality associated with hyponatraemia, offer a practical approach to the differential diagnosis and summarize treatment options for acute and chronic hyponatraemia.

Prevalence of Hyponatraemia

Hyponatraemia is the commonest electrolyte disorder encountered in clinical practice—rates vary according to the patient population, health care setting and diagnostic criteria. Large population-based studies from the United States (Mohan *et al.*, 2013), Sweden (Gisby *et al.*, 2016), and Netherlands (Liamis *et al.*, 2013) have reported rates of 2%–8%, with the highest prevalence reported in females, older patients and those with co-morbidities (Mohan *et al.*, 2013). Rates of 8%–10% percent are reported in ambulatory patients over 60 years attending a geriatric outpatient clinic, and of 18% in a similarly aged cohort of nursing home patients (Miller *et al.*, 1995, 1996), of whom over half had at least one episode of hyponatraemia in the preceding 12 months.

The incidence of hyponatraemia in hospital inpatients is 13%–37% (Frenkel *et al.*, 2010; Sturdik *et al.*, 2014); up to 5% have significant hyponatraemia, defined as [pNa] <130 mmol/L (Upadhyay *et al.*, 2006). Low plasma sodium concentrations are common in intensive care units (ICU, 15%–34%) (Padhi *et al.*, 2014; Nicolini *et al.*, 2017; Funk *et al.*, 2010), neurosurgical (Hannon *et al.*, 2013, 2014; Qureshi *et al.*, 2002; Sherlock *et al.*, 2006, 2009; Agha *et al.*, 2004b; Olson *et al.*, 1997), and oncology units (34%–47%) (Castillo *et al.*, 2012; Doshi *et al.*, 2012; Abu Zeinah *et al.*, 2015). Hyponatraemia is a common complication of chronic disease—more than one third of patients receiving specialist palliative care have low plasma sodium concentrations, which are associated with greater symptom burden compared with eunatremic patients (Kremeike *et al.*, 2018). Hyponatraemia occurs in 8%–31% of adult patients hospitalized with pneumonia (Kruger *et al.*, 2014; Zilberberg *et al.*, 2008; Nair *et al.*, 2007). Data from our own center have shown that 40% of cases are due to SIAD, 40% to hypovolemic hyponatremia, and the remainder hypovolemic (Cuesta, personal communication). Hypervolemic hyponatraemia occurs in up to 24% of patients with heart failure (Gheorghiade *et al.*, 2007a,b; Bettari *et al.*, 2012), and more than 50% of patients with cirrhosis and ascites (Angeli *et al.*, 2006).

Morbidity and Mortality of Hyponatraemia

The severity of symptoms of hyponatraemia depends on how low the plasma sodium concentration is and, more importantly, the rate at which [pNa] falls. Mild hyponatraemia ([pNa] 130–135) can be asymptomatic, but moderate hyponatraemia ([pNa]

125–130) can present with nausea, headache and vomiting. Severe hyponatraemia ([pNa] <125 mmol/L) is a often a medical emergency, particularly if the rate of fall has been rapid, over 1–3 days, and can present with symptoms of cerebral irritation—agitation, confusion, and impaired mental status (Smith *et al.*, 2000). Animal studies, including the classic experiments of Arieff *et al.* (1976), have demonstrated that when hyponatraemia develops over several days, intracerebral fluid, sodium and potassium, followed by organic solutes, are lost from the brain, decreasing intracerebral osmolality and preventing the development of cerebral oedema (Verbalis and Gullans, 1991; Arieff *et al.*, 1976). It is because of this adaptive mechanism that chronic severe hyponatraemia may present with only modest symptoms. Symptoms are far more likely if the drop in [pNa] is rapid. In this setting the osmotic gradient across the blood–brain barrier is increased, the ability of the brain to compensate is exceeded; water is osmotically shifted into the brain and cerebral oedema ensues. This can lead to raised intracranial pressure, cerebral herniation and death, if hyponatraemia is not corrected promptly and effectively (Hannon and Thompson, 2014). The nature of the underlying illness may also affect presentation, for example, neurosurgical patients are more vulnerable to developing symptomatic hyponatraemia due to co-existence of other factors which cause cerebral irritation; hyponatraemic seizures may occur at a higher [pNa] in these patients than might be expected in other settings (Hannon and Thompson, 2014).

Even mild chronic hyponatraemia is associated with gait instability, poor attention span (Renneboog *et al.*, 2006), and increased risk of falls (Harianto and Anpalahan, 2017; Fehlberg *et al.*, 2017; Rittenhouse *et al.*, 2015; Gunathilake *et al.*, 2013). Hyponatraemia is a risk factor for fractures, independent of the presence of osteoporosis (Kinsella *et al.*, 2010). Up to one in five patients admitted with hip fracture are hyponatraemic, and low plasma sodium concentrations are associated with a delay in time to definitive hip surgery (Aqil *et al.*, 2016; Tinning *et al.*, 2015), increased length of stay (Mc Causland *et al.*, 2014), and increased postoperative mortality (Tinning *et al.*, 2015; Madsen *et al.*, 2016; Hagino *et al.*, 2013). Hyponatraemia also has deleterious effects on bone density, as chronic hyponatraemia can increase the odds of having osteoporosis fourfold (Usala *et al.*, 2015). Rat models of SIAD have demonstrated a 30% reduction in bone mineral density (BMD) over 3 months, when compared with eunatremic control rats, while analysis of subjects >50 years of age in the Third National Health and Nutrition Examination Survey (NHANES III) database showed that mild hyponatraemia is associated with increased odds of osteoporosis at the hip when adjusted for other confounders (Verbalis *et al.*, 2010).

Hyponatraemia has been shown to be associated with increased mortality in almost every published series in the literature, spanning a diverse range of medical conditions (Corona *et al.*, 2013; Sturdik *et al.*, 2014; Waikar *et al.*, 2009; Gheorghiade *et al.*, 2007a). An inverse relationship between [pNa] and mortality risk has been proven in population studies such as the NHANES database (Mohan *et al.*, 2013), in ambulatory (Gankam-Kengne *et al.*, 2013), and hospitalized patients (Corona *et al.*, 2013), and in a 2013 metaanalysis (Corona *et al.*, 2013). A large cohort study of 53,236 patients admitted to an academic medical center reported significantly increased odds ratios for inpatient mortality, remarkably at [pNa] cut-off of 138 mmol/L; risk of death was increased by 2.3% for each 1 mmol/L decline in [pNa] (Wald *et al.*, 2010). Not all analyses have supported this inverse relationship however, particularly when [pNa] falls below 120 mmol/L (Chawla *et al.*, 2011; Waikar *et al.*, 2009); the authors of these papers have contended that the underlying illness rather than the [pNa] value accounts for much of the mortality and that patients die "with hyponatraemia" rather than "from hyponatraemia."

Almost all studies published in the literature have produced mortality data associated with hyponatraemia due to all causes. However, a large prospective study which divided patients presenting to hospital with hyponatraemia according to blood volume status has challenged this traditional view. Using the careful application of well-described diagnostic criteria, they showed that although mortality was increased in all three categories of hyponatraemia, there were considerable differences in mortality according to the blood volume categorization (Cuesta *et al.*, 2017a). The data revealed that patients with SIAD had lower mortality rate (RR 1.8) than those with hypervolemic or hypovolemic hyponatraemia (RR 4.9 and 2.8 respectively), when death rate was compared with eunatremic controls (**Fig. 1**). To a certain extent this reflected the seriousness of the disease processes causing hypervolemic hyponatraemia, particularly end stage cardiac and hepatic failure, and the Charlson comorbidity index was significantly higher in this group compared with the other groups. However, this was not the entire explanation for the excess mortality in the hyponatraemic groups. The Charlson comorbidity index was lower in the SIAD group than the eunatraemic group, and despite this, the mortality in the SIAD group was significantly higher. This provides strong circumstantial evidence to support the view that the relationship between hyponatraemia and mortality is partly causal.

Dynamic plasma sodium changes during hospital admission may also increase the mortality risk. Higher mortality rates have been reported in patients whose [pNa] fall during hospital admission, a group Gill and colleagues described as a "sicker" cohort, and whom they suggested would benefit from more intensive monitoring (Gill *et al.*, 2006). On the other hand, resolution of hyponatraemia during hospitalization has been associated with lower mortality risk compared to hyponatraemia that persists or is acquired during admission (Waikar *et al.*, 2009).

Differential Diagnosis of Hyponatraemia

The differential diagnosis of hyponatraemia is wide and there are a number of recommended diagnostic approaches and algorithms. Our clinical approach is to classify patients by extracellular fluid status into hypo-, eu- and hypervolemic hyponatraemia (**Table 1**). While a definitive diagnosis is not always possible at the time of presentation—the distinction between euvolaemia and mild hypovolemia is not always easy—categorizing patients according to extracellular fluid (ECF) volume status and urine electrolyte excretion does allow the initiation of etiology-specific treatment.

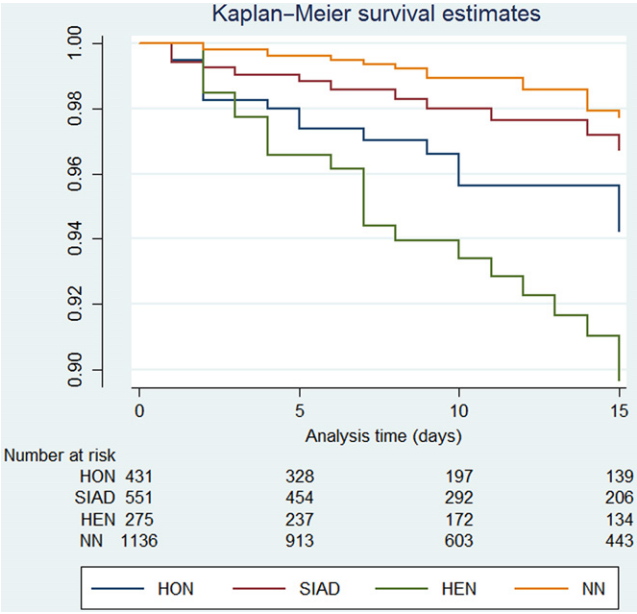

Fig. 1 Kaplan–Meier survival curve in patients with hypovolemic hyponatraemia (HON), SIAD, hypervolemic hyponatraemia (HEN), and normonatraemia (NN). With permission Cuesta, M., Garrahy, A., Slattery, D., Gupta, S., Hannon, A. M., Mcgurren, K., Sherlock, M., Tormey, W. and Thompson, C. J. (2017a). Mortality rates are lower in SIAD, than in hypervolaemic or hypovolaemic hyponatraemia: Results of a prospective observational study. *Clinical Endocrinology* 87, 400–406.

Table 1 Differential diagnosis of hyponatraemia

	Clinical features	*Urine sodium* $<$ *20 mmol/L*	*Urine sodium* $>$ *40 mmol/L*
Hypovolemic	Dry mucus membranes, decreased skin turgor, tachycardia, hypotension (in particular orthostatic), low CVP, raised urea	Dehydration	CSW Diuretics Addison's disease Salt losing nephropathy
Euvolemic	Normal pulse and blood pressure	SIAD with FR	SIAD ACTH insufficiency Hypothyroidism
Hypervolemic	Peripheral oedema, ascites, pulmonary oedema	Inappropriate IV fluids Cardiac failure Cirrhosis	Renal failure

Hypovolemic Hyponatraemia

Hypovolemic hyponatraemia is characterized by ECF depletion secondary to a deficit in total body sodium and water. This loss can occur through the skin, gastro-intestinal tract or kidney; the cause is often suggested by the history. Off-loading of baroreceptors stimulates vasopressin (AVP) release, and together with inappropriate administration of hypotonic fluids (either oral or parenteral), hyponatraemia may develop. Measurement of central venous pressure (CVP) offers the most reliable confirmation of hypovolemia but is invasive. More often a clinical diagnosis is arrived at on the basis of orthostatic hypotension, tachycardia, dry mucous membranes, decreased skin turgor, and laboratory clues such as raised urea to creatinine ratio and uric acid concentration. Urinary sodium concentration is nearly always <20 mmol/L, and often <10 mmol/L in hypovolemia due to activation of the renin–aldosterone system, and mineralocorticoid action at the kidney. Hypovolemia with elevated urine sodium concentrations indicates that site of volume/sodium loss is the kidneys, or that the patient is taking diuretics.

Diuretics frequently cause hyponatraemia and the diagnosis is often obvious from the history. Thiazides are particularly likely culprits, due to their effects on urine diluting capacity; loop diuretics are rarely implicated (Sonnenblick *et al.*, 1993). The reported incidence of thiazide-induced hyponatraemia is 14%–30% (Leung *et al.*, 2011; Clayton *et al.*, 2006). Older age and female gender are associated with increased risk. Three mechanistic explanations are proposed—baroreceptor stimulated AVP secretion due to volume depletion, impairment of diluting capacity at the distal tubule, and depletion of potassium leading to cellular uptake of

sodium (Verbalis *et al.*, 2013). Some patients with thiazide-induced hyponatraemia may appear euvolemic and present with a SIAD-like picture, however expert guidelines would caution against making a diagnosis of SIAD in a patient treated with diuretics and suggest deferring evaluation for SIAD until at least 2 weeks following cessation of the drug (Verbalis *et al.*, 2013).

Addison's disease is another important cause of hypovolemic hyponatraemia. Combined glucocorticoid and mineralocorticoid deficiency leads to renal salt and water loss, and baroreceptor stimulated AVP release. This clinical picture differs from that of central adrenal insufficiency in which mineralocorticoid secretion is retained preventing such profound hypovolemia. Clinical clues to the diagnosis of Addison's disease include hyperpigmentation, history of other autoimmune conditions, metabolic alkalosis, and hyperkalemia (Oelkers, 1996).

Hypervolemic Hyponatraemia

Hypervolemic hyponatraemia is characterized by clinical evidence of fluid overload. Clinical signs include the presence of peripheral or sacral oedema, ascites and elevated central and jugular venous pressures. The underlying pathophysiological process is arterial underfilling, either due to reduced cardiac output in heart failure or splanchnic vasodilation in liver failure (Schrier, 2006). This leads to a baroreceptor mediated increase in AVP secretion and antidiuresis, activation of the renin–angiotensin system and secondary hyperaldosteronism, and increased sympathetic tone. Secondary hyperaldosteronism leads to sodium retention at the distal tubule, made worse by failure of the normal physiological "escape" from the natriuretic effect of high aldosterone levels (Smith *et al.*, 2000). However, it is the relative excess of total body water to sodium, resulting from increased plasma AVP concentrations and up-regulation of aquaporin-2 water channels, that is responsible for the development of hyponatraemia. This notion is supported by the observation that administration of AVP antagonists results in aquaresis and prompt rise in [pNa] in patients with heart and liver failure (Schrier *et al.*, 2006).

Euvolemic Hyponatraemia

Patients without clinical evidence of volume expansion or depletion should be considered euvolemic. Spot urinary sodium concentration is >20–30 mmol/L in most euvolemic patients, with the important caveat that because regulatory mechanisms of sodium excretion are intact, dietary sodium restriction can lead to misleadingly low urinary sodium levels. Other supporting laboratory parameters in euvolemia include low blood urea and low serum uric acid (Decaux and Musch, 2008). The majority of cases of euvolemic hyponatraemia are due to the syndrome of inappropriate antidiuresis (SIAD). Hyponatraemia due to central adrenal insufficiency presents with a similar biochemical picture and should always be considered.

Syndrome of Inappropriate Antidiuresis

SIAD is a clinical and biochemical syndrome characterized by inappropriate urinary concentration and antidiuresis, in the setting of euvolemic hyponatraemia.

Pathogenesis of SIAD

In SIAD, unregulated AVP secretion leads to water retention, with concentrated urine, and manifests biochemically as hypotonic euvolemic hyponatraemia. Although SIAD is classified as euvolemic hyponatraemia, physiologically it is characterized by slight blood volume expansion, characterized by slight suppression of plasma renin and elevation of plasma natriuretic peptide concentrations (Cuesta and Thompson, 2016). Plasma concentrations of AVP have been shown to be elevated in the great majority of cases of SIAD (Robertson *et al.*, 1982). Rarely, gain-of-function mutations in the V2 receptor can lead to the nephrogenic syndrome of inappropriate antidiuresis, in which AVP levels are undetectable (Feldman *et al.*, 2005); therefore syndrome of inappropriate antidiuresis (SIAD) may be more a more precise term than syndrome of inappropriate antidiuretic hormone secretion (SIADH). SIAD can be subclassified into four types defined by the pattern of AVP secretion (**Fig. 2**) (Zerbe *et al.*, 1980).

1. Type A is the commonest cause of SIAD (40%) and is characteristic of lung and nasopharyngeal tumors. Ectopic AVP secretion is unregulated with loss of the close linear relationship between plasma osmolality and plasma AVP. Furthermore, plasma AVP concentrations are not suppressed by drinking and these patients demonstrate a lower osmotic threshold for thirst appreciation —therefore they are at risk of severe hyponatraemia.
2. Type B ("Reset osmostat") is the second most common cause of SIAD in which the osmotic threshold is reset at a lower plasma osmolality. Thus while secretion of AVP occurs at a lower plasma osmolality that normal, it is suppressed below the lower threshold, protecting the subject from severe hyponatraemia.
3. Type C is a rare form of SIAD, thought to be due to dysfunction of hypothalamic inhibitory neurons, in which the linear relationship between plasma osmolality and AVP levels is maintained at normal plasma osmolality, but there is failure to suppress AVP secretion at plasma osmolality below the threshold leading to persistent low grade AVP secretion.
4. Type D is biochemically identical to SIAD but with undetectable circulating AVP and is thought to be due to gain-of-function mutations in the V2 receptor.

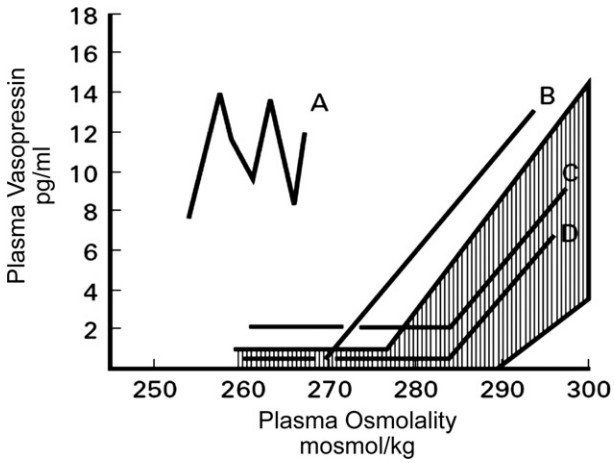

Fig. 2 Patterns of abnormal vasopressin (AVP) secretion in SIAD (A–D). With permission Robertson, G. L., Aycinena, P. and Zerbe, R. L. (1982). Neurogenic disorders of osmoregulation. *The American Journal of Medicine* 72, 339–353.

Table 2 Diagnostic criteria for SIAD (Schwartz *et al.*, 1957)

1. Hypo-osmolality: plasma osmolality <275 mOsm/kg
2. Inappropriate urine concentration: urine osmolality >100 mOsm/kg
3. Elevated urine sodium >40 mmol/L with normal salt and water intake
4. Euvolemia
5. Exclusion of glucocorticoid and thyroid hormone deficiency

Diagnostic criteria

The diagnostic criteria for SIAD are outlined in **Table 2**. In healthy physiology, plasma AVP should be suppressed to undetectable concentrations at plasma osmolalities <280 mOsm/kg; therefore any urine osmolality greater than 100 mOsm/kg in this setting reflects inappropriate urine concentration, and therefore, inappropriate plasma AVP concentrations. Measurement of plasma AVP levels is not performed in day-to-day practice due to limited availability of reliable radioimmunoassays and impractical sample turn-around times, but urine osmolality can be interpreted as a surrogate biomarker of AVP action—the higher the plasma AVP the more concentrated the urine (Robertson *et al.*, 1976).

Ascertainment of the key diagnostic parameters for SIAD in routine clinical practice has invariably been poor (Tzoulis and Bouloux, 2015). The report of the large hyponatraemia registry revealed that in the 1524 patients specifically entered into the registry with a diagnosis of SIAD the triumvirate of key diagnostic parameters—plasma osmolality, urine osmolality and urine sodium concentration—were measured in less than half of patients. In 11% of patients, none of these parameters were measured at all, and plasma cortisol concentrations were measured in only one third of patients (Greenberg *et al.*, 2015). This indicates that the diagnostic accuracy in the largest published registry is open to reasonable question. In our own carefully planned, single-site, prospective study, including over 500 patients with SIAD, only 88% had adequate testing to exclude glucocorticoid deficiency (Cuesta *et al.*, 2016). It is clear that full ascertainment of the diagnostic parameters for SIAD presents significant logistic challenges in both clinical practice and research studies. The clinical importance of measuring these parameters in the workup of SIAD extends beyond making the correct diagnosis—measurement of urinary electrolytes (and subsequent calculation of Furst formula) and urine osmolality have been proposed as predictors of poor sodium response to FR (Cuesta *et al.*, 2017b).

Etiology of SIAD

SIAD has been reported in a wide variety of medical conditions (**Table 3**) and can present to many different specialties; in an single center study performed in an Israeli tertiary center, the diagnosis of SIAD was made in 555 patients across 14 different departments (Shepshelovich *et al.*, 2015).

Of the neoplastic causes, SIAD occurs most commonly in small cell lung cancer (SCLC) with reported rates of up to 15% (Castillo *et al.*, 2012); incidence in nonsmall cell lung cancer is much lower. SIAD occurs due to ectopic secretion of AVP from SCLC tumor tissue—George *et al.* using immunostaining of surgically excised SCLC samples, demonstrated evidence of in-vitro synthesis of AVP (George *et al.*, 1972). In addition, mRNA for AVP has been isolated from tumor cells (Gross *et al.*, 1993). SIAD has been reported in 3% of cases of head and neck cancer (Talmi *et al.*, 1992), and less commonly in a wide variety of other solid tumors and hematological malignancies. SIAD is present in 3% of patients with intracranial tumors; the incidence increases to 15% in the immediate period after neurosurgical intervention (Cuesta and Thompson, 2016). Chemotherapeutic agents may also cause SIAD; vincristine, and to a lesser extent, vinblastine exert neurotoxic effects on the hypothalamus, disrupting osmoreceptor control of AVP release, while cyclophosphamide potentiates the action of AVP at the kidney (Liamis *et al.*, 2008). Opioid

Table 3 Causes of SIAD (Cuesta *et al.*, 2016)

	Cause of SIAD	*n*
Intracranial ($n = 108$, 30%)	Subarachnoid haemorrhage	20
	Ischaemic stroke	12
	Intracranial tumor	18
	Traumatic brain injury	9
	Haemorrhagic	9

	Other respiratory tract infections	31
	Bronchiectasis	9
	Miscellaneous: pneumothorax, pulmonary fibrosis, pulmonary embolism etc.	11
Oncology ($n = 90$, 25%)	Lung cancer	30
	• SCLCA: $n = 14$ • NSCLCA: $n = 21$	25 9
	Gastrointestinal malignancy	9
	Urological malignancy	15
	Haematological malignancies	
	Other malignancies	
Iatrogenic ($n = 31$, 9%)	Carbamazepine	14
	Oxcarbazepine	4
	SSRI	8
	Other	4
Complications of surgery ($n = 28$, 8%)	Orthopedic surgery	20
	Other surgeries	8

Description of the aetiology in patients with SIAD in a prospective cohort of 353 patients in Beaumont Hospital, Dublin, Ireland. *CNS*, central nervous system, *SSRI*, selective serotonin reuptake inhibitor, *CA*, carcinoma.

analgesics, antidepressants, antipyschotics, and antiseizure medications used for symptoms control may also cause SIAD (Castillo *et al.*, 2012), while pain and nausea are nonosmotic triggers for AVP release (Rowe *et al.*, 1979).

SIAD is frequently reported in respiratory illness. In our own prospective study of 1723 patients admitted to our hospital with community acquired pneumonia, 8% had [pNa] <130 mmol/L; 43% of these had SIAD (Cuesta, personal communication). SIAD usually resolves with successful treatment of infection, without specific treatment. Failure of hyponatraemia to resolve with antimicrobial therapy should alert the clinical to the possibility of alternative underlying causes of SIAD, such as bronchiectasis, pulmonary fibrosis or malignancy.

Medications account for 8%–27% of cases of SIAD in hospital inpatients (Shepshelovich *et al.*, 2015; Cuesta *et al.*, 2016), and an even greater proportion in elderly cohorts. Underlying physiological mechanisms include an increase in AVP production in the hypothalamus, potentiation of AVP effect at the renal medulla or a lowering of the osmotic threshold for AVP secretion (reset osmostat). Commonly implicated drugs include selective serotonin reuptake inhibitors, phenothiazine antipsychotics, carbamazepine, sodium valproate, chemotherapeutic agents particularly vincristine and cyclophosphamide, opioid analgesics, and non-steroidal antiinflammatory agents (NSAIDS). More recently, proton pump inhibitors and ACE inhibitors have been recognized as rare causes of drug-induced SIAD (Izzedine *et al.*, 2002; Brewster and Perazella, 2007).

Establishing the underlying cause of SIAD

Once the diagnosis of SIAD is confirmed, identification of the underlying cause is required. The depth of investigation for the etiology of SIAD is made on an individual basis. A careful medication history can identify offending medications that should be discontinued and replaced by alternative agents which are osmotically neutral. Clinical examination, baseline blood-work and radiography may reveal the likely cause for example, lung mass in a smoker. However, in the absence of an obvious candidate pathology, we perform computed tomography of the brain, chest, abdomen, and pelvis as a routine workup for the causation of SIAD. A chest radiograph alone is not sufficient to out-rule a bronchogenic malignancy.

ACTH/Cortisol Deficiency

Secondary adrenal insufficiency can produce a biochemical picture identical to SIAD, with euvolemic hyponatraemia and inappropriate urinary concentration. Mineralocorticoid secretion is preserved as it is under the control of the renin–angiotensin–aldosterone system. This biochemical and clinical picture contrasts with patients with primary adrenal insufficiency, or classical

Addison's disease, in whom combined glucocorticoid and mineralocorticoid deficiency lead to renal salt loss, hypovolemia, and baroreceptor mediated "appropriate" AVP release, manifest as hypovolemic hyponatraemia and hyperkalemia (Oelkers, 1996).

Circulating cortisol is required to excrete free water in the renal medulla. This interplay is exemplified in hypopituitary patients, when diabetes insipidus is often only unmasked when coexisting ACTH deficiency is treated. In animal studies too, there is impairment of water diuresis in adrenalectomised rats with inherited diabetes insipidus; the administration of glucocorticoids and mineralocorticoids restored normal free water clearance (Green *et al.*, 1970).

AVP secretion also plays a role in the hyponatraemia of cortisol deficiency. Experimental animal models of glucocorticoid deficiency have demonstrated an increase in hypothalamic AVP mRNA expression and upregulation of aquaporin-2 mRNA expression in basal conditions, and failure to suppress plasma AVP and downregulate aquaporin-2 mRNA expression after a water load (Boykin *et al.*, 1978; Pyo *et al.*, 1993; Saito *et al.*, 2000, 2009). Administration of AVP antagonist results in restoration of urinary dilution, further supporting the central role of AVP in the development of antidiuresis in ACTH/cortisol deficiency (Ishikawa and Schrier, 1982; Saito *et al.*, 2000).

One to three percent of unselected hyponatraemic patients have underlying ACTH/cortisol deficiency (Winchester Behr *et al.*, 2012; Katoch *et al.*, 2013; Nigro *et al.*, 2015). In a recent prospective series, with full ascertainment of the minimum diagnostic criteria for SIAD in 83% of cases, we have shown that 3.8% of patients presenting with euvolemic hyponatraemia to our institution had adrenal insufficiency. Undiagnosed pituitary disease was responsible for one third of cases while the remaining two-thirds developed hyponatraemia due to adrenal suppression after therapeutic chronic glucocorticoid excess, including the use of inhaled steroids (Cuesta *et al.*, 2016). ACTH/cortisol deficiency should be particularly suspected in patients who develop hyponatraemia after neurosurgical conditions such as posttraumatic brain injury (Hannon *et al.*, 2013) and subarachnoid hemorrhage (Hannon *et al.*, 2014).

Hypothyroidism

Hypothyroidism is an exceptionally rare cause of euvolemic hyponatraemia. The mechanism by which hypothyroidism induces hyponatraemia is incompletely understood but may be due in part to nonosmotic stimulation of AVP release, reduced renal capacity for free water excretion due to impaired renal perfusion, and water retention due to accumulation of mucopolysaccharides (Hierholzer and Finke, 1997; Liamis *et al.*, 2017). The evidence for an association between chronic hypothyroidism and hyponatraemia is, however, unconvincing (Croal *et al.*, 1997). So, while confirmation of normal thyroid function remains a diagnostic criterion in SIAD, and is recommended as part of routine workup in all clinical guidelines (Verbalis *et al.*, 2013; Runkle *et al.*, 2013; Grant *et al.*, 2015), it is our opinion that hyponatraemia due to hypothyroidism is seen only in rare cases of profound myxedema.

Neurosurgical Hyponatraemia

Hyponatraemia is commonly encountered in neurosurgical units. In the national neurosciences center at our hospital, hyponatraemia accounts for approximately 70% of endocrine consults (Hannon *et al.*, 2012). Management can be challenging—multiple potential reasons for impaired mental status in an obtunded patient may make it difficult to say for certain that symptoms are due to hyponatraemia, particularly if [pNa] is only mildly decreased. However, neurosurgical patients are prone to symptoms of cerebral irritation at [pNa]s higher than one would expect for this very reason. Therefore, close monitoring and early treatment of hyponatraemia is important.

Hyponatraemia Following Pituitary Surgery

Hyponatraemia occurs after pituitary surgery in 2%–35% of cases (Jahangiri *et al.*, 2013; Olson *et al.*, 1997; Kristof *et al.*, 2009; Taylor *et al.*, 1995; Sane *et al.*, 1994; Barber *et al.*, 2014). The majority of cases are due to SIAD, secondary to uncontrolled AVP release consequent upon mechanical irritation of the pituitary stalk or neurohypophysis during pituitary surgery. Hyponatraemia can also occur as part of the triple phase response in which initial diabetes insipidus (DI) occurs, usually within the first 48 h after surgery, and is followed by a transient period of hyponatraemia and antidiuresis due to release of pre-formed AVP, before a return to permanent DI due to gliosis of secretory neurons, usually 2 weeks postoperatively. ACTH/cortisol deficiency is an important differential. However, in many pituitary units (including our own) patients are routinely treated with stress dose glucocorticoids thus eliminating this as a cause of hyponatraemia in in the postoperative period.

Delayed hyponatraemia is a significant contributor to hospital re-admission rates following TSS (Bohl *et al.*, 2016; Jahangiri *et al.*, 2013), and it is recommended that patients should be made aware of symptoms suggestive of hyponatraemia. Peak onset is at day 7 (Zada *et al.*, 2007), and typically resolves within 3–5 days; hyponatremia may be severe and symptomatic (Guerrero *et al.*, 2007). Outpatient strategies to reduce readmission rates have given contrasting results (Burke *et al.*, 2017), with a recent study finding a standardized program of outpatient [pNa] monitoring no more effective than close symptom monitoring alone (Bohl *et al.*, 2018).

Hyponatraemia Following SAH

Hyponatraemia occurs following SAH in 30%–56% cases (Sherlock *et al.*, 2006; Qureshi *et al.*, 2002; Hannon *et al.*, 2014; Anas and Vasikaran, 2010). It accounts for one in six readmissions after hospital discharge (Greenberg *et al.*, 2016) and predicts increased morbidity and longer hospital stay (Sherlock *et al.*, 2006). Ninety percent of cases are euvolemic. SIAD accounts for approximately 70% of cases (Hannon *et al.*, 2014; Marupudi and Mittal, 2015); 8% of euvolaemic hyponatraemia patients have acute ACTH/cortisol deficiency, and plasma sodium is restored to normal with steroid therapy (Hannon *et al.*, 2014).

Most cases of acute ACTH/cortisol deficiency occur within the first 3 days. Short synacthen testing is not useful in this setting as it relies on adrenal atrophy, which can take 4–6 weeks to occur and the insulin tolerance test is not appropriate in the acute phase postintracranial hemorrhage due to risk of seizure. Measurement of serial cortisol values is the most practical approach, with empiric replacement of glucocorticoids recommended if cortisol <300 nmol/L (11 μg/dL) followed by more robust assessment once the patient has recovered (Hannon *et al.*, 2012).

Other potential causes of hyponatraemia following SAH include excessive intravenous fluid therapy (often administered to prevent vasospasm) and/or diuretic therapy. Cerebral salt wasting (CSW) is extremely rare. In a series of 187 consecutive cases of neurosurgical hyponatraemia, only 3.7% had CSW and 2.7% had CSW with SIAD (Sherlock *et al.*, 2009). A more recent prospective study of 100 cases of SAH failed to reveal a single case, even after careful clinical and biochemical assessment of volume status (Hannon *et al.*, 2014). It should be noted that SIAD and CSW share many biochemical features—both conditions present with low plasma osmolality, high urine osmolality, and high urinary sodium values. Distinguishing features are outlined in **Table 4**—key is the demonstration of an initial period of naturesis and hypovolemia preceeding the onset of hyponatraemia in CSW (Nelson *et al.*, 1981).

Hyponatraemia Following TBI

Hyponatraemia occurs in approximately 15% of patients during the recovery phase following head injury (Hannon *et al.*, 2013; Agha *et al.*, 2004a). SIAD has traditionally been thought of as the most common cause of hyponatraemia following TBI. However, transient ACTH/cortisol deficiency following TBI may account for a higher proportion of cases of hyponatraemia in this setting than previously appreciated. In a prospective study of acute pituitary dysfunction in which TBI patients underwent sequential measurements of [pNa], cortisol, urine osmolality and fluid balance, 15% of 100 patients developed hyponatraemia. Eighty five percent of hyponatraemic patients had inappropriately low plasma cortisol concentration and [pNa] corrected with glucocorticoid replacement; the remainder had SIAD (Hannon *et al.*, 2013). This raises the possibility that hyponatraemia following TBI is due to acute ACTH/cortisol deficiency rather than SIAD. Chronic hyponatraemia post TBI is rare, and often secondary to antiseizure medications for example, carbamazepine.

Treatment of Hyponatraemia

The key issues which determine optimum management of hyponatraemia are accurate assessment of the underlying cause (**Table 1**) and awareness of the chronicity of low plasma sodium concentrations. Acute hyponatraemia, which occurs over several hours, does not give the brain time to compensate; an osmotic gradient develops between brain and plasma, and cerebral oedema ensues. This is a medical emergency which untreated can culminate in transtentorial herniation and death. In contrast, when the onset of hyponatraemia is slower, the brain adapts by extruding electrolytes and osmolytes which serves to maintain an osmotic equilibrium and minimize cerebral odema. Thus, patients with chronic hyponatraemia may have minimal symptoms, and cerebral herniation is uncommon. In this scenario, it is the risk of osmotic demyelination syndrome (ODS) from overly rapid correction of [pNa] which guides treatment regimens (Verbalis *et al.*, 2013). ODS occurs when correction of chronic hyponatraemia exceeds the ability of the brain to reverse compensatory mechanisms. Failure to recapture organic solutes as [pNa] rises results in an inverse osmotic gradient leading to dehydration of the cells and possible demyelination of white matter (Singh *et al.*, 2014).

Table 4 Distinguishing features between SIAD and CSW

	SIAD	*Cerebral salt wasting*
Blood volume status	Euvolemic	Hypovolemic
Urinary Na	>40 mmol/L	>40 mmol/L
Plasma osmolality	Low	Low
Urine osmolality	High	High
Serum uric acid	Decreased	Decreased/no change
Haematocrit	No change	Raised
Treatment	FR	Fluid replacement

Acute Hyponatraemia

Acute symptomatic hyponatraemia is a medical emergency which is associated with high rates of morbidity and death (Ayus *et al.*, 1985). The immediate goals of treatment are to reduce cerebral oedema and to prevent transtentorial herniation (Ayus *et al.*, 2015; Koenig *et al.*, 2008). Published guidelines have recommended revision of traditional treatment goals, and have emphasized the importance of rapid initial correction of plasma sodium concentration of 3–5 mmol/L over 2–4 h. For severe symptoms, US/Irish guidelines recommend administering 100 mL of 3% saline as a bolus over 10 min, which can be repeated three times if no clinical improvement occurs (Verbalis *et al.*, 2013). European guidelines advocate a similar approach, recommending an initial 150 mL bolus of 3% saline, which can be repeated twice (Spasovski *et al.*, 2014). In patients with mild-moderate symptoms 3% saline infusion at a rate of 0.5–2 mL/kg/h can be administered, with the aim of a gradual increase in plasma sodium concentrations of up to 8 mmol/L over 24 h. Reliance on complex calculations to determine the volume of saline which should be administered in order to correct to target can frequently lead to over-correction (Mohmand *et al.*, 2007) and may delay the start of emergency treatment. The newer guidelines simplify and speed up life-saving treatment. Hourly monitoring of urine output to detect rapid aquaresis is useful. In true acute hyponatraemia (<48 h) the rate of correction may need not be restricted, but the duration of hyponatraemia is often indeterminate, so correction must be limited to safe parameters for the correction of chronic hyponatraemia in most cases.

In suspected ACTH/cortisol deficiency, parenteral glucocorticoids should be given immediately. Blood should be drawn for measurement of plasma ACTH and cortisol concentrations prior to administration but should not delay treatment. A prompt aquaresis after administration of glucocorticoids strongly supports the diagnosis of cortisol deficiency, and [pNa] corrects without any other specific treatment. Close monitoring of [pNa] and urine output is required due to the risk of overcorrection (Verbalis *et al.*, 2013). In Addison's disease intravenous isotonic saline is required to restore intravascular volume and replace sodium losses, while intravenous dextrose should be added if the patient is hypoglycemic.

Chronic Hyponatraemia

Rationale for treatment

Chronic hyponatraemia was traditionally considered a benign condition. However, it is now well established that chronic hyponatraemia negatively affects attention, gait (Renneboog *et al.*, 2006, 2017), bone health (Hannon and Verbalis, 2014) as well as increasing falls (Fehlberg *et al.*, 2017), and fracture risk (Kinsella *et al.*, 2010). There is now a growing body of evidence that suggests that active management of hyponatraemia can reverse these detrimental effects. Treatment of hyponatraemia leads to improvement in balance and attention; Renneboog demonstrated an improvement in tandem gait parameters and reaction time in 23 consecutive patients following treatment of "asymptomatic" chronic hyponatraemia (Renneboog *et al.*, 2017). In the SALT studies, a rise in [pNa] of 6 mmol/L, in patients randomized to treatment with tolvaptan, was associated with significant improvements in the mental component summary of the SF12 Health survey compared with placebo. The INSIGHT trial, designed specifically to look at the effect of tolvaptan on cognition and postural stability in patients with asymptomatic hyponatraemia demonstrated a trend for improvement in neurocognitive tests in the tolvaptan group associated with an increase in [pNa] from 129 to 136 mmol/L. Study numbers were small, baseline hyponatraemia was mild and their findings did not reach statistical significance; however, the observed effect tended to reverse when [pNa] fell again following withdrawal of treatment, strongly supporting a causal relationship (Verbalis *et al.*, 2016a). Based on these data, it is reasonable assume that treatment of chronic hyponatraemia could reduce falls and injury; good quality prospective trial data is, however, needed.

A recent prospective intervention study in a London hospital has suggested that active management of hyponatraemia reduces hospital length of stay (Tzoulis *et al.*, 2017), while a 2015 metaanalysis has reported, for the first time, that improvement in [pNa] in hyponatraemic patients is associated with a reduction in overall mortality (OR 0.57, $P = .002$), which persisted at 12 months. Metaregression analysis showed the reduction to be greatest in older patients and those with lowest [pNa] at baseline (Corona *et al.*, 2015). While a cause-effect relationship cannot be extrapolated from the data included in this analysis, this report provides the first evidence for a potential mortality benefit from treating chronic hyponatraemia, and emphasizes the need for studies of clinical outcomes with effective therapies in such patients.

Rate of correction

Patients with chronic hyponatraemia are much less likely to develop neurological symptoms but are at higher risk of osmotic demyelination. Therefore, risk-benefit analysis favors a slower rise in [pNa] in this patient group. Target rise in [pNa] should be set at <8 mmol/L/24 h and should not exceed 12 mmoL/L/24 h (Verbalis *et al.*, 2013). Added caution is advised in those more vulnerable to the risk of osmotic demyelination including patients with history of alcohol excess, cirrhosis, malnutrition, hypokalemia, and those with [pNa] < 105 mmol/L; target and maximum rise is <6 mmol/L/24 h and <8 mmol/L/24 h respectively in these patients (**Table 5**). Simultaneous treatment of the underlying cause of hyponatraemia, for example, antibiotic treatment of pneumonia, glucocorticoid replacement in steroid deficiency or removal of a thiazide diuretic may lead to greater rise in [pNa] than anticipated as the stimulus for AVP release is removed resulting in a rapid aquaresis (Verbalis *et al.*, 2016b); correction rate may be even higher if active therapy is used.

Table 5 Targets for elevation in plasma sodium concentration [pNa] recommended to avoid osmotic demyelination in chronic hyponatraemia (Verbalis *et al.*, 2013)

	Target rise [pNa]/24 h (mmol/L)	*Maximum rise [pNa]/24 h (mmol/L)*
Standard patient	8	12
High risk patient ([pNa] <105 mmol/L, hypokalemia, alcoholism, advanced liver disease, malnutrition)	6	8

Osmotic demyelination syndrome

Osmotic demyelination syndrome, formerly called central pontine myelinolysis, was first described in 1959 (Adams *et al.*, 1959). It is characterized clinically by spastic quadriparesis and pseudobulbar palsy, reflecting damage to the corticospinal and corticobulbar tracts. Severely affected patients may become "locked in." A rapid rise in [pNa] is the biggest risk factor for ODS; studies in experimental rats have illustrated increased likelihood and severity of brain lesions with increasing rate of correction (Verbalis and Martinez, 1991). Onset of symptoms is typically delayed until 2–6 days after excessive elevation of [pNa]. Diagnosis is based on clinical suspicion, and is supported by characteristic MRI findings of hyperintense lesions in the central pons on T2 weighted imaging (Lopez-Sendon Moreno *et al.*, 2009); up to 40% cases can involve extrapontine areas such as the cerebellum, thalamus, and midbrain. Traditionally the prognosis was reported as poor as diagnosis was made postmortem. However, with increasing use of MRI leading to detection of subclinical radiological abnormalities, it is now accepted that the majority of patients with ODS survive, though 25% are left with significant permanent disability (Singh *et al.*, 2014).

Management of excessive correction

If overcorrection is anticipated based on trend in [pNa] and urine output, further therapy should be held. Once target [pNa] concentration has been reached, [pNa] can be kept stable with the administration of hypotonic fluids (intravenous dextrose) and/or 2–4 μg parenteral desmopressin. An alternative strategy is to administer desmopressin at the onset of treatment, with titration of 3% saline according to [pNa] response. This "proactive approach" may be preferable in those at a particularly high risk of rapid water diuresis with overshooting of [pNa]. Evidence for this strategy is limited to case series (Sood *et al.*, 2013; MacMillan *et al.*, 2015).

If over-correction does occur, therapeutic re-lowering of [pNa] can be considered by administering 2–4 μg desmopressin combined with repeated infusions of 3 mL/kg of 5% dextrose over 1 h with need for further 5% dextrose infusions determined by [pNa] response. Evidence for rescue therapy comes from experimental animal studies in which early re-lowering of [pNa] prevents ODM and reduces mortality (Gankam Kengne *et al.*, 2009). High dose glucocorticoid therapy (Sugimura *et al.*, 2005; Murase *et al.*, 2006), and administration of myoinositol, a major osmolyte lost in cerebral adaptation to hyponatraemia, have been associated with improved survival and reduced myelinolysis in rats (Silver *et al.*, 2006). None of these therapies have been validated in clinical practice.

Hypovolemic Hyponatraemia

Isotonic saline is the treatment of choice for hypovolemic hyponatraemia as specific therapy for the underlying cause is put in place. Correction of hypovolemia eliminates the stimulus for AVP secretion resulting in a rapid aquaresis which can potentially lead to overcorrection. Plasma sodium concentration and urine output should be monitored closely during the first 24–48 h of replacement. Treatment of thiazide diuretic induced hyponatraemia requires particular caution as withdrawal of the drug combined with correction of hypovolemia may result in a rapid aquaresis (Liamis *et al.*, 2016).

Euvolemic Hyponatraemia

SIAD

Treatment of the underlying cause of SIAD is always the first therapeutic step. Drug-induced hyponatraemia usually responds to withdrawal of therapy, and SIAD due to pneumonia resolves quickly with antimicrobial therapy. Symptomatic hyponatraemia needs treatment irrespective of causation and a number of therapeutic options are available in clinical practice. A summary of the key aspects of available therapies for SIAD is presented below and in **Table 6**.

Fluid restriction

Fluid restriction (FR) is the most widely used therapeutic strategy employed in the management of SIAD (Verbalis *et al.*, 2016b). Remarkably, the evidence base to support its efficacy is lacking. In the Hyponatraemia Registry, the largest observational study of routine management of hyponatraemia to date, FR was used first line in half of the 1524 patients. Disappointingly however, 52% of patients with baseline [pNa] <130 mmol/L failed to correct their [pNa] by >5 mmol/L with FR; the majority required the addition of a second-line treatment (Verbalis *et al.*, 2016b). Data from our own unit has found that 60% of patients treated with FR have a criteria which clinical guidelines suggest would predict nonresponse to FR (Cuesta *et al.*, 2017b). Moreover, FR is

Table 6 Comparison of treatment options for chronic SIAD

	Evidence	*Dose*	*Advantages*	*Disadvantages*
Fluid Restriction	Nil	Aim 500 mL/day below 24 h urine volume	Inexpensive	Often ineffective Takes several days to achieve effect Difficult to achieve Can lead to caloric restriction Contraindicated in SAH
Urea	Nonrandomized observational studies	15–60 g daily	Effective	No licence or available preparation Poor palatability Reversible renal impairment
Demeclocycline	Nil	600–1200 mg daily in divided doses	Inexpensive	Takes 3–4 days to achieve effect Reversible renal impairment Rash Not licensed
V2 receptor antagonist—tolvaptan	Robust RCT data	15 mg daily (often 7.5 mg suffices), maximum 60 mg daily	Effective	Relatively expensive Not universally reimbursable Requires supervision for first dose Thirst, polyuria Raised LFTs

difficult to enforce. A target of at least 500 mL/day less than 24 h urine output is recommended—this may not be feasible in the hospital setting if intravenous medications, such as antibiotics, are essential for treatment. In patients with SAH, aggressive hydration to avoid cerebral vasospasm, is accepted as routine therapy by neurosurgeons, who are reluctant to contemplate fluid restriction.

Although fluid restriction is recommended as first line therapy for SIAD by all reputable guidelines (Grant *et al.*, 2015; Runkle *et al.*, 2013; Verbalis *et al.*, 2013), doubts about the efficacy and practicality remain, particularly as the evidence base for fluid restriction is practically nonexistent.

AVP receptor antagonists

The development of AVP receptor antagonists (vaptans) represents a major advance in the management of SIAD. Vaptans competitively bind to the V2 receptor, displacing AVP from the binding site resulting in free water clearance and in a rise in [pNa] (Plosker, 2010). Tolvaptan is an oral selective antagonist of V2 receptor available in Europe and USA while conivaptan is an intravenous antagonist of V1 and V2 receptors available in the United States. In the large multicenter randomized placebo controlled SALT trials tolvaptan has been shown to induce elevation of plasma sodium concentration (Schrier *et al.*, 2006) which is faster and more consistent than FR (Verbalis *et al.*, 2016b) in a mixed population of patients with euvolaemic and hypervolaemic hyponatremia. Plasma sodium concentration fell following cessation of the drug at 30 days, confirming that the positive effect was related to tolvaptan and not spontaneous recovery of hyponatraemia. Subsequent subgroup analysis has confirmed the efficacy of tolvaptan in the SIAD cohort in the study (Verbalis *et al.*, 2011). Thirst and dry mouth are the most commonly reported side-effects, which is unsurprising considering the mechanism of the drug is net water excretion. Administration of tolvaptan at higher doses (average dose 95 mg/day) in autosomal dominant polycystic kidney disease has been associated with increased risk of raised liver enzymes (Torres *et al.*, 2012), however the safe and effective use of long-term tolvaptan in hyponatraemia patients has been confirmed in the SALTWATER open-label 4 years follow-up studies (Berl *et al.*, 2010). Liver function should be monitored regularly (e.g., 3 monthly) and the drug discontinued if liver enzymes increase >2 ULN (Verbalis *et al.*, 2013). We have reported acquired resistance to tolvaptan in two patients with rapidly advancing small cell lung cancer, with escalating plasma vasopressin concentrations (Garrahy *et al.*, 2018); in both cases, loss of effect of the drug heralded deterioration in the underlying malignancy.

Concurrent FR is not recommended and treatment must be initiated in hospital to allow careful monitoring of [pNa] and urine output to prevent over-correction. Target rates of [pNa] correction (>0.5 mmol/L/h) were exceeded in 2% of patients randomized to Tolvaptan in the SALT studies, there were no reported cases of ODM. Patients with lowest starting [pNa] are at greatest risk, and tolvaptan should be used with caution in those with [pNa] <120 mmol/L. Using a lower starting dose of 7.5 mg may reduce the risk of overcorrection (Kenz *et al.*, 2011; Hirai *et al.*, 2016), but does not eliminate it (Shoaf *et al.*, 2017).

Urea

Urea increases solute-free water excretion and decreases naturesis, thereby increasing [pNa]. Retrospective studies have shown it to be effective in SIAD post SAH and in critical care patients (Decaux *et al.*, 2010), and in 12 patients who transitioned to urea therapy following 12 months of vaptan therapy in a clinical trial (Soupart *et al.*, 2012); it is recommended by European Guidelines as a second line agent for the treatment of SIAD. However, urea is unlicensed, difficult to obtain, unpalatable and its reconstitution requires cooperation from pharmacy.

Demeclocycline

This tetracycline derivative induces a nephrogenic form of diabetes insipidus and was historically used in the treatment of SIAD. Response to treatment is variable and it can take several days to reach effect. Adverse effects include reversible renal impairment, liver dysfunction, and photosensitive skin rash (Miller *et al.*, 1980). It is not licensed for use in SIAD.

ACTH/Steroid Deficiency and Hypothyroidism

Chronic hyponatraemia attributed to ACTH/cortisol deficiency or hypothyroidism should be treated with replacement of the deficient hormones.

Hypervolemia Hyponatraemia

In patients with heart failure, combination of FR, and loop diuretics plus neurohormonal antagonism is the recommended first line approach. Use of loop diuretics can be limited by intravascular volume depletion, renal impairment and hypokalemia; overdiuresis may stimulate AVP secretion and worsen hyponatraemia. Vaptans offer an attractive alternative or adjunct to loop diuretics; they are potassium-neutral (Xiong *et al.*, 2015), and cause less neurohormonal activation from intravascular volume depletion compared with diuretics. Several large randomized controlled trials (RCTs) have confirmed tolvaptans beneficial effect on [pNa], weight and dyspnea in heart failure patients (Konstam *et al.*, 2007; Xiong *et al.*, 2015). Posthoc analysis of the large EVEREST trial (4133 patients) demonstrated a reduction in mortality in those patients with [pNa] <130 mmol/L (Konstam *et al.*, 2007), while improvements in hyponatraemia in the smaller ACTIV in CHF trial (319 patients) were associated with improved survival at 60 days (Rossi *et al.*, 2007).

A combination of fluid and salt restriction, loop diuretics and spironolactone is recommended in the treatment of hyponatraemia due to liver failure. Demeclocycline is contraindicated in this setting due to heptatotoxicity. In patients with hyponatraemia and ascites, short term tolvaptan use has been shown to normalize [pNa] in 27%–50% of patients (Gerbes *et al.*, 2003). However, the routine use of tolvaptan is not recommended in patients with cirrhosis, based on the liver injury seen in higher doses used in the TEMPO trial (Torres *et al.*, 2012). One exception is patients awaiting liver transplant, in whom correction of [pNa] preoperatively may reduce the risk of ODS following surgery (Verbalis *et al.*, 2013).

Conclusion

Hyponatraemia is the commonest electrolyte disorder in clinical practice and has a negative impact on falls and fracture risk, bone health and mentation. It is associated with increased length of hospital stay and increased mortality. There is growing evidence that active management negates these effects, with a recent metanalysis confirming for the first time that improvement of hyponatraemia reduces mortality. Clinical evaluation of volume status, interpretation of urinary biochemistry, and confirmation of chronicity are key first steps in deciding appropriate initial fluid management, directing further investigation and ensuring [pNa] rises at a safe rate. Acute symptomatic hyponatraemia is a medical emergency and is treated with hypertonic saline. Traditional treatment options for chronic SIAD are limited by poor efficacy, side-effects and lack of supportive randomized control trial data. In the absence of prospective randomized controlled data investigating the efficacy of FR, its status as first line treatment of SIAD remains questionable. Vaptans offer a novel treatment approach for SIAD that specifically targets the pathophysiological cause of the disorder and their efficacy has been confirmed in large multicenter placebo RCTs. If future studies confirm the observations of the Hyponatraemia Registry that FR is ineffective in a significant proportion of patients with SIAD, bearing in mind that correction of hyponatraemia improves morbidity and mortality, we predict for the future that vaptan therapy will become more mainstay in the management of SIAD.

Pituitary Disorders Following Traumatic Brain Injury

Anne Marie Hannon and Christopher J Thompson, RCSI Medical School, Dublin, Ireland and Beaumont Hospital, Dublin, Ireland

Abbreviation

ACTH	Adrenocorticotrophic hormone
FSH	Follicle stimulating hormone
GH	Growth hormone
LH	Luteinizing hormone
TBI	Traumatic brain injury
TSH	Thyroid stimulating hormone

Introduction

A considerable body of research has emerged over the last 10 years, which points to a significant incidence of pituitary dysfunction in survivors of moderate or severe traumatic brain injury (TBI). Although the key research groups have differed in terms of patient populations studied and diagnostic tests that they employed, most papers with robust methodology estimate that chronic hypopituitarism occurs in 20%–30% of survivors of moderate/severe TBI. The prevalence in patients with mild TBI is much lower. As TBI is incredibly common, the potential number of patients with undiagnosed hypopituitarism is therefore substantial.

It is clear from autopsy studies that vascular damage to the pituitary occurs early after TBI, so that patients may develop hypopituitarism, which is clinically significant, in the acute phase of after brain injury. Some patients recover normal endocrine function in the ensuing months, whereas new hormone deficits may appear in the same time period; pituitary status is therefore unstable following brain injury. The challenge to the endocrine community is how to manage screening and treatment of such a large population of patients, in whom secretory function may vary over several months. Glucocorticoid and growth hormone deficiency are optimally defined by dynamic tests of hormone secretion. As TBI is common, there is a logistic difficulty in identifying which patients should be selected for screening for hypopituitarism. Screening all survivors of moderate/severe TBI with dynamic testing using insulin tolerance testing (ITT) or glucagon stimulation testing (GST) would overwhelm the diagnostic capacity of most endocrine units, so the outcome of studies to identify who does—or, more importantly, who does not—require dynamic testing are important in order to rationalize our approach to this common, and treatable, complication of TBI. In this article, we will document the evidence for posttraumatic hypopituitarism and discuss strategies to investigate and manage this endocrine challenge.

Prevalence of Pituitary Disorders Following TBI

Anterior Pituitary Disorders

Acute hypopituitarism

Post mortem studies conducted in cases of fatal brain injury show that vascular pituitary damage occurs very soon after TBI. Although victims of TBI who die immediately on brain injury display no evidence of pituitary vascular damage, histological features of infarction or hemorrhage occur as early as 3 h after brain injury (Salehi *et al.*, 2007). It is reasonable to expect, therefore, that pituitary dysfunction may occur early after TBI, and this hypothesis is borne out by experimental data; Agha and colleagues showed that blunted cortisol and GH responses to glucagon testing occurred as early as 7–10 days after TBI (Agha *et al.*, 2004a). Hyperprolactinemia and hypogonadism also occurred, though both of these hormonal abnormalities are seen in patients in intensive care patients, as part of the response to acute stress, and so it is difficult to know how much these hormone abnormalities reflect structural pituitary damage.

In a prospective study of 100 patients with moderate to severe TBI, Hannon and colleagues reported plasma cortisol concentrations were measured at day 1,3,5,7, and 10, and compared the results to those derived from a control group of patients, who were admitted to the intensive care unit following major vascular surgery (Hannon *et al.*, 2013). The patients in the control group all had the expected stress cortisol response to surgery, with plasma cortisol concentrations >500 nmol/L (18.2 μg/dL) at day 1, and consistently >300 nmol/L (10.87 μg/dL) for the subsequent days of hospitalization. In contrast, 78 of the TBI cohort had at least one plasma concentration <300 nmol/L, and some displayed evidence of severe cortisol deficiency, for patients recovering from life-threatening stress. In some patients, the dip in plasma cortisol concentrations were very transient, compatible with an acute, reversible, contusion injury, whereas in others, the ACTH/cortisol deficiency persisted; 6/32 patients had chronic glucocorticoid deficiency, as measured by impaired cortisol responses to ITT or GST and SST. The results of this study suggest that acute glucocorticoid deficiency is more common than previously believed and it is frequently transient in nature; it raises the interesting theory that identification and treatment of early glucocorticoid deficiency may lead to therapy which could improve the clinical outcome from TBI. However, this remains to be tested by intervention studies.

Natural history of post TBI hypopituitarism

The results of carefully conducted prospective studies indicate that pituitary function is inconsistent in the months after TBI, with acute deficiencies recovering in some patients, whereas other patients only develop hypopituitarism well after the acute event. Aimaretti and colleagues evaluated 70 patients with TBI (including mild TBI) 3 months following the injury and then repeated the testing at 12 months. At 3 months 32.8% of the patients had at least one pituitary hormone deficiency. When testing was repeated at 12 months this figure had fallen to 22.2%. Interestingly, in 5.5% of TBI patients with no deficit at 3 months, an isolated pituitary deficit was recorded at retesting. Early panhypopituitarism was diagnosed in 5.7% which persisted in all when they underwent repeat evaluation at 12 months. In contrast, isolated pituitary deficiencies, lasted until repeat testing in only 25% of patients (Aimaretti *et al.*, 2005). This study would suggest that more severe early hypopituitarism is more likely to persist and develop into chronic hypopituitarism.

In our own unit, 50 patients with severe or moderate head injury who were evaluated during the acute phase of TBI, underwent repeat dynamic pituitary stimulation at 6 months, and at 12 months after injury. Forty patients had gonadotrophin deficiency in the acute phase, 85% of these patients had recovered by 12 months, as would be expected with an acute adaptive response to critical injury. Evaluation of the growth hormone response to glucagon showed a lower incidence of acute deficiency however (18%), with a more erratic picture of recovery. At 6 months, five patients recovered function and two new deficiencies were subsequently detected at 12 months. The cortisol response was also inconsistent, 16% ($n=8$) of patients had suboptimal responses to glucagon testing in the acute phase, when these patients were retested however, four patients recovered and five developed new deficiencies. All nine patients that were had an insufficient cortisol response at 6 months persisted at 9 months. These results are depicted in **Fig. 1**. This highlights that pituitary dysfunction post TBI may be transient and that periodic evaluation is required even if the initial endocrine evaluation is normal (Agha *et al.*, 2005a).

The natural history of post-traumatic hypopituitarism: Implications for assessment and treatment. *The American Journal of Medicine* **118**, 1416.

A similar picture of fluctuating pituitary function was demonstrated were found by Tanriverdi, who assessed pituitary function in the acute phase and after 12 months in 52 patients with mild/moderate or severe TBI. Five patients demonstrated subnormal cortisol plasma concentrations in the acute phase (<7 μg/dL), four of these recovered however nine patients developed new ACTH deficiency when they were retested at 12 months by low dose synacthen test. The GH axis showed a similar response; 10% were deficient in the acute phase (IGF-I concentration <84 ng/mL), 5% recovered and 13% had a new deficiency at 12 months (combined test, GHRH and GH-releasing peptide (GHRP-6)). Overall, new deficiencies were present in 51.9% of patients on repeat testing (Tanriverdi *et al.*, 2006).

The different recovery rates observed in these studies likely relates to the timing of testing (acute phase vs. 3 months post injury), the diagnostic criteria used and the severity of TBI. It is therefore difficult to predict if hypopituitarism will be transient or chronic. The Aimaretti data suggests however, that if a patient has panhypopituitarism on initial testing, these deficiencies are unlikely to recover.

Chronic hypopituitarism

The prevalence rate of chronic pituitary dysfunction in long term survivors of TBI is the subject of vigorous debate in the literature. **Table 1** shows the results of published studies. Some of the studies report wildly discrepant estimations of the frequency of hormonal deficits, which mainly reflect differences in patient populations studied and methods of screening for hypopituitarism.

One of the earliest attempts to estimate the prevalence of anterior pituitary dysfunction following moderate/severe TBI examined the response of 22 patients, a median of 26 months post injury, to gold standard insulin tolerance testing. The results revealed GH deficiency in four patients, ACTH deficiency in one patient and one patient had gonadotrophin deficiency, suggesting a significant prevalence of chronic hypopituitarism. This landmark study prompted a more widespread investigation of pituitary function after TBI. A subsequent larger study measured the GH response to glucagon stimulation in 70 survivors of TBI, and confirmed a significant minority (15%) had severe GH deficiency (peak GH <3 μg/L). This suggested that almost one patient in six survivors of TBI might benefit from GH treatment. The effect of choice of diagnostic test was underlined by the discrepant cortisol data in this study; although 45% of subjects had a low morning cortisol at <7 μg/L (193 nmol/L), only five patients failed to mount a normal cortisol response of >500 nmol/L to stimulatory testing. This underlines therefore the need for dynamic testing for GH and ACTH/cortisol deficiencies.

A comprehensive study of a large number of chronic survivors of moderate/severe TBI (102 patients), who were studied at a median of 19 months post injury confirmed the significant incidence of anterior pituitary hormone deficits. The glucagon stimulation test (GST) was used as an initial screening test for both GH and ACTH deficiency, but any identified deficits were confirmed by a second test; the ITT or synacthen (where there was a history of seizures) for ACTH, and a GHRH/arginine test for GH deficiency. Patients had to fail both dynamic tests before confirmation of hormone deficits. Using these rigorous criteria, and robust testing, 11% of patients were shown to have severe GH deficiency, 13% had ACTH deficiency, 12% gonadotrophin deficiency, and 1% had TSH deficiency. Several other studies have since confirmed these findings (Aimaretti *et al.*, 2004; Alavi *et al.*, 2016; Bondanelli *et al.*, 2004; Popovic *et al.*, 2004; Leal-Cerro *et al.*, 2005; Schneider *et al.*, 2008) (see **Table 1**).

Other studies however have found a lower prevalence of hypopituitarism post TBI. Kokshoorn *et al.* evaluated 112 patients using ITT and fasting hormone profile, at least 1 year after TBI. Hypopituitarism was diagnosed in only 5.4% of patients (Kokshoorn *et al.*, 2011), prompting the authors to speculate that the prevalence of hypopituitarism after TBI was much lower than previously published. However, they excluded over 90% of eligible patients, and included a large number of patients with mild (Glasgow coma scale 14–15) TBI, who would be expected to have minimal hypopituitarism. Thus, although gold standard testing with ITT was used, the selection of mild TBI patients meant that they were predetermined to identify lower rates of pituitary dysfunction than previous studies.

Table 1 Reported prevalence of chronic hypopituitarism

Author	*Median duration (months)*	*N*	*Total HPit (%)*	*GH (<3 ng/mL)*	*ACTH*	*GN*	*TSH*

[a]Mean duration.

Kokshoorn proceeded to review 14 studies with reported pituitary function testing post TBI, and concluded that the chosen dynamic test influenced the likelihood of identifying hormone deficits. The prevalence of GH deficiency varied from 2% to 39%, with higher rates in studies using the GST compared with studies using GHRH-arginine; only two studies used a combination of two tests (Kokshoorn *et al.*, 2010). The tests used to diagnose GH deficiency therefore can significantly impact the prevalence of GH deficiency; this applies to all disease processes which can potentially altered pituitary function.

Klose *et al.* evaluated the GH axis in 439 patients with a history of TBI and 124 health controls, and found a prevalence of severe GHD of 19%, when the standard guidelines were applied and testing was confirmed with the pyridostigmine (PD)—GHRH test (Klose *et al.*, 2014). However when local cut-off values were used derived from the healthy population the prevalence was 12%. When a combined PD-GHRH test and ITT were performed the prevalence was estimated at only 1%. This is significantly lower than all previous studies. Sixty-nine percentage of the patients in this study suffered mild traumatic brain injury, whereas previous studies, which published high rates of pituitary damage, had limited their analysis to patients with moderate to severe TBI. However, this study does highlight that the test used to diagnose the deficiency may have a significant impact on the prevalence of observed hypopituitarism and that when reporting data on GH and ACTH deficiency it is important to report the results from age matched controls to establish normative data.

A meta-analysis of 19 studies published in 2007 found that the pooled prevalence of anterior hypopituitarism after TBI was 27.5% (95% CI 22.8%–28.9%) with a range between studies of 37.5% to 55%. Associated aneurysmal subarachnoid hemorrhage (SAH) is associated with a significantly higher prevalence of pituitary dysfunction, with a prevalence of 47% (95% CI 37.5%-–56.8%) (Schneider *et al.*, 2007a). GH deficiency and gonadotrophin deficiencies were the most commonly observed pituitary deficiencies following TBI in this meta-analysis (Schneider *et al.*, 2007a). A further meta-analysis of 27 studies reported that the prevalence of anterior pituitary dysfunction, when all pituitary axes were interrogated, was 31.6% (95% CI 23.6%–40.1%) (Lauzier *et al.*, 2014). Significant heterogeneity in time of testing, and method of assessment for each anterior pituitary axis was considered to account for the large part of interstudy discrepancy.

It is clear therefore that several factors affect the prevalence of TBI, including the time interval following the injury, the cut-off values used for diagnosis of hypopituitarism and the severity of brain injury studied (pituitary dysfunction is more common after severe TBI) (Klose *et al.*, 2007a). Whilst there are significant challenges with diagnosing pituitary dysfunction post TBI, these prevalence studies would indicate that hypopituitarism is a reasonably frequent occurrence post moderate to severe TBI.

Posterior Pituitary Disorders

As the posterior pituitary gland secretes the antidiuretic hormone, vasopressin (AVP), posterior pituitary damage may result in disordered water balance, manifesting either as diabetes insipidus or hyponatremia. Although both disorders have been clinically recognized complications of TBI for many years, there is relatively little hard data available regarding the prevalence of posterior pituitary dysfunction following head injury.

Diabetes insipidus

Diabetes insipidus manifests as the passage of large volumes of hypotonic urine. Although most patients with new onset diabetes insipidus can respond to rising plasma sodium concentrations with appropriate thirst (Thompson and Baylis, 1987), patients in intensive care, who are either unable to recognize thirst due to cognitive impairment, or who cannot access sufficient fluid replacement, may develop marked hypernatremia (Hannon *et al.*, 2011). As a result, poorly treated diabetes insipidus can contribute to delayed recovery, and even increased mortality in TBI.

In an initial study of 50 patients with acute moderate to severe TBI, Agha and colleagues found that 13 patients (26%) had acute cranial diabetes insipidus (CDI) in the early post TBI phase. This resolved in nine of these patients by 6 months (Agha *et al.*, 2005a). Subsequent studies would suggest a prevalence of 3%–26% of patients of acute CDI post TBI (Agha *et al.*, 2004a; Hadjizacharia *et al.*, 2008; Boughey *et al.*, 2004).

In a larger prospective study of 100 TBI patients who were assessed daily for development of abnormal water balance, diabetes insipidus was diagnosed using the well described Seckl and Dunger criteria (Seckl and Dunger, 1989). A surprising large number of patients (51%) developed hypernatremia, due mainly to acute diabetes insipidus, though some cases had simple dehydration; 21.6% had persistent DI after day 10 of admission (Hannon *et al.*, 2013). Persistent diabetes insipidus in this cohort was strongly predictive of mortality. Other studies have confirmed both transient and permanent DI are poor prognostic indictors post TBI and are associated with an increased mortality, particularly when hypernatremia develops (Maggiore *et al.*, 2009; Hadjizacharia *et al.*, 2008).

Most cases of posttraumatic diabetes insipidus (DI) are transient. However, a significant proportion have persistent DI. Agha *et al.* evaluated 102 patients who suffered moderate or severe TBI, using standard water deprivation test at a median of 17 months post injury (Agha *et al.*, 2004c). Although 21.6% of patients had evidence from the case notes of diabetes insipidus in the acute period following TBI, only 6.9% of patients had abnormal water deprivation tests. This data suggested a higher incidence of post TBI DI than other studies, which reported a prevalence of 0%–2.9% (Aimaretti *et al.*, 2005, Kreitschmann-Andermahr *et al.*, 2004); the earlier studies did not use formal water deprivation tests and so may have underreported the true incidence. However, it should be recognized also that only 2% of patients in Agha's study had DI of sufficient severity to warrant therapy with desmopressin; it may be that the true figure for symptomatic DI is closer to 2%. Patients with both transient and permanent diabetes insipidus in

this cohort were more likely to have a more severe traumatic brain injury, as assessed by Glasgow coma scale, and evidence of cerebral edema on imaging studies (Agha *et al.*, 2004c).

Whilst the majority of patients with diabetes insipidus will have an intact thirst response and will increase their fluid intake to replace renal water losses, patients with traumatic brain injury are particularly prone to the development of hypernatremia. This is largely due to decreased level of consciousness secondary to brain injury, cerebral edema, sedation for airway management or a combination of factors. Adipsic DI (absent thirst response) has also been reported following head injury (Cuesta *et al.*, 2017). In studies where thirst response was formally measured however, the thirst response is typically intact and adipsic DI is a rare complication of TBI (Agha *et al.*, 2004c).

Rarely, diabetes insipidus may progress to transient SIADH followed by recurrent diabetes insipidus. This is known as the triple phase response. It is hypothesized that the initial phase of DI is an acute contusion injury, with a period of SIAD occurring due to the release of preformed AVP from damaged neurohypophyseal cells, resulting in antidiuresis and water retention. Permanent DI follows as neuronal gliosis attenuates vasopressin secretion. This is thought to occur in less than 5% of neurosurgical diabetes insipidus (Hannon *et al.*, 2012). However, it is important to monitor for this potential complication as continued desmopressin administration during the development of SIADH may lead to the development of profound hyponatremia.

Hyponatremia

Hyponatremia has been reported to occur in 2.3%–36.6% of cases of TBI (Lieberman *et al.*, 2001; Born *et al.*, 1985; Sherlock *et al.*, 2009). The differential diagnosis for hyponatremia is substantial (**Table 2**), and includes Syndrome of Inappropriate ADH secretion (SIADH), glucocorticoid deficiency, and hypotonic intravenous fluids. SIADH is the commonest cause of hyponatremia following TBI, and occurs in approximately 12.7% of patients (Hannon *et al.*, 2014). SIADH typically develops 1–2 days after the trauma, and is usually transient, with complete return to normality. It is important to differentiate SIADH from other causes of hyponatremia as incorrect management may have significant detrimental effects; severe symptomatic hyponatremia, masquerading as SIADH, has been reported to be the principle manifestation of acute glucocorticoid deficiency following TBI (Agha *et al.*, 2005c). **Table 2** demonstrates the different treatment strategies for post TBI hyponatremia, according to etiology.

In a prospective study of 100 patients with moderate to severe TBI, 15% developed hyponatremia. Thirteen of these patients had evidence of glucocorticoid deficiency, as defined by a 09.00 am plasma cortisol <300 nmol. All 13 patients normalized their serum sodium concentrations with the administration of glucocorticoid therapy. The remaining two patients had SIADH, which responded to fluid restriction and resolved. All 15 patients had a normal serum sodium concentration when re-evaluated at 6 months; there was no case of persistent hyponatremia (Hannon *et al.*, 2013). Although hyponatremia following TBI is self-limiting, it may be severe and present with features of cerebral irritation. It is therefore important to monitor plasma sodium concentration following TBI and to implement appropriate evaluation to determine the cause of the hyponatremia.

Cerebral salt wasting is a rare condition that is characterized by marked natriuresis, resulting in hypovolemic hyponatremia. Some authorities have questioned whether cerebral salt wasting really exists, or whether it represents escape from antidiuresis. Although we think that cerebral salt wasting is rare, and our prospective studies of hyponatremia post TBI and SAH, have revealed only very rare cases (Hannon *et al.*, 2014), the occasional presentation of patients with profound diuresis and natriuresis, associated with hypotension and decreased central venous pressure, is so characteristic, and so different from the classical presentation of a case of SIADH, that we feel it merits a special, though rare, diagnostic status.

Pathophysiology of Pituitary Disease Following TBI

There are several potential pathological mechanisms of hypopituitarism post TBI; pituitary gland compression due to raised intracranial pressure and cerebral edema, skull fracture with disruption of the vascular supply to the pituitary gland, hypoxic insult, direct mechanical injury and autoimmunity with antipituitary and antihypothalamus antibodies have all been studied.

The pituitary gland is situated in the median section of the middle cranial fossa in the sphenoid bone. The majority of the vascular supply to the anterior lobe of the pituitary is from the long hypophyseal vessels. The hypophyseal vessels become the hypophyseal portal circulation that transports hypothalamic neuropeptides from the hypothalamus to the pituitary gland.

Table 2 Differential diagnosis of hyponatremia in TBI

Causes of hyponatremia following TBI	*Treatment*
SIADH	Fluid restriction, vaptans
Acute glucocorticoid deficiency	IV hydrocortisone
Inappropriate intravenous fluids	Frusemide, cessation of diuretics
Cerebral salt wasting	High volume IV saline
Drugs, for example, desmopressin, carbamazepine, loop diuretics	Cessation of drug
Triple phase response of acute diabetes insipidus	dDAVP/fluid restriction/dDAVP

The corticotroph and thyrotroph cells are located anteriorly and medially in the anterior pituitary, and derive their vascular supply from the short portal veins. The somatotroph cells are located more laterally and are typically supplied by the long portal veins (Gorczyca and Hardy, 1987). The blood supply to the posterior lobe of the pituitary gland differs and is supplied by an anastomotic arterial circle derived from the inferior hypophyseal vessels, which arise from the internal carotid artery, as they enter the cavernous sinus.

The vascular insult theory for the pathophysiology of pituitary injury post TBI is currently the foremost hypothesis. The long hypophyseal vessels and the portal circulation in the stalk are particularly vulnerable to injury from mechanical and shearing forces at the time of brain injury, as they arise in the subarachnoid space and travel through the diaphragm sella. Interruption of this vascular supply will result in anterior lobe infarction with resultant hypopituitarism. This theory is supported by autopsy studies from the 1960s to 1970s which demonstrated tissue necrosis in the anterior pituitary of patients with traumatic brain injury (Daniel *et al.*, 1959; Ceballos, 1966). Subsequently more recent studies have shown 43% of patients who survive severe traumatic brain injury for longer than 3 h will have pituitary infarction (Salehi *et al.*, 2007) (**Fig. 2**).

The vascular hypothesis is further supported by the pattern of hormonal loss observed in pituitary dysfunction post TBI. Somatotroph and gonadotroph cells lie laterally and are supplied by the long hypophyseal portal vessels, interruption of this blood supply will result in infarction of these cells (Dusick *et al.*, 2012), the GH and Gonadotrophic axes therefore, are the most commonly affected pituitary axes (Schneider *et al.*, 2007a). By contrast, the inferior hypophyseal arteries are much less vulnerable to injury and therefore infarction of the posterior pituitary is therefore rare. Furthermore, magnetic resonance imaging studies of the pituitary gland in the acute phase post TBI have demonstrated an enlarged pituitary when compared to healthy controls with or without associated hemorrhage, infarction or signal loss (Maiya *et al.*, 2008). Schneider *et al.* demonstrated that patients with TBI in the chronic phase often demonstrate loss of pituitary volume, empty sella, loss of pituitary gland heterogeneity or absent posterior pituitary signal. When compared to TBI patients without hypopituitarism these abnormalities occurred in 80% of the patients with hypopituitarism in comparison to 29% of those without hypopituitarism ($P = .032$) (Schneider *et al.*, 2007b).

Secondary insults from hypoxia, hypotension, and cerebral edema frequently complicate major trauma and may contribute to the development of hypopituitarism. Evidence for this is derived from autopsy studies that failed to demonstrate vascular injury in patients with TBI who died less than 3 h. In contrast to this, 43% of patients who survived for between 3 h and 1 week after injury had evidence of pituitary infarction (Salehi *et al.*, 2007). Harper and colleagues examined pituitary infarcts in 38 of 100 consecutive patients with fatal closed head injuries. All patients with large- or medium-sized pituitary infarctions had evidence of raised ICP at some point. The authors concluded that disruption of the portal blood supply, due to raised ICP or direct vascular insult, was the possible mechanism of anterior lobe infarction (Tanriverdi *et al.*, 2015; Harper *et al.*, 1986). It is important to consider that these studies focused on fatal TBI. These patients were likely to have severe injuries with associated hypotension, hypoxia, ischemia and cerebral edema, which limits the ability to generalize these findings to patients with nonfatal TBI.

Autoimmunity has also been hypothesized as a possible contributing mechanism. Antipituitary (APA) and antihypothalamic antibodies (AHA) have been demonstrated in idiopathic and autoimmune hypopituitarism (De Bellis *et al.*, 2014). Observational studies in TBI have demonstrated that pituitary dysfunction post TBI was higher in APA positive patients (46.2%) versus negative patients (12.5%) (Tanriverdi *et al.*, 2008). This association was also observed in 61 boxers when they were compared to normal controls; pituitary dysfunction was significantly higher in AHA positive boxers (46.2%) than in AHA negative boxers (10.4%) with an odds ratio of 7.37, 95% CI (1.8–30.8) (Tanriverdi *et al.*, 2010). Whilst it is possible that autoimmune processes play a role in the development of hypopituitarism post TBI, the exact mechanism behind this is unknown. Furthermore, as this is observational data, causality has not been shown, therefore this observed high incidence of APA may be a response to tissue damage rather than a causative factor.

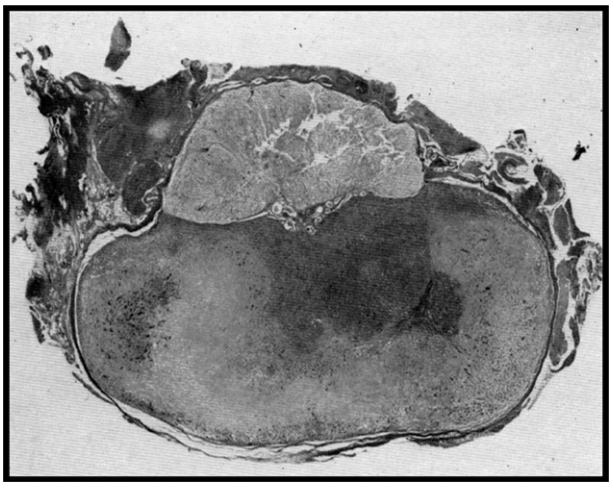

Fig. 2 Pituitary pathological specimen—demonstrating pituitary infarction in the long hypophyseal vein distribution (Daniel *et al.*, 1959).

Whilst the exact mechanism remains unclear, it is likely that the pathophysiology is multifaceted and is likely an interplay between mechanical injury to the pituitary gland or hypothalamus, complicated by secondary insults such as hypotension and raised intracranial pressure and the transient stress of critical illness with resultant inflammatory response.

Predictors of Hypopituitarism Following TBI

Identifying predictors of hypopituitarism in TBI is of paramount importance in order to design appropriate screening strategies for patients with TBI. The suggested predictors of hypopituitarism post TBI include early pituitary dysfunction, raised ICP, radiological changes, ITU admission, and severity of injury.

Early pituitary dysfunction as a predictor

Several studies have evaluated early pituitary dysfunction as a predictor of the development of chronic hypopituitarism. In a prospective study of pituitary dysfunction in the acute setting following TBI, pituitary deficiencies were common in the acute phase (80% of patients had gonadotrophin deficiency in the acute phase), but 85% recovered on repeat testing at 12 months. In fact when patients were retested, some patients who had intact pituitary dysfunction earlier had developed new deficiencies (Agha *et al.*, 2005a). The authors were unable to identify factors predictive of persistent hypopituitarism in this study. Similar data was presented by Tanriverdi and colleagues, who reported that in the acute phase following TBI, 56.5% of patients had at least one pituitary hormone deficiency, with gonadotrophin deficiency the most common (41.6%). They described a recovery rate of 57.7% of patients (Tanriverdi *et al.*, 2006). In this article, there was no discernible pattern to identify those at higher risk of permanent pituitary deficiencies.

Neither of these studies had a control group of critically unwell patients without known pituitary dysfunction. Hannon *et al.* compared sequential plasma cortisol levels in acute TBI patients and compared them to matched controls who had undergone vascular surgery and were cared for in the ICU. All 15 of the control patients had a plasma cortisol concentration >300 nmol/L on repeated testing, however 78% of the TBI patients had at least one plasma cortisol concentration <300 nmol/L. However, when repeat testing was performed 12 months later 6 of 32 patients tested were cortisol deficient, all of whom had acute cortisol deficiency and/or cranial diabetes insipidus in the acute phase. Lower mean plasma cortisol (over the 10 days of the study) and lower plasma cortisol level at day 10 of the study (final day) were strongly associated with the development of chronic hypopituitarism of any pituitary axis ($P=.049$, $P=.015$, respectively) (Hannon *et al.*, 2013).

Severity of trauma as a predictor

The pre-resuscitation Glasgow coma score (GCS) is the most commonly used method to assess the severity of traumatic brain injury. It is score out of a maximum score of 15, mild TBI is graded 13–15, moderate 9–12 and severe is 3–8. Increased trauma severity (as measured by low initial GCS) and number of days of intubation and hospitalization (Herrmann *et al.*, 2006) have been shown to be independent predictors of posttraumatic hypopituitarism in some studies, however, the results in individual studies were not conclusive (Klose *et al.*, 2007a). However, two meta-analysis have been undertaken, both of which identified GCS as a predictor of the development of hypopituitarism following TBI (Schneider *et al.*, 2007a; Lauzier *et al.*, 2014).

Radiological changes as a predictor

Agha *et al.* did not find any association between the initial cranial CT imaging results and hypopituitarism in patients with moderate and severe TBI (Agha *et al.*, 2004b), but some other studies did find an association between chronic hypopituitarism and abnormal cranial CT findings during the acute phase. A meta-analysis of six studies, including 357 patients, found that skull fractures on CT imaging were associated with an increased risk of developing anterior pituitary dysfunction (Lauzier *et al.*, 2014). Brain edema on CT imaging has not been shown to be predictive of pituitary dysfunction in larger studies (Agha *et al.*, 2004b), however one smaller study demonstrated an association between diffuse brain swelling on CT and hypopituitarism (Kelly *et al.*, 2000). Two separate studies have quantitatively reported the effect of secondary brain injuries (hypoxemia and hypotension) on pituitary function, but neither study demonstrated a predictive association (Krahulik *et al.*, 2010; Bavisetty *et al.*, 2008).

Testing/Screening for Pituitary Disease Post TBI

Screening for pituitary disease in TBI presents significant logistical and resource difficulties. This reflects the large number of patients who, as roads become more congested, develop brain injuries, and the requirement for dynamic testing for GH and cortisol deficiency. Whilst the optimal timing for screening for pituitary insufficiency is relatively straight forward, establishing which groups to screen—or not to screen—remains challenging. There continues to be much debate as to the ideal approach to screening in traumatic brain injury.

Acute hypopituitarism

The priority in acute hypopituitarism is to identify the urgent and potentially life-threatening pituitary deficiencies of ACTH and AVP. Failure to correctly identify and treat affected patients may result in increased morbidity and mortality.

Dynamic testing is not appropriate in the acute setting of TBI. The short synacthen test requires time for the adrenal glands to atrophy and is therefore not suitable in the acute setting. The insulin tolerance test may precipitate seizures and as patients with TBI have a reduced seizure threshold this should be avoided. In practice, a 09:00 am plasma cortisol measurement is a reasonable alternative. In critical illness, the normal diurnal variation of cortisol is typically lost, however a 09.00 am plasma cortisol concentration >300 nmol/L has been determined as normal response in our institution (Hannon *et al.*, 2013). Establishing a safe cut-off value for basal cortisol levels requires a high sensitivity due to the potential repercussions of a missed diagnosis. It is also important to consider that serum cortisol concentrations of between 300 and 500 nmol/L do not necessarily exclude acute ACTH deficiency and empiric glucocorticoid cover should be considered if there is a clinical suspicion of hypoadrenalism, particularly in the presence of hyponatremia, hypoglycemia or profound hypotension.

Serum sodium concentrations and urine output should be monitored closely for the development of CDI. The diagnosis of CDI should be made if the Seckl and Dunger criteria are met; plasma sodium >145 nmol/L in the presence of hypotonic (urine osmolality <300 mosmol/kg) polyuria (>300 mL/h for two consecutive hours or >3 L/day) (Hannon *et al.*, 2012). Other potential causes of polyuria, such as diuretic use, steroid induced hyperglycemia or renal impairment should also be excluded. TSH, GH, and Gonadotrophin axes should not be tested in the acute setting as, deficiency in these axes is typically transient, in response to stress (Agha *et al.*, 2005a) (**Table 3**).

Chronic hypopituitarism

Patient selection

Identifying patients that require screening is imperative and is the subject of ongoing debate. A number of guidelines exist which have suggested criteria for screening, which include moderate and severe TBI, long duration of hospital admission and symptom based screening (Aimaretti and Ghigo, 2007; Ghigo *et al.*, 2005; Tan *et al.*, 2017; Garrahy *et al.*, 2017).

In order to determine whether symptom-based screening would improve the diagnostic yield of dynamic testing, we compared the rate of hypopituitarism identified from a referral strategy based only on symptoms suggestive of pituitary dysfunction. When compared with universal screening, whether or not symptoms were present, nonspecific symptoms such as weight loss and anergia produced no higher rate of pituitary dysfunction. In contrast, patients who were referred on the basis of symptoms of gonadal dysfunction, such as erectile dysfunction, menstrual disturbance and loss of libido, were highly likely to be diagnosed to have hypopituitarism (Cuesta *et al.*, 2016). This evidence supports pituitary screening in any patient with gonadal dysfunction following traumatic brain injury but questions the utility of non-specific symptom based screening suggested by some guidelines (Gasco *et al.*, 2012; Aimaretti and Ghigo, 2007; Ghigo *et al.*, 2005; Tan *et al.*, 2017). As the rate of hypopituitarism was no different in patients with nonspecific symptoms and asymptomatic patients, it also suggests that a symptom-based screening process may miss some patients who have asymptomatic hypopituitarism.

Screening based on the severity of injury is also advocated by expert guidelines (Ghigo *et al.*, 2005; Tan *et al.*, 2017). Schneider's meta-analysis reported showed pooled prevalence rates of hypopituitarism in mild, moderate, and severe TBI of 17%, 11%, and 35%, respectively (Schneider *et al.*, 2007a). Therefore, if screening is performed only on those with moderate and severe injury, a significant subset of patients in the mild TBI group will be misdiagnosed.

Timing of screening

Pituitary function after TBI is dynamic; some acute deficiencies will resolve on retesting and other patients may develop new deficiencies over time (Agha *et al.*, 2005a; Tanriverdi *et al.*, 2006). It is reasonable therefore to retest all patients who present with acute deficiencies to assess for resolution. New deficiencies rarely appear after 6 months; therefore, it is sensible to retest at this stage. Although rare, late recovery has been reported 5 years after TBI therefore clinicians should be aware of this and consider retesting if symptoms change (Agha *et al.*, 2005b).

Screening test selection

The expert guidelines recommend basal hormone testing as the initial screening test (see **Fig. 3**) (Tan *et al.*, 2017; Ghigo *et al.*, 2005). If there is any abnormality noted on these tests or if there is a high index of suspicion from symptoms, then provocative testing should be performed. The insulin tolerance test remains the gold standard for the diagnosis of ACTH and GH deficiency. If the insulin tolerance test is contraindicated (due to seizures or heart disease), then the glucagon stimulation, GHRH-arginine test or GHRH + GHRp-6 should be considered as an alternative.

Table 3 Diagnostic tests to consider for anterior pituitary function assessment in each time frame

Timing of assessment	*Adrenal axis*	*GH axis*	*Thyroid axis*	*Gonadotrophin axis*
Acute phase	Early morning cortisol	n/a	n/a	n/a
Midterm (3–6 months)	Insulin tolerance test GST (if ITT C/I) ACTH stimulation test	Insulin Tolerance test GST (if ITT C/I) GHRH-Arg stimulation	TSH and T4	Testo/E2 + FSH/LH
Long term (>12 months)	Insulin tolerance test GST (if ITT C/I) ACTH stimulation test	Insulin tolerance test GST (if ITT C/I) GHRH-Arg stimulation	TSH and T4	Testo/E2 + FSH/LH

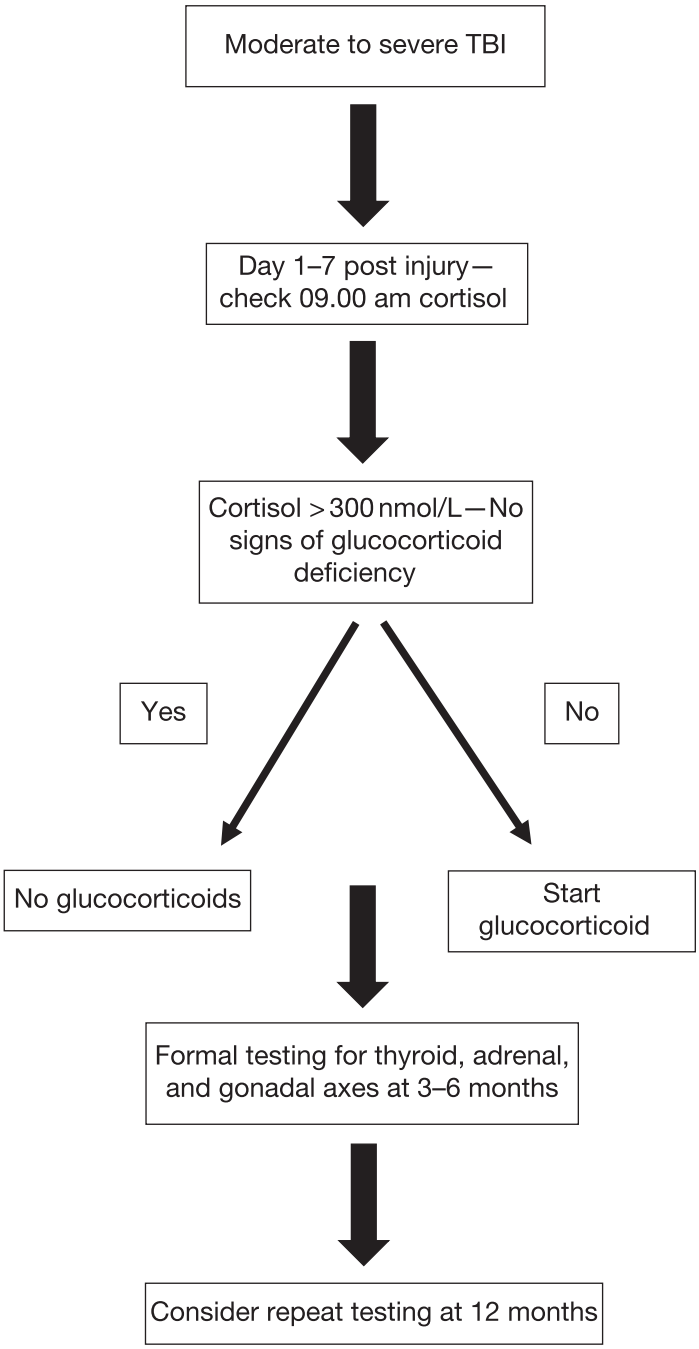

Fig. 3 Proposed algorithm for assessment of patients post TBI.

The screening tests used to make the diagnosis will affect the prevalence rate of hypopituitarism post TBI as discussed earlier. Therefore, robust universal definitions of normal cut-off values need to be developed before systematic screening can be considered in TBI.

Clinical Outcome of Pituitary Disease Post TBI

Outcome of Quality of Life/Cognitive Function

GH deficiency

Data from the KIMS database—an international database metabolic database of patients with GHD—was reported in an observational study in 2015. The authors compared patients with GHD following TBI to patients with GHD and a nonfunctioning pituitary adenoma. TBI patients showed a greater improvement in quality of life following GH therapy (change in QoL-AGHDA

score 5.0 vs. 3.5, respectively, $P = .04$) than patients with pituitary adenomas, an improvement which was sustained over 8 years of follow up (Gardner *et al.*, 2015).

A randomized, placebo-controlled assessment of the impact of GH replacement on cognitive function, in patients with GHD after TBI showed improvements in various functional and in the GH treated group. This suggests that some of the cognitive and functional disturbances seen post TBI may in fact be due to GH deficiency, and offers evidence that these disturbances may a be improved with growth hormone replacement (High *et al.*, 2010).

Other outcomes

There is increasing interest in the impact of TBI on quality of life (QOL) and other social and behavioral sequelae. A number of observational studies have sought to demonstrate an association of hypopituitarism post brain injury and QOL and cognitive outcomes. However, the results of these studies have been conflicting.

A large study of 70 survivors of TBI, conducted 6–9 months after injury, revealed that patients with hormonal deficits had a higher BMI ($P < .01$) and a worse Disability Rating Scale score (multivariate $P = .04$) compared to patients with intact pituitary function post TBI (Bavisetty *et al.*, 2008). Another study reported that patients with hypopituitarism were more likely to be overweight at follow up testing; this was attributed to GH and/or sex steroid deficiency. Otherwise there was no association found between hypopituitarism and quality of life and functional outcome in this cohort (Ulfarsson *et al.*, 2013).

Post TBI hypopituitarism is associated with an adverse lipid profile, unfavorable body composition and poorer quality of life, as measured by the Nottingham Health profile, compared to patients with intact pituitary function post TBI (Klose *et al.*, 2007b). This adverse metabolic profile was found to be independent of other confounding factors such as age, gender and BMI and was unrelated to 12 months IGF-1 and IGF-1 SD scores.

Other studies have described the metabolic effects of growth hormone deficiency and at least some of the adverse metabolic profile observed in patients post TBI likely occurs due to the decreased lipolytic activity associated with growth hormone deficiency (Klose *et al.*, 2007b; Popovic *et al.*, 2004). Furthermore, Mossberg *et al.* evaluated aerobic capacity in patients post traumatic brain injury and found reduced capacity in all patients with a greater reduction observed in GH deficient patients (Mossberg *et al.*, 2008). Similarly, Silva *et al.* found that patients with pituitary insufficiency post TBI were less likely to be working after TBI ($P = .002$), and had lower Global Assessment of Functioning (GAF) scores ($P = .03$) (Silva *et al.*, 2015).

Klose *et al.* published patient-reported outcomes in hypopituitarism post brain injury, using QOL questionnaires in 84 patients. This study failed to demonstrate an independent relationship between pituitary deficiency and QOL/fatigue (Klose *et al.*, 2015). The mixed there are undoubtedly multiple other factors that will influence QOL and fatigue after head trauma, therefore it is currently difficult to definitively conclude the precise impact of pituitary dysfunction on recovery post TBI. Further study is required but data from other causes of pituitary dysfunction may be extrapolated and it is therefore logical that pituitary dysfunction confers an adverse clinical outcome.

Conclusions

Traumatic brain injury is an important cause of morbidity and mortality, particularly in the younger population. The reported prevalence of pituitary dysfunction following brain injury varies depending on research protocol, but seems to consistently occur in 20%–30% of patients. Screening for hypopituitarism post TBI is complicated by the large volume of patients presenting with brain injury and other than severity of brain injury, there are no reliable predictors of the development of pituitary dysfunction post TBI. Therefore, all clinicians must be vigilant for signs and symptoms of pituitary dysfunction and all patients with moderate-severe TBI should be considered for pituitary evaluation.

The Ovarian Reserve of Primordial Follicles

The reserve of primordial follicles is set up before birth in humans. The formation of oocytes, a process also designed as oogenesis, precedes the formation of follicles (reviewed by Hartshorne *et al.*, 2009; Kerr *et al.*, 2013; Ackert *et al.*, 2001; Hutt *et al.*, 2006). In the human ovary, oogenesis begins at 2 weeks postconception (wpc), also referred as 4 weeks of gestation, when the first primordial germ cells are formed within the epiblast. Then, these cells migrate to the hind gut, colonize the gonadal ridges before 7 wpc and proliferate as oogonia into ovarian cysts (also called nests). The cysts also contain the

precursor granulosa cells, derived from the gonadal ridges (Hummitzsch *et al.*, 2013). After 8.5 wpc, the oogonia can cease mitosis, enlarge and develop into primary oocytes, which initiate meiotic prophase. The breakdown of the cysts, occurring between 13 and 30 wpc, leads to the formation of 30-µm-diameter primordial follicles, each consisting of a primary oocyte arrested at the diplotene stage of prophase I of meiosis and surrounded by one layer of flattened granulosa cells. It is worth noting that there is a marked asynchronicity of germ cell development in the human ovary. Even after primordial follicles have started to form, mitosis continues in more peripherally located germ cells for many weeks thereafter (Fulton *et al.*, 2005).

Abnormal follicle formation is associated with a massive loss of oocytes in the fetal ovaries from 22 wpc. At this age, a maximal number of 6.8 million germ cells (healthy and atretic) per pair of ovaries was reported (Baker, 1963). The ovarian reserve of primordial follicles has been estimated at 100,000 primordial follicles/ovary at 15 wpc, and it increases to 350,000 to 1.1 million at birth, the average being about 700,000 (Baker, 1963; Block, 1952; Forabosco and Sforza, 2007) (**Fig. 1**).

Once formed, the primordial follicles may begin to grow immediately or become quiescent. In the latter case, they will either degenerate or resume their growth several months or years later. The activation of primordial into growing follicles occurs throughout life until complete exhaustion of the ovarian reserve. All the growing follicles degenerate by atresia before puberty, whereas a tiny proportion of them (about 0.01%) ovulate in adults.

The isolation of oogonial stem cells from adult mouse and human ovaries has been reported; these cells exhibit both germ and stem cell markers in culture (White *et al.*, 2012). When reintroduced into an ovarian somatic environment, the mouse oogonial stem cells have generated follicles capable of producing healthy offspring (Zou *et al.*, 2009). However, these stem cells are unable to sustain by themselves the ovarian function into an advanced age, which may be partly due to age-related changes in the ovarian microenvironment (reviewed by Truman *et al.*, 2017). Moreover, there are no data on their potential physiological role within the

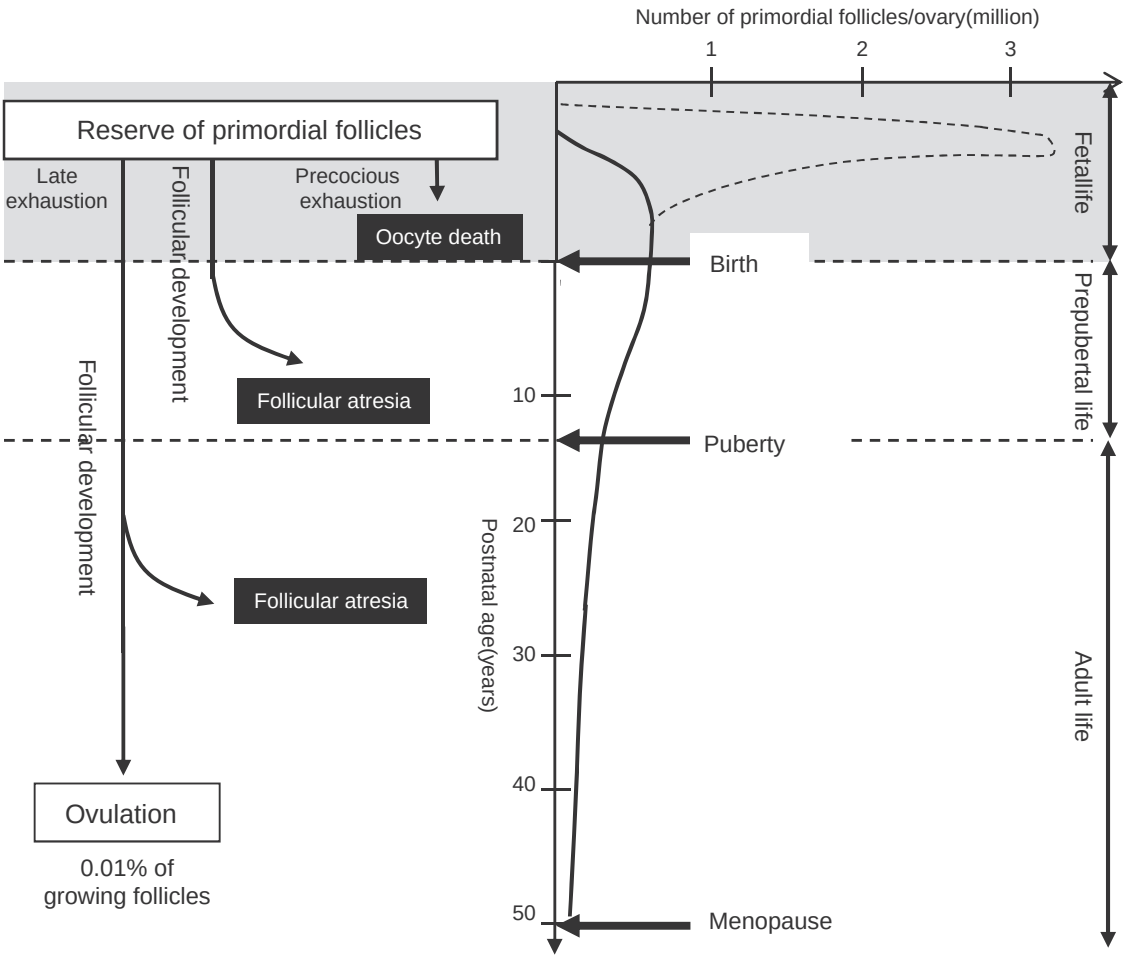

Fig. 1 Changes in the ovarian reserve of primordial follicles throughout life in humans. In the right part of the figure, the *solid* and *dotted lines* represent the number of primordial follicles and the total number of germ cells per ovary, respectively (from the compiled data of Block (1952), Baker (1963), and Forabosco and Sforza (2007)). The main mechanisms leading to the exhaustion of the reserve are indicated in the *left* part of the figure.

ovary, and specifically no evidence that they can contribute to the primordial follicle pool, hence to later stages of follicle development (reviewed by Grieve *et al.*, 2015).

From the Primordial to the Ovulatory Follicle: Morphological and Functional Features

Follicular Morphogenesis and Growth Rates

When a quiescent primordial follicle is activated to grow, its granulosa cells increase in number and change shape; they become cuboidal, while the oocyte starts to enlarge (primary follicle stage). Thereafter, multiple layers of proliferating granulosa cells develop around the oocyte, while the oocyte grows further. At this stage of secondary (or preantral) follicle, a vascularized theca differentiates by recruitment of progenitor cells present in the ovarian cortex (Liu *et al.*, 2015) and surrounds the granulosa tissue. In follicles of about 250 μm in diameter, small cavities filled with follicular fluid appear due to the movement of fluid originating from the thecal vasculature and powered by an osmotic gradient generated by hyaluronan and proteoglycans (reviewed by Rodgers and Irving-Rodgers, 2010). Then, these cavities merge into a central cavity (called the antrum) lined by the granulosa wall. In antral follicles, those granulosa cells closely connected with the oocyte form the cumulus–oocyte complex. The morphology of the follicles at different stages of follicles is illustrated in **Fig. 2** (reviewed by Monniaux *et al.*, 2009).

The duration of folliculogenesis from the initiation of follicular growth to ovulation has been estimated to about 200 days by histological observations in humans (Gougeon, 1996). This timing agrees roughly with the average duration of 4.5 months needed for the restoration of ovarian activity after orthotopic transplantation of frozen–thawed ovarian tissue (Donnez *et al.*, 2013). More than 80% of this duration corresponds to the first part of folliculogenesis, named basal folliculogenesis, during which the number of granulosa cells doubles about 16-fold to form a 5-mm-diameter antral follicle. Terminal folliculogenesis is defined as the developmental phase strictly dependent on gonadotropin (FSH and LH) supply and corresponds to the selection, growth and final maturation of the preovulatory follicle. It covers five additional doublings of the number of granulosa cells to produce in about 14 days a 16- to 20-mm-diameter follicle able to ovulate (reviewed by Gougeon, 1996) (**Fig. 3**).

Functional Changes in Follicular Cells and Oocyte During Folliculogenesis

During basal folliculogenesis, granulosa cells have an increased mitotic activity and they synthesize gap-junction components (GJA1), cytokines (KITLG) and growth factors (EGF (epidermal growth factor), FGF (fibroblast growth factor), AMH (anti-Mullerian hormone)). FSH receptors are present on the granulosa cells from the primary follicle stage onwards, but small follicles can develop in vivo and in vitro in the absence of FSH supply (Xu *et al.*, 2011; Cadoret *et al.*, 2017; Hardy *et al.*, 2017). As they differentiate, theca cells express growth factors, LH receptors and key factors for progestagen (CYP11A1, STAR, HSD3B2) and androgen (CYP17A1) synthesis. The oocyte initiates the synthesis of growth factors, particularly GDF9 and BMP15 (both belonging to the bone morphogenetic protein family) as well as components of its zona pellucida (ZP1, 2, 3, and 4) and of gap junctions (GJA4) involved in the connections with its surrounding granulosa/cumulus cells. Concomitantly, the oocyte accumulates untranslated mRNA in ribonucleic particles.

During terminal folliculogenesis, the granulosa cells loose progressively their ability to proliferate and to produce AMH. At this stage, they become increasingly responsive to FSH, synthesize increasing amounts of inhibin and differentiate into fully steroidogenic cells expressing CYP11A1, STAR, HSD3B2 and notably CYP19A1, the aromatase enzyme catalyzing the synthesis of estradiol (E2) from the androgens produced by theca cells. The volume of the antrum increases rapidly, with the accumulation of follicular fluid formed by serum transudation and the accumulation of metabolism and secretion products from follicular cells. During terminal folliculogenesis, the concentrations of androgens, AMH and IGF binding proteins (IGFBP) decrease in the follicular fluid, while those of estradiol and inhibin increase dramatically. In the 10- to 12-mm-diameter human follicle, the granulosa cells become endowed with LH receptors, and therefore, the follicle is able to ovulate in response to an LH surge (**Fig. 4**).

When the follicle enters terminal folliculogenesis, its oocyte has reached its maximal size. During terminal folliculogenesis, the transcriptional activity of the oocyte decreases steadily and becomes undetectable in the preovulatory follicle. Meiosis resumption in the oocyte is triggered by the LH ovulatory blood surge and will terminate at fertilization. For more details, see the reviews by Monniaux et al. (1997), Hillier (2001), McGee and Hsueh (2000), Hennet and Combelles (2012), Fragouli *et al.* (2014), and Dewailly *et al.* (2016).

Hormonal and Molecular Control of Folliculogenesis

Ovarian Factors and Signaling Pathways Controlling the Different Phases of Folliculogenesis

It is now well established that basal folliculogenesis is controlled by paracrine factors involved in the dialogue existing between the oocyte and its surrounding granulosa cells, whereas terminal folliculogenesis is highly dependent on the pituitary gonadotropins

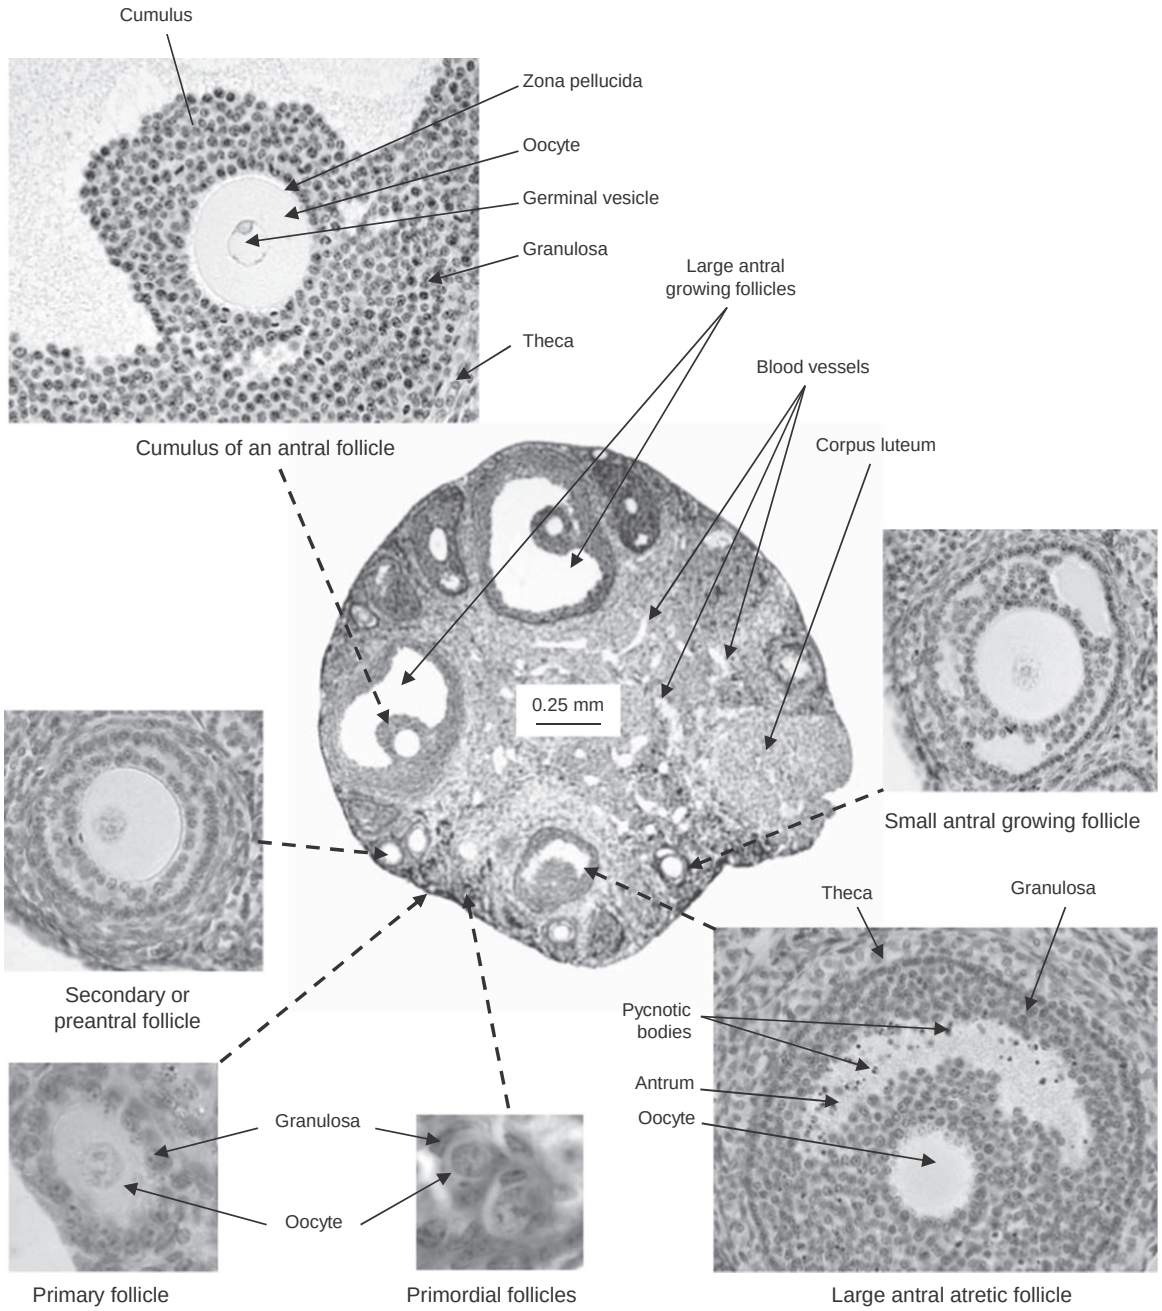

Fig. 2 Histological section of a mouse ovary and morphology of the main stages of ovarian follicles. Adapted from Monniaux, D., Dalbies-Tran, R., Fabre, S., Gérard, N., Monget, P. and Clément, F. (2014). Le développement folliculaire ovarien et l'ovulation. In Saint-Dizier, M. and Chastant-Maillard, S. (Eds.) *La reproduction animale et humaine*, pp. 41–56. Versailles, France: Quae, with permission.

FSH and LH (reviewed by Scaramuzzi *et al.*, 2011). However, the mechanisms triggering the activation of primordial follicles and the relative importance of the numerous ovarian factors able to enhance or modulate follicular development have remained misunderstood until recently. During the last decades, the role of factors specific to the ovarian function has been deciphered, thanks to the generation of transgenic mice using gene knockout, knock-in, targeted deletion or overexpression strategies (reviewed by Edson *et al.*, 2009; Matzuk and Burns, 2012). These genetic models have allowed one to identify the main factors controlling the transitions between follicular stages and involved in follicular activation, growth and maturation (**Fig. 5**A). All these factors are potential candidates for identifying mutations associated with premature ovarian failure or polycystic ovarian syndrome in women. Interestingly, most of them belong to three families of signaling pathways, the phosphatidylinositol 3 kinase (PI3K)/AKT, the SMAD and the gonadotropin signaling networks, depicted in **Fig. 5**B. As it will be detailed below, these pathways are,

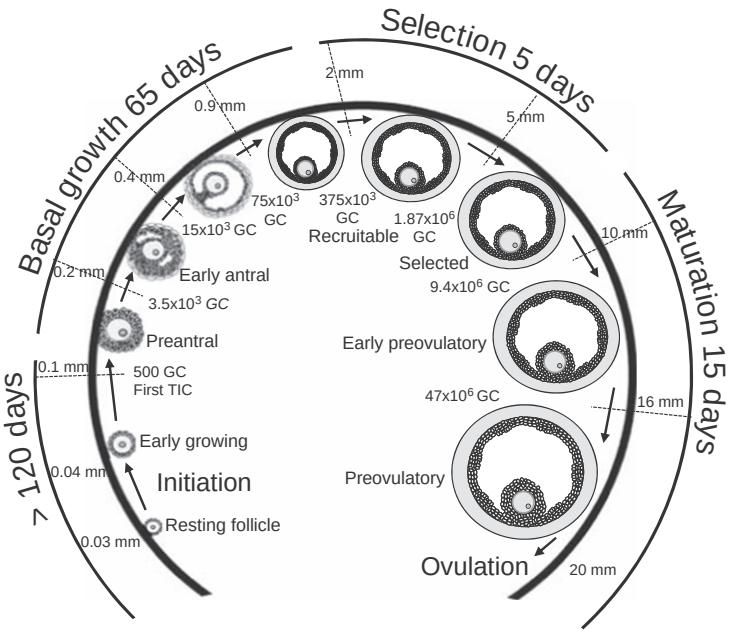

Fig. 3 Morphological and cellular trajectory of an ovulatory follicle in humans. *TIC*, theca/interstitial cells; *GC*, granulosa cells. From Gougeon, A. (1996). Regulation of ovarian follicular development in primates: facts and hypotheses. *Endocrine Reviews* **17**, 121–155, with permission. From our current knowledge, the durations of the selection and maturation phases are more likely about 8 and 12 days, respectively.

respectively, involved in: (1) the activation of primordial follicles and survival of growing follicles, (2) the transition from primary to secondary follicles, basal follicular growth and cumulus metabolism and (3) terminal folliculogenesis up to ovulation.

Activation of Primordial Follicles

Different transcription factors have been identified in the oocyte to maintain the quiescent state (FOXO3A, LHX8) or, on the contrary, to participate in follicular growth activation (SOHLH1, SOHLH2, NOBOX) (reviewed by Jagarlamudi and Rajkovic, 2012). Interestingly, FOXO3A and LHX8 are the effectors of the PI3K/AKT signaling pathway. The oocyte-specific invalidation of genes involved in this pathway has shown that mutations in its stimulating factors (KIT, PDPK1, RPTOR, RPS6) block follicular activation and induce the atresia of primordial follicles, whereas mutations in its inhibiting factors (PTEN, CDKN1B, TSC1, TSC2) lead to the premature and massive activation of primordial follicles in the ovaries of mutant mice (**Table 1**, in Supplemental Data).

The role of the granulosa cells in follicular activation has also been demonstrated. In primordial follicles, the invalidation of the granulosa-specific transcription factor FOXL2 is associated with the failure in the differentiation of the flattened granulosa cells, followed by oocyte death (Schmidt *et al.*, 2004; Uda *et al.*, 2004). The cuboidal granulosa cells are known to synthesize KITLG, the ligand of the KIT receptor which can trigger the activation of the PI3K/AKT pathway in the oocyte. It has been shown recently that primordial follicle activation is initiated in the flattened granulosa cells by the activation of mTORC1 signaling, which induces both the flattened-to-cuboidal-shape transition of the granulosa cells and KITLG expression, triggering in turn the oocyte awakening (Zhang *et al.*, 2014; **Fig. 6**). The protein complex mTORC1 is known to be activated in tissues by various molecules such as growth factors, nutrients, oxygen and stress- or energy-induced metabolites (reviewed by Laplante and Sabatini, 2012); these signals could reach the primordial follicles via the microvascularization of the ovarian cortex. Alternatively or synergistically, the remodeling of the ovarian cortex in the vicinity of the primordial follicles could also promote follicular activation, as suggested by the impressive effects observed on the induction of follicular growth after disruption of HIPPO signaling by ovarian fragmentation (Kawamura *et al.*, 2013).

Basal Folliculogenesis

At the primary stage, the oocyte synthesizes GDF9, which supports follicular growth to the secondary follicle stage (Dong *et al.*, 1996) through the activation of the SMAD2/3 signaling pathway in granulosa cells (**Fig. 5**B). BMP15, which acts as a cofactor of GDF9 (Peng *et al.*, 2013), drives this transition in sheep (reviewed by Otsuka *et al.*, 2011) and also likely in humans (reviewed by Persani *et al.*, 2014). GDF9 is also critical to follicular theca formation since it induces the production of Hedgehog ligands by the granulosa cells of preantral follicles. These ligands act as morphogens involved in the recruitment of progenitor cells in the ovarian cortex and their commitment to the theca cell lineage (Liu *et al.*, 2015; **Fig. 7**).

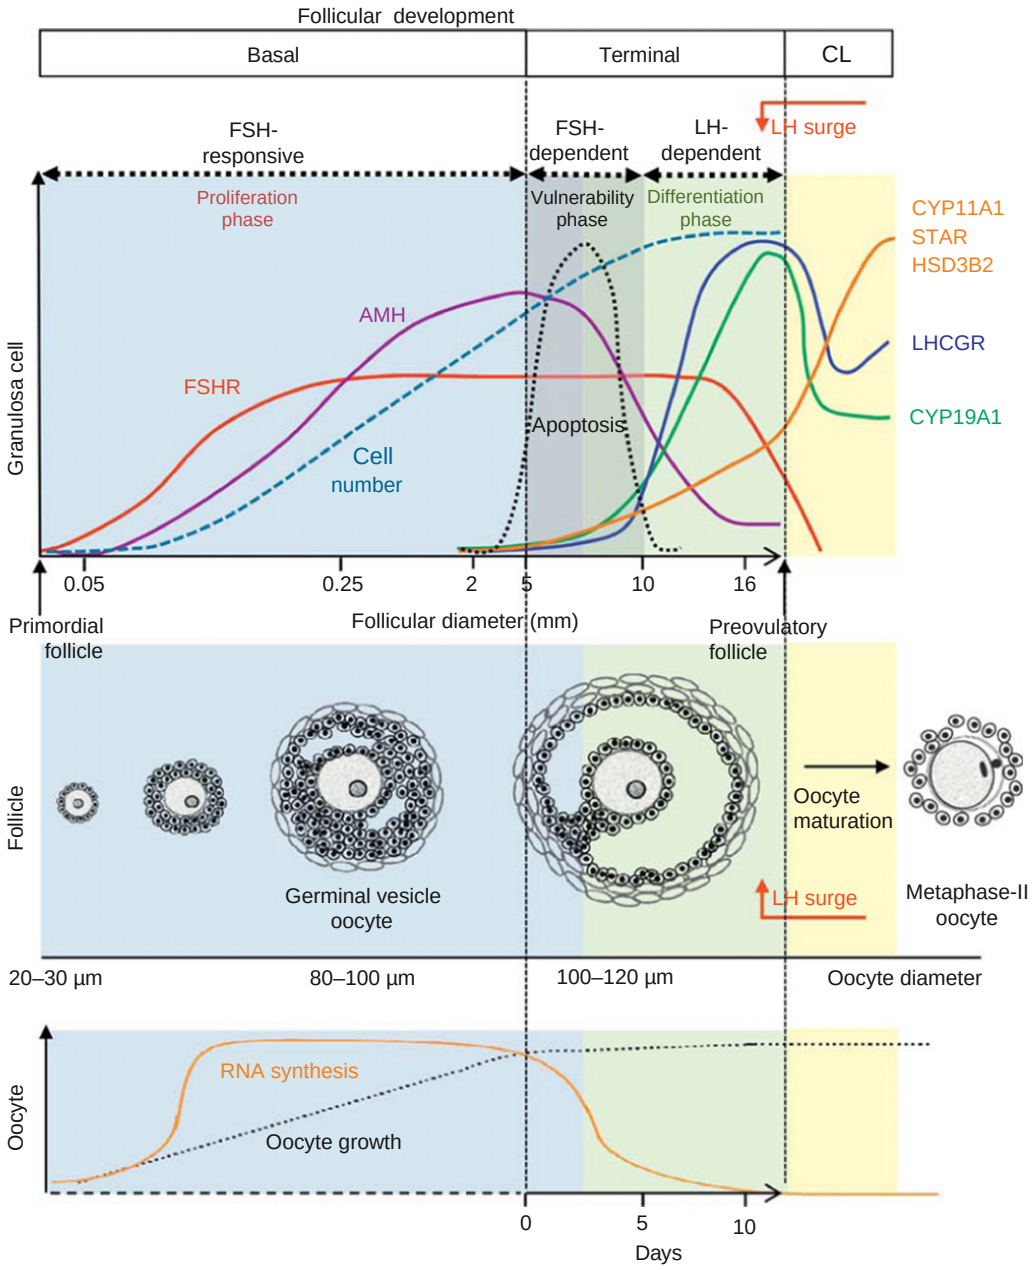

Fig. 4 Main functional changes in granulosa cells and oocyte during follicular development. FSH supply is not essential during the first phase of follicular development, named basal folliculogenesis. During this phase, the growth of FSH-responsive follicles is underlain by granulosa cell proliferation, oocyte growth, and the formation and development of theca and antrum. Terminal folliculogenesis is defined as the developmental phase strictly dependent on gonadotropin (first FSH, then LH) supply. During this phase, the antrum enlarges rapidly, the granulosa cells loose progressively their ability to proliferate and they differentiate into steroidogenic cells, while the oocyte has reached its full size and ceases its transcriptional activity gradually. The first part of this phase is a "vulnerability phase," during which the FSH-dependent follicles enter atresia (characterized by apoptosis of the granulosa cells) when FSH levels fall below a threshold. The last part of this phase corresponds to the final maturation of the LH-dependent, dominant follicle. Meiotic resumption in the oocyte and ovulation are triggered by the LH ovulatory surge. *CL*, corpus luteum. *AMH*, anti-Mullerian hormone; *CYP11A1*, cytochrome P450 family 11 subfamily A member 1; *CYP19A1*, cytochrome P450 family 19 subfamily A member 1; *FSHR*, follicle-stimulating hormone receptor; *HSD3B2*, hydroxy-delta-5-steroid dehydrogenase, 3 beta- and steroid delta-isomerase 2; *LHCGR*, luteinizing hormone/choriogonadotropin receptor; *STAR*, steroidogenic acute regulatory protein. Adapted from Monniaux, D., Dalbies-Tran, R., Fabre, S., Gérard, N., Monget, P. and Clément, F. (2014). Le développement folliculaire ovarien et l'ovulation. In Saint-Dizier, M. and Chastant-Maillard, S. (eds.) *La reproduction animale et humaine*, pp. 41–56. Versailles, France: Quae, with permission.

The balanced growth of the preantral follicle is driven by a finely tuned oocyte–granulosa cell molecular dialog. GDF9 and BMP15 produced by the oocyte activate the SMAD2/3 signaling pathway in granulosa cells and support their proliferation and survival, whereas KITLG produced by the granulosa cells activates the PI3K/AKT pathway essential for the growth and survival of

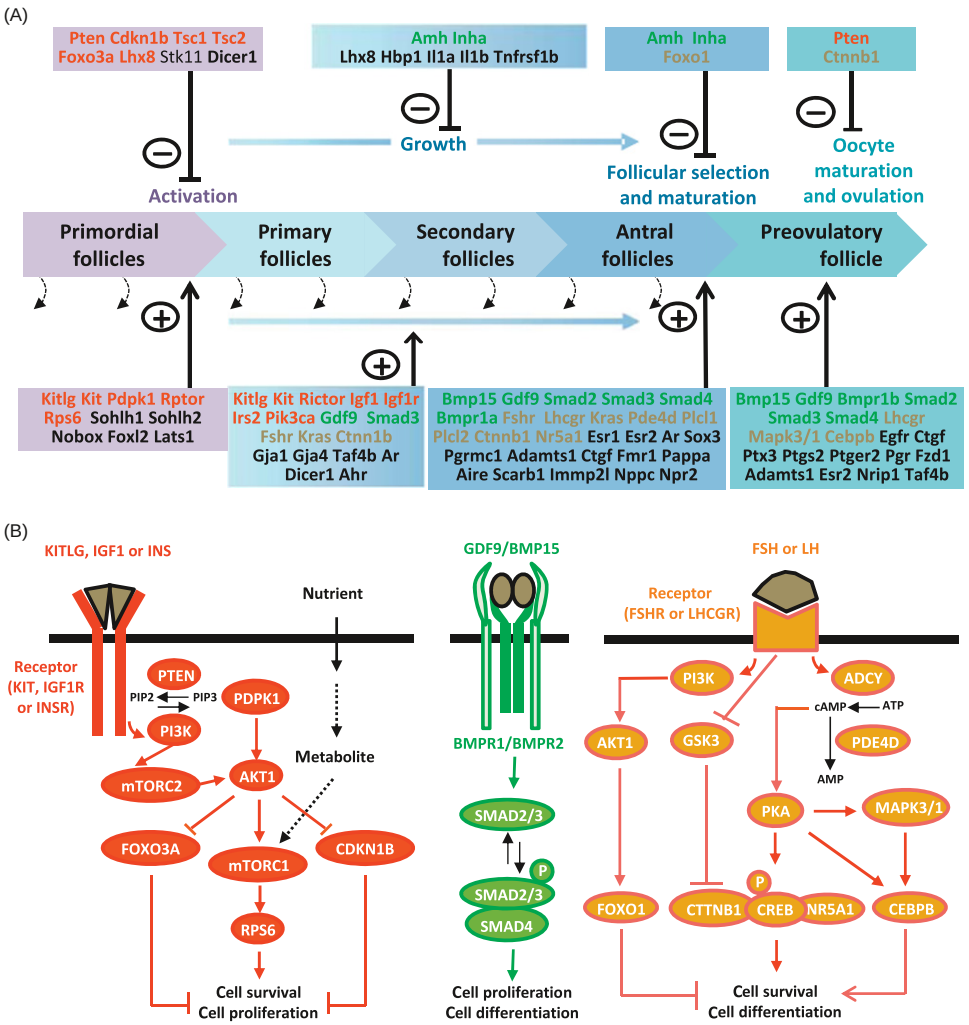

Fig. 5 Current knowledge on factors controlling folliculogenesis, according to the data available from mouse genetic models. (A) Main factors identified by in vivo transgenic approaches in mouse and their importance in controlling the transitions between the different follicular stages. (B) Schematic representation of the three main signaling pathways (PI3K/AKT, SMAD and gonadotropin signaling network) involved in the control of folliculogenesis. In both panels, factors belonging to the PI3K/AKT, SMAD and gonadotropin network are depicted in *red*, *green* and *brown* colors, respectively. In Panel A, the names of factors belonging to other signaling pathways are written in *black*. See **Tables 2–4** for gene nomenclature.

the oocyte (reviewed by Monniaux, 2016). The protein complex mTORC1 is not required for basal folliculogenesis, but a critical role of the mTORC2/AKT1/FOXO3A prosurvival signaling cascade has been recently demonstrated (Chen *et al.*, 2015; **Fig. 5**B). Moreover, the presence of functional gap junctions between the oocyte and granulosa cells (made up of GJA4, also known as connexin 37) and between granulosa cells themselves (made up of GJA1, also known as connexin 43) has been shown to maintain the follicle in a functionally integral state that is essential for its development (Carabatsos *et al.*, 2000; Ackert *et al.*, 2001).

The newly formed theca cells contribute to the regulation of basal folliculogenesis through the synthesis of androgens and growth factors (BMP4, BMP7, NGF (nerve growth factor), FGF7, EGF, TGF (transforming growth factor), etc.) which enhance granulosa cell proliferation. Conversely, granulosa cells control the gene expression and secretory activity of theca through the secretion of growth factors and cytokines, particularly KITLG (reviewed by Hutt *et al.*, 2006) as well as the development of its vascularization through the secretion of angiogenic factors (vascular endothelial growth factors, reviewed by Fraser, 2006) (**Fig. 7**).

FSH supply is not essential for the growth of small follicles up to the large preantral stage in mouse or the small antral follicle (about 5 mm in diameter) stage in humans. However, FSH enhances granulosa cell survival and proliferation and participates in antrum formation by stimulating the synthesis of osmotically active molecules (versican, hyaluronic acid) (Russell *et al.*, 2003). During basal folliculogenesis, the sensitivity of the growing follicle to FSH increases progressively, as various factors (IGF1 (insulin-like growth factor 1), insulin, androgens, aryl hydrocarbon, etc.) induce FSH receptors and/or amplify FSH action on granulosa cells (**Table 2**, in Supplemental Data). Among the factors inhibiting basal folliculogenesis, some inflammatory cytokines (IL1A, IL1B, TNF (tumor necrosis factor)) are known to modulate FSH sensitivity and induce follicular atresia (Greenfeld *et al.*, 2007; Uri-Belapolsky *et al.*, 2014). AMH inhibits both the growth of the small follicles from their activation onwards (Durlinger

et al., 1999) and the sensitivity to FSH of the large preantral and antral follicles (reviewed by Visser and Themmen, 2014). However, some of the AMH effects do not counteract the advance of development, since AMH has been recently shown to prevent follicular atresia (Hayes *et al.*, 2016).

Terminal Folliculogenesis and Ovulation

Terminal folliculogenesis is strictly dependent on the gonadotropins FSH and LH, which act, respectively, upon the granulosa and theca cells, in synergy with various ovarian and endocrine factors (reviewed by McGee and Hsueh, 2000; Hillier, 2001).

LH acts through specific receptors, constitutively present in thecal cells, to stimulate androgen production. These receptors mediate the short-term effects of LH by activating the STAR protein, which translocates cholesterol from the outer to the inner mitochondrial membrane where the first committed step in steroid synthesis is performed by the CYP11A1 enzyme, resulting in the production of pregnenolone (Kallen *et al.*, 1998). Through this mechanism, the pulse frequency of LH tunes the amounts of steroid hormones produced, as each pulse of LH is followed by an increase in androgens and

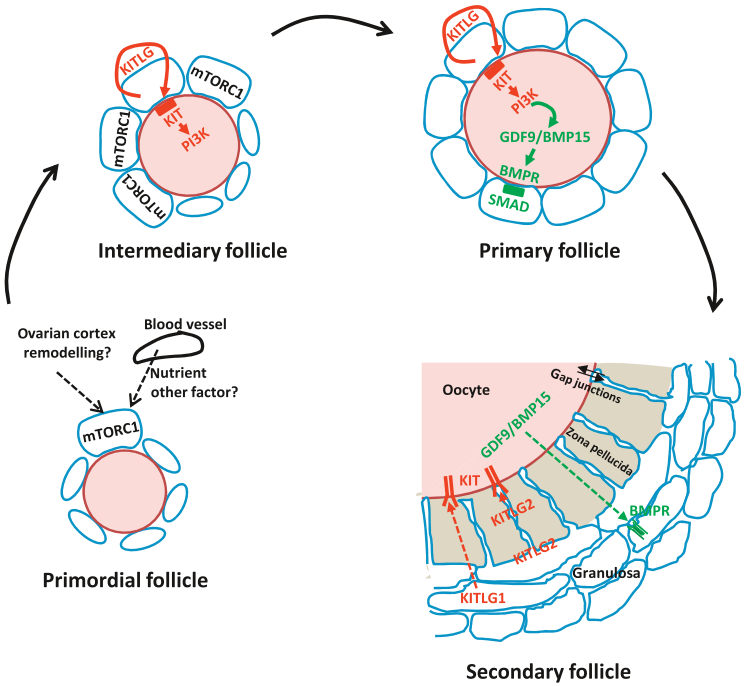

Fig. 6 The oocyte–granulosa cell molecular dialog during follicle activation and growth. The activation of primordial follicle starts with the shape change from flattened cells into cuboidal granulosa cells (through the activation of their mTORC1 protein complex) and is followed by the induction of KITLG expression in the cuboidal granulosa cells. Then, KITLG triggers the awakening of the oocyte from its quiescent state by activating the KIT receptors and PI3K signaling pathway (intermediary follicle stage). From the primary follicle stage onwards, GDF9 and BMP15 synthesized by the oocyte cooperate through SMAD signaling to sustain the proliferation, survival and differentiation of granulosa cells. Conversely, KITLG produced by the granulosa cells and acting as diffusible (KITLG1) and membrane-bound (KITLG2) isoforms can sustain the growth and survival of the oocyte. In addition, intercellular channels consisting of gap junctions located at the tips of granulosa/cumulus cell transzonal cytoplasmic projections permit molecular exchanges (ions, cAMP, cGMP, amino acids, and metabolites) with the oocyte. *BMP15*, bone morphogenetic protein 15; *BMPR*, bone morphogenetic receptor; *GDF9*, growth differentiation factor 9; *KIT*, KIT proto-oncogene receptor tyrosine kinase; *KITLG*, kit ligand; *mTORC1*, mammalian target of rapamycin complex one; *PI3K*, phosphatidylinositol 3 kinase; *SMAD*, SMAD family member.

estradiol secreted from the ovaries. Moreover, LH exerts long-term trophic effects on theca cells by enhancing the expression of factors and enzymes involved in progesterone (STAR, CYP11A1, HSD3B2) and androgen (CYP17A1) production. Insulin and locally produced intrafollicular factors such as IGF1, inhibin, or follistatin enhance the trophic effects of LH, whereas activin, TGFB and BMP exert modulating actions (reviewed by Young and McNeilly, 2010). Importantly, testosterone diffusing into the mural granulosa cell layers is the substrate for the synthesis of follicular estradiol catalyzed by FSH-induced CYP19A1 (**Fig. 8**).

FSH enhances the survival of granulosa cells and their differentiation into steroidogenic cells expressing STAR, CYP11A1, HSD3B2, and CYP19A1 and producing increasing estradiol amounts. FSH also increases the expression of many genes, in particular those encoding the inhibin/activin subunits (INHA, INHBA, INHBB), as well as the gonadotropin receptors FSHR and LHCGR. Moreover, FSH induces the production of PAPPA, a protease able to cleave specifically the IGFBP, increasing IGF intrafollicular bioavailability and thus contributing to increase the sensitivity of follicular cells to gonadotropins in the large antral follicles (reviewed by Giudice, 2001; Mazerbourg *et al.*, 2003). The final maturation of the preovulatory follicle up to ovulation is supported by LH.

Gonadotropins can activate various signaling pathways simultaneously, mainly the cAMP/PKA, PI3K/AKT, MAPK3/1 pathways, and at the same time inhibit the GSK3 pathway (**Fig. 5**B) (reviewed by Gloaguen *et al.*, 2011), which can explain their pleiotropic effects on follicular cells. Numerous factors modulate their actions at different steps of their signaling pathways, in particular through transcription factors such as ESR1 and ESR2 (for estradiol), AR (for androgens), SMAD (for BMP, AMH, activin, and other members of the TGFB family), TCF/LEF (for progesterone action mediated by its membrane receptor PGRMC1), AIRE, SOX3, etc. (**Table 3**, in Supplemental Data). Follicular survival and maturation up to ovulation are supported by a proper rate of stimulation of the gonadotropin pathways. Indeed, excessive stimulation obtained from the invalidation of genes encoding intracellular inhibitors of these pathways, such as the phosphodiesterase PDE4D or the phospholipase C-related but catalytically inactive proteins 1 and 2 (PLCL1 and 2), has led to impaired follicle development with the formation of cystic or prematurely luteinized follicles (Park *et al.*, 2003; Matsuda and Hirata, 2017).

In the large antral follicles, the BMP15/GDF9 heterodimer produced by the oocyte modulates the respective effects of FSH and LH on the differentiation of granulosa and theca cells, through the activation of the SMAD2/3 pathway (Mottershead *et al.*, 2015). In addition, BMP15 and GDF9 play a pivotal role in supporting cumulus function up to the preovulatory stage by promoting the survival and metabolism of cumulus cells (Hussein *et al.*, 2005; Sugiura *et al.*, 2007) and the expression of factors involved in cumulus integrity (PTX3), differentiation (EGFR), expansion ability (PTGS2, PTGER2), as well as in oocyte meiosis arrest (NPR2) (**Tables 3** and **4**, in Supplemental Data, and **Fig. 7**).

Before ovulation, a massive LH surge occurs, which triggers the rupture and luteinization of the wall of the preovulatory follicle, expansion of its cumulus and meiosis resumption of its cumulus-enclosed oocyte. LH activates first its receptor (LHCGR) at the surface of granulosa and theca cells. The spatial propagation of the signal to the cumulus is mediated by transactivation of the EGF network (Hsieh *et al.*, 2011) and involves the activation of the MAPK3/1 signaling pathway and CEBPB transcription factor in granulosa cells (Fan *et al.*, 2009). Ovulation is an inflammatory process induced by cytokines (interleukins, TNF) and prostaglandins (Espey, 1980) which are produced in response to LH and impact the synthesis and/or proteolytic degradation of hyaluronan binding proteins (TNFAIP6, VCAN) underlying cumulus expansion (reviewed by Richards, 2005). Concomitant with cumulus expansion, the cumulus-enclosed oocyte resumes meiosis, as a result of the partial loss of its molecular communication with the somatic cells of the follicle (Wigglesworth *et al.*, 2013). The follicular rupture and folliculo-luteal transition are dependent on the specific remodeling of the extracellular matrix, which involves various matrix metalloproteinases, plasminogen activators/plasmin and ADAMTS (reviewed by Curry and Smith, 2006). The LH-induced progesterone receptor and connective tissue growth factor participate in tissue remodeling by mediating the effects of LH on the expression of the protease ADAMTS1 (Richards *et al.*, 2005; Nagashima *et al.*, 2011). The estradiol receptor ESR2 has also been demonstrated recently to control the expression of the matrix metalloprotease MMP19 (Nalvarte *et al.*, 2016).

The Different Follicular Populations and Their Dynamics

The Dynamic Ovarian Reserve

The ovaries of the young adult contain several thousands of primordial follicles (forming the static reserve of quiescent follicles) and hundreds of growing follicles. Among the latter, a few tens of small antral follicles (with diameters between 2 and 5 mm in humans) constitute a pool of gonadotropin responsive follicles which have not yet entered terminal folliculogenesis and are the

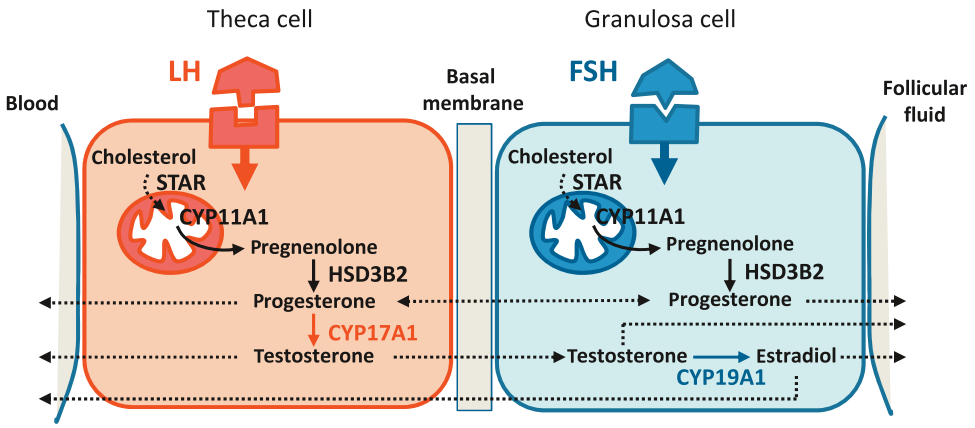

Fig. 8 The "two cell–two gonadotropin" model for steroidogenesis within the follicle during terminal folliculogenesis. *CYP11A1*, cytochrome P450 family 11 subfamily A member 1; *CYP17A1*, cytochrome P450 family 17 subfamily A member 1; *CYP19A1*, cytochrome P450 family 19 subfamily A member 1; *HSD3B2*, hydroxy-delta-5-steroid dehydrogenase, 3 beta- and steroid delta-isomerase 2; *STAR*, steroidogenic acute regulatory protein.

reserve for ovulation and ovarian biotechnologies (reviewed by Monniaux *et al.*, 2014a). The small antral follicles within this permanently renewed, dynamic reserve are the main contributors to AMH circulating levels (Gnoth *et al.*, 2015; Hagen *et al.*, 2015). Assessing the size of this reserve by ovarian ultrasonography (with the antral follicle count index) or by the measurement of AMH levels in blood (reviewed by La Marca *et al.*, 2010) is now a routine practice of primary importance to establish a diagnosis for infertility.

The size of the reserve of small antral follicles decreases with age, in parallel with the decline in primordial follicle numbers (Scheffer *et al.*, 1999; Depmann *et al.*, 2015), but it also appears to be highly variable between individuals of similar age (Broekmans *et al.*, 2004). In the young adult, the dynamic reserve has reached a stationary size (with exits broadly compensated for by entries), which is specific to each individual and correlated with the size of the static reserve.

The dynamic reserve is emptied by the cyclic, FSH-orchestrated entry of follicles in the follicular waves of terminal development and renewed by the continuous growth of smaller follicles (**Fig. 9**). The transition between the static and the dynamic reserves is favored by cytokines and growth factors (KITLG, GDF9, BMP15, and activin). AMH produced by the dynamic reserve exerts a negative endocrine feedback onto the pool of primordial and primary follicles. The survival and growth of the follicles belonging to the dynamic reserve are supported by stimulating factors acting in an endocrine (essentially FSH, insulin, IGF1) or a paracrine way (activin, BMP, EGF, FGF, NGF, testosterone) and modulated by paracrine factors (AMH, IGFBP) lowering the sensitivity of granulosa cells to FSH (reviewed by Monget *et al.*, 2002; Knight *et al.*, 2012; Visser and Themmen, 2014).

In the premenopause period, few aged primordial follicles persist in the static reserve; they can give rise to growing follicles, yet they contain low-quality oocytes. The dynamic reserve has a reduced size and produces low to undetectable AMH endocrine levels, which enhances follicular growth activation. The high FSH endocrine levels present during this period could be responsible for the increased occurrence of multiple ovulations.

Mechanisms of Selection of the Ovulatory Follicle

At each menstrual cycle, the 2- to 5-mm follicles present in the dynamic reserve can enter terminal development, and generally, a single follicle (named the dominant follicle) is selected for ovulation from this cohort (or wave) of growing follicles. From histologic, endocrinological and/or ultrasonographic data, different theories explaining the cohort recruitment have been proposed in humans: a continuous recruitment throughout the menstrual cycle, a single recruitment episode in the late-luteal or early-follicular phase of each cycle, or the recruitment of two or three cohorts during each cycle (reviewed by Baerwald *et al.*, 2012). Generally, the dominant follicle is selected in the mid-follicular phase of each cycle, but it may also be selected within the anovulatory cohorts preceding the ovulatory one in some women.

The emergence and growth of the cohort are triggered by relatively high blood levels of FSH. Each follicle of the cohort secretes increasing amounts of inhibin and estradiol, relative to its cell number and cell maturity level, as it gets more mature. The cumulated contributions of all growing follicles to the release of estradiol and inhibin by the ovaries lead to a drop in FSH secretion by the pituitary gland, and the follicle producing the highest hormonal outputs takes progressively the control of FSH secretion and becomes dominant. The drop in plasma FSH levels is at the source of the selection process for ovulation (reviewed by Clément and Monniaux, 2013; Monniaux *et al.*, 2016). All follicles except the dominant one(s) become atretic when FSH levels fall below the threshold needed to sustain their development. In fact, FSH levels are above this threshold only for a few days (reviewed by Smacklon and Fauser, 2000). Next, only the dominant, most mature follicle will continue its development even in the unfavorable FSH environment, thanks to an increased sensitivity to FSH and a highly developed vascularization. In addition, its granulosa cells become LH responsive before those of all other follicles in the cohort, so that the dominant follicle can benefit

Table 3 Genes involved in follicle selection and maturation, as evidenced from mouse genetic models

Gene name	*Signaling pathway*	*Genetic model*	*Ovarian phenotype and fertility*	*References*
Adamts1 (ADAM metallopeptidase with thrombospondin type 1 motif 1)	Extracellular matrix proteolysis	KO	Decreased number of antral follicles, follicle dysgenesis, subfertility	Brown *et al.* (2006)
Aire (autoimmune regulator)	TF Inflammation	KO	Follicular depletion, subfertility	Jasti *et al.* (2012)
Amh (anti-Mullerian hormone)	SMAD	KO	Enhanced FSH-stimulated follicular growth and increased atresia, accelerated follicular depletion	Durlinger *et al.* (2001), Visser *et al.* (2007)
Ar (androgen receptor)	TF Androgen	KO and cKO in granulosa	Defective folliculogenesis, enhanced atresia, POF, subfertility	Reviewed by Walters (2015)
Bmp15 (bone morphogenetic protein 15)	SMAD	KO double mutant with Gdf9 +/−	Defective cumulus cell development, abnormal folliculogenesis, subfertility	Yan *et al.* (2001), Su *et al.* (2004)

from LH supply until the preovulatory stage. The large estradiol amounts secreted by the preovulatory follicle impact the secretion of GNRH1 from the hypothalamus and ultimately trigger the GNRH1 ovulatory surge. As a result, the pituitary LH surge occurs and brings about ovulation.

Nutrition and Folliculogenesis

Nutritional changes affecting the energy balance or specific nutrients can affect folliculogenesis and ovulation by acting on the hypothalamo-pituitary system and/or directly on the ovary. Their effects are mediated by metabolic sensors (adipokines, AMPK, PPAR, not detailed in this section, reviewed by Dupont *et al.*, 2012, Reverchon *et al.*, 2014, Vitti *et al.*, 2016).

Energy Balance and Fertility

Gametogenesis and reproduction are energetically expensive, especially in females, and are therefore sensitive to energy imbalance (reviewed by Chavarro *et al.*, 2015). Chronic malnutrition induced by starvation (during wars, food insecurity or due to anorexia) reduces the secretion of hypothalamic GNRH1 and leads to anovulation and an endocrine status similar to that of the prepubertal stage (reviewed by Fontana and Della Torre, 2016; Chavarro *et al.*, 2015). Although the primary effect is hypothalamic, direct ovarian effects of hypoglycemia are not excluded (Chen *et al.*, 1992). Young girls or women exposed to high energy exertion (ballet, competitive sport programs, strenuous exercise) also show delays in puberty or amenorrhea and cycle irregularities, through similar mechanisms as in malnutrition conditions (Fontana and Della Torre, 2016).

On the contrary, high body mass index (BMI) is related to an earlier puberty. Overweight women also exhibit a higher frequency of anovulation, infertility, poorer oocyte quality and maturity, and negative outcomes for obese patients undergoing in vitro fertilization (IVF) (reviewed by Fontana and Della Torre, 2016; Broughton and Moley, 2017). Increased BMI is also

Adamts1 (ADAM metallopeptidase with thrombospondin type 1 motif 1)	Extracellular matrix proteolysis	KO	Abnormal morphogenesis of the ovulating follicle, abnormal cumulus matrix remodeling, decreased ovulation rate, subfertility	Brown *et al.* (2010)
Bmp15 (bone morphogenetic protein 15)	SMAD	Bmp15 −/− Gdf9 +/−	Defective cumulus cell development, impaired cumulus integrity and expansion, subfertility or sterility	Yan *et al.* (2001), Su *et al.* (2004)
Bmpr1b (bone morphogenetic protein receptor type 1B)	SMAD	KO	Failure of cumulus expansion, sterility	Yi *et al.* (2001)
Cebpb (CCAAT/enhancer binding protein beta)	TF Gonadotropin	cKO in granulosa (preovulatory follicles)	Impaired ovulation and luteinization, subfertility	Fan *et al.* (2009), Fan *et al.* (2011)
Ctgf (connective tissue growth factor)	Extracellular matrix protein	cKO in granulosa (preovulatory follicles)	Impaired ovulatory process, subfertility	Nagashima *et al.* (2011)
Ctnnb1 (catenin beta 1)	WNT Gonadotropin	cKI in granulosa (activating mutation)	Impaired oocyte maturation, cumulus expansion and ovulation, subfertility	Fan *et al.* (2010)
Egfr (epidermal growth factor receptor)	MAPK1/3	cKO in granulosa (preovulatory follicles)	Impaired oocyte maturation, cumulus expansion and ovulation, subfertility	Hsieh *et al.* (2011)
Esr2 (estrogen receptor 2)	TF Estrogen	KO	Impaired ovulatory process, subfertility	Nalvarte *et al.* (2016)
Fzd1 (frizzled class receptor 1)	WNT	KO	Impaired oocyte maturation and cumulus cell differentiation, subfertility	Lapointe *et al.* (2012)
Lhcgr (luteinizing hormone/choriogonadotropin receptor)	Gonadotropin	KO	Absence of preovulatory follicles and ovulation, sterility	Pakarainen *et al.* (2005)
Mapk3/1 (mitogen-activated protein kinase 3/1)	Gonadotropin	Double cKO in granulosa (pre-ovulatory follicles)	Impaired ovulation and luteinization, subfertility	Fan *et al.* (2009)
Nrip1 (nuclear receptor interacting protein 1)	TF	KO	Failure of cumulus expansion and ovulation, luteinized unruptured follicle syndrome, sterility	White *et al.* (2000), Nautiyal *et al.* (2010)
Pgr (progesterone receptor)	TF Progesterone	KO	Failure of ovulation, sterility	Robker *et al.* (2000), reviewed by Richards (2005)
Pten (phosphatase and tensin homolog)	PI3K/AKT	cKO in granulosa (preovulatory follicles)	Enhanced granulosa cell survival, increased ovulation rate, increased life span of luteal cells, fertility	Fan *et al.* (2008a)
Ptger2 (prostaglandin E receptor 2)	Prostaglandin	KO	Abortive expansion of the cumulus, reduced ovulation, subfertility	Hizaki *et al.* (1999)
Ptgs2 (prostaglandin-endoperoxide synthase 2)	Prostaglandin	KO	Failure of cumulus expansion and ovulation, sterility	Davis *et al.* (1999), reviewed by Richards (2005)
Ptx3 (pentraxin 3)	Inflammation	KO	Defects in the integrity of the cumulus cell–oocyte complex, subfertility	Varani *et al.* (2002)
Smad2/3 (SMAD family member 2/3)	SMAD	Double cKO in granulosa	Impaired cumulus expansion, subfertility	Li *et al.* (2008)
Smad4(SMAD family member 4)	SMAD	cKO in granulosa (preovulatory follicles)	Increased atresia of preovulatory follicles, ovulation defects, subfertility	Yu *et al.* (2013)
Taf4b (TATA-box binding protein associated factor 4b)	TF	KO	Abnormal cumulus, defects in oocyte maturation, sterility	Falender *et al.* (2005)

TF, transcription factor; *KO*, knockout; *cKO*, conditional KO; *cKI*, conditional knock-in.

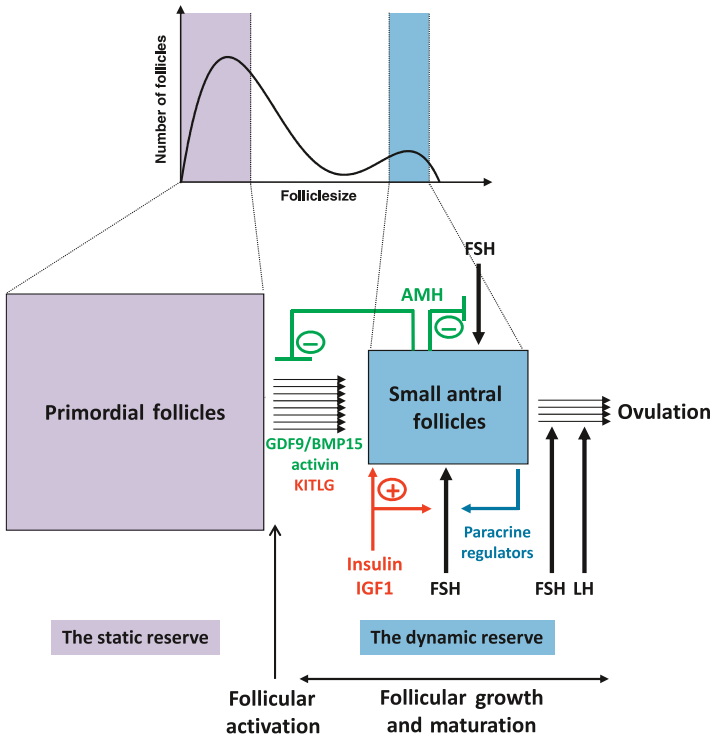

Fig. 9 The ovarian reserves of follicles and their main endocrine and paracrine regulations. The reserves are represented as boxes containing the follicle populations. The reserve of small antral follicles (dynamic reserve) is filled by growing follicles originating from the static reserve of primordial follicles and emptied by the cyclic, FSH-orchestrated entry of follicles into the follicular waves of terminal development. The quantitative distribution of follicles between the static and dynamic reserves is schematically depicted in the *upper part* of the figure. *AMH*, anti-Mullerian hormone; *BMP15*, bone morphogenetic protein 15; *GDF9*, growth differentiation factor 9; *IGF1*, insulin like growth factor 1; *KITLG*, kit ligand.

associated with quantitative alteration of endocrine factors (i.e., insulin, plasma adipokines such as leptin and adiponectin) or reproductive hormones (androgens) that negatively influence folliculogenesis and oocyte development (El-Toukhy and Osman, 2015). For example, increased insulin resistance, hyperinsulinemia or high leptin, consecutive to obesity, can adversely affect folliculogenesis and oocyte maturation by altering the expression of genes involved in meiosis and steroidogenic pathways, or the steroidogenic activity, proliferation and apoptosis rates of granulosa cells (Brannian and Hansen, 2002; Nteeba *et al.*, 2014; Lin *et al.*, 2017).

Nutrients and Folliculogenesis

Carbohydrates

Dietary glycemic load (quality/amount of carbohydrate) was shown to be related to anovulation (Chavarro *et al.*, 2015). In the gonads, glucose is essential for maintaining the quality of oocytes and regulating meiotic maturation (Dupont *et al.*, 2014). Glucose availability in follicular cells is regulated by the glucose transporter system and by glucose transfer between cumulus cells and oocyte through gap junctions (Dupont *et al.*, 2014). In sheep, a higher level of glucose increases the number of small antral (1–2 mm) follicles by a direct action (without altering insulin signaling pathways), while the effect of glucose in estrogenic follicles (reduction in aromatase level in follicular cells and reduction in estradiol level in follicular fluid) is mediated by insulin (Scaramuzzi *et al.*, 2015). Nevertheless, pyruvate is the main energy substrate oxidized in follicles, where both glycolysis and mitochondrial pyruvate oxidation occur, and pyruvate is needed to meet oocyte energetic requirement for the resumption of meiosis (reviewed by Collado-Fernandez *et al.*, 2012).

Amino acids and proteins

Despite their roles as substrates (for proteins, signaling molecules, nucleotides, energy, etc.), little is known on the effect of amino acids on folliculogenesis, contrary to their effects on ovulation or embryo development (reviewed by Collado-Fernandez *et al.*, 2012). A specific system of leucine transport has been reported in the mouse ovarian follicles during folliculogenesis (Chand and Legge, 2011). The oocyte amino acid transport and composition are related to its maturation stage and its ability to cleave once fertilized (reviewed by Collado-Fernandez *et al.*, 2012). In cow, glycine and alanine from follicular fluid were even suggested as predictors of cumulus–oocyte complex quality (Sinclair *et al.*, 2008). Finally, amino acid depletion impairs mTORC signaling and consequently disturbs folliculogenesis (reviewed by Dupont *et al.*, 2014).

Lipids

More and more data point out the role of lipids in female fertility. Indeed, lipid metabolism and in particular fatty acid β-oxidation in cumulus cells are essential for oocyte maturation depending on the species (mouse oocytes would be less sensitive to fatty acid β-oxidation impairment than swine oocyte, with an intermediate position for human) (Paczkowski *et al.*, 2013; Dunning *et al.*, 2014). A high level of fatty acids (as observed in obese patients) will lead to lipotoxicity and prevent the oocyte from maturing. Cumulus cells indeed incorporate lipids from follicular fluid and store them in lipid droplets to protect the oocyte from lipotoxicity (reviewed by Fontana and Della Torre, 2016). Dietary fat supply in bovine, especially with polyunsaturated fatty acids, has been used to improve female fertility, folliculogenesis and oocyte quality (evidenced on blastocyst transition rates after IVF) (reviewed by Leroy *et al.*, 2014).

Human Menstrual Cycle☆

Sophie Christin-Maitre, Hospital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, Paris, France and Sorbonne University, Medical University, Paris, France

Glossary

Corpus luteum The structure formed from the ovarian follicle after ovulation that is primarily responsible for progesterone production.

Estradiol The principal estrogenic hormone secreted by the developing ovarian follicle in response to follicle-stimulating hormone; necessary for proliferation of the endometrium.

follicle The functional unit of the ovary; consists of an oocyte and surrounding granulosa and theca cells.

Follicle-stimulating hormone (FSH) A glycoprotein hormone secreted in a pulsatile fashion by the anterior pituitary that is responsible for selecting a dominant ovarian follicle and stimulating ovarian steroidogenesis, particularly estrogen production from granulosa cells.

Follicular phase Beginning with the first day of menstruation, the phase of the ovarian cycle that correlates with the process of dominant follicle selection from the pool of immature oocytes and culminates in the process of ovulation.

Gonadotropin-releasing hormone (GnRH) A peptide hormone released in a pulsatile fashion from the medial–basal hypothalamus that stimulates the release of luteinizing hormone and follicle-stimulating hormone from the anterior pituitary.

Luteal phase The phase of the ovarian cycle that begins at ovulation and corresponds in timing to its functional production of the hormone progesterone from the corpus luteum.

Luteinizing hormone (LH) A glycoprotein hormone secreted in a pulsatile fashion by the anterior pituitary that is responsible for stimulating ovarian steroidogenesis and promoting ovulation.

Progesterone The predominant hormone produced by the corpus luteum in response to pituitary luteinizing hormone; responsible for secretory transformation of the endometrium in anticipation of embryo implantation.

Proliferative phase The phase in the endometrial cycle during which the glands of the endometrium undergo active growth and maturation in response to estradiol; corresponds temporally to the follicular phase of the ovarian cycle.

Secretory phase The phase in the endometrial cycle during which large secretory glands important to embryo implantation develop within the endometrium; corresponds temporally to the luteal phase of the ovarian cycle.

The presence of a menstrual cycle implies many interactions among the brain, the ovaries and the uterus. A menstrual cycle is defined as the interval between two episodes of menses. Its normal duration in humans is between 26 and 32 days. The first phase of the cycle is called the follicular phase or proliferative phase, the second phase, occurring after ovulation, is called the luteal phase or secretory phase (Chabbert Buffet *et al.*, 1998). The duration of the luteal phase is rather constant, around 14 days. The occurrence of the first menstrual cycle is called menarche. Its mean age of arrival is 12.5 years. The mean delay between breast development and the first menses is 2 years.

Hypothalamus and the Gonadotropin Releasing Hormone (GnRH)

The menstrual cycle is under the control of GnRH. This hormone is a decapeptide, secreted by neurons located in the arcuate nucleus of the hypothalamus. Those neurons need to migrate during fetal life, from the olfactory bulb to the hypothalamus. Failure of such migration to the arcuate nucleus results in Kallmann syndrome (Dodé and Hardelin, 2010). This congenital syndrome, commonly associates hypogonadotropic hypogonadism and anosmia, a failure in the sense of smell. Clinically, these patients present with absent puberty and primary amenorrhea. In the past 20 years, many genes involved in GnRH migration and/or GnRH secretion have been identified in patients with congenital hypogonadotropic hypogonadism. Some of the most important factors are Kiss1 receptor (Kiss1R) or GPR54, as well as its ligand, the protein Kiss. Studies have demonstrated that hypothalamic neurons secreting Kiss peptide are located upstream of GnRH neurons. Kiss neurons secrete the protein Kiss which binds to its receptors located on the membrane of the GnRH neurons (Gahete *et al.*, 2016). Therefore, they are able to regulate GnRH secretion. A subpopulation of Kiss neurons are called KNDY neurons as they release not only Kiss peptide (K) but also neurokinin (N) and dynorphin (DY). Kiss neurons are major players of the gonadotroph axis as they are able to integrate estradiol and progesterone feedbacks, as well as messages issued from fat tissue. This point is illustrated by the fact that a minimal weight is necessary in a child in order to induce puberty and therefore GnRH pulsatility. Factors released by fat tissue, such as leptin, are involved in Kiss peptide secretion and therefore GnRH secretion.

☆*Change History*: May 2018. Sophie Christin-Maitre has updated the article. This article has been totally transformed.

This article is an update of Lee Caperton and Robert Brzyski, Menstrual Cycle: An Integrative View, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 238–241.

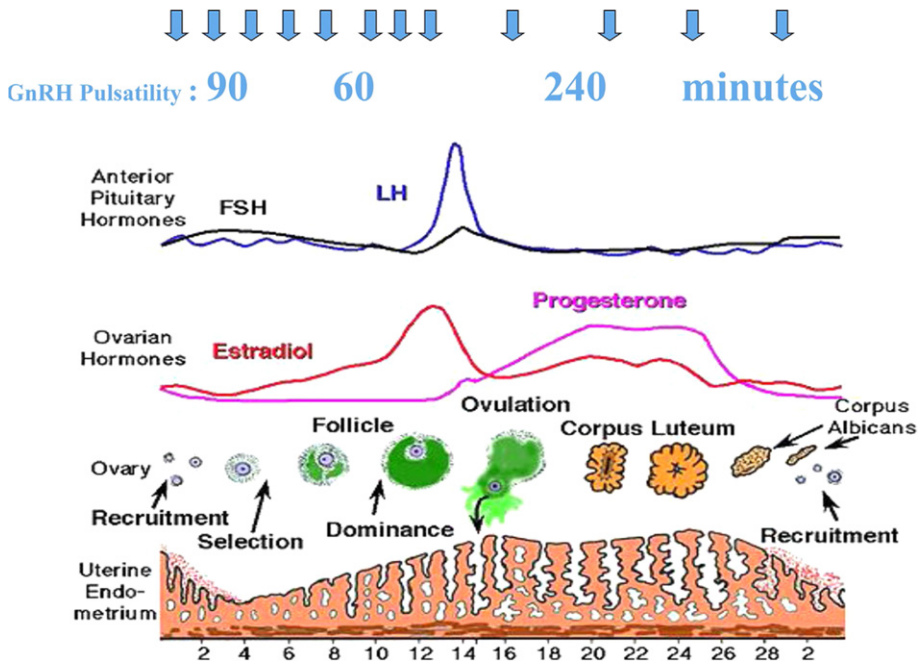

Fig. 1 GnRH pulsatility from the hypothalamus ranges from 90 min during the first phase of the follicular phase, to 60 min at the end of the follicular phase and 240 min during the luteal phase. FSH and LH are secreted by the pituitary and stimulate follicular growth and ovulation. At the beginning of the menstrual cycle, among the cohort of follicles, several are going to be recruited, selected and only one is going to become the dominant follicle. The endometrium proliferates under the effect of estradiol during the follicular phase. During the luteal phase, progesterone induces endometrium differenciation and therefore the window of implantation. In the absence of pregnancy, a decrease of estradiol and progesterone occur and menses are initiated. Reprinted from Reed, B. G., Carr, B. R. The Normal Menstrual Cycle and the Control of Ovulation. In: De Groot, L. J., Chrousos, G., Dungan, K., Feingold, K. R., Grossman, A., Hershman, J. M., Koch, C., Korbonits, M., McLachlan, R., New, M., Purnell, J., Rebar, R., Singer, F., Vinik, A., editors. Endotext [Internet]. South Dartmouth (MA): MDText.com, Inc.; 2000–2015 May 22.

Pulsatile release of GnRH appears to be an innate characteristic of neurons in the arcuate nucleus. In vitro experiments have shown that these neurons have pulsatile activity even when isolated from their normal surrounding structures and microenvironment. In vivo experiments using portal system catheterization have shown in ewes, monkeys and mice, that GnRH secretion is pulsatile. This pulsatility is directly correlated with luteinizing hormone (LH) pulse frequency. Therefore, in humans, the only way to evaluate GnRH secretion is to measure LH in serum every 10 min. It has been shown that in females, GnRH pulses occur every 90 min during the beginning of the follicular phase, every 60 min at the end of the follicular phase and every 240 min during the luteal phase (**Fig. 1**).

Environmental changes, such as stress, intense exercise, extremes of weight may disrupt normal hypothalamic GnRH secretion. Even a selective diet avoiding lipids may induce a hypothalamic hypogonadism. Patients with amenorrhea resulting from hypothalamic–pituitary dysfunction are usually hypoestrogenic.

The Gonadotropin (Follicle-Stimulating Hormone and Luteinizing Hormone) Release From the Pituitary

In response to the pulsatile release of GnRH from the hypothalamus, the anterior pituitary secretes and releases two hormones, called luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Abel *et al.*, 2014). GnRH binds to its receptor, located on the membrane of gonadotroph cells from the pituitary. This receptor belongs to the G protein related family. After its binding, GnRH induces a pulsatile secretion of FSH and LH. Few patients have been described in the literature with GnRH or GnRH receptor loss of function mutations. They have a lack of breast development and no menstrual cycle.

FSH and LH are each made of two subunits, a common alpha subunit and a specific beta subunit (Abel *et al.*, 2014). Those subunits are FSHβ and LHβ, respectively. Both proteins are glycosylated and are therefore called glycoproteins. Several types of gonadotropins are secreted, depending on the degree of their glycosylation. The different forms of gonadotropins are called isoforms. The mean half-lives of gonadotropins are respectively 1 and 5 h, for LH and FSH.

The predominant function of FSH is to stimulate follicular recruitment and development during the follicular phase of the cycle. By definition, the follicular phase starts on the first day of menstruation. Slight but significant increases in FSH secretion can be identified 1 or 2 days before the onset of menstruation, during the period called the luteo-follicular transition, occurring between two menstrual cycles. This FSH increment is a consequence of the decline of ovarian hormone production, especially inhibin A and estradiol, during the late luteal phase. The initial increase in FSH stimulates the development of a cohort of ovarian

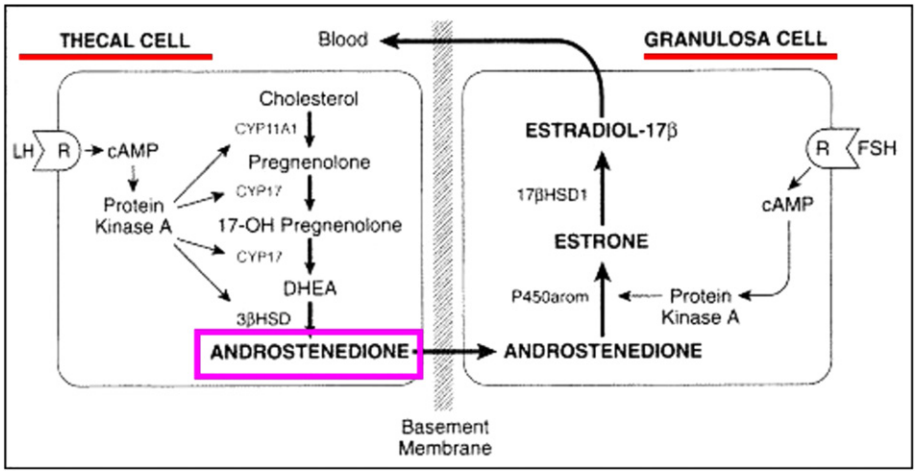

Fig. 2 The two cells- two gonadotropin theory. The two types of follicular cells are the thecal and the granulosa cells. LH binds to its receptor on the membrane of thecal cells and induce the formation of androstenedione. This androgen diffuses through the basement membrane to the granulosa cells. Within this type of cells, androstenedione is transformed to estradiol. This aromatization is under the control of FSH, after its binding on the membrane of granulosa cells. Adappted from http://www.ansci.wisc.edu/jjp1/ansci_repro/lab/lab7/lab7_2003/menstrual.html.http://www.ansci.wisc.edu/jjp1/ansci_repro/lab/lab7/lab7_2003/menstrual.html.

follicles containing immature oocytes. At the beginning of the menstrual cycle, this cohort contains an average of 5 to 10 follicles. This FSH stimulation eventually results in the selection of a single dominant follicle destined for ovulation.

Progressively increasing estradiol secretion during the second part of the follicular phase acts to inhibit FSH release prior to the mid-cycle gonadotropin surge. This negative feed-back of estradiol involves Kiss neurons. This decrease in FSH allows the dominant follicle a unique advantage over other developing follicles that will ultimately degenerate through the process of atresia. This advantage is predominantly a result of a higher density of FSH receptors, greater steroidogenic capacity, and a more profound angiogenic proliferation within the dominant follicle. This process results in mono ovulation. The rise of FSH occurring at the beginning of the follicular phase followed by its decrease during the end of the follicular phase has been called the window of FSH. It has initially described by Baird (1987). The largest is the window, the more follicles are going to be recruited. Only the follicles most sensitive to FSH are going to be able to pursue their maturation up to the dominant stage. In order to obtain a mono follicular development during ovarian stimulation induction, the biggest challenge is to mimic this FSH window and therefore to avoid ovarian hyperstimulation.

At the end of the follicular phase of the cycle, estradiol (E2) increases and exerts a positive feedback on the hypothalamus. This is a reversal of the estradiol negative feed-back to a positive feed-back. At mid-cycle, E2 serum level generally reaches around 200 pg/mL or 680 pmol/L per dominant follicle. The mean size of the dominant follicle is 20 mm in diameter. Estradiol increase promotes the stimulation of the midcycle gonadotropin surge that initiates the events resulting in ovulation of the dominant follicle. The mid-cycle LH surge is under the dependence of a GnRH surge from the hypothalamus. Although a surge in both LH and FSH occurs, LH plays the most significant role in the ensuing ovulation process.

The LH surge plays three major roles during the menstrual cycle. First, it stops granulosa cell proliferation, in the follicle. Secondly it induces granulosa cells differentiation and those cells become able to secrete progesterone. They form the corpus luteum. The third role of the LH surge is to re-initiate oocyte meiosis which has been arrested during fetal life. In summary, the LH surge is critical in regulating the production of progesterone, prostaglandins, and other local factors that contribute to follicle rupture (Richards and Pangas, 2010). The mean delay between the onset of the LH surge and ovulation is 36 h. Ovulation of the follicle occurs 10–12 h after the peak of the LH surge. In response to these conditions, the oocyte is extruded from the ovary into the fimbria of the fallopian tube. Few cases of women carrying loss of function mutation of LH receptors have illustrated the fact that LH is necessary in order to induce follicular ovulation.

Menstrual cycles are ovulatory very early after menarche. Indeed, a study performed in a large cohort of American teenagers has shown that 80% of cycles are ovulatory, as soon as after the first year after menarche (Legro *et al.*, 2000). In physiology, menstrual cycles may be irregular during the first 2 years after menarche but they should be regular after such a delay (van Hooff *et al.*, 2004).

Just after ovulation, a decrease of estradiol is observed. During the luteal phase, pulsatile LH secretion continues to promote the production of estradiol and progesterone. In case of pregnancy, hCG secreted by the placenta stimulates progesterone secretion from the corpus luteum. Progesterone secretion is essential for the induction of secretory changes within the uterine cavity. These changes are a prerequisite for proper embryo implantation.

The Follicles in the Ovary

The number of ovarian follicle is maximal during fetal life. At 20th week of gestation, the number of primordial follicles reaches around 6 million. At birth, the number of follicles is around 1 million, 500,000 at puberty and less than 1000 at menopause. The growing follicles develop from a reserve of primordial follicles constituted early in life. From this preestablished reserve, a second ovarian reserve is formed, which consists of gonadotropin-responsive small antral growing follicles and is a dynamic reserve for ovulation (Monniaux *et al.*, 2014). From this reserve of follicles, many are being recruited constantly up to the preantral stage or early antral stage. This recruitment is permanent. Cohorts of primordial follicles start growing. Primordial follicles during their maturation have to pass several stages, such as secondary, preantral, antral and finally preovulatory stages. However, more than 99.9% of follicles are not able to mature to the last stage and are submitted to apoptosis.

After puberty, FSH rises and induces a second type of recruitment occurs. It is called the cyclic recruitment of follicles. One should remember that only the last stages of folliculogenesis are FSH dependent. This has been illustrated by the rare cases of female patients carrying FSHβ or FSH receptor mutations. Those patients present a blockade in their folliculogenesis and are not able to secrete estradiol. This phenomenon is also observed in women taking combined contraceptive pills. In such cases, progestins inhibit FSH secretion and follicular growth is blocked at the early antral stage.

In the ovarian follicles, FSH receptors are expressed on the membrane of granulosa cells and LH receptors are typically expressed on the membrane of thecal cells. Furthermore, when the follicle is mature, it expresses LH receptors not only on thecal cells but also on the membrane of granulosa cells. The basis of steroid synthesis within the follicle relies on the two cells, two gonadotropins theory. The two cells are respectively granulosa cells and thecal cells. In order to synthetize steroids, the first step is the binding of LH to its receptor, localized on thecal cells (**Fig. 2**). This binding induces within thecal cells the production of androgens, originating from cholesterol metabolism. Androstenedione, the main androgen, then crosses the basal membrane separating thecal cells from granulosa cells. In the granulosa cells, androgens are aromatized to estradiol. This enzymatic transformation depends on FSH, after its binding to its receptor on the granulosa cells. The respective roles of FSH and LH in females have been illustrated in the early 90s, in studies using recombinant gonadotropins. In women with a hypogonadotropic hypogonadism, a treatment using recombinant FSH, in the absence of LH, was able to induce follicular growth. However, estradiol secretion was very low, due to the absence of endogenous LH in those patients (The European Recombinant Human LH Study Group, 1998). This study illustrated the respective roles of FSH and LH during the human cycle.

After ovulation, granulosa cells form the corpus luteum. Their main characteristic is the acquisition of 3-β-hydroxysteroid enzyme. This enzyme enables the production of progesterone. The corpus luteum appears to have a programmed life span, rapidly regressing 9–11 days following ovulation in the absence of pregnancy. Progesterone secretion by the corpus luteum exerts a negative feedback on GnRH pulsatility. This feedback involves progesterone receptors located on the membrane of hypothalamic Kiss neurons. GnRH pulses during the luteal phase occur every 240 min. This low frequency induces low levels of FSH and LH.

During early pregnancy, the conceptus produces human chorionic gonadotropin (hCG), a glycoprotein nearly identical to LH in structure and function. hCG binds to the same receptor as does LH. This sustains the steroid-producing capacity of the corpus luteum until the placenta develops sufficient steroidogenic activity.

The cessation of ovarian function, which results in menopause, is related to the depletion of ovarian follicles. This process usually occurs at approximately 51 years of age. Premature ovarian insufficiency (POI) is defined as cessation of ovarian function prior to 40 years of age. The diagnosis is established in front of a primary or a secondary amenorrhea lasting more than 4 months, with elevated FSH serum levels. FSH is higher than 25 IU/L and estradiol level is low (ESHRE POI, 2016). POI usually results from an early follicular depletion.

The Uterus and Menstruation

Distinct changes in the uterine lining are noted throughout the menstrual cycle. The proliferative phase of the menstrual cycle corresponds with the follicular phase of the ovarian cycle and is marked by estrogen-dependent proliferation of glandular structures and vasculature within the endometrium. Mitotic activity is prominent, and the endometrial lining increases in thickness as much as 10-fold.

After ovulation, the thickness of the endometrium is rather constant. Tortuosity of the vessels and secretory activity within the glands are the hallmarks of the secretory phase of the cycle. At the time of implantation of the blastocyst, marked edema can be seen within the stroma of the endometrium. Concomitantly, decidualization occurs. The decidua is derived from the stromal cells of the endometrium and is rich in glycogen and lipid content. This layer of cells displays the ability to produce a large number of autocrine and paracrine regulatory peptides. The decidua is integrally involved in the processes of implantation and placentation. The window of implantation occurs around day 21–23 of the cycle or 8 days after ovulation.

In the absence of pregnancy, the demise of the corpus luteum results in the withdrawal of estrogen and progesterone. This results in apoptosis of the endometrial cells and contraction of the spiral arteries nourishing the surface of the endometrium. Hemorrhage into the stroma and infiltration of the endometrium with inflammatory mediators follow. The decreases of estradiol and progesterone result in menstruation. The normal length of menstruation is from 3 to 6 days.

In conclusion, regular menstrual cycles involve a functional hypothalamus containing Kiss neurons and GnRH neurons, which secrete pulsatile GnRH. GnRH binds to its receptor located on the membrane of gonadotroph cells in the pituitary. Those cells

secrete both gonadotropins, FSH and LH. Those hormones bind respectively to granulosa and thecal cells, from the ovarian follicle. The follicle is able to secrete steroids such as estradiol and progesterone which regulate respectively endometrium growth and differentiation. Their feedback on the hypothalamus involves Kiss neurons. Disorders of menstrual cycle may involve defects at each level of the gonadotroph axis: the hypothalamus and/or the pituitary, the ovaries and/or the uterus. In order to evaluate the endogenous estradiol secretion, in front of an amenorrhea, a progestin test may be performed. It consists of giving to the patient, 10 days of progesterone or progestins. If menses occur within two weeks after stopping the progesterone or the progestin, the test is positive. This indicates that there is an endogenous secretion of estradiol. If the test is negative, and if the patient has a uterus, it means that the patient's endogenous estradiol level is too low. The second hypothesis in front of a negative progestin test is that the patient is pregnant.

Implantation☆

Lechosław T Putowski and M Nowak, Medical University of Lublin, Lublin, Poland

Glossary

Embryo Animal in the stage of development starting after the first division of fertilized oocyte; the embryo stage in humans lasts 8 weeks.

Endometrium Inner lining of mammalian uterus composed of two compartments: epithelial and stromal cells.

Human chorionic gonadotropin (hCG) A gonadotropin produced during pregnancy by the placenta; prolongs ovarian corpus luteum life span and stimulates progesterone production.

Introduction

Implantation is a process that occurs in the mammalian uterus in which the conceptus apposes, attaches itself to the maternal endometrium, and finally invades it (Fig. 1).

Apposition and Attachment

The entire implantation process can be divided into three stages—apposition, attachment, and invasion— and ends when the placenta starts to form.

Embryo during Apposition and Attachment

The fertilized oocyte, during its way through the oviduct and after several cell divisions, reaches the stage of blastocyst. On the fifth day after fertilization, the human blastocyst possesses two clearly defined groups of cells: an external single-layer group of epithelial cells attached called trophoectoderm and internally located cells gathering on one side of the blastocoelic cavity. At this stage of conceptus development, the embryo is surrounded by the zona pellucida. This envelope is degraded by lytic factors present in the uterine cavity before starting the process of implantation. Plasmin produced from plasminogen present *in utero* is probably responsible for degradation of the zona pellucida. However, the blastocyst itself seems to be also involved in the process of zona lysis. Approximately 7 days after fertilization, the human blastocyst hatches and the embryo is prepared for the next stage of implantation, that is, attaching to the endometrial epithelial cells. Cellular adhesion molecules expressed on the endometrial epithelium are responsible for contact of the hatched blastocysts. At this point, the human trophoblast starts to differentiate into two layers: inner cytotrophoblast and outer syncytiotrophoblast. The syncytiotrophoblast is responsible for human chorionic gonadotropin (hCG) production that stimulates progesterone production by the ovarian corpus luteum. In clinical practice, hCG

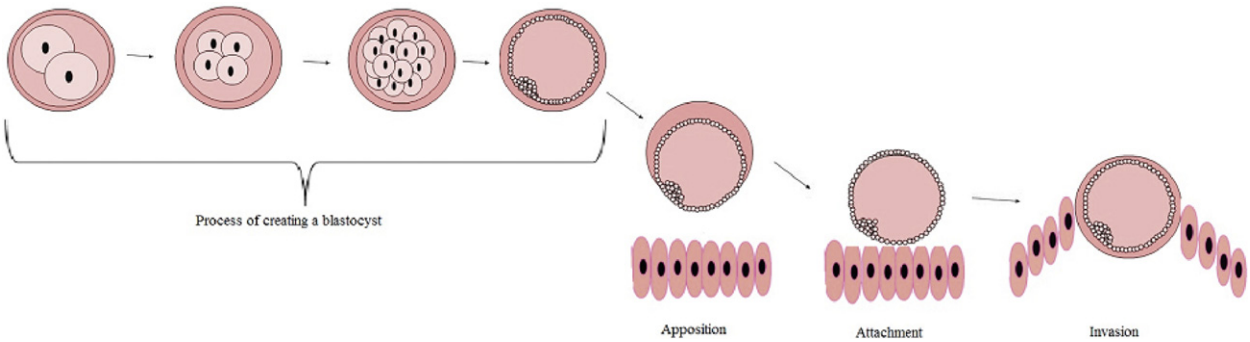

Fig. 1 Stages of blastocyst implantation.

☆*Change History:* July 2014. LT Putowski and M Nowak introduced small edits in the text of the article and Figure 1 was slightly changed.

This article is an update of Lechosław T. Putowski, Implantation, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 761–763.

 doi:10.1016/B978-0-12-801238-3.03895-2

is used as a pregnancy marker. The cross-talk between blastocyst and endometrium results in precisely tuned regulation of cytokines production and other regulatory molecular factors expression.

Endometrium During Apposition and Attachment

Blastocysts interact with the uterine epithelium that has been properly sensitized with ovarian hormones. Cyclic histological changes in the endometrium were initially described in 1950 by Noyes and colleagues. The endometrium starts to prepare for the implantation during the follicular phase of the menstrual cycle under the influence of estradiol (E_2) secreted by the ovaries. When the ovulation occurs, rising progesterone transform the endometrium into the secretory histological type. Progesterone, in cooperation with E_2, initiates decidual transformation of the endometrium, induces prostaglandin production by endometrial macrophages, and causes stromal edema and angiogenesis in the endometrium. In addition, progesterone decreases uterine irritability and contractivity and, together with hCG, suppresses immunological response that prevents embryo rejection by the maternal immunological system.

During embryo implantation, the uterine endometrium undergoes morphological and physiological changes to host conceptus. The restricted period of time when the endometrium is receptive for the conceptus is called the 'implantation window.' The embryo being transferred to the uterus at an inappropriate time is not able to implant. In the normal human menstrual cycle lasting 28 days, the implantation window lasts between 19 and 24 days of the cycle. One of the earliest indexes for transmission of embryonic signals to the endometrium that surrounds the blastocysts is capillary permeability and local stromal edema. This leads to the changes in the endometrium termed 'decidualization.' During this process, endometrial stromal cells transform into large decidual cells that are rich in glycogen.

Attachment of the embryo to the endometrium is facilitated by the specific cell adhesion structures and molecules located on the apical epithelial plasma membrane.

Pinopodes

A characteristic feature for the status of endometrial receptivity is formation of the pinopodes. Pinopodes, a large cytoplasmatic projection located on the apical surface of endometrial epithelium, are associated with changes in cell membrane morphology during the implantation window opening. Progesterone is responsible for the formation of these structures. Pinopodes are involved in facilitating adhesion of the blastocyst to the endometrial epithelium.

Trophinin/Tastin

Trophinin, together with its adhesion molecule tastin (trophinin-assisting protein), is additional protein responsible for trophoblast cell adhesion to the endometrial epithelium. Tastin is located in the endometrial cell membrane. The cytoplasmatic domain of trophinin is bound to the cytoskeleton. The presence of highly concentrated areas of trophinin 'patches' is believed to be adhesion sites for the embryo. The trophinin is expressed exclusively when the implantation window is opened.

Mucin: MUC1

MUC1 is an integral membrane glycoprotein. MUC1 has high molecular weight, a highly glycosylated extracellular domain, and a relatively short domain associated with the cytoskeleton. The endometrial expression of MUC1 is menstrual cycle dependent. It is believed that MUC1 prevents adhesion of the embryo to endometrial epithelium adhesion and that only healthy blastocysts are able to decrease MUC1 expression leading to the contact of the cells. In addition to the endometrium, MUC1 is expressed in blastocyst during the preimplantation period.

Integrins

Cell-to-cell adhesion seems to be a crucial process in the course of implantation. Integrins are transmembrane glycoproteins responsible for this process. They are members of an immunoglobulin superfamily. Integrins are composed of two units: α and β. Between several types of integrins, heterodimers $\alpha_4\beta_3$ and $\alpha_v\beta_1$ seem to play an important role in the implantation. Integrin α_4 and integrin β_3 coexpress in the apical secretive endometrium when the implantation window is opened. For this reason, integrin β_3 is proposed to be a marker of uterine receptivity. Integrins are believed to be receptors for extracellular matrix components: fibronectin, collagen, and laminin. A sequence most often recognized by integrins is the peptide sequence arginine-glycine-aspartic acid (RGD) and this is also the sequence that fibronectin, gluten and laminin most often have. Because trophoblasts express oncofetal fibronectin, the presence of integrins on apical endometrial epithelial cells may have a major role in the initial process of embryo adhesion to decidual cells. Contact of the embryo with endometrium trigger the production of proteases by trophoblasts, and this is crucial for the next step of implantation.

Cadherins

They belong to the superfamily of adhesive glycoproteins, which are involved in inter-cell interactions. Their correct process is dependent on the presence of calcium ions. E-cadherin is the most extensively studied cadherin with the function of cell to cell adhesion. It is present on the endometrial cells throughout the entire menstrual cycle, whereas during the implantation window expression significantly increase and it participates in the adhesion of the trophoblast to the maternal cells.

Invasion

Proteases degrade the endometrial extracellular matrix, helping the embryo to invade the uterine wall. Matrix metalloproteinases and urokinase-type plasminogen activator are involved in extracellular matrix proteolysis. In addition, first-trimester cytotrophoblasts express specific enzymes called gelatinases, which are responsible for matrix degradation. Enzymes are controlled indirectly by cytokines and by interaction with the extracellular matrix. Proteolytic activity of invading trophoblasts is a result of balance between matrix metalloproteinases secreted by the embryo and specific inhibitors, including tissue inhibitors of metalloproteinases originating from decidua.

Markers of Implantation

Trophoblasts and decidua produce lots of factors and their receptors affecting events associated with the process of implantation. Changes in the expression of platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), insulin-like growth factor (IGF), transforming growth factor (TGF), IL-1, IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IL-11, IL-12, colony-stimulating factor (CSF), leukemia inhibitory factor (LIF), and hemoglobin-binding epidermal growth factor (HB-EGF) were observed at the time of implantation.

However, in a successful implantation the most important role is played by the cells from the mother's immune system. The local (in endometrium) immune system of the mother must be reordered so as to protect the semi-allogeneic embryo from destruction by the maternal immune response. It is necessary to mute the inflammatory (effector) cells of the Th2 type. The most important role in this mechanism is played by the following factors:

Regulatory T-Cell (Treg)

Tregs are a subpopulation of lymphocytes having immunosuppressive properties with respect to effector cells. After fertilization, their amount in the decidual mucosa and the peripheral blood doubles. Tregs are involved in creating an immunologically privileged environment in the decidual mucosa which is the point of contact with the embryo, and they maintain the immune tolerance of the mother in relation to alloantigens derived from the father. Their presence is essential in a successful implantation process. It is believed that there are two possible mechanisms by which Tregs activate suppression processes in relation to the trophoblast. One of them is the recognition of maternal antigens on the surface of the semi-allogeneic trophoblast. The second one – the pre-exposure to paternal alloantigens (the so-called sensitization) in the seminal fluid. To maintain the immunosuppressive action, Tregs increase the secretion of several factors, the most important of these being IL-10 and TGF-b.

Helper Cells (Th1/Th2)

Th1 and Th2 are subpopulations of lymphocytes that secrete cytokine groups with different behaviours. They correspond to two types of immune response, cellular response (Th1) and humoral response (Th2). Both the implantation process and the entire pregnancy favor the Th2-type immune response. As a result, in the peri-implantation period during the luteal phase the secretion of Th-2 cytokines (IL-3, IL-4, IL-6, IL-10, and TGF-beta) is increased and the secretion of Th-1 cytokines (IL-2, IL-12, IFN-gamma, TNF-alpha) is reduced.

Uterine NK Cells (uNK)

The uNK cells occur in the endometrium, and in the luteal phase of the menstrual cycle, their amount in decidua increases significantly. The uNK in the decidual secrete cytokines and other factors (vascular endothelial growth factor-VEGF) that are responsible for the normal growth of the trophoblast and the successful pregnancy while playing a minor role in the implantation compared to other immune system cells.

Leukemia Inhibitory Factor

LIF is a cytokine belonging to the IL-6 family which is considered crucial for the correct implantation process. The role of this cytokine in the process of implantation is confirmed by results showing that mouse lacking LIF become infertile. An increased expression of LIF and its receptor in the uterine epithelium occurs at exactly the same time when pinopodes appear on the surface of the endometrium, which confirms the necessity of the presence of LIF for the proper implantation of the blastocyst, and points to the particular role of LIF in blastocyst apposition and attachment. LIF enhances STAT3 activation (phosphorylation pathway). Studies have confirmed the importance of the proper functioning of the STAT3 pathway for blastocyst attachment and successful implantation.

Transforming Growth Factor(TGF-Beta)

In the preimplantation period, increased expression of TGF-beta in the glandular epithelium of the uterus can be observed. At the same time, TGF-beta promotes the secretion of LIF and directly takes part in the nesting of the blastocyst.

IL-1

This cytokine stimulates the production of metalloproteinases (MMP-9) by the conceptus in the preimplantation period, which increases its invasive ability. IL-1 also stimulates the production of LIF, indirectly affecting the implantation.

The process of implantation lead to the formation of placenta and is crucial for the reproduction of mammals including humans.

Steroid Hormones in Pregnancy

Total steroidogenic output during pregnancy results from interactions of the fetal, placental, and maternal compartments. The fetus and placenta lack certain steroidogenic enzymes and thus utilize maternal precursors and metabolic clearance of steroids.

Progesterone

The placenta, located between the mother and fetus, utilizes precursors from either of them to circumvent its own deficiencies in enzyme activities. Cholesterol and pregnenolone are obtained from the maternal bloodstream for progesterone (P) synthesis. P acting through a cytosolic receptor that belongs at steroid and thyroid superfamily (Lee *et al.*, 2016). There are two isoforms of P receptor (PR) A and B, both transcribed from the same gene located on chromosome 11q22-23. The two isoforms differ structurally in N-terminal domain. PR-B expression is more relevant than PR-A expression. Functionally, PR-A is necessary for optimal uterine physiology and reproduction, PR-B is important during gestation to maintain the quiescence of uterus (Mesiano *et al.*, 2011; Bahia *et al.*, 2017).

Until week 10 of gestation, maternal P largely originates from the corpus luteum. After a transition period of shared function between the 7th and 10th weeks, the placenta becomes the major source of P and the maternal serum levels increase progressively up to 100–200 ng mL^{-1} at term (Chasen, 2014). Most of the P produced enters the maternal circulation. Estrogen (E) stimulates placental low-density lipoprotein (LDL) uptake and cholesterol production in the fetal liver and increases its placental conversion to pregnenolone. A small amount of human chorionic gonadotropin (hCG) must be present for P production. The decidua and fetal membranes also synthesize and metabolize P, utilizing pregnenolone sulfate as the precursor.

Amniotic fluid P is maximal between weeks 10 and 20 and then decreases gradually. Myometrial levels are three times higher than maternal plasma levels in early pregnancy and gradually equalize with serum levels toward term. Two active metabolites of P, 5α-reduced P and 5α-pregnane-3,20-dione, increase significantly during pregnancy and contribute to maternal resistance to angiotensin II.

P, acting through PR-A and PR-B, regulates the development and function of the endometrium and induces changes in cells (decidualization) essential for implantation and the establishment and maintenance of pregnancy (Gellersen and Brosens, 2014). Because implantation occurs 5–6 days after ovulation and hCG must appear by the 10th day to rescue the corpus luteum, the blastocyst must successfully implant and secrete hCG within a narrow window of time. Although E levels begin to increase at 4–5 weeks due to placental secretion, P production by the placenta does not significantly increase until approximately 10–11 weeks after ovulation. During pregnancy, progesterone via the PRs promotes myometrial relaxation and cervical closure (Pabona *et al.*, 2015). Withdrawal of PR-mediated progesterone signaling triggers menstruation and parturition. At term of pregnancy, the ratio of PR-A to PR-B in myometrium increases. Specifically, the withdrawal of PR-B follows an activation of E receptor (ER) leading to an inflammatory response by expression of cytokine/chemokine, whereas the mechanism that leads to increase of PR-A is totally unclear (Bahia *et al.*, 2017).

In the fetus, P serves as the substrate for adrenal production of glucocorticoids and mineralocorticoids. Cortisol synthesis also relies in part on LDL-cholesterol obtained in the fetal circulation or synthesized in the fetal liver. The fetus lacks significant activity of the 3β-hydroxysteroid dehydrogenase, Δ4–5 isomerase system. Thus, the fetus takes up P from the placenta to synthesize corticosteroids. At the same time, the fetus supplies what the placenta lacks, that is, the 19'carbon compounds that serve as precursors for E.

There is an emerging interest in the P metabolite and neuro-steroid allopregnanolone (Brunton *et al.*, 2014). Allopregnanolone is produced in increasing amounts during pregnancy both in the periphery and in the maternal and fetal brain. Allopregnanolone protects the fetus from exposure to harmful levels of maternal glucocorticoids, released during pregnancy as a result of stress events. Furthermore, allopregnanolone prevents premature secretion of oxytocin and minimize the risk of premature delivery. Allopregnanolone also plays a key role in the fetal brain, where it promotes development and is neuroprotective.

Finally, even if still matter of research, another point of interest is the role of P in the regulation of immune response of the mother. In fact, the P plays a role in induction and maintenance of tolerance in T-cells toward the semi-allogenic fetal antigens (Areia *et al.*, 2015; Li *et al.*, 2016).

 doi:10.1016/B978-0-12-801238-3.03913-1

Estrogens

E production in pregnancy is under the control of the fetus and is a fundamental signaling tool. E influences P production, uteroplacental blood flow, mammary gland development, fetal adrenal gland function, and has antiinflammatory effects. The precursors of E are 19-carbon androgens. Due to the virtual absence of 17α-hydroxylation and 17,20-desmolase activity in the placenta, 21-carbon steroids (P and pregnenolone) cannot be converted to 19-carbon steroids [androstenedione and dehydroepiandrosterone (DHEA)]. Thus, in early pregnancy, androgens are derived from the mother and later the fetus becomes the major source.

The fetus rapidly conjugates steroids with sulfate, protecting itself from the effects of high steroid levels. The placenta is extremely efficient in cleaving these sulfate conjugates. The fetal adrenal provides dehydroepiandrosterone sulfate (DHEAS) as precursor for placental production of estrone (E1) and estradiol (E2). The placenta, which lacks 16α-hydroxylation ability, also uses 16α-DHEAS produced in the fetal liver as precursor for estriol (E3), but 90% of E3 production results from fetal adrenal DHEAS production. E3 is the E produced in greatest quantity during pregnancy, whereas E1 and E2 are derived equally from fetal and maternal precursors.

E1 in the maternal plasma rises from 6 to 10 weeks and reaches 2–30 ng mL^{-1} at term. E2 rises from 6 to 8 weeks and reaches 6–40 ng mL^{-1} at term. During pregnancy, E1 and E2 excretion is increased approximately 100-fold compared to nonpregnant levels, whereas E3 excretion increases 1000-fold. The maternal level of E2 is higher than in the fetus, whereas the level of E3 is lower.

The maternal cardiovascular adaptations to pregnancy are also regulated by Es. Blood volume is increased by E stimulation of the maternal and trophoblastic renin–angiotensin systems and uteroplacental blood flow is influenced by the vasodilator effects of E (Heidari *et al.*, 2017). Placental aromatization is so efficient that no androgens from the maternal side reach the fetus, protecting it from masculinization. The Es presented to the maternal bloodstream are rapidly metabolized by the maternal liver prior to excretion into the maternal urine. Only approximately 8%–10% of the maternal blood E3 is unconjugated.

E, as well as P, are essential for the implantation process and for the regulation of immune system of the mother. In murine models the ablation of corpus luteum, such as the administration of only P, does not permit the implantation of blastocyst, whereas the implantation process is possible only with the synchronous administration of P and E in the same animal models. In addition, E induce and maintain the immune-tolerance toward semi-allogenic fetal antigens both in the innate immune response and in the adaptative immune response playing a role in the balance of Th2/Th1 response in favor of Th2 response and a prevalent Th2 immune response is useful in the maintenance of physiological pregnancy (Muzzio *et al.*, 2014; Areia *et al.*, 2015).

Vitamin D

Vitamin D are a group of steroid hormones, which play a pivotal role in enhancing intestinal absorption of calcium, phosphate, iron, magnesium, and zinc. In humans, vitamin D is mainly synthesized in the skin from 7-dehydrocholesterol (provitamin D3), which on exposure to sunlight [ultraviolet B (290–315 nm)], is isomerized into cholecalciferol (vitamin D3) (Zhou *et al.*, 2017). A small proportion of vitamin D in humans originates from dietary sources that is, fish, meat, milk, eggs, and from vegetables [ergocalciferol (vitamin D2)]. The liver enzyme, 25-hydroxylase, converts both vitamin D3 and D2 into 25-hydroxyvitamin D3 and 25-hydroxyvitamin D2, respectively. These then enter the circulation, and almost all binds to vitamin D binding protein (VDBP), which in turn is taken up by the epithelial cells of the proximal tubules of the kidney and converted to the active hormonal form of vitamin D—di-hydroxy-vitamin D [1,25(OH)2D or calcitriol]—by the action of the mitochondrial enzyme 1-α-hydroxylase. Interestingly, by the end of the first trimester of pregnancy, 1,25(OH)2D levels are more than double what they are during the nonpregnant state without parallel alterations in circulating calcium concentrations (Aghajafari *et al.*, 2013). Furthermore, during pregnancy, the placenta is the most important site for extra-renal activation of vitamin D. However, the clinical role played by placenta as site of activation of vitamin D is little. In fact, the changes in calcitriol concentration are not significant in anephric women during pregnancy (De-Regil *et al.*, 2016).

Vitamin D acts through the interaction with a nuclear receptor called vitamin D receptor (VDR). VDR is presents in many tissues and belongs to the super-family of steroid receptors. It is transcribed from a gene located on chromosome 12q12-14 and has a large promoter region that can generate several tissue-specific isoforms of VDR.

Vitamin D is a crucial hormone in the maintenance of metabolic, cardiovascular, musculoskeletal, nervous, and immune health. In pregnancy, vitamin D impacts upon both maternal and fetal health, including fetal skeletal development, tooth enamel formation, and general fetal growth and development (Wagner *et al.*, 2012). Deficiency in vitamin D is associated with an increased risk of fetal miscarriage, preeclampsia, gestational diabetes and, preterm birth (Zhang *et al.*, 2018; von Websky *et al.*, 2018). In fact, vitamin D improves the trophoblast invasion enhancing the epithelial mesenchymal transition of extravillous trophoblast via specific signaling pathways (such as ERK pathways) (Kim *et al.*, 2017; Ganguly *et al.*, 2018). Vitamin D seems also modulates the proliferation and differentiation of preadipocytes during pregnancy influencing the methylation of several genes, and its deficiency could influence not only the birth weight, and the risk of intrauterine growth restriction (IUGR) fetus and small for gestational age (SGA) babies, but also the offspring obesity (Nguyen *et al.*, 2018; Santamaria *et al.*, 2018). Finally, recent experimental and clinical data seem to demonstrate that vitamin D deficiency can be the link between complicated pregnancy and

infertility and/or polycystic ovary syndrome (PCOS) (Wen *et al.*, 2018). However, the effects of vitamin D during pregnancy are extremely variable due to the influence of polymorphisms with particular regard for placental VDR (Colonese *et al.*, 2015).

The Fetal Adrenal Cortex

By gestational weeks 8–9, the fetal adrenal cortex is differentiated into a thick inner fetal zone and a thin definitive outer zone, the forerunner of the adult cortex (Mesiano and Jaffe, 1997). By the end of the first trimester, the gland reaches a size equal to or larger than that of the adjacent kidney. After the 20th to the 24th week, the adrenal glands slowly decrease in size until a second growth spurt at approximately 34–35 weeks. After delivery, the fetal zone (~80% of the bulk of the gland) rapidly involutes to be replaced by simultaneous expansion of the adult adrenal cortex. Experimental data suggest that the decline in fetal reticular zone DHEAS production and cortisol to DHEAS ratio is modulated by E2 (Pepe *et al.*, 2016).

The expression and the isomerase activity of 3β-hydroxysteroid dehydrogenase are low in the fetal adrenal and therefore DHEA and DHEAS are its major products. Fetal DHEA and DHEAS production rises steadily, concomitant with the increase in the size of the fetal zone and increase in adrenal weight. Maternal E levels follow the increased availability of the fetal DHEAS as a precursor. Early in pregnancy, the gland grows and functions without adrenocorticotropic hormone (ACTH), perhaps in response to hCG. After 15–20 weeks, fetal ACTH is required (Pepe and Albrecht, 1995). Paradoxically, during the last 12–14 weeks of pregnancy when fetal ACTH levels are declining, the adrenal gland quadruples in size, via processes including cell proliferation and angiogenesis at the gland periphery, cellular migration, hypertrophy, and apoptosis.

Because prolactin (PRL) is the only fetal pituitary hormone to increase throughout pregnancy, paralleling changes in the size of the fetal adrenal, it was proposed as the critical tropic substance. The development and/or function of the fetal adrenal cortex may be regulated by a repertoire of molecules, including transcription factors, extracellular matrix components, locally produced growth factors (GFs), and placenta-derived corticotropin-releasing hormone (CRH), in addition to the primary regulator, fetal pituitary ACTH. However, only ACTH exerts adrenal steroidogenesis. It activates adenylate cyclase, increases LDL receptors, and increases the expression of its own receptors. These cause increased uptake of circulating LDL-cholesterol, largely derived from the fetal liver, and de novo synthesis of cholesterol in the adrenals to sustain the high rates of DHEAS and E formation. The tropic support of the fetal adrenal gland by ACTH from the fetal pituitary is protected by the placental conversion of cortisol to cortisone by 11β-hydroxysteroid dehydrogenase. In late gestation, when E levels are high, less cortisol is transferred to the fetus, fetal ACTH secretion increases, the fetal adrenal gland undergoes greater maturation, and fetal cortisol synthesis from endogenous cholesterol increases. Recent data demonstrated that IUGR/SGA fetus have a smaller adrenal gland at ultrasound suggesting a relationship between adrenal steroidogenesis and fetal growth and vice versa (Ishimoto and Jaffe, 2011).

CRH production and the size of the fetal adrenal gland are closely correlated. CRH augments fetal ACTH secretion in a positive feedback mechanism, producing adrenal growth and cortisol and DHEAS secretion. CRH may also directly stimulate DHEAS production.

Adrenal steroidogenesis is subject to autocrine and paracrine regulation by various GFss, such as inhibin A, activin A, transforming GF-α, basic fibroblast GF, insulin-like GF-I (IGF-I) and IGF-II, and kisspeptin 1. As below detailed, kisspeptin1 and its receptor are expressed in the fetal adrenal cortex from 8 week of gestation and play a role in the regulation of the fetal adrenocortical development (Mesiano *et al.*, 1997; Katugampola *et al.*, 2017). In fact, kisspeptin 1 increases DHEAS production and fetal adrenal volumes in the second trimester of pregnancy.

Polypeptide Hormones

The placental villus exterior has cytotrophoblasts (CT), separate mononuclear cells that are prominent early in pregnancy and sparse late in pregnancy, and syncytiotrophoblasts (ST), cells that form a continuous multinuclear layer on the surface. CT is the basic placental stem cell from which the ST arises by differentiation. ST is the functional cell type of the placenta. Trophoblast differentiation is influenced by hCG and several other GFs. Since the surface of the ST is in direct contact with the maternal blood, placental proteins are secreted directly and preferentially to the mother. Several hypothalamic-like peptides originate in the CT and influence the ST to secrete pituitary-like hormones. In addition, locally produced hormones, GFss, and peptides work together to regulate placental function (Petraglia *et al.*, 1996).

Hypothalamic-Like Releasing Hormones

Several isoforms of GnRH and GnRH receptor (GnRHR) are described. The hypothalamic decapeptide, GnRH-I, binds to the anterior pituitary and induces the synthesis and secretion of luteinizing hormone and follicle-stimulating hormone. It is also found in extra-hypothalamic sites. A second isoform, GnRH-II, acts both in the hypothalamus and other organ systems, including placenta, breast, endometrium, and ovary. Both GnRH-I and GnRH-II signal through a single receptor, GnRHR-I, in humans. In the early pregnancy, GnRH regulates trophoblast invasion and placentation increasing the expression of matrix metalloproteinase (Peng *et al.*, 2016). Placental gonadotropin-releasing hormone (GnRH-II) regulates placental steroidogenesis and release of

prostaglandins (PGs) as well as hCG (Sasaki and Norwitz, 2011). The placental receptors for GnRH have lower affinity than that of GnRH receptors in the pituitary, ovary, and testis. GnRH receptors are present in both CT and ST in a pattern that parallels hCG secretion, suggesting that GnRH regulates hCG secretion. GnRH release is increased by E, activin A, insulin, and PGs and inhibited by P, endogenous opiates, inhibin, and follistatin.

Recently, kisspeptin and its receptor (KISS1R, also called GPR54), have been reported to be strong stimulators of GnRH neurons and are involved in various mechanisms regulating the gonadotrope axis such as puberty induction or positive and negative feedback regulation on the gonadotrope axis by gonadal steroids. They also mediate metabolic or environmental cues on the reproductive axis. Kisspeptins are secreted by hypothalamic nuclei located in the arcuate nucleus and anteroventral periventricular nucleus. This system is complex because neurons located in the arcuate nucleus coexpress many neuromediators such as neurokinin B (NKB) and dynorphin, involved in the control of the gonadotrope axis. During pregnancy, kisspeptins seems implicated in trophoblast invasion. Recent data have demonstrated an elevation of kisspeptin 1 level, as well as an enhancement of the kisspeptin 1/KISS1R signaling, in the endometrium the day of the implantation and in the decidual tissue (Fayazi *et al.*, 2015). The decidual increase of the kisspeptin 1/KISS1R signaling is related to a reduced extravillous trophoblast migration and invasiveness, and to an increased adhesion of trophoblast cell to type I collagen (Taylor *et al.*, 2014). High placental kisspeptin concentrations are related with higher risk of preeclampsia (Matjila *et al.*, 2016). Kisspeptin 1 administration in cell model reduces matrix metalloproteinases (MMP) and vascular endothelial GF (VEGF), and increases the specific tissue inhibitors. Kisspeptins are significantly secreted by the placenta (Babwah, 2015). The stimulatory effect of E on GnRH and kisspeptin expression in the placenta and the uterus is of similar magnitude. In placenta cells, GnRH is able to stimulates GnRH itself, whereas kisspeptin did not stimulate/control GnRH neither kisspeptin itself. NKB is also directly stimulated by E2, and it stimulates the GnRH and kisspeptin expression (Oride *et al.*, 2015). Both GnRH and kisspeptin seem the effectors of E/NKB system to increase hCG mRNA expression in placenta cells. Of interest, kisspeptin expression seems to have a circadian rhythm in the placenta (de Pedro *et al.*, 2015).

CRH is produced in the trophoblast, fetal membranes, and decidua. Its production is decreased by P and increased by glucocorticoids, which are responsible for the rise in ACTH and cortisol during the last weeks of pregnancy and during labor. The progressive increase in maternal CRH levels during pregnancy is due to the secretion of intrauterine CRH into the maternal circulation. Furthermore, CRH is involved in the timing of birth by modulating signaling systems that control the contractile properties of the myometrium via prostaglandins expression and release. This effect seems to be enhanced by urocortin decrease. To this regard, it seems that CRH is one of the crucial factors determining the duration of the gestation, and the onset of labor (Thomson, 2013). CRH (and hCG, see below) are controlled by cortisol, since cortisol increases aromatase expression, and E production, in the placenta tissue via their stimulatory effect. This mechanism is particularly active toward the end of gestation. In the placenta, cortisol stimulates CRH synthesis via activation of nuclear factor kappa B (NF-κB), a component in a cellular messenger system that may also be triggered by stressors such as hypoxia and infection, indicating that intrauterine stress could bring forward childbirth and cause low birth weight infants. Recently, CRH has been found to modulate glucose transporter (GLUT) proteins in placental tissue, and therefore there may be a link between CRH levels and fetal growth.

Human Chorionic Gonadotropin

hCG is a glycoprotein $\alpha\beta$-dimer. A high content of sialic acid prolongs its half-life compared to its analogue, luteinizing hormone (LH). The α-subunit is identical in hCG, LH, follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). The biological activity is specific to the β-subunit. hCG production and secretion are stimulated by GnRH, interleukin-1β, activin, and E and inhibited by endorphins, inhibin, P, and follistatin.

Blastocyst secretion of hCG has been reported to contribute to endometrial cross-talk to enable implantation (Choi and Smitz, 2014). Endometrial expression of LH/choriogonadotropin receptor (LHCGR) increases mid-luteal phase, during a short period in which the endometrium is receptive to implantation (i.e., the implantation window); it is plausible that a blastocyst producing locally high concentrations of hCG could extend the implantation window, thereby increasing the chances for a successful pregnancy.

During early pregnancy, hCG is also believed to support implantation and placentation by modulating endometrial tissue remodeling, fostering maternal immunotolerance of fetal tissue, promoting neoangiogenesis and increasing the uterine natural killer cell population (Nwabuobi *et al.*, 2017). These functions all contribute to endometrial receptivity. hCG expressed by the blastocyst stimulates receptors on the endometrium, eliciting a variety of effects on downstream molecules, including VEGF, transforming GF-β, cytokines (i.e., leukemia inhibitory factor) and proteinases (i.e., MMP), which contribute to different aspects of endometrial receptivity. For example, hCG-mediated upregulation of VEGF is believed to promote angiogenesis, whereas stimulation of MMP-9 expression by hCG is involved in regulation of tissue remodeling.

Expression of hCG continues throughout pregnancy, with peak levels occurring at 10 weeks of gestation. hCG concentrations decrease to a nadir at 18–20 weeks and remain at that level until term. Clearance of hCG is carried out mainly by renal metabolism. As many as 20–30 isoforms of hCG can be detected during pregnancy. Hyperglycosylated hCG (hCG-H) secreted by root or extravillous CT is the predominant species early in gestation, but it is gradually surpassed in proportion by regular hCG, which is produced by fused and differentiated STs. hCG is crucial to the maintenance of pregnancy by supporting progesterone production by the corpus luteum (Braunstein, 1996). Placental production of P takes over in the later part of the first trimester, at a

time when hCG levels are in decline. Beyond its role in luteal support, hCG is believed to promote angiogenesis, thereby supporting blood flow to the placenta and nutrition for the fetus. Emerging evidence also suggests that hCG is involved in umbilical cord growth and development, synchronizing uterine growth with that of the developing fetus and relaxation of myometrial contractions. In addition, the presence of LHCGR in the brain has led to speculation that gonadotropin signaling is involved in the nausea and vomiting experienced during pregnancy. hCG stimulates steroidogenesis in the early fetal testes, so that androgen production will ensue and masculine differentiation can be accomplished. It is also possible that the function of the inner fetal zone of the adrenal cortex depends on hCG in early pregnancy. The β-hCG gene is expressed in fetal kidney and adrenal gland, suggesting that hCG may affect the development and function of these organs. Detection of LHCGR in fetal organs, including the kidney, liver, lung, pancreas and gastrointestinal tract, has led to speculation that hCG may have a further role in fetal organ growth and differentiation.

Human Placental Lactogen

Human placental lactogen (hPL) is a single-chain polypeptide of 191 amino acids. hPL is very similar to human growth hormone (GH) but has only 3% of its activity. Its lactogenic contribution in human pregnancy is uncertain. Its half-life is approximately 15 min. The hPL level in the maternal circulation is correlated with fetal and placental weight, steadily increasing until it plateaus in the last month of pregnancy (5–7 mg mL^{-1}). There is no circadian variation and only minute amounts enter the fetal circulation.

Its metabolic role is to mobilize free fatty acids from lipids (Handwerger and Freemark, 2000). Relative hypoglycemia in fasting pregnant women ("accelerated starvation") is due to the transfer of glucose to the fetus by facilitated diffusion and due to the diabetogenic effect of placental hormones (E, P, and especially hPL) causing peripheral insulin resistance and hyperinsulinism. hPL and PRL increase maternal food intake by induction of central leptin resistance and promote maternal beta-cell expansion and insulin production to defend against the development of gestational diabetes mellitus. As the fasting glucose level decreases, hPL levels rise to stimulate lipolysis and increase free fatty acids, which are an alternative fuel for the mother, sparing glucose and amino acids for the fetus. With sustained fasting, maternal serum ketone levels rise. Due to limited transport of free fatty acids across the placenta, fetal tissues then utilize these ketones, which do cross the placenta. hPL also enhances the fetal uptake of ketones and amino acids. Insulin antagonism by hPL is mediated by the increase in free fatty acid levels, which, in turn, directly interfere with insulin-directed entry of glucose into cells. With a sustained state of inadequate glucose intake, maternal ketosis may impair fetal brain development and function (Wadhwani *et al.*, 2017).

hPL, despite its lower levels in the fetus, directly affects fetal tissue metabolism, including synergistic actions with insulin, especially actions on glycogen synthesis in the liver (Newbern and Freemark, 2011). The failure of fetal growth hormone to affect fetal growth suggests that hPL may be the fetal growth hormone.

Human Chorionic Adrenocorticotropic Hormone

The rise in maternal free cortisol, cholesterol, and pregnenolone is due to secretion of placental ACTH and CRH, which are not suppressible by glucocorticoids. ACTH production in the ST is stimulated by CRH from the CT. CRH levels in maternal plasma rise in the second trimester, increasing to peak values at term. Oxytocin is a potent stimulator of CRH and ACTH placental production. A decrease in CRH-binding protein near term further increases the cortisol availability during labor and delivery.

Growth Hormone

Growth hormone (GH), growth hormone-releasing hormone (GHRH), and somatostatin GHRH and somatostatin itself are found in the placenta and somatostatin alone is present in the decidua too. Somatostatin decreases with advancing gestation. Placental GHRH and somatostatin do not contribute to maternal circulating levels. During the second half of gestation, placental GH gradually replaces pituitary GH in the maternal circulation. Placental GH is not present in fetal blood. Maternal IGF-I levels increase during pregnancy in parallel with GH. Placental GH is not regulated by placental GHRH, but responds inversely to maternal glucose levels, securing glucose availability for the fetus. It also stimulates gluconeogenesis and lipolysis in the mother.

α-Fetoprotein

α-Fetoprotein (AFP) is a glycoprotein derived mainly from fetal liver and partially from the yolk sac. It is comparable in size to albumin and may serve as a protein carrier of steroid hormones in fetal blood. AFP may also be a modulator of cell proliferation, synergizing with various GFs, and play a role in fetal organogenesis.

Peak values of AFP in the fetal blood are reached at the end of the first trimester. Thereafter, levels decrease gradually until a rapid decrease begins at 32 weeks. Maternal blood levels are much lower than fetal levels, rising until week 32 and then declining

(Mizejewski, 2004). Elevated maternal levels of AFP are associated with a variety of fetal anomalies, multiple pregnancies, and increased risk of spontaneous miscarriage, stillbirth, preterm birth, preeclampsia, neonatal death, and low birth weight. Low maternal levels of AFP are associated with trisomies 21 and 18.

Relaxin

Relaxin is a peptide hormone produced by the corpus luteum of pregnancy, and by the placenta, decidua, and chorion. It rises during the first trimester and declines in the second. It may have a role in implantation, placentation and vascularization, ripening the cervix, inhibiting uterine contractions, and relaxing the pubic symphysis (Anand-Ivell and Ivell, 2014). More recently, there is emerging evidence suggesting that the vasodilator effects of relaxin is in part responsible for the increase in glomerular filtration and renal blood flow in normal pregnancy.

Prolactin

Following ovulation, the endometrium becomes a secretory organ and remains so throughout pregnancy. It secretes renin, relaxin, and PRL. PRL production requires the combined effect of P and E plus the presence of other placental and decidual factors, including relaxin, IGF-I, and specific stimulatory and inhibitory proteins (Marano and Ben-Jonathan, 2014). PRL derived from the decidua is the source of that found in the amniotic fluid. The PRL in the fetal circulation is derived from the fetal pituitary. Beginning at 8 weeks, PRL levels rise from the normal level of 10–25 ng mL^{-1} to a peak of 200–400 ng mL^{-1} at term. There is marked maternal variability and a diurnal variation as in the nonpregnant state.

Amniotic fluid concentrations parallel maternal serum levels until week 10, rise markedly until week 20, and then decrease until delivery. PRL reduces the amnion permeability from fetus to mother and contributes to the regulation of fetal water and electrolyte balance by acting as an antidiuretic hormone (Tenorio *et al.*, 1992). The increase in maternal levels represents pituitary secretion in response to E.

PRL plays a critical role in mammary gland development during pregnancy, and milk production postdelivery (Macias and Hinck, 2012). PRL also promotes neurogenesis in both maternal and fetal brains, and more recently has been implicated in pulmonary surfactant synthesis in fetal lungs (Mendelson, 2000; Pathipati *et al.*, 2011; Yarlagadda *et al.*, 2015).

Cytokines and Growth Factors

Local placental cytokine production is believed to be important for embryonic growth and in the maternal immune response essential for the survival of the pregnancy (Rutanen, 1993). A system of communication is present between maternal decidual and fetal tissue to provide GF support for the placenta, which would include fetal hematopoiesis, a known response to colony-stimulating factor-1. Decidual interleukin (IL)-1β and placental tumor necrosis factor-α synergistically release placental interleukin-6 and secrete hCG.

Cytokines are also considered as pivotal modulators of immune tolerance at the maternal-fetal interface (Robinson and Klein, 2012). Specifically, IL-10 acts in either autocrine or paracrine manner inhibiting inflammatory signals and blocking major histocompatibility complex class II expression and costimulatory molecules (such as CD80/CD86) (Cheng and Sharma, 2015). In addition, IL-10 regulates differentiation and proliferation of several immune cells (Cheng and Sharma, 2015). IL-10 is produced by several cell of immune system but also by nonimmune cells, and its levels increase during the first and the second trimester and decrease prior to labor. Alterations in cytokines production and release are associated with adverse pregnancy complications, including preterm birth, miscarriage, IUGR, and preeclampsia.

IGF-I and IGF-II are involved in placental, fetal and postnatal growth (Gluckman 1995). IGFs do not cross the placenta. The fetus can influence maternal IGF-I levels by placental secretion of hPL. During pregnancy, IGF-binding proteins (IGFBP)-2 and-3 decrease thereby promoting the bioavailability of IGF-I in maternal tissues and enhancing nutrient transfer to the fetus. Placental IGF-I production further enhances transfer of nutrients across the placenta. On the other hand, IGFBP-1 produced in the decidua rises during pregnancy, interferes with IGF-I action, and inhibits fetal growth. Other GFs, such as epidermal-GF platelet-derived-GF, nerve-GF, fibroblast-GF, and transforming-GFs, are involved in differentiation, proliferation, and growth associated with pregnancy.

With the epidemic of obesity, there has been an increasing interest in adipose tissue secreted cytokines (adipokines) and its impact on reproductive health. Leptin, the first adipokine discovered in 1994, has been shown to be important for placentation and maternal–fetal exchange processes regulating growth and development. In later stages of a healthy pregnancy, central leptin resistance occurs to allow increased nutrient availability for the fetus (Tessier *et al.*, 2013). Fetal adiponectin promotes the expansion of adipose tissue and stimulate fetal growth. Adiponectin is the most abundantly expressed adipokine in adipose tissue. In addition, regulation of placental function by adiponectin constitutes a novel physiological mechanism by which the endocrine functions of maternal adipose tissue influence fetal growth (Aye *et al.*, 2013).

Inhibin, Activin, and Follistatin

Placental inhibin A rises in the maternal circulation and peaks at 8 weeks, and at term. Activin A produced by the placenta also increases. Activin stimulates and inhibin inhibits placental production of hCG, GnRH, and steroids (Qu and Thomas, 1995). Follistatin is an activin-binding protein expressed in the placenta, membranes, and decidua. It antagonizes the stimulatory effects of activin. Both inhibin A and B are located in the ST and the intermediate trophoblast of the placenta, during early pregnancy (inhibin A) and present throughout pregnancy (inhibin B) (Kondi-Pafiti *et al.*, 2013). The inhibins, activins, and follistatins have been implicated in the pathophysiology of pregnancy disorders such as preeclampsia and premature delivery (Shelling, 2012).

Endogenous Opiates

Fetal and maternal endogenous opiates originating from the pituitary glands are secreted in parallel with ACTH, in response to CRH, which is, in part, derived from the placenta. Endorphins, enkephalins, and dynorphins are produced also by the ST in response to CRH. They inhibit oxytocin, vasopressin, and gonadotropins and increase PRL secretion.

Beta-endorphins are endogenous-opioid substances produced by the pituitary gland and placenta. Plasma levels of beta-endorphin display a significant decrease in gestational weeks 28 and 33 compared to week 10, followed by a subsequent increase between gestational weeks 28 and 37 (Dabo *et al.*, 2010). However, no difference in levels of beta-endorphin between gestational weeks 10 and 37 can be detected (Dabo *et al.*, 2010). Low levels of beta-endorphin at the end of pregnancy are associated with need for additional pain medication beyond nitrous oxide during labor, although the causal relationship is unclear (Dabo *et al.*, 2010).

The Renin–Angiotensin System

In human pregnancy, the maternal and fetal circulating renin–angiotensin–aldosterone systems (RAAS) and various tissue renin–angiotensin systems (RAS) interact to ensure a satisfactory pregnancy outcome (Lumbers and Pringle, 2014). Tissue RASs crucially involved in normal pregnancy are the ovarian, intrauterine (placental and decidual), and the intra-renal RASs. The nonrenal RASs not only play key roles in ovulation, implantation, placentation, and development of the utero-placental and umbilico-placental circulations, but they also contribute to the activity of the circulating maternal RAAS, so influencing maternal cardiovascular and renal function. The fetus also has a circulating functional renin–angiotensin system, and this system together with its intra-renal RAS is essential for normal renal development and function.

Increased maternal renin activity is the result of an E induced increase in angiotensinogen and a compensatory response to maintain blood pressure in the presence of vasodilation. Renin cleaves angiotensinogen (AGT), to form angiotensin (ANG) I. ANG I is converted to ANG II by angiotensin-converting enzyme (ACE). Furthermore, angiotensin-converting enzyme 2 (ACE2), which has 40% homology with ACE can cleave ANG II to form ANG (1–7) or ANG I to form ANG (1–9), which can subsequently be cleaved to ANG (1–7) by ACE. ACE2 is primarily localized to endothelial cells, highly expressed in early pregnancy on the ST, and may be shed into the circulation. ANG II is the main ANG peptide; its biological actions are mediated predominantly by the angiotensin 1 receptor (AT1R). Other ANG peptides in the circulation include ANG (1–7), which is formed at the fastest rate from ANG II, ANG III, and ANG IV. ANG II also binds to the type 2 receptor, AT2R. Many actions of the ANG II/AT2R interaction oppose the actions of ANG II/AT1R. ANG II/AT1R interactions cause vasoconstriction, aldosterone synthesis, secretion, angiogenesis, and cell proliferation. Those mediated by ANG II/AT2R include vasodilatation and apoptosis. ANG (1–7) interacts with MasR, a G protein-coupled receptor, and many of its actions oppose the ANG II/AT1R effects, as do the actions of ANG IV mediated via the AT4R, also known as IRAP (insulin regulated aminopeptidase). ANG IV/IRAP-induced effects include hypertrophy, vascularization, inflammation, and vasodilation, as well as actions mediated via AT1Rs. IRAP is also known as placental oxytocinase.

Prorenin, the precursor of active renin was initially regarded as being biologically inert. However, the discovery of a prorenin receptor, (P)RR, altered this notion (Mikami *et al.*, 2017). (P)RR binds prorenin, exposing its catalytic site so that ANG I can be cleaved from AGT. The fact that (P)RR knockouts are embryo lethal suggests that (P)RR plays a pivotal role in embryonic development. A soluble form of (P)RR, s(P)RR, has also been described, and may influence the rate of formation of ANG I from AGT.

Recent data suggest a close relationship between RAS and hypertensive disorders in pregnancy and preterm birth (Bertagnolli, 2017). Specifically, the RAS seems one of the major candidates for preterm birth. Decidual RAS may play a role in inhibiting inflammation and maintaining the integrity of the fetal membranes during pregnancy. Interesting, sex-specific alterations in the intrauterine RAS could contribute to the increased risk of PTB in male babies (Pringle *et al.*, 2017). RAS alterations may occur as consequence of kidney and heart immaturity to promote adaptive responses, suggesting a dual role of this system on fetal and neonatal organogenesis. Fetal exposure to deleterious stress conditions can significantly impact on this dual RAS role, contributing to the establishment of hemodynamic and structural alterations (Tkachenko *et al.*, 2014).

Atrial Natriuretic Peptide and Corin

Atrial natriuretic peptide (ANP) is produced in the heart atrium and in the placenta. It is a potent natriuretic, diuretic, and smooth muscle-relaxant peptide that contributes to the regulation of volume and electrolyte changes associated with pregnancy and delivery (Burlingame *et al.*, 2017). Corin is a transmembrane serine protease discovered in the heart, where it converts pro-ANP to active ANP. Corin is upregulated in the decidua of the pregnant uterus, suggesting a potential role of corin in pregnancy. In mice lacking corin or ANP, high blood pressure and proteinuria were found at late gestational stages (Zhou and Wu, 2013). Histological analysis indicated delayed trophoblast invasion and impaired spiral artery remodeling in the uterus. In humans, CORIN gene mutations were identified in patients with preeclampsia. An enhanced corin signal has been detected not only in case of pre-eclampsia but also in patients with unexplained IUGR without hypertension (Miyazaki *et al.*, 2016).

Prostaglandins

Thromboxane (TXA2) is the most powerful vasoconstrictor known, whereas prostacyclin (PGI2) is a potent vasodilator. Platelets predominantly synthesize TXA2 whereas PGI2 is derived mainly from the endothelium. The endothelial production of PGI2 plays an important role in the marked vasodilation/contractility, that occurs during pregnancy, with particular regard for the decidualization process (Majed and Khalil, 2012; Broegger *et al.*, 2016).

The placenta is a major source of TXA2. The predominant effect of PGs in the fetal and maternal cardiovascular system is to maintain the ductus arteriosus, the renal, mesenteric, uterine, and placental arteries, and probably the cerebral and coronary arteries in a dilated state (Hansen *et al.*, 1999). Control of ductus arteriosus patency and closure is mediated through PGs. The arterial concentration of oxygen is the key regulator of the ductus caliber. With increasing gestational age, the ductus becomes increasingly responsive to increased oxygen. Prostaglandin E2 (PGE2) is the most important functional PG in the ductus, whereas PGI2, the major product in the main pulmonary artery, is the major factor in maintaining vasodilation in the pulmonary bed. With increasing maturation, the lung shifts to TXA2 formation. With the onset of pulmonary ventilation at birth, leading to vascular changes that deliver blood to the duct directly from the lungs, TXA2 serves as vasoconstrictor to the ductus.

Prior to parturition, fetal breathing is very shallow. Placental PGE2 may suppress breathing by acting in the fetal brain. Occlusion of the umbilical cord is rapidly followed by a loss of this PGE2 influence and the onset of air breathing.

Finally, initial experimental data seems to suggest that COX-2 expression in the decidua and the elevation of PGF2α in maternal serum is negatively regulated by vitamin D.

IGs	Imprinted genes
ICRs	Imprinting control regions
IVF	In vitro fertilization
ICSI	Intracytoplasmic sperm injection
IUGR	Intrauterine growth restriction
LBW	Low birth weight

Introduction

In mammals, the placenta is vital for gestation and fetal well-being by ensuring fetal-maternal exchange (gases, nutrients, and waste products) (Zhang *et al.*, 2008). The placenta also plays a critical role in mediating programming of the fetus for future disease (Barker and Thornburg, 2013). Modifications in placental morphology/function can predict a wide range of conditions in later life (Barker *et al.*, 2013). An increased incidence of placental anomalies has been observed in assisted reproductive technology (ART) conceptions. Notably, several human studies reviewed by Thomopoulos *et al.* (2013) found an increased risk of gestational hypertension, preeclampsia, placenta praevia, and placental abruption. These placental defects may contribute to abnormal fetal growth such as low birth weight (Jackson *et al.*, 2004) and prematurity (Jackson *et al.*, 2004; Pinborg *et al.*, 2013), which are also more frequent following ART than following natural conception (Choux *et al.*, 2015). The placenta originates from the peripheral cells of the blastocyst, the trophectoderm cells that have been directly exposed to the environmental *milieu* up to implantation. In humans, placental syncytiotrophoblasts formed by the fusion of cytotrophoblasts make up the site of exchange between the maternal and fetal circulation; this interface has specific endocrine functions, but also functions as a barrier against various stresses (oxidative, xenobiotic, and chemical) (Huang *et al.*, 2013). The finely-tuned regulation of trophoblastic invasion, essential for proper future function of the placenta and fetal development, involves molecular crosstalk between the endometrium and trophoblast tissue driven notably by epigenetic factors (Chelbi and Vaiman, 2008). Epigenetics plays an important role not only in placental development, but also in adaptation to environmental stress (Novakovic and Saffery, 2012). Because ART procedures typically coincide with epigenetic reprogramming events, they represent models of extreme exposure to periconception epigenetic stress, which could impair trophoblastic invasion and contribute to the pathophysiology of disease seen in the postnatal period.

Epigenetics is defined as a set of cell-based molecular mechanisms able to modify gene expression without DNA sequence variation. Epigenetic regulation controls DNA transcription (through DNA methylation/hydroxymethylation mechanisms) and involves the proteins around which the DNA is wrapped to constitute nucleosomes (histone posttranslational modifications) (Nelissen *et al.*, 2011). Epigenetic regulation also controls translation or mRNA stability by the expression of noncoding RNAs (such as microRNA, Piwi, Miwi, …).

Imprinted genes (IGs), representing a small percentage of all genes, are known to be involved in important biological processes to enable in utero development. IGs are preferentially expressed by one parental chromosome as a consequence of epigenetic events (DNA methylation being the most often described) in the germline. These epigenetic modifications (reprogramming) are established in a sex-specific manner during gametogenesis on regulatory sequences referred to as imprinting control regions (ICRs). After fertilization, these ICRs act in *cis* to achieve complete or partial monoallelic expression of most imprinted genes (IGs). Up to now, approximately 150 imprinted genes have been identified in mice and humans. In mice, these are under the control of 23 identified ICRs (Barbaux *et al.*, 2012; Proudhon *et al.*, 2012; Court *et al.*, 2014) (http://www.geneimprint.com/site/genes-by-species). IGs are generally not imprinted in all tissues, and the imprinted pattern can be limited to a precise developmental stage. In addition, the conservation of imprinted status or even the sex involved (i.e., whether the maternal or paternal allele is expressed for a given IG) may vary between mammalian species (Barbaux *et al.*, 2012). Interestingly, the majority of IGs identified in mice are both expressed and imprinted in the placenta (Tunster *et al.*, 2013). Current findings indicate that IGs converge on two key placental functions in placental development and the regulation of fetal growth: nutrient transport and placental signaling (Tunster *et al.*, 2013).

As discussed in this review, compelling evidence indicates the particular role of epigenetics in placental regulation and the potential link between epigenetic dysregulation and adverse pregnancy outcomes. In addition, the purpose of this review is to provide a summary of current knowledge regarding placental epigenetic regulation and consequences in children conceived after ART.

Placental Epigenetic Modifications and Adverse Pregnancy Outcomes

Disturbed placental epigenetic regulation may cause abnormal trophoblastic invasion, which may contribute to the pathophysiology of some spontaneous miscarriages, intrauterine growth restriction (IUGR), and preeclampsia (**Fig. 1**).

 doi:10.1016/B978-0-12-801238-3.64949-8

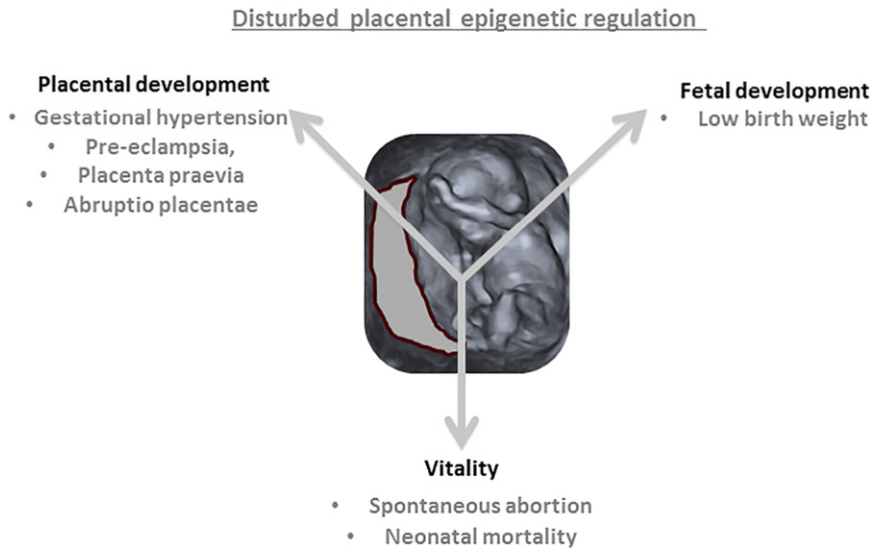

Fig. 1 Potential impact of placental epigenetic disturbance.

Miscarriages

In humans, the expression of DNA methyltransferase 1 (*DNMT1*), which is involved in DNA methylation maintenance throughout cellular divisions, and global DNA methylation were significantly lower in chorionic villi from early fetus losses than in those harvested following selective pregnancy termination (Yin *et al.*, 2012). In addition, in a large study on 165 human spontaneous abortions, aberrant DNA methylation levels were observed for some imprinted loci, suggesting that inappropriate DNA methylation status may lead to spontaneous abortions. However, the conception modes (natural vs. ART) or the fertilization methods (in vitro fertilization [IVF] vs. intracytoplasmic sperm injection [ICSI]) did not seem to affect the DNA methylation patterns of IGs (Zheng *et al.*, 2013). Earlier, in a smaller number of abortions and stillbirths, even though a significant difference was found between ART and non-ART samples for the methylation levels of *LIT1* (=*KCNQ1OT1*), no major differences were reported between ART and natural conceptions (Zechner *et al.*, 2010).

Intrauterine Growth Retardation

In humans, a large number of associations have been found between IUGR and epigenetic variations in placentas. Banister and colleagues found that the DNA methylation pattern of several loci was highly predictive of IUGR (Banister *et al.*, 2011). Some authors demonstrated that the *PHLDA2* imprinted gene was upregulated in the placenta in cases of IUGR (McMinn *et al.*, 2006; Diplas *et al.*, 2009; Kumar *et al.*, 2012) and that its expression level correlated negatively with birth weight (Apostolidou *et al.*, 2007). As *PHLDA2* is considered a negative growth regulator, the authors suggested that this IG potentially plays a direct role in the pathophysiology of IUGR.

Other imprinted genes were also upregulated (*CDKN1C*), or downregulated (*MEG3*, *GATM*, *ZAC1*, *GNAS*, *MEST*, *IGF2*) in IUGR placentas (McMinn *et al.*, 2006; Guo *et al.*, 2008; Diplas *et al.*, 2009; Koukoura *et al.*, 2011). Some of these differential expressions were associated with decreased placental methylation, as was the case for *H19/IGF2* ICR1 (Bourque *et al.*, 2010), or loss of imprinting, as was the case for *ZAC1* (=*PLAGL1*) and *H19* (Diplas *et al.*, 2009).

In addition, other examples of nonimprinted genes highlight the possibility that fetal growth potential could be negatively impacted by epigenetic dysregulation in the placenta. Ruebner and colleagues pointed out that the expression of Syncytin-1, a protein that promotes cellular fusion in the syncytiotrophoblast, was lower in human IUGR placentas than in controls (Ruebner *et al.*, 2010). The same team linked decreased expression of this protein to epigenetic hypermethylation of its promoter (Ruebner *et al.*, 2013). Additionally, another example concerns the *WNT2* gene. This gene, which is implicated in placental vascularization, exhibited decreased expression and increased DNA methylation in placentas of growth-restricted neonates as compared to controls (Ferreira *et al.*, 2011).

Interestingly, epigenetic changes were also found on repeated sequences. For example, Michels and colleagues found an increased LINE-1 methylation level in placental tissues from low birth weight infants (Michels *et al.*, 2011).

Preeclampsia

Evidence about preeclampsia reinforces the idea that epigenetic disorders may be involved in abnormal trophoblastic invasion. Besides, global DNA methylation changes were found in placentas from pregnancies with preeclampsia as compared with gestational age-matched controls (Blair *et al.*, 2013). Some of these methylation modifications correlated negatively with expression changes, especially for genes implicated in angiogenesis (*EPAS 1* and *FLT I genes*). In addition, the expression of maspin (*SERPINB5*), a serine protease

inhibitor and an inhibitor of cell migration (Khalkhali-Ellis, 2006), which may modify trophoblast cell invasion in the first trimester (Dokras *et al.*, 2002), could also be modified in preeclampsia. Additionally, SERPIN A3, a specific inhibitor of elastase, which is crucial during the implantation process, displayed decreased methylation and increased gene expression in placentas from pregnancies complicated by preeclampsia compared with controls (Chelbi *et al.*, 2007). As for IUGR, several studies highlighted the increased methylation (Ruebner *et al.*, 2013) and reduced expression of the *syncytin-1* gene, as well as the downregulation of *WNT2* in pre-eclamptic placentas. These modifications were possibly responsible for impaired placental function (Huang *et al.*, 2014). Interestingly, epigenetic modifications could also correlate with the severity of the disease (Yu *et al.*, 2009; Anton *et al.*, 2014).

Placental Epigenetic Modifications and ART Pregnancy Outcomes

Evidence from human epidemiological studies supports the hypothesis that ART could affect placentation and placental function. Indeed, an increased incidence of anomalous placentation and placental size has been observed following ART even after adjustments for length of gestation, gender, parity, and maternal age (Walker, 2000; Rinaudo and Lamb, 2008; Haavaldsen *et al.*, 2012). Indeed, two prospective studies on very large cohorts of singletons reported an almost twofold increased risk of preeclampsia following the use of in vitro fertilization (IVF) as well as a significantly higher risk of placenta praevia and abruptio placentae (Katalinic *et al.*, 2004; Kallen *et al.*, 2005). Moreover, placentas from ART pregnancies were overrepresented in the highest quartile of placenta weight (Haavaldsen *et al.*, 2012). Consequently, these placental defects may contribute to abnormal fetal growth and to low birth weight (LBW), which is also a well-described complication of ART pregnancy (Pandey *et al.*, 2012; Qin *et al.*, 2016).

These placental dysfunctions and the subsequent LBW may result from changes in epigenetic reprogramming, notably with modifications affecting IGs (Choux *et al.*, 2015).

In support of this hypothesis, it has recently been demonstrated in mice that suboptimal ART conditions could induce genomic imprinting alterations in the placenta and affect its development and function (Chen *et al.*, 2015; de Waal *et al.*, 2015).

Epigenetic Regulation Studied at Birth

In humans, several studies analyzed DNA methylation and/or gene expression in ART-conceived newborns compared with those naturally conceived. However, of these, only three studied DNA methylation (Gomes *et al.*, 2009; Rancourt *et al.*, 2012; Camprubi *et al.*, 2013) and, two DNA methylation and expression (Katari *et al.*, 2009; Turan *et al.*, 2010) of IGs in both cord blood and placenta (**Tables 1** and **2**).

Concerning the DNA methylation analysis, conflicting data were generated when the analyses were carried out on a global scale and when they focused on IGs. Indeed, for large DNA methylation analyses using arrays, one reported no variability in DNA methylation (Camprubi *et al.*, 2013) whereas another one (Katari *et al.*, 2009) described quantitative differences in global DNA methylation (briefly with a higher and a lower degree of DNA methylation in post-IVF cord blood and placenta samples, respectively) (**Tables 1** and **2**). However, the two studies are not comparable regarding the sample size (73 individuals vs. 10) and the mode of reproductive treatment (unspecified ART vs. IVF).

Moreover, as discussed above, studies focusing on the DNA methylation of specific IGs also reported conflicting results. Indeed, although some authors reported no epigenetic changes after ART (Gomes *et al.*, 2009; Shi *et al.*, 2011; Wong *et al.*, 2011; Zheng *et al.*, 2011), several authors reported variations in methylation levels in both cord blood and/or placentas for a number of IGs such as *MEST* (Tierling *et al.*, 2010; Rancourt *et al.*, 2012), *H19* (Turan *et al.*, 2010; Rancourt *et al.*, 2012; Nelissen *et al.*, 2013), *SNRPN* (Rancourt *et al.*, 2012), *GRB10* (Song *et al.*, 2015), *NDN* or for retrotransposable elements such as LINE1 (Ghosh *et al.*, 2017). However, none of them agreed on the changes in DNA methylation. Once again, comparisons between these studies are difficult given the limitations similar to those mentioned above and also given that the most of analyses were performed on different IGs or IG-sequences and that different methods were used (bisulfite pyrosequencing, methylation array, etc. …).

Concerning the analysis of IG expression, conflicting data were also found (**Table 2**). In the only two studies that analyzed both cord blood and placenta, dysregulations were reported, mainly in the placenta, but only for three IGs (*H19*, *IGF2*, *MEST*) (Katari *et al.*, 2009; Turan *et al.*, 2010; Nelissen *et al.*, 2013) (**Table 2**). Even though minimal expression changes on a few specific IGs were also found in cord blood after ART, no significant modifications in expression were observed in global analysis using microarray methodology (Feng *et al.*, 2011).

Therefore, all of these discrepancies in expression and DNA methylation results at term do not allow us to draw strong conclusions. Certainly, we still have to search for epigenetic modifications using robust methodologies that take into account potential confounding factors in a homogeneous cohort of singletons, and to determine the contribution of each reproductive technique and the role of infertility per se.

In addition, even though they are few in number, these epigenetic "defects" in ART-placentas should not be underestimated and should not simply be regarded as allelic polymorphisms. Indeed, we have to carry out more investigations to determine what they mean. They could originate from epigenetic errors at imprinted genes (de Waal *et al.*, 2014), or could correspond to epigenetic adaptation mechanisms (Choux *et al.*, 2015). Moreover, what also remains to be determined is whether epigenetic defects in the placenta are simply compensatory in nature or whether these early epigenetic modifications could be a risk factor for certain diseases later in life.

Epigenetic Regulation Studied During Childhood

Low birth weight and impaired fetal growth are assessable signs of embryonic/fetal stress, and the developmental origins of health and disease (DOHaD) hypothesis emphasizes that these features, even though within the spectrum of normal birth weight, are markers of adult disease, notably cardiometabolic defects (Bubb *et al.*, 2007; Meas *et al.*, 2010; Vrooman and Bartolomei, 2016). Currently, it is difficult to determine whether the risk of these chronic diseases in adulthood originates in the embryo as the direct

result of a suboptimal ART-environment, or instead in subsequent growth modifications, or both. Therefore, the possible existence of epigenetic defects in ART-offspring should not be underestimated. Specifically, data reported by our team and other teams show that the type of culture medium used in human reproduction may influence the birth weight of the children thus conceived (Dumoulin *et al.*, 2010; Nelissen *et al.*, 2012; Hassani *et al.*, 2013; Zandstra *et al.*, 2015) and may have an impact on their postnatal development (Bouillon *et al.*, 2016). Nevertheless, in humans, there is no evidence of epigenetic changes persisting into childhood. Indeed, in children conceived after IVF, reassuring data have been reported for DNA methylation for IGs and on a global scale (Kanber *et al.*, 2009; Oliver *et al.*, 2012; Puumala *et al.*, 2012; Whitelaw *et al.*, 2014). Only one study observed some epigenetic errors for the imprinted gene *SNRPN* during childhood (Whitelaw *et al.*, 2014). However, DNA methylation levels of this IG were not found to be modified at birth in ART-cord blood. Only one study found some DNA methylation modifications of *SNRPN* in the placenta after ART (Rancourt *et al.*, 2012).

However, the heterogeneity of biological samples, age range, type of reproductive technique and the analysis of methylation could hide potential underlying differences and confirm that more research is still needed.

Conclusion

This review highlights the relationship between epigenetic dysregulation and subsequent placental response. The dialogue between the endometrium and the embryo is a crucial step to achieve successful trophoblastic invasion and thus ensure a noncomplicated pregnancy and healthy offspring. The initially disturbed placentation may trigger compensatory mechanisms, in line with adaptive responses, through epigenetic mechanisms. The hypothesis is that if these mechanisms are overwhelmed, inappropriate maternal-fetal exchange could occur, potentially leading to abortion or adverse pregnancy outcomes (Choux *et al.*, 2015).

ART procedures or parental factors, for which a greater risk of placenta-related diseases is reported, could induce perturbations in genomic imprinting by impairing endometrial receptivity or by modifying the early steps in the epigenetic development of the embryo. However, studies that carried out DNA methylation analyses at birth found conflicting data. Nevertheless, these studies are not comparable regarding the mode of reproductive treatment (IVF vs. unspecified ART), notably. Concerning the analysis of IG expression, conflicting results at birth were also reported. Thus, we cannot be totally reassured and further evidence is required to determine whether alterations in the regulation of IGs induced by ART could exist in newborns. In addition, to better decipher the epigenetic mechanisms and to determine which factors/procedures are involved, analyses have to be performed jointly in cord blood and placenta. Moreover, it also remains to be determined whether some epigenetic feto-placental changes could have further consequences.

Endocrinology of Delivery

Silvia Vannuccini, University of Florence, Careggi University Hospital, Florence, Italy and University of Siena, Siena, Italy
Felice Petraglia, University of Florence, Careggi University Hospital, Florence, Italy

Introduction

Parturition is a coordinated process of transition from a quiescent myometrium to an active rhythmically contractile state, requiring complex interplay between placental, fetal, and maternal compartments (Vannuccini *et al.*, 2016). It involves the synchronization between coordinated myometrial activity, cervical changes, including effacement and dilatation, and rupture of membranes (Mohan *et al.*, 2004).

Labor at term may be regarded best physiologically as a release from the inhibitory effects of pregnancy on the myometrium rather than as an active process mediated by uterine stimulants. The myometrium is normally maintained in a relaxed and quiescent state until the balance between the inhibitory effect of progesterone and pro-labor stimuli, including oxytocin and inflammatory mediators, are preserved. In fact, the mechanisms for initiation of parturition involve progesterone withdrawal, increased estrogen bioavailability, corticotrophin releasing hormone (CRH) and neuroendocrine mediators and finally, increased responsiveness of the myometrium to prostaglandins (PGs) and oxytocin (OT) (Smith, 2007). While parturition in most animals results from changes in circulating hormone levels in the maternal and fetal circulations at the end of pregnancy, in human it is both an endocrine and an inflammatory event with a complex interplay between the mother and the placenta–fetal unit.

Understanding the initiation signals and sequential set of events culminating in normal labor is still challenging. The role of fetal endocrine signals functioning as the biologic clock of organ maturation and as triggers for labor at term has been well documented. However, knowledge gaps still exist in our understanding of the initiator and effecter signals of normal term labor. In fact, recent evidences are supporting the role of other mechanisms playing a major role in triggering labor and delivery, as chorio-amniotic senescence (Menon *et al.*, 2016b).

Parturition as an Endocrine Event

Estrogens

Human pregnancy is characterized by a hyperestrogenic state and the placenta is the primary source of estrogens. Concentrations of estrogens increase in the maternal circulation with increasing gestational age. Placental estrone and 17β-estradiol are derived primarily from maternal C19 androgens (testosterone and androstenedione), whereas estriol is derived almost exclusively from the fetal C19 estrogen precursor (dehydroepiandrosterone sulfate, DHEAS) (Weiss, 2000). Studies on the effect of administered androgen to pregnant rhesus monkeys have provided evidence that estrogen synthesized from androgens plays a central role in labor and delivery in monkeys (Nathanielsz *et al.*, 1998). Estrogens do not themselves cause uterine contractions but do promote a series of myometrial changes, including increasing the number of prostaglandin receptors, oxytocin receptors (OTR), and gap junctions, and upregulating the enzymes responsible for muscle contractions (myosin light chain kinase, calmodulin) that enhance the capacity of the myometrium to generate contractions. In fact, estrogen has a key role in priming myometrium for labor by inducing expression of contraction associated proteins including OTR and PG receptors in myometrium (Challis *et al.*, 2000). However, the pathway to estrogen production in the human placenta is unique as P450c17 is not induced and the direct conversion of progesterone to estrogen does not occur. Instead, the human placenta relies on DHEAS from the fetal and maternal adrenal glands for the supply of precursor for estrogen synthesis, and bypasses the step catalyzed by P450c17 (Mesiano and Jaffe, 1997). Hence there is no reciprocal fall in plasma progesterone and rise in plasma estrogen in humans and other primates. Rather both estrogen and progesterone increase progressively toward term but the ratio of estrogen/progesterone begins to favor estrogen. Upon reaching the placenta and sequential actions by sulfatase, 3β-HSD and aromatase, DHEA, and its hydroxylated product 16-hydroxy-DHEA are converted to estrogen in placental syncytiotrophoblasts. Glucocorticoids increase the conversion of DHEA to estrogen via induction of aromatase expression in human placenta (Wang *et al.*, 2012).

CRH has been shown to stimulate placental production of estrogens and to inhibit placental synthesis of progesterone (Yang *et al.*, 2006; You *et al.*, 2006). Placental CRH is also released into the fetal circulation, and in vitro CRH directly stimulates DHEAS production from the fetal zone of the fetal adrenal, that is the precursor for placental estriol (E3) synthesis. E3 is an inhibitor of the action of the potent estrogen estradiol (E2) at low concentrations but becomes an effective agonist when the ratio of E3 to E2 exceeds 10:1. Placental CRH may therefore lead to increased E3 production and reduced progesterone synthesis. Smith *et al.* showed in a cohort of 500 women at 26 weeks' gestation and during the last weeks of pregnancy that the very rapid rise of CRH in late pregnancy is associated with an E3 surge and critically altered P/E3 and E3/E2 ratios that create an estrogenic environment at the onset of labor. Thus, a critical feature of parturition appears to be a change in the ratio of the two estrogens E2 and E3 as labor approaches, leading to a more than 10-fold excess of E3 (Smith *et al.*, 2009).

Progesterone

Progesterone is a "pro-gestational" agent; it sustains the pregnant state and promotes myometrial relaxation. The balance between the inhibitory effects of progesterone and the stimulatory actions of estrogens is pivotal in determining the contractile state of the pregnancy myometrium and the timing and process of parturition (Mesiano and Welsh, 2007). In contrast to most animal species, the circulating levels of progesterone during human labor are similar to prelabor levels (Walsh *et al.*, 1984), suggesting that the systemic withdrawal of progesterone is not a prerequisite for labor in humans. However, as RU486 treatment induces labor at all stages of human pregnancy, it is generally considered that human parturition involves a form of progesterone withdrawal that does not depend on a decrease in circulating progesterone levels. The mechanisms involved in progesterone functional withdrawal are mainly related to a decreased myometrial progesterone responsiveness mediated by changes in the levels of specific nuclear progesterone receptors (nPRs) or nPR co-activator/co-repressors (Mesiano, 2007; Mesiano *et al.*, 2002, 2011). PR signaling can be regulated through two general mechanisms: changes in ligand concentration or changes in PR responsiveness. Levels of the progesterone ligand can be regulated at the systemic level through an endocrine regulation. They can also be regulated locally through the presence of metabolic enzymes in the target tissues that increase or decrease the levels of ligand available (paracrine or autocrine regulation). Progesterone signaling can also be regulated at the receptor level through changes in the relative expression of the nuclear PR isoforms, reduced expression of membrane receptors, and changes in the expression levels of coactivators and/or corepressors, including nuclear factor kB (Byrns, 2014). Functional progesterone withdrawal in human parturition is mediated by an increase in the myometrial PR-A (or PR-C)/PR-B ratio; in addition, the progesterone responsiveness is differentially regulated in fundal (by PR-C) and lower segment (by PR-A) myometrium. Most of human pregnancy, progesterone via PR-B promotes uterine quiescence, in part by inhibiting the responsiveness of myometrial cells to pro-inflammatory stimuli and preventing tissue level inflammation, and that functional progesterone withdrawal at parturition is caused by increased PR-A-mediated trans-repression of PR-B (Merlino *et al.*, 2007). As pregnancy advances, the capacity for PR-B to mediate inhibitory and antiinflammatory actions of progesterone on the pregnancy myometrium decreases due to increased repression by PR-A (Tan *et al.*, 2012). Interestingly, the amount and trans-repressive activity of PR-A in myometrial cells is increased by pro-inflammatory stimuli suggesting a causal link between inflammation and PR-A-mediated functional progesterone withdrawal (Madsen *et al.*, 2004).

The biochemical and physical changes induced by the combined effects of progesterone withdrawal and estrogen activation are (Mesiano and Welsh, 2007): (a) increased Cx43 expression leading to increased coupling between myocytes so that contractions are synchronized across the whole uterus; (b) increased sensitivity and contractile responsiveness to stimulatory uterotonins such as OT an PGF2 due respectively to increased OTR expression; (c) increased production of PGs by the gestational tissues and decreased inactivation of PGs in the myometrium; (d) lowered threshold for myocyte excitability; (e) decreased capacity for the cAMP/PK-A signaling pathway to maintain relaxation.

CRH and Neuropeptides

The complex mechanisms controlling human parturition involves mother, fetus, and placenta, and stress is a key element activating a series of physiological adaptive responses (Petraglia, 2010; Voltolini and Petraglia, 2014). The hypothalamus-–pituitary–adrenal (HPA) axis plays a key role in the neuroendocrine response to stress and CRH, a 41-amino-acid peptide hormone discovered in the 1980s, emerged as a crucial hypothalamic hormone regulator of human labor (Petraglia *et al.*, 1987). CRH is classically synthesized in the hypothalamus, but during human pregnancy, the placenta and fetal membranes produce large amounts of CRH and its related urocortin peptides, the circulating concentration of which rise exponentially in the third trimester of pregnancy (Smith, 2007; Challis *et al.*, 2000; McLean and Smith, 2001). CRH, in turn, further drives maternal and fetal HPA activation, thereby establishing a potent positive feed-forward loop. In normal pregnancy, the increased production of CRH from decidual, trophoblastic, and fetal membranes leads to an increase in circulating cortisol beginning in mid-gestation. It has been noted that the rise of maternal CRH level occurs earlier and more rapidly in women delivered preterm and more slowly in women delivered postterm, than in women delivered at term (Challis *et al.*, 2000). Because of this, CRH has been proposed to regulate a placental clock that controls a cascade of physiological events leading to parturition (McLean *et al.*, 1995). In addition, CRH stimulates fetal ACTH release, activating fetal adrenal steroidogenesis. The increased production of glucocorticoids is responsible for fetal lung maturation and on the other hand the increased DHEA and DHEAS levels creates an estrogen-dominant environment favorable to parturition.

Plasma CRH levels rise during the second half of pregnancy, peak during labor, and rapidly decline postpartum. Near term, CRH concentrations begin to exceed concentrations of the CRH-binding protein, leading to a rapid increase in circulating concentrations of bio-active CRH at term (Perkins *et al.*, 1993). CRH also enhances prostaglandin production by amniotic, chorionic, and decidual cells. Prostaglandins, in turn, stimulate CRH release from the decidual and fetal membranes.

Thus, human parturition is achieved by a series of positive-feedback hormonal loops that operate at multiple levels to drive labor forward. On one side, placental CRH promotes fetal cortisol and DHEA-S production, and these steroids return via the umbilical circulation to the placenta where cortisol promotes further CRH secretion, and DHEA-S is converted to estrogen (Yang *et al.*, 2006). CRH has also been shown to directly stimulate placental estrogen synthesis (You *et al.*, 2006) and similarly estrogen indirectly promotes further placental CRH secretion through its action on PG synthesis. On the other side, CRH increases the synthesis and release of PGE_2 and $PGF2_\alpha$ from the cells of the amnion, chorion, and decidua. These PGs, in addition to glucocorticoids derived from fetal urine, promote further CRH secretion by the placenta and fetal membranes. Besides, recent

evidences suggest that pro-inflammatory mediators may be direct and/or indirect promoters of placental CRH release. In fact, IL-6 and CRH are both secreted in a pulsatile fashion during the active phase of human labor and their time-integrated concentrations are positively correlated (Papatheodorou *et al.*, 2013).

Urocortins belong to the CRH superfamily and have recently been implicated as novel neuroendocrine mediators in physiologic and pathologic pregnancy and parturition. Human myometrium expresses urocortin 1 (Ucn) and a twofold increase of contractility is observed when Ucn is added after $PGF2_{\alpha}$ administration. Ucn activates diverse intracellular signaling pathways that contribute to the activation of myometrial contractility (Petraglia, 2010). Moreover, Ucn stimulates MMP-9 protein level in the culture medium of chorionic trophoblast, syncytiotrophoblast, and amniotic epithelial cells (Li *et al.*, 2006), suggesting a local role in tissue remodeling and cervical ripening at the time of labor.

A role for Ucn2 in the control of myometrial contractility during human pregnancy has been demonstrated, involving binding to CRH receptor 2 (CRH-R2) and enabling actin–myosin interaction and cell contraction. Ucn2 affects placental conversion of fetal adrenal C19 steroid precursors into E2 and appears to do so by increasing P450 aromatase expression via CRH-R2, thus suggesting a putative novel role for CRH family peptides in the sequence of steps involved in estrogen biosynthesis. CRH and Ucn2 participates also in the inflammatory mechanisms of parturition. In Jeg-3 cell line has been demonstrated that Ucn2 is a potent pro-inflammatory neuropeptide via NF-kB and MAPK pathways and CRH via MAPK (Novembri *et al.*, 2015). Recent experiments in laboring/nonlaboring human gestational tissues and in mouse utero-placental tissues showed that Ucn2 is a neuroendocrine factor that is upregulated at time of parturition and acts as a pro-inflammatory agent in placenta and in myometrium. The data suggest that Ucn2 has a role in mediating inflammatory processes of parturition but also has implications for Ucn2 being involved in the pathogenesis of obstetric complications (Voltolini *et al.*, 2015).

Glucocorticoids

Glucocorticoids (GC) play a pivotal role in initiation of labor and in the maturation of fetal organs in several mammalian species (Li *et al.*, 2014). GC activity depends on the 11β-hydroxysteroid dehydrogenase family (11β-HSDs), catalyzing the interconversion between "active" cortisol into inactive cortisone. The type 1 enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD1) is bi-directional but operates mostly as an oxo-reductase, facilitating the production of active cortisol (or corticosterone, murine equivalent), in a NADPH-dependent manner. The type 2 (11β-HSD2) is a NAD^+-dependent enzyme, uni-directional and inactivating cortisol to cortisone (or corticosterone to dehydrocorticosterone) (Michael *et al.*, 2003). The biochemically distinct activities of the two 11β-HSDs are present in the placenta, where the balance between the reductase activity of 11β-HSD1 and the oxidative activity of 11β-HSD2 changes at different stages of gestation. Specifically, 11β-HSD2 appears to be the major form expressed in the human placenta, suggesting a potential importance of local glucocorticoids increase in the placenta in preparation for labor (Murphy and Clifton, 2003). During pregnancy, cortisol is synthesized in the adrenal glands and placenta and plays a primary role in the maturation of fetal organs at the end of pregnancy, thus contributing to the onset of labor (Alfaidy *et al.*, 2003). Recent evidences demonstrated in both murine and human samples that 11β-HSD1 expression in the human myometrium significantly decreases at the onset of labor (Damiani *et al.*, 2017). In addition local cortisol regeneration by 11β-HSD1 in amnion causes the downregulation of lysyl oxidase (LOX) expression, a collagen cross-linking enzyme, thereby contributing to the rupture of fetal membranes (ROM) (Liu *et al.*, 2016).

Although the maternal adrenal glands undergo chronic hyperplasia and secrete increasing cortisol with advancing gestation in pregnancy, the placental syncytiotrophoblasts express increasing amounts of 11β-HSD2 toward term (Schoof *et al.*, 2001), thus limiting transfer to the fetus and minimizing the negative feedback of maternal cortisol on the fetal HPA axis. This protects the developing fetus from the growth restrictive and programming effect of maternal GCs that is much higher than the fetal concentration. It also allows the fetal adrenal glands to secrete copious amounts of DHEAS in the presence of high maternal GC concentrations during pregnancy.

Limitation of the negative feedback of maternal cortisol on the fetal HPA axis by the placental enzyme 11β-HSD2 also allows the secretion of cortisol from the androgenic fetal adrenal glands to increase toward the end of gestation. In addition, the fetal membranes and decidua express increasing amounts of 11β-HSD1 with gestational age, and are regarded as an important extraadrenal source of GCs locally within the intrauterine tissues during gestation (Alfaidy *et al.*, 2003; Li *et al.*, 2006; Sun and Myatt, 2003).

Thus, cortisol level rises in parallel with estrogen in maternal and fetal circulations as well as in the amniotic fluid toward the end of human gestation. Considering that glucocorticoids are potent stimulants of prostaglandin synthesis, cortisol regenerated locally in the fetal membranes play a central role in the initiation of parturition in humans (Li *et al.*, 2014; Challis *et al.*, 2000; Lye *et al.*, 1998). In addition, GC also upregulate expression of CRH from the placenta and fetal membranes (Petraglia *et al.*, 1996).

The final common pathway toward parturition in the human appears to be maturation and activation of the fetal HPA. Fetal HPA axis activity starts at mid-gestation, after the maturation of the fetal pituitary. Interestingly, fetal stress responses are independent from those of the mother: the fetal hypothalamus releases CRH, together with placental CRH, inducing fetal pituitary ACTH secretion. ACTH in turn controls adrenocortical functional development, including angiogenesis and expression of steroidogenetic enzymes (Mesiano and Jaffe, 1997). Parturition is a very stressful condition for the fetus and an adequate adrenocortical secretion of steroids (mainly cortisol) enables its adaptation to extrauterine life. Stimulation of the fetal pituitary by CRH increases ACTH production and, consequently, the synthesis of cortisol by the fetal adrenal gland and maturation of fetal lungs. In turn, the rising fetal cortisol concentrations further stimulate placental CRH production. The maturation of the fetal lungs as a result of increasing cortisol concentrations represents a fundamental aspect of fetal adaptive mechanisms to extrauterine life

activated by the stress of delivery. Moreover, fetal lung maturation is associated with increased production of surfactant protein A and phospholipids, both pro-inflammatory agents, that may stimulate myometrial contractility through increased production of prostaglandins by fetal membranes and the myometrium itself (Smith, 2007).

Oxytocin

OT is synthesized in the hypothalamus and secreted by the posterior pituitary; its major target organs are the pregnant uterus and mammary glands, as it regulates myometrial contractility and milk ejection. Although placental expression and secretion of OT have been shown, their contribution to the mechanisms of parturition remains unknown at this stage. Human decidua expresses greater levels of OT mRNA than amnion, chorion, and trophoblast. Placental OT secretion is increased by several paracrine factors such as CRH, activin A, and PGs operating within human intrauterine tissues (Florio *et al.*, 1996). At the onset of labor, the uterine sensitivity to OT markedly increases in association with both an upregulation of OT receptor mRNA levels and a strong increase in the density of myometrial OT receptors, reaching a peak during early labor (Havelock *et al.*, 2005). Since OT infusion can initiate labor and an OT antagonist is effective in delaying threatened preterm labor in several species, an important role for OT in driving parturition is suggested.

Parturition as an Inflammatory Event

Parturition is associated with increased tissue-level inflammation within the myometrium, decidua, and cervix (Norman *et al.*, 2007). A pivotal role for PGs in the inflammation process leading to labor initiation has been shown. The presence of cytokines, interleukins and estrogen seems to promote the production of PGs from myometrial cells, fetoplacental unit and predominantly from the maternal decidua in pregnancies near term. In labor, PGs increase in maternal urine and blood, and in fetal membranes. PGF2α is produced primarily by the maternal decidua and acts on the myometrium to upregulate oxytocin receptors and gap junctions, thereby promoting uterine contractions. PGE_2 is primarily of fetoplacental origin and is likely more important in promoting cervical ripening (maturation) associated with collagen degradation and dilation of cervical small blood vessels and spontaneous rupture of the fetal membranes. In fact, PGE_2 stimulates uterine contractions by upregulation of oxytocin receptors (OTRs) and synchronization of contractions, and acts in collaboration with IL-8 to remodel the cervix. PGE_2 also attenuates the expression of lysyl oxidase (LOX), the enzyme that cross-links collagen fibrils in human amnion fibroblasts, thereby reducing the tensile strength of the membranes. Uncross-linked collagen fibrils also predispose the fibrils to degradation by MMPs, inducing fetal membranes rupture (Liu *et al.*, 2016).

The increase of PGs exert a positive feedback action, further stimulating placental CRH release and sustaining a positive loop that results in increased intraamniotic concentration of cortisol (influence 11b-HSD1 activity), prostaglandins, and membrane matrix metalloproteases (MMP-9) that finally lead in fetal membrane activation and initiation of parturition (Sun *et al.*, 2006).

Increasing evidence suggests that, near term, also mechanical uterine distension and fetal neuroendocrine hormonal signaling enhance the production of pro-inflammatory chemokines (cytokines IL-1b, Il-6, IL-8) in the amniotic fluid that act as chemoattractants. As a result, larger amounts of cytokines are released inducing the activation of pro-inflammatory transcription factors that promote myometrial contractility, including gap junction protein connexin 43, the oxytocin and the $PGF2_\alpha$ receptor, cycloxygenase-2 and ion channels (Mendelson, 2009). These proteins act within the uterus to facilitate coordinated, rhythmic contraction as they promote intercellular connection, excitability of myometrial cells, and propagation of the electrical activity. In addition, chemokines influx induces both calcium entry in myometrial cells and degradation of cAMP via stimulation of phosphodiesterase activity (Oger *et al.*, 2002).

Labor Mechanisms

Myometrial Contractility

During pregnancy, the myometrium undergoes changes in cellular phenotype, characterized by an early proliferative phase, an intermediate phase of cellular hypertrophy and matrix elaboration, a third phase in which the cells become highly active assuming a contractile phenotype. The phenotypic modulation of the uterine myocytes is the result of integration of endocrine signals and mechanical stimulation of the uterus by the growing fetus (Shynlova *et al.*, 2009b). The proliferative phenotype is associated with dramatic changes in the expression of IGF family proteins and coincided with an upregulation of the antiapoptotic pathway (Shynlova *et al.*, 2007). The growth and remodeling of the myometrium during pregnancy is associated with increased synthesis of extra cellular matrix (ECM) proteins and their corresponding integrin receptors (Shynlova *et al.*, 2009a). A decrease in expression of fibrillar collagens and a coordinated temporal increase in expression of components of the basement membrane near term is observed, together with decreased progesterone levels and increased mechanical tension. In the labor phase, myometrial cells are characterized by increased excitability, spontaneous activity, responsiveness to agonists, and effective coupling of the myocytes. In fact, in the contractile phase an upregulation of contraction-associated proteins and downregulation of myometrial inhibitory pathways is observed, and, finally the expression of myometrial labor genes, synthesis of uterotonic agonists, and development of

the intense contribute to a synchronous contractions of labor (Shynlova *et al.*, 2009b). Myometrial cells play also an important role in the generation and regulation of uterine inflammation, actively participating through the release of the pro-inflammatory chemokine monocyte chemoattractant protein-1 (MCP-1).

Rupture of Membranes

Rupture of the fetal membranes is one of the labor phenomenon where stretch forces act upon preweakened tissue (Kumar *et al.*, 2016) and although part and necessary for delivery, it is likely controlled separately from uterine contractions. In fact, the rupture of membranes is the result of a remodeling-maturation process analogous to that seen in the cervix. The physiological mechanisms which cause membranes to fail, term or preterm, are not completely understood. Changes in collagen type and matrix cause initial structural weakening (McLaren *et al.*, 2000), which is then followed by cellular apoptosis, especially in a focal area overlying the cervix (McLaren *et al.*, 1999). A biochemically remodeled para-cervical fetal membranes region seems to be physically weaker than other and have been names "physiological weak zone" (El Khwad *et al.*, 2005), where the spontaneous rupture of membranes seems to initiates, even though mechanisms are not fully understood.

Cervix

The final process of parturition is ultimately effected by cervical effacement and dilatation, allowing a progressive and controlled delivery of the fetus. In the cervix, cytokines, prostaglandins, nitric oxide, and steroids, especially androgens (Makieva *et al.*, 2014), seem to induce ripening by mediating the remodeling of the extracellular matrix and collagen (Sennström *et al.*, 2000). It is postulated that the underlying mechanism involves an increased expression of metalloproteases by cervical fibroblasts and the breakdown of collagen in the cervical tissue (Iwahashi *et al.*, 2003).

Other Mechanisms Involved in Parturition

Senescence of Chorio-Amniotic Membranes

The role played by hormones in labor and onset progression has been widely investigated, however the mechanisms underlying the initiation of parturition are still not fully understood. Recently, cellular senescence of fetal membranes has been hypothesized as the initiator of a coordinated, redundant signal cascade leading to parturition (Menon, 2016). Multiple inputs into an inflammatory load converge on common labor effectors such as progesterone withdrawal and increased sensitivity to oxytocin and PGs to transform the uterus into a laboring phenotype (Menon *et al.*, 2016b).

Cellular senescence refers to the physiologic and biomolecular mechanisms normally associated with aging (Munoz-Espin and Serrano, 2014). However, premature senescence may also lead to pathologic states. Morphologic evidence of senescence is characterized by enlargement of cells and biochemically by the presence of senescence associated (SA) b-galactosidase (gal) and formation of DNA-damaged foci with chromatin alterations. Unlike apoptosis (programmed cell death), senescent cells persist and change the tissue environment with a unique inflammatory milieu. Senescence of the chorio-amniotic membranes is a natural and physiological process and term labor can be considered as an end stage of life for chorioamnion. Morphologic evidence of cellular senescence (enlarged cells and organelles) and a higher number of SA b-galactosidase stained amnion and chorion cells were observed in chorio-amniotic membranes obtained from women in labor at term, when compared to term not in labor. Additionally, a phenomenon known as the senescence-associated secretory phenotype (SASP), characterized by the promulgation of pro-inflammatory cytokines, chemokines, growth factors, and MMPs, manifest a form of intrauterine sterile inflammation, functioning as a signal to promote labor. The concentration of pro-inflammatory SASP markers has been shown to be significantly higher in the amniotic fluid of women in labor at term than women not in labor (Behnia *et al.*, 2015). Fetal membrane senescence is also associated with oxidative stress and telomere length loss with release of telomere fragments (Polettini *et al.*, 2015), that elicit pro-inflammatory responses, acting as signals for parturition (Menon *et al.*, 2016a; Phillippe, 2014). Chorio-amniotic membrane senescence constitutes a counting device, that is, a clock, that measures maturation of the fetal organ systems and the production of hormones and other soluble mediators and that promotes inflammation and orchestrates an immune cascade to propagate signals across different uterine compartments. This mechanism in turn sensitizes decidual responsiveness and eventually promotes functional progesterone withdrawal in the myometrium, leading to increased myometrial cell contraction and the triggering of parturition (Menon *et al.*, 2016b).

Conclusion

Human labor is a multifactorial physiological event involving an integrated set of changes within the maternal tissues of the uterus (myometrium, decidua, and uterine cervix) and fetal membranes, which occur gradually over a period of days to weeks. A parturition cascade exists in humans that is responsible for the removal of mechanisms maintaining uterine quiescence and for the recruitment of factors acting to promote uterine activity (Snegovskikh *et al.*, 2006). Whereas there may be a final common pathway

for the initiation of labor, there are multiple, sometimes complementary, endocrine, paracrine, and autocrine initiating factors involved. The "final common pathway" to delivery is likely to be multiple, parallel, interactive paths that tip the balance in favor of coordinated uterine contractility and cervical dilation.

Premenstrual Syndrome (PMS)☆

M Link, University of Utah, Salt Lake City, UT, United States

Glossary

Premenstrual dysphoric disorder (PMDD) A subtype of premenstrual syndrome that is characterized by emotional symptoms such as depression, anxiety, and irritability that are severe enough to interfere with social or role functioning and are verified by prospective daily symptom ratings.

Premenstrual syndrome (PMS) A constellation of physical and emotional symptoms that recur repetitively during the 1 or 2 weeks before the onset of a menstrual period and cannot be accounted for by other underlying disorders.

Selective serotonin reuptake inhibitors (SSRIs) A category of antidepressant medications that increase the levels of serotonin at the junction between nerve fibers.

For centuries, many women have recognized that they experience physical and emotional symptoms during the week before the onset of their monthly menstrual period. However, it was not until 1931 that Frank and Horney validated their experience by describing a medical disorder termed premenstrual tension syndrome (Knaapen and Weisz, 2008). Twenty years later, Green and Dalton described the same syndrome but used the term premenstrual syndrome (PMS). In the 1990s, psychiatrists described a subtype of PMS that consisted of severe emotional symptoms and behavioral changes and referred to it as premenstrual dysphoric disorder (PMDD).

Epidemiology

Although mild physical and emotional symptoms may occur during the week before the onset of menstruation in up to 80%–90% of women, population studies have demonstrated that premenstrual symptoms that are severe enough to warrant medical evaluation and therapy occur in only 3%–5% of menstruating women (Segebladh *et al.*, 2009; Halbreich *et al.*, 2012; Freeman *et al.*, 2012; Yonkers *et al.*, 2008). Although women commonly present for treatment during the fourth decade of life, many of them can trace the onset of their symptoms to their adolescence. They also often describe other family members with PMS/PMDD as well as a personal history of postpartum depression or the exacerbation of their symptoms when combined oral contraceptives or progesterone alone is administered (Backstrom *et al.*, 2011).

Pathophysiology

There are numerous theories regarding the etiology of PMS/PMDD, but its pathogenesis remains elusive. Ovarian steroidal hormones play a central role, as demonstrated by the fact that symptoms resolve with anovulation and oophorectomy (Yonkers *et al.*, 2008). Also, because symptoms occur in the late luteal phase, progesterone has been implicated as a causative agent, although the mechanism by which it acts to instigate symptoms is unclear (Segebladh *et al.*, 2009). It has been suggested that progesterone and its metabolites act on γ-aminobutyric acid (GABA) receptors; stimulation of GABA-A receptors has been shown to have paradoxical effects with negative mood symptoms like those observed in women with PMS/PMDD (Backstrom *et al.*, 2011). In contrast to this theory, however, is that fact that many women with PMS/PMDD begin experiencing symptoms at the start of ovulation, before the decline in progesterone has occurred, and administration of progesterone during the late luteal phase does not ameliorate symptoms (Yonkers *et al.*, 2008). Estrogen may also play a role, although its contribution to the pathogenesis of PMS/PMDD is less well studied. Lastly, the neurotransmitter serotonin has been implicated in PMS/PMDD. Serotonin helps regulate mood and behavior, and studies in serotonin-deficient rodent led to increased sex-steroid dependent behaviors (Ho *et al.*, 2001). In addition, PMS/PMDD symptoms are improved with administration of selective serotonin reuptake inhibitors (see below) and other serotonin-enhancing agents (Yonkers *et al.*, 2008; Marjoribanks *et al.*, 2013). Individual biological, genetic, and psychological factors as well as sociocultural conditions may also play a role in the etiology of the symptoms as well as their severity.

Diagnosis

Because there is no biochemical marker for PMS/PMDD, the diagnosis is made upon the patient's clinical history. PMS and PMDD are distinguished from each other based upon the presence and severity of symptoms (see **Table 1**) (Freeman *et al.*, 2011).

☆*Change History:* January 2015. M Link updated the text and further readings and added references to this entire article. Also added new table 1.

This article is an update of William R. Keye, Premenstrual Syndrome (PMS), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 73–75.

 doi:10.1016/B978-0-12-801238-3.03915-5

Table 1 Diagnostic criteria for PMS and PMDD

Premenstrual syndrome (PMS)	*Premenstrual dysphoric disorder (PMDD)*
At least one affective or somatic symptom[a] in the 5 days before menses	At least 5 of 11 specified symptoms[b] at a severe level in the week before menses for the past year
Remission of the symptom(s) on cycle days 4–13	Remission for 1-week post-menses
Symptoms impair functioning	Symptoms impair functioning or relationships
Symptoms confirmed in 2 cycles of prospective symptom ratings	Symptoms confirmed in at least half of the woman's menstrual cycles within the past year
Symptoms are not due to another disorder	Symptoms are not due to another disorder

[a]Affective symptoms include depression, angry outbursts, irritability, anxiety, confusion, and/or social withdrawal. Physical symptoms include breast tenderness, abdominal bloating, headache, and/or peripheral edema.

[b]Specified symptoms: depression, anxiety, mood swings, irritability, decreased interest, difficulty concentrating, fatigue, appetite changes, sleep disturbance, feeling overwhelmed, physical symptoms. Symptoms must include at least one of the first four symptoms and only one physical symptom.

Adapted from Box 1 in Freeman *et al.*

Recently, PMDD was added to the Fifth Edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) (Epperson *et al.*, 2012). To meet diagnostic criteria, patients must experience a premenstrual pattern of symptoms in at least half of their menstrual cycles during the previous year. Both psychological and physical symptoms typify PMS/PMDD; those most commonly reported by patients include mood lability, irritability, bloating, and breast tenderness (Epperson *et al.*, 2012).

Because some women may have selective recall of their symptoms, prospective charting of the symptoms is necessary to establish the relationship of these symptoms to the onset of the menstrual period and to establish a diagnosis of PMS or PMDD. While the DSM-5 diagnosis of PMDD also requires prospective daily self-ratings of symptoms for at least six menstrual cycles within a year, many find this tedious and unnecessary in clinical practice. Though prospective charting is ideal for establishing the diagnosis of PMS/PMDD, some women presenting for evaluation and treatment will be unwilling or unable to prospectively record their daily symptoms and it may be necessary to initiate therapy without adequate prospective charting. Finally, the fact that the symptoms never last for more than 2 weeks distinguishes PMS and PMDD from other mood or physical disorders (Epperson *et al.*, 2012).

It is important during the course of the evaluation to rule out other conditions such as anxiety disorders, depressive disorders, anemia, hypothyroidism, chronic fatigue syndrome, central nervous system tumors, or autoimmune disorders. It is also important to evaluate the impact of the symptoms on her self-esteem and relationships with family, friends, and co-workers. It is prudent to discuss stresses in the lives of these women for they may exacerbate the symptoms of PMS/PMDD.

Treatment

Overview

Because no single treatment is universally effective for PMS/PMDD, many have doubted the existence of this disorder and criticized attempts to help women with their premenstrual symptoms. However, in the past decade there have been over 200 prospective randomized clinical trials of various therapies, which have led to an evidence-based approach to the treatment of PMS/PMDD.

Initial Nonspecific Therapy

The initial treatment of PMS/PMDD can begin during the phase of evaluation using nonspecific therapies. These nonspecific therapies include non-pharmacologic approaches such as patient education, validation of symptoms through daily prospective charting, relaxation training, and self-help measures such as exercise and nutrition. Alternative and complementary therapies like acupuncture and herbal medicine may also be employed, though with limited evidentiary support (Jang *et al.*, 2014). Because social support is often essential for relief of symptoms, it may be helpful to the women with PMS/PMDD if the clinician involves family members or friends in the process of evaluation so that they may support her and help validate her symptoms. Although data supporting the effectiveness of these non-pharmacologic therapies are limited, these therapies are often used because they lack significant side effects, are very practical, and may benefit the woman's physical and emotional health (Jarvis *et al.*, 2008).

First-Line Pharmacologic Therapies

Once the diagnosis of premenstrual syndrome has been made, more specific therapy can be initiated for those women who desire pharmacologic intervention. Because of their demonstrated effectiveness in prospective randomized clinical trials, selective serotonin reuptake inhibitors (SSRIs) are considered first-line treatment (Marjoribanks *et al.*, 2013; Freeman *et al.*, 2011; ACOG, 2010; Dimmock *et al.*, 2000). A recent Cochrane review included thirty-one randomized controlled trials

(RCTs) comparing fluoxetine, paroxetine, sertraline, escitalopram, and citalopram versus placebo. SSRIs were found to be more effective in reducing self-reported symptoms than placebo, though medication withdrawal and side effects were more common in the SSRI group (Marjoribanks *et al.*, 2013). Notably, SSRIs may be taken throughout the menstrual cycle or during the luteal phase only, the latter of which clearly distinguishes PMS/PMDD from other mood disorders (Marjoribanks *et al.*, 2013; Epperson *et al.*, 2012). In addition, in contrast to the gradual and delayed response of individuals with chronic depressive disorders to SSRIs, women with premenstrual syndrome may note improvement of their symptoms within days of starting their medication (Epperson *et al.*, 2012).

Despite these positive findings, up to 40% of women with PMS/PMDD fail to respond to SSRI treatment (Freeman *et al.*, 2011). This may be related to the heterogeneity of PMS/PMDD, with a wide range of both physical and psychological symptoms. A study of 447 women found that sertraline significantly improved symptoms in women diagnosed with predominately psychological and mixed psychological/physical PMS/PMDD subtypes but was not effective in women in the predominately physical subtype (Freeman *et al.*, 2011).

Second-Line Therapies

In addition to SSRIs, combined oral contraceptives (COC) may be used to treat symptoms of PMS/PMDD. The first published RCTs comparing COC to placebo utilized a 24/4 regimen (24 days of hormonally active pills followed by 4 days of inactive pills) containing drospirenone 3 mg and ethinyl estradiol 20 mcg (Lopez *et al.*, 2012; Yonkers *et al.*, 2005; Pearlstein *et al.*, 2005). These studies found improvements in both mood and psychological symptoms as well as an improvement in overall quality of life, although sample sizes were low and there was a large placebo effect seen. Small studies have shown equivalent effect with levogestrol and levonorgestrol as the progestin component (Sangthawan and Taneepanichskul, 2005; Freeman *et al.*, 2012; Halbreich *et al.*, 2012). While effective, many women note increased symptoms while taking the hormonally inactive pills, leading to the administration of COC in an extended cycle or continuous pattern to suppress menstruation and ovarian hormonal fluctuations that are thought to precipitate PMDD.

When the above therapies are either ineffective or unacceptable to the patient, there are other treatment options that may be helpful even though scientific support for their use is not as strong as for SSRIs and COC. Second-line non-pharmacologic treatment may include cognitive behavioral therapy, which has been shown to be as effective as fluoxetine in the treatment of PMDD (Hunter *et al.*, 2002). Second-line pharmacologic agents include other agents to suppress ovulation and anxiolytics. Although obliteration of the menstrual cycle and ovulation by gonadotropin-releasing hormone (GnRH) agonists has been shown to be effective, their side effects limit their widespread use (Segebladh *et al.*, 2009). GnRH agonists are associated with menopausal symptoms including hot flashes, night sweats, and insomnia. A randomized, double-blind, crossover clinical trial evaluated three different hormonal add-back regimens to women with PMDD treated with leuprolide acetate found increased PMDD symptoms with all regiments, though symptoms were worse with add-back progesterone regimens (Segebladh *et al.*, 2009). Lastly, newer treatment options like acetazolamide may be helpful by potentiating GABAergic transmission, but evidence is limited regarding their utility and effectiveness (Sani *et al.*, 2014).

This wide array of potentially effective therapies offers new hope to women with PMS or PMDD. However, the therapy of PMS/PMDD should be more than just pharmacologic and should include self-help measures so that the patient becomes an active partner in her therapy. In addition, attempts should be made to recognize and help the patient deal with stresses in her life and to help her establish an effective social support system. The importance of validation, social support, and the elimination of stress cannot be emphasized enough. It is hoped that further research will uncover new and even more effective and safe therapies for premenstrual syndrome.

Amenorrhea

Sophie Christin-Maitre, Hospital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, Paris, France and Sorbonne University, Medical University, Paris, France

Definition

Amenorrhea is an absence of menses. In physiology, menses are bleeding occurring at the beginning of the menstrual cycle, due to the desquamation of the endometrium, the inner layer of the uterus. They usually last from 3 to 6 days. The occurrence of the first menses is called menarche. Its mean age is 12.5 years. The average time between the first pubertal sign, that is, the increase in breast development, and the first menses is of 2 years. Amenorrhea is called primary, when the patient has never had any episode of menses. It is called secondary, after 3 months of amenorrhea, in a patient who has already had menses.

In all cases of amenorrhea, pregnancy must be ruled out. The physiological conditions of amenorrhea are pregnancy, lactation and the time after menopause (i.e., the last menstrual bleeding). Apart from these obvious causes, an etiological assessment, including clinical and hormonal evaluations must be carried out. The different causes are of hypothalamic- pituitary, ovarian, adrenal or uterine origin.

Primary Amenorrhea

In the case of primary amenorrhea, etiological assessment must be carried out in the absence of menses, at the age of 15 years.

If there is no breast development, the assessment must be done before the age of 14. The items to look for when questioning the patient are (1) the age of the menarche of the mother and/or the sisters; (2) a past history of hypogonadism in the family; (3) the presence of eating disorders; (4) the degree of physical activity per week; (5) the presence of headaches and visual field abnormalities; (6) the absence of smell, called anosmia or a diminished smell called hyposmia; (7) a previous history of chronic disease such as renal failure, pulmonary disease or coeliac disease; and (8) a previous history of chemotherapy and/or radiotherapy. Clinically, the stage of breast development should be characterized as well as the presence of pubic and/or axillary hair, hirsutism, acne, the patient's height, her weight and her body mass index. A pelvic mass on abdominal examination favors hematocolpos which is a blood accumulation in the uterus, due to a lack of hymenal perforation.

In the initial assessment, laboratory tests include hCG, FSH, LH, estradiol (E2), prolactin and testosterone. A progestin test can be used in order to evaluate the patient's endogenous estrogen secretion. The test is positive if bleeding occurs at the end of 10 days of treatment with progestin. It is in favor of a normal endogenous E2 secretion. On the opposite, the test is negative in the absence of bleeding at the end of 10 days of treatment with progestin. The causes are endogenous estrogen deficiency, a lack of uterus and pregnancy.

The pelvic ultrasound is useful in order to measure the ovarian sizes, evaluate the presence of ovarian follicles and a uterus. A uterine length greater than 25 mm is in favor of a beginning of puberty. Transvaginal ultrasound is usually much more informative than transabdominal ultrasound. However, in some patients, vaginal ultrasound cannot be performed if the patient has not had sexual intercourse.

The diagnostic procedure is presented in **Fig. 1**. Serum FSH and estradiol levels will discriminate between hypogonadotropic and hypergonadotropic hypogonadism. Normal or low levels of FSH in the face of low E2 levels suggest a hypothalamic-pituitary disease. Congenital hypogonadotropic hypogonadism (CHH) is a rare disease. In Kallmann syndrome, CHH is associated with anosmia (see chapter on delayed puberty). High FSH levels are in favor of primary ovarian insufficiency (POI), such as Turner syndrome (see chapter on Turner syndrome).

In case of breast development, the diagnostic procedure is similar to that of secondary amenorrhea. However, some specific diagnostic procedures should be mentioned in case of primary amenorrhea. Uterine abnormalities include an absence of uterus, called Rokitansky syndrome. A second abnormality is hymenal imperforation leading to hematocolpos with a history of cyclic pelvic pains. A rare disease called the complete androgen insensitivity syndrome (CAI) is due to loss-of-function mutations of the androgen receptor, in 46 XY individuals. The diagnosis is made in a patient with primary amenorrhea, breast development with a lack of hair and high testosterone serum levels, higher than those of a normal male range.

Secondary Amenorrhea

In case of secondary amenorrhea, pregnancy must first be ruled out. The diagnosis procedure is presented in **Fig. 2**.

During the questionnaire, one should record: the age of menarche, the regularity of menses, history of sexual intercourses and previous history of chemotherapy, radiotherapy or chronic diseases. Headaches and visual field abnormalities are in favor of a hypothalamic-pituitary tumor. Medication inducing a hyperprolactinemia (see chapter on hyperprolactinemia) or an atrophy of

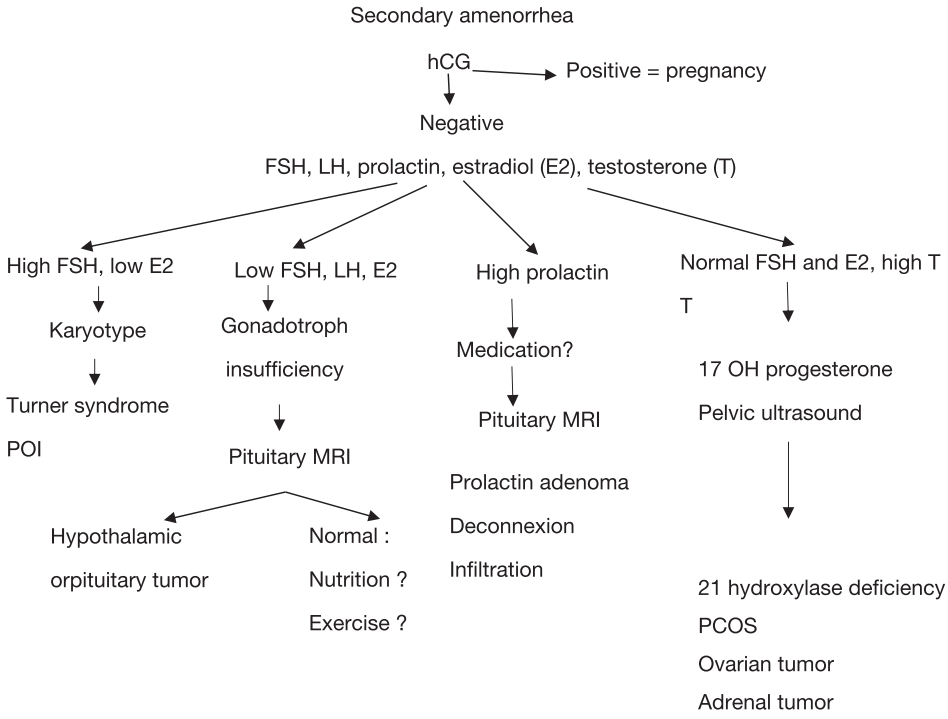

Fig. 2 Diagnostic procedure for secondary amenorrhea. *hCG* = human choriogonadotropin hormone, *FSH* = follicle stimulating hormone, *LH* = luteinizing hormone, *E2* = estradiol, *T* = testosterone, *MRI* = magnetic resonance imaging.

the endometrium should be searched for. Nowadays, acquired uterine adhesions, called synechiae are becoming quite a rare cause of secondary amenorrhea.

The laboratory evaluation includes FSH, LH, E2, testosterone (T) as well as prolactin levels. The most frequent cause of secondary amenorrhea is polycystic ovarian syndrome. It affects around 10% of the female population. Women may have biological and/or clinical hyperandrogenism with hirsutism, acne, as well as severe oligomenorrhea or amenorrhea. The ultrasound usually find a large amount of arrested follicles, higher than 20 per ovary. If testosterone serum level is very high (>1.5 ng/mL), an ovarian or an adrenal tumor should be ruled out. In young women, acquired hypogonadotropic hypogonadism is usually related to hyperprolactinemia or to an occult food selection associated with excessive physical activity.

In summary, physicians should identify the cause of primary or secondary amenorrhea before introducing any treatment. After ruling out a pregnancy, the initial laboratory assessment includes FSH, LH, E2, prolactin and T measurements. The ultrasound is useful to confirm the presence of a uterus, to measure ovarian volume and count ovarian follicles. An MRI must be requested in front of a hypogonadotropic hypogonadism.

Congenital Hypogonadotropic Hypogonadism in Females☆

Jacques Young, University of Paris-Sud and Bicêtre Hospital, Le Kremlin-Bicêtre, France

Introduction

Congenital isolated gonadotropin-releasing hormone deficiency (GnRH), also called congenital hypogonadotropic hypogonadism (CHH) or isolated hypogonadotropic hypogonadism (IHH) is a rare condition in women and is characterized by GnRH and/or gonadotropin deficiency associated with low serum ovarian sex steroids levels and low circulating gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH) (Boehm *et al.*, 2015). In IHH/CHH, the underlying hypothalamo-pituitary neuroendocrine abnormalities are classically divided into two main groups: 1) Molecular defects of actors involved in the gonadotrope cascade leading hypothalamic GnRH deficiency or pituitary resistance to GnRH and causing isolated normosmic CHH (nCHH), and 2) Developmental abnormalities affecting development and/or migration and the normal hypothalamic location of GnRH neurons in post natal life, but also olfactory bulbs/tracts morphogenesis and responsible for an anosmic/hyposmic IHH/CHH form called Kallmann syndrome (KS) (Boehm *et al.*, 2015; Stamou *et al.*, 2016). The main clinical sign that reveals the condition is primary amenorrhea (Shaw *et al.*, 2011; Bry-Gauillard *et al.*, 2017; Tang *et al.*, 2017). Knowledge of the broad clinical reproductive spectrum of IHH/CHH in women has improved during the last two decades. As a result, the detection of partial forms with significant pubertal development seems to be more effective in adolescents who consult for primary amenorrhea. Discovery of tens of genes associated with IHH/CHH/KS has provided major insights into the molecular pathways critical for the development, maturation of GnRH neurons and for function of the gonadotrope axis.

Prevalence

There is no specific epidemiologic studies on the prevalence of IHH/CHH/KS particularly in women. Two old studies suggested a prevalence comprised between 1/10000 and 1/86000 in males (Boehm *et al.*, 2015). The prevalence of IHH/CHH/KS has classically been considered to be lower in females with a male/female ratio of 5:1(Boehm *et al.*, 2015). However, a bias in the diagnosis of female IHH/CHH/KS is likely as they often are treated with hormonal therapy without etiological investigation and are not referred to teaching hospitals where prevalence is usually evaluated (Boehm *et al.*, 2015).

Clinical Presentation

In women, IHH/CHH/KS is revealed after the age of puberty by delayed pubertal development associated with primary amenorrhea in more than 95% of cases (Shaw *et al.*, 2011; Bry-Gauillard *et al.*, 2017; Tang *et al.*, 2017). At diagnosis, before any hormonal therapy, breast development is highly variable, absent in only a minority of cases, but often present (breast Tanner stages B2-B4) and sometimes even normally developed (Shaw *et al.*, 2011; Bry-Gauillard *et al.*, 2017; Tang *et al.*, 2017) (**Fig. 1**). On the same way, pubic hair may be absent, sparse or even normal. These partial forms, in majority not referred to hospital also contribute to explain the underestimated prevalence of this condition in women (Boehm *et al.*, 2015). In rare very mild forms, IHH/CHH/KS can be restricted to isolated chronic anovulation. In these IHH women estradiol secretion seems adequate for uterine and endometrial development explaining the existence of a single or few menses (primosecondary amenorrhea) (nejm) or even chronic oligomenorrhea (Sarfati *et al.*, 2015). Growth and final height in IHH/CHH/KS women have been evaluated in very few studies (Dickerman *et al.*, 1992). The scant reported data indicate that the final height in these women is similar to that of the reference population. Contrary to hypogonadal women with Turner syndrome IHH women are not at risk of small height, (Dickerman *et al.*, 1992).

IHH/CHH/KS are not always congenital lifelong disorder as initially thought, because in nearly 10% of patients the disease seems not permanent, as evidenced by partial or complete recovery of the pulsatile activity of the hypothalamic-pituitary-gonadal axis after discontinuation of treatment in adulthood (the so-called reversible CHH/IHH) (Dwyer *et al.*, 2016).

Hormonal Evaluation

Most women with IHH/CHH/KS have very low serum pituitary gonadotropin levels (Shaw *et al.*, 2011; Bry-Gauillard *et al.*, 2017) when sensitive LH and FSH immunoassays are used. However, circulating gonadotropins in a subset of patients can be low-normal, which is inappropriate in the setting of low estradiol and low inhibin B levels. Circulating estradiol levels in untreated

☆*Change History:* April 2018. Jacques Young updated the text and references to this article.

This article is an update of Lawrence C. Layman, Gonadotropin-Releasing Hormone Deficiency, Congenital Isolated, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 302–305.

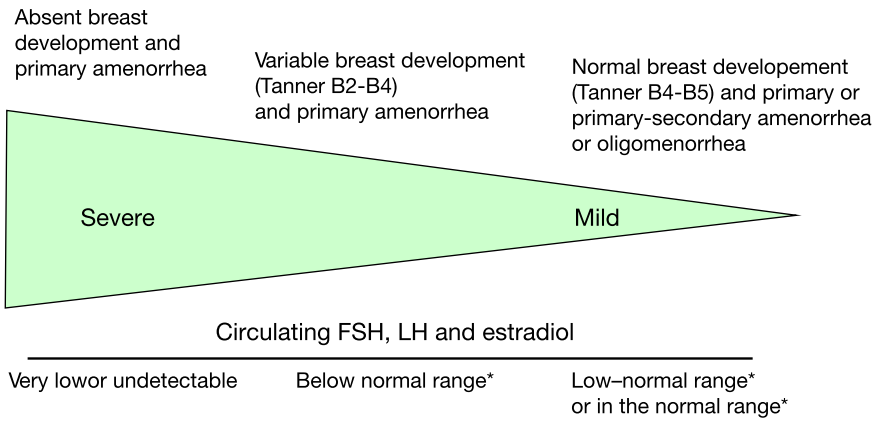

Fig. 1 Reproductive phenotype in IHH/CHH women, wide clinical spectrum at diagnosis. * In early follicular phase in normal women.

IHH/CHH/KS women are low or in the lower end of the normal range during the follicular phase when sensitive assays are used (radioimmunoassays or GCMS and LCMS methods) that allow detection of very low estradiol levels (Bry-Gauillard *et al.*, 2017). Fiew studies have investigated circulating inhibin B levels in IHH/CHH/KS female patients (81). Low Inhibin B concentrations are reported to be very low, as in prepubertal girls (Bry-Gauillard *et al.*, 2017). Circulating AMH levels are significantly lower in women with complete untreated IHH than in healthy women (Bry-Gauillard *et al.*, 2017). The severity of AMH deficiency seems related to the severity of FSH deficiency as IHH/CHH/KS women with lower circulating FSH levels have lower serum AMH levels (Bry-Gauillard *et al.*, 2017). The low AMH levels in these latter patients are associated with low antral follicular count (AFC)(see below). However and importantly, these patients' low ovarian volume, low AMH, and/or AFC should not be considered to indicate a poor fertility prognosis, as fertility can be effectively restored by both pulsatile GnRH and gonadotropin administration (Bry-Gauillard *et al.*, 2017).

In the endocrine evaluation of IHH/CHH/KS, it is important to evaluate all pituitary functions in order to rule-out hyperprolactinemia and to exclude additional pituitary deficiencies (Boehm *et al.*, 2015).

Pituitary and Pelvic Imaging

Pituitary MRI is useful to rule out expansive, infiltrative, or malformative disorders of the hypothalamo–pituitary region that can be responsible for pubertal delay associated with hypogonadotropic hypogonadism (HH) in the context of hypopituitarism (Higham *et al.*, 2016). Brain MRI can also be used to analyze olfactory bulbs (OB) and furrows in a search for signs suggesting Kallmann syndrome (unilateral or bilateral OB aplasia or hypoplasia, and effacement of the furrows), particularly when semi-quantitative olfactometry is not locally available (Boehm *et al.*, 2015; Maione *et al.*, 2013).

Studies on uterine morphology in IHH/CHH/KS women are scarse (Shaw *et al.*, 2011; Bry-Gauillard *et al.*, 2017; Tang *et al.*, 2017). Pelvic or transvaginal ultrasound demonstrated prevalent but variable uterine hypoplasia (Shaw *et al.*, 2011; Bry-Gauillard *et al.*, 2017; Tang *et al.*, 2017) which correlated with the importance of estradiol deficiency and endometrial atrophy (Shaw *et al.*, 2011; Bry-Gauillard *et al.*, 2017; Tang *et al.*, 2017). Ovarian volume (OV) in IHH females, evaluated in two studies, showed a significant decrease in mean OV compared to healthy adult women of similar age (Shaw *et al.*, 2011; Bry-Gauillard *et al.*, 2017). Only one recent study quantified the number of ovarian antral follicles (AF) and showed a significant decrease in the average number of AF compared to normal, age-matched women, in agreement with low levels of AMH (see above).

Differential Diagnosis

One challenge in women with IHH/CHH, particularly when the condition is sporadic and with normal sense of smell and normal hypothalamo-pituitary MRI and no identified causative mutation (see below and **Table 1**) is the differential diagnosis of functional hypothalamic amenorrhea (Caronia *et al.*, 2011; Gordon *et al.*, 2017). Therefore, in women referred for primary amenorrhea and with an hormonal profile suggesting HH but without anosmia or hyposmia, the diagnosis of IHH/CHH must only be considered with caution, after ruling out underweight, eating disorders, excessive physical activity, and chronic underlying conditions (**Fig. 2**) (Caronia *et al.*, 2011; Gordon *et al.*, 2017). When body weight or BMI are at the lower limit of normal (22 Kg/m^2), body fat measurement can also be useful to screen for functional hypothalamic amenorrhea (Caronia *et al.*, 2011; Gordon *et al.*, 2017). Another challenge in adolescent girls presenting with delayed puberty, primary amenorrhea and low pituitary gonadotropins is to differentiate an IHH/CHH from a constitutional delay of puberty (CDGP). The presence of associated clinical signs such as anosmia or other signs usually associated with Kallmann syndrome or complex syndromes including IHH/CHH help to exclude CDGP (Boehm *et al.*, 2015; Varimo *et al.*, 2017; Cassatella *et al.*, 2018). No hormonal marker can reliably differentiate these two

Table 1 Genes and loci associated with in isolated congenital hypogonadotropic hypogonadism (CHH), Kallmann syndrome and syndromic forms of CHH

conditions. CDGP is therefore a diagnosis of exclusion, and will only be retained if spontaneous pubertal development and regular menses occur after the age of 18 (Varimo *et al.*, 2017).

Genetic Basis

Since the discovery of the first causative gene KAL1/ANOS1 in 1991 (Boehm *et al.*, 2015; Stamou *et al.*, 2016; Maione *et al.*, 2018), mutations affecting more than 30 genes have been identified to be involved in IHH/CHH and/or KS (**Table 1**). These genes account for approximately 50% of cases but some loci are exceedingly rare and/or occur in the context of complex syndromes. These genes have been identified different approaches: either via cytogenetic or candidate gene studies, linkage analysis (Boehm *et al.*, 2015;

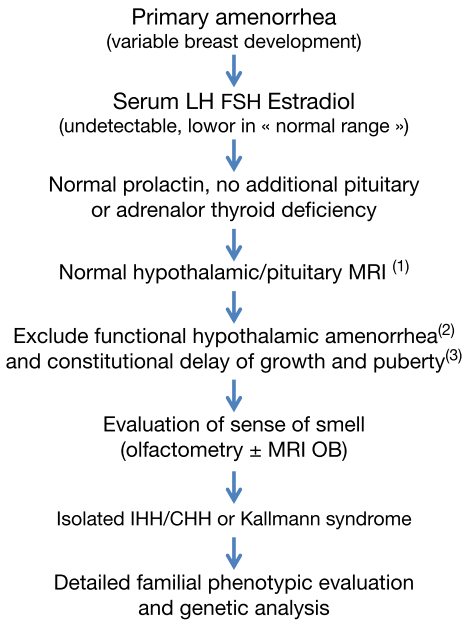

Fig. 2 Successive steps to overcome before confirming the diagnosis of IHH/CHH in a woman referred for primary amenorrhea. (1) Sometimes partial pituitary hypoplasia is observed in Kallmann syndrome. (2) Especially if Body Mass Index is below 22 kg/m^2 (Shaw et al., 2011) which requires follow-up at least until the age of 18 years. (3) MRI: magnetic resonance imaging. OB olfactory bulbs.

Stamou *et al.*, 2016; Maione *et al.*, 2018), and more recently by pathway analysis, or by next-generation sequencing (i.e., targeted or whole exome sequencing) (Boehm *et al.*, 2015; Cassatella *et al.*, 2018).

Genes involved in CHH or KS are classified according to their function in the development of the gonadotrope axis or in the neuroendocrine control of GnRH homeostasis (Stamou *et al.*, 2016): (1) GnRH differentiation; (2) GnRH neuron migration and olfactory axon guidance; (3) GnRH neuron secretion; and (Bry-Gauillard *et al.*, 2017) pituitary gonadotrope cell defects. The modes of transmission of the known genetic causes are shown in **Table 1**. In IHH/CHH/KS inheritance was initially proposed to be exclusively Mendelian with autosomal recessive, autosomal dominant, de Novo or X-linked (males) modes of transmission (**Table 1**) (Maione *et al.*, 2018). However, in many familial cases, the IHH/CHH/KS phenotype and/or associated reproductive signs are not consistent with these classical modes of transmission. Since almost a decade it gradually emerges that either the transmission and the penetrance and the phenotypic variability could be oligogenic in nature (**Table 1**). This new, complex genetic architecture is increasingly recognized by simultaneous analysis of tens or hundreds of genes with next-generation sequencing more efficient techniques (Maione *et al.*, 2018).

Identification of a genetic cause in patients with CHH/IHH is important for clarify the pathophysiological mechanism of the disease and to guide the phenotypic evaluation in propositus and relatives but is above all crucial for determine the mode of transmission within a family which is essential for genetic counseling of both the referred patient and his relatives (Maione *et al.*, 2018). Indeed, IHH/CHH/KS is responsible for a treatable form of infertility in both males and females and is then a genetic condition that can be transmitted to patients' offspring (Maione *et al.*, 2018).

Therapy

The aim of therapy in female IHH teenagers is to induce feminization and normal sexual function, to stimulate statural growth, to promote bone health and to address concerns about future fertility (Boehm *et al.*, 2015). In CHH/IHH/KS girls puberty can be induced by oral or transdermal estradiol administration associated with progestin. In adulthood, estradiol is typically given orally or transdermally (by patch or pumps gel daily) as a maintenance dose associated with a cyclic progestin regimen to avoid endometrial hyperplasia. In the majority of women with CHH, estroprogestin therapy is effective in inducing development of the breasts and genitals, which contributes to an increased sense of femininity and a satisfactory emotional and sexual life. Estrogen therapy also increases uterine size and combined estrogen/progestin therapy induces monthly menses.

Infertility in CHH/IHH women is related to insufficient follicular maturation, which leads to chronic anovulation. Ovulation induction can be achieved either with pulsatile GnRH therapy alone or, alternatively, with FSH and LH administration followed by hCG or LH to trigger ovulation and maintain the functioning of corpus luteum before the relay is taken by the embryonic/placental hCG (Kaufmann *et al.*, 2007). Infertility therapy must be preceded by genetic counseling (Maione *et al.*, 2018). The latter requires the search for abnormalities in many genes involved in this group of diseases (**Table 1**) and will be significantly facilitated by the Next Generation Sequencing (Maione *et al.*, 2018; Cassatella *et al.*, 2018).

Conclusion

Diagnosis of IHH should be considered in any teenager or young woman referred for primary amenorrhea, whatever the degree of breast and pubic hair development. The diagnosis is strengthened in the presence of concomitant low gonadotropin and estradiol levels. After excluding pituitary organic disease, multiple pituitary deficits and functional hypothalamic amenorrhea the main diagnostic challenge is to differentiate in teenagers chronic IHH from transient hypogonadism related to CDGP. The search for a genetic IHH/CHH/KS causes is currently facilitated by the simultaneous analysis of many responsible genes by next generation sequencing allowing a more reliable genetic counseling. Hormone replacement therapy is effective to both enable feminization and to allow normal sexual life as well as to successfully treat these women infertility.

Functional Hypothalamic Amenorrhea

Sarah L Berga, Division of Reproductive Endocrinology and Infertility, University of Utah School of Medicine, Salt Lake City, UT, United States

Glossary

Allostasis Adaptive processes that produce a new stable physiological state through the production of mediators such cortisol and other chemical messengers. These mediators of the stress response promote adaptation in the face of acute stress, but when chronic contribute to allostatic overload and wear and tear on the body and brain.

Cognitive behavior therapy (CBT) A form of psychotherapy based on the notion that the way that individuals perceive a situation is more closely connected to their reaction than the situation itself. The aim of CBT is to help the individual modify dysfunctional emotions, behaviors, and thoughts. Unlike traditional psychoanalysis, which probes childhood wounds to get at the root causes of conflict, CBT focuses on solutions, encouraging patients to challenge distorted cognitions and change unhelpful thinking and behavior to catalyze enduring improvement in mood and functioning.

Introduction

Functional hypothalamic amenorrhea (FHA) is a form of hypothalamic hypogonadism that presents clinically as amenorrhea due to chronic anovulation. It is a diagnosis of exclusion: FHA must be distinguished from all other causes of amenorrhea and anovulation. Functional hypothalamic anovulation manifests clinically as amenorrhea. The proximate cause of chronic anovulation is insufficient hypothalamic GnRH drive to support folliculogenesis. Specifically, GnRH pulse frequency is too slow to drive sufficient release of pituitary LH and FSH secretion that is required to initiate and then sustain folliculogenesis. Chronically low levels of estradiol and progesterone lead to lack of endometrial development and thus absence of menses. The term functional implies that the condition is reversible and that the cause of the reduced GnRH drive is related to potentially modifiable factors that are viewed as stressors because they activate the hypothalamic–pituitary–adrenal axis and lead in increased cortisol secretion. We demonstrated that FHA represents an adaptation to chronic stress that results not only in reduced GnRH drive but also a constellation of concomitant neuroendocrine adjustments including hypothalamic hypercortisolism and hypothalamic hypothyroidism (Berga *et al.*, 1989). The constellation of endocrine adaptations associated with FHA represents an allostatic state that diverts and directs metabolic and psychological energy to acute and chronic challenges. Given the energetic expense of reproduction, it is no surprise that metabolic factors play a fundamental role in gating reproductive function.

Evidence that stress is the cause of FHA includes the demonstration that cortisol levels are higher in women with FHA than in those who are eumenorrheic and ovulatory (Berga *et al.*, 1989) and also higher than in women with other forms of anovulation (Berga *et al.*, 1997). Additionally, recovery from FHA is associated with a reduction in circulating cortisol levels (Berga *et al.*, 1997; Michopoulos *et al.*, 2013b). In practice, it may be difficult to detect hypercortisolemia because the elevation of cortisol is most evident at night (Berga *et al.*, 1989; Michopoulos *et al.*, 2013b) and the cortisol level from a single day time blood sample in unlikely to be outside the normal range. FHA may result from chronic or severe illness such as cancer or pneumonia. Indeed, the term functional means that the hypothalamic GnRH-pituitary gonadotropin apparatus is anatomically and physiologically intact and therefore capable of generating LH pulses and causing pituitary secretion of FSH. In clinical practice, it is often difficult to exclude insufficient GnRH drive due to mutations in genes critical to GnRH ontogeny and function and it has been hypothesized that women with genetic mutations may be more sensitive to stressors (Caronia *et al.*, 2011).

Differential Diagnosis

The causes differ for primary and secondary presentations of amenorrhea. The differential diagnosis includes: (1) Mullerian anomalies, congenital and acquired, that block the outflow tract, including vaginal agenesis, imperforate hymen, and Asherman syndrome; (2) ovarian causes of anovulation such as gonadal agenesis, Turner syndrome (45, XO), polycystic ovary syndrome, and premature ovarian insufficiency (premature menopause); (3) other endocrine conditions such as primary hyper- and hypothyroidism, Cushing syndrome and disease; (4) pituitary causes such as pituitary adenomas and hyperprolactinemia; and (5) organic central causes such as meningioma and Kallmann syndrome and variants. The causes to be investigated can be categorized as vaginal, cervical, uterine, ovarian, adrenal, thyroidal, pituitary, hypothalamic, and central. **Table 1** presents the endocrine concomitants of common causes of amenorrhea due to anovulation (Gordon *et al.*, 2017).

Defining reproductive tract anatomy is the first step in excluding anatomic causes of amenorrhea and doing so is especially important in primary amenorrhea. Outflow tract anomalies often present as primary amenorrhea and require a physical exam and

often imaging with ultrasound or MRI to exclude and/or define anatomic anomalies. Asherman syndrome may present as secondary amenorrhea and is due to injury of the endometrial basal layer that is necessary for the generation of the endometrial functional layer. Findings may include intrauterine scarring, synechiae, and/or adhesions. A history of D&C for miscarriage, retained products of conception, or postpartum bleeding and/or pelvic infection should raise the index of suspicion for endometrial injury and hysteroscopy is typically needed to establish the diagnosis of Asherman syndrome. Polymenorrhea may be due to intrauterine polyps or intramural fibroids rather than functional hypothalamic hypogonadism. A karyotype is needed to evaluate the possibility of gonadal dysgenesis and Turner syndrome, although typically there are physical stigmata. Amenorrhea in the setting of a 46,XY karyotype may reflect Müllerian agenesis and either (1) 5-alpha reductase deficiency causing insufficient production of dihydrotestosterone (DHT) from testosterone or (2) androgen insensitivity syndromes (AIS) due to variable androgen receptor sensitivity. In both of these conditions, the uterus regressed during development and the gonad is a testis, but its location may be inguinal or pelvic. If the karyotype is 46,XX, a testosterone level will be in the male range in 5-alpha reductase deficiency and AIS and very low in gonadal dysgenesis (Swyer syndrome).

In the setting of secondary amenorrhea, history is important because physical examination often shows normal reproductive anatomy and external genitalia. Delineating the timing of pubertal milestones such as adrenarche and thelarche provides clues as does a history of weight gain and loss, dietary habits, and athletic endeavors. History must be supplemented with testing hormone levels as outlined in **Table 1** to establish the diagnosis. A panel that includes LH, FSH, estradiol (E2), progesterone, TSH, thyroxine, prolactin, and androstenedione detects most important causes if properly interpreted. The pattern of hormone levels is more critical than absolute values. In FHA, FSH will be in the normal range and typically it will be slightly higher than LH, which will also be in the low normal range, with E2 <50 pg/mL and progesterone <1 ng/mL. Very low LH and FSH levels suggest organic HA due to genetic mutations affecting GnRH ontogeny and function or central causes such as brain or pituitary tumors. Anosmia indicates Kallmann syndrome, which is failure of GnRH neurons to migrate from the olfactory placode to the hypothalamus. Androstenedione (or testosterone) is typically in the lower range of normal except when FHA is superimposed on polycystic ovary syndrome, both TSH and thyroxine will be in the lower range of normal indicating hypothalamic hypothyroidism or sick euthyroid syndrome, and prolactin will be in the low normal range. It is critical to exclude chronic health conditions that may be a cause of undernutrition such as food allergies including gluten enteropathy (celiac disease).

In contrast, elevated LH and FSH with low E2 and progesterone indicate low or absent ovarian reserve or premature menopause. High LH and FSH with E2 $>$ 150 pg/mL and progesterone <2 ng/mL indicates a midcycle gonadotropin surge. If TSH is low and thyroxine is high, then one must consider the possibility of autoimmune hyperthyroidism (Grave's disease). Similarly, if TSH is in upper limit of normal with thyroxine is in the lower range of normal, then autoimmune thyroiditis and hypothyroidism must be considered and the next step would be to measure antithyroid antibodies such as thyroid peroxidase and thyroid stimulating immunoglobulin. If frank hyperprolactinemia is found, additional evaluation is needed. Prolactin levels are elevated by food, sleep, exercise, coitus, nipple stimulation, physical examination, lactation, and many medications. Acromegaly may present with oligo- or amenorrhea and an elevated somatomedin-C (IGF-1). Diabetes may present as oligo- or amenorrhea due to reduced GnRH drive. Amenorrhea and anovulation associated with Cushing syndrome and disease is also due to reduced GnRH drive.

While the cause of FHA is stress, the increase in cortisol secretion in FHA is less than that seen with Cushing's syndrome and disease and the circadian pattern is preserved, so the cortisol increase is highest overnight and in the early morning hours (Berga *et al.*, 1989; Michopoulos *et al.*, 2013b). If Cushing's is suspected, a 24-h urinary free cortisol (UFC) is a reasonable screening test. Rarely secondary adrenal insufficiency presents as fatigue and anovulation. Serum dehydroandrosterone sulfate (DHEAS) will be in the lower range for age. The differential diagnosis of low normal DHEAS includes Sheehan's syndrome with partial or complete pituitary apoplexy. Provocative stimulation testing helps to establish pituitary hypofunction due to injury, tumor, autoimmune hypophysitis, or other CNS conditions. History is essential for elaborating the differential diagnosis and guiding the evaluation.

MRI of the pituitary and the brain should be considered to exclude or confirm serious CNS conditions (Lowry *et al.*, 1996). A history of trauma should raise the index of suspicion to include pituitary stalk damage. The differential diagnosis of central lesions and conditions is extensive. A high index of suspicion and a low threshold for obtaining a MRI or other relevant neuroimaging is recommended.

Certain medications and drugs of abuse suppress GnRH drive or cause other endocrine perturbations. Chronic drug use is often a marker of stress and undernutrition. An evaluation for syndromal psychiatric conditions such as eating disorders, depression, and personality disorders is critical. Formal psychiatric evaluation may be indicated. Psychiatric conditions are associated with activation of the hypothalamic–pituitary–adrenal axis and appropriate treatment may reverse the functional suppression of GnRH drive. Paradoxically, stress often drives individuals to take drugs and medications that alone may suppress GnRH drive. Opioid use is both mechanistically and clinically linked to suppression of GnRH and the development of hypothalamic hypogonadism in both men and women (Daniell, 2008). Psychotropics induce hyperprolactinemia which secondarily suppresses GnRH drive (Ajmal *et al.*, 2014). Marijuana and alcohol have been linked to inhibition of GnRH drive (Rettori *et al.*, 2010). Exercise and dietary restrictions and excesses also gate GnRH drive. In short, medications, drugs, lifestyle adjustments initiated in response to psychological stress may interact synergistically to suppress ovarian function. If the root cause for substance use and abuse is stress, then clearly the management must involve stress as well as addiction management. The suppression of GnRH by a variety of stresses can be blocked by CRH antagonists, suggesting a pivotal role for endogenous CRH (Li *et al.*, 2010; Michopoulos *et al.*, 2013a).

Pathophysiology

Functional hypothalamic amenorrhea is more than an isolated disruption of GnRH drive. Functional suppression of GnRH is universally accompanied by increased cortisol secretion due to increased hypothalamic–pituitary CRH-ACTH drive and reduced thyroxine (T4) and thyroxine (T3) due to decreased hypothalamic–pituitary TRH-TSH input. The constellation of neuroendocrine alterations characteristic of FHA reflects altered feedback sensitivity to estradiol, cortisol, and thyroxine. Other feedback sensitivities may be altered, including leptin and ghrelin signaling. Increased circulating and CSF cortisol levels are specific to FHA (Berga *et al.*, 1997; Brundu *et al.*, 2006). Many of the clinical consequences of FHA such as osteoporosis reflect the clinical impact of the full constellation of neuroendocrine aberrations that accompany FHA (Berga *et al.*, 1989; Brundu *et al.*, 2006).

Reduced GnRH input decreases circulating LH and FSH to levels too low to fully support folliculogenesis to the point of ovulatory adequacy. Amenorrhea is the most clinically recognizable manifestation of reduced GnRH and occurs when there is sustained suppression of GnRH pulsatility to $<50\%$ of expected (Berga *et al.*, 1989). Because the suppression of GnRH exists on a spectrum, so too does the clinical presentation. More clinically occult forms result from intermittent suppression of GnRH that causes partial folliculogenesis that manifests as anovulatory cycling or luteal insufficiency. In luteal insufficiency, there is embryo-endometrial asynchrony that impairs or prevents implantation. The patient may present with infertility with regular menstrual cycle intervals rather than with more clinically recognizable oligo- or amenorrhea. To complicate recognition, FHA and PCOS may coexist. The following clinical presentations may be due to functional insufficiency of GnRH drive: complete anovulation and amenorrhea, hypermenorrhea with short menstrual intervals, oligomenorrhea with long cycle intervals, menometrorrhagia, and eumenorrheic infertility. Men can also develop functional hypothalamic hypogonadism due to insufficient GnRH drive that results in oligoasthenospermia with or without reduced testosterone levels (Berga, 1997).

Risk factors for the development and persistence of FHA include any factors that chronically activate the HPA axis and commonly include greater energy expenditure than intake, excessive exercise, nutritional restriction of protein and fats, unrealistic expectations of self and others, attitudes that increase reactivity to common and uncommon stressors including perfectionism, high need for social approval, and conditional love (Berga and Girton, 1989; Giles and Berga, 1993; Marcus *et al.*, 2001). We found that the endocrine impact of stressors is synergistic rather than additive (Williams *et al.*, 2007; Berga, 2008; Sanders *et al.*, 2017). We also demonstrated that addressing problematic attitudes and behaviors using cognitive behavior therapy (CBT) not only restored ovarian function (Berga *et al.*, 2003) but also reduced cortisol levels (Berga *et al.*, 1997; Berga and Loucks, 2006; Michopoulos *et al.*, 2013b). Recovery from FHA included amelioration of hypothalamic hypothyroidism and an increase in leptin levels independent of weight gain (Michopoulos *et al.*, 2013b). These data underscore the tight link between metabolic and reproductive function (**Fig. 1**).

Acute and Chronic Health Consequences

Many of the health consequences linked to FHA are likely due to the combined alterations in metabolism, neuroendocrine function, and anovulation (Michopoulos *et al.*, 2013b). Health conditions that accrue from chronic FHA putatively include osteoporosis, syndromal psychiatric conditions, and infertility. Longer-term health consequences may include an increased risk of cardiovascular diseases (Bairey Merz *et al.*, 2003) and neurodegenerative diseases due to persistent stress and hypercortisolism (Brundu *et al.*, 2006). Treatment of osteoporosis with bisphosphonates in women intending to become pregnant is discouraged because the bisphosphonates incorporate into maternal bone and can then be mobilized during pregnancy and incorporated into

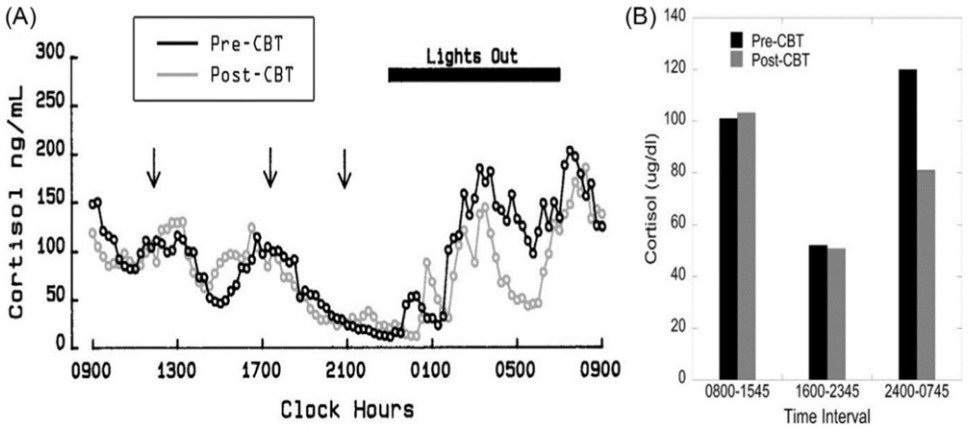

Fig. 1 (A) Circulatory cortisol concentrations (ng/mL) in 15 min intervals over 24 h in a woman with FHA before (pre) and after (post) CBT (cognitive behavior therapy). Meals are indicated by arrows. (B) Circulatory concentrations of cortisol displayed as 8-h mean in the same woman before (pre) and after (post) CBT (Michopoulos *et al.*, 2013b).

fetal bone. Hormone replacement regimens also have limitations and may not permit full bone accretion because glucocorticoids abrogate the impact of estrogens by competing for transcriptional coactivators and interfering with estrogen action (Whirledge *et al.*, 2013; Gordon *et al.*, 2017). There is no reason to assume that chronic stress is benign or that hormone replacement regimens can fully counteract the clinical impact of chronic stress or fully reverse the constellation of neuroendocrine aberrations that accompany FHA.

Management

As the term functional implies, functional hypothalamic amenorrhea improves or even remits altogether when the allostatic load is reduced. Thus, when all other causes of FHA have been excluded, stress management is indicated. The goal of treatment is to identify and reduce the neuroendocrine impact of stressors. Amelioration of FHA requires that stressors are identifiable and manageable or that they spontaneously cease. Appropriate management of stress has been shown to ameliorate hypothalamic hypercortisolism and reverse concomitant neuroendocrine adaptations (Berga *et al.*, 2003; Berga and Loucks, 2006; Berga, 2008; Michopoulos *et al.*, 2013b). Since stress is an inevitable consequence of living, psychoeducation about how to manage typical and specific stressors is more practical than trying to avoid stressors. Our research indicates that stressors are multiple and seemingly personal or minor yet interact synergistically to elicit FHA. For practical purposes, stressors are often categorized as metabolic in which energy expenditure exceeds energy intake and psychogenic or behavioral which alter energy intake or expenditure because of cognitions and attitudes but the neuroendocrine cascade that follows is similar regardless of the behavioral antecedents (Berga, 2008). Psychogenic stressors reflect cognitive expectations and often present as unrealistic attitudes that compromise coping with daily demands that are to some extent externally imposed. Typically, individuals with FHA report a combination of both metabolic and psychogenic variables (Berga and Girton, 1989; Giles and Berga, 1993; Marcus *et al.*, 2001) that we have shown interact synergistically (Williams *et al.*, 2007; Berga, 2008) to induce chronic hypothalamic hypogonadism.

Women with FHA often display greater neurobiological reactivity to stressors than individuals who are ovulatory and presumably are more stress-resilient. Metabolic stressors such as exercise and nutritional restriction are often undertaken to reduce psychological stress and yet have to potential to serve independently as metabolic or even psychogenic stressors. We found that exercise elicited a greater rise in cortisol in FHA than ovulatory women that was attributed to a drop in circulating glucose during exercise in FHA that was not observed in eumenorrheic, ovulatory women who instead showed a rise in circulating glucose during exercise (Sanders *et al.*, 2017). We acknowledge that what is stressful to one individual may be less so to another due to personal valences and underlying neurobiological reactivity. Identifying stressful attitudes and behaviors and teaching better coping styles has been shown to reduce the neuroendocrine impact of stressors (Berga *et al.*, 2003; Berga and Loucks, 2006) and results not only in a decrease in cortisol, particularly during sleep, but also an increase in TSH and leptin independent of weight gain (Michopoulos *et al.*, 2013b).

Stress management can be undertaken before or concurrently with other interventions, including infertility therapy. In our pilot study, 75% of women with FHA randomized to cognitive behavior therapy (CBT) designed to address problematic attitudes and behaviors regained ovulatory ovarian function whereas only 25% of those randomized to observation did (Berga *et al.*, 2003; Michopoulos *et al.*, 2013b). Clomiphene citrate is less effective in eliciting an increase in FSH release if the cause of anovulation is hypothalamic hypogonadism because of reduced feedback sensitivity to hypoestrogenism. The efficacy of aromatase inhibitors has not been studied in women with FHA. While antidepressants reduce hypercortisolemia in those with depression and PTSD, their use for treatment of FHA has not been studied. It is important to screen for syndromal psychiatric disorders, particularly eating disorders, and refer individuals so identified to appropriate psychiatric care.

The Endocrine Society recently published a clinical practice guideline on FHA that comprehensively addressed therapeutic options (Gordon *et al.*, 2017). The authors concluded that oral contraceptive pills should not be used for the sole purpose of improving bone mineral density and patients who do use oral contraceptive pills should be cautioned that their use may not prevent ongoing bone loss. A meta-analysis included in the clinical practice guideline reported that there were no reliable data examining the relationship between hormone use and bone fractures and very limited data on their impact on bone density in women with FHA. The authors concluded it is unlikely that hormone use will improve bone density or foster bone accretion in women with FHA because ongoing hypercortisolism, hypothyroidism, and undernutrition places women with FHA in a catabolic rather than anabolic state. As noted earlier, bisphosphonates should not be used in women intending to become pregnant as they may become incorporated into the fetal skeleton. Further, there are good data demonstrating that cortisol directly interferes with estrogen action (Whirledge *et al.*, 2013; Whirledge and Cidlowski, 2017). Since there are no data to suggest that instituting hormone therapy for other indications is harmful and women with FHA may spontaneously recover, those wishing to avoid pregnancy should use some form of birth control. However, hormonal contraception may not confer the same benefits such as cardioprotection as touted for eumetabolic women and hormone use should not be expected to reverse the metabolic impact of stress. The situation is similar for vitamin and nutrient supplementation. Regardless of menstrual status, women need sufficient dietary calcium intake and vitamin D levels. However, neither exogenous vitamin D nor increased calcium intake will overcome the hypoestrogenism and catabolism induced by chronic stress.

Women with FHA often seek treatment for infertility. However, clomiphene and letrozole may prove ineffective as the hypothalamic GnRH drive is suppressed by mechanisms other than estradiol feedback inhibition and antagonizing estradiol action does not lead to increased GnRH drive. In our recent Endocrine Society clinical practice guideline on FHA (Gordon *et al.*,

2017), we recommended exogenous pulsatile GnRH be offered for ovulation induction because the approach is more physiological and more likely to result in monofollicular development and less likely to result in multiple gestation than is the use of injectable gonadotropins (Martin *et al.*, 1993). However, many patients with FHA undergo gonadotropin therapy and assisted reproductive therapies (ART) to treat the infertility associated with FHA. The pros and cons of these approaches are open to debate. The risks are many, including multiple gestation and high expense. At the very least, women with low body mass index should not be treated for infertility. In our recent Endocrine Society clinical practice guideline on FHA (Gordon *et al.*, 2017), we recommended a minimum BMI of 18.5 kg/m^2, however, we also noted that women with a BMI < 20 kg/m^2 have a fourfold higher risk of preterm labor (ESHRE Capri Workshop Group, 2006) and the infants have lower birth weights (Koubaa *et al.*, 2005). Therefore, we recommended that clinicians limit ovulation induction to women of satisfactory body weight. Independent of weight, potential maternal and fetal consequences of ongoing maternal stress and undernutrition include preterm labor (Moutquin, 2003), intrauterine growth restriction (Koubaa *et al.*, 2005), and fetal neurodevelopmental disorders such as learning disabilities and autism spectrum disorders. ART is likely to increase, rather than decrease, metabolic and psychogenic stress. Indeed, controlled ovarian hyperstimulation with gonadotropins has been demonstrated to increase TSH levels and presumably metabolic demand due to associated with multiple folliculogenesis associated with ovarian hyperstimulation (Muller *et al.*, 2000). Women conceiving by ART had a greater increase in TSH earlier in gestation, indicating a greater need for thyroxine early in gestation (Alexander *et al.*, 2004). Thus, ART may amplify the neuroendocrine consequences of preexisting stress, exposing oocytes, the mother, and the fetus to persistent neuroendocrine aberrations including lower thyroxine and higher cortisol levels. Since the mother is the sole source of thyroxine in the first trimester and since thyroxine is critical for fetal neuronal migration and differentiation (Lavado-Autric *et al.*, 2003; Ausó *et al.*, 2004), fetal neurodevelopment may be compromised (Glinoer, 1997). Further, even intermittent hypercortisolemia may accelerate placental aging as indicated by telomere shortening (Menon *et al.*, 2012) and induce epigenetic changes in fetal DNA. Ultimately, the consequences of these exposures may be to potentiate the fetal origins of adult disease.

Conclusions

Functional hypothalamic amenorrhea (FHA) is a reversible form of anovulation that is not due to organic causes. While the proximate cause is insufficient GnRH drive, FHA is more than an isolated reduction in GnRH. Behavioral and psychological factors such as undernutrition, excessive exercise, and unrealistic cognitions serve as stressors that elicit hypothalamic hypercortisolism and a cascade of neuroendocrine adaptations including hypothalamic hypothyroidism. The neuroendocrine constellation conserves and diverts energy to perceived challenges and thereby promotes short-term survival at the expense of longer-term health. Behavioral interventions such as cognitive behavior therapy that address problematic attitudes and behaviors reduce hypothalamic hypercortisolism and restore ovulatory eumenorrhea. Hormonal therapies offer less promise but contraception should be offered for those wishing not to conceive as spontaneous recovery of ovulation precedes menses. Infertility treatment should be undertaken with caution. The role of psychotropic medications has not been appropriately studied. Because of the many health consequences of chronic stress and hypoestrogenism, women with FHA should be closely followed by an appropriate team of physicians and other health care providers. FHA is a prototypic example of psychoneuroendocrinology and illustrates how cognitions and emotions drive behaviors that eventuate in neuroendocrine allostasis.

Polycystic Ovary Syndrome☆

Stephen Franks, Imperial College, London, United Kingdom and Hammersmith Hospital, London, United Kingdom

Glossary

Polycystic ovaries The characteristic morphological features of polycystic ovaries are multiple antral follicles and increased stroma. Typically, polycystic ovaries hypersecrete androgens.

Polycystic ovary syndrome Clinical and endocrine abnormalities—typically manifestations of anovulation and hyperandrogenism—associated with polycystic ovaries.

Introduction

Polycystic ovary syndrome (PCOS) is the commonest endocrine disorder in women, accounting for the majority cases of anovulatory infertility and of hirsutism (Jayasena and Franks, 2014). Polycystic ovary syndrome is heterogeneous in its presentation and this has resulted in some discussion about how to define PCOS. The classic definition includes the association of anovulatory menses (or estrogen-replete amenorrhoea) with clinical and/or biochemical evidence of excess androgen secretion. Using this definition, the estimated prevalence of PCOS is in excess of 5% of the female population of reproductive age. The range of clinical presentation of women with polycystic ovaries—as defined by pelvic ultrasonography—is, however, wide. It includes patients with anovulation who are non-hirsute and those with hirsutism who have regular menstrual cycles. Indeed, polycystic ovaries are found in over 80% of women who would otherwise have been labeled as having "idiopathic hirsutism". Acknowledgement of the broad spectrum of presenting features in women with PCOS led to reappraisal of the accepted diagnostic criteria at a consensus conference in Rotterdam (2003) featuring experts representing the European Society for Human Reproduction and Embryology (ESHRE) and the American Society for Reproductive Medicine (ASRM) (Rotterdam, 2004). The resulting "Rotterdam Criteria" for diagnosis of PCOS require the presence two of three features: (1) oligo- or anovulation, (2) clinical and/or biochemical hyperandrogenism, and (3) polycystic ovarian morphology. The results of ultrasound studies of "normal" populations suggest that polycystic ovaries are present in about 20% of women of reproductive age. The cause(s) of polycystic ovaries (PCO) and PCOS are not known for certain but there is strong evidence for a major genetic contribution as will be discussed in section "Genetic Studies of PCOS."

In addition to the reproductive consequences of the syndrome, PCOS is characterized by a metabolic disorder (amplified by obesity) in which hyperinsulinemia and peripheral insulin resistance are the central features (Jayasena and Franks, 2014). This metabolic dysfunction may play a part in the etiology of anovulation but also has important implications for long-term health. Women with PCOS are two to four times more likely to develop type 2 diabetes mellitus (T2D) in later life and carry risk factors for development of cardiovascular disease (although there is currently no firm evidence of an increase in cardiovascular events).

Endocrine Abnormalities in PCOS

The major endocrine abnormalities in women with PCOS are elevated serum concentrations of androgens and luteinizing hormone (LH) and, particularly in those with the classic definition of PCOS (i.e., including menstrual disturbances). Women with PCOS are relatively more insulin resistant (with compensatory hyperinsulinaemia) than normal subjects, a distinction that is amplified by obesity.

Hypersecretion of Androgens

The most common biochemical abnormality in women with polycystic ovaries is hypersecretion of androgens. The ovary appears to be the predominant source of excess androgen production although many studies have pointed to evidence for an additional adrenal abnormality. Nevertheless, the ovary is clearly the more important contributor to hyperandrogenemia because suppression of LH in women with PCOS leads to a fall of androgen concentrations to levels which are indistinguishable from those in menopausal or oophorectomized women. Cultured thecal cells from women with polycystic ovaries, regardless of presenting symptoms, produce some 20 times more androstenedione in primary culture than do cells from women with normal ovaries. Increased steroidogenic activity is, however, not confined to androgen production. All stages of the steroidogenic pathway—including progesterone production—appear to be amplified in PCO theca. These results have been confirmed in subsequent studies, using theca cells from PCO and normal theca which had undergone several passages in culture and retained the phenotype.

This article is an update of Barry Donesky, Polycystic Ovary Syndrome (PCOS), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 1–3.

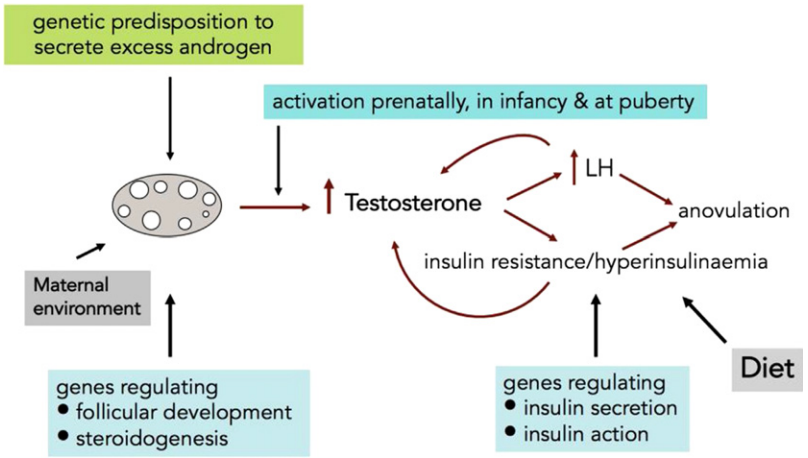

Fig. 1 Proposed developmental etiology of PCOS. It is suggested that the ovary is genetically predisposed to hypersecrete androgens, perhaps as early as intrauterine life but certainly during the activation of the hypothalamic-pituitary-ovarian axis that occurs transiently in infancy and in a sustained manner at puberty. Higher than normal circulating levels of testosterone "program" the hypothalamic-pituitary unit to produce high tonic levels of LH, and also amplify the physiological insulin resistance of puberty. Higher than normal concentrations of LH and insulin further enhance ovarian androgen production and may contribute to the mechanism of anovulation. The maternal environment, particularly metabolic dysfunction associated with obesity, may also play a part. Adapted from Franks, S. (2008). Polycystic ovary syndrome in adolescents. *International Journal of Obesity(Lond)* **32**, 1035–1041.

Androgen Programming and the Etiology of PCOS

We have proposed that PCOS has its origins in early life and that the polycystic ovary is genetically predisposed to hypersecrete androgens, certainly at puberty but possibly also in the early postnatal period or even during fetal development (Fig. 1). It is unlikely that maternal androgen excess affects fetal exposure to androgen because high circulating concentrations of sex hormone-binding globulin (SHBG) and placental aromatase activity provide an effective barrier between mother and fetus. Using evidence from studies in the prenatally androgenized (PA) rhesus monkey or sheep, we put forward the hypothesis that increased exposure to androgens during development leads to the abnormalities of endocrine and metabolic function that are characteristic of PCOS. The PA rhesus monkey, during adulthood displays abnormal ovarian morphology, ovarian hyperandrogenism (and adrenal androgen excess), hypersecretion of LH, insulin resistance and anovulation in relation to increased body weight. Studies to date in the PA sheep have yielded similar findings with respect to reproductive and metabolic sequelae. We suggest that, in human PCOS, the source of excess androgen is the ovary which may be activated during fetal life, during the "mini-puberty" of infancy or during puberty itself. The genes that may be involved in excess ovarian androgen production remain to be determined. Genes that affect insulin secretion and action have been well described but their role in glucose/insulin homeostasis in PCOS remains speculative (Fig. 1).

Metabolic Abnormalities in PCOS

In recent years, there has been a great deal of interest in the metabolic associations of PCOS (Jayasena and Franks, 2014). The classic syndrome is characterized by a distinctive form of insulin resistance. Women with PCOS have higher fasting and glucose-stimulated insulin concentrations and significantly reduced insulin sensitivity compared with weight-matched control subjects. The cause of this abnormality is unclear but clinical and laboratory-based studies in PCOS have variously pointed to abnormalities of insulin receptor binding, or more plausibly, post-receptor signaling as well as to evidence for a primary abnormality of insulin secretion. It has been demonstrated that weight reduction in obese women with PCOS results in normalization of insulin sensitivity but "first-phase" insulin secretion in response to an intravenous glucose challenge remains abnormal. These data also illustrate an important principle in understanding the etiology of PCOS which is that whatever the genetic basis for the syndrome, the phenotype can be influenced by environmental (in this case nutritional) factors. Women with PCOS are at increased risk of long health problems related to insulin resistance, including gestational diabetes (GDM), impaired glucose tolerance and type 2 diabetes (T2D) (see "Management" section below). Obesity greatly amplifies the metabolic abnormalities in PCOS and further increases the risk not only of diabetes but also of non-alcoholic fatty liver disease (NAFLD) and of sleep apnea.

Ovarian Follicular Abnormalities in PCOS

A further phenotypic feature of PCOS is the polycystic ovarian morphology itself. The polycystic ovary is characterized by the presence of an increased number not only of antral follicles but also of early growing and larger preantral follicles. Since these earlier stages of follicular development are thought to be largely independent of gonadotrophins, the implication is that local ovarian factors may have a role in genesis of the polycystic ovary (Franks *et al.*, 2008). Many growth factors have been shown to have an influence on early follicular development, including those of the transforming growth factor beta (TGFβ) superfamily and growth factors signaling through tyrosine kinase coupled receptors such as the type 1insulin-like growth receptor (IGFR-1). Indeed, results of recent studies of mouse preantral follicles in culture indicate that androgens have a direct stimulatory effect on growth and that this effect is due, at least in part, to interaction with TGFβ growth factors (Laird *et al.*, 2017).

Anovulation in PCOS is characterized by arrested development of medium sized antral follicles. Granulosa cells from these follicles display evidence of premature responsiveness to LH and increased steroidogenesis (indicative of advanced differentiation) compared with similar-sized follicles from normal ovaries. The reasons for these differences are not yet entirely clear but granulosa cells of small antral follicles from polycystic ovaries exhibit premature responsiveness to LH and this may be related to the characteristic hyperinsulinemia of PCOS, since insulin can greatly enhance the response of the granulosa cell to LH (Franks *et al.*, 2008).

Genetic Studies of PCOS

The important contribution of genetic factors in the genesis of androgen excess and etiology of PCOS is clear, with evidence of hereditability of both endocrine (including serum testosterone levels) and metabolic indices. Despite obvious candidate pathways, case-control association studies have yielded few, if any, robust candidates for susceptibility loci, and that has led to the recent interest in genome-wide association studies (GWAS). The first large scale GWAS was performed in Han Chinese women and intriguingly, significant signals have emerged at loci close to the genes on chromosome 2 coding for the gonadotropin receptors LHCGR and FSHR (Chen *et al.*, 2011). Subsequent GWAS studies in women from East Asia and in those of European origin have shown loci that are in common with the Chinese study, as well as novel loci, notably that close to the gene coding for the β subunit of FSH (Hayes *et al.*, 2015; Day *et al.*, 2015).

Clinical Management Issues

Diagnosis of PCOS

The diagnosis of PCOS is reached primarily on a clinical basis. A patient presenting with irregular menses, oligomenorrhoea or amenorrhoea and who has signs of hyperandrogenism is very likely to have PCOS. Even in the absence of hirsutism, PCOS is the most likely cause of these menstrual symptoms (it accounts for about 30% of cases of amenorrhoea overall and about 90% of amenorrhoeic women with normal estrogen levels).

The majority of patients presenting with hirsutism have polycystic ovaries, irrespective of menstrual history. Much rarer but more serious causes of hirsutism and menstrual disturbances include Cushing's disease, acromegaly, hyperprolactinemia, and tumors of the adrenal or ovary. In such cases, however, there are usually other clues, both clinical and biochemical, to the diagnosis for example, short history of increasing hirsutism and significantly raised serum testosterone (>5 nmol/L). For this reason, serum testosterone should be measured in all hirsute patients as a screening test to exclude more serious causes of hyperandrogenism. Late-onset ("non-classical") congenital adrenal hyperplasia due to 21-hydroxylase deficiency may be difficult to distinguish clinically from PCOS but it is debatable whether this makes much practical difference to management of symptoms. In our clinic, where the prevalence of non-classical 21-hydroxylase deficiency is $<5\%$, measurement of 17-alpha-hydroxyprogesterone (the biochemical marker of 21-hydroxlyase deficiency) is not performed routinely. However, its measurement is recommended in most currently available clinical guidelines.

No single test is diagnostic of the syndrome and choice of investigations should be tailored to the clinical presentation. Serum LH levels are typically elevated in PCOS (FSH is normal) but up to 50% of women with all other clinical and biochemical features of the syndrome may have normal serum LH. Measurement of LH is therefore of limited diagnostic value; it is quite specific—raised LH and normal FSH essentially occur only in PCOS—but it is not very sensitive. Pelvic ultrasonography will define the polycystic ovarian morphology but accurate assessment of the ovaries by ultrasound is a particular skill so that false negative results are not uncommon. Conversely, the presence of polycystic ovaries does not necessarily mean that the patient has polycystic ovary syndrome. Polycystic ovaries may be found coincidentally in women who have, for example, hypothalamic, estrogen-deficient amenorrhea. Anti-Müllerian hormone (AMH) is produced by the granulosa cells of the ovary, predominantly from small antral follicles and serum levels of AMH show a close correlation with antral follicle count (AFC) on ultrasound. Measurement of AMH has therefore been suggested as a surrogate of AFC in the diagnosis of PCOS but the range of serum AMH levels in women with or without PCOS is wide and its usefulness as a diagnostic test for PCOS remains in doubt.

In summary, pelvic ultrasonography and measurements of LH, FSH and testosterone may be of some diagnostic value when set in the appropriate clinical context. Routine measurements of adrenal androgens are not indicated. Measurement of sex hormone-binding globulin (which is affected by body weight) is recommended (to allow calculation of the free androgen index) in the diagnosis of hyperandrogenism when total testosterone is normal. Because of the increased risk of T2DM it is recommended that overweight and obese women with PCOS should have an oral glucose tolerance test (to identify impaired glucose tolerance as well as frank diabetes) on presentation and, if negative, at least once every 2 years thereafter. Also, in view of the associated dyslipidemia, it is advisable to check the serum lipid and lipoprotein profile at the same time.

Management

Since the physiological basis of PCOS is unknown, treatment is largely symptomatic. Patients with anovulation may require induction of ovulation (ESHRE Capri Workshop, 2012). The antiestrogen, clomiphene is usually effective but even this "simple" treatment should be monitored at a specialist center because of the risk of ovarian hyperstimulation and multiple pregnancy. Recent studies show that the use of the aromatase inhibitor, letrozole, is an effective alternative to clomiphene for induction of ovulation in PCOS. The effect of both clomiphene and letrozole is to raise endogenous levels of FSH. That may be enough to trigger an ovulatory cycle but in women who do respond to either of these oral agents, the use of low-dose, exogenous FSH is safe and effective, if carefully monitored. For those not concerned about fertility, menstrual regulation by means of the oral contraceptive or cyclical progestagens should be considered. Non-androgenic progestagens (e.g., desogestrel, gestodene) are obviously preferable to norgestrel and norethisterone in women who may anyway have symptoms of androgen excess.

Symptoms of hyperandrogenism can be managed by antiandrogens such as cyproterone acetate or spironolactone. In women with acne, mild or moderate hirsutism, this can usually be given be given in the form of co-cyprindiol (Dianette: cyproterone acetate 2 mg + ethinylestradiol 35 mg). Cosmetic advice about removal of hair should not be forgotten, whether or not antiandrogens are given.

Obese subjects with PCOS require particular attention. It has been clearly demonstrated that calorie restriction in obese women with PCOS improves insulin sensitivity and glucose tolerance. It also leads to resumption of spontaneous ovulatory cycles and normal fertility in many subjects. Significantly, such improvements in glucose-insulin homeostasis and reproductive function can be achieved with weight reduction of as little as 5% of the initial body weight. Insulin-sensitizing drugs may also have a role in reducing the risk of diabetes and improving ovarian function. The thiazolidinediones (TZDs) are insulin sensitizing drugs which have been introduced primarily for the control of type 2 diabetes. They may be effective in improving insulin sensitivity but there are serious concerns about their safety in pregnancy and are best avoided in women of reproductive age. Metformin is a well-established medication in management of type 2 diabetes. Its mechanism of action is complex but its effects include reduction of IR and insulin levels. Studies in women with PCOS have suggested that this may be a safe and effective means of improving the metabolic profile and reproductive function in both lean and obese women with PCOS. Results so far have been encouraging but by no means conclusive. What is clear is that metformin alone is associated with a low chance of pregnancy (live birth rate 7%) and adds no advantage to clomiphene therapy for induction of ovulation.

Exercise is complementary to calorie restriction in management of overweight or obese women with PCOS (Domecq *et al.*, 2013). Indeed, exercise has been shown to improve both reproductive and metabolic function although we lack large, prospective studies of long-term efficacy.

Summary

PCOS is clinically and biochemically heterogeneous the major endocrine hallmark is hyperandrogenemia and whilst it is clear that hypersecretion of adrenal androgens may contribute to the hyperandrogenemia of women with polycystic ovary syndrome, the weight of evidence favors the ovary as the major source of excess androgen secretion.

Recent studies of the genetic susceptibility to PCOS using GWAS have highlighted new, and sometimes unexpected, loci which are already providing novel insight into the etiology of PCOS. An international consortium of key centers across the globe has been established with the aim of coordinating and consolidating data from several large cohorts of women with PCOS and providing further targets for improved diagnostic and therapeutic measures in PCOS.

From the viewpoint of clinical management, the major issues relate to correction of infertility, menstrual disturbance and hirsutism. The metabolic abnormalities in PCOS have implications both for management of anovulatory infertility and of the increased risk of T2DM in later life. Diet and lifestyle measures are very important in overweight subjects but insulin-sensitizing agents may also have an important part to play in management both of anovulation and of metabolic consequences of PCOS.

Polycystic Ovary Syndrome: Implications for Cardiovascular, Endometrial, and Breast Disease

The polycystic ovary syndrome (PCOS) is among the most common endocrine and metabolic disorders in premenopausal women, with frequencies in the 5–15% range (Yildiz *et al.*, 2012). Even though PCOS is considered mainly an androgen excess disorder nowadays (Azziz *et al.*, 2009), mounting evidence suggests that its consequences exceed largely the classic cutaneous and reproductive manifestations of hyperandrogenism. To this regards, PCOS is associated with almost all known cardiovascular risk factors and may influence the risk of gynecological cancer.

Cardiovascular Disease

Sexual dimorphism in cardiovascular disease, derived from the marked differences in body fat distribution in men and women, has been known for decades (Nedungadi and Clegg, 2009). Adult men show a predominantly central and visceral accumulation of body fat, as opposed to the more subcutaneous and peripheral fat deposition characteristic of premenopausal women (Borruel *et al.*, 2013).

Women with PCOS, on the contrary, show increased global adiposity and a masculinized pattern of body fat distribution characterized by visceral and abdominal deposition of adipose tissue (Borruel *et al.*, 2013). Recent evidence suggests that the effects of androgen excess on body fat distribution are accompanied by effects on the function of adipose tissue. The patterns of gene expression and protein abundance of subcutaneous and visceral adipose tissue of obese women with PCOS resembled that of obese men instead of being similar to that of control obese women in recent transcriptomics and protemics studies (Martinez-Garcia *et al.*, 2013; Montes-Nieto *et al.*, 2013). Hence, the androgen excess characteristic of PCOS may result in masculinization of body fat distribution and function.

We have recently proposed that a vicious circle underlies the pathogenesis of PCOS, especially when associated with obesity. This vicious circle would consist of androgen excess favoring masculinization of body fat distribution and adipose tissue dysfunction. The latter may stimulate androgen secretion by direct endocrine effects of inflammatory mediators and adipokines secreted by dysfunctional adipose tissue on the ovaries and the adrenals, or indirectly by the facilitation of insulin resistance and compensatory hyperinsulinemia (Escobar-Morreale and San Millan, 2007).

Importantly, all the steps in this vicious circle may contribute to the well-known clustering of cardiovascular risk factors in women with PCOS (Wild *et al.*, 2010). Among others, PCOS may be associated with visceral adiposity, low grade chronic inflammation, obesity, metabolic syndrome, type 2 diabetes, dyslipidemia, and abnormal blood pressure profiles (Wild *et al.*, 2010). Moreover, subclinical markers of atherosclerosis such as increased carotid intima-media thickness (Luque-Ramirez *et al.*, 2007) or coronary artery calcification (Talbott *et al.*, 2004) are also associated with PCOS. However, definite proof that these associations result into actual cardiovascular disease is still lacking (Wild *et al.*, 2010; Schmidt *et al.*, 2011) since large longitudinal prospective studies addressing the future occurrence of cardiovascular events in well characterized women with PCOS are definitely needed. Nevertheless, it must be highlighted that many patients with PCOS, especially when weight excess is absent, show no cardiovascular risk factors or metabolic dysfunction.

Considering the possible association of PCOS with cardiovascular risk factors and subclinical atherosclerotic disease current guidelines recommend assessing cardiovascular risk in certain patients with PCOS and treating modifiable risk factors as early as possible (Wild *et al.*, 2010). The Androgen Excess and PCOS Society guidelines (Wild *et al.*, 2010) consider *at risk* for cardiovascular disease patients with PCOS who are obese or show abdominal adiposity, smoke, have hypertension, dyslipidemia, subclinical vascular disease, impaired glucose tolerance or family history of premature cardiovascular disease, and at high risk those who meet criteria for the metabolic syndrome, type 2 diabetes or overt vascular or renal disease.

Accordingly, women with PCOS must be assessed for assessed for abdominal adiposity and hypertension by measuring waist circumference and blood pressure at every visit and, at least in obese patients, screening for lipid and glucose tolerance abnormalities should be considered every 2 years by obtaining a complete lipid profile and a standard oral glucose tolerance test (Wild *et al.*, 2010).

Considering that women with PCOS may be exposed to cardiovascular risk factors for many years, primary cardiovascular prevention should include aggressive treatment of cardiovascular risk factors by means of life-style modification programs, lipid

and blood pressure lowering drugs and insulin sensitizers such as metformin and, in selected cases presenting with severe obesity, bariatric surgery (Wild *et al.*, 2010; Escobar-Morreale *et al.*, 2005).

Endometrial Cancer

The theoretical basis for the association of polycystic ovary syndrome with endometrial cancer derives from the prolonged exposure of the endometrium to estrogens, in the absence of the protective effects of cyclic exposure to progesterone resulting from the oligoovulation characteristic of this disorder. This association was suggested by small observational studies and has been confirmed nowadays not only by epidemiological studies but also by meta-analyses. A recent Danish cohort study found an almost four-fold increase in the risk of endometrial cancer in patients with PCOS (Gottschau *et al.*, 2015). Such a risk was confirmed in a recent meta-analysis of 5 studies, including 138 patients with PCOS and 5593 controls, that showed that PCOS associated a 2.8 odds ratio (95% confidence interval 1.3–6.0) for endometrial cancer, a figure that increased to 4.1 (95% confidence interval 2.4–6.8) in women under 54 years old (Barry *et al.*, 2014). However, this meta-analysis showed evidence of publication bias favoring studies reporting the aforementioned association, casting doubt about its strength (Barry *et al.*, 2014). Nevertheless, considering the possible negative consequences for the health of patients with PCOS, current guidelines strongly recommend avoidance of prolonged severe menstrual dysfunction in these women by means of treatment with hormonal contraceptives or cyclic progestin administration (Conway *et al.*, 2014).

Breast Cancer

The possibility that women with PCOS could be at increased risk for breast cancer arises from their subfertility since younger age at first pregnancy, larger number of pregnancies and breast feeding are among protective mechanisms against this gynecological cancer in the general population (Layde *et al.*, 1989). However, a recent meta-analysis of 3 studies (Barry *et al.*, 2014), including 529 patients with PCOS and 39795 controls showed no evidence of increased risk for breast cancer in the former (0.95 odds ratio, 95% confidence interval 0.6–1.4), even when restricting the analysis to women under 54 years old (0.8 odds ratio, 95% confidence interval 0.5–1.3). Hence, women with PCOS should follow the same recommendations made for the general population regarding the prevention of breast cancer.

Ovarian Androgen-Producing Tumors☆

Michael DiMattina, Dominion Fertility, Arlington, VA, United States
Callum Potts, Inova Fairfax Hospital, Falls Church, VA, United States

Glossary

Androgen A steroid hormone which produces masculinizing features. Androgens include testosterone, androstenedione, and dehydroepiandrosterone.
Crystals of Reinke Rod-shaped crystalline structures sometimes seen in the cytoplasm of Leydig cells, their presence helps confirm the diagnosis of a Leydig cell tumor or hyperplasia.
Cushingoid features Clinical features that resemble Cushing syndrome related to excess cortisol production, these include round "moon" facies, adipose deposits on the back of the neck "buffalo hump," central obesity, and abdominal striae.
Hilus of the ovary The anatomic center of the ovary.
Hysterectomy The surgical removal of the uterus.
Oophorectomy The surgical removal of the ovary.
Ovarian stroma The tissue that surrounds the ovarian follicles and comprises the bulk of the ovary. Ovarian androgens are normally produced by the stroma.
Selective venous catheterization A radiologic procedure that involves placement of catheters into an organ's venous system for blood sampling.
Virilization The appearance of secondary male sexual characteristics; in a woman this will include enlargement of the clitoris, increased acne and hair growth on the face and chest, male-type balding, as well as an increased propensity for acne.

Introduction

Androgen-producing tumors of the ovary represent $<1\%$ of all ovarian neoplasms. Their dramatic clinical presentation reflects the effect of acute increases in ovarian androgen production.

Clinical Presentation

The key feature in the clinical presentation of patients with androgen-producing ovarian tumors is the rapid onset of androgenic signs. Features include dermatologic changes with acne, oily skin, and menstrual irregularities leading to amenorrhea. Frank masculinization and virilization follow soon thereafter, with clitoromegaly, increased muscle bulk, temporal balding, decreased breast size, and deepening of the voice. This clinical presentation can occur within weeks or months. This is in marked contrast to conditions such as polycystic ovarian syndrome or congenital adrenal hyperplasia that is associated with chronic elevations of androgen production, resulting in menstrual irregularities and androgenic symptoms that develop gradually over years. However, patients with androgen-producing tumors may also present without these characteristic signs, instead presenting with pelvic pain, a pelvic mass, or abnormal uterine bleeding.

Classification of Androgen-Producing Ovarian Neoplasms

Androgen-producing ovarian neoplasms may be classified as either functional (the tumor itself secretes androgen) or nonfunctional (the mechanical pressure from the tumor triggers increased androgen production from the surrounding stroma) (Table 1). Functional tumors include Sertoli–Leydig cell tumors (formerly called arrhenoblastomas); Leydig cell, hilus cell, and lipoid cell tumors; granulosa–theca cell tumors; gynandroblastomas (in which both granulosa and Leydig cell elements exist); and luteomas of pregnancy. In addition to androgen secretion, functional tumors may also produce other steroids, including estrogen, progesterone, and cortisol. Many of these tumors respond to hormonal suppression with oral contraceptives and dexamethasone, and they may respond to gonadotropin-releasing hormone agonists and antagonists. Nonfunctional ovarian androgen-producing tumors include benign epithelial serous or mucinous cystadenomas, cystadenocarcinomas, and Brenner and Krukenberg tumors.

Sertoli–Leydig Cell Tumors

Sertoli–Leydig cell tumors (SLCTs) are the most common of the functional ovarian androgen-producing tumors. The reported incidence of androgenic symptoms in patients with SLCTs is 38%–62%. Therefore the gross tumor morphology does not always

☆*Change History:* September 2017. Michael DiMattina and Callum Potts updated the text of the entire article and added information to "Sertoli–Leydig Cell Tumors" and "Diagnosing Androgen-Producing Ovarian Tumors," with additional references.

 doi:10.1016/B978-0-12-801238-3.03904-0

Table 1 Ovarian androgen-producing tumors

Functional	*Nonfunctional*
Sertoli–Leydig cell	Serous cystadenoma
Leydig cell	Mucinous cystadenoma
Hilus cell	Cystadenocarcinoma
Lipoid cell	Brenner
Granulosa–Theca cell	Krukenberg
Gynandroblastomas	
Luteoma of pregnancy	

correlate with functional or clinical pathology. In Young and Scully's review, patients' ages ranged from 4 to 67 years, with 72% in their twenties or thirties. Almost all tumors were unilateral, with sizes ranging from 9 to 25 cm. Cohen reported a patient with a very small SLCT of only 0.8 cm, but this is unusual. In Young and Scully's report, hyperandrogenic manifestations lasted from 6 months to 4 years before surgical removal. Serum testosterone levels ranged from 4.9 to 13.4 nmol/L.

Prognosis and treatment modalities are controversial because these tumors are rare and only a few studies have been published. SLCTs are classified as malignant sex cord-stromal tumors. In a series of 207 cases of SLCTs, Young and Scully reported a good correlation between pathologic differentiation and clinical outcome at FIGO stage I disease. Well-differentiated tumors behaved clinically benign, whereas 59% of poorly differentiated tumors were malignant. In tumor stage II and higher, mortality increased to 100%. Ovarian rupture had a negative impact at stage I; 7% of unruptured vs. 30% of ruptured tumors displayed malignant behavior.

Therapies for SLCTs depend on the stage, the presence or absence of rupture, and the differentiation of the tumor, as well as the patient's age and desire for preservation of fertility. In women who have completed their childbearing, hysterectomy with bilateral salpingo-oophorectomy is generally considered appropriate treatment. In young women with stage I disease, unilateral salpingo-oophorectomy is usually advised. Beyond stage I, more aggressive surgical and medical therapy is required. Hillemanns reported successful conservative management of a 17-year-old nulligravid patient using surgical excision of the SLCT without oophorectomy. Such management is reserved only for young women of low parity with stage I, well-differentiated disease, with no ovarian rupture and negative peritoneal washings.

The benefit of adjuvant chemotherapy is uncertain, but may be considered in patients with poorly differentiated or advanced stage tumors. Common regimens include BEP (bleomycin, etoposide, and cisplatin) or, more recently, paclitaxel and carboplatin. Radiotherapy has also been rarely reported as an adjunct in patients with poor prognosis or disease recurrence.

Other Functional Tumors

Leydig and hilus cell tumors are mostly composed of Leydig cells. They are usually small tumors, unilateral, occur postmenopausally, and secrete testosterone. The pathognomonic feature is crystals of Reinke. The term hilus cell tumor describes tumors localized to the hilus of the ovary. These tumors are not generally malignant, and in some cases they will be histologically classified as Leydig cell hyperplasia.

Lipoid cell tumors are larger than Leydig cell tumors and usually occur in premenopausal women. They do not contain crystals of Reinke. In addition to androgen, other steroids (e.g., estrogen, progesterone, and cortisol) can be secreted, producing Cushingoid features.

Granulosa cell tumors and thecomas, which usually secrete estrogen, may occasionally produce androgens. A pure thecoma that only produced testosterone and no estrogen, and that was also gonadotropin sensitive, has been reported.

Luteomas of pregnancy are nonneoplastic ovarian androgen-producing tumors that only occur in pregnant women. They can be unilateral or bilateral solid ovarian tumors. They are usually not palpable, asymptomatic, and found incidentally at time of cesarean section or postpartum tubal ligation. These benign tumors regress spontaneously after pregnancy, with no adverse effect on the mother's health or her future fertility. Given the challenges of accurate ultrasound diagnosis during pregnancy, MRI may be considered. Not all luteomas cause maternal virilization, but if the mother is virilized, female offspring can also be affected.

Diagnosing Ovarian Androgen-Producing Tumors

The first step is to determine tumor localization to either the ovary or the adrenal glands. No androgen is exclusively produced by the ovary. In general, testosterone serves as the best marker for ovarian androgen activity. Dehydroepiandrosterone sulfate (DHEAS), produced almost exclusively by the adrenal gland, is the best serum marker for adrenal androgen activity. Total serum testosterone levels >6.9 nmol/L denote abnormal ovarian androgen activity, and ovarian androgen-producing tumors are often found to have testosterone levels at least three times the upper normal limit. In postmenopausal women, testosterone levels >3.5 nmol/L may be abnormal. Frequent sampling of serum testosterone may be necessary due to episodic variation in

testosterone secretion and assay and tumor characteristics. DHEAS levels >27 μmol/L suggest adrenal disease. Dynamic endocrine testing has little clinical usefulness. It is important to emphasize that all virilized patients require evaluation, regardless of their serum testosterone levels.

Vaginal ultrasound is the preferred radiologic method for detecting ovarian tumors. Tumors as small as 0.5 cm can be localized using ultrasound. Color Doppler techniques may further determine tumor blood flow characteristics. Computerized tomography and magnetic resonance scans are better utilized for adrenal imaging, though may also be useful to better characterize ovarian masses. Even with the availability of high-grade imaging technology, many of the ovarian tumors cannot be localized due to their very small size. There may still be a role for selective venous catheterization in diagnosing and localizing very small tumors in difficult cases, however, even this is not universally effective in localization. Definitive diagnosis sometimes requires oophorectomy in appropriately selected patients. Due to their rarity misclassification is possible, with approximately one-third of diagnoses being reclassified after consensus review.

Increasing experience with genetic and genomic tools may allow for more accurate diagnosis, classification, prognosis, and management of ovarian androgen-producing tumors. Sertoli–Leydig cell tumors are recognized as part of the *DICER1* syndrome, an inherited disorder also classically found to involve pleuropulmonary blastoma and thyroid carcinoma. Up to 60% of Sertoli–Leydig cell tumors have been found to involve mutations in the *DICER1* gene. Further investigation into specific molecular markers is warranted.

Sport and Menses

Angelica Lindén Hirschberg, Karolinska Institute, Stockholm, Sweden and Karolinska University Hospital, Stockholm, Sweden

Glossary

Anovulation Lack of ovulation.
Delayed menarche No menstruation by age 16.
Delayed puberty in a girl No pubertal sign by age 13.
Hirsutism Increased body hair of male type.
Hyperandrogenism Increased androgen production with associated symptoms.
Oligomenorrhea Irregular menstruation with intervals of 6–12 weeks.
Primary amenorrhea Spontaneous menstruation has never occurred.
Secondary amenorrhea Absence of menstruation for at least 3 consecutive months.
Virilization Masculinization of the body including increased muscle mass and body hair, deepening of the voice, breast atrophy and clitoromegaly.

There is clear evidence that regular physical activity has positive physical and mental health effects in both women and men. It is therefore worrying that the average physical activity level in the Western population has gradually declined. More and more people become physically inactive, that is, have sedentary employment and do not exercise in their spare time. At the same time, there has been a dramatic increase in the proportion of women who engage in sports at all levels in recent decades. The increase of female athletes is also reflected in Olympic sports with an increasing proportion of women as participants. At the summer Olympics in Munich in 1972, 15% of the participants were women. In London 2012, the proportion was 44% and this was the first Olympics in which women competed in all sports in the program. The increase of women at the elite level shows a positive trend that can hopefully lead to increased physical activity for the entire population. However, we have also gained knowledge that sports women may be at greater risk of medical complications, including menstrual disorders, loss of bone mass, and musculoskeletal injury.

Athletic Amenorrhea—Functional Hypothalamic Amenorrhea

In the late 1970s, an increased prevalence of menstrual disorders in female athletes was first reported (Loucks and Horvath, 1985). This finding and subsequent investigations gave rise to the term "athletic amenorrhea," that is, loss of menstruation due to intense physical exercise. Athletic amenorrhea can be either primary (spontaneous menstruation has never occurred) or secondary (absence of menstruation for at least three consecutive months). The estimated prevalence of secondary amenorrhea in the general population is 2%–5% (Bachmann and Kemmann, 1982). In comparison, the prevalence of athletic amenorrhea has been reported to range from 6% to 69% depending on the type of sport, age, and definition (Nattiv *et al.*, 2007). The sports with highest occurrence of athletic amenorrhea are those in which a lean body composition is regarded an advantage for physical performance, such as esthetic or endurance sports, for example, gymnastics and long-distance running. Leanness is also of critical importance for effective performance in events involving weight classes, for example, wrestling, boxing, and martial arts and gravity opposing events such as the high jump and pole vaulting. However, the frequency of menstrual disorders may be underestimated, since mild disorders with luteal phase defects and ovulatory disturbances also have been demonstrated in athletes and these disturbances often are asymptomatic and thereby not clinically detected (De Souza *et al.*, 1998).

High intensity training at an early age could affect pubertal development adversely, including a delay of growth and menarche (Warren, 1980; Abraham *et al.*, 1982; Baxter-Jones *et al.*, 1994). Delayed puberty in girls is defined as no pubertal signs by age 13 and delayed menarche is defined as no menstruation by age 16. The incidence of delayed puberty differs between sport disciplines, but is particularly common in gymnasts and ballet dancers. Some studies suggest that a genetically dependent delay in pubertal development leads to a selection bias to some disciplines such as gymnastics due to desirable physique characteristics related to delayed puberty. This would overestimate the rate of pubertal delay seen in these disciplines. However, a break from exercise due to for instance injury often results in a rapid catch-up in pubertal development, indicating that environmental factors also play a role.

Endocrine Disturbances

Athletic amenorrhea is a functional disturbance attributed to inhibition of the hypothalamic–pituitary–gonadal (HPG) axis, that is, functional hypothalamic amenorrhea, which leads to a disruption of the pulsatile release of gonadotropin-releasing hormone (GnRH). This in turn causes a reduced secretion of luteinizing hormone (LH) and follicle stimulating hormone (FSH) resulting in

a low production of sex steroids, including estradiol, progesterone, and testosterone from the ovaries with ensuing anovulation and amenorrhea (Loucks *et al.*, 1989; **Fig. 1**).

Several mechanisms are involved in the inhibition of the HPG axis in female athletes. There is evidence of exercise-induced activation of the hypothalamic–pituitary–adrenal axis with increased release of stress hormones, including cortisol from the adrenal glands (Loucks *et al.*, 1989). In the normal case, cortisol increases acutely in response to physical activity to mobilize energy such as glucose and then the levels normalize at rest. In female athletes, however, chronic elevation of cortisol has been associated with increased blood glucose levels, low body fat, and amenorrhea (Lindholm *et al.*, 1995). The increased cortisol levels indicate catabolic metabolism and adaptation to negative energy balance and are probably a manifestation of a general activation of the stress response, which also includes increased secretion of corticotropin-releasing hormone (CRH) from the hypothalamus

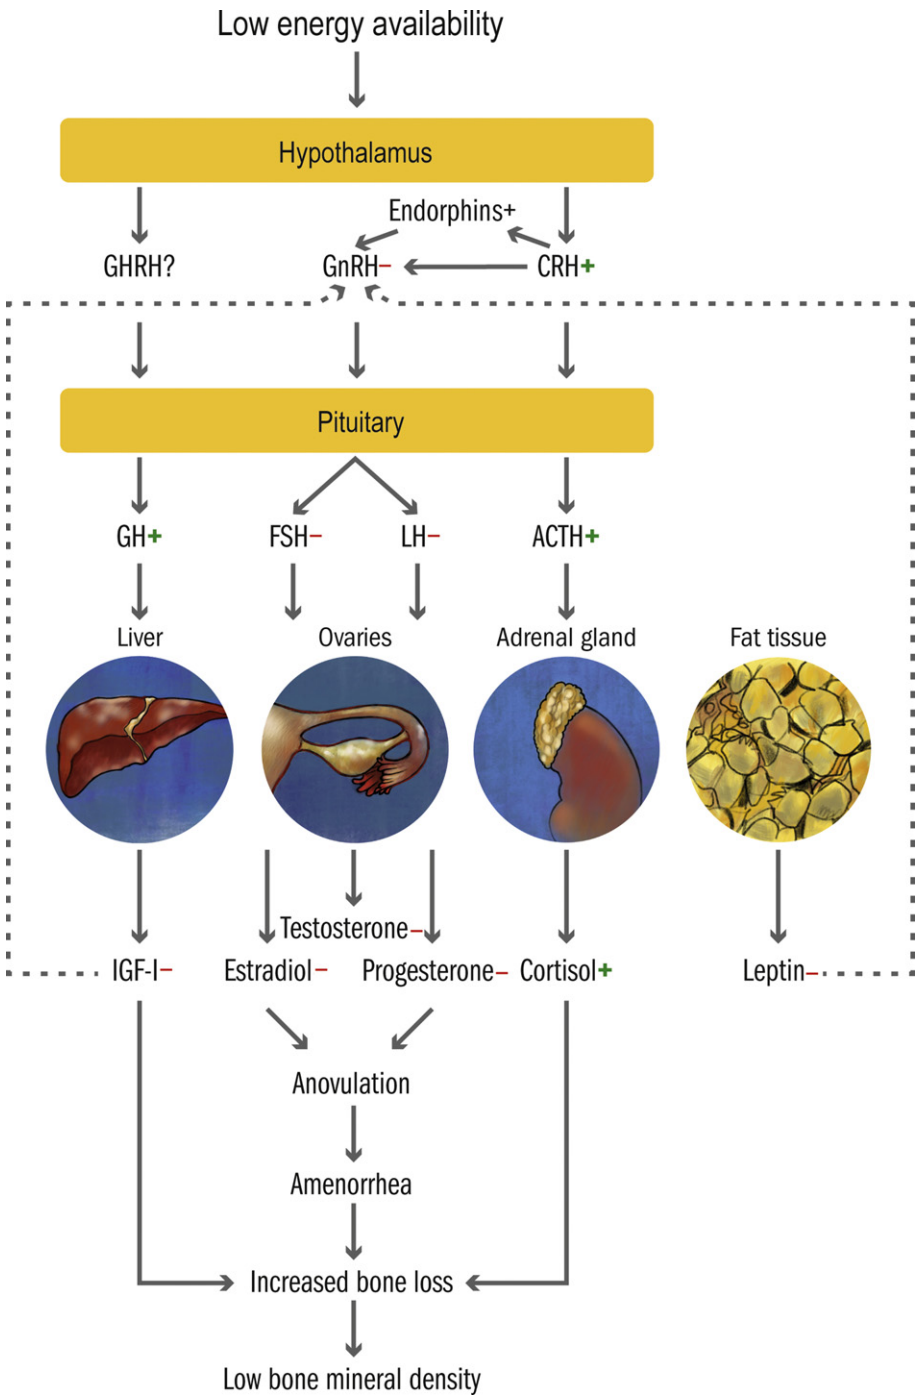

Fig. 1 A summary of endocrine disturbances associated with athletic amenorrhea. For explanations and abbreviations, see the accompanying text.

(Fig. 1). CRH has an inhibitory effect on GnRH secretion in hypothalamus. Endorphins, released in response to physical activity, might also inhibit GnRH secretion in the hypothalamus in concert with CRH (Barbarino *et al.*, 1989).

A hypometabolic state in athletes is furthermore reflected by low levels of insulin and insulin-like growth factor I (IGF-I) and high levels of growth hormone and IGF binding protein (Laughlin and Yen, 1996; Rickenlund *et al.*, 2010). IGF-I, which is secreted from the liver, is an anabolic hormone of importance for muscle and skeletal growth. Because IGF-I also stimulates GnRH and LH release, decreased IGF-I activity may reduce LH secretion in amenorrheic athletes (Fig. 1).

Leptin is another marker of energy availability. This hormone, produced in adipocytes, is an independent regulator of metabolism and levels are positively associated with body fat mass. Leptin is furthermore an important link between nutritional status and reproductive capacity. The exact mechanism is not known, however leptin receptors in hypothalamic neurons indicate that the hormone is engaged in the pulsatile secretion of GnRH. There are also leptin receptors in the ovary suggesting a direct regulatory effect on estrogen production. Leptin levels are markedly reduced in amenorrheic athletes (Laughlin and Yen, 1997; Fig. 1). Thyroid hormones are also considered as markers of energy balance and low levels of thyroxin (T4) and triiodothyronine (T3) are observed in female athletes with functional amenorrhea (Loucks *et al.*, 1992).

Taken together, athletic amenorrhea can be explained by central inhibition of the reproductive system by stress hormones and endorphins, and by reduced stimulation of GnRH due to low levels of IGF-I and leptin.

Low Energy Availability and Disordered Eating

It is today understood that the most important cause for athletic amenorrhea is low energy availability due to failure to ingest adequate energy in relation to energy expenditure (Loucks *et al.*, 1998; Loucks and Thuma, 2003). The intense physical training necessary for top athletic achievement requires a high-energy output that many athletes do not match with a corresponding caloric intake. Recent advances have therefore led to the understanding that many sportswomen are chronically energy deficient.

The reasons for this common discrepancy between energy intake and output include the difficulties involved in eating and digesting large portions of food alongside a demanding training program, and poor knowledge about energy and nutritional requirements. Another problem for athletes is that biological feedback mechanisms for energy balance are unreliable. For example, appetite does not necessarily reflect the caloric deficit induced by an intense training session (Truswell, 2001). However, a more common cause of energy deficiency is a conscious pursuit of leanness (Hagmar *et al.*, 2008), that is, a relatively low amount of body fat in relation to muscle mass, which is an important factor in sports performance in many disciplines. These include endurance sports such as long-distance running and cycling as well as sports that overcome gravity, such as high jump. A low body weight or body fat content is also often an advantage in sports that are divided into weight classes, such as wrestling, boxing, and martial arts, or in sports with esthetic considerations, such as gymnastics and figure skating. These sports are the same as those with the highest incidence of athletic amenorrhea.

Eating Disorders

Female athletes have an increased risk of developing eating disorders compared with nonathletes and male athletes (Sundgot-Borgen, 1993; Beals and Hill, 2006; Sundgot-Borgen and Torstveit, 2010). Besides optimizing body composition for performance, some female athletes are also under the pressure to attain an appealing appearance. This is particularly true for athletes in esthetic disciplines, such as gymnastics and figure skating, but is becoming increasingly important in many other disciplines, due to scrutinizing media coverage and the importance of sponsorship. Disordered eating in athletes may advance along a continuous scale ranging from a normal but often strictly controlled food intake to a disturbed eating behavior that meets the diagnostic criteria for any of the eating disorders, such as anorexia nervosa or bulimia nervosa. The prevalence of eating disorders in the general population in young women is about 1% for anorexia nervosa and 2%–5% for bulimia nervosa. In comparison, the prevalence of clinical eating disorders in female athletes has been reported to be about 20% to 30% in adult female elite athletes, and as high as 70% in weight-class sports (Gibbs *et al.*, 2013). However, it should be mentioned that most of these results are based on surveys and not on clinical interviews, and survey data usually yields higher numbers than the actual occurrence. All types of eating disorders are related to menstrual disorders.

Bone Mass

Today it is well-known that long-term amenorrhea and estrogen deficiency are associated with loss of bone mass, particularly of trabecular bone such as the lumbar spine and pelvis (Lambrinoudaki and Papadimitriou, 2010). If the condition remains untreated, it is estimated that the loss of bone mass is approximately 2%–3% per year and there is a risk of irreversible changes of bone mass (Miller *et al.*, 2006). The definition of low bone mineral density (BMD) in a premenopausal woman is a *Z*-score (i.e., standard deviation score of the mean of an age- and sex-matched reference population) lower than 2, whereas osteoporosis in this age group is defined as *Z*-score less than 2 combined with secondary clinical risk factors such as eating disorders, hypogonadism, or previous fracture (Lewiecki *et al.*, 2008). Since physical activity usually stimulates bone formation, low BMD in female athletes

was defined as a *Z*-score between −1.0 and −2.0 SD together with additional risk factors, and osteoporosis as defined earlier (**Fig. 2**; Nattiv *et al.*, 2007). It was initially considered paradoxical that elite athletes could develop reduced bone mass (Warren, 1980; Drinkwater *et al.*, 1984). The mechanism is not entirely clear but has been explained by nutritional deficiency together with its endocrine consequences such as low levels of estradiol and IGF-I and increased levels of cortisol (De Souza *et al.*, 2008).

Mechanisms of Bone Loss

Estrogen is important for bone turnover and acts through specific receptors in bone tissue to prevent bone resorption. Consequently, estrogen deficiency is associated with bone loss due to increased bone resorption (Almeida *et al.*, 2017). Chronic elevation of cortisol can also contribute to increased bone resorption (Tauchmanovà *et al.*, 2007), whereas low levels of IGF-I result in impaired bone formation (Snow *et al.*, 2000). Furthermore, energy deficiency adversely affects bone formation. Thus, even though physical activity usually increases bone mass, the overall result from energy deficiency and a catabolic hormone balance is suppressed bone formation and increased bone resorption resulting in a net loss of bone mass. Women seem to be more vulnerable than men to the consequences of energy deficiency on bone mass (De Souza *et al.*, 2014a,b). One explanation for this could be sex differences in androgen production. Testosterone exerts potent anabolic effects and has direct stimulatory effects on bone tissue (Almeida *et al.*, 2017). Since men have on average more than 10 times higher circulating levels of testosterone than women (Turpeinen *et al.*, 2008), the higher levels of testosterone might be protective against bone loss.

The prevalence of low BMD in female athletes has not been clearly established mainly because of different criteria used to define low BMD and osteoporosis. Furthermore, bone mass could vary depending on athletic population, elite level, and ethnicity. The reported prevalence to date on low BMD ranges from 0% to 40% and 0% to 13% in terms of osteoporosis (Gibbs *et al.*, 2013). In contrast, studies in Swedish female Olympic athletes have consistently shown high BMD and none athlete in these studies has presented low BMD (Hagmar *et al.*, 2009; Eklund *et al.*, 2017).

Athletic amenorrhea is also associated with an increased risk of musculoskeletal injuries (Feingold and Hame, 2006; Barrack *et al.*, 2014). The relative risk of stress fracture, for example, in the lower limb, is two to four times higher in female athletes with amenorrhea compared with regularly menstruating athletes (Bennell *et al.*, 1999). Skeletal damage also includes more severe fractures in the pelvis, hip, and spine with serious long-term consequences. It is well-known that a prior fracture increases the risk of another fracture.

The Female Athlete Triad

The concept of "the female athlete triad" was first described at a consensus conference 1992 organized by the American College of Sports Medicine (ACSM) and defined as the three associated conditions: disordered eating, functional hypothalamic amenorrhea, and osteoporosis (**Fig. 3**; Yeager *et al.*, 1993). A revised position stand was published in 2007 when the triad was redefined as a syndrome linking low energy availability (with or without disordered eating), menstrual

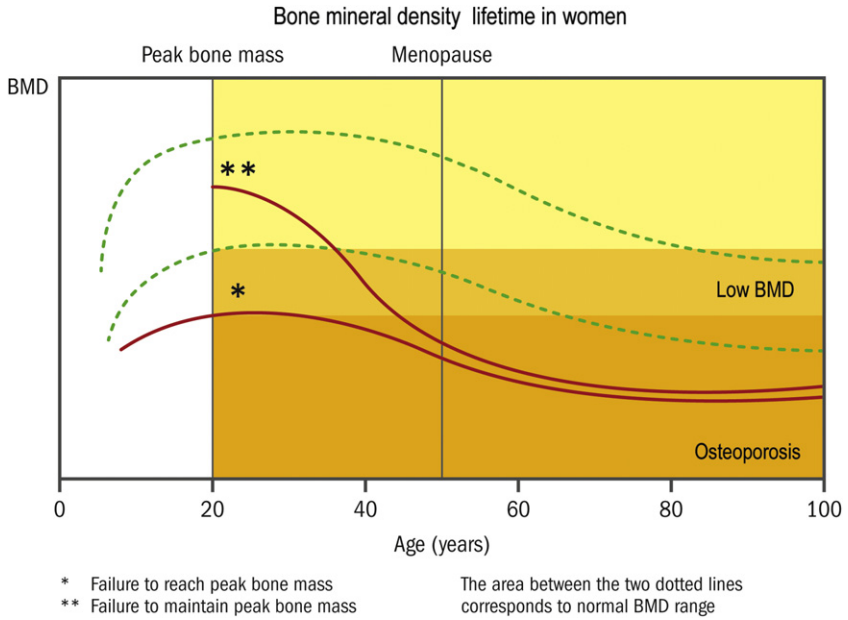

Fig. 2 Changes in bone mass in women during lifetime and the hypothetical consequences of low energy availability and estrogen deficiency.

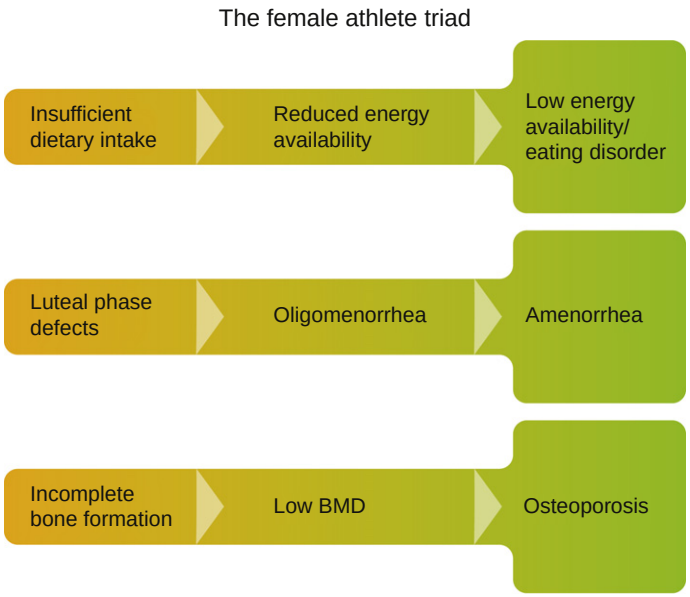

Fig. 3 The three components of the female athlete triad.

dysfunction, and low BMD (Nattiv *et al.*, 2007). It is today well established that energy deficiency plays a causal role in the development of menstrual dysfunction, and that amenorrhea and estrogen deficiency can cause increased loss of bone mass leading to low BMD (De Souza *et al.*, 2014a,b).

The triad has been highlighted as the most serious medical problem in female athletes and is considered most frequent in sports that emphasize leanness. As illustrated in **Fig. 3**, the different entities may present as symptoms along a continuous scale between normality and apparent pathology. Caloric intake and the degree of menstrual disorder may vary according to sport season, and to the amount and quality of training, age, and a variety of physiological and psychological factors. Whereas menstrual disturbances and low energy availability are more variable from time to time, the decline in BMD is slow and may partly be irreversible. The prevalence of the triad is not well documented due to methodological problems and lack of clear definitions of the criteria. However, in a review of in total 65 studies, the prevalence of all three components of the female athlete triad was reported to range from 0% to 16% (Gibbs *et al.*, 2013). In general, the prevalence of low BMD was lower than estimates of menstrual disturbances and disordered eating.

The triad is not limited to reproductive and skeletal outcomes but also to other medical consequences. For instance, amenorrhea and estrogen deficiency in athletes is associated with impaired endothelial function and lipid dysfunction (Rickenlund *et al.*, 2005a). Furthermore, problems with the central nervous system, gastrointestinal system, and renal system have been described (De Souza *et al.*, 2014a,b).

Management of Athletic Amenorrhea

Menstrual dysfunction is a sign of hormonal imbalance that should always be investigated by means of gynecological examination and endocrine evaluation. Athletic amenorrhea is an acquired condition, that is, functional hypothalamic amenorrhea, most often caused by low energy availability with or without disordered eating. This disorder can be normalized including ovulation and thereby fertility once the balance between energy intake and energy expenditure has been restored. An early intervention is essential to prevent from serious clinical consequences such as irreversible bone loss.

The typical clinical appearance is a lean woman with low body weight/body fat. A careful review of eating habits in relation to training is important, and counseling by a dietitian is recommended. In case of suspicion of eating disorders, the individual must be referred to a specialist clinic. Laboratory tests should include measurement of hormones and nutritional factors. The most characteristic endocrine pattern of functional hypothalamic amenorrhea includes suppressed levels of gonadotropins, particularly LH, estradiol, testosterone, IGF-I, and thyroid hormones, whereas cortisol levels could be elevated (Rickenlund *et al.*, 2004a,b). Delayed puberty and/or menarche in an athlete girl should be evaluated by a specialist in pediatrics or gynecological endocrinology.

Longstanding hypothalamic amenorrhea and low energy availability are associated with a loss of bone mass. Dual-energy X-ray absorptiometry (DXA) is the golden standard method for assessment of bone mass and body fat. Indications for a DXA scan include amenorrhea more than 6 months, low body weight/body fat, suspected eating disorder, and prior stress fracture. *Z*-scores for BMD spine and hip are most relevant for evaluation of bone mass. Whole body scan is used for the assessment of body fat.

Nutrition Counseling and Pharmacological Treatment

Adequate nutrition in relation to energy expenditure should always be the first line strategy of intervention (De Souza *et al.*, 2014a, b). Improved energy intake and increased body weight/fat mass have documented effect on restoration of menstrual function in functional hypothalamic amenorrhea (Misra *et al.*, 2008). A gradual increase of 200–600 kcal/day have been recommended (De Souza *et al.*, 2014a,b). In case of low bone mass, supplementation of calcium and vitamin D may also be beneficial. However, weight gain and subsequent resumption of menses are the most important changes to prevent further loss of bone mass.

If there is a lack of response to nutrition counseling and adjustment of training for at least 1 year without resumption of menses, pharmacological treatment should be considered particularly in athletes with osteoporosis and fracture history. However, bisphosphonates are not recommended since this treatment is not approved for use in premenopausal women and there are risks of atypical fractures and osteonecrosis by long-term use. There are conflicting data about to what extent estrogen substitution will restore low BMD in amenorrheic women. Reductions in BMD of amenorrheic athletes have not been fully restored by oral estrogen. This has been explained by a suppressive effect of oral estrogen on hepatic IGF-I production since IGF-I is a bone trophic factor. To overcome the first-passage effect of exogenous estrogen, the transdermal route is recommended (De Souza *et al.*, 2014a, b). Indeed, transdermal estrogen does not suppress IGF-1 and has been demonstrated to improve bone mass in combination with cyclic progesterone/progestogen in adolescent girls with anorexia nervosa (Misra *et al.*, 2011). Addition of progesterone/progestogen to estrogen substitution is necessary to avoid deleterious effects of unopposed estrogen on the endometrium.

Finally, it should be noted that low BMD is not the only indication for estrogen substitution in athletes with longstanding amenorrhea but also because of other symptoms of estrogen deficiency such as endothelial dysfunction, adverse lipid profile, urogenital symptoms, dyspareunia, and sexual dysfunction (Rickenlund *et al.*, 2005b; De Souza *et al.*, 2014a,b).

Hyperandrogenism in Female Athletes

The most common cause of amenorrhea among athletes is probably low energy availability resulting in functional hypothalamic amenorrhea. This condition is acquired and should be reversible by optimal nutrition in relation to energy expenditure. However, not all athletes with menstrual disorders have chronic energy deficiency. Research in the past decade has demonstrated essential hyperandrogenism, such as the polycystic ovary syndrome (PCOS), as an alternative etiology of menstrual disorders in female athletes.

Polycystic Ovary Syndrome

PCOS is probably the most frequent endocrine disorder in women of fertile age, affecting about 10% of the female population (Rosenfield and Ehrmann, 2016). The syndrome is characterized by increased ovarian production of androgens, anovulation, and ultrasound findings of polycystic ovaries (**Fig. 4**). The typical symptoms are oligomenorrhea (menstruations at an interval exceeding 6 weeks) or amenorrhea, hirsutism, and acne. PCOS is also associated with accumulation of abdominal fat and obesity although this is not common in athletes. The etiology of PCOS is largely unknown, but there is strong evidence for a genetic predisposition although environmental factors also play a role.

Hyperandrogenism and insulin resistance are the endocrine cornerstones in the pathogenesis of PCOS explaining the various symptoms of the disorder (Rosenfield and Ehrmann, 2016). There is evidence of a primary abnormality of increased ovarian production of androgens. This production is augmented by disordered feedback control of pulsatile GnRH secretion, resulting in elevated LH secretion and a relative FSH deficiency, which will favor androgen synthesis. The clinical consequences of increased production of androgens are the typical polycystic ovarian morphology, anovulation causing menstrual disorders and reduced fertility, hirsutism, and acne. Women with PCOS also have an increased occurrence of insulin resistance, independent of obesity, leading to secondary hyperinsulinemia. Hypersecretion of insulin directly stimulates androgen production from the ovarian theca cells. Furthermore, insulin inhibits hepatic synthesis of sex hormone-binding globulin (SHBG), and thereby increases free and bioavailable testosterone levels. Thus, hyperinsulinemia contributes to hyperandrogenism and ovarian dysfunction in PCOS women. Insulin resistance may cause metabolic symptoms including abdominal obesity. However, regular physical activity counteracts insulin resistance and is beneficial in PCOS.

It has been demonstrated that PCOS is a common disorder in female elite athletes (Rickenlund *et al.*, 2003; Rickenlund *et al.*, 2004a; Hagmar *et al.*, 2009; Coste *et al.*, 2011; Javed *et al.*, 2015). Endocrine studies have shown enhanced diurnal secretion of LH and testosterone in athletes with PCOS compared to those without (Rickenlund *et al.*, 2004a; **Fig. 5**). Thus, the hormonal profile of PCOS is completely different from that of functional hypothalamic amenorrhea. However, the levels of testosterone in PCOS typically remain within the normal upper range for women and are seldom pathologically increased. Athletes with PCOS also demonstrate a more anabolic body composition with more muscle mass and higher BMD than other athletes (Rickenlund *et al.*, 2003). Hyperandrogenism appears to provide good protection from bone loss despite oligomenorrhea/amenorrhea and relative estrogen deficiency in PCOS.

There are data to support that PCOS is advantageous for physical performance. For instance, endurance athletes with PCOS have shown higher maximal oxygen uptake and performance levels than athletes without PCOS (**Fig. 6**; Rickenlund *et al.*, 2003). It has also been reported that PCOS is overrepresented and is the most frequent cause of menstrual disorders among Olympic sportswomen (Hagmar *et al.*, 2009). These studies suggest that mild forms of hyperandrogenism like PCOS may be beneficial for

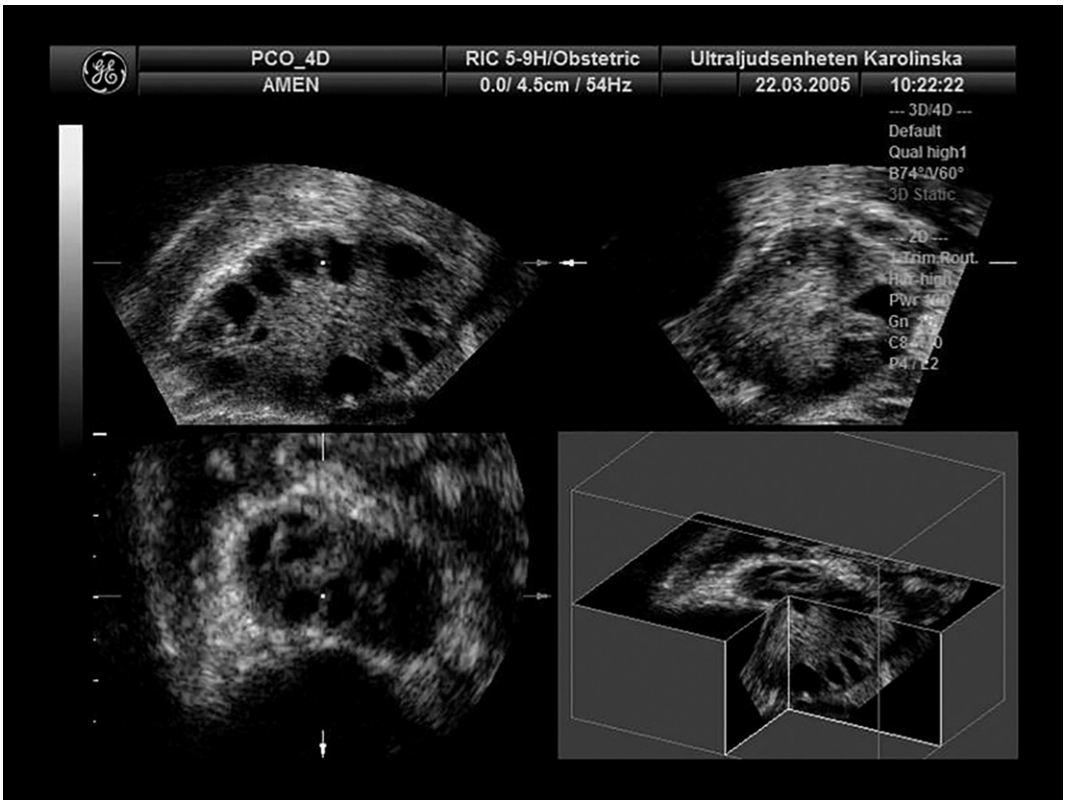

Fig. 4 Ultrasound picture of a typical enlarged polycystic ovary with an increased number of small follicles.

physical performance and could play a role in the recruitment of women to competitive sport activities. There is no support for the opposite, that is, that sport could induce PCOS. Androgen levels even within the normal range seem to play a role for physical performance. Thus, recent studies have shown associations between androgen levels, muscle mass, and physical performance in female top athletes (Eklund *et al.*, 2017).

The performance-enhancing effects of PCOS are likely explained by the anabolic effect of androgens. Testosterone exerts potent anabolic actions by direct stimulation of muscle mass and bone tissue (Mooradian *et al.*, 1987; Almeida *et al.*, 2017). Furthermore, testosterone stimulates the formation of new blood cells and the immune system, and promotes competitive behavior. All these effects of testosterone could be beneficial for physical performance.

Severe Hyperandrogenism

Men have on average more than 10 times higher concentrations of testosterone in the blood as compared to women (Turpeinen *et al.*, 2008), which is likely one reason to sex differences in physical performance. However, a few women are born with rare conditions, named disorders of sex development (DSD) in which the development of chromosomal, gonadal, and anatomic sex is atypical. These conditions may cause a greatly increased production of testosterone in the male range. If the individual has normal sensitivity to androgenic hormones, her muscle mass will develop as in males, along with increasing signs of virilization such as increased body hair, deepening of the voice, breast atrophy, and clitoromegaly.

The prevalence of such rare conditions is estimated to be about 140 times increased among elite female athletes (Bermon *et al.*, 2014). Since sports are divided into male and female classifications, many female athletes consider it unfair if they must compete against a woman who has the advantage of a male physiology. Recently, the International Association of Athletics Federations (IAAF) and the International Olympic Committee (IOC) finalized guidelines for management of hyperandrogenism in female athletes. However, the regulations are controversial and the Court of Arbitration of Sport (CAS) has requested further scientific evidence of the degree of athletic performance advantage sustained by hyperandrogenism in female athletes.

Management of Hyperandrogenism in Athletes

PCOS is a highly heterogeneous disorder, presenting a spectrum of symptoms and manifestations that vary over time. The condition is managed according to symptoms, such as menstrual disorders, infertility, hirsutism, and overweight/obesity but

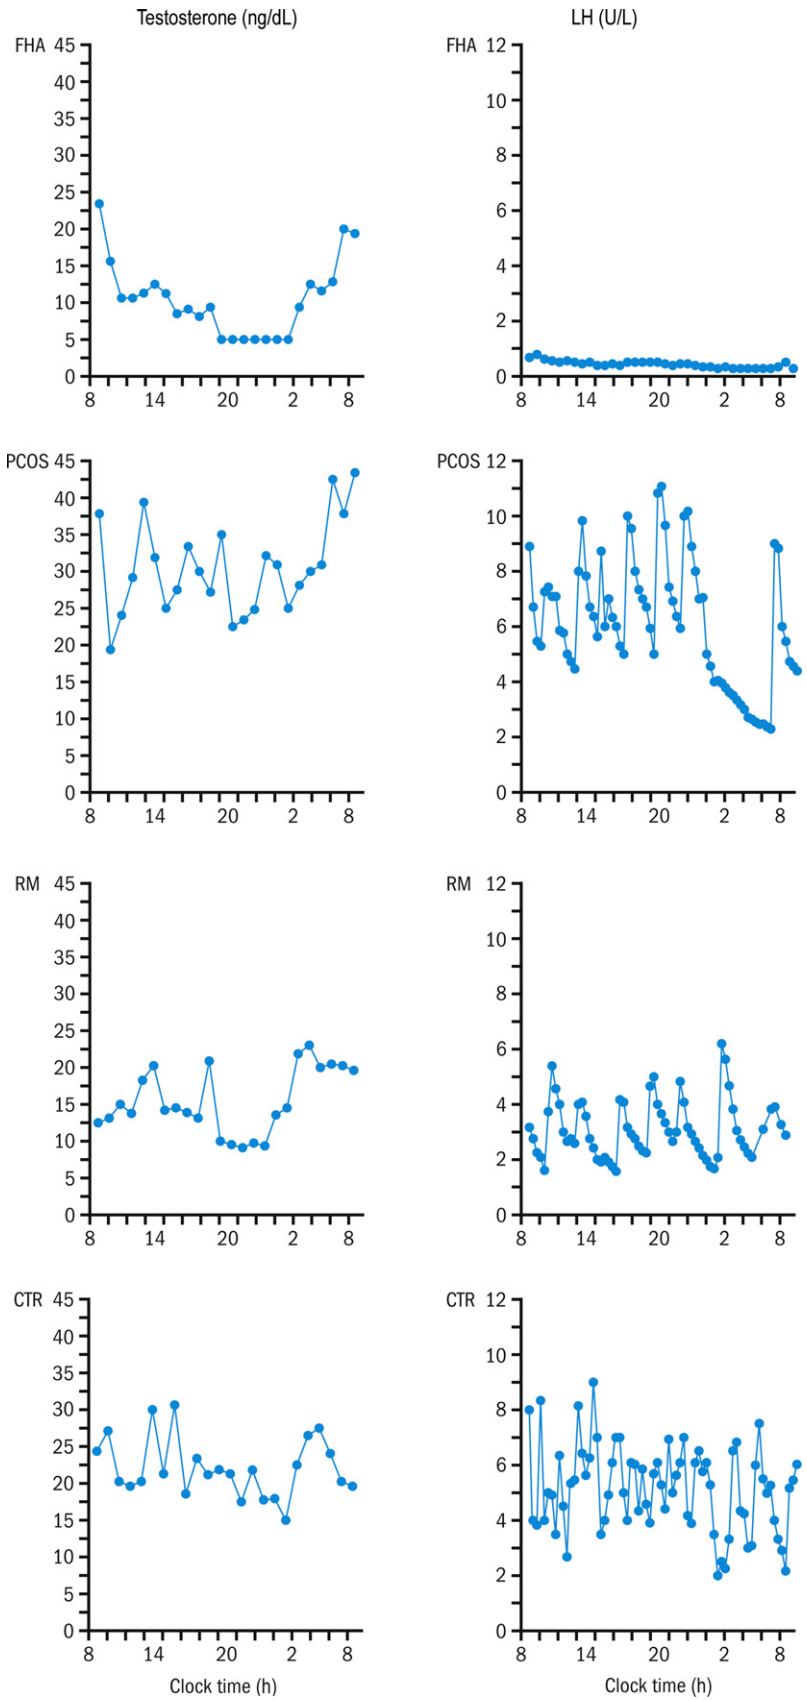

Fig. 5 Typical diurnal hormonal profiles in individual female athletes and a sedentary control woman. *FHA*, athlete with functional hypothalamic amenorrhea; *PCOS*, athlete with polycystic ovary syndrome; *RM*, athlete with regular menstruation; *CTR*, sedentary control.

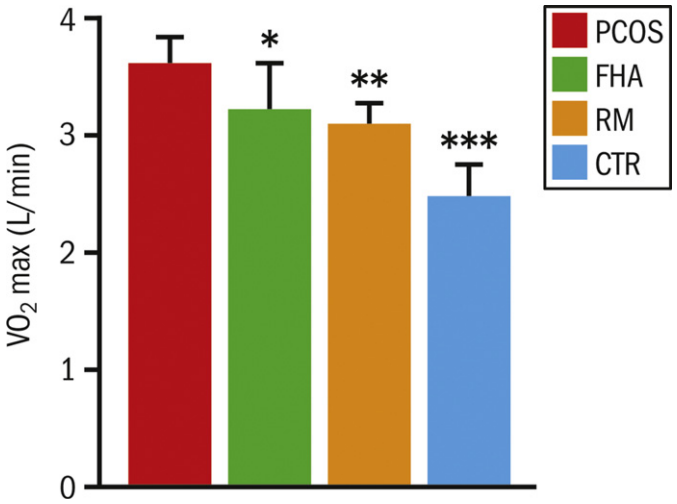

Fig. 6 Maximal oxygen uptake in groups of athletes with polycystic ovary syndrome (PCOS), functional hypothalamic amenorrhea (FHA) and regular menstruation (RM), and in a sedentary control group (CTR).

specific treatment is not always needed. The first choice of strategy to improve symptoms of PCOS in overweight and obese women is change of lifestyle including healthy diets and increased physical activity aiming at weight loss (Moran *et al.*, 2011). There is no support that weight loss improves clinical symptoms in normal-weight women with PCOS, however regular physical activity can be recommended to all women with PCOS. There is evidence that physical activity alone or in combination with dietary changes causes decreased insulin resistance, lower androgen levels, decreased hirsutism, and increased ovulation rate (Moran *et al.*, 2011). The main mechanism for improvement is probably increased insulin sensitivity, resulting in reduced compensatory hypersecretion of insulin, which in turn leads to increased SHBG and thus lower levels of free testosterone.

Longstanding anovulation should be treated due to an increased risk of endometrial hyperplasia and endometrial cancer in PCOS. The mechanism is attributed to lack of progesterone and unopposed estrogen stimulation of the endometrium. Treatment with oral contraceptives or cyclic progestogens abolishes this risk and is used to regulate menstruation. Combined oral contraceptives also inhibit androgenic effects and counteract hirsutism and acne. However, there is no evidence that oral contraceptives impair physical performance, as long as body weight/body composition is stable (Rickenlund *et al.*, 2004b).

Physical activity usually improves fertility in women with PCOS, and in contrast to women with functional hypothalamic amenorrhea, there is no support that reduction or discontinuation of sport training improves reproductive function in athletes with PCOS. For women with PCOS who do not conceive spontaneously, fertility treatment using ovulation stimulation or in vitro fertilization can be offered.

The clinical evaluation and care of women with severe hyperandrogenism like DSD should be managed by a multidisciplinary team at tertiary clinics (Lee *et al.*, 2016). Many of these individuals have already been diagnosed and treated in early childhood due to ambiguous genital development, but in some cases, they might enter puberty undiagnosed. During adolescence, individuals with DSD can present with primary amenorrhea or progressive virilization in a phenotypic girl. The evaluation includes a thorough medical history focusing on hereditary factors, a comprehensive physical examination, ultrasound or magnetic resonance tomography of internal genital organs, karyotyping and specific genetic testing, as well as endocrine evaluation.

Primary Ovarian Insufficiency☆

Luca Persani, University of Milan, Milan, Italy

Nomenclature

MIM: Mendelian Inheritance in Man

Glossary

Primary amenorrhea Absence of menarche.

Secondary amenorrhea Absence of menstruation for at least four consecutive months.

Introduction

Premature ovarian Insufficiency (POI) is the condition of hypergonadotropic hypogonadism due to an anticipated loss of ovarian follicle reserve. It can be associated with primary amenorrhea (PA) or secondary amenorrhea (SA) lasting for >4 months in women before 40 years of age. A serum follicle-stimulating hormone (FSH) level >25 IU/L on two occasions drawn >1 month apart associated with low estradiol defines the hypergonadotropic hypogonadal state (Webber *et al.*, 2016). POI occurs in 1/100 women before the age of 40, in 1/1000 women before the age of 30 and is very rare before menarche in women with a normal karyotype. Turner syndrome (estimated frequency 1:2000 phenotypically females) is the prototype of POI generally associated with PA but also with SA in 20%–25% of the cases. Intermittent or resumptive forms of POI are not so rare (up to 20% of cases) and unexpected pregnancies have also been reported in women with the diagnosis of POI. For this reason, the previous usual terms of premature ovarian failure or premature menopause have been discarded (Gago and Ginsburg, 2004; Beck-Peccoz and Persani, 2006; Goswami and Conway, 2005; Welt, 2008; Nelson, 2009).

The clinical relevance of POI raised exponentially in the last decades because of two main reasons: (a) the frequent postponing of the fertility desire and programmed conception by women beyond their 30–35 years of age; (b) the prolongation of life expectancy.

Clinical Features and Diagnosis

The clinical features include the menstrual irregularities up to amenorrhea, anovulation and infertility, and the manifestations of hypoestrogenism (Goswami and Conway, 2005; Beck-Peccoz and Persani, 2006). The ovarian phenotype can then be associated with several different extra-ovarian clinical manifestations that depend upon the underlying cause or genetic defects.

The follicular depletion before puberty is associated with a pubertal delay, and POI should be suspected in girls that do not go through puberty by the age of 13 years. If untreated, eunuchoidism may develop. In cases with short stature a Turner syndrome should be suspected. Other particular extra-ovarian phenotypes may suggest alternative syndromic forms of POI (**Table 1**) (Persani *et al.*, 2013; Rossetti *et al.*, 2017; Martin *et al.*, 2017). In postpubertal onset, POI is not associated with a characteristic preceding menstrual history. The development of amenorrhea may be acute or it may be insidious. SA is generally accompanied by typical climacteric manifestations (flushes, sweating, vaginal dryness, urogenital manifestations, irritability/anxiety, sleep disorders). Hypoestrogenism is associated with sexual dysfunction and impaired physical performance and may then lead to osteoporosis, and predispose to neurodegenerative and cardiovascular diseases (Nelson, 2009). About one out of four POI cases are probably of autoimmune origin and POI can be part of classic polyglandular autoimmune diseases (PGA). POI can be present in about half of the patients with PGA type 1 caused by *AIRE* mutations and in about 1 out of 10 patients with PGA type 2, in both of these diseases POI is associated with Addison disease. In these cases, the patients have antisteroid cell antibodies (SC-Abs) (La Marca *et al.*, 2010). An autoimmune origin may alternatively be supported by the association of POI with other autoimmune diseases, such as Hashimoto thyroiditis (Welt, 2008; Martin *et al.*, 2017).

Because of the involvement of particular genes, POI women can be predisposed to malignancies (Rossetti *et al.*, 2017). Women with POI have a diminished life expectancy likely due to the increased risk of malignancies, cardiovascular and autoimmune diseases (Goldberg *et al.*, 2015; Tao *et al.*, 2016).

The ESHRE guidelines indicate that diagnosis of POI should be confirmed by AMH determinations and ovarian US (Webber *et al.*, 2016). The low/undetectable levels of AMH and/or absence of preantral follicles at US are indicative of a complete

☆*Change History*: March 2018. Luca Persani rewrote the article of Gago, L.A., Ginsburg, K.A. (2004).

Table 1 Particular phenotypes of POI patients associated with specific gene variations

Genes	*Associated phenotypes*
HSD17B4, *HARS2*, *CLPP*, *LARS2*, *C10ORF2*, *KIAA091*, *ERAL1*	Hearing defects (Perrault syndrome)
POLG	Progressive external ophthalmoplegia and tremor and parkinsonism
FOXL2	Blepharophimosis, ptosis, epicanthus inversus (BPES)
GNAS	Resistance to multiple hormones (PTH, GHRH, LH/FSH, TSH), short stature, short IV metacarpus, overweight
AIRE	Candidiasis, Addison disease
AIRE (mutations in the PHD1 domain), *MCM8*	Hypothyroidism
FMR1 premutation	X-linked mental retardation or tremor-ataxia in relatives
LHCGR	LH elevation higher than FSH, large ovarian follicles present, anovulation
FSHR	Variable presence of small preantral follicles
NR5A1, *SOX8*	DSD (Swyer Syndrome) in male relatives
GALT	Galactosemia
EIF2B	Vanishing white matter (VWM) disease with progressive neurological deterioration
ATM	Ataxia-Teleangiectasia
BMPR1	Dehmiran syndrome
Turner mosaicism	Short stature (cardiac malformations, lymphedema)
GDF9	Recurrent spontaneous dizygotic twinning
BMP15, *MCM9*, *FSHR*, *NUP107*, *PSMC3IP*, *ATM*	46,XX ovarian dysgenesis
BLM, *WRN*, *ANTXR1*	Premature aging syndromes (Bloom syndrome, Werner syndrome, GAPO disease)

exhaustion of the follicular reserve and predict the inefficacy of attempts aimed to retrieve fertilizable oocytes from the affected women. In these cases, oocyte donation is the only solution for the desired fertility. Conversely, detectable AMH levels and preantral follicles indicate the possibility to retrieve fertilizable oocytes.

Causes of POI

The origin of POI is highly heterogeneous. The possible mechanisms at the origin of POI can be: (a) a deficient primordial follicle pool; (b) an accelerated follicular atresia; or (c) a hampered maturation/recruitment of primordial follicles (Gago and Ginsburg, 2004; Persani *et al.*, 2013). However, in most of the cases POI occurs because of a dramatic reduction in the size of the preantral follicular pool. The etiological causes that may activate such mechanisms are highly heterogeneous and include chromosomal, genetic, autoimmune, metabolic, infectious and iatrogenic factors (**Table 2**). At present, about 25% of all forms of POI can be classified as iatrogenic and related to cancer treatment, but >50% of the cases remain idiopathic. The most frequent known cause is therefore iatrogenic and mainly due to chemo- or radio-therapeutic or surgical interventions for cancer in young age. Since the number of cancer survivors is constantly increasing, so is the relevance of fertility preservation in young cancer patients. This phenomenon led to the diffusion of fertility units in cancer centers (Woodruff, 2015). Excessive and long-standing but also passive smoking, pollutants or alcohol addiction can also diminish the fertility potential of women (Ertunc *et al.*, 2015; Grindler *et al.*, 2015). Viral or bacterial infections with a potential gonadal toxicity are generally prevented by vaccination. All the other forms of POI have an autoimmune or genetic origin.

Autoimmune POI

Autoimmune POI can be mainly classified into two groups, the one associated with autoimmune adrenal disease and the one associated with other autoimmune diseases. However, a clear autoimmune ovarian disease can be demonstrated only when POI is found in patients with adrenal autoimmunity or failure, probably due to common antigens between the two glands both constituted by steroidogenic cells. This association was reported in up to 10% of the POI cases (Nelson, 2009; Martin *et al.*, 2017) and can be part of both PGA type 1 and type 2 (Welt, 2008; La Marca *et al.*, 2010). PGA1 is typically manifest since childhood and it is characterized by mucocutaneous candidiasis, hypoparathyroidism and Addison disease and is accompanied by POI in 60% of cases. PGA1 has a known genetic cause, resulting from mutations in the *AIRE* gene that is involved in regulatory T cell development and maturation (Gago and Ginsburg, 2004; Nelson, 2009). PGA2 is defined by adrenal insufficiency and hypothyroidism, and is associated with POI in approximately 10% of cases. SC-Abs and/or enzyme antibodies are present in 60%–90% of POI women with SA and Addison disease. Antibodies can be directed against enzymes common to the ovary and adrenal glands, including cytochrome P450 side-chain cleavage enzyme (P450SCC), 17-α hydroxylase/17,20-lyase (CYP17A1) and 21-hydroxylase (CYP21) enzymes. The most sensitive indicators of adrenal autoimmunity are SC-Abs or CYP21 antibodies. These antibodies represent serological indexes of the autoimmune disease and would lack a pathogenic role. A combination of antibody and cell-

Table 2 Acquired extrinsic and genetic factors accounting for an early age at menopause or POI

Acquired extrinsic factors	*Genetic susceptibility*
Chemo-, radio-therapy (e.g., Hodgkin disease, alkylating drugs, pelvic irradiation), ovariectomy	X chromosome defects (e.g., Turner syndrome and related variants)
Exposition to toxics/disruptors (e.g., heavy and/or long-lasting smoking, passive smoking, alcohol addiction, pollutants, radiations)	Autoimmunity (e.g., Polyglandular Autoimmune Syndromes type 1, 2, 3a)
Ovarian infections	Genetic defects (>50 candidate genes for isolated or complex diseases)

mediated immunity is likely to play a role in ovarian autoimmunity (Martin *et al.*, 2017). In several POI cases, the theca cells of preantral and antral follicles appear to be the main target of the autoimmune process. In these cases, the inflammatory infiltration does not affect the primordial follicles and granulosa cells are generally spared until they luteinize after ovulation. Since primordial follicles are frequently unaffected, fertility may be partially conserved in autoimmune oophoritis and intermittent ovarian failure may be more common. However, the immune reaction in the ovary may finally lead to a more generalized process and POI as the clinical end-point (Nelson, 2009; Martin *et al.*, 2017).

POI associated with other autoimmune disease is rarely characterized by SC-Abs thus it appears more difficult to document a direct connection. Nevertheless, POI is associated most commonly with thyroid autoimmunity (about 20%) when adrenal autoimmunity is absent. Other most commonly associated autoimmune alterations are parietal cell antibodies (4%), acetylcholine receptor antibodies in myasthenia gravis (2%) and insulin dependent diabetes (2%). The risk for these diseases in women with POI is higher than in the general population (Nelson, 2009; Persani *et al.*, 2013), suggesting that there may be a still unknown autoimmune component.

Because of the possible coincident adrenal failure it is important to exclude adrenal insufficiency in all women with unexplained POI in order to prevent the possible clinical consequences of Addison's disease. Basal and dynamic testing of the hypothalamus–pituitary–adrenal axis should be considered in any women with positive SC-Abs and if adrenal autoimmunity cannot be excluded.

Familial and Genetic POI

Several observations support a prevalent role of genetic mechanisms in the pathogenesis of idiopathic POI. Epidemiological evidences support the inheritance of menopausal age between mothers and daughters and genome wide studies found loci that were significantly associated with age at natural menopause. Interestingly, POI has also a frequent familial incidence. In large series of POI women, the incidence of familial forms reaches more than one third of cases if a familial history of early menopause between 40 and 45 years of age is considered (Nelson, 2009; Persani *et al.*, 2013; Martin *et al.*, 2017). Pedigree analysis demonstrates different modes of inheritance, but the more frequent maternal transmission would be consistent with an X-linked inheritance with incomplete penetrance. The presence in one pedigree of women with PA or SA, or with EM indicates that POI may be a genetic disease with a highly variable expressivity, thus supporting the view of POI as a complex multifactorial disease probably involving the contribution of several alleles (Rossetti *et al.*, 2017).

More than 50 gene loci have nowadays been associated with POI. A recent work brought evidence that POI may have an oligogenic origin (Bouilly *et al.*, 2016). Oligogenic involvement was also shown to lead to younger age at menopause. Genetic POI can occur within complex syndromes or constitute an isolated phenotype. The most relevant genetic causes of POI are briefly illustrated.

Turner Syndrome and X Chromosome Defects

Turner syndrome (TS) is the consequence of complete or partial loss of one X chromosome (Gravholt *et al.*, 2017). The resulting phenotype is that of a female with infertility due to POI and short stature, variably associated with other extra-gonadal abnormalities. The 45,X is the characteristic karyotype but 45,X/46,XX mosaicisms or structural abnormalities of the X chromosome account for about half of the patients. TS has an estimated prevalence of about 1:2000 females. In women with TS, oocyte-loss occurs in the early stages of meiotic prophase and ovarian development, resulting in OD and PA with elevated FSH levels since infancy. Nevertheless, spontaneous menarche and pregnancies have been reported in about 20% of cases (Gravholt *et al.*, 2017; Webber *et al.*, 2016). The TS phenotype may be explained by several mechanisms, but the most substantiated one is the lack of required dosage of particular X-linked gene products (like *SHOX*) that physiologically escape X inactivation. The requirement for a double dosage of X-linked genes is supported by the complete spontaneous puberty reached in about one third of patients with high mosaicism level. We documented the spontaneous puberty in one TS patient with short stature and a full duplication of the *BMP15* gene on the short arm of X chromosome in presence of low level mosaicism (<10%), suggesting a relevant role for a double dose of this gene in ovarian development (Castronovo *et al.*, 2014).

X chromosome abnormalities have long been recognized as a frequent cause of many forms of familial as well as sporadic POI. They include Triple X syndrome, Turner mosaics, deletions, isochromosomes and translocations between X chromosome and autosomes (Persani *et al.*, 2013; Gravholt *et al.*, 2017).

PGA1 or Autoimmune Polyendocrinopathy Syndrome Type 1 (APS1)

APS1 (MIM #240300) is caused by mutations in the autoimmune regulator gene (*AIRE* MIM #607358). The syndrome is characterized by having two out of three major clinical findings: Addison disease (AD), and/or hypoparathyroidism, and/or chronic mucocutaneous candidiasis. Generally in this syndrome, the Addison disease has its onset in childhood or early adulthood. APS1 is frequently associated with chronic active hepatitis, malabsorption, juvenile-onset pernicious anemia, alopecia (Persani *et al.*, 2013; Rossetti *et al.*, 2017).

Two laboratories concurred in the isolation of the causal gene for APS1 in 1997 and designated it *AIRE* (autoimmune regulator). The gene is located at 21q22.3 The AIRE protein contains two zinc finger motifs consistent with a role as transcription factor. AIRE is involved in the induction of tolerance to self-antigens by inducing the expression of peripheral tissue self-antigens in thymic stromal cells. Normally, this promotes the clonal deletion of differentiating T cells that recognize these self-antigens. In the absence of AIRE protein, many tissue-specific self-antigens fail to be expressed in the thymus, thus leading to multi-organ autoimmunity due to the failure in the negative selection of auto-reactive T cells. Negative selection normally causes death of T cells having receptors that are highly specific for self-peptides. If these auto-reactive T cells are left unchecked autoimmunity may result. The *AIRE* mutations ($n > 50$) are generally inherited in a recessive manner (Nelson, 2009; Persani *et al.*, 2013).

However, several mono-allelic mutations in the homeodomain of AIRE have been identified to exert a dominant negative effect. They were found in cases with delayed onset and milder manifestations compared to classical APS1, and follow incomplete inheritance. In this context, POI might represent the first or even the only manifestation of a nonclassical form of organ-specific autoimmunity (Persani *et al.*, 2013).

Blepharophimosis, Ptosis, Epicanthus Inversus Syndrome (BPES)

BPES (MIM #110100) is an autosomal dominant eyelid malformation that is classified as BPES type 1 when it is associated with POI. In the absence of POI, it is classified as type 2 BPES. *FOXL2* (forkhead transcription factor L2) (MIM *605597) mutations represent the cause of BPES. Animal models of human BPES, including the goat with polled/intersex syndrome (PIS) and the Foxl2 knock-out mice, were shown to replicate the human findings. FOXL2 role in granulosa cells (GC) physiology includes the promotion of granulosa cells differentiation and ovarian function (Caburet *et al.*, 2012). FOXL2 regulates: (a) AMH expression through the interaction with SF-1; (b) follistatin gene transcription by cooperating with SMAD3; (c) estradiol signaling by triggering the Activin-dependent expression of ESR2, and (d) maintenance of GC identity through the indirect repression of SOX9 (Caburet *et al.*, 2012; Rossetti *et al.*, 2017).

Numerous FOXL2 variants have been reported in individuals with BPES types 1 and 2 (*FOXL2* Mutation Database at http://medgen.ugent.be/LOVD2/home.php). *FOXL2* intragenic mutations resulting in truncated proteins before the poly-Ala tract are typically associated with BPES type 1, whereas poly-Ala expansions would rather lead to BPES type 2. However, the missense mutations mainly located within the forkhead domain are associated with discrepant ovarian phenotypes, and recently reported cases emphasize the importance of long-term clinical follow-up of ovarian function also in patients with a poly-Ala expansion. In contrast, *FOXL2* variants in women with POI but without palpebral abnormalities appear to be a rare event (Rossetti *et al.*, 2017).

Galactosemia

Galactosemia (MIM #230400) is a hereditary disorder of galactose metabolism caused by deficiency of *GALT* (MIM *606999) enzyme (galactose-1-phosphatase uridyltransferase), with an incidence in Europe and North America of about 1:30,000–50,000) (Rossetti *et al.*, 2017; Martin *et al.*, 2017). Galactosemia presents with the worst complications in organs with high GALT expression (liver, kidney, ovary and heart). Up to 80%–90% female patients with *GALT* homozygous mutations that partially or completely abolish GALT activity show a severe phenotype including early onset of POI. Several causative mutations have been described in *GALT* gene, but >70% of cases associated with impaired GALT function are caused by two common mutations (p.Q188R and p.K285N). The patients with GALT mutations accumulate galactose in the ovary leading to accelerated follicle atresia. FSH levels can be increased since birth to puberty and the disease is frequently associated with PA. Spontaneous pregnancies have seldom been reported in women with galactosemia (Coelho *et al.*, 2014).

Pseudo-Hypoparathyroidism Type 1a (PHP1A)

PHP1a (MIM #103580) is a generalized form of hormone resistance characterized by renal resistance to parathyroid hormone (PTH), resulting in hypocalcemia and hyperphosphatemia (Persani *et al.*, 2013; Rossetti *et al.*, 2017). Moreover, it is characterized by partial resistance to other hormones, including gonadotropins, and a variety of clinical features known as Albright hereditary osteodystrophy. Gonadal dysfunction with delayed or incomplete sexual maturation and infertility is frequent. In about

70%–80% of cases, PHP1a is caused by maternally inherited heterozygous loss-of-function variants in the *GNAS* gene (MIM *139320), which lays in a locus that is under a differential parental imprinting. The *GNAS* gene encodes for the protein Gsα, which is the first intracellular element downstream of PTH and gonadotropin receptors. The presence of gonadotropin resistance and POI in these patients is the consequence of the preferential expression of a mutant maternal allele in gonads as in other target tissues of hormones acting through the same Gsα-cAMP pathway.

Progressive External Ophthalmoplegia

The *POLG* gene (MIM *174763) encodes the enzyme synthesizing the mitochondrial DNA and correcting mitochondrial DNA errors. Patients with POLG mutations present with autosomal dominant (MIM #157640) or recessive (MIM #258450) progressive external ophthalmoplegia (PEO), a disease characterized by weakness of the ocular muscles and myopathy secondary to the depletion of mitochondria. The POLG mutations clustering in the polymerase domain undergo a typical dominant inheritance pattern, while those affecting the proofreading domain follow recessive inheritance. The polymerase-domain mutations have been reported in several families in cosegregation with POI and parkinsonism (Rossetti *et al.*, 2017).

Ovarioleucodystrophy

Ovarioleukodystrophies are neurological disorders characterized by the involvement of the white matter of the central nervous system associated with POI. Some of the patients have unusual association of POI with "vanishing white matter disease" (*VWM*, MIM #603896) observed on cerebral MRI, with variations in any of the five subunits of the *EIF2B* gene. This factor acts in response to cellular stress preventing the accumulation of denaturated proteins. The age at onset of neurologic degeneration correlates with the severity of ovarian dysfunction. In some cases, SA occurs before the neurological symptoms or occurs when neurological abnormalities are subclinical (Rossetti *et al.*, 2017).

Ataxia Telangiectasia

ATM (Ataxia Telangiectasia Mutated) gene (MIM *607585) encodes a cell-cycle checkpoint kinase which is involved in the cellular response to DNA damage, in the processing of the DNA strand breaks that occur during meiosis, during immune system maturation and for telomere maintenance. *ATM* mutations are the underlying causes of ataxia telangiectasia (MIM #208900), an autosomal-recessive disorder which includes cerebellar degeneration, oculomotor dysfunction, immunodeficiency, predisposition for cancer, radiosensitivity and chromosome instability as well as gonadal abnormalities and reduced germ cell pool. Loss-of-function mutations of the ATM gene have been associated with ovarian dysgenesis and defects in primordial germ cells development (Persani *et al.*, 2013; Rossetti *et al.*, 2017).

Premature Aging Syndromes

Several syndromes characterized by symptoms of "premature aging" are associated with POI (or azoospermia in males). Bloom syndrome (MIM# 21090) is a rare autosomic recessive disorder caused by mutations in the gene coding for the DNA helicase BLM (MIM# 604610), which result in genomic instability. The main symptoms of Bloom syndrome include short stature, distinctive skin rashes on sun-exposed areas, moderate immuno-deficiency, increased cancer risk and hypogonadism in both sexes. Recessive mutations in the *WRN* gene (MIM#604611), which encodes another DNA helicase, are the causatives of Werner syndrome (MIM#604611), a form of adult progeria characterized by sklerodermic-like skin, cataract, premature arteriosclerosis, increased cancer risk and atrophic gonads. Another form of syndromic premature aging associated with POI is represented by GAPO syndrome (MIM# 230740), which is caused by recessive mutations in a gene involved in cell adhesion and migration, *ANTXR1* (MIM# 606410). GAPO syndrome is characterized by severe growth retardation, alopecia, optic atrophy and distinctive facial features. Ovaries of women affected by GAPO syndrome display extensive deposition of hyaline extracellular material and premature follicular depletion.

The epidemiological observations that POI is often associated with syndromes characterized by premature aging further support the growing idea that even nonsyndromic POI could be considered as a form of ovary-specific accelerated aging (Rossetti *et al.*, 2017).

Perrault Syndrome

Perrault syndrome (PS) is a highly heterogeneous autosomal recessive syndrome mainly characterized by ovarian dysfunction and sensorineural deafness. Several genes implicated in mitochondrial functions or metabolism have nowadays been associated with PS (Chatzispyrou *et al.*, 2017; Lerat *et al.*, 2016; Demain *et al.*, 2017).

HARS2 and *LARS2* encode mitochondrial histidyl or leucyl-t-RNA synthetases involved in translation of mitochondrially encoded genes. *CLPP* encodes a highly conserved endopeptidase component of a mitochondrial ATP-dependent proteolytic complex, involved in degradation of unfolded or misfolded polypeptides. *C10orf2* encodes Twinkle, a mitochondrial primase-

helicase essential for replication of mitochondrial DNA yielding a mitochondrial DNA depletion syndrome and leads also to PEO. Very recently, mutations of *ERAL1* and *KIAA0391* were involved in PS (Chatzispyrou *et al.*, 2017). *KIAA091* encodes the metallonuclease subunit of the mitochondrial RNase P complex responsible for the 5′-end processing of mitochondrial precursor tRNAs. ERAL1 protein binds to the mitochondrial 12S rRNA and is involved in the assembly of the small mitochondrial ribosomal subunit affecting mitochondrial respiration and function. Mutations in a peroxisomal enzyme involved in fatty acid ß-oxidation and steroid metabolism, 17ß-hydroxysteroid dehydrogenase type 4 (HSD17B4), can also lead to PS.

Given the role of apoptosis in ovarian follicle functions, inappropriately timed or diffuse apoptosis is the most likely cause of POI.

Nonsyndromic POI

Fragile X Mental Retardation 1 (FMR1)

The FMR1 gene is located on the X chromosome and includes a trinucleotide repeat sequence, (CGG)n, in its 5′ untranslated region. Common alleles include 6–44 CGG repeats, typically with AGG interspersions every 9 or 10 repeats. When expanded to 55–200 repeats, this "premutation" becomes unstable when transmitted and has the potential to expand beyond 200 repeats in the next generation. The resulting "full" mutation then leads to the full silencing of the *FMR1* gene due to hypermethylation of the repeat and regulatory regions and causes fragile X syndrome, the most common inherited form of intellectual and developmental disabilities in males. The premutation is carried by about 1/250 women, with a higher frequency in the Mediterranean population. Approximately one out five women who carry the premutation will develop a POI. Differently, about 12% of women with familial POI and 3% of those with sporadic POI carry the premutation. Thus, the *FMR1* premutation has emerged as one of the main inheritable factors predisposing to POI (Wittenberger *et al.*, 2007; Martin *et al.*, 2017).

Studies conducted on women carrying the premutation allele that are still having regular menstrual cycles revealed that their hormonal hypothalamic–pituitary–gonadal axis profile is strikingly similar to that of aging ovaries with increased FSH and decreased inhibin B in the follicular phase. Low AMH levels among young premutation carriers are also consistent with an anticipated ovarian aging.

Two risk factors act as predictors of risk and severity of POI, the repeat size and mean age at menopause of first-degree relatives. The premutation carriers with the highest risk for POI turn out to be those with about 80–100 repeats. Consistently, the onset of FXPOI is earliest among those with 80–100 repeats, but rarely before 20 years. The second established risk factor is mean age at menopause of first-degree relatives. It is thus possible that modifier genes could play a substantial role in the variability of age at menopause among premutation carriers.

The mechanism leading to FXPOI is still unexplained. As the premutation repeat size increases, the level of FMR1 transcripts abnormally increases and the level of FMRP, the resulting protein, decreases. The toxic effect of the premutation could have its influence at several levels. *FMR1* mRNA studies in the mouse and FMRP expression studies in fetal ovaries indicate that FMRP is highly expressed in the germ cells of the fetal ovary. Thus, FMRP may play a role in oogonia proliferation and the determination of the initial size of the ovarian reserve. Interestingly, several studies have indicated that FMRP is also expressed in GC of maturing follicles, but not in primordial/primary stages. It was suggested that this cellular shift of FMRP expression to GC during follicle maturation after birth indicates a role for FMRP in the maturation of an oocyte.

Since FMRP appears to be involved in the control of transcripts' translation, it is possible that increased levels of FMRP in specific moments during development could lead to the insufficiency of proteins necessary in follicle development and survival (Persani *et al.*, 2013; Rossetti *et al.*, 2017; Martin *et al.*, 2017).

Gonadotropin Receptors

Rare loss-of-function mutations can cause gonadotropin resistance with hypergonadotrophic hypogonadism. The homozygous missense mutation (p.A189V) in the extracellular domain of the *FSHR* gene (MIM *136435) was the first reported to cause PA with hypoplastic ovaries in women with 46,XX karyotype. This mutation causes an intracellular retention of FSHR but appears to be particularly frequent only in the Finnish population, as result of a founder effect (Aittomaki *et al.*, 1995). Other mutations in different regions of the *FSHR* gene have been reported in women with the classic biochemical phenotype of premature ovarian insufficiency (FSH higher than LH levels). Complete FSH resistance is associated with absent pubertal development and PA, whilst postpubertal POI and SA are characteristics of partial resistance. Both the complete and partial forms undergo a typical recessive inheritance (Beck-Peccoz and Persani, 2006; Persani *et al.*, 2013; Rossetti *et al.*, 2017).

Homozygous inactivating variants of the *LHCGR* gene (MIM + 152,790) are a rare cause of POI in women with 46,XX karyotype. They represent a particular form of hypergonadotropic hypogonadism characterized by LH levels higher than those of FSH. Studies in families with Leydig cell hypoplasia showed in female carriers of complete LH resistance a POI phenotype characterized by anovulatory oligoamenorrhea or SA with evidence of multiple follicles at the antral stage at ultrasound (Persani *et al.*, 2013; Rossetti *et al.*, 2017).

Transforming Growth Factor-Beta (TGF-β) Family

Both the oocyte and GC within the ovarian follicle express several TGF-β-like factors, which promote proliferation and differentiation in the tissues where they are expressed. These factors include: growth and differentiation factors (GDFs), bone

morphogenetic proteins (BMPs), as well as inhibins, activins or anti-mullerian hormone (AMH). TGF-β-like factors are commonly expressed as pre-pro-proteins, which undergo proteolytic cleavage during the secretory pathway. The precursors are specifically cleaved to generate the "mature" ligand, which alone or in combination with other secreted factors promote the cell signaling cascade. The pro-region is important for the processing of the pro-protein by driving the dimerization and secretion of the mature peptides. Several of these factors acting within the ovarian follicles are required for maintaining the follicle homeostasis and for proper folliculogenesis. Therefore the related encoding genes are considered as candidates to be investigated in women with POI (Persani *et al.*, 2014; Rossetti *et al.*, 2017).

Inhibin A (INHA)

Inhibin is a candidate gene given its important role in regulating ovarian function either as negative modulator of pituitary FSH synthesis or as a paracrine factor within the ovarian follicles. The association between inhibin and POI was first suggested by the identification in a woman with POI of a 46,XX,t(2;15)(q32.3;q13.3) translocation causing a breakpoint in the α subunit of inhibin (INHA; MIM *147380, locus 2q33–36) therefore prompting the mutational screening of this gene. One recurrent variation of *INHA* (p.A257T) has been consistently found in women affected by POI of different ethnicities, with a prevalence of 0%–11% depending on the population studied. A meta-analysis of the random effects on the risk of POI in carriers of the INHA variant from the most relevant studies revealed a slight increase in the risk to develop POI in the female carriers of the polymorphism. Based on these results, INHA gene might be considered as a susceptibility locus for POI (Rossetti *et al.*, 2017).

Bone Morphogenetic Protein 15 (BMP15)

BMP15 (MIM *300247) is an oocyte-specific growth/differentiation factor involved in follicular development and regulation of many GC processes (Persani *et al.*, 2014). The main BMP15 actions include: (a) the promotion of follicle growth and maturation; (b) regulation of follicular GC sensitivity to FSH; (c) prevention of GC apoptosis; (d) promotion of oocyte developmental competence and (e) determination of ovulation quota. Consistent with a relevant role of *BMP15* gene in folliculogenesis and ovulation, ewes with heterozygous natural mutations have an increased ovulation rate, while homozygous carriers show infertility with complete block of folliculogenesis. Several data indicate that the role of BMP15 appears more critical in mono-ovulating species (such as sheep and human) than in the poly-ovulating ones (mice). However the overexpression of a biologically active BMP15 in mice leads to accelerate folliculogenesis and causes an early onset of ovarian failure. *BMP15* maps to a locus on Xp critical to ovarian reserve determination where several of the TS traits are located including ovarian failure. In women, mutations in BMP15 gene have been associated with both PA and SA in several POI cohorts with a prevalence ranging from 1.5% to 15%. BMP15 p.Y235C was the first mutation reported in association with hypergonadotropic ovarian insufficiency in two Italian sisters with PA and OD. The Y235 residue is highly conserved among species and corresponds to a site of positive selection in the hominidae clade during evolution (Auclair *et al.*, 2013). When functionally tested, this alteration enhances the BMP15-induced transcriptional activity and causes increased GC steroidogenesis. In contrast, BMP15 p.Y235C was unable to increase GC proliferation. Several other variants have been further identified with variable frequency in worldwide POI cohorts. Although some of these variants have also been found in low percentage in the control populations, a finding that may question their pathogenic role, a recent revision of the frequency of BMP15 variants in POI and control populations revealed a 10-fold higher frequency of heterozygous BMP15 variations in cases. In a recent study on X chromosome mosaicism in TS, a tandem duplication of the single BMP15 gene was identified in a patient with 45,X karyotype but spontaneous menarche followed by regular menses for 4 years. This BMP15 duplication would have enabled a small amount of functional follicles to survive atresia and reach pubertal age by means of a partial compensation to the haploinsufficiency for the other X-linked genes. Consistent with this, FISH and array-CGH experiments demonstrated that the presence of a mosaicism with the euploid cell line $>10\%$ would be sufficient to induce spontaneous menarche. Taken together, these data highlight how BMP15 gene dosage contributes to the ovarian phenotype of patients with TS and further support the hypothesis that BMP15 is an ovary-determining X-linked gene. This finally brings additional support to the idea that inactivating mutations in this gene can represent a predisposing event for POI (Persani *et al.*, 2014).

Growth Differentiation Factor 9 (GDF9)

GDF9 (MIM *601918) is homologous to the gene encoding BMP15. GDF9 expression is high in the oocytes, where its products can form noncovalent heterodimers with BMP15, which are active on surrounding follicular GC. Evidences from experimental animals have strongly suggested that GDF9 activity is crucial in poly-ovulating species: in mice, for instance, GDF9 is fundamental for folliculogenesis (Persani *et al.*, 2014). Concerning mono-ovulating species, natural GDF9 mutations have been described both in Cambridge and Belclare sheeps, where the ovarian phenotype was analogous to that seen in BMP15 mutants. In humans, several heterozygous missense GDF9 variations affecting the pro-region of the translated protein were described in POI women (prevalence of 1.4%). Some insertion/deletion or missense variants in GDF9 have been reported in mothers of dizygotic twins,

with an incidence around 4%, thus supporting GDF9 as a determinant of the ovulation quota also in humans (Persani *et al.*, 2014).

Genes Affecting DNA Replication, Meiosis and DNA Repair

Variations in genes involved in replication and repair of DNA double-strand breaks for recombination, DNA damage checkpoint control, cell cycle progression or formation of the synaptonemal complex may be associated with POI, as strongly suggested by mouse models showing a POI-like phenotype (Rossetti *et al.*, 2017).

Genetic variations have been described to affect DMC1 or LIM15 (MIM *602721), MSH5 (MIM *603382), *STAG3* (encoding a meiosis-specific subunit of the cohesin ring), SMC1β, REC8 (genes encoding protein of the cohesin complex and thus controlling sister chromatid cohesion and recombination between homologous chromosomes), POF1B (an X-linked gene located within the critical region for normal ovarian function, known to escape X inactivation, which encodes a protein that interacts with actin filaments, and the authors speculate that POF1B could have a role in the pairing of meiotic chromosomes), HFM1 (encoding a protein necessary for homologous recombination of chromosomes), PSMC3IP (MIM *608665) (another gene required for homologous recombination), MCM8 and MCM9 (encoding members of the highly conserved mini-chromosome maintenance proteins complex involved in homologous recombination and repair of double-stranded DNA breaks), *SYCE1* (gene encoding an essential component of the synaptonemal complex, where paired chromosome homologs closely associate in meiosis before crossover), NUP107 (MIM *607617) (encoding a component of the nuclear pore complex, which mediates nucleocytoplasmic transport of macromolecules such as transcription factors, thus promoting cell-specific gene-expression) (Caburet *et al.*, 2014; de Vries *et al.*, 2014; Wang *et al.*, 2014; Goldberg *et al.*, 2015; Al Asiri *et al.*, 2015). More recently, microdeletions involving the *CPEB1* gene (MIM *607342) (a gene encoding the cytoplasmic polyadenylation element-binding protein 1 involved in the regulation of translation and senescence) have been reported to play a relevant role in an oligogenic model of POI (Hyon *et al.*, 2016; Tšuiko *et al.*, 2016). Finally, another chromosomal instability disorder associated with POI is Fanconi Anemia, which can be caused by alterations in *FANCA* (MIM *607139), *FANCC* (MIM *613899) and *FANCG* (MIM *602956) genes (Rossetti *et al.*, 2017).

Transcription Factors

NR5A1

The *NR5A1* (MIM + 184,757) gene encodes for a nuclear receptor whose expression can be detected early in embryo development in bipotential gonads, where it plays a key role as a transcriptional regulator of genes involved in the adrenal and gonadal axis (Persani *et al.*, 2013; Rossetti *et al.*, 2017). Mutations of NR5A1 have been reported in cases of 46,XY disorders of sex development (DSD), with or without adrenal failure. The first evidence of an association between NR5A1 function and POI came from the detection of mutations in this transcription factor in members of four families with histories of both 46,XY DSD and 46,XX POI, as well as in 2/25 women with isolated ovarian insufficiency. The association between NR5A1 mutations and POI pathogenesis was further confirmed with a mutation frequency of 1.6%. Patients carrying NR5A1 mutations show a wide spectrum of ovarian anomalies, ranging from SA to PA, or even gonadal dysgenesis.

SOX8

Variations in *SOX8* gene have very recently been reported in women POI (Portnoi *et al.*, 2018). SOX8 is an HMG-box transcription factor closely related to SRY and SOX9. Deletion of the gene encoding Sox8 in mice causes reproductive dysfunction. SOX8 is expressed in the somatic cells of the early developing gonad in the human and influences human sex-determination. In fact, several individuals with 46,XY DSD were found to carry variable genetic variations leading to SOX8 defects.

Oocyte specific transcription factors

NOBOX (newborn ovary homeobox) (MIM *610934) and *FIGLA* (factor in germline alpha) (MIM *608697) both encode for oocyte-specific transcription factors. NOBOX is a homeodomain-containing, oocyte- and granulosa cell-specific protein able to directly regulate the expression of key oocyte-specific factors such as Gdf9, Oct4 and KIT-L. Heterozygous NOBOX mutations have been reported in women with sporadic POI of African and Caucasian origin at a prevalence of ~6% (POF5, OMIM #611548), suggesting to consider NOBOX as the first autosomal candidate gene involved in POI. Vice versa, mutations in the homeobox domain of NOBOX seem not to be common explanations for POI in Asian women. We recently documented that several NOBOX mutants form intracellular aggregates and are unable to enter the nucleus and activate transcription. Interestingly such mutants conserve the ability to interact with FOXL2, thus presumably reducing also its access to the nucleus (Ferrari *et al.*, 2016).

FIGLA is a basic helix-loop-helix transcription factor involved in the regulation of the expression of zona pellucida genes. A mutational study conducted on 100 Chinese women affected by POI revealed two heterozygous deletions in two unrelated cases. Functional in vitro studies confirmed that both variants might have a pathogenic role. Two additional variants, p.R83C (positioned within the functional domain bHLH) and p.S141T (located outside the functional domain, but possibly impairing the protein–protein interaction between FIGLA and TCF3), were further identified in a cohort of Indian women with POI. Both variants were predicted as potentially pathogenic and disease-causing by in silico analysis, but were not experimentally tested.

Recently, thanks to the NGS approach a rare loss-of-function variant (p.A41V) has been identified in 1 out of 100 women with idiopathic POI (Rossetti *et al.*, 2017).

Hormone Replacement Therapy (HRT)

In females with pubertal delay and PA due to POI estradiol supplementation should be started as soon as possible after diagnosis (Christin-Maitre, 2017). ESHRE guidelines and TS management guidelines recommend to start with low dose of transdermal estradiol followed by a progressive increase every 3–4 months depending upon the age and clinical evaluation of the girls (Webber *et al.*, 2016; Gravholt *et al.*, 2017). Oral progesterone should be given when an adequate uterine growth and thickening have been detected at US. Cyclic HRT is generally preferable in young POI patients, who should also be involved in the choice of the route of administration. Oral hormonal contraceptives may have positive psychological and social implications in young POI women.

The transdermal route should in principle be advised in POI women beyond 40 years of age because HRT should then be recommended to all POI women at least until the age of physiological menopause, since these women are at higher risk for osteopenia, osteoporosis, and accelerated atherogenesis (Atsma *et al.*, 2006; Gallagher, 2007). Cyclic or continuous estrogen and progestogen relieve symptoms of hypoestrogenism and maintain bone density. Additional benefits of estrogen therapy include potential cardioprotective effects, delayed onset of Alzheimer's disease, decreased incidence of colorectal cancers, and improved vulvovaginal and urethral tissue structure and function.

Absolute contraindication to HRT should be reserved only to POI women with breast cancer. The carriers of BRCA1–2 variants should receive HRT after prophylactic breast surgery. Other conditions like migraine, hypertension or increased thromboembolic risk do not represent absolute contraindications to HRT in POI women but particular caution should be applied in order to prevent the associated risks. Breast examinations with sensitive radiological techniques should always be recommended.

Low androgen supplementation can be useful to alleviate the sexual dysfunction. Calcium supplementation and weight-bearing exercise are also important for skeletal health.

Importantly, psychological support should be provided to patients afflicted with this difficult diagnosis. Frequently, these women feel that fertility potential is taken away from them before they have even had the option to consider their reproductive desires. This can be devastating and threatening to their self-esteem. Thorough education regarding their general health and fertility options is important. In certain circumstances, individual counseling may also be appropriate (Webber *et al.*, 2016; Gravholt *et al.*, 2017; Christin-Maitre, 2017).

Fertility Defect

The natural history of premature ovarian failure includes spontaneous pregnancies in 10% of women after diagnosis. Hormone replacement therapy does not provide birth control and those not desiring pregnancy should be placed on oral contraceptives. Undetectable AMH instead indicates the loss of ovarian reserve.

The infertility represents a major issue in the POI women. Nowadays, oocyte donation is the only solution if AMH is undetectable. Implantation rates using young oocyte donors are very favorable and pregnancy outcome in these women who have donated oocyte-derived embryos is excellent.

Early diagnosis or prediction of POI may instead open other possible strategies (Gago and Ginsburg, 2004; Martin *et al.*, 2017). These include harvesting of immature oocytes with their in vitro maturation and co-culture prior to in vitro fertilization. The prospective identification of women at risk for developing POI can instead allow the oocyte harvest and cryopreservation for subsequent use before the onset of clinical ovarian failure. Because of the frequent familial recurrence of POI, this strategy should be recommended in young daughters or close female relatives of a POI woman and can be further improved if a genetic diagnosis is reached (Rossetti *et al.*, 2017; Webber *et al.*, 2016).

Conclusion

As mentioned above, prospective cryopreservation of primordial follicles may become a more practical option in the future for women at risk of developing POI. This availability stresses the importance of early diagnosis and specific testing of women with POI and their younger female relatives. With increasing capabilities in molecular medicine and diagnosis, genetic therapies to correct the dysfunction or prevent the follicular loss can be envisioned. Improved measures of protecting primordial follicles during cytotoxic therapies and the ability to preserve primordial follicles in vitro and mature them successfully are also therapeutic strategies under intense investigation. Specific therapy for autoimmune POF—which could include highly specific blocking antibodies that would potentially prevent the follicular dysfunction and loss and avoid the adverse systemic effects associated with corticosteroids and other immunomodulatory therapies—may become possible in the future.

Other possible interventions include the in vitro activation (IVA) by AKT stimulators of residual dormant follicles potentially present in ovarian biopsies from POI patients (Zhai *et al.*, 2016). Ultimately, the reconstitution of complete oogenesis was obtained from induced pluripotent stem (IPS) cells in the mouse (Hikabe *et al.*, 2016). These novel technique would represent a

potential alternative for poor responders to gonadotropin stimulation but may probably prove unsuccessful in POI women affected with oogenesis defects unless coupled to gene editing techniques.

Adult Care of Turner Syndrome

Claus H Gravholt, Mette Viuff, and Kirstine Stochholm, Aarhus University Hospital, Aarhus, Denmark
Niels H Andersen, Aalborg University Hospital, Aalborg, Denmark

Introduction

Knowledge of Turner syndrome (TS) is expanding rapidly, especially aspects concerning adult care are recognized, and new international guidelines have recently been published (Gravholt *et al.*, 2017). The syndrome only affects females and clinical care emphasize the need for multidisciplinary care, involving several specialties including genetics, embryology, pediatrics, gynecology and obstetrics, fertility, endocrinology, cardiology, radiology, otorhinolaryngology and ophthalmology.

Here, we review the diverse and complex clinical aspects encountered throughout adulthood in TS.

Epidimiology

Turner syndrome (TS) is a congenital syndrome, present in approximately 1 in 2000 live born girls (Nielsen and Wohlert, 1990; Stochholm *et al.*, 2006). The 45,X karyotype is still the most common karyotype identified, however during the last decades the number of females diagnosed with mosaic TS (45,X/46,XX) has increased (Stochholm *et al.*, 2006). Other karyotypes exist, including ring X chromosomes, iso chromosomes, deletions of a part of the X chromosome, or karyotypes including part of a Y chromosome. Only 30%–66% of all with TS are ever diagnosed, with a wide range of age at diagnosis, from prenatally to after postmenopausal age (Stochholm *et al.*, 2006). There is no obvious explanation for this lack of diagnosis, but new avenues for better diagnostics, such as neonatal screening programs using genome sequencing should be put in place (Gravholt *et al.*, 2017; Murdock *et al.*, 2017). The median age at diagnosis in general is 15 years, lower in those with a 45,X karyotype or a mosaic karyotype, and higher in those with "another" karyotype. Generally, the phenotype of the mosaic TS person is milder, however the overall health status varies greatly within the karyotypes and one cannot predict the phenotype from the karyotype.

Of those diagnosed, the majority is diagnosed at birth, probably due to typical TS clinical findings such as a combination of webbing of the neck, oedema of hands and feet, low set ears, and a low birth weight. During adolescence, diagnosis is due to the late or lacking pubertal development and/or absent menarche, or due to low height. Similarly, in young adulthood, diagnosis is most likely due to infertility. However, diagnosis is possible at all ages. With the increasing use of prenatal diagnosis, an identification of an increasing number of diagnosed TS fetuses is expected (Viuff *et al.*, 2015). A postnatal karyotype is always recommended for confirmation. Convincing data on the prenatally diagnosed population is lacking; however, it is most likely that their phenotype *is* affected but possibly milder than in the postnatal diagnosed population (Gunther *et al.*, 2004). Among the TS fetuses, there is a high degree of spontaneous abortion, also late abortions. Danish data show that in prenatally diagnosed TS fetuses with a median gestational age of 14 weeks, $>80\%$ with 45,X karyotype and $>40\%$ with other TS karyotypes are legally aborted (Viuff *et al.*, 2015).

Most women with TS are of average intelligence, however about 10% have some degree of intellectual disability. Most function better verbally than perceptually, and language functioning is average to above average. The most frequent cognitive problem is visuospatial, such as finding way on a map. Other problems are deficits when switching attention, reduced processing speed, social cognition (recognizing faces etc.) and attention deficits. Further, social isolation, fewer friendships, and limited sexual experience is more common in TS (Boman *et al.*, 2004; Fjermestad *et al.*, 2016; Amundson *et al.*, 2010), and sexual functioning seem slightly reduced compared to controls although data differ. They leave their parents at an older age compared to their peers, and a reduced number of TS women is in a relationship. The degree of education is similar to or higher in TS women compared to their peers. Income is lower than expected in the younger years (Stochholm *et al.*, 2012; Gould *et al.*, 2013); however, among those working there is a catch-up in the late twenties; hereafter income is similar to age-matched controls. Due to the hypogonadism and social factors, fertility is reduced, however more and more become mothers, typically using oocyte donation (Hagman *et al.*, 2011). Women with TS retire at a younger age and more frequently compared to age-matched controls. Data show that those diagnosed >30 years ago differ from those diagnosed more recently. Those diagnosed recently have more often been in a relationship, have a higher education, they become mother more often, and they retire later. It is noteworthy that the more recently diagnosed group includes relatively more with a mosaic karyotype.

Compared to the background population, morbidity and mortality is significantly increased (Schoemaker *et al.*, 2008a,b; Stochholm *et al.*, 2012; Gravholt *et al.*, 1998a). The increased morbidity in TS includes a wide range of diseases, such as recurrent otitis media in the child, congenital malformations, renal abnormalities, cardiovascular abnormalities, abnormal or absent pubertal development due to hypogonadism, hearing loss, osteoporosis, skin disorders including oedema, infertility, hypothyroidism, adiposity, type 2 diabetes, hypertension, and autoimmune diseases (Gravholt *et al.*, 1998a). There is more often need for correction of refractory errors due to hyperopia and myopia. Cancer is not increased in TS; especially the risk of breast cancer is low (Schoemaker *et al.*, 2008a). However, rare

 doi:10.1016/B978-0-12-801238-3.64353-2

tumors such as gonadoblastomas are more frequent. It is found in TS women whose karyotype includes part of a Y chromosome and prophylactic gonadectomy is recommended. A Dutch study in TS women with a mean age of 31 years identified >30% lacking medical follow-up at first screening at a multidisciplinary clinic (Freriks *et al.*, 2011).

Mortality is significantly increased in TS, with a mortality three times higher than age-matched female controls at all ages, and highest in the 45,X karyotype group. In line with the almost universally increased morbidity, mortality is increased due a wide range of diseases, especially cardiovascular disorders including aortic dissection, see later. Mortality is increased in almost all diagnosis chapters in the International Classification of Diseases 10th edition, when compared with the female population in general. It is expected that mortality will decrease and hopefully normalize with careful follow-up, however sound data are still lacking.

Although morbidity and mortality is increased, quality of life (QoL) or life satisfaction seem rather unaffected in TS. Various studies show different results including a QoL worse, similar to or better than compared to controls. Thus, findings include: higher satisfaction with leisure and economy; lower self-esteem; more life strain, and better health related quality of life on social functioning. QoL seem better in those reporting normal puberty.

Cardiovascular Disorders

Congenital Heart Disease

TS is associated with a significant higher prevalence of congenital heart disease and aortic dissection than the normal population. There is an unexplained relation between the 45,X karyotype and development of the left-sided heart congenital malformations. The major common denominator is the presence of a bicuspid aortic valve, which is seen in >15%–30% of an adult Turner population (Mortensen *et al.*, 2012). Along with aortic valve disease, Turner syndrome is associated with coarctation of the aorta, aortic arch anomalies and abnormal head and neck vessels, mitral valve disease, ventricular septal defects, subaortic obstruction, abnormal pulmonary vein drainage, presence of a left caval vein, and coronary anomalies (Mortensen *et al.*, 2012a,b, 2016; Viuff *et al.*, 2016; Ho *et al.*, 2004).

Most congenital heart defects of an adult population will already have been diagnosed during fetal and pediatric care, however, the rarer defects with low morbidity may have been missed and can cause symptoms in adult life, like abnormal pulmonary vein drainage or abnormal coronary anatomy (Mortensen *et al.*, 2016; Viuff *et al.*, 2016; Gutmark-Little *et al.*, 2012).

For this reason, it is important to do a detailed cardiovascular examination when approaching the adult Turner woman who is either diagnosed for the first time, or has transitioned from pediatric care (Gravholt *et al.*, 2017). A detailed echocardiogram may in most cases be enough to determine aortic valve morphology, coronary and aortic arch morphology and the pulmonary vein anatomy. If not so, it is important to do either a magnetic resonance scan (MRI) (Mortensen *et al.*, 2011, 2013) or at computed tomography (CT-scan) to determine the cardiac anatomy anomalies (Mortensen *et al.*, 2016).

Aortic Disease

In early adult life, aortic dilatation and eventually aortic dissection is seen in significant numbers (Ho *et al.*, 2004; Gravholt *et al.*, 2006c). In clear contrast aortic dissection is a disease mostly seen among the elderly in the normal population, (Craiem *et al.*, 2017). This is probably why aortic disease is misdiagnosed and mistreated in young TS women, where the significance of aortic dilatation is underestimated and prophylactic surgery is not offered in time (Ho *et al.*, 2004; Gravholt *et al.*, 2006c).

The presence of a bicuspid aortic valve is a major determinant for aortic dilatation, as well as for the presence of elevated diastolic blood pressure, and aortic arch anomalies (Mortensen *et al.*, 2013).

Medical management of aortic dilatation has never been thoroughly examined neither in the general population or a TS population. For this reason, the common recommendation is blood pressure reduction, preferably with a betablocker, and close follow-up. If the aorta becomes significantly enlarged, prophylactic surgery should be offered with aortic root replacement, to avoid a type A–dissection (Gravholt *et al.*, 2017). Type A dissection is defined as a dissection of the proximal ascending part of the aorta, while type B dissection occurs in the distal or descending part of the aorta.

A smaller part of TS women with aortic disease (10%) develop a type B dissection. Type B dissection is also associated with hypertension, but may also originate from an aortic coarctation without hypertension (Di *et al.*, 2012). This emphasizes the importance of a full assessment of the aortic size in women with TS. Since repeated scans are important, this assessment is best done with MRI and assessed by cardiologist with special interest in TS.

In TS women with normal aortic size, full MRI-scans should be done every 3–5 years, depending on aortic valve morphology and the presence of either a repaired aortic coarctation or arch anomalies. Some TS patients may need a closer follow-up (Gravholt *et al.*, 2017).

Hypertension

Hypertension is a common phenomenon in TS. The true prevalence is uncertain but up to 50% of an adult population may have arterial hypertension (De Groote *et al.*, 2015). The cause of hypertension in TS is multifactorial. The high prevalence of overweight

and obesity in TS contributes significantly to the hypertension disease burden as well as the association to both type 1 and type 2 diabetes (Mortensen *et al.*, 2012). At present it is not known which anti-hypertensive treatment is most effective.

Congenital defects like repaired aortic coarctation or aortic arch hypoplasia or congenital kidney disease also contribute to the number of hypertensive TS patients (De Groote *et al.*, 2015).

The more unresolved issues in TS, like estrogen deficiency, increased intima media thickness (Mortensen *et al.*, 2012), aortic stiffness, and high sympathetic activity may also increase the blood pressure in women with TS. Direct causal links between these factors and the presence of hypertension is yet to be found but numerous studies implicate that these complex factors play a role in blood pressure regulation.

Ischemic Heart Disease and Stroke

Adult TS women also have a high prevalence of ischemic heart disease (Schoemaker *et al.*, 2008b). The cardiovascular morbidity and mortality in adult life is significantly higher in adult TS women, compared to the background population (Stochholm *et al.*, 2006), and comorbidity plays a significant role. The lean and well-controlled TS woman may never develop ischemic heart disease. However, the TS women with type 2 diabetes, overweight, poor estrogen substitution through life and with hypertension is very likely to develop coronary heart disease in very young age. It is therefore important to assess the TS patients risk factors and motivate the patient to exercise, weight loss, and to sustain from smoking. Additional risk factors as dysregulated diabetes, elevated blood pressure and hypercholesterolemia are also important to treat.

There is not a particular dyslipidemia associated with TS, but many patients develop an unhealthy lipid profile due to obesity, diabetes, or poor estrogen substitution (Landin-Wilhelmsen *et al.*, 2001; Gravholt *et al.*, 2000). Therefore, it is important to have a multifactorial approach to the women with TS, who presents with an unhealthy risk profile and the task will often include a cardiologist, an endocrinologist and a dietitian (Gravholt *et al.*, 2017).

Cerebrovascular disease (stroke) is also more common in TS. This is probably due to the excessive presence of hypertension, but disturbances in thrombosis and fibrinolysis in TS can also be the cause of a thromboembolic strokes. The risk of thrombotic disease in TS has never been addressed in large studies, but there seems to be an increased risk of thrombus formation (Gravholt *et al.*, 2012). On the individual level, many TS patients may have procoagulant levels of clotting and fibrinolytic factors. Especially, fibrinogen has been found elevated in approximately two thirds of females with TS, and proteins C and S have also been found in significantly lower concentrations (Gravholt *et al.*, 2012). Nevertheless, this must not deter the treating physician from treating TS women with hormone replacement therapy, consisting of 17β-estradiol and a progestin normally given in a sequential manner, since no data support that there is a specific risk of thromboembolism in TS patients in estrogen treatment.

Arrhythmia

Women with TS often have an excessive sympathetic drive. Therefore, it is not uncommon that the women with TS has an increased resting heart rate (Gravholt *et al.*, 2006a). The patients are mostly asymptomatic, but some may sense that their pulse is high.

Presence of a prolonged QT-interval is also a common electrophysiological phenomenon in TS. This can easily be missed in patients with a high resting heart rate, therefore it is advised to calculate the corrected QT-interval according to Hodge's formula over Bazett's formula because it takes higher heart rates into account (Gravholt *et al.*, 2017). The mechanism behind QT-prolongation is unresolved but an increased number of patients with polymorphisms in the QT-genes have been found among TS women with prolonged QT-intervals (Trolle *et al.*, 2013). The clinical significance of prolonged QT-intervals is unresolved, but there may be a risk in treating women with TS with QT-prolonging drugs (Nielsen *et al.*, 2017).

Ovarian Failure

TS is usually accompanied by hypergonadotropic hypogonadism leading to low levels of estrogens and compared to healthy girl's lower levels of androgens (Gravholt *et al.*, 1999; Apter *et al.*, 1982). The ovarian failure leads to pubertal delay, primary or secondary amenorrhea, poor development of secondary sex characteristics, impaired sexual functioning and in most cases infertility.

The phenotype differentiates depending on karyotype, as 45,X show more pronounced symptoms. A higher percentage of mosaicism results in milder symptoms and lesser ovarian failure.

The etiology and genetics of the ovarian insufficiency is still being investigated, with different theories. One theory is lack of a particular X-linked gene that require double dosages. Another suggesting an epigenetic component (Trolle *et al.*, 2016).

Puberty can be divided into two independent events: gonadarche and adrenarche. During gonadarche the ovaries start producing sex hormones, and thelarche (development of breasts) is usually the first sign. During adrenarche, the maturation and secretion of adrenal androgens, initiates the growth of pubic and axillary hair (pubarche). This occurs independently of the hypothalamic–pituitary–gonadal axis.

The gonadal functioning in TS is extremely variable and dependent of karyotype. Approximately 20% of monosomy X enters puberty spontaneously, compared to 70% of mosaics. About one-third of these develops secondary failure. Pubarche is in most cases the first sign of puberty, compared to 46,XX girls where the first feature is thelarche (Negreiros *et al.*, 2014).

About one third of girls with TS has spontaneous breast development (Tanaka *et al.*, 2015; Negreiros *et al.*, 2014; Pasquino *et al.*, 1997). Regular menstrual cycles occur in 6% of these subjects (Pasquino *et al.*, 1997). Mosaic karyotypes were associated with similar preservation of ovarian function, as determined by the frequency of spontaneous menarche (Tanaka *et al.*, 2015).

TS women are most often infertile, this being the greatest factor influencing their quality of life (Sutton *et al.*, 2005). Very few can become pregnant with own oocytes. Most females with TS are likely to experience premature ovarian failure and hence less likely to become pregnant.

Spontaneous pregnancies occur in 4.8%–7.6% of women with TS (Bryman *et al.*, 2011; Bernard *et al.*, 2016), however one study showed that of the fertile women registered with 45,X/46,XX, several had 45,X in $<10\%$ of analyzed cells, indicating that some of these women might not have many, if any, signs of TS (Birkebaek *et al.*, 2002).

According to the new international TS guidelines (Gravholt *et al.*, 2017), it is recommended to initiate estrogen replacement when the patient is between 11 and 12 years of age, increasing to adult dosage over 2–3 years. Low-dose estradiol is recommended and transdermal administration is preferred due to lesser side effects compared with oral use. Once bleeding occurs, progesterone should be added.

With adequate hormone replacement, it is possible to stimulate uterine growth, which will become susceptible to oocyte donation from a foreign donor. In mosaic TS women pregnancy after FSH-stimulated oocyte retrieval, freezing of own oocytes until the female becomes older, followed by IVF treatment is possible, if it is initiated in a young age before ovarian failure (Borgstrom *et al.*, 2009; Hovatta, 2012). Counseling not to postpone pregnancy is advisable.

If pregnancy is accomplished, TS women experience a higher number of complications and miscarriages. A study reported a complication rate of up to 45% (Bryman *et al.*, 2011; Bernard *et al.*, 2016). It is also clear that pregnancy after oocyte donation carries a higher risk than the rare spontaneous pregnancy among TS women (Chevalier *et al.*, 2011).

Endocrine Disorders

The risk of both type 1 and type 2 diabetes mellitus is increased (Gravholt *et al.*, 1998a). In a general cohort of patients with TS, fasting glucose levels tend not to be different from healthy peers but fasting hyperinsulinaemia is present and impaired glucose tolerance has been found in 25%–78% of adult patients with TS (Gravholt *et al.*, 1998b; Bakalov *et al.*, 2004). In addition to higher glucose levels during oral glucose loading, the insulin response is altered and a delayed insulin peak is seen. The impaired glucose homeostasis seems to be partly explained by an attenuated "first phase insulin response" which could be viewed as an inappropriately low β-cell response (Gravholt *et al.*, 1998b; Bakalov *et al.*, 2004). Body composition is altered in TS with increased BMI, decreased muscle mass and increased total fat mass and visceral fat mass (Gravholt *et al.*, 2006b; Elsheikh and Conway, 1998). A relatively sedentary lifestyle and decreased physical fitness has also been demonstrated (Landin-Wilhelmsen *et al.*, 1999). These factors may be causally linked with reduced insulin sensitivity, although this trait has only been shown in some (Caprio *et al.*, 1991; Salgin *et al.*, 2006; Stoppoloni *et al.*, 1990), but not all studies (Hjerrild *et al.*, 2011; Bakalov *et al.*, 2004), and linked with manifest diabetes (Gravholt *et al.*, 1998a; Bakalov *et al.*, 2009).

Appropriate estrogen replacement also seems to be important for glucose homeostasis even though the findings in TS diverge. Exogenous estrogen reduced fasting glucose and fasting insulin in TS (Elsheikh *et al.*, 2000), and increased fat free mass and physical fitness, although insulin sensitivity was not improved (Gravholt *et al.*, 1998b). In the latter study, a decreased glucose tolerance was seen during HRT (Gravholt *et al.*, 1998b). On balance, HRT may slightly improve glycemic control though more studies are necessary to elucidate the relation between glucose metabolism and states of deficiency of and replacement with estrogens in TS.

Insulin levels increase during GH treatment, given for growth-promoting reasons during childhood and adolescence, decrease after termination of treatment but remain higher than pre-treatment levels (Sas *et al.*, 2000). GH generally reduces insulin sensitivity in the first 6–12 months of treatment, where after it stabilizes. This stabilization could be due to changes in body composition with increasing lean body mass and decreasing fat mass. The proportion of patients with TS patients with overtly impaired glucose tolerance does not seem to increase and HbA_{1c} remains unchanged or even decreases during GH therapy (Sas *et al.*, 2000). While most of the effects on the glucose metabolism seem to reverse after cessation of GH treatment, the long-term effects of hyperinsulinism and insulin resistance induced during GH delivery are not known.

In the face of widespread abnormalities of glucose homeostasis and increased risk of type 1 and type 2 diabetes mellitus there is a need for persistent attention to these factors in clinical follow-up. Recommendations for diagnosis and treatment of diabetes adhere to general population guidelines and annual screening of fasting glucose and HbA1c should be performed (Gravholt *et al.*, 2017).

Autoimmune thyroid disease is very frequent in TS, with hypothyroidism occurring in up to 50% of women at the age of 50 years (El Mansoury *et al.*, 2005). Hyperthyroidism also occurs more frequently than among controls. Treatment follows clinical guidelines on thyroid diseases. The occurrence of all other autoimmune diseases is also increased in comparison with the background population and the reason for this increase remains obscure (Jorgensen *et al.*, 2010). Therefore, the clinician should be vigilant and examine TS women at the slightest suspicion. Currently, there are recommendations for how a clinical care program

should be tailored for adults with TS (Gravholt *et al.*, 2017). Diseases like coeliac disease, inflammatory bowel disease, and rheumatoid disease occur sufficiently frequent to warrant special attention.

Peak bone mass depends on several factors, such as genetic background, nutrition, physical activity, local growth factors and a spectrum of hormones. Estradiol secretion in TS is deficient already in childhood and adolescence, and children and younger and middle-aged adult patients with TS have low bone mineral density, and studies show that the risk of fracture and frank osteoporosis is increased (Gravholt *et al.*, 1998a, 2003; Ross *et al.*, 1991). Estrogen substitution therapy is crucial in order to induce maximal peak bone mass in adolescents and young adults and avoid a rapid decline in density (Bertelloni *et al.*, 2000). TS with spontaneous menstruation have normal BMD, while absent menarche associates with a reduced BMD (Carrascosa *et al.*, 2000). A 3-year longitudinal study of 21 women with TS (age 20–40) showed marked improvements of estrogen on bone structure (Khastgir *et al.*, 2003) resulting in estradiol levels comparable to levels in premenopausal women. The bone biopsies pointed

Table 1 Guidelines for adult health surveillance

	Action	*Suggested frequency*	*Comments*
Obesity	Weight	Annually	Many co-morbidities are weight-related, for example, diabetes, elevated cholesterol, and liver dysfunction. Weight management is the most important health intervention at annual visits. Obesity may be due to low physical fitness, sedentary lifestyle, and poor food choices
Cardiovascular	Echocardiogram	3–5 years—yearly if aortic root >3 cm	Management shared with GUCH (grown-ups with congenital heart defects) clinic preferable. Congenital malformations include bicuspid aortic valve, coarctation of the aorta, and aortic dilatation
	MRI aorta	As appropriate	Some units use echocardiography for routine monitoring and reserve MRI for ambiguous findings or as part of pre-pregnancy assessment. MR is always recommended if available.
	Blood pressure	Annually	Hypertension affects up to 50% of young adults and contributes to the risk of aortic dissection. Refer to age-specific reference data. Hypertension can be treated to normal guidelines including use of beta blockers or angiotensin-receptor blockers. For aortic root >3.0 cm and BAV, aim for systolic blood pressure <140 mmHg if tricuspid aortic valve or <120 mmHg if bicuspid valve
Bone metabolism	DEXA scan	Every 5 years	Estrogen replacement required until ~ 50 years (or older if there have been many years of estrogen deficiency) to prevent osteoporosis. Bone density of spine reads low in short stature with DEXA. Osteoporosis can be treated as in other situations
	Vitamin D and calcium profile	3–5 years	Monitor bone profile in those with low calcium and low vitamin D levels; exclude celiac disease (see below)
Liver	Liver function tests	Annually	Liver enzymes, especially gammaglutamyl transaminase (GGT), are commonly elevated. Slowly progressive, but improves with estrogen and weight loss. Consider viral screen for acute changes (rarely positive)
	Liver ultrasound	As appropriate	Liver US required for markedly raised GGT, alkaline phosphatase or transaminases. Consider special scans measuring fibrosis and steatosis, and biopsy if structural defects identified on UL
Diabetes	HbA1c $\pm$ fasting plasma glucose	Annually	Consider OGTT if HbA1c is elevated. High risk of developing impaired glucose tolerance (50%) due a combination of insulin deficiency and insulin resistance. Fasting plasma glucose underestimates defect of insulin secretion
Fertility	Adoption and oocyte donation education	As appropriate	Spontaneous pregnancy occurs in 2%–5%. Ovarian failure occurs in 90%. Medical review on advisability of pregnancy with regard to risk of aortic dissection is required
	Uterine ultrasound	As appropriate	US of the uterus should take place on arrival in the adult clinic and again during the work-up for pregnancy
Psychological	Review psychological issues	As appropriate	Increased risk of social isolation, anxiety, and obsessive behavior. Higher levels of shyness and social anxiety, and reduced self-esteem. Review problems in work place or in relationships. Problems are responsive to clinical psychology support.
Audiology	Audiogram ENT History	3–5 years	Deafness is common and under reported. Self-reporting unreliable. Otitis media is common in childhood (60%–80%) which can lead to conductive hearing loss. Sensori-neural hearing loss common and progressive in adults
Dermatology	Skin inspection	Annually	Assess for keloid and changes and in pigmented nevi
Orthodontics	Teeth inspection	Annually	Referral recommended if required
Blood tests	Thyroid function	Annually	Increased risk of autoimmune thyroiditis. In hypothyroidism (24%) or hyperthyroidism (2.5%) include TPO antibodies if previously negative
	Celiac screen	With suggestive symptoms	Increased risk (4%–6%) of celiac disease. Check transglutaminase IgA antibodies (and total IgA) and vitamin B12

From Gravholt, C.H., Andersen, N.H., Conway, G.S., Dekkers, O.M., Geffner, M.E., Klein, K.O., Lin, A.E., Mauras, N., Quigley, C.A., Rubin, K., *et al.* (2017). Clinical practice guidelines for the care of girls and women with Turner syndrome. Proceedings from the 2016 Cincinnati international Turner syndrome meeting. European Journal of Endocrinology 177, G1–G70, with permission.

towards an anabolic effect on the skeleton of high-dose estradiol substitution therapy in young adult patients with TS (Khastgir *et al.*, 2003), and growth hormone treatment may also improve bone mineral density in TS (Sas *et al.*, 2001). No very long-term studies of the effect of estradiol have been published but 5 years of appropriate HRT maintain BMD unchanged (Cleemann *et al.*, 2009). Furthermore, the optimal dosage of estrogen during adult life has yet to be determined, but recent recommendations should be followed (Gravholt *et al.*, 2017). Vitamin D-deficiency is frequent and appropriate substitution should be in place, and general recommendations on a bone healthy life style should be advised.

Co Morbidity

A wide range of comorbidities can be seen in TS and it is therefore helpful to assemble a multidisciplinary team to enable pervasive care (**Table 1**).

Hearing impairment is frequent and most TS will experience early hearing loss compared with controls and many times necessitate the need for hearing aids. The hearing loss is multifactorial. During childhood otitis media is frequent and during adulthood, many experience sensorineural hearing loss and some also conductive hearing loss.

Conclusions

Patients with TS are in need comprehensive monitoring and care preferably delivered by a multidisciplinary team. This has recently been very clearly documented in a study where the authors followed clinical guidelines in their clinical setup and found a substantial and hitherto undiagnosed morbidity in a large cohort (Freriks *et al.*, 2011), and this can be most optimally handled with centralized care. Glucose metabolism, weight, thyroid function, bone metabolism, blood pressure, liver function and cardiovascular status should be regularly assessed. Estrogen deficiency should be treated, preferably with natural estrogens and a progestin, and growth hormone treatment should be commenced early in life. Accompanying medical problems should be detected and aggressively treated.

Unfortunately, an array of important clinical questions is left to be answered regarding optimal care in patients with TS. There is a substantial deficit in our understanding of the syndrome but a hope to improve patient outcome through not only a specialized multidisciplinary clinical approach but also via a continuous effort to span disciplines in future research.

Initial Evaluation of the Infertile Couple

Jean-Marie Antoine and Jacqueline Mandelbaum, Tenon Hospital, Paris, France and Pierre and Marie Curie University, Paris, France

Introduction

Infertility affects around 13%–15% of couples worldwide (Mascarenhas *et al.*, 2012), seriously impacting their life and representing a common clinical issue as well as a public health problem. Infertility is clinically defined as "the inability of a couple to achieve pregnancy after 12 months or more of regular unprotected sexual intercourse." For healthy young couples, the probability to conceive per reproductive cycle is about 20%–25% and the cumulative probabilities of conception approximate 90% within the first year (Kamel, 2010).

Infertility may be primary, occurring in couples with no previous history of conception, or secondary. The most common causes in developed countries are the result of female factors in 30% of cases, male factors in 20%, combined male and female in 40%, and in approximately 10% of couples no obvious etiologic factor can be detected (unexplained infertility).

Before applying any therapy, an evidence-based diagnostic will be performed in both members of the couple, relying on medical history, physical examination, and appropriate investigations (semen analysis, ovarian function, and female genital tract). An efficient and complete initial evaluation is essential to identify and prove the cause(s) of infertility, provide accurate information, and choose the most adequate treatment. Emotional aspects of reproductive disorders should never be overlooked and a psychosocial support should be available besides medical care.

Evaluation of Female Infertility

For women, the initial assessment should include at least hysterosalpingography, hormonal assays, and pelvic ultrasound with antral follicle count.

When to Start the Infertility Work-Up?

Time is essential: too many couples complain about a long delay in effective management. Infertility is classically defined by the absence of pregnancy after 2 years of unprotected regular intercourse. However, it is currently recommended to start infertility evaluation:

- After 1 year of regular intercourse before the women's age of 35, the majority of pregnancies occurring in the first 6 months,
- After 6 months between 35 and 37,
- Immediately from the age of 38 or in case of a major cause of infertility already known: endometriosis, genital malformation, bilateral salpingectomy, azoospermia.

Where to Start the Infertility Work-Up?

The first tests may be prescribed by a general practitioner or a gynecologist. Specialized structures such as Fertility Assessment and Counseling (FAC) Clinics are also available in some countries to inform women about their fertility and give them preventive advice (Birch Petersen *et al.*, 2017).

History

Women's age is of paramount importance: desire to succeed in professional careers, lifespan prolongation, and second unions drive more and more women to delay their first pregnancy. Older age is associated with a reduction in the pregnancy rate and an increase in miscarriages, mainly due to deterioration of the ovarian reserve and oocyte quality. Uterine aging comes later and has more limited effects, as shown by oocyte donation model. Age of the male partner and reduction in the intercourse frequency are also involved. Many infertility cases can only be explained by advanced female age, raising the question of the limits between physiological fertility decline and so-called unexplained infertility (Somigliana *et al.*, 2016).

It is also necessary to search for information about:

- Duration of infertility,
- Family and personal genetic, oncologic, or thromboembolic events,
- Weight, height, smoking, previous surgery, chemotherapy or radiotherapy,
- Gynecological history: in utero exposure to diethylstilbestrol, age at first menstruation, contraception (modalities, complications), past pregnancies, infections, pelvic pain,

 doi:10.1016/B978-0-12-801238-3.64962-0

- Cycle features: duration (short/long in favor of ovarian insufficiency/polycystic ovaries), regularity, periods of amenorrhea, signs of lack of estrogens (hot flushes),
- Sexual intercourse frequency, programming, dyspareunia, or other sexual troubles,
- Lifestyle: smoking, alcohol, or other drugs use.

Physical examination

- Height, weight, and BMI,
- General morphology, secondary sexual characteristics, hirsutism,
- Malformation of the vulva or vagina,
- Congenital malformation of the womb, myomas, adenomyosis, fixed uterine retroversion suggestive of pelvic endometriosis,
- Adnexal pain at uterine mobilization (chronic or acute inflammation), increase in volume (ovarian cyst, hydrosalpinx),
- Galactorrhea in favor of functional or organic hyperprolactinemia.

Ovarian function assessment

Basal body temperature chart reflects the plasma progesterone pattern during the cycle:

- Normoovulatory cycle: middle of the cycle fast shift in 1–2 days, followed by a plateau of about 10 days,
- Dysovulatory cycle: delayed and slow shift, short and irregular plateau,
- Anovulatory cycle: temperature constantly below 37°C.

Vaginal ultrasound on the third day of the cycle evaluates:

- Volume and appearance of ovaries: polycystic ovaries, ovarian atrophy,
- Antral follicles count for ovarian reserve evaluation, taking into account previous oral contraception (Letourneau *et al.*, 2017).

Midluteal phase serum progesterone: low in dysovulation or anovulation.
Plasma hormone assays on the third day of the cycle:

- Anti-Müllerian hormone: >2 ng/mL (low in early ovarian failure), a good predictor of ovarian response in controlled ovarian stimulation, not of pregnancy (Meczekalski *et al.*, 2016),
- FSH (follicle-stimulating hormone): between 1 and 6 mIU/mL (high in early ovarian failure),
- LH (luteinizing hormone): between 1 and 6 mIU/mL (high in polycystic ovaries),
- Estradiol: <80 pg/mL (high in early ovarian failure or hormones producing ovarian cyst),
- Prolactin: <20 ng/mL (high in some drugs intake or pituitary prolactin secreting adenomas),
- Testosterone: <0.6 ng/mL and delta-4 androstenedione <2.5 ng/mL (high in polycystic ovaries or ovarian hyperandrogenism),
- Progesterone: <0.5 ng/mL (high in unknown pregnancy, corpus luteum cyst or 21 hydroxylase blockage),
- TSH (thyroid stimulating hormone) for hyper- or hypothyroidism detection, to be treated before starting a pregnancy (Cho, 2015).

More tests are needed in some conditions:

- Hypothalamic or pituitary failure, hyperprolactinemia: pituitary MRI,
- Hyperandrogenism: DHA, SDHA, 17 hydroxyprogesterone, Synacthen test, ovarian and adrenal imaging,
- Ovarian failure: genetic screening (karyotype, fragile X premutation) (Rossetti *et al.*, 2017), bone densitometry, search for associated autoimmune diseases.

Infectious assessment

Before invasive uterine examinations, bacteriological samples in the cervix, vagina, and urine look for banal germs, chlamydiae, or mycoplasma infection, leading to treat both partners.

Chlamydia antibody testing helps in identifying possible tubal factor infertility (Singh *et al.*, 2016).
Rubella, toxoplasmosis, HIV, syphilis, hepatitis B and C serology detect:

- Lack of immunization: vaccination against rubella with temporary contraception,
- Infections requiring specific management before pregnancy. Specialized tests dealing with hepatitis B and C (viral DNA or RNA, liver evaluation) or HIV (CD4, viral load) are required before ART in the context of a viral risk.

Cervical factors assessment

The Hühner postcoital test is controversial in the international literature (Hessel *et al.*, 2014), but still used in France. It consists of examining cervical mucus during the preovulatory period, 6–12 h after sexual intercourse. Its anomalies may be related to:

- insufficient mucus secretion, infection, or excessive acidity,
- sperm deficiency, to be confirmed by semen analysis,
- or disorder in their interaction, despite apparently normal mucus and sperm. It leads to cross penetration tests, using control sperm and mucus, and to search for antisperm antibodies (ASA) in mucus and sperm. All these results are taken into account in the choice between intrauterine insemination and intracytoplasmic sperm injection (ICSI).

Female genital tract assessment

Transvaginal sonography provides information about:

- Myometrial pathologies: malformation, fibroids, adenomyosis (Phillips *et al.*, 2015).
- Adnexal diseases: ovarian cysts, hydrosalpinx, endometriosis which is associated with an age-adjusted 2-fold increased risk of infertility (Prescott *et al.*, 2016).

Endo-uterine invasive examinations must be done:

- after ruling out recent hemorrhage or infection,
- in the first part of the cycle, between the end of menstruation and periovulatory period to avoid unknown pregnancy and false tubal blockage by uterotubal junction spasm.

Hystero-sonosalpingography has quite good sensitivity and specificity for evaluation of tubal patency. It is inexpensive, minimally invasive and quick, without radiation risk (Malik *et al.*, 2014).

However, conventional hysterosalpingography remains the first-line diagnostic method for most reproductive medicine experts (Capobianco *et al.*, 2015). Regarding the technique, it has recently been shown that spontaneous ongoing pregnancy and live births rates are higher among women who underwent hysterosalpingography with oil than with water contrast (Dreyer, 2017). Besides uterine cavity imaging, tubal patency can be evaluated:

- at the proximal level: postinfectious or endometriotic occlusion, endometrial polyp, or round horn aspect leading to rule out a tubal spasm by selective catheterization under radiological or laparoscopic control,
- at the middle-isthmus level: genital tuberculosis, sequelae of tubal sterilization,
- at the distal part:
  - Hydrosalpinx: complete closure with or without mucosal folds preservation,
  - Phimosis: partial patency with distension and ampullary retention on late control,
  - Peri-tubo-ovarian adhesions: patent tube but limited peritoneal scattering of the contrast.

Hysteroscopy allows direct vision of the uterine cavity and tubal ostia. It ensures:

- the correction of false positive at hysterosalpingography due to air bubbles or clots,
- a better evaluation of organic lesions, mainly their resectability by operative hysteroscopy.

The risk of perforation is low, but interpretation is operator dependent. Hysteroscopy is mostly performed as a second-line examination, according to clinical signs and imaging. Opinions are divided about the interest of systematic hysteroscopy in any infertility assessment or after a certain age (35 or 40 years): it does not belong so far to the first-line guidelines (Di Spiezio Sardo *et al.*, 2016).

Endometrial biopsy evaluates the endometrial growth, maturation, and implanting capacity, depending on the date of the cycle. A subacute endometritis can sometimes be diagnosed and treated. More specialized tests deal with numerous genomic, biochemical and immunologic markers of implantation (Katzorke *et al.*, 2016). The possible beneficial effect on pregnancy rate of endometrial microtrauma remains controversial (Shokeir *et al.*, 2016; Maged *et al.*, 2016).

Laparoscopy is no longer indicated systematically during any infertility work-up, but in cases of suspected genital endometriosis, pelvic mass, tubal abnormality, or pelvic adhesions (Hassa and Aydin, 2014; Berker *et al.*, 2015). Both diagnostic and operative, it allows a direct assessment of:

- Tubes condition: proximal node, hydrosalpinx, phimosis with the degree of conservation of the ampullary wall, and blue test for evaluating tubal permeability.
- Ovaries: size and aspect, endometrioma or other types of cysts.
- Peritoneum: subacute or chronic inflammation due to chlamydia infection, fine granulations suggestive of genital tuberculosis, pelvic adhesions, or endometriosis localization and staging.

More Specialized Examinations

- *Genitourinary malformations or deep and/or extended pelvic endometriosis*: pelvic MRI, endorectal ultrasound, rectoscopy, intravenous urography, cystoscopy.
- *Recurrent spontaneous miscarriages*: karyotype, immunological factors, and coagulation assessments.

Risk Factors for the Female Infertility Treatment

According to personal or family history, additional examinations may be necessary before starting an infertility treatment:

- Genetics: karyotype, molecular genetics,
- Thromboembolic: coagulation assessment,
- Cancer risk: mammography, BRCA1 and BRCA2 mutations,
- Risk of ovarian hyperstimulation: FSH receptors polymorphisms should make possible to better predict ovarian response to stimulation.

Evaluation of Male Infertility

In almost 50% of involuntarily childless couples, a male factor is found, either isolated or associated with female factors. Therefore, a clinical assessment is essential in all men, as well as semen analysis.

History Taking

The male partner should be questioned about:

- Age and other information relevant to male fertility (occupation …)
- Fertility history with his partner or another, duration of infertility, and any previous evaluation ± treatments
- Family history of infertility or other reproductive disorders
- General history of diseases that may influence fertility: fever exceeding 38°C and affecting spermatogenesis for ≥3 months, diabetes (retrograde ejaculation), respiratory problems as bronchiectasis (may be part of the immotile cilia syndrome), neurological disorders that may affect sexual function, any irradiation of the genital area, or any medical treatment that may impair spermatogenesis (cytotoxic, antidepressants, antihypertensive drugs, …)
- Genitourinary and andrological background: age at puberty, history testicular problem (cryptorchidism, testicular torsion, or injury), testicular and scrotal surgery, or any locoregional operation which may impact fertility (inguinal hernia repair, …), infectious diseases (sexually transmitted, mumps orchitis, tuberculosis)
- Is sexual activity normal? Libido, frequency of intercourse (a too long abstinence may decrease motility), matching with the time of the partner's ovulation, is there any erectile or ejaculatory dysfunction?
- Search for environmental or occupational toxic factors to male fertility (heat, solvents, pesticides, …). Personal habits may impair sperm count and/or motility: wearing tight pants, taking hot baths, excessive alcohol drinking, cigarette smoking, or regular cannabis use.

Clinical Examination

Aims to assess secondary sexual characteristics such as distribution of facial and pubic hair, pubertal stage, body configuration and possible gynecomastia, looking for signs of hypogonadism.

A general physical examination is also performed and body weight, height, and blood pressure are recorded.

The rest of the medical screening will be focused on the urogenital system:

- inspection of the penis and location of the urethral meatus (hypospadias will prevent the normal delivery of semen into the vagina),
- verification of the presence of both testis in the scrotum and evaluation of their volume (approximately 25 mL or 5 × 3 cm in adults), consistency as 80% of the testis mass is represented by the germinal tissue (seminiferous tubules) and possible nodes to be explored by ultrasound. Small and soft testis indicate a hypogonadism,
- palpation of the epididymis along its entire course could reveal abnormalities (partial agenesis, distension suggesting a downstream obstruction)
- presence of the vas deferens should be assessed within the spermatic cord
- varicocele is better detected while the patient is standing
- rectal examination to evaluate the prostate and seminal vesicles is only performed on warning signs (history of infection, dysuria, cancer screening in men over 50)

Semen analysis should be performed in all couples presenting with infertility and represents the primary and basic biological testing of the male partner. Abnormal values suggest a possible male factor cause, direct the etiological diagnosis requiring further clinical assessment and biological tests, and may orientate therapeutic proposals.

Standard semen analysis

A semen sample should be obtained by masturbation in the laboratory setting, after an abstinence interval of 2–5 days. The entire ejaculate should be collected in a clean, sterile, nontoxic plastic container and analyzed, according to WHO criteria (2010), within

1 h of collection, after liquefaction (occurring usually within 15–30 min at 37°C). Any loss should be recorded, keeping in mind that losing the first semen fraction (containing the spermatozoa expelled together with prostatic fluid) has more consequences on the results than spilling the rest of the ejaculate (seminal vesicular fluid).

The main parameters assessed include the volume of ejaculate, sperm concentration, progressive motility (percentage of spermatozoa displaying a progressive movement, essential for fertilizing ability), vitality, and sperm morphology. They have to be interpreted in accordance with the WHO references values (2010) (**Table 1**).

- The lower reference limits were generated from men whose partners had a time-to-pregnancy $\leq$12 months. They provide, together with clinical data, a useful guide to a patient's fertility status. Nevertheless, it would be inappropriate to consider that a man with a semen analysis below the reference limits is necessarily infertile as well as to think that semen parameters within the 95% intervals guarantee fertility. Indeed, there is a considerable overlap between semen characteristics in fertile and subfertile men.
- The two major quantifiable attributes of a semen sample in normal conditions are:
  - the total fluid volume reflecting the secretory activity of accessory glands (mainly seminal vesicles and prostate).
  - the total number of spermatozoa or total sperm count (TSC) (sperm concentration $\times$ volume of the whole ejaculate) indicative of testis sperm production. Both also reflect the patency of the male reproductive tract.
  - Vitality (assessed with the eosin test or the hypo-osmotic swelling test and quantifying living cells independently of their motility), progressive motility, and normal morphology are also essential for sperm function.

Normozoospermia refers to a semen sample with parameters of number, progressive motility, and normal morphology equal to or above the lower reference limits (**Table 1**).

- Abnormalities may be isolated or associated (oligoasthenozoospermia, asthenoteratozoospermia, etc.). Often, all three parameters are simultaneously impaired, defining the oligo-astheno-teratozoospermia syndrome, remaining frequently unexplained, contrary to azoospermia (Punab *et al.*, 2017).
- TSC, sperm concentration, and progressive motility are the semen parameters correlating the best with fertility potential (time to pregnancy and pregnancy rates) and when comparing proven fertile and infertile male cohorts (Slama *et al.*, 2002; Nallella *et al.*, 2006).
- Complete absence of motility of live spermatozoa can be seen in men with ciliary dyskinesia (Kartagener syndrome).
- Necrozoospermia may originate from testis causes (hyperthyroidism, local hyperthermia, varicocele), posttesticular causes (epididymal dysfunction, dysregulation of seminal plasma, cytotoxic ASA), or both (infection, toxic, …).

If the first semen analysis is normal, no additional investigation is required. If it is abnormal, a new testing is needed for confirmation, owing to the wide intra-individual variation in semen quality (Castilla *et al.*, 2006) and the potential problems occurring before (fever) or during semen collection. It will be performed 3 months later, according to the length of spermatogenesis cycle in humans (about 74 days).

Table 1 Main semen parameters: lower reference limits (5th centiles and their 95% confidence intervals)

Sperm parameter	*Lower reference limit (range)*	*Abnormalities*
Semen volume (mL)	1.5 (1.4–1.7)	<1.5 mL: hypospermia in case of congenital bilateral absence of the vas deferens (CBAVD) or obstruction of ejaculatory duct or loss of part of the ejaculate during collection or androgen deficiency 0 mL: aspermia (search for retrograde ejaculation)
Total sperm count (10^6 per ejaculate)	39 (33–46)	<39: oligozoospermia No spermatozoa in the ejaculate: azoospermia Sperm only observed in a centrifuged pellet: cryptozoospermia
Sperm concentration (10^6 per mL)	15 (12–16)	<15: oligozoospermia
Progressive motility (%)	32 (31–34)	<32: asthenozoospermia
Vitality (% live spermatozoa)	58 (55–63)	High percentage of immotile dead spermatozoa: necrozoospermia
Morphology (% normal forms)[a]	4	<4: teratozoospermia
Morphology (% normal forms)[b]	23	<23: teratozoospermia Usually multiple anomalies are recorded. Occasionally almost all spermatozoa have the same structural defect which may be linked to infertility. It may be the case for the absence of the acrosome: "small round-head defect or globozoospermia," microcephaly, short-tail sperm

[a]According to Kruger *et al.* (1986).
[b]According to David in: Auger *et al.* (2016).

Other semen parameters might be of interest:

- Agglutination of motile spermatozoa sticking to each other by heads, midpieces, or tails should be recorded and graded (1–4) as it may be indicative of the presence of ASA requiring further testing.
- Evaluation of sperm morphology on stained semen smears allows identification of other cell types than spermatozoa. The presence of immature germ cells may result from spermatogenesis dysfunction.

  Leucocytes can be seen in most human ejaculates and granulocytes can be quantified by their peroxidase activity. Excessive leucocyte numbers ($>1 \times 10^6$ per mL), called leukocytospermia, reflect an inflammatory condition but the association with infection remains controversial. Leucocytospermia is >2-fold higher in a group of patients with idiopathic reduced sperm counts compared to controls (Punab *et al.*, 2017).
- The semen pH (lower threshold value: 7.2; WHO, 2010) represents an equilibrium between alkaline seminal vesicular and acidic prostatic secretions. A low pH (<7) is indicative of an absent or reduced seminal vesicular secretion as seen in congenital bilateral absence of the vas deferens (CBAVD) or in ejaculatory duct obstruction.

Additional semen investigations

Biochemical analysis: markers of the secretion of epididymis and accessory glands can be measured in the seminal fluid and give information about their functional state. The amount of zinc (≥2.4 μmol/ejaculate) reflects the secretory capacity of the prostate, neutral α-glucosidase (≥20 mU/ejaculate) is the more reliable marker for epididymal condition, and fructose (≥13 μmol/ejaculate) correlates with the secretion of seminal vesicles (WHO, 2010). A decrease in the concentration of these markers may suggest an infection, an androgen deficiency, or an obstruction on the male tract. A low fructose concentration is typical of CBAVD but may also indicate an ejaculatory duct obstruction.

ASA are present in about 4% of men consulting for infertility.

- ASA may be checked in case of high sperm agglutination and/or deficient postcoital test, despite normal mucus and semen. Sperm cells display various surface antigens that may induce the synthesis of ASA when the blood-testis barrier is ruptured. Antibodies adsorbed on the surface of motile spermatozoa can be detected by immunological assays using IgG and IgA antibodies coupled to beads. The mixed antiglobulin reaction (MAR test) is performed on a fresh semen sample while the immunobead test uses washed spermatozoa.
- When 50% or more of the motile spermatozoa have adherent beads (Barratt *et al.*, 1992), except on the tail tip, a feature also seen in fertile men (Chui and Chamley, 2004), immunological infertility may be suspected and responsible for impaired in vivo and conventional in vitro fertilization.

Evaluation of complete or partial retrograde ejaculation should be performed by looking for sperm in the pellet of postejaculatory urine, in case of aspermia or low sperm volume.

Other Basic Investigations

Infectious

Semen culture will be prescribed in case of history or clinical signs of a genitourinary tract infection or semen anomalies (abnormal appearance, viscosity or pH, leukocytospermia) and is mandatory before ART. A concentration $>10^3$ CFU (colony forming unit) of known male tract pathogens is indicative of a significant bacteriospermia but it is difficult to differentiate active infection from commensal microflora.

Hepatitis B, C, and HIV serological tests are required before ART to avoid any viral risk.

Hormonal testing is recommended in case of abnormally low sperm concentration, impaired sexual function, or clinical signs of hypoandrism or endocrine disease and has to be interpreted according to standard values of reference laboratories (Sikka and Hellstrom, 2016).

- FSH levels (1–15 mIU/mL) are inversely correlated with the number of spermatogonia. LH values (1.5–13 mIU/mL) and total testosterone (2.3–9.5 ng/mL) with Leydig cell function.
- Hormonal profiles may distinguish isolated abnormal spermatogenesis (high FSH, normal LH, and testosterone), hypogonadotropic hypogonadism with low levels of LH, FSH, and testosterone (pituitary or hypothalamic origin, treatable by gonadotropins or gonadotropin-releasing hormone), and hypergonadotropic hypogonadism (complete testicular failure) with high levels of FSH and LH and decreased testosterone.
- In azoospermic men, normal FSH suggest an obstructive origin (OA, obstructive azoospermia) with normal spermatogenesis, except for men with maturation arrest at the spermatocyte or spermatid level whose FSH values are within the normal range.
- Inhibin B, product of Sertoli cells, combined with FSH assay may be of value, in nonobstructive azoospermia (NOA), to indicate the presence or absence of testicular spermatozoa.
- Prolactin has to be checked in case of impotence, gynecomastia, galactorrhea, low testosterone. High levels may indicate some drug intake or a pituitary tumor.
- TSH assay for hyper or hypothyroidism is only valuable in the presence of suggestive clinical features (Lotti *et al.*, 2016).

Ultrasonography (US)

Scrotal US can be helpful in men with anatomy particularities hindering physical examination or presenting a risk factor for testicular cancer (cryptorchidism) but not as a routine procedure. Screening for nonpalpable varicocele has no demonstrated clinical significance (ASRM, 2014).

Transrectal US may help in a minority of patients to evaluate abnormalities of the male genital tract that may adversely affect fertility.

Genetic Screening

When indicated, identifying genetic causes for infertility may greatly influence the choice and outcome of treatment. Genetic counseling must be offered to patients.

Blood karyotype: the prevalence of numerical or structural (translocation, inversion) chromosomes anomalies is increased in infertile men and inversely correlated to the sperm count (Clementini *et al.*, 2005). A karyotype is therefore indicated in men with azoospermia (NOA) and still on debate in case of severe oligozoospermia ($<5 \times 10^6$ spermatozoa/mL) (Dul *et al.*, 2012). Sex chromosome aneuploidy (essentially Klinefelter syndrome: 47, XXY and mosaic variants) represents about two-third of all aneuploidies observed in infertile patients.

Y-chromosome microdeletions: 16% of men with severely damaged spermatogenesis (spermatozoa $<1 \times 10^6$ per mL) display Yq microdeletions in the azoospermia factor (AZF) regions (AZFa, AZFb, and AZFc). Identification by polymerase chain reaction techniques of these microdeletions, too small to be detected on standard karyotype, has a diagnostic and prognostic value for testicular sperm retrieval (Krausz *et al.*, 2000). Men with AZFc deletion have severe oligozoospermia or azoospermia with presence of testicular sperm. However, in case of complete AZFa or AZFb loss, it is extremely unlikely to find any testicular sperm and testicular biopsy should not be proposed.

Cystic fibrosis mutations: almost all men with unilateral or bilateral (CBAVD) absence of the vas deferens have mutations in the cystic fibrosis transmembrane regulator gene, except men with an associated unilateral renal agenesis (McCallum *et al.*, 2001). The patient and his partner have to be tested for CF gene mutations.

Sperm DNA aneuploidy can be assessed by multicolor fluorescent in situ hybridization in men referred to ICSI and presenting with karyotype anomalies, as they have an increased risk of sperm aneuploidy. However, results can only be indicative as the sperm to be injected cannot be screened.

Advanced Investigations for Etiological or Therapeutic Approach

Sperm function tests

Selection survival test: it is required before any ART procedure and consists in selecting good-quality spermatozoa and assessing their ability to maintain progressive motility during a 24 h culture period at 37°C. Selection is performed usually using semen centrifugation over discontinuous density gradients. Seminal plasma and epithelial cells are discarded while spermatozoa with forward motility are recovered and the total number of progressively motile spermatozoa in the ejaculate is calculated and will help in choosing the appropriate ART technique. Survival is evaluated as the percentage of still motile sperm cells at the end of the culture and is indicative of the fertilizing ability of the selected spermatozoa.

Sperm chromatin integrity tests: several direct (Comet, TUNEL: Terminal deoxyUridine Nick End Labeling) or indirect (sperm chromatin structure assay) methods have been developed to measure DNA fragmentation rates. However, despite extensive studies, the clinical values of these tests remain to be proven.

Computer-aided semen analysis is still only performed in a small number of clinical laboratories, mainly for assessment of sperm movement characteristics.

Other tests of sperm function are used in research procedures but have limited clinical relevance: assessment of hyperactivation, acrosome reaction, reactive oxygen species, gamete interaction, …

New predictive seminal biomarkers for male infertility may emerge from the genomic, transcriptomic, proteomic, and metabolomics fields (Bieniek *et al.*, 2016).

Surgical sperm retrieval

First applied to OA, sperm retrieval by microsurgical or percutaneous epididymal sperm aspiration has 100% probability of finding sperm suitable for ICSI in the aspirates.

In NOA, testicular sperm extraction (TESE) allows harvesting spermatozoa from the tissue samples in about 50% of the cases, even in Klinefelter syndrome (Corona *et al.*, 2017).

Multiple biopsies and micro TESE maximize the results (Verheyen *et al.*, 2017). Retrieved sperm are microinjected immediately or cryopreserved for later use.

Endometriosis

Alain Audebert, Bordeaux, France

Glossary

Adenomyosis The presence of endometrial glands and stroma in the uterine myometrium.
Dysmenorrhea Painful menses.
Dyspareunia Pain with sexual intercourse.
Endometrioma A cystic lesion of endometriosis, which typically involves the ovary and is filled with brown fluid; also known as a chocolate cyst.
Endometriosis A gynecologic disorder that involves the presence of endometrial glands and stroma outside of the uterine cavity.
Infertility The inability to conceive spontaneously after 1 year of unprotected intercourse.

Endometriosis is defined as the presence of endometrial glands and stroma outside of their normal anatomic location, forming a lining of the uterine cavity. Endometriosis was first described by Rokitansky in Vienna in 1860 and was later given the name endometriosis by Sampson in 1925.

Adenomyosis is characterized by the presence of endometrial glands in the uterine myometrium. Adenomyosis was previously referred to as endometriosis interna, whereas endometriosis outside the uterus was termed endometriosis externa.

Endometriosis is differentiated from endosalpingiosis, which involves only the presence of ectopic endometrial glands without stroma.

Endometriosis is a multifactorial estrogeno dependent inflammatory and chronic disease.

Epidemiology

Endometriosis is estimated to affect 5%–10% of women in general (Eskenazi and Warner, 1997), but the true prevalence of this disease may never be known unless a valuable plasmatic test becomes routinely available.

Endometriosis is a disorder which mainly afflicts women of reproductive age. Age distribution of women with a histologically confirmed endometriosis indicates that the peak incidence is between 35 and 45 years old (Haas *et al.*, 2012). Endometriosis in adolescents appears more common than formerly claimed. Endometriosis is rare in postmenopausal women. Whether or not the occurrence of endometriosis is increasing remains yet unclear.

In selected populations, such as patients with pelvic pain or infertile women, the prevalence may attain 70%.

Endometriosis is more common in first-degree relatives of affected women, but no clear pattern of genetic transmission has been established.

This disorder was long considered to be more common among Caucasian women; however, recent data suggest that the incidence is similar across ethnic origin.

Types of Lesions and Locations

Four basic types of endometriotic lesions have been described. They are frequently associated in the same patient:

- *Superficial implants*: Superficial implants (SI) are the most frequent lesions encountered. The classical appearance of SI is bluish or blue-black or "powder-burn" lesions. Many other appearance have been reported. Nonpigmented, also called atypical or subtle, lesions have been described (**Fig. 1**) (Jannsen and Russel, 1986). These latter lesions are early stages of the disease and have been proved to be very active. They are more frequently encountered in adolescents or young adult women. A biopsy with histologic analysis is mandatory to confirm. Endometriosis, because many other diseases may causes similar lesions.
- *Endometriotic cysts*: Endometriomas (OMA), frequently with associated adhesions, contain a chocolate-like fluid (**Fig. 2**). The etiology of these lesion is still debated.
- *Deep infiltrating endometriosis*: Deep infiltrating endometriosis (DIE) is defined as lesions infiltrating the peritoneum, or the serosa of vital organs, greater than 5 mm (Cornillie *et al.*, 1990). Typically DIE is a nodular blend of fibromuscular tissue and adenomyosis, located in the uterosacral ligaments or the rectovaginal septum (**Figs. 3** and **4**). DIE is apparently more and more frequent' and associated with severe pain symptoms.
- *Adhesions*: Endometriosis is considered as a very "adhesiogenic" disease, demonstrated by the frequent occurrence of associated adhesions.

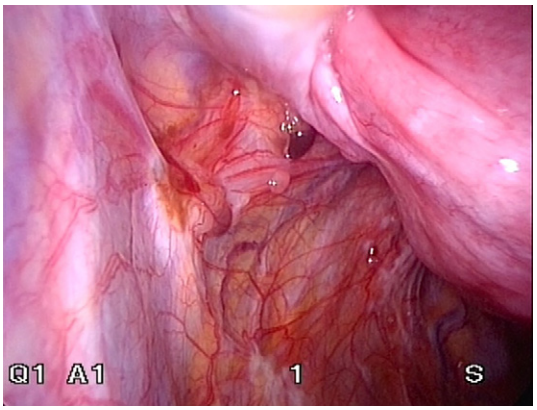

Fig. 1 Early implants in the left fossa ovarica, note the hypervascularization of the surrounding peritoneum.

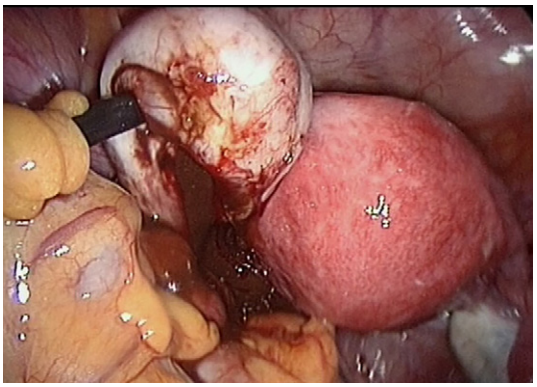

Fig. 2 Ovarian endometrioma with leakage of "chocolate" liquid content.

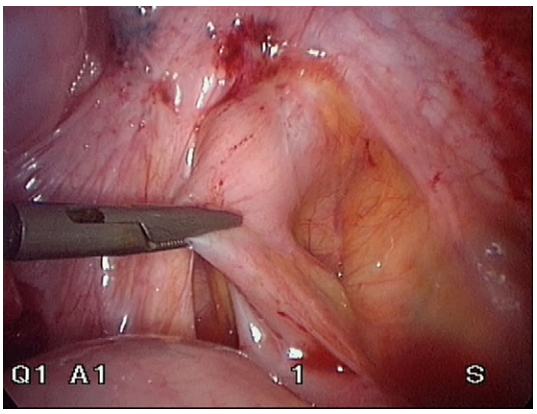

Fig. 3 Adhesion of the sigmoi to torus uterinum suggestive of associated DIE.

Many sites including the ovaries, ovarian fossae, uterosacral ligaments, and pouch of Douglas, which are the most common sites for endometriotic lesions, with a left predominance (Jenkins *et al.*, 1986). Extra-pelvic locations of endometriosis are rare (Matalliotakis *et al.*, 2017; Maccagnano *et al.*, 2013; Nezhat *et al.*, 2014). Some of the sites where endometriosis may be found are shown in **Table 1**. The myriad of involved sites explain the huge variety of symptoms associated with endometriosis.

The extent of the disease may be staged and it is recommended to use a staging system at the time of the diagnosis. The most commonly used staging system is the American Society for Reproductive Medicine (ASRM) revised classification

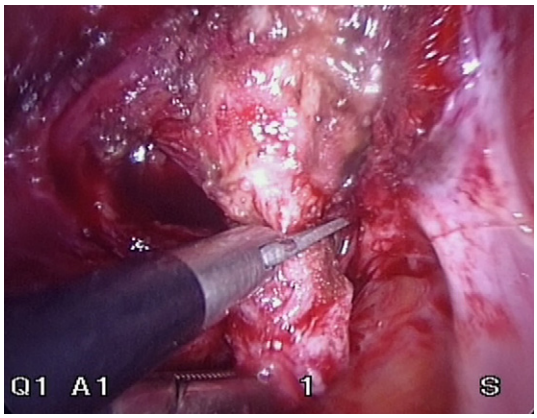

Fig. 4 Nodule of the rectovaginal septum attached to the vagina.

Table 1 Locations of endometriosis

Common sites	*Less common sites*
Ovary	Brain
Pelvic peritoneum	Lung
Uterine serosa	Bowel
Fallopian tube	Ureter
Posterior cul-de-sac	Kidney
Uterosacral ligaments	Appendix
Rectovaginal septum	Vulva
Anterior cul-de-sac	Incision

system AFS (1985). The system involves a point system based on the size, depth, and location of both implants and adhesions. Points are tallied on a form and a stage is assigned based on the number of points (**Fig. 5**). These include stage I (minimal, 1–5 points), stage II (mild, 6–15 points), stage III (moderate, 16–40 points), and stage IV (severe, 40+ points).

But the correlation between lesions and pain symptom or infertility is unclear.

The evolution of lesions is unpredictable. It is assumed that 70%–80% of lesions are stable or progress, thus endometriosis is considered as a recurrent chronic disease requiring a long term management. Degenerescence of endometriotic lesions is rare (0.5%) and related to aging.

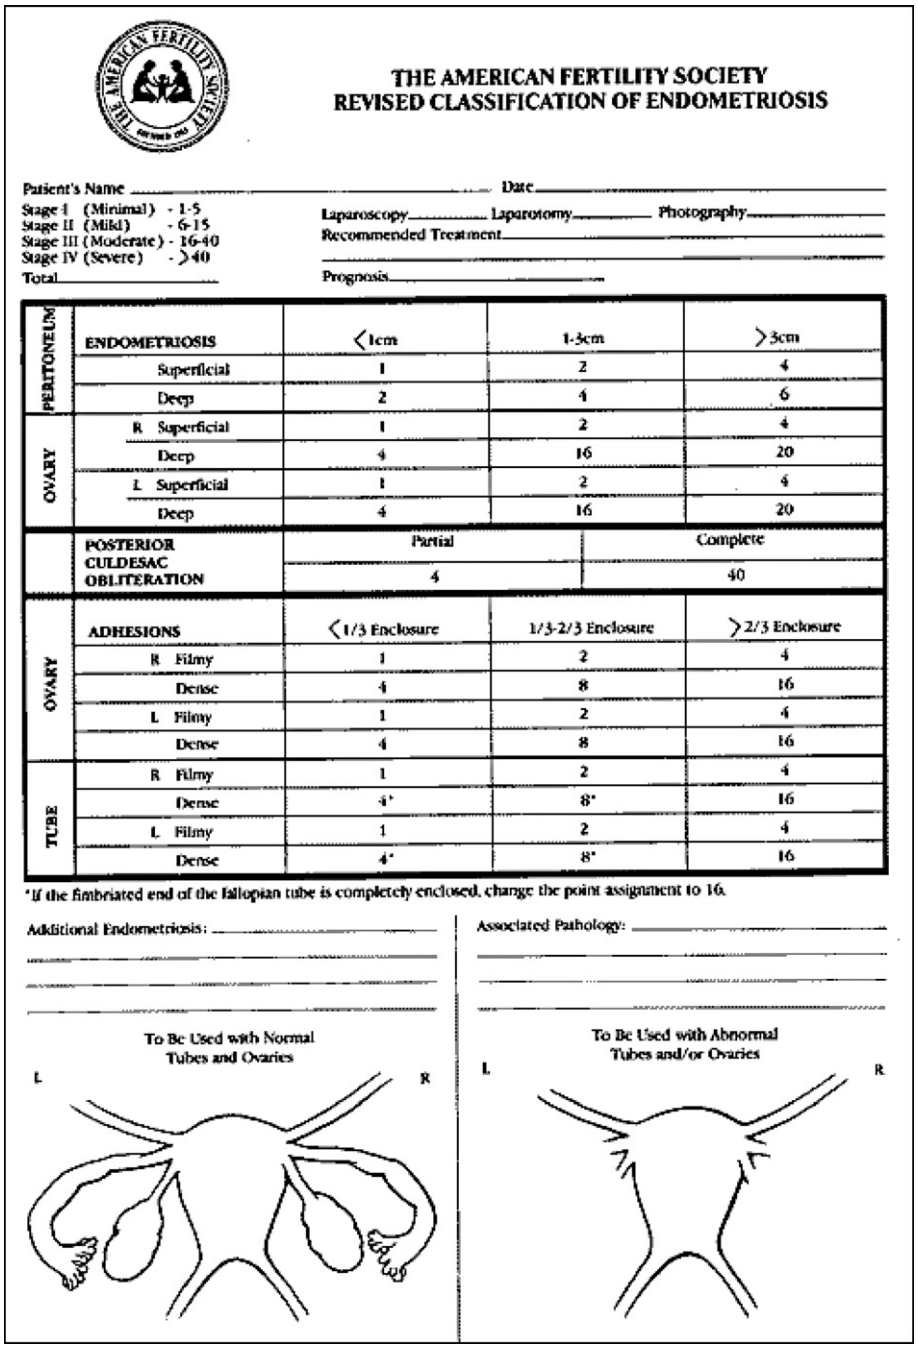
Etiology

The etiology of endometriosis remains unclear. Theories that have been put forth to explain the disorder include retrograde menstrual flow, hematogenous spread, lymphatogenous spread, coelomic metaplasia, embryonic Mullerian rests, and immunologic abnormalities (**Table 2**) (Gleicher and Pratt, 1993).

Women with uterine congenital reproductive anomalies, in particular those that involve obstruction of menstrual outflow, are at particularly high risk for endometriosis. Especially during adolescence. However, the vast majority of women with endometriosis have normal outflow tracts. Since none of the theories put forth can explain all cases, it is likely that endometriosis may be multifactorial in origin.

Several immunologic changes are noted in women with endometriosis. Women with the disease are more likely to be deficient in T cell- and natural killer cell-mediated toxicity. The peritoneal fluid of women with endometriosis contains greater numbers of macrophages and greater macrophage activity than that of normal controls. The fluid also contains higher levels of interleukin-8, a leukocyte chemotactic cytokine. The immunologic differences in these women may explain why most women experience retrograde menstruation yet not all women will develop endometriosis.

In addition many other predisposing factors have been proposed (Burney and Giudice, 2012): genetic predisposition, fetal exposure to diethylstilbestrol, environmental toxins exposition, epigenetic modifications, stem/progenitor cells….



THE AMERICAN FERTILITY SOCIETY
REVISED CLASSIFICATION OF ENDOMETRIOSIS

Patient's Name _____ Date _____

Stage I (Minimal) - 1-5
Stage II (Mild) - 6-15
Stage III (Moderate) - 16-40
Stage IV (Severe) - >40
Total _____

Laparoscopy _____ Laparotomy _____ Photography _____
Recommended Treatment _____
Prognosis _____

Fig. 5 The American Fertility Society revised classification of endometriosis.

Symptoms

Endometriosis may be asymptomatic or may present with symptoms mainly related to location of lesions. Two symptoms are predominant: pain and infertility, but these symptoms are very similar to other common conditions.

Pain Associated With Endometriosis

The cardinal symptom of endometriosis is pelvic pain, typically temporally related to menses. The severity of the pain is variable, altering markedly the quality of life when pain is intense. Pain tends to increase over time. In addition 1/5 of women with endometriosis do have concurrent pain chronic conditions. Different types of pain are common: dysmenorrhea (painful period),

Table 2 Theories regarding endometriosis pathogenesis

- Endometrial spread (tubal and vascular)
- Coelomic metaplasia
- Mullerian rests
- Immunologic changes
- Fetal exposure to DES
- Environmental toxins
- Obstruction of menstrual flow
- Genetic defects
- Stem/progenitor cells
- Epigenetic modifications

dyspareunia (pain with intercourse), chronic pelvic pain. Some pains are less common but often associated with DIE: dysuria (pain with urination), dyschezia (pain with defecation) or bowel pain.

Although all of the above symptoms are common, there is no symptom that is pathognomonic for endometriosis, but when dysmenorrhea is refractory to routine medical treatment the prevalence of endometriosis attains 70%–80%.

Other Symptoms

Many other symptoms may be associated with endometriosis: excessive bleeding, diarrhea or bloating during menstrual periods, fatigue ….

Another clinical presentation of endometriosis is pelvic mass with or without pain.

In rare cases, endometriotic foci may be located in other parts of the body, such as a surgical scar (causing cyclical incision bleeding), in the lungs (causing cyclic hemoptysis or pneumothorax), or in the brain (causing catamenial seizures). When unusual, seemingly nongynecological symptoms occur only with menses, endometriosis often becomes part of the differential diagnosis.

Infertility

Many women will present with no physical symptoms, yet endometriosis will be discovered during the course of an infertility evaluation.

The incidence of endometriosis in infertility patients undergoing diagnostic laparoscopy is relatively high (38%), yet the association between endometriosis and infertility remains unclear. Advanced cases of endometriosis (stage III and IV disease) are associated with decreased fertility, presumably on the basis of pelvic adhesions and mechanical factors. Less advanced cases (stages I and II) are considered by some authors to be causal of infertility and others as merely coincidental. The suggested mechanisms include interference of peritoneal fluid with sperm function and fertilization, decreased oocyte quality, tubal alterations associated with endometriosis (Brichant *et al.*, 2016).

Diagnosis

The only conclusive diagnosis of endometriosis is direct visual inspection preferably by laparoscopy, with histologic confirmation (Hsu *et al.*, 2010). The challenge is to select properly cases for whom laparoscopy is indicated, particularly patients with a high suspicion of endometriosis. The diagnosis of endometriosis is thus difficult and often delayed.

The first step, through a detailed analysis of past history and symptoms, is to identify risk factors, such as familial history, early menarche, pelvic pain, cyclic or not refractory to routine medical treatment, indicating patients more likely to have endometriosis.

The next step is the pelvic examination. Often normal, the pelvic examination may reveal evocative abnormalities of endometriosis such as focal tenderness, nodularity of the uterosacral ligaments, mass in the rectovaginal septum of fixed ovarian mass causing pain during palpation. Experienced clinicians can predict the presence of endometriosis in 80% of cases.

Noninvasive diagnostic tools are serum biomarkers and imaging technics.

Many serum markers have been evaluated. CA-125, a tumor marker, has been studied and was initially thought to be appropriated. Unfortunately CA-125 did no prove to have a good specificity and sensibility according to many published studies. None of the biomarkers evaluated in a review for Cochrane Database could be evaluated in a meaningful way and there was insufficient or poor-quality evidence all other marker do have a limited value (Mol *et al.*, 1998). Some hopes may result from proteomic research.

Table 3 Medical treatments for endometriosis

Oral contraceptives (continuous or cyclic)
Progestins (oral, parental or intra uterine)
Danazol
GnRH agonists (leuprolide, nafarelin, goserelin, buserelin, histrelin)
Antiprogestins (mifepristone, ulipristal acetate)
Aromatase inhibitors (anastrozole, letrozole)
Immunomodulators

Imaging technics did improve their performances for the diagnostic of endometriosis but performances are operator dependent and limited to identify adhesions or SI (Spaczynski and Duleba, 2003). Ultrasound is useful for evaluating pelvic masses for identifying genital malformation, bladder lesions, and nodular DIE.

MRI offers similar performances to identify endometriotic lesions but less operator dependent. MRI is also useful to detect associated adenomyosis present in 25% of patients with endometriosis. MRI is helpful for DIE providing an accurate staging guiding further surgical approach.

Treatment

The goal of treatment of endometriosis is either to ablate or excise lesions by surgery or to improve symptoms with a hormonal agent. Both modalities have a temporally effects. The choice is guided by individual lesions and presenting symptoms. For many years the only treatment was surgery. Then a myriad of hormonal agents were available and practically all of them have been clinically tested and proved to be more or less successful.

Treatment Modalities

- Abstention: A woman who is asymptomatic but is diagnosed with endometriosis at the time of an unrelated surgical procedure (e.g., a laparoscopic tubal sterilization) does not necessarily require treatment. In the absence of pain or infertility, the disease may be managed expectantly.
- Surgery, preferably by laparoscopy, can now treat all types of lesions including the more severe ones. Frequently, surgical treatment is performed at the time of the initial laparoscopy when the diagnosis of endometriosis is made. After the diagnosis is established, the lesions discovered may be fulgurated or resected. Various modalities have been used to ablate the implants including various lasers (CO_2, KTP, Nd-YAG), bipolar or monopolar cautery, endocoagulation, the harmonic scalpel, and sharp resection. Although many physicians have advocated the use of laser for ablation, there are no data that show better outcomes associated with a specific energy source. At the time of surgery, any pelvic adhesions noted may be lysed in order to reduce the pain. Additionally, the uterosacral ligament, which carries sensory nerve fibers from the uterus, may be ablated at this time to assist in pain relief. If an endometrioma or chocolate cyst is encountered, when possible the cyst is opened, the chocolate fluid is aspirated, and the cyst wall is excised. DIE involving digestive or urinary tract can also be excised with the laparoscopic approach. Surgery for these lesions may be difficult to perform and is associated with severe complications in less than 5% of the cases.
- Other surgical procedures are available for the treatment of endometriosis. The procedures described above for laparoscopy may also be performed at the time of laparotomy. A presacral neurectomy may be performed to interrupt the sympathetic nerves at the level of the superior hypogastric plexus. In some instances, one or both ovaries may be removed and sometimes a hysterectomy may be required. Many patients with intractable endometriosis pain and multiple prior surgeries benefit from a "pelvic clean-out," which involves total abdominal hysterectomy with bilateral salpingoophorectomy. It should be noted that most definitive of therapies are approximately 90% effective in the resolution of pain.
- Postoperative adhesions occur frequently after surgery for endometriosis (adhesions may cause pain or infertility). The operative procedure must include routine use of adjuvants measures (gel, barrier …) in order to reduce the development of postoperative adhesions.
- Medical therapies are indicated in patients presenting endometriosis-related pain.

Medical treatment for endometriosis-related pain involves the use of drugs against pain and hormonal therapies to suppress ovulation.

Anti-inflammatory drugs appears to be more efficient among drugs used for pain treatment, and none is superior to others (Allen *et al.*, 2009).

The hormonal therapies are listed in **Table 3**. The rationale for this type of treatment is that the implants of endometriosis are similar to normal eutopic endometrium and will respond to estrogen and progesterone in the same way. Thus, the same hormonal therapies that can induce amenorrhea in women with dysfunctional bleeding would be expected to decrease pain in women with pelvic endometriosis.

Oral contraceptive is the most commonly regimen used for initial treatment. Due to the benign nature of this therapy, treatment is often initiated prior to obtaining a definitive diagnosis. A standard monophasic low dose birth control pill is taken continuously, with no days off and no placebo pills. This will mimic the hormonal milieu found during pregnancy in which high levels of estrogen and progesterone are observed. In general, pregnant women with endometriosis experience a significant abatement of symptoms during pregnancy. Alternatively, progestational agents may be used (Brown *et al.*, 2012). Depot formulations of progestational agents, such as medroxyprogesterone acetate (Depo-Provera), or daily oral progestins, such as medroxyprogesterone acetate (Provera, Cycrin) and norethindrone (Aygestin), or dienogest may be used. A levonorgestrel-releasing intrauterine device LNG-IUD has demonstrated a good efficiency according to randomized control studies (Bahamondes *et al.*, 2013).

An even more effective way to treat endometriosis pain involves what is called a "pseudo-menopause" regimen. Various medications can be used to suppress the hypothalamic–pituitary axis, resulting in a hypogonadotropic, hypoestrogenic state.

One of the first pseudo-menopausal agents to be widely used was Danazol (Danocrine). Danazol is an orally active androgenic steroid believed to both suppress ovulation and act directly to cause atrophy of the endometriotic implants. Given in doses of 200—400 mg twice daily, it is accompanied by side effects that may include hot flashes, vaginal dryness, muscle aches, deepening of the voice, and hirsutism.

Gonadotropin-releasing hormone (GnRH) agonists, such as leuprolide (Lupron), goserelin (Zoladex), nafarelin (Synarel), and buserelin, have become the agents of choice to induce a pseudo-menopause. These medications are all administered parenterally, oral formulations are under investigation. Some are designed to be used monthly or even at 3-month intervals for prolonged suppression of endogenous gonadotropins. This suppression will create a hypoestrogenic milieu and will cause the involution of the endometriotic implants, which are estrogen-dependent. The side effects of the GnRH agonists include headaches, hot flashes, vaginal dryness, and bone loss. In order to prevent the sequelae of osteoporosis later in life, Danazol and GnRH analogues are limited to 6–9 months of use.

The GnRH agonists may also be used on a longer term basis when accompanied by low doses of estrogen plus progestin replacement. This type of regimen is referred to as add-back therapy and its rationale is based on the estrogen threshold hypothesis (Barbieri, 1992). This hypothesis states that endometriosis and bone loss respond to different circulating estrogen levels. The goal thus is to attain an estrogen level that is high enough to conserve bone density yet low enough to prevent regrowth of the endometriosis lesions. The patient is started on a long-acting GnRH agonist, and concurrently or at a later date, low-dose estrogen/progestin replacement therapy is added in a dose that is similar to that given to menopausal women. Alternatively, a norethindrone-only regimen may be used. Add-back therapy has been demonstrated to be safe and effective when used for up to 1 year. Although there exists no general consensus on how long a patient may be kept on such a regimen, many clinicians will continue such therapy for a number of years, with intermittent monitoring of bone density by DEXA scan to ensure that there is no significant bone loss (Surrey and Hornstein, 2002).

Treatment with antiprogestins, aromatase inhibitors or immunomodulators is considered experimental and will not be reviewed in this article (Platteeuw and D'Hooghe, 2014).

Indications and Results of Treatments

Pain treatment

When a patient presents with endometriosis-related pain, she may be treated using a myriad of various medical or surgical therapies.

Initial treatment is surgical or medical. Medical therapy is often used as a first-line therapy and can also be used in conjunction with those patients who undergo surgical therapy for pain.

Comparative studies indicate that combined oral contraceptive pills, GnRHa and progestogens are all effective and well tolerated by patients in treating endometriosis associated pain and improvement of quality of life (Apers *et al.*, 2018), though side effects have to be considered. Rates of improvement of symptoms and quality of life vary from 40% to 90%. The rates of recurrence of pain after cessation of treatment varies from 17% to 32%, depending on the initial severity of pain and lesions, the agent used, the length of follow-up and the presence of a genetic susceptibility.

Combined oral contraceptive pills and progestogens are relatively cheap and more suitable for long-term use as compared to GnRHa.

Surgical treatment of pain associated with endometriosis is improved within the same ranges compared to medical treatment. Recurrence rates of pain occur in 24%–54% of patients. Usually to improve results and reduce the risk of recurrences a medical treatment is prescribed after surgery.

Infertility treatment

A patient who presents with endometriosis and infertility may be treated using surgical means or other types of infertility treatments that are not directly related to endometriosis.

No medical therapy has proven effective for infertility. A meta-analysis by Hughes on the treatment of infertility in early stage endometriosis found no benefit of medical treatment on pregnancy rates (Hughes *et al.*, 1993). The sole exception is the use of GnRHa as a pretreatment for 3 months before proceeding to IVF, for moderate to severe endometriosis associated infertility. In fact medical treatment may be detrimental by causing a delay in pregnancy due to suppression of ovulation.

Superovulation with gonadotropins accompanied by intrauterine insemination resulted in a significant increase in pregnancy rates in women with infertility associated minimal and mild endometriosis (Tummon *et al.*, 1997; Hughes, 1997).

The use of laparoscopic surgery to treat early stage endometriosis was evaluated in two randomized controlled trials. A large Canadian multicenter study showed an increase in monthly fecundity in patients in whom endometriosis was ablated compared with those in whom it was left in situ (Marcoux *et al.*, 1997). A much smaller Italian trial failed to show any benefit (Prazzini, 1999). Thus, it appears likely though not certain that early stage endometriosis may increase the chances of future pregnancy and live birth. For more severe lesions (OMA, DIE, and adhesions) the reported rates of pregnancy is 50%.

Infertility in endometriosis patients can be treated by the same modalities used to treat those with unexplained infertility. IVF is often used in case of failure of surgical treatments and according to recent meta-analysis provides similar results in comparison with a reference group of tubal alterations (Gonzalez-Comadran *et al.*, 2017).

Summary

Endometriosis is an enigmatic disease that is defined by the presence of endometrial stissue in an ectopic location. The etiology remains unknown, though there are certain changes in the immune system as well as an association with abnormal outflow tracts. The symptoms of endometriosis include various manifestations of pelvic pain and infertility and are often temporally related to menses. Diagnosis is made by surgical visualization and treatment may involve hormonal manipulation and/or surgical ablation or resection.

Epigenetics of Endometriosis

Daniel Vaiman, Paris Descartes University, Paris, France

Endometriosis: A Short Definition

Endometriosis is a frequent gynecological disease (affecting 10% of women) resulting in pain and infertility. It is characterized by the implantation of uterine tissue from the endometrium in various places in the abdominal cavity (de Ziegler *et al.*, 2010; Bulun, 2009; Giudice, 2010), such as the peritoneum, the ovaries, the uterosacral ligaments, etc. One way of classifying endometriosis is in three sub categories (OMA = ovarian endometriosis, SUP = superficial endometriosis where the lesions do not reach more than half a centimeter in depth, and DIE = deep infiltrating endometriosis (Borghese *et al.*, 2008)). Another way of classifying endometriosis is similar to the way cancer is classified, in four stages I–IV from moderate to severe (Johnson *et al.*, 2017). An important aspect of endometriosis pathophysiology is the cell proliferation of the ectopic implant(s). This proliferation is hormone-dependent, and women with the disease have an abnormal steroid estrogenic response at the level of the endometrium together with an abnormal expression profile for genes involved in inflammation, cell proliferation, and angiogenesis (Sherwin *et al.*, 2008; Burney *et al.*, 2007). Reciprocally, a quite general finding in endometriosis is progesterone resistance, with a very strong decrease of the PR-B receptor in the lesions (Borghese *et al.*, 2008; Attia *et al.*, 2000; Patel *et al.*, 2017). This down-regulation of the PR-B gene expression could be achieved via epigenetic deregulation; in the lesion, the inflammatory state increases the level of proinflammatory cytokines such as IL1β or TNFα. This latter molecule has been shown to increase methylation at the level of the PR-B promoter (Wu *et al.*, 2008).

Endometriosis: A Benign Proliferative Lesion

Despite its negative effect on the quality of life of women, endometriosis is considered a benign disease since it is not lethal. In fact, although recent reports associate the occurrence of certain ovarian cancers with endometriosis (Ruderman and Pavone, 2017), it seems that cancer-associated somatic mutations are found in specific genes in endometriosis lesions, without cancer development. A recent study using exome sequencing (Anglesio *et al.*, 2017) revealed the existence of somatic mutations in 19 patients out of 24 in genes previously associated with tumorigenesis (*ARID1A*, *PIK3CA*, KRAS, and *PPP2R1A*). These somatic mutations were found in the glandular epithelium of some DIE lesions; interestingly, these non-ovarian deep infiltrating lesions almost never transform into cancer. Therefore, the cellular environment of the endometriosis lesion appears generally unconducive to cancer development, probably owing to a specific epigenetic state of the cells in hormone-dependent lesions.

The Epigenetic Context in Endometriosis

Epigenetics concerns the intricate regulation and modifications able to reversibly modify gene expression, without altering the DNA sequence. In an adult organism, these modifications are transmitted stably from one cell generation to the next. Epigenetic transmission takes place through mitosis but an increasing number of reports indicate that epigenetic inheritance can in some cases also occur through meiosis, and thus can be transmitted from one generation of individuals to the next (Anway *et al.*, 2005; Carone *et al.*, 2010). Three major epigenetic pathways co-exist and interact to modulate gene expression, two pathways change the structure and accessibility of the chromatin either by chemical modifications of the DNA, or by chemical modifications of the histones, the third involves the complex cellular machinery generating and regulating the biogenesis of non-coding RNAs, mainly micro RNAs (miRNA) but also long non coding RNAs (lncRNA). Concerning epigenetic chemical modifications in mammalian tissues, DNA is mainly modified at CG sites, by methylation or hydroxymethylation, and this has been extensively studied in the context of brain development, metabolic diseases, or cancer progression, but also recently in the decidualizing uterus (Gao and Das, 2014). The epigenetic machinery also chemically modifies histones. Histones are proteins that constitute basically charged cores (nucleosomes) built from eight polypeptides (2 × HISTH2A, 2 × HISTH2B, 2 × HISTH3, and 2 × HIST4) around which 146 bp of DNA are wrapped. The N-terminal of these proteins protrudes outside the nucleosome and is the target of numerous post-translational modifications (PTM) generally associated with specific chromatin states, for instance, H3K27ac is associated with active promoters, H3K4me3 with transcriptionally active regions and H3K27me3 with transcriptionally inactive regions (Natsume-Kitatani and Mamitsuka, 2016). Finally, the epigenetic machinery can also modulate the capacity of mRNAs to be translated by affecting their stability. This is performed through the action of small RNA molecules, such as miRNAs, while longer RNAs (e.g., lncRNAs) also play a role in gene regulation. The DNA and histone chemical modification involve short

aliphatic residues with generally one (methyl-) or two carbons (acetyl-) but also phosphorylations, sumoylation and more exotic modifications generally at the level of histone lysine residues (Tan *et al.*, 2011). There is an enzymatic machinery of increasing complexity that is described to perform all these modifications. The necessary chemical residues are provided by food, making it clear that epigenetic mechanisms constitute an interface between the environment and the genome, leading to the concept of the existence of environmental metabolites. The availability of environmental metabolites may alter the offspring epigenome including that of germ cells (Sharma and Rando, 2017). Epigenetic changes in endometriosis have classically been analyzed by two types of comparison: either the comparative analysis of the eutopic endometrium between control and endometriotic women (Houshdaran *et al.*, 2016), or the comparative analysis of the ectopic versus eutopic endometrium in a given patient (Dyson *et al.*, 2014; Borghese *et al.*, 2010).

We published a recent review (Borghese *et al.*, 2017) on the genomics and epigenetics of endometriosis. Therefore, in the present article, we will concentrate on five recent topics linking endometriosis and epigenetic regulation that were not addressed in detail in the previous review:

(i) In recent papers there has been an increasing interest in histone modifications in endometriosis, modifications which were less studied previously and certainly represent a field where research will intensify due to technical improvements in ChIP-seq or ATAC-seq from tissues;
(ii) Using gene-targeted mouse models, there have been several papers focusing on the zinc finger-containing transcription factors KLF10 and KLF11, which appear to be important epigenetic regulators;
(iii) In terms of DNA methylation, recent studies have been increasingly concerned about women's cycles, and focused rather on the comparison between the eutopic endometrium, either in endometriotic or control women, as well as attempting to connect these alterations with gene expression modifications. The comparison between the lesion (ectopic endometrium) and the endometrium of patients have been the subject of numerous articles, both at the genomic level (Dyson *et al.*, 2014; Borghese *et al.*, 2010) and at the level of specific genes, such as *HOXA10*, *SF1*, *CYP19*; thus the reader can consult recent reviews on the subject (Borghese *et al.*, 2017; Koukoura *et al.*, 2016), and we will not deal extensively with this topic here;
(iv) Some recurrent investigations concern the miRNA profile in endometriosis; however, results appear highly variable from one study to another;
(v) Also, the carcinogenic properties of endometriotic lesions have recently been addressed in the aforementioned New England Journal of Medicine study (Anglesio *et al.*, 2017), and this can be considered in terms of epigenetic regulation.

These five points will be addressed in the next part of this review, and are tentatively summarized in **Fig. 1**.

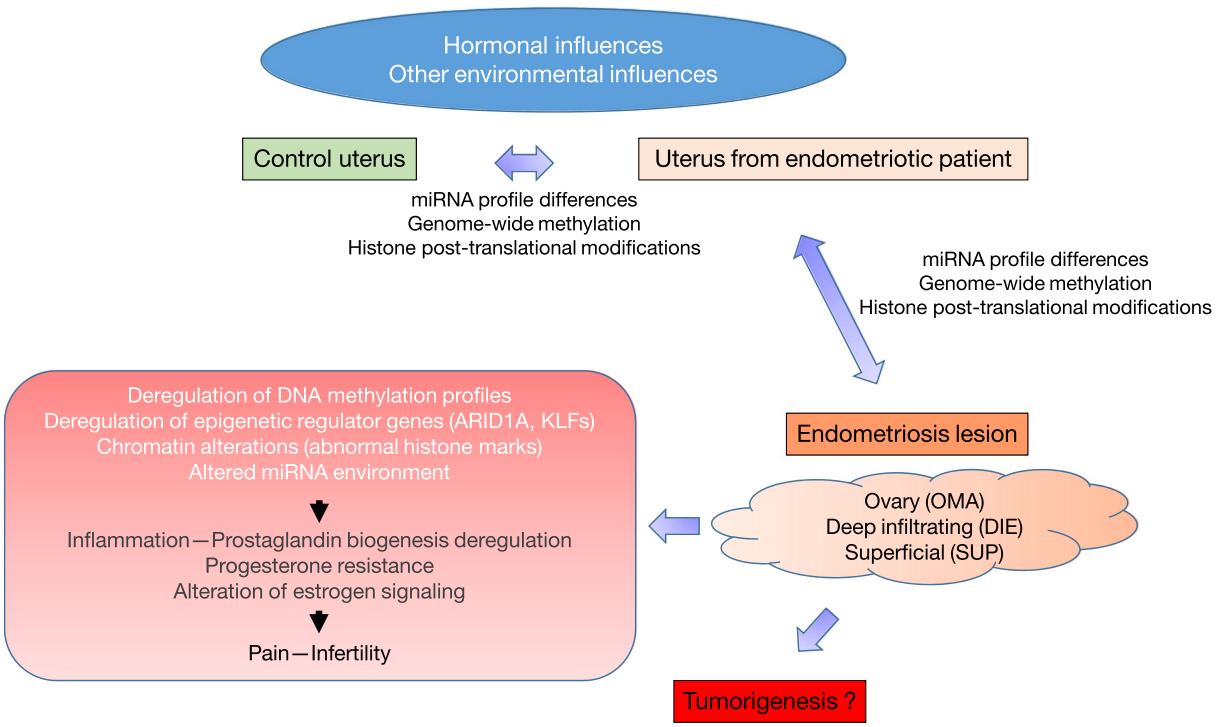

Fig. 1 Endometriosis is a complex disease where numerous genes are implicated. Their deregulation is accompanied (or sometimes caused) by epigenetic alterations and concerns both differences between the lesion and the eutopic endometrium in patients and eutopic endometrium from patients and controls. The various epigenetic alterations affect genes involved in inflammation and hormonal regulation, which may contribute to the symptoms of the disease (pain and infertility). Environmental influences, including endocrine disrupters, may contribute to the disease.

Recent Issues on Endometriosis Epigenetic Research

Histone Mark Alterations in Endometriosis

As mentioned above, endometriosis is an estrogen-dependent disease. Actually, the major therapy is estrogen inhibition using oral contraceptives, aromatase inhibitors, androgenic reagents or GnRH homologues. The symptoms reappear very often within a year after the treatment is interrupted (Kyama *et al.*, 2008). Estrogen signaling depends primarily on ~100 major genes, as illustrated by the KEGG pathway hsa04915 (http://www.genome.jp/dbget-bin/www_bget?hsa04915). To understand how the chromatin is regulated in these genes could result in novel therapeutic targets, and drugs better able to treat the symptoms, and this could be done by manipulating histone PTM marks. Several drugs are able to alter these marks (Borghese *et al.*, 2017). Indeed, specific histone marks, such as H3K27Me3, seem specifically enriched in endometriotic lesions (Colon-Caraballo *et al.*, 2015; Monteiro *et al.*, 2014). Drugs such as valproic acid (VPA), trichostatin A, or sodium butyrate, which are histone deacetylase inhibitors, but also lysine-specific demethylase inhibitors (such as tranylcypromine, which targets KMD1A), are able to decrease cell proliferation and invasiveness (Ding *et al.*, 2014), and have been shown to improve the symptoms of endometriosis in a mouse model (Sun *et al.*, 2016). Such epigenetic regulation has been studied for the *CYP19* aromatase gene in cell models with VPA treatment inhibiting histone acetylation in the promoter of *CYP19*, and suppressing its expression (Chen *et al.*, 2015). In endometriotic stromal cells, acetylation of H3 and H4 is considerably reduced compared to normal endometrial cells, while VPA was also able to increase considerably the acetylated histone marks. On the other hand, the specific analysis of the *CYP19* promoter revealed a decreased presence of acetylated H3 and H4 following VPA treatment, associated with a decreased expression of this gene, an increase in apoptosis and reduced proliferation. Therefore, this study shows that global modifications of histone PTMs may have paradoxical consequences at the level of specific genes, sometimes crucial for endometriosis progression. Recently, Hosseini and coworkers showed that in cumulus cells from endometriotic women, CYP19A1 expression was reduced compared to infertile women without endometriosis (Hosseini *et al.*, 2016), consistent with previous studies (Barcelos *et al.*, 2015). The authors also showed by ChIP-qPCR an increased presence of MeCP2 (a methylated CpG binding protein) at the more distal promoter (PII), and at the proximal promoter PI.4. They also showed a decreased H3K9ac (transcription activation mark) presence at PII, and increased H3K9 me2 (transcription repression mark) at PI.4. This was accompanied by differences in ERβ binding at the promoter element that was decreased at PII, but increased at PI.3 and PI.4. As suggested by this example, it is an intermingling of epigenetic factors that modulate promoter accessability to transcription factors in a complex way. The results suggest specificities of endometriosis-related infertility compared to other types, and show the complexity of the epigenetic regulation of gene expression, suggesting that until a general deciphering of epigenome dynamics is available, the consequences of epigenetic regulation on gene expression should be addressed on a case by case basis.

Along the same line of ideas, it has recently been shown that the downregulation of ARID1A (AT-rich Interactive Domain 1A) in endometriotic cells increases cell colony formation capacity, adhesiveness and invasive properties. ARID1A is a member of the SWI/SNF family of chromatin remodelers, known to be mutated in endometriosis precursor lesions. In these lesions, together with the phenotypic alterations of the cells where ARID1A was down-regulated, there was a strong deregulation of the distribution of H3K27ac, that increased considerably at the promoter levels for 61% of them while only 39% were unchanged and <1% decreased; at the enhancer level, on the contrary, H3K27Ac was reduced for 23.54% of the enhancers (Lakshminarasimhan *et al.*, 2017). The latter findings were compared with gene expression information, revealing that only a subset of genes was regulated by this mark (a total of 72 genes up- and 27 genes down-regulated). In summary, a discrepancy was seen between the extensive reorganization of epigenetic marks and a relatively mild effect on transcription alterations, that may occur more significantly at later stages. In analyzing more directly endometiotic lesions, Liu and coworkers revealed by histology that EZH2, H3K9me3, and H3K27me3 are more intense in OMA and DIE lesions compared to eutopic endometrium (Sutton *et al.*, 2017). In sum, the technical difficulties of analyzing the histone code in endometriosis are being overcome at an increasing pace. This suggests that in the future, both for issues of basic science and medicine, this mode of epigenetic regulation will play a pivotal role.

Epigenetic Regulation by KLF10 and KLF11 Transcription Factors

KLF11 (Kruppel Like Factor 11) is a zinc finger transcription factor involved in TGFB signaling and B cell receptor signaling, known for its involvement in MODY (Maturity-Onset Diabetes of the Young). KLF11 is known to intervene in the mechanisms achieving gene expression repression through contributing to the binding of HP1 to the chromatin. In turn, HP1 provokes the recruitment of H3K9 and its methylation by SUV39H1. This finally leads to chromatin compaction and silencing of specific genes (Lomberk *et al.*, 2012). In 2014, the team of GS Daftary focused on the function of KLF11 in the context of endometrial biology, first analyzing its effect at specific promoters of nearby genes important for endometrial biology, such as glycodelin (Tabbaa *et al.*, 2014), through the recruitment of the SIN3/histone deacetylase corepressor complex to the glycodelin promoter, glycodelin being a protein important for immnomodulation during pregnancy (Bersinger *et al.*, 2008; Seppala *et al.*, 2009). The same team went on to study the endometrial impact in *Klf11* $-/-$ KO mice on surgically provoked lesions (Daftary *et al.*, 2013). They showed in cell models that cytochrome p450 metabolic enzymes (especially *CYP3A4*, an enzyme involved in the metabolism of many drugs, steroids and carcinogens) are targets of KLF11 that alter their expression through epigenetic mechanisms (Zheng *et al.*, 2014). The same team also showed involvement of KLF11 in the regulation of TGFB-mediated cascades (Correa *et al.*, 2016), modulation of COL1A1 and fibrosis (Zheng *et al.*, 2016; Shenoy *et al.*, 2017) or dopaminergic signaling (Richards *et al.*, 2017). Paradoxically, the expression of

KLF11 in endometriosis by transcriptome analysis gives highly contrasting results and did not emerge as deregulated in many studies, at least at the mRNA level (Sha *et al.*, 2007; Hawkins *et al.*, 2011; Crispi *et al.*, 2013). According to the data presented in 2013 (Daftary *et al.*, 2013), this could be compatible with a difference occurring at the protein level and not at the mRNA level, suggesting that in endometriosis, the stability of KLF11 could be decreased, without changes in the level of the mRNA. In sum, while the effects of KLF11 on endometriosis lesions in mice appear well-documented, the position of this factor in the cascade of events leading to the lesion is still an open question. Recently, the same team showed that KLF10 also plays a role in the promotion of endometriosis (Delaney *et al.*, 2016). Contrary to KLF11, KLF10 appears modified at the transcriptomic level (Hawkins *et al.*, 2011), where the transcript NM_001032282 is induced 2.2-fold ($P = 0.003$), calculated from the GDS3975 dataset in GEO Profiles. The *Klf10* $-/-$ animals presented with an abnormal regulation of the CD40/CD154 immune pathways leading to progression without massive fibrosis as observed in the *Klf11* $-/-$ animals. The authors suggested that both transcription factors contribute to specific aspects of endometriosis progression, through epigenetic regulation of specific promoters.

DNA Methylation in the Normal and Endometriotic Uterus

A very recent paper exhaustively studied endometrium DNA methylation with the Illumina HumanMethylation450 array, in parallel with gene expression analyzed by RNAseq at two periods of the cycle (on days 2—prereceptive endometrium—and 8—receptive endometrium—after the LH surge of the same cycle for 17 women—34 biopsies). Statistically, 5% of the CpGs were modified, and 30% of those were associated with modifications of gene expression. 5′ UTR methylation was often inversely correlated with gene expression, while gene body methylation was rather positively correlated to gene expression (Kukushkina *et al.*, 2017). Another recent study analyzed the same question in the context of endometriosis (Houshdaran *et al.*, 2016), using the older Illumina platform analyzing ~27,000 CpG dinucleotides (Illumina 27 K). In terms of methylation, the authors observed no difference for most sites in terms of percentage of hypomethylation (<20%) or hypermethylation (>80%) according to the phases of the cycle. Also no obvious differences were found between control and endometriotic patients. Nevertheless, the largest differences were mainly found in the P4-dominant mid secretory phase (MSE), with 137 differential CpG sites corresponding to 125 loci, while only 58 and 39 CpG sites were found different in proliferative phase (PE) and early secretory phase (ESE), respectively. Analyzing the correlation between methylation and gene expression, the authors found that outside CpG islands (CGI), the correlation between endometriosis-increased methylation with gene expression level was mainly negative in the proliferative phase, mainly positive in CGI in the early secretory phase, rather negative outside CGI in the mid secretory phase. Therefore, the correlation of gene expression and gene methylation throughout the genome in the various menstrual phases of the cycle was shown by this recent paper to be extremely complex. Overall, these results tend to show that the uterus of endometriotic women is molecularly different than that of control women. The differences are visible at the DNA methylation level. Furthermore, various reports show that mRNA levels differ for numerous genes between patients and controls; for instance, Santulli and coworkers showed that *PTGS2*, *PTGER2*, *PTGER3*, *PTGER4* differ in terms of mRNA levels (while this can be untrue at the protein level) (Santulli *et al.*, 2014). In the same study, the authors showed that oral contraceptives may also have a strong influence on the mRNA level for PTGS1 and mRNA/protein levels for PTGS2, making the situation more complex if this parameter of oral contraception is not taken into consideration. Interestingly, it has recently been shown that *PTGS2* promoter methylation differences are present in the endometrium of endometriotic women, at the binding site of NF-IL6 (CEBPB). It may be hypothesized in this case that methylation interferes with binding and that its decrease fosters activation of PTGS2 expression.

Recent Data, Questions and Paradoxes About miRNA Expression in Endometriosis

As in most physiological or pathological processes, it is established that miRNAs can be used as biomarkers of a specific state. In addition, and interestingly compared to other epigenetic marks, the consequences of an abnormal miRNA concentration in terms of gene function may be considered as quite straightforward functionally. miRNAs are encoded by nuclear genes, generally transcribed by RNA polymerase II as a pri-miRNA (Nothnick, 2017), processed in the nucleus to form a pre-miRNA through the action of the specific ribonuclease III, Drosha, to generate a stem-loop structure of ~70 base pairs. This structure is exported from the nucleus by the XPO5 exportin, linearized as a miRNA duplex by DICER and associated to the RISC complex, where it will induce the targeted degradation of the cognate mRNA. One major issue of miRNA research in the context of endometriosis is that the panel of deregulated miRNAs either between the ectopic lesion and the endometrium, or between the eutopic endometrium in patients versus controls, varies considerably from one study to another (Saare *et al.*, 2017). This last review points to a series of 14 miRNAs discovered deregulated in endometriotic lesions compared to eutopic endometrium and in common in more than three independent studies (Hawkins *et al.*, 2011; Ohlsson Teague *et al.*, 2009; Filigheddu *et al.*, 2010; Shi *et al.*, 2014; Yang *et al.*, 2016; Braza-Boils *et al.*, 2014).

To use miRNAs as non-invasive biomarkers of endometriosis, numerous studies are still being published, with improvements in the detection techniques. For instance, next generation sequencing (NGS) has recently been carried out on the plasma of 30 patients (19 in the proliferative phase, and 11 in the secretory phase), compared to 20 controls (17 in the proliferative and 3 in the secretory phase) (Wang *et al.*, 2016). This study discovered 108 differentially expressed miRNAs, 98 down-regulated in endometriosis and 10 up-regulated, of which only 21 (all down-regulated) were shared by other studies. The most spectacular study in terms of the capability of miRNAs to be used systematically as serum biomarkers was published in 2013 (Wang *et al.*, 2013). The

authors found that miR-199a and miR-122 were up-regulated, while miR-145*, miR-141*, miR-542-3p, and miR-9* were down-regulated in the patients. Four of these miRNAs led to a sensitivity of 93.2% and specificity of 96% for revealing endometriosis, with an area under the curve (AUC) reaching an impressive value of 0.994. In common with the previous study, miR-199a-5p and miR-122-3p were found in the study of Wang *et al.* (2016), but both were down-regulated (~2.5 and ~16-fold, respectively). More consistently between the two studies, miR-145-3p, miR-141–3p were found reduced (~2.7 and ~3, respectively). MiR-542-3p was found upregulated >fivefold in the Solexa NGS study of Wang and coworkers. In summary and taking these two studies as exemplary, highly inconsistent results were surprisingly obtained between two apparently rigorously carried out studies. The authors of such studies indicate these discrepancies without providing convincing explanations, despite the question of reproducibility being at the center of every scientific process. Possibly, the technical maturity of the different experimental approaches used is still disputable in studies that were performed before 2015. If this is the case, consensus panels of miRNAs should eventually come to light in the years to come. In the latest Cochrane database census, including 15,141 participants (Nisenblat *et al.*, 2016), 9 miRNAs were selected (miR-122, miR-141*, miR-145*, miR-17-5, miR-199a, miR-20a, miR-22, miR-532-3p, and miR-9) as blood markers among 122 markers including cytokines, immune cells, etc. As discussed before, some miRNAs yielded discrepant observations, suggesting that evolution of these lists of miRNAs should be published in the future. As the authors conclude "A subset of blood biomarkers could prove useful either for detecting pelvic endometriosis or for differentiating ovarian endometrioma from other benign ovarian masses, but there was insufficient evidence to draw meaningful conclusions. Overall, none of the biomarkers displayed enough accuracy to be used clinically outside a research setting."

Endometriosis and Cancer

One important question in endometriosis research is the study of a putative link with tumorigenesis, since endometriosis shares common features with cancer. One major form of endometriosis is ovarian endometriosis (mentioned above as OMA), therefore, specific attention was paid to endometriosis-associated ovarian carcinoma. Two studies published in 2007 and 2008 by Kobayashi *et al.* (2007, 2008), evaluated the risk of developing ovarian cancer among OMA women. Forty-six women out of 6398 (0.72%) developed an ovarian cancer (RR = 8.95 [4.12–15.3]). A 2010 study indicated that two types of ovarian tumors could be distinguished, low-grade endometrioid, clear cell, mucinous and transitional carcinomas, confined to the ovary with a relatively slow progression (Type I), and another (Type II) more classical highly aggressive including high-grade serous carcinoma, undifferentiated carcinoma, and malignant mixed mesodermal tumors (carcinosarcoma) with TP53 mutations in 80% of the cases (Kurman and Shih, 2010), emphasizing the necessity to discriminate ovarian tumors. Endometriosis was then considered as a source of endometrioid and clear cell tumors. The link between endometriosis, ovarian cancer and epigenetics has recently been associated with dysfunction of the *ARID1A* gene. This chromatin remodeler is expressed ubiquitously, and particularly in the glandular cells of the uterus (https://www.proteinatlas.org/ENSG00000117713-ARID1A/tissue/endometrium#img). Its link with endometriosis has been evoked above in ovarian carcinomas since 2010 (Wiegand *et al.*, 2010). Mutations of *ARID1A*, initially found in clear cell and endometrioid carcinomas of the ovary, appear frequent in endometrial carcinomas, but infrequent in other tumors, leading the authors to conclude that loss of ARID1A is a common feature of carcinomas arising from the endometrial glandular epithelium (Wiegand *et al.*, 2011). Interestingly, a recent study of 70 samples from endometriotic patients revealed a partial loss of ARID1A (as monitored by immunohistochemistry) in some of the patients sampled, suggesting that, since only a small proportion of endometriosis leads to carcinogenesis, no direct correlation can be made between ARID1A partial loss and tumor development (Borrelli *et al.*, 2016). As mentioned before, exome sequencing revealed that mutations in genes known to be specific cancer targets in endometriosis lesions (*ARID1A*, *PIK3CA*, *KRAS*, *PPP2R1A*) do occur, but presumably the niche environment in the uterus does not lead to malignancy (Anglesio *et al.*, 2017). In a recent study, Shibuya and coworkers studied by NGS 48 samples of ovarian clear cell carcinoma tissue in comparison with adjacent non-cancerous tissue, revealing frequent mutations in *ARID1A* (66.7%), *PIK3CA* (50%), *PPP2R1A* (18.8%), and *KRAS* (16.7%). Interestingly, the authors also found clusters of mutations related to APOBEC activation (Shibuya *et al.*, 2018), APOBEC being a family of cytidine deaminases involved in mRNA editing mechanisms, recently shown to be regulated by miRNA (Cao and Wu, 2018). In summary, there is an abundant literature linking the chromatin remodeler ARID1A, endometriosis and ovarian cancer; the next step will be understanding how its loss-of function mutations change the histone profile in endometriotic lesions. Once the epigenetic chromatin status modification is deciphered, it will pave the way to understand how gene deregulation is triggered, and which genes are affected by these transitions.

Temporary Conclusions

The history of the links between epigenetics and endometriosis followed the development of technical advances; until recently, genome-wide analysis of epigenetic deregulation focused on DNA methylation and miRNA profiling. While the DNA methylation profiles obtained by different teams appear relatively consistent when lesions are compared to eutopic endometrium, the miRNA profiles either in the comparison of ectopic versus eutopic, or between patient versus control endometria appear much less consensual. This may be due to a certain immaturity in the techniques used, an issue that could be solved shortly. Histone PTM profiling is becoming more and more accessible to technical analysis and will certainly become a major issue in the years to come, with a predictable profusion of published papers on this topic.

Introduction

Uterine fibroids (also known as leiomyomas or myomas) are the most common form of benign uterine tumors (Donnez and Jadoul, 2002; Islam *et al.*, 2013; Bulun, 2013; Donnez and Dolmans, 2016). They are monoclonal tumors of uterine smooth muscle, thus originating from the myometrium (Kim and Sefton, 2012). They are composed of large amounts of extracellular matrix (ECM) containing collagen, fibronectin, and proteoglycans (Kim and Sefton, 2012). Leiomyomas occur in 50%–60% of women, rising to 70% by the age of 50 (Baird *et al.*, 2003), and, in 30% of cases, cause morbidity due to abnormal uterine bleeding (heavy menstrual bleeding inducing anemia), pelvic pressure (urinary symptoms, constipation, tenesmus) (Donnez and Jadoul, 2002; Donnez *et al.*, 2014a,b), and/or infertility.

Risk Factors

The risk factors for uterine fibroids are illustrated in **Fig. 1**.

Race

Race constitutes an important risk factor for leiomyoma development (Wise *et al.*, 2004; Stewart *et al.*, 2013). A US study found that the incidence of uterine fibroids was 60% by age 35 among African-American women (Baird *et al.*, 2003). It is clear that African-American women have a greater chance of being affected by uterine fibroids, particularly at an earlier age (Wise *et al.*, 2004, 2005; Wise and Laughlin-Tommaso, 2016).

Age

The average growth rate was 9% over 6 months in a study by Peddada *et al.* (2008) who followed the size of 262 uterine fibroids for up 12 months, but growth rates differed between races when age was taken into account.

Delaying the first pregnancy until the third decade of life also places women at higher risk of uterine fibroids (Petraglia *et al.*, 2013).

Early menarche and parity

Menarche at an early age increases the risk of developing fibroids and is also considered a risk factor for other hormonally mediated diseases. Pregnancy has been found to have a protective effect but the mechanism remains unclear. During postpartum uterine remodeling, small lesions may be subject to selective apoptosis (Laughlin *et al.*, 2010).

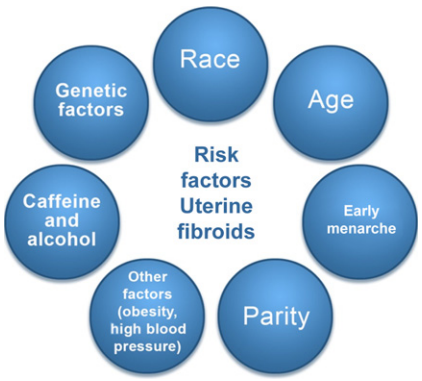

Fig. 1 Risk factors for uterine fibroid. These include race, age, delayed pregnancy, early menarche, parity (protective effect), caffeine, genetic alterations, and others, such as obesity and a diet rich in red meat.

Genetic factors

Mehine *et al.* (2013) performed whole genome sequencing and gene expression profiling of 38 uterine leiomyomas and corresponding myometrium. The common occurrence of chromothripsis in uterine fibroids suggests that it also plays a role in their genesis and progression (Mehine *et al.*, 2013, 2014).

Other factors

An association has been reported between alcohol and caffeine intake and an increased risk of developing uterine fibroids (Wise *et al.*, 2004; Wise and Laughlin-Tommaso, 2016).

General health status may also be predictive of leiomyoma growth, with factors such as obesity and high blood pressure playing a role (Kim and Sefton, 2012).

Evidence of the Crucial Role of Progesterone Pathways in the Pathophysiology of Uterine Fibroids

Genetic and epigenetic factors, sex steroids, growth factors, cytokines, chemokines, and ECM components have been identified as being implicated in the pathogenesis of leiomyomas (Islam *et al.*, 2013; Bulun, 2013; Marsh *et al.*, 2015, Protic *et al.*, 2015; Yin *et al.*, 2015; Donnez and Dolmans, 2016).

In the past, estrogen was considered to be the major growth factor in myoma development. However, already in the late 90s, Nisolle *et al.* reported increased expression of both progesterone receptor A (PR-A) and progesterone receptor B (PR-B) in leiomyoma tissue (Nisolle *et al.*, 1999). Higher proliferative activity, demonstrated by proliferating cell nuclear antigen and the mitotic index, was observed in leiomyomas during the luteal (secretory) phase (Nisolle *et al.*, 1999). There is evidence from preclinical and clinical trials, as well as from histological and pharmacological studies, that progesterone and its receptors play a key role in uterine fibroid growth (Bouchard *et al.*, 2011; Bouchard, 2014; Chabbert-Buffet *et al.*, 2005, 2012, 2014; Kim and Sefton, 2012; Bestel and Donnez, 2014; Moravek *et al.*, 2015).

Very recently, Tsigkou *et al.* (2015) showed that PR-B mRNA and PR-A and PR-B proteins were more concentrated in leiomyomas than in matched myometrium.

The PI3K/AKT pathway is mediated by progesterone which, through its receptors, can quickly activate this pathway, which is increasingly considered to be a potential promoter of leiomyoma growth. PTEN, on the other hand, should be considered as a negative regulator of AKT (Kim and Sefton, 2012). Progesterone and growth factor signaling pathways are interconnected and govern numerous physiological processes such as proliferation, apoptosis, and differentiation; nevertheless the initial event that triggers the first stages of tumorigenesis involves somatic mutations (Kim and Sefton, 2012).

Symptoms

Many fibroids are asymptomatic, but in 30%–40% of cases, they show a variety of symptoms, depending on the location and size. The FIGO classification, published (Munro *et al.*, 2011), describes eight types of fibroids, as well as a hybrid class (association of two types of myomas) (**Fig. 2**). As different types of fibroids are often present at the same time (depending on site), this classification offers a more representative 'map' of fibroid distribution and will be used further for the establishment of new algorithms (Donnez and Dolmans, 2016).

Fibroids can cause heavy menstrual bleeding with subsequent anemia, which could be life-threatening (Parker, 2007; Nelson and Ritchie, 2015). African-American women have more severe symptoms in terms of heavy bleeding and anemia compared with white women (Stewart *et al.*, 2013). Large fibroids can also result in pressure symptoms (bulk symptoms). Abdominal distention

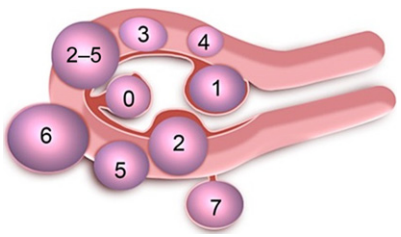

Fig. 2 FIGO classification of uterine fibroids according to Munro *et al.* (2011). Fibroid types range from 0 to 8. 0 = Pedunculated, intracavitary; 1 = submucosal, <50% intramural; 2 = submucosal, ≥50% intramural; 3 = contact with endometrium, 100% intramural; 4 = intramural; 5 = subserosal, ≥50% intramural; 6 = subserosal, <50% intramural; 7 = subserosal, pedunculated; 8 = other (e.g., cervical, parasitic). Where two numbers are given (e.g., 2–5), the first number refers to the relationship with the endometrium, while the second number refers to the relationship with the serosa; for example, 2–5 = submucosal and subserosal, each with less than half the diameter in the endometrial and peritoneal cavities, respectively. Fibroid classification cartoon republished with permission from Munro, M. G., Critchley, H. O., Broder, M. S. and Fraser, I. S. (2011). FIGO classification system (PALM-COEIN) for causes of abnormal uterine bleeding in nongravid women of reproductive age. FIGO Working Group on Menstrual Disorders. *International Journal of Gynecology & Obstetrics* **113**, 1–2.

or distortion and pelvic pressure on the ureters (causing hydronephrosis) and pelvic blood vessels (particularly pelvic veins) could also interfere with quality of life (Spies *et al.*, 2002; Donnez *et al.*, 2014a,b, 2016).

Infertility and recurrent miscarriage may also be symptoms of fibroids, depending on their location and size, especially for submucous and intramural myomas distorting the uterine cavity (Pritts *et al.*, 2009; Zepiridis *et al.*, 2016; Donnez and Dolmans, 2016).

Fibroids can impair fertility through several possible mechanisms, including (**Fig. 3**): (1) alteration of the local anatomy (anatomic distortion of the uterine cavity), subsequent alterations to endometrial function (Somigliana *et al.*, 2007); (2) impairment of the endometrial and myometrial blood supply (Donnez and Jadoul, 2002; (3) functional changes, such as increased uterine contractility; (4) changes to the local hormone milieu and paracrine molecular changes induced by fibroids, which could impair gamete transport and/or reduce blastocyst implantation (Sinclair *et al.*, 2011; Galliano *et al.*, 2015); (5) thicker fibroid capsule; and (6) changes in gene expression (↓HOXA 10).

Fibroids can affect obstetric outcomes and are significantly associated with preterm delivery, primary cesarean section, breech presentation, and lower birthweight infants (Blitz *et al.*, 2016).

Diagnosis

Examination of the pelvis may reveal an enlarged uterus or mass. An ultrasound is the gold standard test for uterine fibroids. Its widespread availability enables easy and inexpensive confirmation in almost all instances. Moreover, ultrasonography after infusion of saline into the uterine cavity can delineate submucous myomas and indicate the proximity of intramural myomas to the endometrial cavity (Seshadri *et al.*, 2015).

Hysteroscopy is usually performed in an outpatient setting and does not require any anesthesia (Bettocchi *et al.*, 2003). In case of irregular bleeding or if the patient has risk factors for endometrial hyperplasia (obesity, chronic anovulation), hysteroscopy may be combined with an endometrial biopsy.

MRI (magnetic resonance imaging) can provide information on the number of fibroids, their size, vascularization, relationship with the endometrial cavity and serosal surface, and boundaries with normal myometrium. It should nevertheless be stressed that like ultrasonography, MRI cannot diagnose malignancy with any certainty (Lumsden *et al.*, 2015; Donnez and Dolmans, 2016).

Current Surgical Management Strategies

Current management strategies involve mainly surgical interventions, but the choice of treatment is guided by the patient's age and desire to preserve fertility or avoid 'radical' surgery such as hysterectomy (Donnez and Jadoul, 2002; Donnez *et al.*, 2014a,b, 2016).

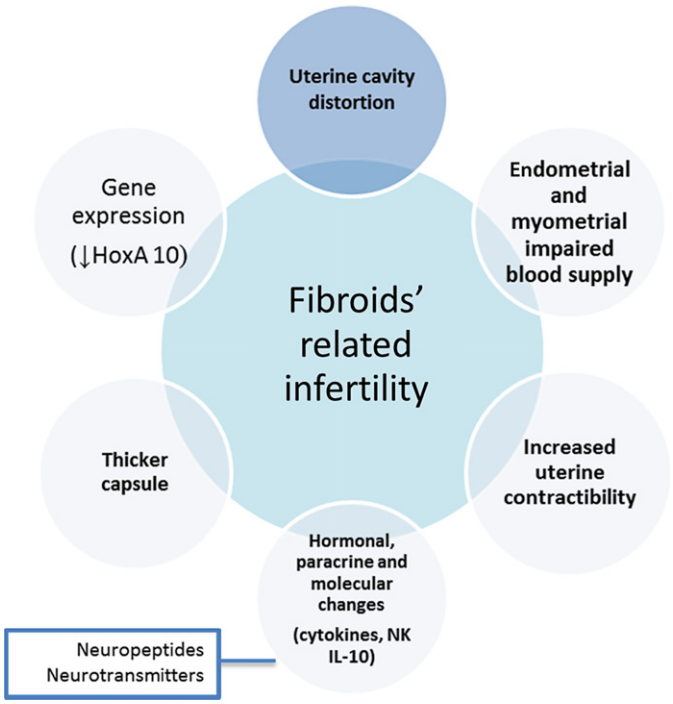

Fig. 3 Fibroids could impair fertility through several possible mechanisms.

Surgical and nonsurgical approaches include hysterectomy (vaginal, abdominal, or laparoscopic), myomectomy by hysteroscopy, myomectomy by laparotomy or laparoscopy, uterine artery embolization (UAE), and other interventions performed under radiologic or ultrasound guidance (**Fig. 4**; Donnez and Jadoul, 2002).

Contraindications to laparoscopic myomectomy usually include: the presence of an intramural myoma >10–12 cm in size or multiple myomas (≥ 4) in different sites of the uterus, requiring numerous incisions.

The dimensions and localization of the main myoma are the principal criteria for choosing the laparoscopic approach (Dubuisson *et al.*, 2000; Alessandri *et al.*, 2006; Palomba *et al.*, 2007; Nezhat *et al.*, 2009; Thomas *et al.*, 2010; Malzoni *et al.*, 2010; Segars *et al.*, 2014; Donnez *et al.*, 2014a,b; Parazzini *et al.*, 2015). Thus, depending on the skill of the surgeon and his/her ability to suture the myometrial defect without delay, either laparoscopy or minilaparotomy may be selected.

In terms of infertility, several noncontrolled studies have suggested that myomectomy yields a decrease in the miscarriage rate in women with myomas distorting the uterine cavity (Saravelos *et al.*, 2011; Bernardi *et al.*, 2014; Parazzini *et al.*, 2015). In a review of prospective and retrospective studies, Donnez and Jadoul reported a pooled pregnancy rate of 49% (95% CI 46–52) in patients who underwent laparoscopic myomectomy (Donnez and Jadoul, 2002). These postmyomectomy pregnancy rates have been confirmed by other studies, but the lack of randomized trials represents a serious drawback.

In cases of infertility related to pediculated or myomas distorting the uterine cavity, complete resection by hysteroscopy improves the pregnancy rate (Di Spiezio Sardo *et al.*, 2015; Donnez *et al.*, 2014a,b).

Why We Need New Options

Fibroids are highly prevalent and represent a high health burden. Indeed, about 30% of women with leiomyomas will request treatment due to morbidities such as heavy menstrual bleeding, abdominal pain, pressure symptoms, and/or infertility.

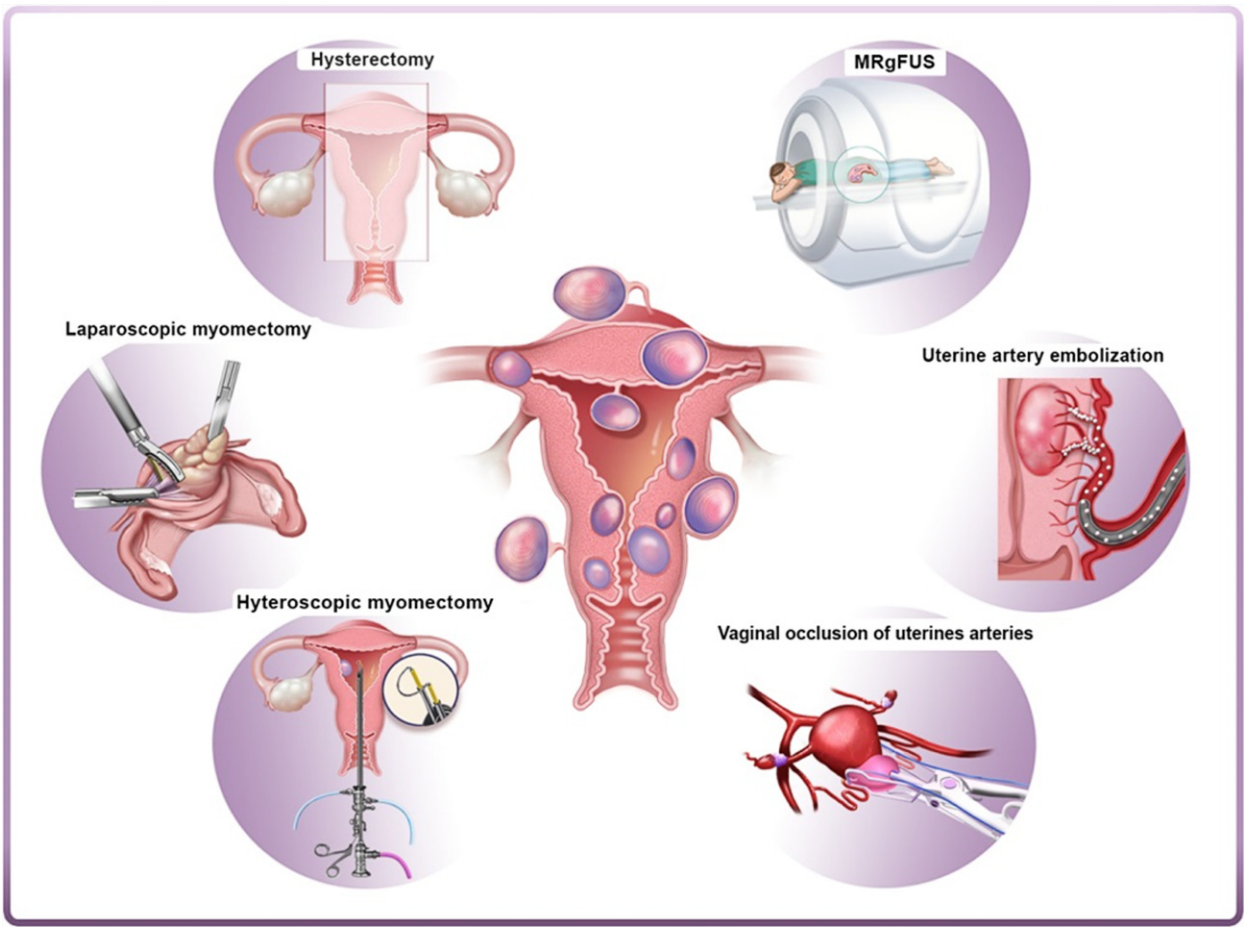

Fig. 4 Current surgical and nonsurgical management strategies of myomas. Left panel: hysterectomy, laparoscopic myomectomy, and hysteroscopic myomectomy are the most widely used surgical interventions for myomas. Right panel: alternatives to surgical intervention include uterine artery embolization (UAE), high-frequency magnetic resonance-guided focused ultrasound surgery (MRgFUS), and vaginal occlusion of uterine arteries.

Despite the lack of relevant medico-economic evaluations of the different therapeutics, it is likely that reducing the number of hysterectomies and other surgical procedures will reduce costs and morbidity. It is therefore necessary to develop and evaluate alternatives to surgical procedures especially when fertility preservation is the goal (Donnez *et al.*, 2014a,b).

Selective Progesterone Receptor Modulators and Fibroids

The crucial role of progesterone in the growth and development of myomas having been established, we can modulate the progesterone pathway by use of selective progesterone receptor modulators (SPRMs) (Donnez *et al.*, 2012a,b; Kim and Sefton, 2012; Bouchard *et al.*, 2011, Bouchard, 2014; Bestel and Donnez, 2014). SPRMs are synthetic compounds that exert either an agonistic or antagonistic effect on PRs (**Fig. 5**). Their binding allows these receptors to interact with coactivators and/or corepressors, and this is further impacted by the presence of coregulators in a particular cell type, which will dictate whether an SPRM acts more as an agonist or antagonist.

Courtoy *et al.* suggested an important role of ulipristal acetate (UPA) in collagen degradation induced by matrix metalloproteinase 2 (MMP-2), offering an explanation for the sustained beneficial effect. Indeed, this study strongly points to multifactorial mechanisms of action involving: (1) a persistently low cell death rate; (2) a limited period of cell death; and (3) ECM remodeling concomitant with stimulation of MMP-2 expression (Courtoy *et al.*, 2015).

Four members of the family of compound SPRMs have been investigated clinical trials: mifepristone, asoprisnil, UPA, and telapristone acetate.

The latest antiprogestin to be widely studied in large clinical trials, UPA, showed promising results in terms of efficiency and safety. UPA was compared to a placebo and to leuprolide acetate (a GnRH agonist) in two randomized trials (Donnez *et al.*, 2012a, b). In these first clinical studies, uterine bleeding was controlled in more than 90% of patients receiving a 3-month course of UPA, and the median times to control bleeding were shorter in the UPA group (5–7 days) than in the GnRH agonist group (21 days).

UPA was also found to have a sustained effect (up to 6 months) in women who did not undergo surgery after the 3-month study period. By contrast, those treated with GnRH agonist experienced rapid regrowth of their fibroids, whose size reached pretherapy dimensions by 6 months posttreatment (Donnez *et al.*, 2012a,b).

Importantly, the induced effects on the endometrium, now described as progesterone receptor modulator-associated endometrial changes (PAECs), present in almost 70% of patients at the end of treatment, have proved to be benign and reversible, as they disappear 2 months after the end of therapy (Donnez *et al.*, 2012a,b; Williams *et al.*, 2012).

Because of the sustained effect observed in the first two trials, additional intermittent (12-week) courses of SPRMs with off-treatment intervals may be an alternative for long-term medical management of fibroids. The results of the first long-term intermittent administration study suggested that more than one course of SPRMs can maximize its potential benefits in terms of bleeding control and fibroid volume reduction (Donnez *et al.*, 2014b, 2016).

The latest clinical trial investigated the efficacy and safety of four repeated 12-week courses of either 5 or 10 mg UPA daily for intermittent treatment of symptomatic uterine fibroids (Donnez *et al.*, 2015a,b). As a similar degree of response was observed in both treatment groups, we focus on the results in terms of efficacy and safety of this trial using the approved dose of 5 mg UPA in a

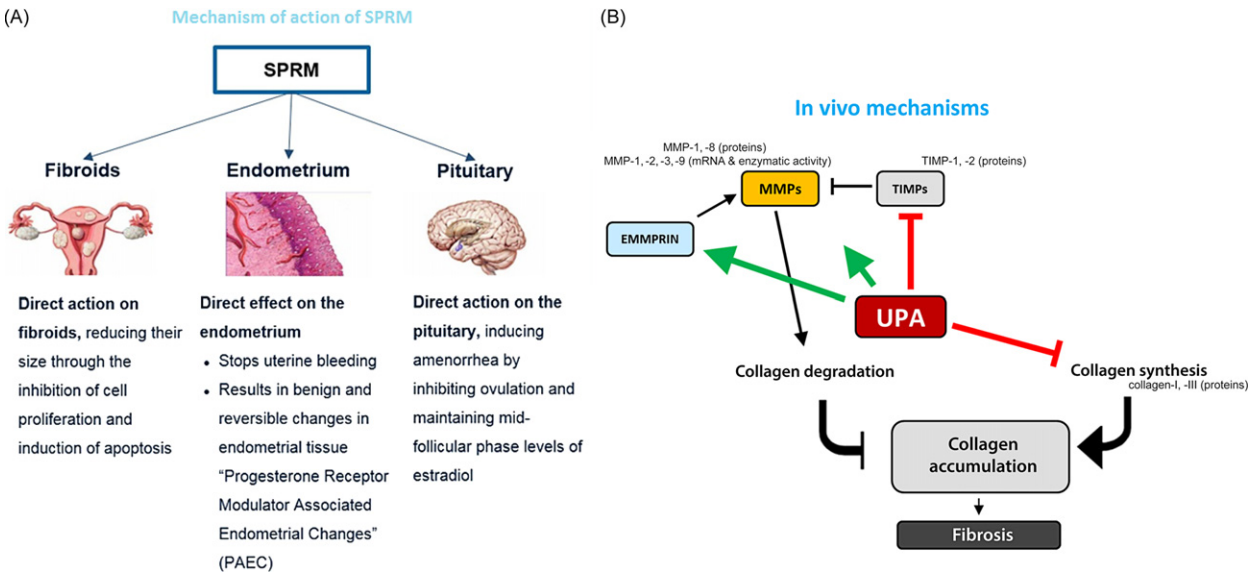

Fig. 5 (A) Mode of action of SPRMs (selective progesterone receptor modulators). SPRMs have a direct impact on fibroids, endometrium, and the pituitary. (B) In vivo mechanism of action, explaining the sustained effect of UPA treatment.

repeated intermittent therapy setting (four courses) (Donnez *et al.*, 2015b). The percentages of subjects identified as being in amenorrhea after each individual treatment courses were 75.8%, 84.1%, 86.4%, and 87.5% in the 5 mg group (Donnez *et al.*, 2015a) (**Fig. 6**). The pictorial blood assessment chart (PBAC) (Higham *et al.*, 1990) score was measured at initial screening and after 1, 2, and 4 courses to assess the level of menstrual bleeding during the off-treatment period. In the 5 mg group, (median) levels at screening were 224.0, dropping significantly with each subsequent course, and finally reaching 77.5 after course 4 (Donnez *et al.*, 2015a). The percentage of subjects with a clinically significant volume reduction of $\geq$25% increased from course 1 to course 4 (from 62.3% to 78.1%), and those with a volume reduction of $\geq$50% also increased from course 1 to course 4, proving that repeated courses considerably maximize the impact of treatment. The volume reduction of the three largest fibroids was increased from course 1 to course 4 (**Fig. 6**). The findings of this study therefore demonstrate the efficacy of 5 mg UPA treatment and further confirm the efficacy and safety of repeated intermittent administration of UPA for symptomatic myomas (Donnez *et al.*, 2015a,b,c).

Concerning endometrial safety, no increased occurrence of more serious conditions of the endometrium, such as hyperplasia with atypia or endometrial carcinoma, was noted after up to 4 treatment courses. Data further confirm the rapid reversibility of PAEC following completion of treatment and subsequent menstruation.

Novel Algorithms, With a Special Emphasis on Infertility

There is a clear need for alternatives to surgery, even the less invasive endoscopic techniques, especially when fertility preservation is the goal (Donnez *et al.*, 2014a,b, 2015b). There is no doubt that surgery remains indicated in some instances, but we must now establish whether SPRMs (UPA) allow less invasive surgery or even complete avoidance of surgery (Donnez and Dolmans, 2016).

It is crucial to consider key factors determining the management of uterine fibroids: patient age, severity of symptoms, wish to preserve the uterus and/or fertility, localization of fibroids according to FIGO classification, and myoma volume.

Women of Reproductive Age With Fibroids Related Infertility

Type 0 and Type I Myomas (Fig. 7A and B)

If type 0 myomas are present, cutting the pedicle by hysteroscopy is indicated. In the majority of cases, hysteroscopic myomectomy for type 1 myomas is relatively easily performed for experienced surgeons, especially in case of type 1 myomas $<$3 cm in size (**Fig. 8**). If a fibroid is of type 1 but larger than 3 cm, or if the patient presents with anemia, prehysteroscopic medical therapy (SPRMs or GnRH agonist) is indicated.

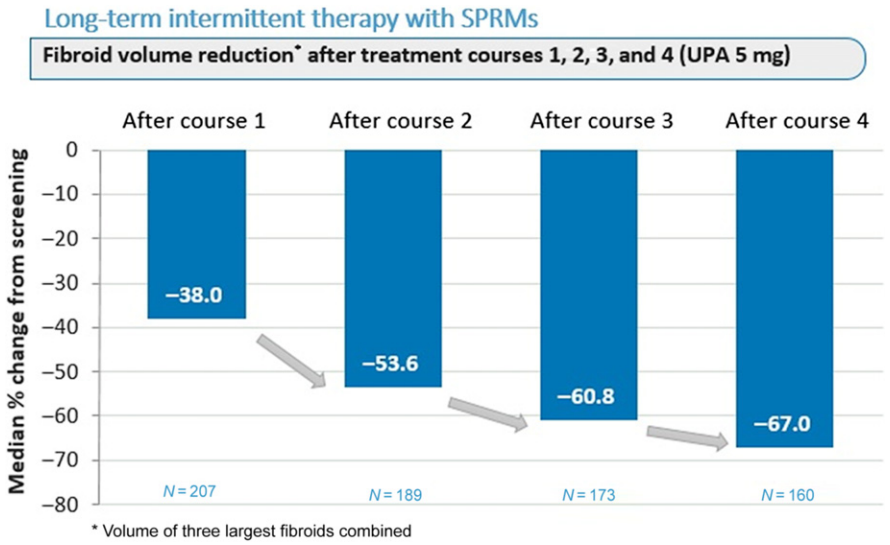

Fig. 6 Effect on fibroid volume reduction after four courses of 3 months of ulipristal acetate (UPA) 5 mg daily. The off-period between two courses was two natural cycles. Adapted from Donnez, J., Hudecek, R., Donnez, O., Matule, D., Arhendt, H. J., Zatik, J., Kasilovskiene, Z., Dumitrascu, M. C., Fernandez, H., Barlow, D. H., *et al.* (2015). Efficacy and safety of repeated use of ulipristal acetate in uterine fibroids. *Fertility and Sterility* **103**, 519–527; Donnez, J., Donnez, O., Matule, D., Ahrendt, H. J., Hudecek, R., Zatik, J., Kasilovskiene, Z., Dumitrascu, M. C., Fernandez, H., Barlow, D. H., *et al.* (2016). Long-term medical management of uterine fibroids with ulipristal acetate. *Fertility and Sterility* **105**, 165–173.

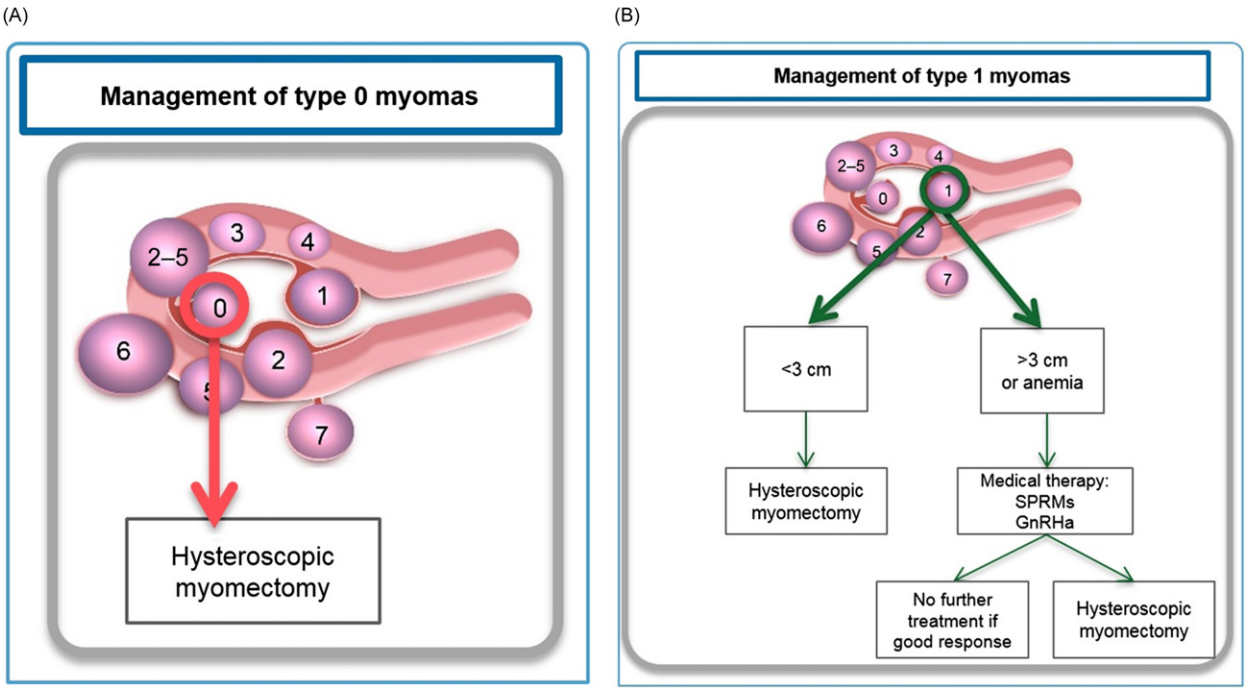

Fig. 7 (A) Management of type 0 myomas. Hysteroscopic myomectomy is the most appropriate approach. (B) Management of type 1 myomas. Depending on the myoma size, presence of anemia and the surgeon's skill, hysteroscopic myomectomy combined or not with ulipristal acetate (UPA) should be proposed.

In terms of reproductive outcomes, most studies are retrospective (Bosteels *et al.*, 2010a,b). They report postsurgery pregnancy rates ranging from 16.7% to 76.9%, with a mean of 45% (Donnez *et al.*, 2014a). Their robustness could be criticized, but the authors of a recent review (Bosteels *et al.*, 2015) acknowledge that the benefits of hysteroscopic removal of submucous myomas for improving the chances of pregnancy "cannot be excluded." In addition, one prospective randomized study (Casini *et al.*, 2006) has provided good-quality evidence that surgical therapy (hysteroscopic myomectomy) yields higher pregnancy rates than alternative treatments in women with submucous myomas.

Types 2–5, Myomas (Single or Multiple) Distorting the Uterine Cavity

Young infertile women of reproductive age and wishing to conceive

In case of type 2 myomas, medical therapy (SPRMs) can be proposed (**Fig. 9**).

If myomas are multiple (≥ 2) or of different types (types 2–5), medical therapy (SPRMs) can be given in two courses of 3 months, as described in clinical trials with UPA (Donnez *et al.*, 2014a,b, 2015a,b). After these two courses of 3 months, there are three possible outcomes. Myoma regression is very significant ($>50\%$ decrease in volume). The uterine cavity is no longer distorted, and the patient can try to conceive naturally or undergo assisted reproductive techniques, if indicated. In some cases, surgical treatment is not required and patients can conceive and deliver healthy offspring (Luyckx *et al.*, 2014; **Fig. 9**).

Myoma regression is significant ($\geq 25\%$ but $<50\%$) but the uterine cavity remains distorted. In this case, indication for surgery stand and medical treatment may allow surgery to be performed by a laparoscopic approach once the hemoglobin level is normalized, avoiding laparotomy.

The response to medical therapy is inadequate. In this case, surgery remains indicated.

Young women of reproductive age with symptomatic myomas and wishing to preserve their fertility but having no immediate desire for pregnancy

When there is no immediate wish to conceive, there is no pressing need for surgery (even if the uterine cavity remains distorted and/or large myomas are still present).

It is known that the rate of recurrence of myomas after myomectomy can reach almost 60% after an interval of 4–5 years, and that the risk of pelvic adhesions is significantly increased after a repeat myomectomy (Malone, 1969; Donnez *et al.*, 2014a,b).

Medical therapy can be proposed (**Fig. 8**): four courses of 3 months to induce a significant improvement, course upon course (decrease in myoma size and PBAC score) (Donnez *et al.*, 2015a,b). In the vast majority of cases, regression of myoma size and control of bleeding will allow avoidance of surgery and restoration of hemoglobin levels (**Fig. 10**).

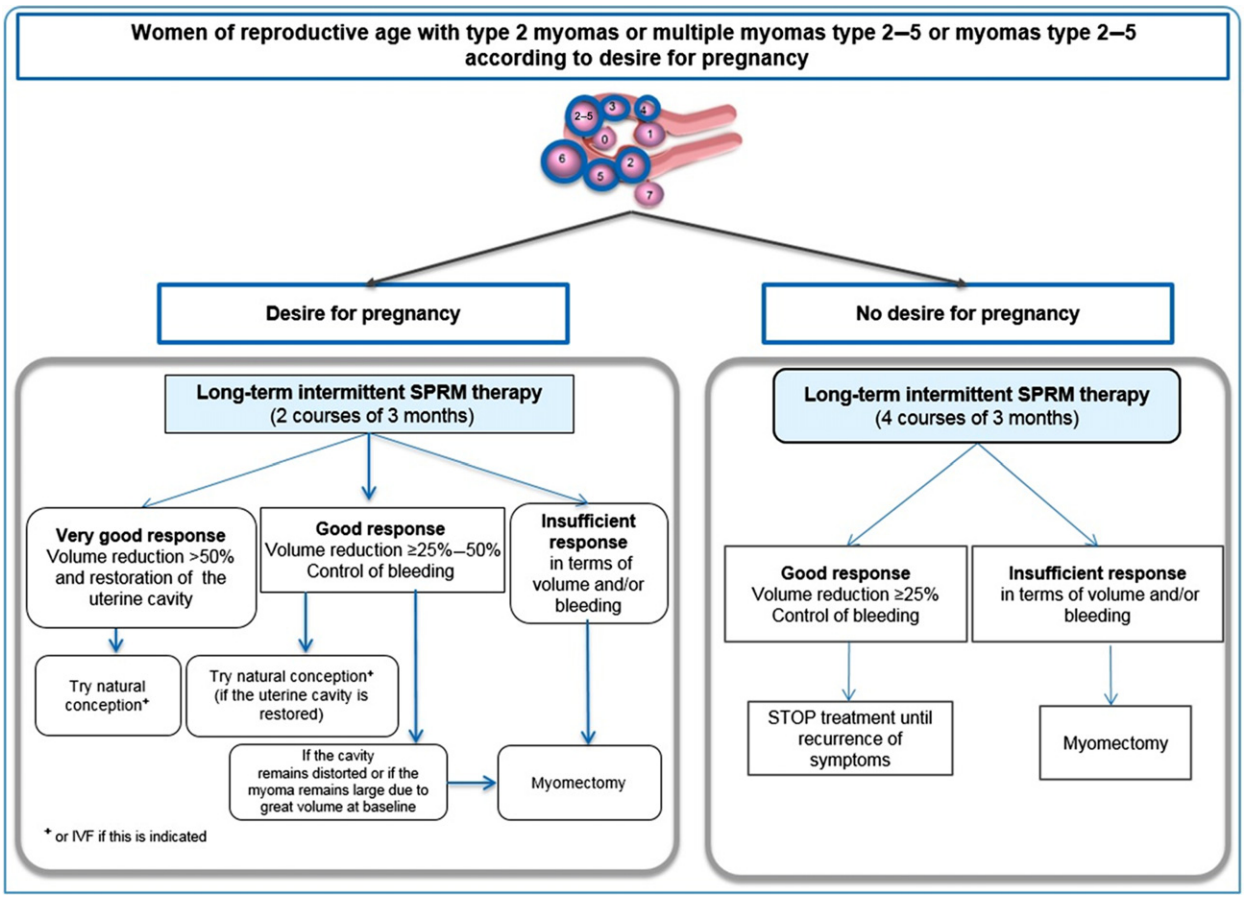

Fig. 8 Management in case of myomas or multiple myomas (types 2–5) in women of reproductive age, according to desire for pregnancy. In cases of infertility, two courses of 3 months are recommended (left panel). Subsequent therapy is determined depending on the response to treatment and restoration of the uterine cavity. If there is no desire to conceive (right panel), long-term (four courses) intermittent therapy may be proposed. In case of a good response in terms of fibroid volume reduction and bleeding, treatment is stopped and only restarted if symptoms recur (Algorithm republished with permission of HRU).

Myomectomy should only be considered when the patient wishes to become pregnant, and if really necessary according to the localization and volume of the fibroids still present. Surgery remains indicated only when the patient wishes to conceive, and if large myomas (>3–4 cm) distorting the uterine cavity are present, as these could be the cause of her infertility. This is important to take into account, especially for women of African descent who have a greater chance of developing symptomatic myomas at an earlier age than Caucasian women (Baird *et al.*, 2003). Medical treatment with SPRMs can thus be beneficial, since long-term intermittent therapy (repeated in case of symptom recurrence during the interval) may help avoid or at least postpone the need for surgery until the patient wishes to conceive (**Fig. 10**).

Asymptomatic women with myomas and undergoing IVF or oocyte donation

It could be proposed that patients with myomas be treated with one or two courses of SPRMs before IVF or oocyte donation, in order to reduce the size of myomas and restore the uterine cavity and subsequently improve implantation rates (**Fig. 8**). A meta-analysis by Pritts *et al.* (2009) showed a significant drop in pregnancy and implantation rates in the presence of myomas, especially submucous and/or intramural myomas distorting the uterine cavity. In another meta-analysis, Sunkara *et al.* (2010) demonstrated their impact on fertility, even in case of intramural myomas not distorting the uterine cavity. A recent study by Yan *et al.* (2014) confirmed that intramural fibroids >2.85 cm in size significantly decreased the delivery rate of patients undergoing IVF/intra-cytoplasmic sperm injection.

Future Prospectives for Medical Therapy

Future clinical trials should focus on prevention strategies, such as preventing occurrence in women genetically predisposed to this condition, and avoiding recurrence after surgery in women at high risk (i.e., those of a young age or with a family history).

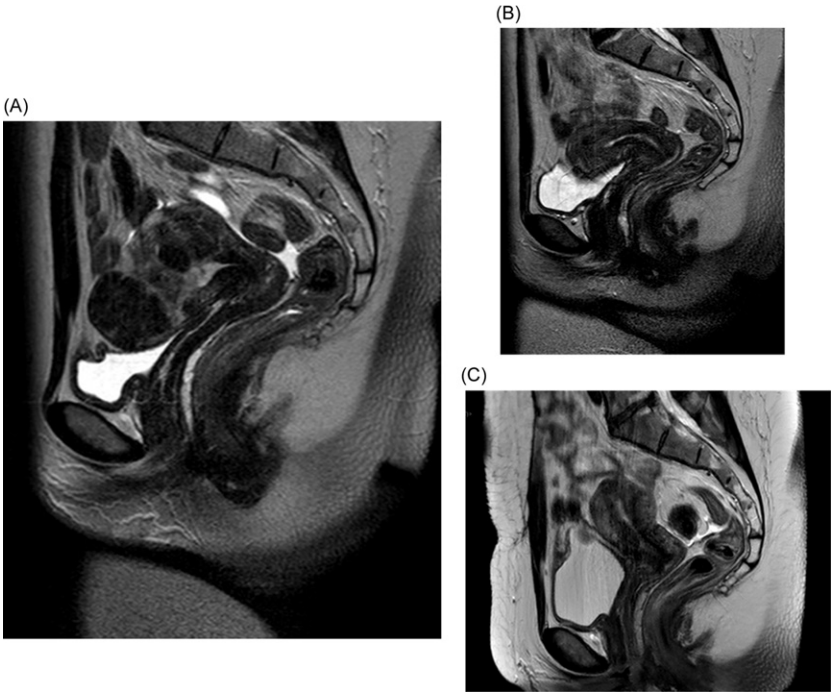

Fig. 9 Considerable shrinkage of all myomas after four courses of intermittent ulipristal acetate (UPA) therapy. A patient aged 30 years presented with heavy menstrual bleeding and an unclear desire for pregnancy. (A) Before treatment, a midline sagittal T2-weighted magnetic resonance image (MRI) demonstrated the presence of multiple myomas: types 2, 3, 4, and 6. (B) Upon completion of treatment (intermittent UPA therapy (four courses of 3 months), the uterine cavity was no longer distorted. (C) One year after delivery of a healthy baby, no fibroid regrowth was observed after delivery. Adapted from Donnez, J. and Dolmans, M. M. (2016). Uterine fibroid management: From the present to the future. *Human Reproduction Update* **226**, 665–686; Donnez, J., Donnez, O., Matule, D., Ahrendt, H. J., Hudecek, R., Zatik, J., Kasilovskiene, Z., Dumitrascu, M. C., Fernandez, H., Barlow, D. H., *et al.* (2016). Long-term medical management of uterine fibroids with ulipristal acetate. *Fertility and Sterility* **105**, 165–173.

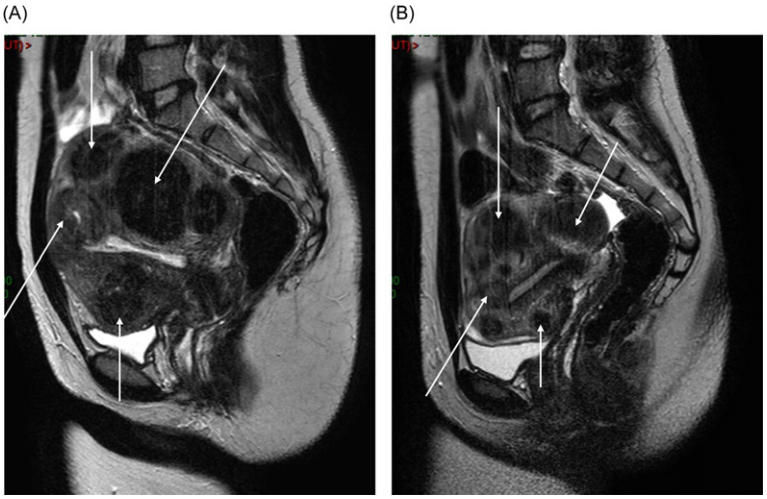

Fig. 10 Important shrinkage of the submucosal myoma was obtained after two courses of 3 months of intermittent ulipristal acetate (UPA) therapy. (A) Coronal T2-weighted MRI image illustrated the presence of multiple myomas (type 2, types 2–5) distorting the uterine cavity in a 19-year-old nulligravid patient, who presented to the emergency department, with heavy menstrual bleeding and anemia (hemoglobin level of 7.4 g/L). The patient received two courses of UPA (5 mg) and iron. (B) At the end of therapy, MRI demonstrated a significant reduction in myoma volume ($<50\%$) and restoration of the uterine cavity. Amenorrhea was achieved, with a hemoglobin level of 11.9 g/L. The patient was free of symptoms and did not wish to conceive; therefore, surgery was avoided.

Conclusion

The choice between less invasive techniques (uterine-sparing options such as myomectomy) is guided by the size, number, and location of fibroids, as well as the personal experience of the gynecologist and available equipment. Other surgical techniques, such as laparoscopic cryomyolysis, thermocoagulation, or uterine artery occlusion, are rarely used. Nonsurgical interventions, such as UAE and MRgFUS, are also available but the desire for future pregnancy is a relative contraindication.

The need for medical therapy remains a reality and it is indeed essential that new treatments be developed to be able to offer as there is a pressing need for alternatives to surgical intervention, particularly when fertility preservation is the goal.

We demonstrated that more than one 3-month course of UPA maximizes its potential benefits in terms of bleeding control and fibroid volume reduction. SPRMs should be considered an alternative to surgical therapy, or at least an adjunct to surgery.

Abbreviations

AhR	Aryl hydrocarbon receptor
AMH	Anti-Müllerian hormone
ANM	Age at natural menopause
ART	Assisted reproductive technology
BMI	Body mass index
BPA	Bisphenol A
CYP17A1	Cytochrome P450 17 hydroxylase gene
DDE	*p,p′*-Dichlorodiphenyldichloroethylene
DES	Diethylstilbestrol
DOHaD	Developmental Origin of Health and Diseases
EDCs	Endocrine-disrupting chemicals
ERα, ERβ	Estrogen receptor α, β
IVF	In vitro fertilization
LH	Luteinizing hormone
miRNA	MicroRNA
NCOR1	Nuclear corepressor factor 1
PCB	Polychlorinated biphenyls
PCOS	Polycystic ovaries syndrome
PCO	Polycystic ovaries
PFOA	Perfluoro octanoic acid
PFOS	Perfluoro octane sulfonate
PPARγ	Peroxysome proliferator-activated receptor γ
P450 scc	P450 side chain
SHBG	Sex hormone-binding globulin
StAR	Steroidogenic acute regulatory protein

Introduction

The total fertility rate has declined dramatically over the past decades in developed countries reaching such a low rate for Europe and Japan (around 1.5 children per couple) that it might contribute for the first time in Japan, while life expectancy is still increasing, to a decrease of the population while life expectancy is still increasing (Skakkebaek *et al.*, 2016). Cultural changes, including the widespread use of contraception by women, a deliberate choice to raise fewer children, and delayed childbearing (Richardson *et al.*, 2014; Hart, 2016), may partly explain this continuous decline. However, there are many indices suggesting that impaired female reproduction linked to environmental factors may also be contributing to this trend. In most developed countries, the use of assisted reproductive technology (ART) is growing, as reported in Denmark, where the percentage of women between 20 and 40 years old has decreased, yet the percentage of couples resorting to ART has dramatically increased (Skakkebaek *et al.*, 2016). Association between environmental factors and decreasing trend of sperm characteristics and increasing male reproductive abnormalities have been widely explored and documented over the last two decades (Skakkebaek *et al.*, 2016).

The next challenge is to verify if female reproduction is also influenced by the changing environment, including exposures to deleterious nutritional factors and/or endocrine-disrupting chemicals (EDCs). There are limited data concerning the prevalence of diseases that affect women's reproductive health. It is less easy to evaluate the trend of female fertility than that of male fertility since gametes are less accessible, and objective markers of ovarian reserve are all imperfect. Identifying the time taken to become pregnant could be a relatively good approach, even though it also depends on the male partner. Most female reproductive disorders such as polycystic ovaries syndrome (PCOS), premature ovarian decline and/or failure, endometriosis, and uterine fibroids share several interesting characteristics, which are as follows: prevalence is relatively high and possibly increasing although not yet demonstrated; the disorders are all associated with impaired fertility with an unclear pathophysiology, which cannot be explained by genetic factors alone; and for all of the disorders, simple and efficient therapeutic solutions are lacking (**Fig. 1**). The most recent hypotheses suggest that interactions between genetic, epigenetic, and environmental factors could also play an important role. These hypotheses are supported by epidemiological and experimental evidence that we analyze in the following sections. Annual worldwide chemical production is dramatically increasing (Neel and Sargis, 2011) and these chemicals are present in large quantities in our domestic environments especially in food. We focus on nutrition and exposure to EDCs, two main environmental factors, depending on lifestyle changes which may have important implications in development of fetal and adult reproductive disorders. We exclude premature puberty and hormone-dependent cancers which may also be influenced by environmental factors, infectious factors through sexually transmitted diseases leading to tubal obstruction, and the consequences of surgery or radiochemotherapy.

Nutrition

Adipose Mass, Energetic Balance, and Female Reproduction

The role of nutrition in female reproduction has long been known; Rosa Frisch linked the onset of puberty with the increasing fat mass in girls more than 40 years ago (Frisch and McArthur, 1974). The mechanisms linking energetic balance and the

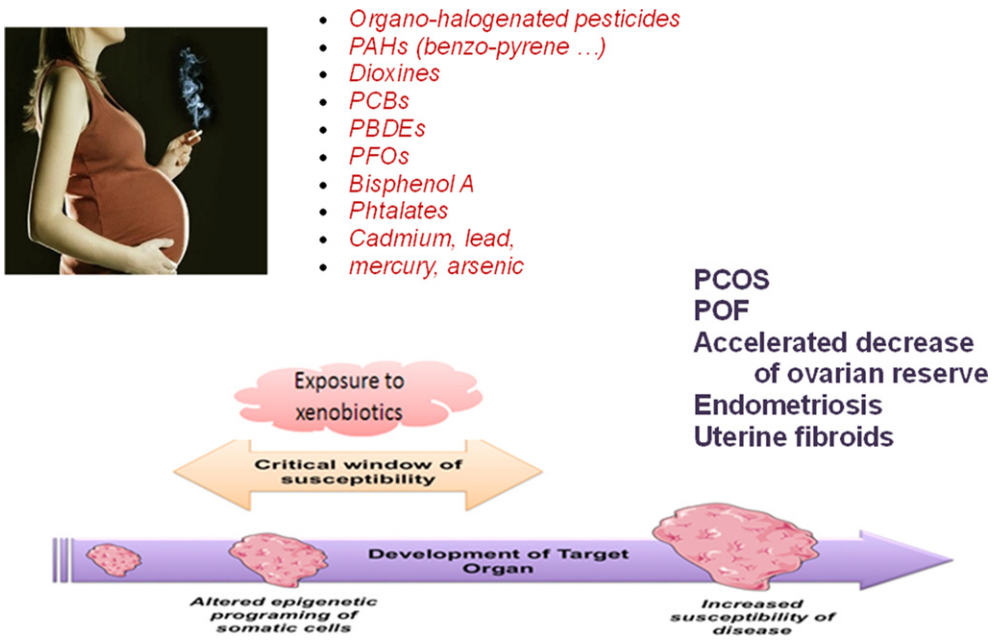

Fig. 1 Exposure to EEDs and impaired ovarian function.

hypothalamic control of the pituitary–ovarian axis were elucidated first with the discovery of leptin (Welt *et al.*, 2004), an adipokine, then with the integrative role of kisspeptin neurons (Tena-Sempere, 2010). Low levels of leptin and insulin indeed played an important inhibitory role in ancient times when the risk of starvation was frequent and women therefore needed to avoid conceiving, as they would not be able to produce enough free fatty acids to ensure healthy fetal growth and subsequently to breastfeed. This security system likely led to a self-selecting bias toward women with a low basal metabolic rate, a greater ability to store adipose tissue, and insulin-resistance susceptibility. These women would survive and conceive, but their offspring would be susceptible to obesity or the development of metabolic syndrome and diabetes when exposed to a more favorable environment, where food was no longer scarce. This selective bias may have contributed in developed or developing countries with improving economic conditions to the dramatic increase in cases of obesity, metabolic diseases, and polycystic ovaries (PCO) all around the world (Corbett and Morin-Papunen, 2013).

Impaired reproductive function may still occur in pathological conditions associated with a negative energetic balance such as that observed in addictive behaviors, like excessive restrictive diet, intensive sport practice, or drug use, associated with severe general diseases or with anorexia nervosa. Less severe restricted food-intake behavior is relatively common among young women and may be associated with disrupted menstrual cycles and decreased fertility rate (Miller *et al.*, 1998), even in cases of women with normal weight.

Fetal Nutritional Environment and Female Reproductive Disorders

One susceptible period during which nutrition seems particularly important for the future reproductive axis is the fetal stage. It is well established that physiological development during prenatal life is influenced by the intrauterine environment and that deleterious nutritional, metabolic, toxicological, or stressful conditions linked to the mother's exposure could increase the risk of adult onset of diseases as first proposed by David Barker in the 1980s (Barker and Osmond, 1986). Barker *et al.* showed that intrauterine growth retardation could cause a predisposition later to the development of adult metabolic and cardiovascular diseases, which is a hypothesis known as the Developmental Origin of Health and Diseases (DOHaD) (Barker, 2007). The question of whether poor maternal nutrition could have an adverse effect on ovarian reserve has been reviewed by Richardson *et al.*(2014). Reduced ovarian volume, low ovulation rates and increased FSH have been described in young women born small for gestational age (SGA) (Ibanez *et al.*, 2002), and the age at natural menopause (ANM) has been associated with both extremes (<2.5 kg or >4 kg) of birth weight standardized for gestational age (Tom *et al.*, 2010). However, these results were not confirmed by two other studies examining ovarian reserve related to birth weight (Hart *et al.*, 2009 Shayeb *et al.*, 2014). One of those studies found a correlation between weight at 2 years and ANM, but not between weight at the time of birth and ANM (Hardy and Kuh, 2002). However, the potential link between fetal or child nutrition and development of ovarian reserve is supported by experimental data in sheep, pigs, and cows (Richardson *et al.*, 2014), associating restricted maternal food intake with reduced ovary size, ovarian reserve, and adult ovulation rate. Fetal epigenetic ovarian modifications are likely to be responsible for this.

Obesity and Reproduction

Obesity and female fertility

Although a minimum of adipose mass may indeed be necessary for a woman to activate and maintain her hypothalamic–pituitary–ovarian axis (Frisch and McArthur, 1974), it seems that obesity, especially visceral obesity with insulin resistance and low-grade inflammation, is associated with: (1) a lower rate of ovulation, meaning less chance to conceive spontaneously or after ART (Broughton and Moley, 2017); (2) an increased risk of miscarriages (Meldrum, 2017); and (3) more adverse pregnancy outcomes including premature labor, stillbirth, and perinatal risks such as gestational diabetes and hypertension, need for operative delivery, wound infection, and thromboembolism (Meldrum, 2017). This is becoming a real public health concern with the occurrence of worldwide pandemics of obesity; in 2009, 23% of American women of reproductive age were classified as obese (Vahratian, 2009).

Obese women take longer to become pregnant, as shown in large prospective studies such as the Danish cohort (Wise *et al.*, 2010), even in the case of normal ovulating obese women included in the large American cohort (Gesink Law *et al.*, 2007), or the large Dutch cohort (van der Steeg *et al.*, 2008), which reported a linear declined probability of spontaneous conception for each body mass index (BMI) point over 29. Obese women undergoing in vitro fertilization (IVF) also have oocytes and embryos of poorer quality (Shah *et al.*, 2011) and have decreased pregnancies and/or a decreased live birth rate (Luke *et al.*, 2011) when compared to nonobese women.

Obesity, insulin resistance and PCOS

Prevalence of PCOS among obese women has been estimated at around 30% (Alvarez-Blasco *et al.*, 2006), and between 38% and 88% of women with PCOS were overweight or obese (Barber *et al.*, 2006). This obesity is most often "visceral" or "metabolically active." It is associated with other metabolic markers including insulin resistance, which is in fact the common starting point, regardless of whether or not the woman is already overweight. Obesity contributes to insulin resistance and exacerbates the symptoms of PCOS. Hyperinsulinism potentiates luteinizing hormone (LH) stimulation of the internal theca LH receptor, activating CYP17A1, increasing hyperandrogenism, and disrupting follicular maturation. Hyperinsulinism also increases circulating hyperandrogenism via the decrease of sex hormone-binding globulin (SHBG) and potentiates the action of insulin growth factor-1 via the decrease of insulin growth factor-binding proteins. Whatever its origin, hyperinsulinism is a gateway through which environmental factors such as nutrition, energy balance, intestinal microbiota (Guo *et al.*, 2016), and chemical pollutants (Fenichel *et al.*, 2017) are able to influence the chances of infertility. As for its origin, it may be genetic; thus insulin receptor gene variants were associated with PCOS (Lee *et al.*, 2008). It can also integrate into a developmental origin and preprogramming by impairment of the fetal environment (Fenichel *et al.*, 2017). In fact, both metabolic syndrome and PCOS may have an intrauterine developmental origin (DOHaD). An intrauterine growth retardation, known (Barker, 2007) to be associated with an increased risk of developing metabolic and cardiovascular diseases in adulthood, has been reported in adolescents with premature pubic hair and ovarian hyperandrogenism (Ibanez *et al.*, 2007; Melo *et al.*, 2010), as well as in a prospective cohort of 165 women with PCOS born at term (Cresswell *et al.*, 1997).

Obesity and female infertility: which mechanisms?

As discussed earlier, obesity is an aggravating factor of PCOS. Hyperinsulinemia, hyperandrogenism, and increased adipokines like leptin contribute to a central impairment of the pituitary–ovarian axis and the follicular maturation. However, infertility in obese women is not only due to lack of ovulation. Both human IVF results and animal experimental studies have shown that obesity has a direct and complex effect on the microenvironment of oocytes, preimplantation embryos, and endometrium mediated by insulin resistance, low-grade inflammatory state, oxidative stress, or lipotoxicity by higher levels of circulating free fatty acids and deleterious adipokines (Broughton and Moley, 2017). In obese woman, the use of IVF has resulted in altered follicular fluid biomarkers with a pro-inflammatory environment. Observation of oocytes that failed to fertilize in severely obese women has revealed high rates of meiotic aneuploidy with fragmented disorganized meiotic spindles with misaligned metaphase chromosomes (Machtinger *et al.*, 2012). Similar observations have been made in diet-induced obesity (DIO) mouse models with more apoptotic follicles, smaller and less mature oocytes with high rates of meiotic aneuploidy (Luzzo *et al.*, 2012), and alteration of mitochondrial function in the oocyte (Igosheva *et al.*, 2010). A similar pro-inflammatory and lipotoxic state can affect the microenvironment of the preimplantation embryo, as observed in the same DIO model with lower expression of insulin-like growth factor 1 receptor, influencing insulin sensitivity and glucose transport (Jungheim *et al.*, 2010), and contributing later to higher frequency of preeclampsia, due to abnormal trophoblast invasion.

In the oocyte donation model in relation to obesity, out of three reports on the pregnancy rate, one (Dessolle *et al.*, 2009) showed the receiver's BMI to be an independent negative predictor, illustrating the direct effect of obesity on the endometrium receptivity, as confirmed in the DIO mouse model (Rhee *et al.*, 2016).

Fetal outcomes and transgenerational effects

A very recent and large Swedish cohort study of 1.2 million singletons has shown that major congenital malformations and several subgroups of organ specific malformations increased with maternal overweight and increasing severity of obesity (Persson *et al.*, 2017).

There is also an increasing body of evidence suggesting that maternal obesity may contribute to pandemics of metabolic diseases by conferring a transgenerational risk (Van Dijk *et al.*, 2016) through in utero epigenetic modifications (Jungheim *et al.*, 2010). Moreover, in the DIO mouse model, it has been shown that metabolic dysfunction mediated through impaired mitochondrial function can be transmitted through the maternal germline from aberrant oocytes to several generations of offspring (Saben *et al.*, 2016). These recent data and the impaired fertility associated with obesity highlight the importance of medical programs to be proposed to obese women who want to conceive.

Medical interventions before pregnancy

It is obvious that weight loss should be proposed to every obese woman before they conceive and that efforts should be made to reduce adiposity through efficient educational programs. In fact, such programs still have room for improvement. Many ART centers from different countries set a weight cutoff before accepting obese women for fertility treatment. However, this rule could be ineffective and even harmful in some cases, as discussed recently by Legro (2016). There were no evidence-based theories to support the idea that weight loss before IVF had a beneficial effect on outcomes when comparing a 6-months evidence-based lifestyle intervention to immediate ART (Mutsaerts *et al.*, 2016). It is possible that BMI is a poor marker of fat distribution, insulin resistance, and low-grade inflammatory state (Legro, 2016). Instead of significant weight loss, which is difficult to obtain rapidly, efficient lifestyle changes from 3 months before IVF, and then during and after that IVF, should improve the rate of success, as was shown by regular exercise (Palomba *et al.*, 2014) and healthy diet (Vujkovic *et al.*, 2010) reducing oxidative stress inflammation and insulin resistance. Legro (2016) concluded that "weight limits used to deny women access to fertility care are not only arbitrary but discriminatory and not evidence-based." The best program and strategy to be proposed remain to be determined. Bariatric surgery in the case of morbid obesity is the right solution. However, excessive rapid weight loss may be associated with SGA offspring, which can itself increase the risk of adult metabolic diseases (Johansson *et al.*, 2015). It may also rapidly release persistent pollutants with EDC effects (Kim *et al.*, 2011) in the circulation. For all these reasons, it is recommended that a woman waits for 1 year after bariatric surgery before attempting start spontaneous or medically induced conception.

EDCs and Female Reproductive Health

Endocrine-Disrupting Chemicals

The human population is exposed to a large number of chemical pollutants that may interfere with physiological functions. Since worldwide annual production of synthetic chemical is dramatically increasing (Neel and Sargis, 2011), questions have arisen in the last few decades about the role of chronic exposure to low doses of chemicals pollutants in terms of animal and human health and diseases; these questions focus particularly on reproductive and neurodevelopmental outcomes, but also on chronic diseases including metabolic disorders or cancers. The first observations were made on animals and concerned the reproductive system, after exposure to chemicals showing estrogenic or anti-androgenic effects. Together with the diethylstilbestrol (DES) story (discussed below), this led to the concept of *endocrine disruptors*. EDCs are natural or synthetic chemical compounds, present in the everyday domestic environment, that interfere with hormonal regulation systems critical for development or homeostasis (Diamanti-Kandarakis *et al.*, 2009). Many EDCs are present in the food chain, and will after absorption be sequestered in adipose tissue. They may represent, after low-dose exposure during critical windows or via chronic exposure to cumulative doses, one aspect of the genetic/environment interface involved in many chronic diseases. They will act through different nuclear and membrane receptors specific to the female reproductive function, estrogen receptors including ERα and ERβ (estrogen receptor α, β) (Crain *et al.*, 2008), G protein-related receptor 30 (Bouskine *et al.*, 2009, Chevalier *et al.*, 2012), or the aryl hydrocarbon receptor (AhR) (Cavallini *et al.*, 2016), an orphan nuclear receptor able to bind dioxins and dioxin-like endocrine disruptors.

Many EDCs are lipophilic chemicals called persistent organic pollutants (POPs), for example (**Table 1**), many organohalogenated pesticides such as estrogenic DTT and its persistent metabolite *p,p'*-dichlorodiphenyldichloroethylene (DDE), which is

antiandrogenic, phenols such as polychlorinated biphenyls (PCBs) used as electric isolants, polycyclic aromatic hydrocarbons (PAHs) present in tobacco or industrial dust such as dioxins, polybromated compounds used as flame retardants, and polyfluoroalkyls compound used as impermeants or flame retardants. Others are more rapidly eliminated after oxidation and conjugation in the liver, and are called nonpersistent pollutants such as Bisphenol A (BPA) and phthalates; both are used in plastics but found in blood and urine since we are continuously exposed to them. BPA is used in many plastics, resins, and PVC. It is found in the everyday domestic environment (receipts, infusion bags, CDs) and in the food chain (packaging, plastic bottles, plastic bottles, cans, etc.). BPA was discovered as an estrogen in the wake of DES but was soon used as a monomer to polymerize plastic polycarbonate chains with interesting properties. Some heavy metals such as cadmium, arsenic, lead, or mercury are nonessential and toxic. They are resistant to degradation, may persist or bioaccumulate in the environment, and may be toxic as EDCs for female reproduction and offspring (Hart, 2016; Choy *et al.*, 2002).

Cigarette smoke contains several thousand toxic components with diverse effects; these components include EDCs such as polycystic aromatic hydrocarbons acting through the AhR receptor or cadmium with estrogenic effects. Cigarette smoking in females is associated with lower fecundity rates, deleterious reproductive outcomes, and a higher risk of IVF failures depending on the time of exposure (in utero development or adult) and with multisites of action (ovaries, endometrium, uterus, tubes) (Dechanet *et al.*, 2011). The prevalence of cigarette smoking among women of reproductive age is still important and was estimated around 25% in the United States and 23% in the United Kingdom (WHO, 2009 in: World Health Organization (Ed), Prevalence of tobacco use among adults and adolescents 2014) and represents a real concern for female reproduction (Camlin *et al.*, 2014).

EDCs are found in the blood (Diamanti-Kandarakis *et al.*, 2009), including cord blood (Fenichel *et al.*, 2012; Woodruff *et al.*, 2011; Brucker-Davis *et al.*, 2008), milk (Brucker-Davis *et al.*, 2008), adipose tissue, amniotic fluid (Fini *et al.*, 2017), and placenta (Fernandez *et al.*, 2016). The ability of EDCs to alter female reproductive function and health is illustrated by the DES story, and is also supported by epidemiological and experimental studies and direct observations during IVF.

The DES Story

DES is a synthetic estrogenic compound; discovered in 1938, it was given to pregnant women until the 1970s to prevent miscarriages. Occurrence of very rare and severe cervical-vaginal cancers in young girls who had been exposed to DES in utero led to its banishment. However, this dramatic experience has also provided unexpected progress by suggesting new pathophysiological concepts such as fetal programming of adult diseases and/or transgenerational transmission of environmental effects through epigenetic modifications induced in selective windows by fetal exposure to xenoestrogens (Fenichel *et al.*, 2015). In the second generation, enhanced risk of early cervical-vaginal cancer, impaired reproducctive function and adult breast cancer (after 40 years) have been reported in large prospective follow-up. This follow-up includes significant hazard ratios of uterine malformations, infertility, spontaneous abortion, ectopic pregnancy, stillbirth, preeclampsia, and early menopause after exposure in utero to DES. Experimental studies in rodents have confirmed such an impact and allowed the identification of molecular mechanisms such as epigenetic changes (Fenichel *et al.*, 2015).

Fecundity and EDCs: Time to Become Pregnant

Time to become pregnant after stopping contraception is a useful way to explore the link between exposure to EDCs and female fertility. Epidemiological studies have concerned either occupational exposures or the general population. Danish female workers in flower greenhouses with potential exposure to pesticides had a reduced fecundity in terms of increased time to pregnancy, and this was related to their more or less direct exposure to pesticides (Abell *et al.*, 2000). In order to assess the real role of environmental factors in human fecundity, Buck Louis *et al.* (2013) designed a large prospective Longitudinal Investigation of Fertility and the Environment (LIFE) study on the effects of POPs on both partners in a couple. Women were recruited prior to conception and were followed through 12 observed cycles. Adjusted reduced fecundity was associated with the increase of several POPs in serum, PCBs 118, 167, and 209 and perfluoro octane sulfonate (PFOS) in females, and *p*,*p*′-DDE and PCBs 138, 156, 157, 167, 170, 172, and 209 in males. The same stringent methodology adapted to non-POPs like BPA and phthalates measured in urine did not show any correlations for females, but did indicate a positive correlation in males for selective phthalate metabolites (Buck Louis *et al.*, 2014). A similar difference was found for heavy metals related to time to pregnancy only in males (Buck Louis *et al.*, 2012). In the French PELAGIE cohort, which included more than 3000 pregnant women in Britain, time to pregnancy was significantly increased when seafood was consumed more than twice weekly when compared to less than eight times monthly or when total serum PCBs or *p*,*p*′-DDE were at the highest tercile, compared to the lowest one (Chevrier *et al.*, 2013). POPs and heavy metals bioaccumulate easily in fish and seafood. However, the most interesting epidemiological evidence supporting a developmental role for exposure to POPs in the decrease of female fertility was reported by Cohn *et al.* (2003). These authors measuredmaternal serum levels of DTT, an estrogenic pesticide, in a historical biobank of serum collected 30 years before in an American maternity. The levels were then correlated to the time to become pregnant taken by the daughters 30 years later. The concept that fetal or perinatal exposure to toxicants is able to influence the reproductive capacity of a young woman later in her life is supported by the DES story and by several animal models that we describe in the next section.

EDCs and Ovarian Reserve: Premature Ovarian Failure: Effects on Oocytes

Premature ovarian failure

Ovarian reserve depends on two kinds of factors: (1) the follicular pool established definitively before birth and (2) the velocity at which the ovarian reserve decrease. Premature ovarian failure (POF), a hypergonadotropic and hypoestrogenic amenorrhea, is present in 2% of women under the age of 40. There are no objective data to verify if the prevalence of premature decline of ovarian reserve or real POF is increasing. Spontaneous POF is idiopathic in more than 75% of cases. Environmental, nutritional, and/or toxicological factors could play a role in some of these cases, as suggested by epidemiological and experimental evidence (Richardson *et al.*, 2014). There are no reliable ovarian reserve biomarkers in adulthood, even though basal serum FSH level at the beginning of the menstrual cycle, serum anti-Müllerian hormone (AMH) level, antral follicle count, and ANM are usually assessed.

Human data

Hairdressers who are exposed to chemicals have been shown to be at increased risk of POF when compared with women employed in other occupations (Gallicchio *et al.*, 2009). POF has been associated with exposure to a solvent containing 2-bromopropane (Koh *et al.*, 1998), but the causal link was discussed by Beranger *et al.* (2012). Exposure to perfluorocarbons (perfluoro octanoic acid (PFOA), PFOS) was associated with an earlier ANM in a very large population of women aged over 42 years (Knox *et al.*, 2011). Using the US population National Health and Nutrition Examination Survey (NHANES) database in a cross-section study including 31,575 females, and analyzing 111 EDCs focusing on persistent chemicals, women with high levels of 15 identified EDCs had mean ages of menopause 1.9–3.8 years earlier than women with lower levels. Women exposed to EDCs were up to six times more likely to have menopause than nonexposed women (Grindler *et al.*, 2015). Classical measures of ovarian reserve among patients undergoing fertility treatments showed an association with urinary phthalate monoester concentrations (Souter *et al.*, 2011). Loss of ovarian reserve linked to cigarette smoking is supported by several studies reviewed by Richardson *et al.* (2014), reporting correlations with elevated FSH levels, earlier onset of menopause, and reduced retrieval of oocytes in IVF cycles. A causal relation is enhanced by the significant FSH elevation and inhibin B decrease, which are both correlated with increased serum cadmium, a heavy estrogenic metal present in cigarette smoke (Gallagher *et al.*, 2010). Maternal exposure to cigarette smoke was associated with earlier ANM in daughters (Strohsnitter *et al.*, 2008). While conflicting data have been published on the developmental effect of maternal smoking (Richardson *et al.*, 2014), several experimental studies have confirmed such a possible link (see later). In the Avon Longitudinal study of parents and children, paternal but not maternal smoking prior to and during pregnancy was inversely associated with AMH levels in female adolescents (Fraser *et al.*, 2013). Antenatal exposure to monoethyl phthalate, widely found in cosmetics, measured in maternal serum, correlated negatively with AMH levels in adolescent girls (Hart *et al.*, 2014).

Animal studies

There are many experimental studies reporting the effects of EDCs exposure on an ovarian reserve, especially during the developmental period. Animal studies enable one to study a single chemical alone or in a cocktail, identifying the dose and the time of exposure and the molecular mechanisms involved. Fetal and perinatal exposure to low environmentally relevant doses of methoxychlor, an organochlorine pesticide, impaired ovarian folliculogenesis in adult rats (Armenti *et al.*, 2008) with morphological and molecular changes leading to an accelerated ovarian failure. Hypermethylation of the CPG islets of the ERβ gene promoter was involved in this developmental induced POF (Zama and Uzumcu, 2009). Perinatal exposure to environmentally relevant levels of BPA decreased fertility and fecundity in CD61 mice (Cabaton *et al.*, 2011) and reduced the pool of primordial follicles in rat ovaries (Rodriguez *et al.*, 2010) by acting as an activator of the neonatal recruitment. This effect in granulosa cells got through an estrogenic pathway involving ERβ and ERα. Prenatal exposure of female mice to a phthalate mixture which mimics human exposure to phthalates present in consumer products, including personal care products and plastics, disrupted estrus cycles and reduced fertility related indices in F1 offspring (Zhou *et al.*, 2017b), and impaired female reproduction in F2 and F3 through a transgenerational effect (Zhou *et al.*, 2017a). AhR could be involved since Chen *et al.* (2012) had shown that benzyl butyl phthalate induced necrosis by AhR mediation of CYP1B1 expression in human granulosa cells. Exposure of adult mice to concentrations of cigarette smoke proportional to those involved in human exposure resulted in a significant primordial follicle loss. This provides further support for the idea that cigarette smoke is a reproductive toxicant resulting in POF, but curiously without enhancing apoptosis even with isolated high doses of benzopyrene (BaP), a major PAH present in tobacco (Tuttle *et al.*, 2009). In fact, the molecular mechanisms involved depend on the time of exposure. Maternal exposure during pregnancy or lactation, to PAHs in mice, induced POF in female offspring by activation of the aromatic hydrocarbon receptor driving bax-dependent apoptosis (Matikainen *et al.*, 2002). This signaling pathway including Harakiri activation is also involved in human ovaries as xenografted human ovarian cortex exposed to PAHs, caused by activation of the identical cell death cascade (Jurisicova *et al.*, 2007). This raises concerns about the transgenerational impact of maternal smoking on ovarian function in human.

Fecundity and EDCs: observations during IVF

Many persistent and nonpersistent organic pollutants have been found in follicular fluids collected during IVF and correlated with IVF outcomes. PCB congeners and DDE were identified in follicular fluids and inversely related to number of oocytes retrieved and live births obtained (Bloom *et al.*, 2017). BPA was detectable in follicular fluid in the majority of women undergoing IVF and inversely associated with the number of oocytes retrieved (Mok–Lin *et al.*, 2010). Higher urinary BPA concentrations were found to

be associated with decreased ovarian response, number of fertilized oocytes, and decreased blastocyst formation (Ehrlich *et al.*, 2012). Cigarette smoking is associated with lower fertility rates, adverse reproductive outcomes, and a higher risk of IVF failures (Dechanet *et al.*, 2011). Many pollutants with endocrine-disrupting effects and/or toxicological effects have been identified in follicular fluids such as cadmium, PAH like BaP, or cotidine (Dechanet *et al.*, 2011), which have been shown in vivo or in vitro in rodents to induce deleterious effects on ovarian function. A recent French study reported a significant correlation between abnormal oocytes collected by IVF, showing centrally located cytoplasm granulation and domestic exposure to pesticides in an intensive agriculture area, assessed by geolocation (Merviel *et al.*, 2017). All these observations and epidemiological correlations are supported by experimental studies. Several studies in mice reviewed by Richardson *et al.* (2014) have reported meiotic abnormalities including synaptic defects and increased levels of recombination in oocytes linked to exposure to BPA either in utero or at the adult stage (Susiarjo *et al.*, 2007). BPA similarly altered oogenesis in the fetal ovary of the rhesus monkey. BPA has also been shown to impair steroidogenesis in vitro in rat theca-interstitial and granulosa cells (Zhou *et al.*, 2008).

A new and important question concerns the potential reprotoxicity of nanoparticles. Preliminary studies have shown, for example, that cerium dioxide nanoparticles widely used as a diesel additive or as promising therapy in cancerology are able to reduce fertilization rates in mice during IVF when added in low doses in a culture medium (Preaubert *et al.*, 2016). Decreased fertilization rates could result from genotoxicity observed in gametes, a mechanical effect disrupting gamete interaction and oxidative stress (Preaubert *et al.*, 2016). Regarding the increasing use of nanoparticles in everyday life, there is an urgent need for evaluation of their toxicity, including reprotoxicity by in vivo studies after low-dose exposure.

Polycystic Ovaries Syndrome and Endocrine-Disrupting Chemicals

PCOS: an environmental disease?

PCOS, the most common female endocrine disorder, affects 7%–10% of women of childbearing age. It includes ovarian hyperandrogenism, impaired follicular maturation, anovulation, and subfertility. Insulin resistance is present in most cases and increases with obesity. The origin of hyperandrogenism and hyperinsulinemia has a genetic component, as demonstrated by familial aggregation studies and recent identification of associated genomic variants, conferring a particular susceptibility to the syndrome (Fenichel *et al.*, 2017). However, experimental and epidemiological evidences also support a developmental origin via a deleterious fetal environment, concerning the nutritional level (intrauterine growth retardation), the endocrine status (fetal hyperandrogenism), or the toxicological exposure (endocrine disruptors). Epigenetic changes recently reported in the literature as being associated with PCOS enhance this hypothesis of fetal reprogramming by environmental factors of the future adult ovarian function (Fenichel *et al.*, 2017).

Hyperandrogenism

It has been well demonstrated in the rhesus monkey that fetal exposure to an excess of androgens induced an irreversible and predictable sequence of physiological changes. These changes included delayed puberty, ovarian dysfunction (Dumesic *et al.*, 1997), ovarian hyperandrogenism with anovulation (Abbott *et al.*, 1998), increased BMI within adulthood, and insulin resistance (Eisner *et al.*, 2000), all of which closely belong to the PCOS phenotype (Eisner *et al.*, 2002). Works carried out in ewes treated with testosterone at different times of pregnancy have shown similar results (Padmanabhan and Veiga-Lopez, 2014). In this model, induction of prepubertal obesity by overfeeding could amplify ovarian disorders (Steckler *et al.*, 2009). Women with adrenal hyperplasia due to a congenital enzymatic block in 21-hydroxylase often present a PCOS phenotype (Dunaif, 1992) with hypertonic LH, which may be consecutive to prenatal androgen exposure. Excluding this case, the question arises of the origin of such fetal hyperandrogenism, since maternal SHBG is usually elevated during pregnancy (Morel *et al.*, 2016) and placental aromatase activity theoretically protects the fetus from maternal androgens. However, one cannot exclude a decrease of SHBG due to hyperinsulinemia (Sir-Petermann *et al.*, 2002 Nestler, 1987) in the case of maternal PCOS or due to the presence of a specific genetic variant (Xita *et al.*, 2003 Hogeveen *et al.*, 2001 Cousin *et al.*, 2004), which could also explain a decreased aromatase activity (Balakrishnan *et al.*, 2010). Several potential mechanisms have been proposed to explain the fetal programming linked to hyperandrogenism whatever its origin (Petry *et al.*, 2005): modifications of the neuroendocrine control of the gonadotropic axis leading to permanent excessive LH secretion or some epigenetic changes concerning ovarian genes involved in follicular maturation.

Endocrine disruptors and PCOS

EDCs generally have less affinity to the binding proteins like maternal SHBG, are not transformed in estrogens by aromatization, and easily cross the placenta (Corbel *et al.*, 2014). In addition, the fetal liver keeps an enzymatic immaturity, with a weak detoxifying power by oxidation and conjugation. Both experimental and epidemiological evidence support a role for EDCs in PCOS through an in utero exposure via the mother or through chronic adulthood exposure interfering with follicular maturation, ovarian steroidogenesis, and/or occurrence of insulin resistance. Fetal exposure to BPA may determine the changes of the hypothalamic-pituitary-ovarian axis (Tena-Sempere, 2010) in adults as demonstrated in ewes (Collet *et al.*, 2010) or rhesus monkeys (Kurian *et al.*, 2015) and also act on the oocyte maturation with increased follicular atresia, as reported in the mouse in vivo (Susiarjo *et al.*, 2007; Eichenlaub-Ritter *et al.*, 2008) or in vitro (Peretz *et al.*, 2012). Neonatal exposure to BPA in rats results in a similar picture of PCOS, with hyperandrogenism, anovulation, infertility, and PCO (Fernandez *et al.*, 2010). All these

experiments with perinatal exposure of the female gonads are accompanied in adult by impaired steroidogenesis with modifications in the expression of key enzymes such as P450c17, P450scc, and StAR (Abbott *et al.*, 2008): activity which is known to be impaired in human PCO (Nelson *et al.*, 1999).

Moreover, many chemical pollutants with endocrine-disrupting activity are considered to be able to play a role in obesity and type 2 diabetes through an in utero fetal effect, leading in adulthood to insulin resistance. BPA is one of them and is particularly relevant since it can, at low concentrations, be found in human cord blood (Fenichel *et al.*, 2012), and can promote both ovarian hyperandrogenism and hyperinsulinemia in animals, two major features of PCOS (Chevalier and Fenichel, 2015). Measures of BPA performed at the time of diagnosis have been reported in humans. They are higher in men than in women and higher in women with PCOS than in those with normal cycles. The measures correlate positively with total or free testosterone (Takeuchi and Tsutsumi, 2002), suggesting an effect of hyperandrogenism on BPA metabolism. Free serum BPA has been found to be higher in women with PCOS, regardless of whether or not obesity was present and correlated with both testosterone levels and insulin resistance (Kandaraki *et al.*, 2011). These findings were confirmed in a group of adolescents aged 13–19 years with PCOS (Akin *et al.*, 2015). Potential bi-directional interactions between BPA and hyperandrogenism were modeled by Palioura and Diamanti-Kandarakis (2015). Hyperandrogenism can slow down BPA metabolism in the liver. BPA can interfere with hyperandrogenism at various levels such as circulating SHBG, androgen receptor, synthesis via steroidogenic enzymes, and androgen metabolism (Peretz *et al.*, 2012). However, formal evidence supporting a role of in utero exposure to BPA in the occurrence of PCOS has yet to be confirmed in humans. In vitro experiments have shown that methoxychlor (an organochlorine pesticide) and dioxin (derived from the combustion of industrial products or wastes) are able to inhibit follicular maturation at the antral stage and to disrupt steroidogenesis (Patel *et al.*, 2015) by stimulating the production of AMH (Uzumcu *et al.*, 2006). In a recent US case/control study assessing blood and urine levels of different classes of EDCs a correlation was found in PCOS with two perfluorinated components, PFOA and PFOS in blood after correction for age, BMI, and ethnic origin (Vagi *et al.*, 2014).

Epigenetic modifications in PCOS

It seems likely that PCOS occurs as a result of the conjunction of both genetic and environmental factors (**Fig. 1**). The protective or susceptible genomic variants involved (Fenichel *et al.*, 2017) may also be influenced by environmental factors through epigenetic modifications. In the PCOS model induced in the rat by fetal hyperandrogenism, hypermethylation of the *PPARγ* gene and hypomethylation of the nuclear corepressor factor NCOR1 have been reported (Qu *et al.*, 2012). The LH/CG receptor, which regulates the thecal steroidogenesis, has several variants that represent a susceptibility factor, as found in several studies of the genome-wide association study type (Hayes *et al.*, 2015 Wang *et al.*, 2014). It is therefore quite consistent that methylation changes have also been found on the promoter of the *LH/CG* receptor gene in the PCOS mouse model induced by fetal exposure to androgens (Zhu *et al.*, 2010), as well as in a series of 85 women with PCOS who had an excess of hypomethylated sites compared to 88 control subjects (Wang *et al.*, 2014), with overexpression of the *LH/CG* gene on the surface of the thecal cells. Several authors have attempted to analyze methyloma more systematically in the case of PCOS. Shen *et al.* (2013) reported 79 genes with differential methylation in a PCOS group with insulin resistance compared to a group of women with PCOS without insulin resistance and 43 genes with a different methylation profile in PCOS compared to controls. Using the DNA chip method, Kokosar *et al.* (2016) in Sweden found 1720 genes differentially expressed in adipose tissue in 64 women with PCOS compared to 30 controls. Thirty-three of these genes exhibited corresponding modifications at some of their methylation sites. In a similar Chinese study (Wang *et al.*, 2014), comparing DNA methylation profile and transcriptional analysis in the ovarian tissue of women with or without PCOS, a match could be established in the case of PCOS for 54 genes between the perturbation of the ovary gene expression and the methylation modifications at the CpG sites of their promoter. Some of these genes were involved in molecular signaling, inflammation, metabolic control, or proliferation processes consistent with their involvement in the development of PCOS. Several recent studies have analyzed the profile of microRNAs (miRNAs) in PCOS (Sorensen *et al.*, 2014 Ding *et al.*, 2015) in serum or in follicular fluid (Roth *et al.*, 2014). Differences have been found for some miRNAs involved in the control of genes necessary for androgen synthesis, inflammation, adipogenesis, and signaling, thus being able to integrate into the pathophysiology of PCOS (Ilie and Georgescu, 2015 Murri *et al.*, 2013). Two miRNAs appear to be of particular interest as biomarkers in PCOS; one (miR-222) is positively correlated with insulin and the other (miR-146a) is negatively correlated with testosterone, after multivariate adjustment for age and BMI (Long *et al.*, 2014). These results, which need to be confirmed and consolidated, therefore strongly suggest that epigenetic changes induced, for example, by environmental factors (Anway *et al.*, 2005) could influence the molecular mechanisms leading to PCOS (**Fig. 2**).

EDCs and Endometriosis

Endometriosis, defined by the presence of functional ectopic endometrial glands and stroma outside the uterine cavity, affects 6%–10% of women of reproductive age, causing chronic pain and infertility; it remains a pathophysiological and therapeutic enigma. Recent experimental studies suggest a developmental in utero origin with epigenetic changes (Borghese *et al.*, 2017), which could be induced by exposure to EDCs (Smarr *et al.*, 2016) acting through the AhR and target genes controlling estrogen metabolism (Bulun *et al.*, 2000; Huang *et al.* 2016). In a case–control study of women enrolled in a large health care system in the US Pacific Northwest, serum concentrations of *β*-HCH (lindane) and mirex were positively associated with endometriosis (Upson

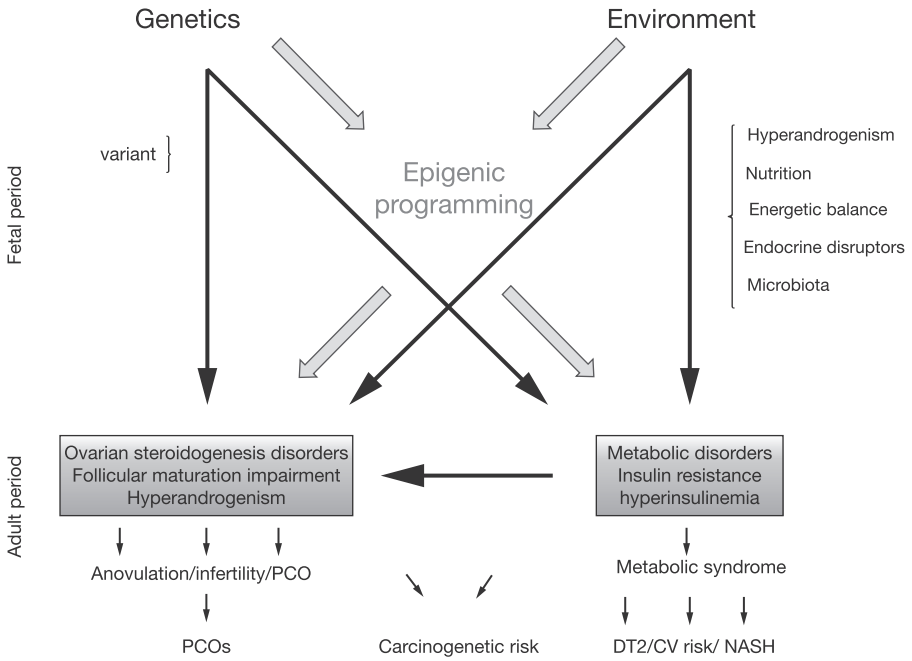

Fig. 2 PCOS physiopathology: interactions between genetic, epigenetic, and environmental factors (Fénichel *et al.* 2017).

et al., 2013; Sofo *et al.*, 2015). The role of dioxins, dioxine-like PCBs (Martinez-Zamora *et al.*, 2015), phthalates (Reddy *et al.*, 2006), DES, benzophenones, and some metals/trace elements are supported by clinical and experimental studies (Smarr *et al.*, 2016; Crain *et al.*, 2008), with some methodologic concerns needing confirmation.

Uterine Fibroids

Uterine fibroids (leiomyomas), the most common tumor of the female reproductive tract occur in 25%–50% of all women (Cramer and Patel, 1990), and in some cases can impair fertility. Several risk factors such as genetic susceptibility or hormonal climate have been reported. Both in vitro and in vivo studies suggest a role for estrogenic EDCs in promoting leiomyomas in women (Crain *et al.*, 2008). Only one human study with ultrasound detection clearly showed a significant relationship with prenatal exposure to DES (Baird and Newbold, 2005). Further investigations are needed.

Conclusion

Environmental factors seem to contribute significantly to physiological and pathophysiological aspects of female reproductive function. While a minimal fat mass is necessary to maintain the menstrual cycle, obesity is associated with impaired fertility and obstetrical, fetal, and postnatal complications. EDCs present in the domestic sphere may influence fetal development by epigenetic imprinting and later by the occurrence of current gynecological diseases associated with impaired reproductive function. It is important to evaluate the effect of the environment on female reproduction in order to identify simple preventive strategies, including advices to be given to young women before they become pregnant, as proposed recently by the Endocrine Society and FIGO, in order to set in motion a virtuous cycle to limit toxicological exposure for future generations.

Miscarriages

Hervé Fernandez and Perrine Capmas, Bicetre Hospital, Le Kremlin Bicetre, France

Introduction

Miscarriages are the most frequent complication of pregnancy. They happened in at least 12% of pregnancy (one woman out of four before 39 years old) (Blohm *et al.*, 2008). They cause maternal death in a small number of cases (0.05–0.22/100000) (Cantwell *et al.*, 2011).

They are defined by a pregnancy loss before 14 weeks of gestation. The risk factors for miscarriage are maternal age (with a higher risk after 35 years old) (Nybo Andersen *et al.*, 2000; Maconochie *et al.*, 2007), paternal age (after 45 years old) (Maconochie *et al.*, 2007), maternal body mass index (with a higher risk for body mass index more than 25) (Metwally *et al.*, 2008), toxic consumption (coffee, tobacco and alcohol) (Henriksen *et al.*, 2004; Maconochie *et al.*, 2007; Weng *et al.*, 2008; Waylen *et al.*, 2009) and exposure to magnetic fields and ionizing radiation (Fucic *et al.*, 2008; Wang *et al.*, 2013; Delabaere *et al.*, 2014). A previous miscarriage or a previous abortion are also risk factors such as infertility and alteration of ovarian reserve (Brigham *et al.*, 1999; Maconochie *et al.*, 2007; Sahu *et al.*, 2010).

Aim of this article is to recall how to manage first trimester pregnancy loss (i.e., miscarriage) from diagnosis to therapeutic but also how to manage repeat miscarriages.

Diagnostic Criteria (Lavoue *et al.*, 2014)

Gold standard for diagnosis of miscarriage is pelvic sonography (Wieringa-de Waard *et al.*, 2002; Doubilet *et al.*, 2013). Sensibility and specificity of evaluation of symptoms (pain and bleeding), history and clinical examination are poor compared to sonography. Then a sonography is recommended in case of bleeding or pain at the first trimester of pregnancy. Transvaginal sonography might be useful for very early pregnancies (Jain *et al.*, 1988; Cacciatore *et al.*, 1989; Pennell *et al.*, 1991; Ferrazzi *et al.*, 1993). First of all, diagnostic of an intrauterine pregnancy has to be done. The diagnosis of a gestational sac can be made only in case of a yolk sac or an embryo inside the sac. Others signs such as double decidual sac or intradecidual sign cannot allow a diagnosis of an intrauterine pregnancy (Mueller, 1979; Bradley *et al.*, 1982; Doubilet and Benson, 2013).

A gestational sac larger than 25 mm without embryo and with or without a yolk sac allows a diagnosis of miscarriage such as the presence of a gestational sac with an embryo of more than 7 mm without cardiac activity (Abdallah *et al.*, 2011; Jeve *et al.*, 2011).

In case of pregnancy of uncertain viability, defined by a gestational sac less than 25 mm, a sonographic control has to be performed after 14 days when there is no yolk sac in the gestational sac and 11 days if there is a yolk sac. After this delay, the diagnosis of miscarriage can be done if there is still no embryo with cardiac activity. When an embryo is present, less than 7 mm, a sonographic control after 7 days is recommended to search for cardiac activity and to allow the diagnosis of miscarriage if there is still no cardiac activity (Bree *et al.*, 1989; Doubilet and Benson, 2013).

For pregnancy of unknown location (no gestational sac inside uterus and no visible ectopic pregnancy), the threshold of hCG above which an ongoing intra uterine pregnancy can be excluded if there is no gestational sac inside uterus is 3510 UI/mL. At this threshold, a gestational sac is visible in 99% of cases of ongoing pregnancy. However, above this threshold, diagnosis between a miscarriage and an ectopic pregnancy can be done only with sonography. An ongoing pregnancy can also be excluded under the threshold of 3.2 ng/mL for progesterone rate (Verhaegen *et al.*, 2012; Connolly *et al.*, 2013). But no conclusion between intrauterine pregnancy and ectopic pregnancy can be done on hCG or progesterone rates.

When initial hCG rate is less than 20,00 UI/L, a control of sonography and hCG rate after 48 h allow elimination of an ongoing intrauterine pregnancy if increase of hCG rate is less than 15%. The two possible diagnoses are then ectopic pregnancy or miscarriage. For initial hCG rate between 2000 and 3510 UI/L, published data didn't allow any conclusion on the evolution of hCG rate to conclude between an ongoing pregnancy or not.

In case of women with abnormal uterine bleeding or pain with an intrauterine ongoing pregnancy, there is no published data about the period before a sonographic control. There is no evidence of the benefit of any therapeutic (progesterone, vitamins, hCG, bed rest) for threatened miscarriage (Aleman *et al.*, 2005; Rumbold *et al.*, 2011; Haas and Ramsey, 2013; Morley *et al.*, 2013).

Management of a First Trimester Miscarriage (Beucher *et al.*, 2014)

There are three options for the management of a first trimester miscarriage: expectant management, medical treatment or surgery.

 doi:10.1016/B978-0-12-801238-3.64956-5

For asymptomatic women with a first trimester miscarriage, expectant management led to higher risk of spontaneous expulsion but the delay for expulsion is often prolonged (2–6 weeks) with a risk of emergency consultation or surgery in 28%–80% of cases and a higher risk of blood transfusion (1.4% vs. 0%) (Graziosi *et al.*, 2004; Sotiriadis *et al.*, 2005; Neilson *et al.*, 2006; Trinder *et al.*, 2006; Nanda *et al.*, 2012).

When a medical treatment is decided, vaginal misoprostol (800 μg) should be preferred because of shorter delay for expulsion (Neilson *et al.*, 2006). A second administration 24 to 48 h later is required in up to 30% of cases (Lister *et al.*, 2005; Zhang *et al.*, 2005). Administration of mifepristone doesn't improve results (Gronlund *et al.*, 2002; Stockheim *et al.*, 2006; Kollitz *et al.*, 2011; Torre *et al.*, 2012). It leads to a success rate of more than 80%. When gestational bag is still present at the end of the medical treatment, a delay before surgical management should be respected (few days to 2 weeks). Medical management reduces the costs with less hospitalization and less surgery and anesthesic appointment (Graziosi et al., 2005b; Rausch *et al.*, 2012). Women satisfaction is equivalent (more than 80%) between medical management and surgery (Neilson *et al.*, 2006; Nice, 2012). Surgery consists of an aspiration followed by curettage; success rate are between 95% and 98% significantly higher than those after medical management (Graziosi et al., 2005a; Sotiriadis *et al.*, 2005).

Women Have to be Informed About the Two Methods and Their Results

For women with an incomplete first trimester miscarriage, an expectant management can be performed leading to success rates between 71% and 100% without a higher risk of complications (Luise *et al.*, 2002; Graziosi et al., 2005a; Sotiriadis *et al.*, 2005; Trinder *et al.*, 2006; Casikar *et al.*, 2010). However, the delay of expectant management cannot be specified. Medical treatment (misoprostol) doesn't improve these rates and should not be performed for incomplete miscarriage (Neilson *et al.*, 2013). Surgical management led to high success rate (around 98%) (Graziosi et al., 2005a; Neilson *et al.*, 2006; Trinder *et al.*, 2006). Curettage should be avoided and aspiration has to be preferred as it is significantly less painful, led to less bleeding and is shorter (Tuncalp *et al.*, 2010).

When retention is diagnosed later, hysteroscopic management is probably the method of choice leading to less synechiae, less incomplete treatment and a higher pregnancy rate but published data are scarce (Cohen *et al.*, 2001; Faivre *et al.*, 2009; Rein *et al.*, 2011).

After a previous miscarriage, synechiae are frequent in case of surgical management (between 16% and 23% of cases) (Hooker *et al.*, 2014). If there are any reasons at all for concern, an office hysteroscopy has to be performed.

Subsequent fertility is equivalent whatever the treatment received (expectant management, medical treatment or surgery) (Tam *et al.*, 2005; Smith *et al.*, 2009). There is however less miscarriage when next pregnancy occurs within the next 6 months after the miscarriage (El Behery *et al.*, 2013).

Finally, psychological aspect has to be taken into account, as risk of subsequent miscarriage is higher in women with stress and depression after previous miscarriage. This risk is lower with repeated medical consultation and sonographies at the beginning of subsequent pregnancy (Legendre *et al.*, 2014). A feeling of grief after a miscarriage as after the loss of a loved one is frequent. Depression is frequent (10%–50% of women in the first months but less than 1 year), such as anxiety (20%–40% of women until 6 months). Depression or anxiety doesn't seem different depending on the treatment received and systematic psychological support doesn't revel any benefit at 1 year from miscarriage. Some time ago, without any support, depression and anxiety scores are similar to general population (Legendre *et al.*, 2014).

Repeat Miscarriages (Gallot *et al.*, 2014)

Repeat miscarriage is defined as the repetition of no less than three consecutive miscarriages before 14 weeks of gestation. It concerns 1%–5% of couples looking for pregnancy (Berry *et al.*, 1995; Regan and Rai, 2000; Hogge *et al.*, 2003; Rai and Regan, 2006). Numerous risk factors have been identified such as maternal age over 36 years old (Stefanidou *et al.*, 2011), alteration of ovarian reserve (Trout and Seifer, 2000), uterine malformation (Homer *et al.*, 2000; Kowalik *et al.*, 2011; Jaslow and Kutteh, 2013), obesity with BMI higher than 30 (Lashen *et al.*, 2004), folic acid or B12 vitamin deficiency (Reznikoff-Etievant *et al.*, 2002; Sikora *et al.*, 2007; Puri *et al.*, 2013), hyperhomocysteinemia (Robertson and Greer, 2005; Jaslow and Kutteh, 2013; Puri *et al.*, 2013), maternal tobacco consumption (Kumar, 2011; Stefanidou *et al.*, 2011), coffee consumption more than one cup per day (Stefanidou *et al.*, 2011). In women with repeat miscarriage, an increased prevalence of chromosal parental abnormalities is noticed (Gardner and Sutherland, 1996).

Out of these risk factors, chronic endometritis is more frequent in women with repeat miscarriage without it being possible to conclude for such a cause effect relationship (Zolghadri *et al.*, 2011).

In case of repeat miscarriage, it is recommended to realize the following examinations: a morphological diagnosis of the uterus (for septate uterus particularly but also T-shaped uterus), plasma dosage of B9 and B12 vitamins and homocysteinemia, evaluation of ovarian reserve (follicular count and anti-Mullerian hormone), karyotype of both man and woman, search for an antiphospholipid syndrome (lupus anticoagulant screening, beta1GP1 and anticardiolipid antibody), dosage of TSH, search for TPO and TG antibody, blood glucose and blood prolactin.

Management of repeat miscarriage should begin with eviction of toxic (tobacco and coffee particularly). In case of any abnormality, an appropriate management will have to be performed: vitamin B9 or B12 supplementation in case of deficiency or of hyperhomocysteinemia (Quere *et al.*, 2001), aspirin and low molecular weight heparin for antiphospholipid syndrome (Rai *et al.*, 1997; Mak *et al.*, 2010), levothyroxine supplementation for hypothyroidism or thyroid antibody (Negro *et al.*, 2010), diabetes management in case of high sugar blood concentration (Wahabi *et al.*, 2010), bromocriptine in case of hyperprolactinemia (Hirahara *et al.*, 1998). Preimplantation diagnostic in case of anomalies of parental karyotype and oocyte donation in case of alteration of ovarian reserve will be discussed in multidisciplinary meeting (Budak *et al.*, 2007; Molina Gomes *et al.*, 2009; Hammoud *et al.*, 2010; Jungheim *et al.*, 2013).

The correction of a uterine abnormality has to be performed in case of repeat miscarriage (Homer *et al.*, 2000; Giacomucci *et al.*, 2011). A metroplasty has to be performed in septate uterus as it seems to enhance ongoing intrauterine pregnancies (Bendifallah *et al.*, 2013). For T-shaped uterus, published data are scarce but also suggest a positive effect of metroplasty (Fernandez *et al.*, 2011).

For women with repeat miscarriage with normal results, a folic supplementation 0.4 mg/day until 14 WG combined with progesterone until 14 WG (no recommendation can be done about dose and way of administration) and psychological support with repeated sonography (Haas and Ramsey, 2013).

Evaluation is not recommended after one miscarriage. However, published studies are controversial whether to perform examinations after two or three repeated miscarriages. It seems that risk of subsequent miscarriage is almost the same after two or three previous miscarriage (24%–29% vs. 31%–33%) (Jaslow *et al.*, 2010). More data need to be published to clarify whether we have to wait for three miscarriages or not.

Conclusion

Miscarriage is a very frequent pregnancy complication and should be managed following recommendations for diagnosis. It will avoid numerous sonographic controls before diagnosis. For management, surgery and medical treatment are equivalent for asymptomatic women but expectant management should be avoid whereas, all of these treatments can be performed in women with bleeding.

When there are three or more miscarriages, the diagnosis of repeat miscarriages can be done and required a restricted medical check to diagnose abnormalities that can be corrected to avoid a subsequent miscarriage. When the medical check is normal, folic acid and progesterone supplementation should be given until 14 weeks of gestation.

In all cases, women with a previous miscarriage need to be reassure and repeated early sonographies for the next pregnancy might be necessary all the more in case of repeat miscarriage.

Glossary

Adipokines Term that refers to inflammatory and immune mediators, including several hormones, that are secreted by adipose tissue. Adipsin was the first adipokine described back in 1987.

Bariatric surgery Surgical intervention which main purpose is obtaining a quick and marked weight loss. Roux-en-Y by-pass gastric and vertical gastrectomy ("gastric sleeve") are the most widely used techniques nowadays.

Decidualization Process characterized by significant changes that endometrium cells suffer in preparation for future pregnancy. Morphological and functional changes of the endometrial stromal cells, presence of decidual white blood cells, and also, vascular changes to maternal arteries will conduct the endometrium to become into a structure called the decidua.

Idiopathic hyperandrogenism Functional androgen excess disorder in which there is no evidence of ovarian dysfunction: ovulation is present and ovarian morphology is normal.

Male obesity-associated secondary hypogonadism Functional form of hypogonadism typical of obese men that results from decreased secretion of gonadotropins and testosterone and may resolve with weight loss.

Miscarriage Death of an embryo or fetus before the 20th week of gestation.

Obesity-associated gonadal dysfunction Subset of patients presenting with polycystic ovary syndrome in women or secondary hypogonadism in men, in whom obesity and visceral adipose tissue excess and dysfunction appear to play a major causative role, considering the frequent resolution of these gonadal disorders following weight loss.

Polycystic ovary syndrome Functional androgen excess disorder characterized by the association of clinical and/or biochemical hyperandrogenism with ovarian dysfunction in the form of chronic oligo-ovulation and/or polycystic ovarian morphology.

Stillbirth Death of the fetus from weeks 20th to 28th of pregnancy.

Introduction

Obesity, defined as a body mass index (BMI) over 30 kg m^{-2}, is a health concern with an increasing worldwide incidence and prevalence in children, adolescents and adults. The American Association of Clinical Endocrinologist and the American College of Endocrinology (AACE/ACE), estimate that approximately 500 million adults are obese all over the world, with an overall prevalence around 33% (Garvey *et al.*, 2016). Moreover, prevalence between children and adolescents is approximately 17%, with a trend to continue rising in future years (Ogden *et al.*, 2012). Obesity impacts negatively on healthcare because of the risk of developing metabolic complications such as insulin resistance, type 2 diabetes, hypertension, sleep apnea and cardiovascular disease.

Infertility is common in the general population and is usually associated with reduced quantity and quality of ejaculated semen in men, occurrence of pregnancy at older ages in women, and also with environmental conditions that include overweight and/or obesity (Calderón *et al.*, 2016). The links between obesity and reproductive impairment gained attention in the last decades. Increased waist circumference and/or increased waist-hip ratio in women have been reported to impact negatively fertility through combined effects on ovulation, oocyte development, implantation, pregnancy loss and endometrial development (Brewer and Balen, 2010). In addition, obesity will also impair male fertility though a deterioration of in sperm quantity and quality. **Table 1** summarizes the impact of obesity on male and female reproduction.

During puberty, the correct balance of sex between androgens and estrogens leads to a dimorphic sexual distribution of adipose tissue. As a result, premenopausal women at have greater adipose tissue than lean mass and a typical deposition of body fat in the subcutaneous and gluteal femoral areas; conversely, in men adipose tissue is stored in the visceral and abdominal compartments (Wells, 2007).

This article will focus on the impact of obesity on reproduction, the reproductive disorders associated with obesity in women and men and the main mechanisms and hormonal imbalances underlying them.

Effects of Obesity on Female Reproductive Function

For ages, undernutrition was the main responsible of subfertility in women, explaining why obese women represented fertility goddesses in many ancient civilizations. However, with the sudden change in environmental conditions occurred in the past century in most parts of the world, it has become apparent that, compared with normal weight women, obesity actually impairs

Table 1 Impact of obesity in male and female reproduction

Women	
Androgen-circulating concentrations	Increased free testosterone and adrenal androgens
	Low—normal gonadotropin concentrations
	Decreased SHBG plasmatic concentrations
Menstrual cycle	Oligomenorrhea and/or amenorrhea
	Anovulatory cycles
Effects on conception and implantation	Quality and maturation of the oocyte impaired
	Abnormal folliculogenesis
	Impaired endometrium decidualization and oocyte implantation. Placentation process is also disturbed
Effects on pregnancy	Increased rates of early pregnancy loss and miscarriages
	Metabolic complications: hypertension, pre-eclampsia, venous thromboembolism, gestational diabetes
	Macrosomic fetus
Metabolism	Increased prevalence of PCOS, hyperandrogenism, hyperinsulinemia, and metabolic syndrome
Men	
Androgen-circulating concentrations	Decreased circulating testosterone concentrations
	Increased estradiol concentrations
	Low—normal gonadotropin concentrations
	Decreased circulating SHBG concentrations
Sperm parameters	Subnormal quantity and quality of sperm
	Increased sperm DNA damage
	Increased sperm oxidative stress
Impact on testicular function	Increased testicular temperature
	Reduced intra-testicular testosterone
	Abnormal spermatogenesis

Abbreviations: PCOS: Polycystic ovary syndrome; *SHBG*: sex-hormone-binding globulin.

fertility in affected women. Women with weight excess and obesity associate decreased fecundity, increased incidence of anovulatory cycles, and prolongation of the time to pregnancy when fertility is desired (Brewer and Balen, 2010).

The mechanisms involved in the impairment of fertility in obese women include gonadal dysfunction characterized by androgen excess leading to ovulatory and menstrual disturbances (Escobar-Morreale and San Millán, 2007). However, subfertility is also characteristic regularly menstruating women presenting with overweight or obesity suggesting that other mechanism may collaborate with androgen excess in the impairment or reproductive function in these women (Gesink Law *et al.*, 2007). Accordingly, pregnancy loss and elevated miscarriage rates are also observed in obese women after spontaneous or assisted conception (Fedorcsák *et al.*, 2004). These findings may be associated with gestational insulin resistance and diabetes, pre-eclampsia, hypertension, venous thromboembolism, gestational diabetes and fetal macrosomia (Dutton *et al.*, 2018).

Influence of Obesity on Regulatory Hormones in Women

Sex Hormones

The influence of weight and fat mass on the balance of sex steroids has been studied extensively. Sex hormone-binding globulin (SHBG) binds both testosterone and estradiol with high affinity thereby determining the concentrations of free hormones available to target tissues (Pugeat *et al.*, 1996). The affinity of SHBG is higher for testosterone and dyhidrotestosterone (DHT) than for estradiol (Pasquali, 2006). Weight excess and obesity decrease the circulating concentrations of SHBG (Pasquali, 2006) because of the combined effects of portal hyperinsulinism and inflammatory mediators secreted by abdominal visceral adipose tissue and hepatic ectopic fat (Simo *et al.*, 2015). Hence, circulating SHBG concentrations are correlate inversely with body mass index and waist hip ratio in women (Pasquali, 2006). Decreasing levels of SHBG contribute to the increase in unbound testosterone concentrations in women, especially in those with abdominal visceral adipose deposition.

Adiposity also contributes to androgen excess in predisposed women by stimulating the secretion of androgens by the ovaries and the adrenals by the direct effect of proinflammatory cytokines secreted into the circulation and also through the indirect effects of insulin resistance (and the compensatory hyperinsulinism) on these glands (Escobar-Morreale and San Millán, 2007). Moreover, androgen excess may favor further deposition of adipose tissue in the visceral abdominal fat depot, which in turns facilitates further androgen excess closing a vicious circle that is particularly severe in obese hyperandrogenic women (**Fig. 1**).

Sex Steroid Metabolism and Fat Tissue

Obese women, especially those with visceral abdominal adiposity, have increased secretion of androgens such as androstenedione and dehydroepiandrostenedione—that are not bound to SHBG—and also an increased metabolic clearance of these substances (Kirschner *et al.*, 1990). In addition, since most androgens concentrate within adipose tissue, obese women have larger amounts of

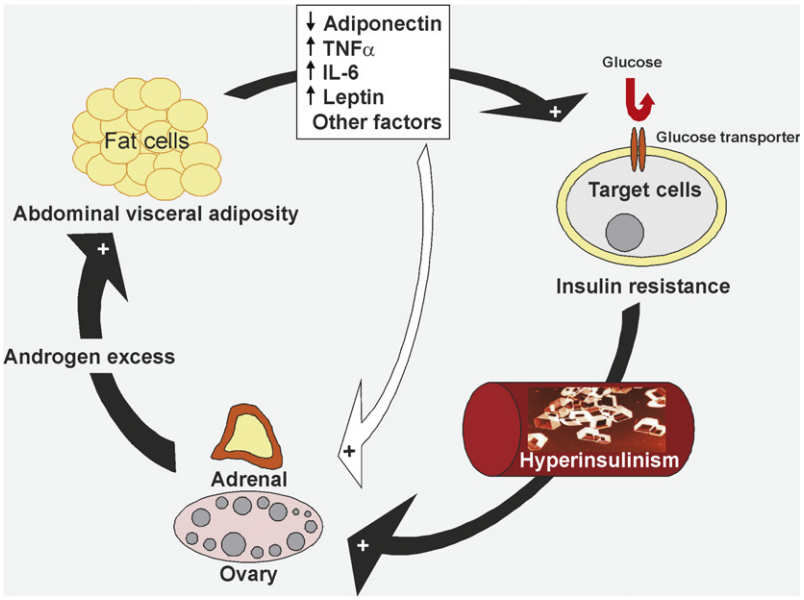

Fig. 1 The interplay between the polycystic ovary syndrome and abdominal adiposity may be the result of a vicious circle represented by the *black arrows*: androgen excess favors the abdominal deposition of body fat, and visceral fat facilitates androgen excess of ovarian and/or adrenal origin by the direct effects (*white arrow*) of several autocrine, paracrine and endocrine mediators, or indirectly by the induction of insulin resistance and hyperinsulinism. Reproduced with permission from Escobar-Morreale, H. F. and San Millán, J. L. (2007). Abdominal adiposity and the polycystic ovary syndrome. *Trends in Endocrinology and Metabolism* 18, 266–272, Copyright Elsevier, 2007.

sex-steroids stored in their fat compared with their lean counterparts. Moreover, adipose tissue has a direct influence on the metabolism of sex steroids, especially with regards to the conversion of androgens into estrogens mediated by aromatase. Hence, the larger the fat mass, the higher the production of sex-steroids will be (Pasquali, 2006).

Finally, proinflammatory cytokines synthesized by adipocytes favor androgen excess by a direct effect on the ovaries and the adrenal glands (Escobar-Morreale and San Millán, 2007). Adipose tissue is considered as an active endocrine and metabolic organ, playing its role by producing several proinflammatory and immune mediators, known as "adipokines." The dysfunctional secretion of this molecules correlates with the amount of visceral adipose tissue (Kershaw and Flier, 2004) and its excess may impact negatively upon reproductive function and the balance among sex steroids.

Taken together, all these mechanisms contribute to explain why androgen excess is very frequent in obese women. The polycystic ovary syndrome (PCOS) is the most frequent disorder of female androgen excess, showing a prevalence in the general population in the 5%–20% range depending on the population studied and the criteria used for its diagnosis (Azziz *et al.*, 2016). The prevalence of PCOS increases to 28% in overweight and obese women seeking medical advice for weight loss (Alvarez-Blasco *et al.*, 2006) and reaches 36% in women with severe obesity submitted to bariatric surgery (Escobar-Morreale *et al.*, 2017). Women with PCOS are at risk of developing metabolic abnormalities such as insulin resistance, hyperinsulinemia, gestational and type 2 diabetes, especially when obese (Wild *et al.*, 2010). Importantly, patients with PCOS have increased global and visceral adiposity regardless of obesity, yet obesity worsens both the reproductive and metabolic consequences of androgen excess (Escobar-Morreale *et al.*, 2017).

Insulin

Insulin is synthesized by pancreatic β-cells and their main role in adults is to regulate glucose homeostasis. Ovary, adrenal glands and pituitary express receptors for insulin, playing an important role by stimulating ovarian steroidogenesis in a direct way by acting on ovarian theca and granulosa cells, increasing the biosynthesis and androgen secretion, and in an indirect way by enhancing the sensitivity of pituitary cells to the actions of gonadotropin-releasing hormone that will lead to impair the quality of ovarian secretion (Poretsky *et al.*, 1999). In turn, androgen excess will promote visceral fat deposition, situation that will impact negatively upon insulin sensitivity and adipocyte dysfunction (Luque-Ramírez *et al.*, 2009). In fact, it has been well studied the association between overweight and obesity and resistance to insulin, relation that will derive into a compensatory insulin secretion and hyperinsulinemia. Moreover, hyperinsulinemia will also inhibit the synthesis of SHBG, and this will contribute to the dysregulation of sex steroids bioavailability, hyperandrogenemia, and, finally, impaired gonadal function and infertility.

Leptin and Kisspeptin

Leptin is a signaling proteic hormone that is secreted by adipocytes after food intake stimulus. As obese people have increased fat amounts, higher levels of leptin are expected in this population (Isidori *et al.*, 1999). Leptin is involved in several roles in body

homeostasis, including metabolic and reproductive functions. In relation to the first, leptin induces a reduction of appetite and an increase of energy expenditure (Brewer and Balen, 2010). Since increased leptin concentrations in obese humans are not associated with any of these effects, leptin resistance may occur in these subjects (Myers *et al.*, 2010).

Regarding reproductive function, leptin deficiency results in delayed puberty and hypogonadotropic hypogonadism in animal models and humans, conditions that may be reversed by leptin administration (Clarke *et al.*, 2015). Albeit the central effect of leptin on the HPG axis appears to be stimulatory, its peripheral effects on gonadal steroidogenesis are mostly inhibitory (Greisen *et al.*, 2000; Tena-Sempere *et al.*, 2001).

Moreover, even though leptin has been proposed to link nutrition with fertility, GnRH neurons lack receptors for leptin and kisspeptin has been recently proposed to participate in the link between adipose tissue and the reproductive axis (Clarke *et al.*, 2015). Kisspeptin is the neuropeptide product of the *KISS1* gene and plays a central role in the modulation of the hypothalamic—pituitary—gonadal axis by a direct stimulating effect on GnRH secretion, and therefore, on LH and FSH secretion (Meczekalski *et al.*, 2011; Avendano *et al.*, 2017; Roseweir and Millar, 2009). In fact, since kisspeptin neurons express both leptin and insulin receptors, kisspeptin might mediate some of the effects of these hormones on the HPG axis (Avendano *et al.*, 2017; George *et al.*, 2010; Smith *et al.*, 2006).

Adipokines and Inflammatory Mediators

Adipose tissue is considered nowadays as an endocrine organ because of the secretion of cytokines and adipokines from adipocytes and stromovascular cells (Kershaw and Flier, 2004). Adipose tissue dysfunction in obesity may include decreased adiponectin secretion and excessive production of tumor necrosis factor α, interleukin-6 and plasminogen activator inhibitor type-1 among other mediators which may influence are described in the literature as HPG function in the obese population (Kershaw and Flier, 2004). These mediators will favor insulin resistance, impaired folliculogenesis, gonadotropins dysregulation and disturbances in the metabolism of sex steroids. Other pro-inflammatory and immune mediators may also contribute to HPG dysfunction and cardiometabolic disturbances by indirect effects upon renin–angiotensin-system, cortisol hypersecretion, hypercoagulability, low-grade chronic inflammation, and by and increased sympathetic tone (Escobar-Morreale *et al.*, 2017). **Fig. 2** summarizes the effect of the principal adipokines upon metabolism and reproductive parameters.

Effects on the Oocyte

Quality and maturation of the oocyte in obese women after natural or assisted conception is compromised. Several studies performed in overweight and obese women who underwent in vitro fertilization (IVF) reported a diminished number, quality and maturation of oocytes retrieved from obese women (Shah *et al.*, 2011; Wittemer *et al.*, 2000; Dokras *et al.*, 2006). Furthermore, folliculogenesis is also disturbed in women with weight excess, a fact that might be related to an abnormal follicular environment characterized by excessive insulin, triglycerides, inflammatory mediators and oxidative stress (Broughton and Moley, 2017).

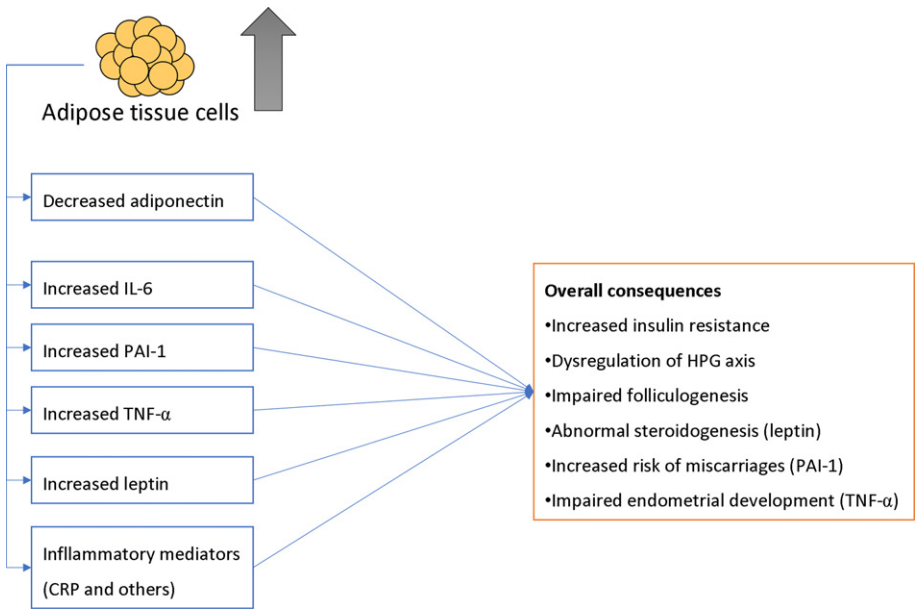

Fig. 2 Adipose tissue dysfunction, adipokine and inflammatory mediators, and reproductive consequences of obesity. Abbreviations: *CRP*, C-reactive protein; *HPG*, hypothalamic pituitary axis; *IL-6*, interleukin 6; *PAI-1*, plasminogen activator inhibitor type 1; *TNF-α*, tumor necrosis factor alpha.

Effects on Endometrium

Impaired endometrium decidualization—an essential step during the implantation process—may contribute to the increased risk of miscarriages before the 20th week of gestation observed in women with weight excess and obesity (Broughton and Moley, 2017). This may contribute to abnormalities in placentation, that will consequently lead to gynecological comorbidities along pregnancy, such as, placental dysfunction, pregnancy hypertension or pre-eclampsia (Brewer and Balen, 2010). In addition, insulin resistance and hyperinsulinemia may also impact on the endometrium, because of the association between of hyperinsulinemia and reduced levels of glycodelin and insulin growth factor binding protein 1. The decrease in the levels of these molecules is linked to higher rates of pregnancy loss in relation to impaired implantation (Carrington *et al.*, 2005).

Obesity and the Embryonic and Fetal Development

The same mechanisms impairing folliculogenesis and oocyte maturation may interfere with the normal embryonic development. Among them, lipotoxicity has been proposed as one of the most important mechanisms because higher levels of free fatty-acids, particularly α-linoleic acid, are associated with decreased pregnancy rates in women undergoing IVF (Broughton and Moley, 2017).

Obesity also interferes with fetal development. Fetal abnormalities are more frequent in obese women, including spina bifida and omphalocele in spite of folic acid supplementation and heart anomalies (Ramsay *et al.*, 2006). The impact of obesity upon endometrium, oocyte and embryo and fetus are summarized in **Fig. 3**.

Reversibility of Reproductive Dysfunction in Obese Women

For the reasons described above, possibility exists that, by targeting weight excess, the gonadal and reproductive dysfunction associated with female obesity improve and even resolve after weight loss (Escobar-Morreale *et al.*, 2017).

Increasing exercise and reducing caloric intake are the mainstay of life-style recommendations focused on weight reduction, and should be offered to all obese women. Modest weight loss may result into improvement in the metabolic and reproductive comorbidities of obesity (Moran *et al.*, 2011) yet the evidence supporting the long-term efficacy of life-style modification for obesity is scarce (Tam and Yeung, 2017). Hence, for severely obese women in whom life-style modification strategies have failed, bariatric surgery is a valid and effective long-term approach, not only to warrant substantial weight loss but, more importantly, because of the potential for resolution of any comorbidity associated with obesity, including gonadal and reproductive dysfunction (Escobar-Morreale *et al.*, 2017). Of note, a recent meta-analysis reported resolution of hirsutism and of menstrual

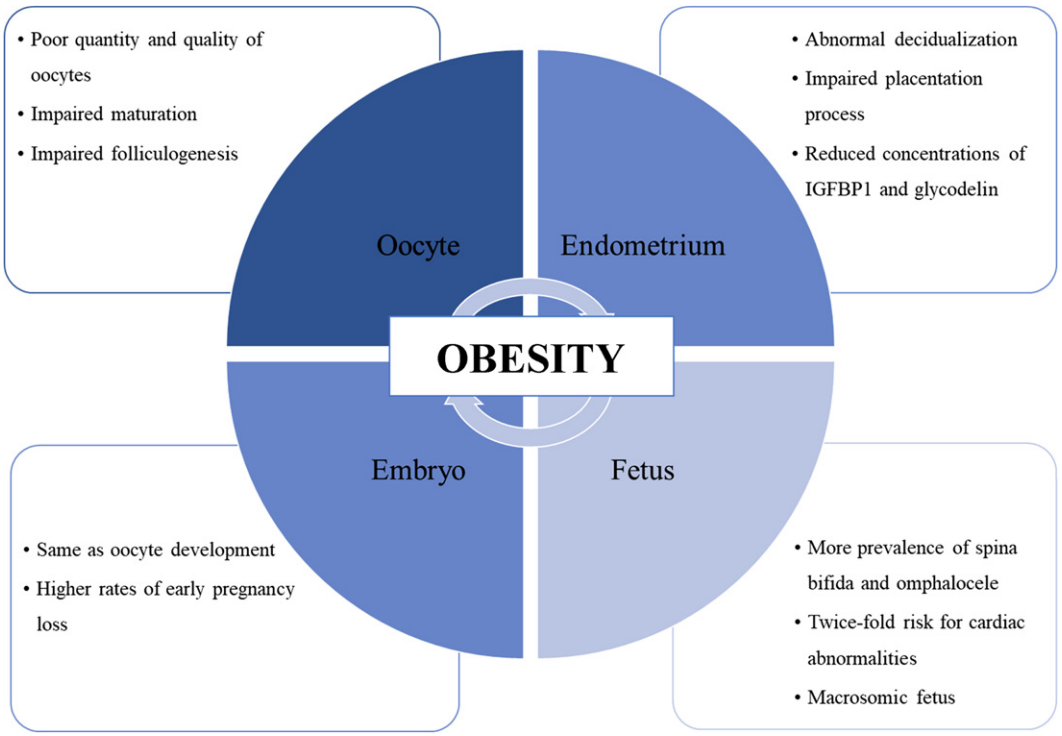

Fig. 3 Negative effects of obesity on fecundity and pregnancy. Abbreviations: *IGFBP1*, Insulin growth factor binding protein 1.

dysfunction after bariatric surgery in 53% and 96% of women showing those symptoms, leading to an overall 96% resolution rate of PCOS in these morbidly obese women. A shortened follicular phase and the improvement of sexual function after bariatric surgery have been also reported in response to obesity surgery in obese women (Legro *et al.*, 2012). Overall, the prevention of obesity-associated infertility and obstetrical complications such as gestational diabetes, macrosomia and pre-eclampsia in women submitted to bariatric surgery before pregnancy clearly compensate for the increased incidence of intrauterine growth restriction and the risk of mechanical complications of the previous abdominal surgery, provided that pregnancy is delayed for at least 1-year after surgery to avoid the initial phase or rapid weight loss, and appropriate nutritional support and obstetrical follow-up is offered throughout pregnancy (Guelinckx *et al.*, 2009).

Impact of Obesity on Male Reproduction

The sexual dimorphism in the consequences of obesity for reproduction also translate into the ancient imagery of fertility deities, which for the male sex was usually represented by lean men showing large or even monstrous penises. As opposed to women, adiposity does not associate any apparent survival advantage for fertility and, in fact, the negative consequences of obesity for gonadal function are even more frequent in men than in women (Escobar-Morreale *et al.*, 2017).

Strikingly, androgen deficiency is the main gonadal abnormality in obese men, as opposed to androgen excess in women. The main mechanism underlying androgen deficiency is the inhibition of gonadotropin secretion leading to male obesity-associated secondary hypogonadism (MOSH), a disorder that reaches a 64% prevalence in severely obese men submitted to bariatric surgery (Escobar-Morreale *et al.*, 2017). The hormonal profile of MOSH consists of low concentrations of total testosterone, free testosterone, FSH and LH resulting from dysfunctional GnRH secretion (Saboor Aftab *et al.*, 2013; Corona *et al.*, 2013). Moreover, in men reduced androgen concentrations facilitate body fat deposition in the abdominal and visceral depots and a decrease in lean mass. This might result into a vicious circle whereby abdominal adiposity leads to androgen deficiency by the mechanisms described above, and reduced androgen concentrations facilitate visceral fat accumulation and decreased lean body mass (**Fig. 4**) (Escobar-Morreale *et al.*, 2014).

One of the major causative mechanisms that underlie MOSH derives from the increase in aromatase activity in adipose tissue that occurs with obesity (Saboor Aftab *et al.*, 2013). An increased activity of this enzyme may convert androstenedione to estrone and testosterone to estradiol that will result into higher estrogen concentrations in obese men, with reduced circulating. SHBG concentrations amplifying the increase in circulating free estradiol concentrations. The latter may impact negatively on the HPG axis leading to alterations of LH pulsatility (Corona *et al.*, 2013; Palmer *et al.*, 2012). The causative role of increased aromatase activity on MOSH is supported by the

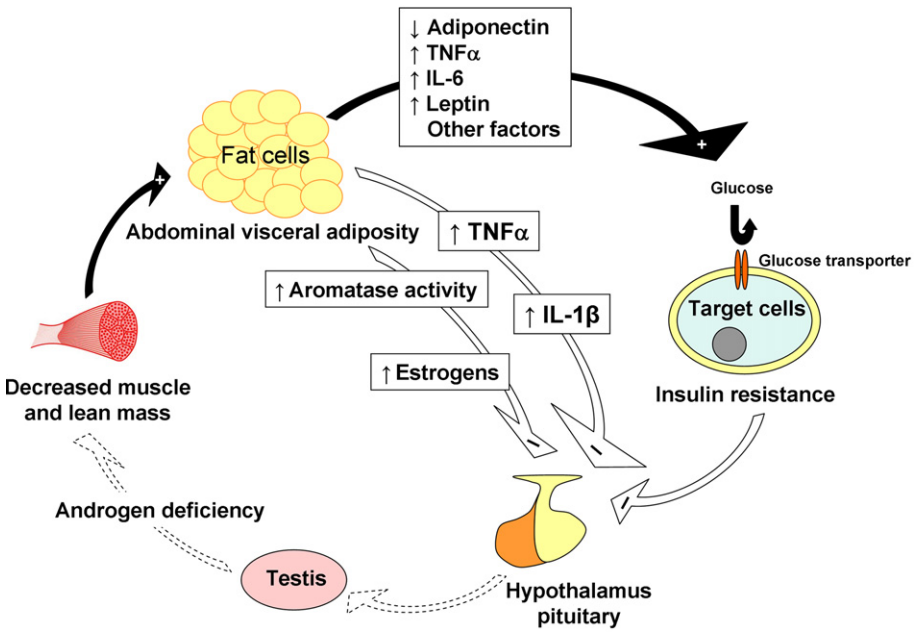

Fig. 4 The interplay between male obesity-associated hypogonadism and abdominal adiposity may be the result of a vicious circle represented by the arrows: androgen deficiency decreases lean and muscle mass thereby increasing the relative amount of visceral adipose tissue, and visceral fat facilitates androgen deficiency by inhibiting gonadotropin secretion at the hypothalamic–pituitary level through the combined action of increased aromatase activity and estrogen generation and increased secretion of inflammatory cytokines in visceral fat, and through the induction of insulin resistance. Reproduced with permission from Escobar-Morreale, H. F., Alvarez-Blasco, F., Botella-Carretero, J. I. and Luque-Ramirez, M. (2014). The striking similarities in the metabolic associations of female androgen excess and male androgen deficiency. *Human Reproduction* 29, 2083–2091; Copyright Oxford University Press, 2014.

favorable effects of aromatase inhibitors such as letrozole on the gonadal dysfunction of obese men (de Boer *et al.*, 2005). The reduction in total testosterone concentrations in parallel to the increase in estrogen concentrations will contribute to subfertility and gonadal dysfunction in severe obese male patients (Saboor Aftab *et al.*, 2013). Moreover, MOSH and the concomitant androgen deficiency will decrease lean mass and increase visceral fat mass as exemplified in **Fig. 4** (Escobar-Morreale *et al.*, 2014).

Hyperinsulinism derived from insulin resistance might also play a role in MOSH because circulating testosterone concentrations correlate negatively with BMI, insulin resistance and inflammatory markers in diabetic patients (Saboor Aftab *et al.*, 2013). On the one hand, hyperinsulinemia may also reduce the hepatic secretion of SHBG thereby contribution to the increase in free estradiol derived from aromatase activity. Moreover, hyperinsulinemia in parallel with hypogonadism will increase the activity of lipoprotein lipase, and as consequence, enhance the uptake and storage of triglycerides into the visceral fat cells (Saboor Aftab *et al.*, 2013). On the other hand, inflammatory mediators secreted by the excess in dysfunctional adipose tissue may not only contribute to insulin resistance and hyperinsulinemia (Fernandez-Real *et al.*, 2003) but also to decreased SHBG concentrations (Simo *et al.*, 2015) and to impairment of hormone signaling within hypothalamic neurons (Saboor Aftab *et al.*, 2013).

Other mechanisms that may contribute to the effects of obesity upon the male hypothalamic–pituitary–gonadal axis are mediated through the effect of leptin, kisspeptin and other adipokines. **Fig. 5** represents the complex mechanisms in relation to the effect of obesity upon male fertility and hormonal regulation.

Role of Obesity in Male Infertility

Despite sperm abnormalities not being necessary for the diagnosis of MOSH, semen alterations are common in severely obese men, who may present with decreased sperm volumes, concentrations and total counts possibly contributing to subfertility (Calderón *et al.*, 2016; Liu and Ding, 2017; Ramaraju *et al.*, 2017). These findings appear to be more frequent in the subset of patients with very high BMI. To these regards, low ejaculate volume is associated with weight excess and ejaculate volume correlates inversely with BMI and waist circumference (Calderón *et al.*, 2014).

However, the pathophysiology of sperm abnormalities in obese men is poorly understood. In line with this, MOSH may contribute directly because high intra-testicular testosterone concentrations are necessary for optimal spermatogenesis (Michalakis *et al.*, 2013; Eisenberg *et al.*, 2014). Oxidative stress and chronic inflammation characteristic of obese men may also contribute to impair sperm quality (Liu and Ding, 2017). Other possible mechanism involves the excess of scrotal adiposity and the consequent increase of testicular temperature (Palmer *et al.*, 2012). Because of the marked sensitivity of spermatogenesis to temperature changes, this mechanism may contribute to decrease sperm motility and to increase sperm oxidative stress and sperm DNA damage (Palmer *et al.*, 2012). Finally, fertility may also be impaired by mechanical factors that difficult effective coitus in severely obese patients, and by obesity-associated negative psychosocial factors that may impair sexual function (Kolotkin *et al.*, 2012; Han *et al.*, 2011). **Table 2** describes the alterations of sperm parameters due to obesity.

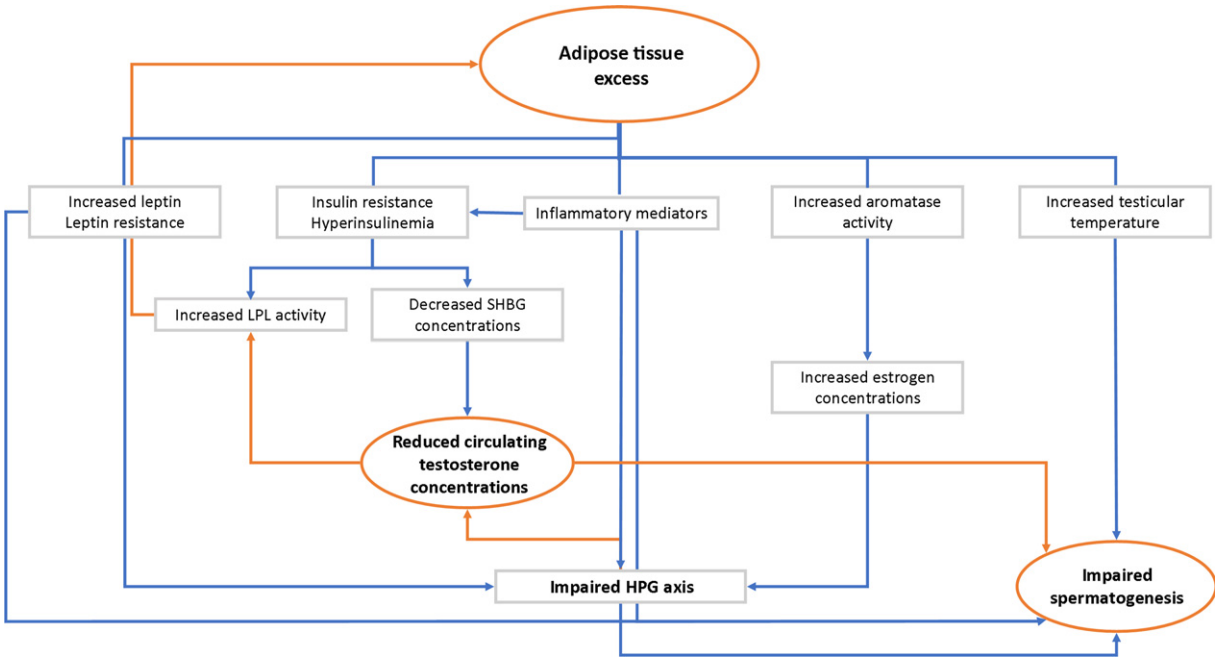

Fig. 5 The complex link between obesity and reproductive function in obese men. A direct negative effect upon HPG axis leads to androgen deficiency, which collaborates with other mechanisms in the impairment of spermatogenesis. Abbreviations: *HPG*, hypothalamic–pituitary–gonadal axis; *LPL*: lipoprotein lipase.

Table 2 Sperm abnormalities in severely obese men

Semen parameters	*Observed effect*
Volume	Reduced ejaculate quantity
Sperm count	Reduced
Concentration	Reduced
Progressive motility	Reduced
Total motility	Reduced
Average curve and path velocity	Reduced
Morphological alterations	Thin heads, pyriform heads and mid-piece defects

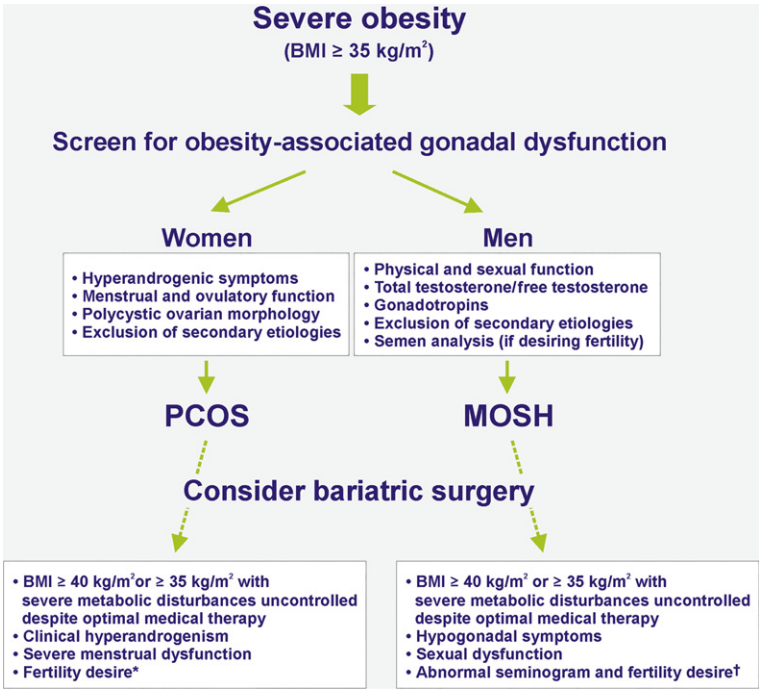

Fig. 6 Relevance of obesity-associated gonadal dysfunctions for the clinical management of severe obesity in men and women. *BMI*, Body mass index; *MOSH*, male obesity-associated secondary hypogonadism; *PCOS*, polycystic ovary syndrome. *Women desiring fertility must be advised to postpone pregnancy for at least 1 year after bariatric surgery and to maintain close nutritional and obstetric support throughout pregnancy. †The impact of surgically-induced weight loss on male fertility and sterility is unclear at present and men presenting with fertility desire and an abnormal semen analysis may need hormonal treatment or even assisted reproductive techniques.

Reversibility of Reproductive Dysfunction in Obese Men

As happens with obese women, MOSH may improve or even resolve with weight loss (Calderón *et al.*, 2016). Total and free testosterone concentrations rise after weight loss interventions (Corona *et al.*, 2013) and weight loss is one of the factors associated with spontaneous recovery of MOSH (Rastrelli *et al.*, 2015). Bariatric surgery is quite effective in improving all the factors associated with the development of MOSH and, accordingly, a recent meta-analysis reported that obesity surgery resolved MOSH in 87% of severely obese men presenting with this disorder (Escobar-Morreale *et al.*, 2017).

On the contrary, the impact of weight loss and particularly bariatric surgery on semen parameters is unclear. Large prospective studies reported benefits upon fertility and the quality of semen (Bardisi *et al.*, 2016), whereas other small case-control series have found the opposite effect (di Frega *et al.*, 2005; Lazaros *et al.*, 2012; Sermondade *et al.*, 2012). Screening for obesity-induced gonadal dysfunction and bariatric surgery indications are schematized in **Fig. 6**.

Conclusions

Obesity is associated with impairment of the reproductive dysfunction in women and men, showing a marked sexual dimorphism in the gonadal consequences of weight excess. In women, obesity associates androgen excess disorders—mostly PCOS—whereas in

men, androgen deficiency—namely, MOSH—is the dominant gonadal dysfunction associated with weight excess. The very large prevalence of obesity-associated gonadal dysfunction in obese women and men warrant screening strategies in these populations, especially in the subset of patients submitted to bariatric surgery. Weight loss therapies, such as life-style intervention or bariatric surgery, may improve and even resolve these disorders in obese men and women, normalizing circulating androgen concentrations and improving gonadal and reproductive function.

Developmental Epigenetics and the Contribution of Parental Diet to Offspring Outcomes

Oliver J Rando, University of Massachusetts Medical School, Worcester, MA, United States
Rebecca A Simmons, University of Pennsylvania, Philadelphia, PA, United States

Metabolic diseases contribute a significant burden to human health throughout the world. Although a large number of Mendelian disorders of metabolism have been identified, the vast majority of metabolic disease burden stems from complex diseases such as diabetes, which have both heritable genetic components as well as environmental contributions. However, the genetic variants identified by GWAS studies typically contribute a small fraction of the heritability of a given complex trait such as diabetes. A number of potential factors could explain this so-called "missing heritability," including many rare variants contributing to a given phenotype, and epistasis. In addition to these, another emerging theme is the potential contribution of epigenetics—the inheritance of information beyond DNA sequence—to the heritability of such diseases. Indeed, increasing evidence links parental nutritional status to metabolic traits in offspring, potentially providing an explanation for a subset of missing heritability in metabolic diseases.

The development of disease later in life has been linked to exposure to an adverse intrauterine environment, as observed in offspring of pregnancies complicated by intrauterine growth restriction (IUGR), obesity, or diabetes (Hales and Barker, 1992, 2001). The period from conception to birth is a time of rapid growth, cellular replication and differentiation, and functional maturation of organ systems. These processes are very sensitive to alterations in nutrient availability and an abnormal intrauterine metabolic milieu can have long-lasting effects on the offspring.

The metabolic or nutritional state of the organism directly influences epigenetic modifications, as essentially all known epigenetic modifications rely upon substrates derived from intermediary metabolism such as S-adenosyl methionine (SAM), acetyl CoA, α-ketoglutarate, and nicotinamide adenine dinucleotide (NAD^+) (Kaelin and McKnight, 2013). A role for nutritional regulation of DNA methylation in offspring is best exemplified by experiments performed in *agouti viable yellow* (A^{vy}) mice or *axin fused* ($Axin^{Fu}$) mice (reviewed in Martin *et al.*, 2008). A^{vy} mice carry an intracisternal A particle (IAP) retrotransposon upstream of the *Agouti* gene, and animals exhibit a range of coat colors which is linked to repression of *Agouti* transcription in some animals by encroaching cytosine methylation from the IAP element. When pregnant agouti-colored female A^{vy} mice are fed a diet supplemented with methyl donors, a larger percentage of offspring have a wild-type coat color compared to offspring of mothers fed standard chow. These phenotypic changes are associated with changes in DNA methylation at the IAP element (Cooney *et al.*, 2002; Dolinoy *et al.*, 2006; Waterland *et al.*, 2006), suggesting that early-life access to specific metabolites can stably change gene expression via epigenetic modifications, thus affecting the phenotype of the adult.

A number of animal studies in non-agouti models have shown that maternal nutritional status and fetal nutrient availability induce epigenetic modifications at numerous key loci across the genome. In uteroplacental insufficiency models, fetal access to glucose, amino acids, and fatty acids is reduced, and diabetes develops in adult animals at approximately 15–26 weeks of age with underlying β-cell secretory defects and insulin resistance (Simmons *et al.*, 2001; Stoffers *et al.*, 2003). Genome-wide DNA hypomethylation is observed in postnatal IUGR liver, along with an increase in total H3 acetylation (MacLennan *et al.*, 2004). Acetylation of multiple lysines on the histone H3 N-terminal tails are increased at the promoters of *Ppargc1* and *Cpt1* in neonatal IUGR liver (Fu *et al.*, 2004), and this hyperacetylation persists in male offspring at least until postnatal day 21. Whether hyperacetylation at these sites influences transcription of *Ppargc1* or *Cpt1*, and how these findings relate to a phenotype in the offspring, remains to be determined.

Studies in the IUGR rat also demonstrate that fetal growth restriction induces epigenetic modifications of key genes regulating β-cell development such as *Pdx1* (Park *et al.*, 2008). Repression of *Pdx1* occurs in two waves, as early repression of this gene involves recruitment of the mSin3A histone deacetylase complex, followed later by H3K9 dimethylation and eventual recruitment of DNMT3A and cytosine methylation. Prior to cytosine methylation—at the neonatal stage—this epigenetic process is reversible and may define an important developmental window for therapeutic approaches. Indeed, early reversal of *Pdx1* deacetylation can prevent the onset of diabetes (Pinney *et al.*, 2011), demonstrating that IUGR-induced epigenetic modifications are responsible for the development of diabetes in this animal model.

The pancreatic transcription factor Hnf4α is also epigenetically regulated by maternal diet and aging in rat islets from offspring of protein restricted dams (Sandovici *et al.*, 2011). Increased DNA methylation and repressive histone modifications at the P2 promoter of Hnf4α were associated with a significant reduction in expression, while reversal of DNA methylation and histone modifications could re-activate transcription of *Hnf4α* via the P2 promoter. Another relatively well-characterized epigenetic target of caloric restriction during pregnancy and lactation is the *Glut4* promoter in skeletal muscle, where altered levels of activating and repressing TFs in response to caloric restriction lead to repression via diminished histone acetylation and increased H3K9 methylation, although in this case there is no apparent increase in cytosine methylation (Raychaudhuri *et al.*, 2008). These events effectively create a metabolic knockdown of *glut4*, an important regulator of peripheral glucose transport and insulin resistance and contributing to the adult T2D phenotype.

There are numerous studies in humans examining the relationship between fetal nutrient availability and epigenetic modifications in the offspring (Rakyan *et al.*, 2011). Many of these are confounded by small sample size, cellular heterogeneity of

tissues examined, and lack of validation. Moreover, most DNA methylation assays are performed in total peripheral blood monocytes, where the unique methylation profiles of the various cellular lineages complicate interpretation of the data. Despite these issues, multiple studies in diverse populations repeatedly show changes in DNA methylation associated with low birth weight and or altered nutrient availability. Thus, it is likely that an adverse in-utero milieu does indeed induce epigenetic modifications in the offspring, but whether these modifications have biological relevance remains to be determined.

Obesity is a growing threat worldwide, and the prevalence has risen dramatically over the last two decades with many studies indicating that early life exposures are important in promoting adult obesity. It is becoming increasingly evident that the prenatal stage represents a window of susceptibility for early life exposures (Bayol *et al.*, 2005; Chang *et al.*, 2008; Guo and Jen, 1995; Jungheim and Moley, 2010; Simmons, 2005; Sullivan *et al.*, 2011), as offspring of obese humans and animals exhibit increased fat mass very early in life. In fact, several studies suggest that obesity has adverse effects on the oocyte and embryo (Jungheim and Moley, 2010; Jungheim *et al.*, 2010; Marquard *et al.*, 2011; Sen and Simmons, 2010), suggesting the possibility that exposure to an adverse metabolic milieu even prior to pregnancy could account for some of the metabolic outcomes observed in offspring. Using reciprocal embryo transfer studies, we showed that a pre-gestational exposure to maternal obesity impaired fetal and placental growth despite the conceptus being exposed to a normal gestational milieu after transfer, with changes in placental gene expression being observed for offspring generated from high fat oocyte donors (Sasson *et al.*, 2015), as well as the brain reward system (Grissom *et al.*, 2014), suggesting that obesity prior to pregnancy may program food preferences and or food intake. These results have profound implications as it is possible that the effects of maternal obesity may be transmitted to subsequent generations.

While the impact of maternal environment on their children has long been clear, the father's contribution to offspring is less understood. Several studies have linked paternal environmental conditions—largely stress and dietary paradigms—to offspring phenotypes. Interestingly, in humans paternal body mass appears to be a better predictor of childhood metabolic traits than is maternal BMI (Figueroa-Colon *et al.*, 2000).

The timing of exposure is a key factor to take into account when considering paternal effect paradigms, as primordial germ cell (PGC) development occurs during the last week of gestation in male mice. A number of major epigenomic transactions, such as erasure of previous imprints and establishment of male-specific cytosine methylation patterns, occur during this period (Feng *et al.*, 2010), meaning that dietary paradigms starting after birth (generally after weaning) are less likely to influence the epigenome. That said, much remains to be learned about the plasticity of the epigenome and the ability of spermatogonial stem cells to respond to environmental alterations.

Many different metabolic phenotypes have been measured in offspring and reported to change in response to paternal diet. The most common metabolic phenotypes measured are related to glucose control, and include fasting glucose, glucose clearance, insulin release in response to glucose, and glucose clearance in response to insulin (Jimenez-Chillaron *et al.*, 2009; Ng *et al.*, 2010; Watkins and Sinclair, 2014; Carone *et al.*, 2010). Beyond glucose control phenotypes, cholesterol and lipid metabolism, and other cardiovascular phenotypes such as blood pressure, are reportedly altered in response to paternal dietary conditions.

Sperm cytosine methylation patterns have been reported to change at a number of loci in both an in utero undernutrition paradigm (Radford *et al.*, 2014), and in response to paternal prediabetes (Wei *et al.*, 2014). Methylation differences were generally modest changes of ~20% between sperm samples. However, even if the methylation status of a cytosine in question were *completely* responsible for some phenotype in offspring, at best this 20% methylation change would alter the fraction of a rodent's litter expressing the phenotype from 1 out of 5 to 2 out of 5. Thus, a 20% change in methylation at a cytosine is unlikely to result in penetrant changes in offspring.

Several paternal effect studies in mammals have documented changes in small RNA profiles in the sperm of treated versus control males (Rodgers *et al.*, 2013; Gapp *et al.*, 2014). However, mammalian sperm carry extremely low levels of RNA, and considering the volume of a sperm relative to the oocyte suggests that sperm are unlikely to carry enough RNAs to significantly alter the concentrations of a given RNA species in the oocyte, unless the RNA in question is absent or nearly so from the oocyte. Thus, although small RNAs represent a very strong candidate for the molecular basis of dietary information in sperm based on their roles in other model organisms, many mechanistic questions remain to be resolved to consider sperm delivery of small RNAs to be a credible influence over offspring metabolism.

How then might sperm alter maternal resource provisioning? Intriguingly, numerous studies have found effects of brief embryo culture on metabolic phenotypes in offspring (Rinaudo and Wang, 2012). One of the earliest cell fate decisions in mammalian embryos is cell fate allocation between the inner cell mass (ICM) and the trophectoderm (TE) of the blastocyst, which give rise to the embryo and to the extraembryonic tissues, respectively. It is thus theoretically possible that molecular changes in sperm induced by paternal diet somehow influence cell fate allocation between ICM and TE—by altering cell cycle dynamics for the first few cleavage divisions, for instance—with resulting effects on placental development then resulting in metabolic changes in offspring as detailed above.

In summary, the combined epidemiological, clinical, and animal studies clearly demonstrate that the intrauterine environment influences both growth and development of the fetus and the subsequent development of adult diseases. There are specific critical windows during development, often coincident with periods of rapid cell division, during which a stimulus or insult may have long-lasting consequences on tissue or organ function postnatally.

Anti-Müllerian Hormone (AMH) in Adults

Agathe Dumont, Geoffroy Robin, Sophie Catteau-Jonard, and Didier Dewailly, Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Introduction

Anti-Müllerian hormone (AMH) is the latest marker for the assessment of the ovarian reserve (OR) in women. Although the physiology and clinical utility of AMH are not completely established, this hormone appears to best reflect the OR. Despite the lack of an international standard for serum AMH assay and some technical issues in the past, serum AMH assay now tends to become an essential tool for the evaluation of the OR and for the treatment of infertility.

Physiology of AMH

AMH is a dimeric glycoprotein and a member of the transforming growth factor β family of growth and differentiation factors (Cate *et al.*, 1986). AMH has been predominantly known for its role in male sexual differentiation (Jost, 1947). From castration experiments in the fetal rabbit, Jost demonstrated that a testicular factor distinct from testosterone was responsible for the regression of the Müllerian ducts (Jost, 1947). In later years, it was demonstrated that this factor was produced by Sertoli cells in the testis (Josso *et al.*, 1993).

AMH was only isolated and purified in 1984. Genes for AMH and its receptor were sequenced and cloned in 1986 and 1994, respectively (Rajpert-De Meyts *et al.*, 1999). In women, AMH expression is restricted to one cell type: the granulosa cells of the ovary. It starts around the 25th week of gestation continuing until menopause (Rajpert-De Meyts *et al.*, 1999; Kuiri-Hanninen *et al.*, 2011). AMH is expressed at all steps of folliculogenesis. It is initiated as soon as primordial follicles are recruited to grow into small preantral follicles and its highest expression is observed in preantral and small antral follicles. AMH expression then decreases with the selection of follicles for dominance and is no longer expressed during the FSH-dependent stages of follicular growth (except in the cumulus cells of pre-ovulatory follicles) or in atretic follicles (Salmon *et al.*, 2004; Durlinger *et al.*, 2002a; **Fig. 1**; Dewailly *et al.*, 2014a; van Houten *et al.*, 2010).

The functional role of AMH in early follicular growth has been characterized by the study of "knocked out" models for the AMH gene (AMHKO) (Durlinger *et al.*, 1999, 2001, 2002a,b). When there is no AMH, primordial follicles are recruited faster, resulting in more growing follicles and thus in exhaustion of primary follicle pool at younger age than wild-type animals. AMH therefore has an inhibitory effect on early follicular recruitment by preventing the entry of primordial follicles into the growing pool and thus premature exhaustion of follicles/oocytes (Iliodromiti *et al.*, 2013). AMH also has an inhibitory effect on cyclic follicular recruitment in vivo by reducing the follicle sensitivity to FSH (Durlinger *et al.*, 2001). In vitro AMH inhibits FSH induced preantral follicle growth (Salmon *et al.*, 2004; Durlinger *et al.*, 1999, 2001, 2002a).

AMH also reduces the number of LH receptors in granulosa cells, also an FSH induced process (Teixeira *et al.*, 2001). Thus, it is clearly established that AMH is involved in the regulation of follicle growth initiation and in the threshold for follicle sensitivity to FSH.

AMH Assay

In clinical application, AMH presents many opportunities but unfortunately there are difficulties due to several biological features of this molecule (Pigny, 2014). First, there is a molecular heterogeneity of the circulating AMH level with a noncleaved biologically inactive form and a cleaved biologically active form (Pankhurst and McLennan, 2013; Nachtigal and Ingraham, 1996). Also, there is variable sensitivity of the immunoassays to interference by complement C1q and C3 (Han *et al.*, 2014). Then, the stability of AMH samples during the storage is not well known (Rustamov *et al.*, 2012). Moreover, AMH concentration varies according to the situation: in adults they are low (from 10.7 to 98 pmol/L) whereas in male newborns they are much higher (749–1930 pmol/L) (Pigny, 2014). Measurement thus involves different assays with different sensitivities. The last but not the least technical problem is the interlaboratory variability, mainly for low values of serum AMH. The difficulty lies in the fact that there are currently different ELISA immunoassays used worldwide; mainly the Gen II (Beckman Coulter) and the AL-105-i (Anshlabs), which use different monoclonal antibody and different standards (Pellatt *et al.*, 2011). The lack of agreement between these assays explains the absence of consensual reference values and decision thresholds between teams in the literature (Iliodromiti *et al.*, 2013). But progresses were made and the main two assays would now be superimposable (Pigny *et al.*, 2016). Likewise, automation on immuno-analyzers (Access Dxi of Beckman Coulter and Elecsys of Roche Diagnostics) yield nearly identical values (van Helden and Weiskirchen, 2015; Nelson *et al.*, 2015; Anderson *et al.*, 2015). The development of an ultrasensitive assay ("pico AMH" kit,

 doi:10.1016/B978-0-12-801238-3.64948-6

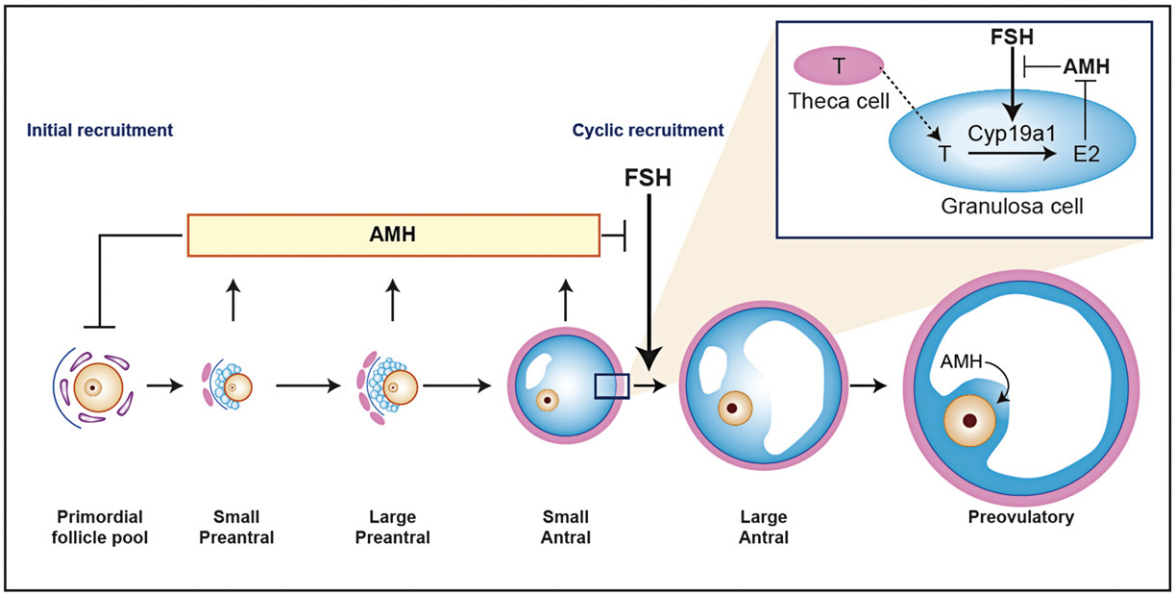

Fig. 1 Schematic model of AMH actions in the ovary. AMH, produced by the granulosa cells of small growing follicles, inhibits initial follicle recruitment and FSH-dependent growth and selection of preantral and small antral follicles. In addition, AMH remains highly expressed in cumulus cells of mature follicles. The inset shows in more detail the inhibitory effect of AMH on FSH-induced CYP19a1 expression leading to reduced estradiol (E2) levels, and the inhibitory effect of E2 itself on AMH expression. Reproduced from Dewailly, D., Andersen, C. Y., Balen, A., Broekmans, F., Dilaver, N., Fanchin, R., Griesinger, G., Kelsey, T. W., La Marca, A., Lambalk, C., Mason, H., Nelson, S. M., Visser, J. A., Wallace, W. H. and Anderson, R. A. (2014). The physiology and clinical utility of anti-Mullerian hormone in women. *Human Reproduction Update* 20, 370–385.

Anshlabs) is also a progress. Hopefully, an international standard for serum AMH assay will soon be established in order to maximize its clinical utility.

Variability of Serum AMH

Serum AMH assay has many benefits over the other markers of OR (Iliodromiti *et al.*, 2013). First, its plasmatic level is quite stable from one cycle to another and throughout the same cycle since the dominant follicle and corpus luteum do not secrete AMH (Fanchin *et al.*, 2005; van Disseldorp *et al.*, 2010). Conversely, the antral follicle count (AFC) and the FSH E2 pair have to be measured on the first 5 days of the cycle (Hehenkamp *et al.*, 2006; La Marca *et al.*, 2006; Tsepelidis *et al.*, 2007). Also, a recent study has shown that ethnicity does not influence serum AMH level, contrary to previous studies (Bhide *et al.*, 2015). Besides its minor variability, serum AMH is also useful when the AFC cannot be done such as in obese, virgin, or poorly echogenic patients (Dewailly *et al.*, 2014a). Moreover, serum AMH level is rather independent from the hypothalamic pituitary axis and as such is not modified in pathologies such as hyperprolactinemia, functional hypothalamic amenorrhea, or in incomplete and recent hypogonadotropic hypogonadism, providing serum FSH level remains normal or subnormal (Tran *et al.*, 2011). The question thus actually arises about the replacement of the conventional markers of OR by the AMH assay (La Marca *et al.*, 2009).

However, serum AMH can be influenced by many factors and some controversies persist. Obesity is often associated with a significantly lower level of serum AMH, but not in all studies (Freeman *et al.*, 2007; Steiner *et al.*, 2010; Lefebvre *et al.*, 2017). There is also a controversy regarding the influence of hormonal contraception: to some authors, combined estrogen progestin does not change AMH serum levels whereas others have recently reported a decrease of 29%–50% that could be explained by the suppression of gonadotropin secretion (Bentzen *et al.*, 2012; Somunkiran *et al.*, 2007; La Marca *et al.*, 2004; Dolleman *et al.*, 2013; Plouvier *et al.*, 2016). Similarly a decrease of serum AMH has been shown 7 days after injection of depot leuprolide 3.75 mg, a GnRH agonist (HI *et al.*, 2013).

AMH as Indicator of Ovarian Follicular Status

Ovarian Reserve

The OR refers to the number of primordial follicles defined at birth (around 1 million). This follicular capital decreases gradually throughout reproductive life, with the continuous initiation of growth of some follicles, and then mostly their apoptosis. There are

about 400,000 follicles in adolescents' ovaries (leading roughly to 400 ovulations), whereas only a thousand remains at the time of menopause.

Serum AMH concentration is strongly correlated with the number of growing follicles since it represents AMH secretion from all developing follicles (Laven *et al.*, 2004; Pigny *et al.*, 2003). Considering that the rate of initiation of follicle growth is deeply related to the initial follicular pool, we can assume that serum AMH is an indirect reflection of OR. There is actually a very good correlation between serum AMH levels and ultrasonographic measure of the AFC (van Rooij *et al.*, 2002; Fanchin *et al.*, 2003). This is explained by the fact that circulating AMH is mostly produced by granulosa cells of follicles from 2 to 9 mm in diameter (60%), and those small follicles are precisely the ones counted on the ultrasound when the AFC is done (Jeppesen *et al.*, 2013). Measurement of serum AMH is even more sensitive and specific than the AFC as it also reflects pre-antral and small antral follicles (<2 mm), which are hardly seen in ultrasound. Serum AMH is therefore a deeper "probe" for the growing follicular pool than the AFC (Dewailly *et al.*, 2014a).

Most published studies that report AMH in normal girls and women include only a relatively small age range; thus a "data-driven" approach has been used (Kelsey *et al.*, 2012). This involved extracting data using a semi-automated procedure, and combined it with other unpublished data. The resulting combined dataset ($n = 3260$; age range -0.3 years to 54 years) (Kelsey *et al.*, 2011) forms a representative sample of AMH levels in the population of healthy female humans, and can therefore be used as a basis for a predictive model of serum AMH level with changing age and was used to generate and validate the model. Analysis of the model shows that the dynamics of circulating AMH levels throughout life can be split into several distinct phases (**Fig. 2**; Dewailly *et al.*, 2014a; Kelsey *et al.*, 2012; Wallace and Kelsey, 2010). A peak shortly after birth confirms that girls also undergo a "mini puberty" of the neonate, following which there is a sustained rise to about 9 years of age. There is an inflection with even a slight decline during the pubertal ages (9–15 years), followed by a second growth phase to a peak at an age of about 25 years. After this, there is a steady decline to undetectable levels at an average age of 50–51 years, corresponding to the menopause.

When nongrowing follicle (NGF) recruitment dynamics are considered and compared to AMH levels (**Fig. 2**) there is a strong and positive correlation ($r = 0.96$) between declining AMH and declining numbers of recruited NGFs after age 25 (the average age of peak AMH). This observation underpins the use of serum AMH level as an indirect indicator of human OR for ages after the

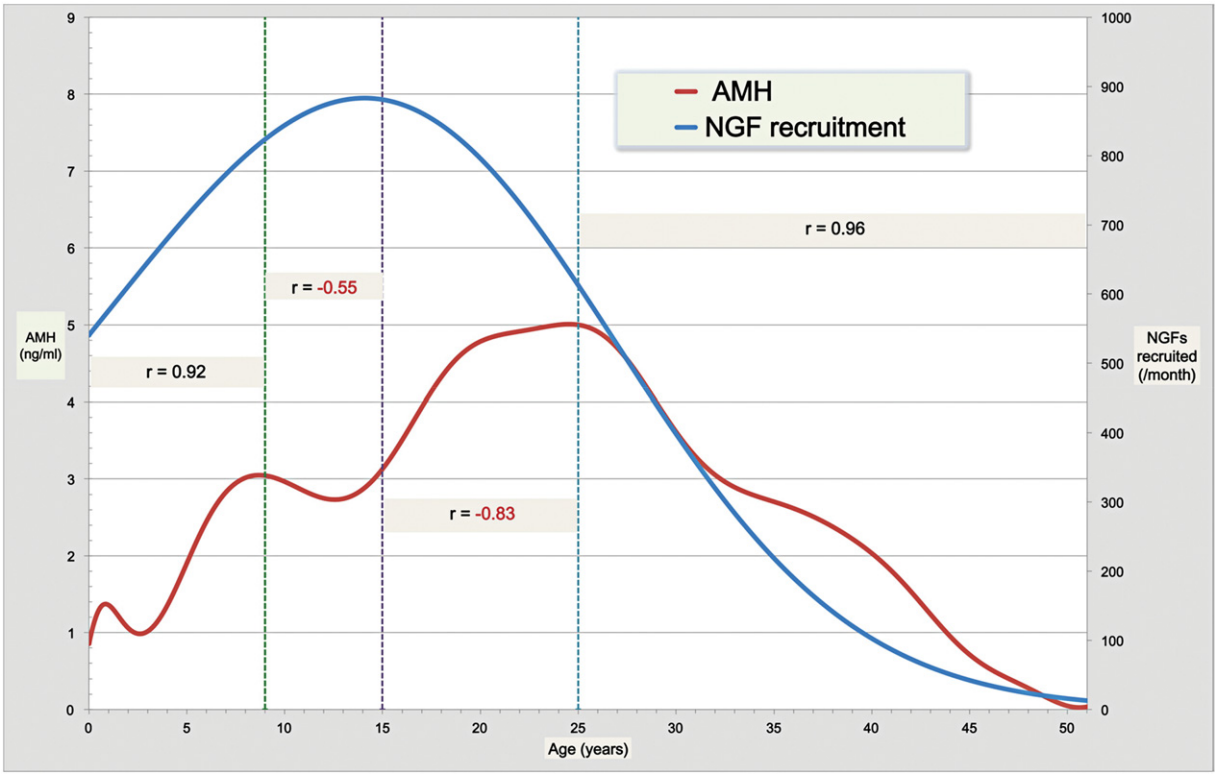

Fig. 2 AMH and follicular recruitment profile across the human reproductive lifespan. The *red line* is the log-unadjusted validated AMH model, peaking at 24.5 years. The *blue line* denotes the numbers of nongrowing follicles (NGF) recruited per month for the maturation population (Wallace and Kelsey, 2010), with peak numbers lost at age 14.2 years on average. Correlation coefficients (r) are given for AMH concentrations against follicular recruitment for each developmental phase; from birth to puberty (age 9 years), during puberty (9–15 years), postpuberty (15–25 years), and mature adults (0.25 years). Reproduced from Dewailly, D., Andersen, C. Y., Balen, A., Broekmans, F., Dilaver, N., Fanchin, R., Griesinger, G., Kelsey, T. W., La Marca, A., Lambalk, C., Mason, H., Nelson, S. M., Visser, J. A., Wallace, W. H. and Anderson, R. A. (2014). The physiology and clinical utility of anti-Mullerian hormone in women. *Human Reproduction Update* 20, 370–385.

mid-20s. Before the age of 25, the relationships between AMH and OR are more complex with overall a positive relationship between rising AMH and increasing follicle growth activation, and thus we would recommend caution in the interpretation of AMH concentrations in girls and young women as an indirect indicator of OR.

Predicting the Time of Menopause

The value of predicting age at menopause serves multiple targets. First of all, the ability to assess the future OR status, and thereby the reproductive lifespan of an individual women, will have implications for female infertility. Because of the fixed time interval that is believed to be present, prediction of age at menopause will predict the age of natural end of fertility. If such predictions could be made early in life, with sufficient accuracy, this could have a great influence on individual women making decisions regarding career and a wish to have children. Genetic factors have proven to play a major role in determining the variation in menopausal age, as demonstrated in several mother–daughter, twin and sib-pair studies. Next to genetic factors, several environmental and life-style factors like smoking, body mass index, use of alcohol, and parity have claimed to influence menopausal timing as well. Thus, menopausal age is considered a complex genetic trait.

To study the value of AMH in the assessment of the future OR status, long-term follow-up studies are required, where several factors assessed at initiation of the follow-up are linked to the final outcome age at menopause. As menopause has a fixed time relation to earlier events such as onset of cycle irregularity (average age 46 years) and the loss of natural fertility (average age 41 years), a woman's reproductive lifespan can be predicted from forecasting age at menopause. To date, a total of four datasets are available addressing this issue and show that women with low age-specific AMH will have menopause earlier and vice versa (Tehrani *et al.*, 2009; Broer *et al.*, 2011a; Tehrani *et al.*, 2013; Freeman *et al.*, 2007). All these datasets however have very wide confidence intervals in the predictive value of a single AMH measurement. The role for AMH as a predictor of the age of menopause is therefore not yet assessed.

Assessment of Ovarian Damage

The relationship between serum AMH and the number of small growing and indeed primordial follicles has made it a prime potential tool for the investigation of gonadotoxicity of cancer therapy and of loss of the OR from ovarian surgery. AMH offers the possibility of a more accurate assessment, revealing partial loss of the OR, as well as ovarian failure. AMH was decreased in a study of ovarian function in young adults following treatment for childhood Hodgkin lymphoma with a clear dose–response relationship demonstrated between the number of chemotherapy cycles and the serum AMH level (van Beek *et al.*, 2007). FSH also rose with increasing treatment, but AMH appeared to have greater sensitivity to detect ovarian damage at lower doses of chemotherapy. Radiotherapy is also widely recognized to cause ovarian damage even at low doses and women treated with radiotherapy that includes the pelvis (including abdominal pelvic therapy in children or total body irradiation) generally have very low or undetectable AMH concentrations (Gracia *et al.*, 2012; Lie Fong *et al.*, 2009). The predictive value of AMH for postchemotherapy ovarian function has subsequently been confirmed (Anderson *et al.*, 2013) allowing the development of prediction tools combining age and AMH. It therefore appears that in addition to reflecting postchemotherapy (or radiotherapy) damage, AMH is also able to predict on-going ovarian activity after such treatment, and the existing data suggest it is likely to be more robust than either FSH or inhibin B in this regard. Consistent with this, a study in younger women has demonstrated that pre-treatment AMH predicts postchemotherapy recovery, with a more rapid recovery in women with higher pretreatment AMH (Dillon *et al.*, 2013).

The impact of ovarian surgery on the OR as measured by AMH has also been investigated, and two systematic reviews of the impact of ovarian surgery for endometriosis have been published (Raffi *et al.*, 2012; Somigliana *et al.*, 2012). Both analyses highlight the heterogeneity of study design and the difficulty in pooling data. However both conclude that ovarian endometrioma surgery is associated with a decline in serum AMH, indicating the removal of a significant part of the OR. A subsequent large retrospective analysis has confirmed the impact of endometrioma surgery on the OR as detected by serum AMH (Streuli *et al.*, 2012), and these findings should be taken in to account in the planning and decision-making process relating to ovarian surgery in women desirous of future pregnancy.

Substantial prospective studies are required to develop a clearer analysis of the predictive value of AMH in all those different circumstances and it may be of value in information provision for example regarding the need for fertility preservation strategies. However, low serum AMH level does not predict the chance of spontaneous fertility. A recent analysis showed a high prevalence of successful pregnancy in childhood lymphoma survivors despite low AMH concentrations (Hamre *et al.*, 2012). Another study on oocyte donor also showed that low serum AMH does not predict the chance of spontaneous pregnancy (Catteau-Jonard *et al.*, 2017).

Polycystic Ovary Syndrome and AMH

Polycystic ovary syndrome (PCOS) is the most common cause of chronic anovulation and hyperandrogenism in young women and affects 5%–10% of the female population (Franks, 1995; Norman *et al.*, 2007). PCOS is a diagnosis of exclusion and is defined by the Rotterdam classification (Rotterdam ESHRE/ASRM sponsored PCOS Consensus Workshop Group, 2003) requiring at least two out of the three following characteristics: (i) cycle disorder, (ii) clinical or biological hyperandrogenism, (iii) antral follicular excess on ultrasound with $\geq$12 follicles from 2 to 9 mm per ovary and/or ovarian volume $\geq$10 mL. PCOS is almost

certainly a genetic condition but the precise causes of hyperandrogenism and anovulation, which are not always associated, are still under investigations (Cui *et al.*, 2015; Kosova and Urbanek, 2013).

PCOS is characterized by an increased number of follicles at all growing stages (Hughesdon, 1982; Webber *et al.*, 2003; Maciel *et al.*, 2004). This increase is particularly seen in the pre-antral and small antral follicles, those which primarily produce AMH (Weenen *et al.*, 2004; Bhide *et al.*, 2014). Thus elevated serum AMH level, as a reflection of the stock of pre-antral and small antral follicles, is two- to fourfold higher in women with PCOS than in healthy women (Pellatt *et al.*, 2007; Azziz *et al.*, 2009). This increase in serum AMH was first thought to be only due to the higher number of pre-antral and small antral follicles. However, production of AMH by granulosa cells was found in vitro to be 75-fold higher in anovulatory PCOS and 20-fold higher in normo-ovulatory PCOS than in normal ovaries (Pellatt *et al.*, 2007). This suggests that increased serum AMH levels in PCOS would also reflect an intrinsic dysregulation of the granulosa cells, in which AMH, itself, could be involved since an over expression of the AMH receptor type II (AMHRII) has also been described (Catteau-Jonard *et al.*, 2008; Alebic *et al.*, 2015).

The cause of such high production of AMH in antral follicles from PCO is currently unknown, but there is evidence to support a role played by androgens. Indeed, a positive correlation between serum androgen and AMH levels has been reported and the overproduction of androgens could be an intrinsic defect of thecal cells in PCOS (Laven *et al.*, 2004; Pigny *et al.*, 2003; Gilling-Smith *et al.*, 1994; Carlsen *et al.*, 2009; Eldar-Geva *et al.*, 2005).

Studies demonstrated contradictory results concerning AMH regulation by gonadotropins. For some authors, gonadotropins (especially FSH) inhibit serum AMH production in vivo in normal ovaries (Panidis *et al.*, 2011). Pellatt *et al.* (2007) demonstrated a reduced AMH production in granulosa cells from women with PCOS stimulated by FSH, but no such effect was found in "normal" women. On the contrary, others demonstrated a stimulating effect of FSH on AMH expression in normal ovaries as well as in PCOS (Pierre *et al.*, 2013). The recent finding that E2 inhibits AMH expression could reconcile those different results (Grynberg *et al.*, 2012). FSH may directly stimulate AMH in small antral follicles, as long as they do not express aromatase. But in larger follicles, by increasing E2 production with the recruitment of a dominant follicle, FSH would have an indirect inhibitory effect on AMH expression through the negative feedback of E2 via its receptor ERβ (**Fig. 3**; Grynberg *et al.*, 2012; Dumont *et al.*, 2015).

It has also been demonstrated that AMH significantly decreases not only the FSH receptor expression but also ovarian aromatase expression (Pellatt *et al.*, 2011). This allows protection of the small follicles from premature aromatase expression. However, when this protective effect exceeds its physiological role, because of AMH excess and/or because it lasts longer than it should in larger follicles, this could result in a defect in the selection of the dominant follicle, thus causing the so called the "follicular arrest." The fact that AMH is inhibitory to FSH-dependent factors required for follicle dominance adds considerable

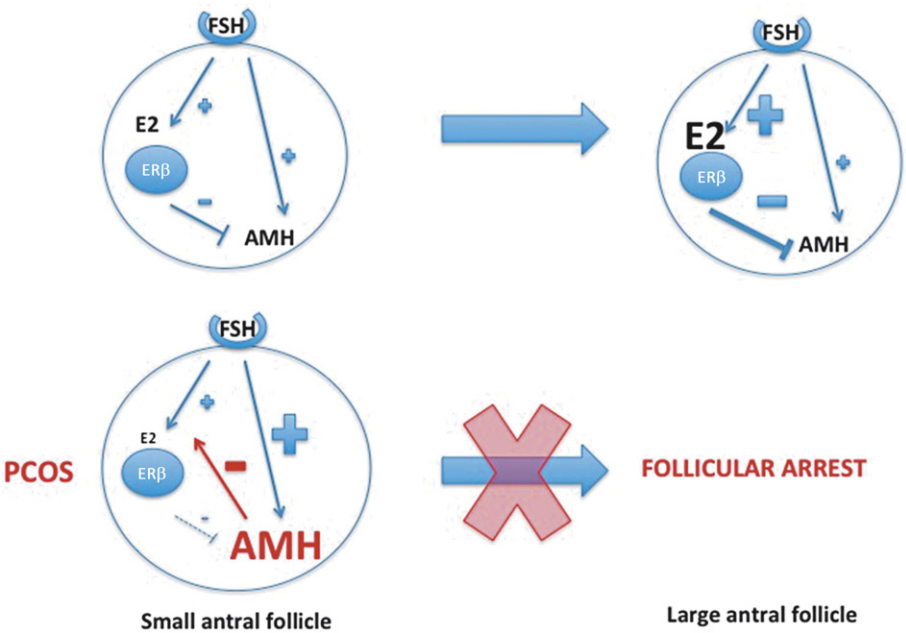

Fig. 3 Schematic diagram of AMH regulation by FSH and E2 in GC of small and large antral follicles. Until the small antral stage, AMH secretion is stimulated by different factors like FSH. Estradiol (E2) production under the influence of FSH is impaired by the inhibiting effect of AMH on aromatase. When estradiol concentration reaches a certain threshold in large antral follicles, it is capable of completely inhibiting AMH expression through ERβ, which predominates in growing follicles, thus overcoming the stimulation by FSH. In large follicles from PCOS, the lack of FSH-induced E2 production and the high level of AMH impair the shift from the AMH to the E2 tone, thus leading to the follicular arrest. Reproduced from Dumont, A., Robin, G., Catteau-Jonard, S. and Dewailly, D. (2015). Role of anti-Mullerian hormone in pathophysiology, diagnosis and treatment of polycystic ovary syndrome: a review. *Reproductive Biology and Endocrinology* 13, 137.

significance to the high serum AMH expression found in PCOS and makes AMH a putative central actor of the "follicular arrest." In good agreement, clinical studies have shown a relationship between high AMH and ovulatory disorder (Pellatt *et al.*, 2007). Besides FSH, acquisition of LH receptors by the granulosa cells happens sooner in PCOS (Willis *et al.*, 1998). Some authors demonstrated that LH reduces AMHRII expression in granulosa luteal cells in normal ovaries and in women with normo-ovulatory PCOS, whereas it cannot do so in women with anovulatory PCOS (Pierre *et al.*, 2013; Pellatt *et al.*, 2010). This lack of LH-induced downregulation of AMHRII expression in women with anovulatory PCOS could contribute to anovulation. Therefore, the premature action of LH might also contribute to the "follicular arrest" through a mechanism involving the AMH system (Willis *et al.*, 1998; Jakimiuk *et al.*, 2001).

To sum up, in PCOS, there are many abnormalities of folliculogenesis: (i) an increased number of small growing follicles (Webber *et al.*, 2003), (ii) an inhibition of the terminal follicular growth (Maciel *et al.*, 2004), resulting in a lack of selection of the dominant follicle, so-called the follicle arrest (Jonard and Dewailly, 2004), and (iii) a follicular apoptosis defect aggravating the excess of growing follicles (Das *et al.*, 2008; Webber *et al.*, 2007).

The robust association between AMH and AFC has led some authors to compare their performance in the diagnosis of PCOS (Eilertsen *et al.*, 2012). Even though serum AMH would be theoretically more accurate than AFC, as it reflects also the excess of small follicles nonvisible on ultrasound (Dewailly *et al.*, 2011, 2014a; **Fig. 4**), it is still considered premature to make this diagnostic transition.

The results from the current literature on the subject are not homogeneous due to the lack of well-defined populations. In particular, some authors have used the PCOS definition established in 2003 at the Rotterdam conference, using 12 follicles of 2–9 mm diameter per ovary for the polycystic ovaries morphology (PCOM) (Balen *et al.*, 2003). This cut-off is highly dependent on ultrasound equipment and operator skill, as demonstrated by Dewailly *et al.* (2014b). Therefore, with the latest ultrasound generation, the threshold has evolved and is now up to 19 or 25 (Dewailly *et al.*, 2011; Lujan *et al.*, 2013; Robin *et al.*, 2012). This threshold will probably continue to increase as newer ultrasound technologies and equipment are developed. Additionally, there are critical issues regarding what populations are included or excluded in the normative population. Lastly, technical issues remain regarding serum AMH assays. It is therefore impossible, so far, to propose a consensual and universal diagnostic threshold for serum AHM in the prediction of PCOS. However, in our experience, a cut-off at 35 pmol/L (4.9 ng/mL) with the enzyme immunoassay AMH-EIA (EIA AMH/MIS kit) ("Immunotech," ref. A16507) provided by Beckman Coulter (France) had a good specificity (97%) and a better sensitivity than the AFC (92%) to distinguish women with PCOS from normal women (Dewailly *et al.*, 2011). Pigny *et al.* (2016) have also compared the five serum AMH assays (as described earlier) for the diagnosis of PCOS. They proposed, with manual ELISAs assays, a higher cut-off at 5.6 ng/mL (40 pmol/L), as biological criteria indicative of PCOM, corresponding to the 95th percentile of "pure" controls. They also proposed a threshold at 4.2 ng/mL (30 pmol/L) for the automatic assays. If confirmed with the new automatized serum AMH assays or the ultrasensitive assay, a high serum AMH level could then become a reliable and accurate marker for PCOM, and eventually replace the AFC.

Serum AMH level is also correlated to the severity of PCOS symptoms (Pellatt *et al.*, 2010) and is higher when hyperandrogenism or oligo-anovulation is present (Pellatt *et al.*, 2007; Eldar-Geva *et al.*, 2005; Piouka *et al.*, 2009). By a principal component analysis, it has been shown that a high serum AMH level can be considered as a marker of hyperandrogenism and could also be used as a substitute for this item in the Rotterdam classification (Dewailly *et al.*, 2010). This would reconcile the different classifications currently available for PCOS because some require hyperandrogenism as a necessary criterion. In 2011, the

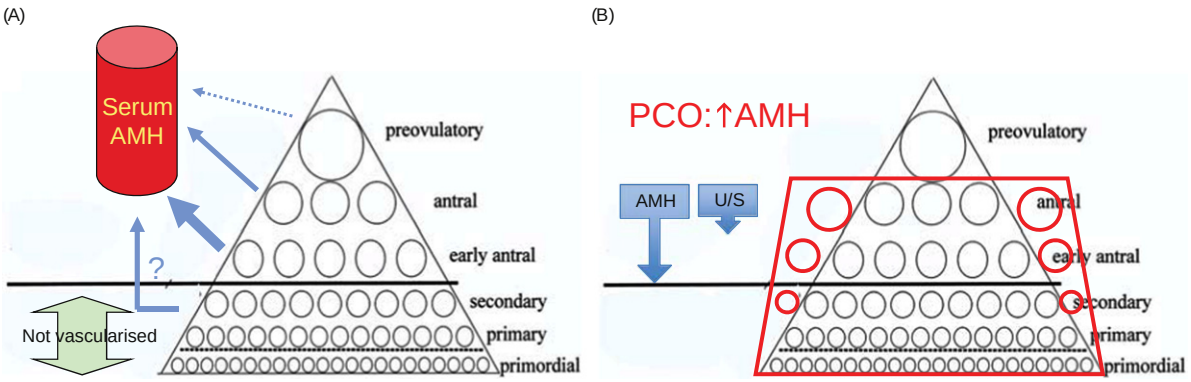

Fig. 4 Rationale for the use of serum AMH assay as a probe for PCOM. (A) All growing follicles secrete AMH but serum AMH reflects only the secretion from bigger follicles that are in contact with the vascular bed. As the numbers of follicles in all growth stages are strongly related to each other, serum AMH is considered to reflect the sum of growing follicles but not the number of primordial follicles that do not secrete AMH. (B) In PCO, the numbers of all growing follicles are increased, resulting in a marked increase in serum AMH level. AMH may be considered as a deeper and more sensitive probe to define follicle excess than the follicle count by ultrasound (U/S) since it appraises more follicle classes (*blue arrows*). Reproduced from Dewailly, D., Andersen, C. Y., Balen, A., Broekmans, F., Dilaver, N., Fanchin, R., Griesinger, G., Kelsey, T. W., La Marca, A., Lambalk, C., Mason, H., Nelson, S. M., Visser, J. A., Wallace, W. H. and Anderson, R. A. (2014). The physiology and clinical utility of anti-Mullerian hormone in women. *Human Reproduction Update* 20, 370–385.

following strategy was proposed (Dewailly *et al.*, 2011): for the diagnosis of PCOS, hyperandrogenism and oligo-anovulation should be first sought. If one is missing, PCOM (i.e., high FNPO or/and high serum AMH level) can be used instead (Dewailly *et al.*, 2011). Thus, there are four PCOS phenotypes and it is important to differentiate them, as they do not involve the same reproductive concerns and/or metabolic consequences. Many studies have tried to identify a predictive level of serum AMH for the different phenotypes but results remain mixed (Hwang *et al.*, 2013; Sahmay *et al.*, 2013). Although it is clear that complete phenotypes of PCOS (phenotype A) have the highest serum AMH levels, it was observed that nonhyperandrogenic oligo-anovulatory phenotypes (phenotype D) had higher median serum AMH levels than hyperandrogenic normo-ovulatory phenotypes (phenotype C) (Dewailly *et al.*, 2014b). Alebic *et al.* (2015), described a steadily increase in median serum AMH levels across the phenotypes (PCOM < phenotype C < phenotype D < phenotype A). They also used the ratio AMH/AFC as a marker of per-follicle AMH production and found it to be significantly increased in a stepwise manner: low in controls, intermediate in eumenorrheic women (PCOM/phenotype C), and high in oligo-amenorrheic women, regardless of androgen status (phenotype A/phenotype D) (Alebic *et al.*, 2015). Recently, Carmina *et al.* (2016) reported that FNPO was significantly more sensitive than serum AMH in the overall diagnosis of PCOS (93% vs. 79%) and especially in nonhyperandrogenic phenotypes (93% vs. 53%) or ovulatory phenotypes (95% vs. 50%). AMH appeared to be mostly helpful in anovulatory phenotypes (sensitivity 91% vs. 92%) (Carmina *et al.*, 2016).

AMH and Assisted Reproductive Technologies

In addition to its diagnostic role, serum AMH level is useful to establish treatment protocols and to define the best strategy for ovulation induction and stimulation in ART.

Clomiphene citrate (CC) is the first-line treatment for ovulation induction in PCOS. So far, there are very few studies that have examined the predictive power of serum AMH level in the response to CC. Mahran *et al.* (2013) have proposed a threshold at 3.4 ng/mL above which a resistance to CC is highly expected, suggesting a higher starting dose should be used.

Laparoscopic ovarian drilling (LOD) is currently recommended as a successful second-line treatment for ovulation induction in women with PCOS. It is considered to be an alternative to gonadotropin stimulation in the case of CC resistance (Thessaloniki Eshre Asrm-Sponsored PCOS Consensus Workshop Group, 2008). The aim is to trigger spontaneous ovulation by destroying small amounts of ovarian stoma. The physiological mechanism remains unknown, but drilling significantly alters the hormonal environment within the ovary. The utility of the AMH assay as a predictor for LOD outcome has been recently questioned (Abu Hashim, 2015). Elmashad *et al.* (2011) showed LOD was followed by lower serum AMH levels and less elevated Doppler flow indices. Amer *et al.* (2009) also showed that women who ovulated after LOD had lower preoperative AMH levels. They identified a pretreatment AMH level cut-off of 7.7 ng/mL (sensitivity 78%, specificity 76%), which predicted failure of LOD.

Concerning the use of gonadotropins in in vitro fertilization, there is a linear relationship between AMH and the number of oocyte yield (Nelson *et al.*, 2007; La Marca *et al.*, 2010). The fact that AMH can predict ovarian response accurately (Broer *et al.*, 2009, 2011b) enables clinicians to avoid iatrogenic complications and to choose the optimal stimulation strategy (treatment protocol and doses). For example, we can identify women at risk of ovarian hyperstimulation syndrome (PCOS), and maximize the protocols to prevent this risk (Broer *et al.*, 2011b; Al-Inany *et al.*, 2011). Conversely, maximizing follicular recruitment in women with low OR seems appropriate because a poor response is anticipated, although the optimal strategy for the poor responder remains debated (Ferraretti *et al.*, 2011). This also ensures that patients are counseled appropriately with realistic expectations of the outcome of their ovarian stimulation. Given that many women do not fully appreciate the detrimental effect of age on oocyte number, the ability to guide them on overall success using a combination of their age as a surrogate for oocyte quality, and AMH for oocyte yield would be a powerful tool (La Marca *et al.*, 2011). It is likely in the future that with standardization of AMH measurement and stimulation strategies, multivariate prediction models with tight confidence intervals will be able to be created and individualized reports generated. Steps on this path have already been made with optimal prediction of excessive response achieved by combining age, AMH and AFC (Broer *et al.*, 2011b) and refinement of gonadotropin dosing by combining AMH with FSH and age (La Marca *et al.*, 2012).

Conclusion

It is now undeniable that serum AMH is one of the most important ovarian hormones and the best marker of the ovarian function. Although knowledge of its precise roles in ovarian physiology still requires extensive fundamental and clinical studies, it is already clear that AMH is crucial in maintaining the right tempo of folliculogenesis in the ovary, making it one of the most crucial factors underpinning female fertility. As for its benefit in the treatment of infertility, there may be an advantage in therapeutic decision support, but this needs to be confirmed by further studies.

However, the current technical difficulties to set up consensual serum AMH thresholds (stability and heterogeneity of circulating AMH, wide range of values, interlaboratory variability, different immunoassays used worldwide) may have curbed the enthusiasm of some clinicians to make it "THE" marker of PCOM. But we must remain optimistic regarding the latest progress made.

Ovarian Stimulation with Clomiphene Citrate☆

J Gianfortoni, Life Source Fertility Center, Richmond, VA, United States

Glossary

Follicle-stimulating hormone (FSH) The pituitary hormone that causes the development and maturation of the oocyte and stimulation of the granulosa cells to produce estrogen.

Gonadotropin-releasing hormone (GnRH) A hypothalamic decapeptide released in a pulsatile manner that causes the release of FSH and LH by the pituitary.

Luteinizing hormone (LH) The pituitary hormone that completes oocyte maturation, stimulates oocyte release and initiates corpus luteum progesterone production.

World Health Organization group 1 anovulation Women with hypogonadotropic hypogonadism (low levels of estrogen and low FSH and LH). They tend to be thin and have a limited response to either clomiphene citrate or progestin withdrawal.

World Health Organization group 2 anovulation Women with normal gonadotropins or elevated LH/FSH ratios. They may have polycystic ovaries and have a tendency toward obesity, hyperandrogenism or insulin resistance.

Pathophysiology

Clomiphene citrate is a triphenylethylene derivative chemically related to DES and tamoxifen. The novelty of this compound is that it produces a chemical rather than a hormonal stimulation for ovulation induction. Although there are receptors in the ovaries and pituitary, it is generally believed that its therapeutic action is derived through hypothalamic stimulation increasing gonadotropin-releasing hormone (GnRH) pulse frequency and/or amplitude in order to stimulate pituitary release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). A simplistic view is that it binds to the estradiol receptors in the medial basal hypothalamus, antagonizing the negative feedback mechanism of estrogen. The increase in FSH then stimulates follicular development, eventually allowing dominant follicle predominance.

Clomiphene citrate is a racemic mixture distributed only in 50-mg tablet form. A typical prescription is 1–3 tablets per day for 5 days. In more resistant cases, 4–5 tablets per day are suggested. Other dosing schedules may require longer intervals at lower doses, such as 1–2 pills a day for 8–12 days. Slowly increasing the dose every 5 days in a given cycle has also been suggested in resistant cases. The objective is to achieve the desired response (ovulation) with the least amount of medication and minimal number of side effects. Starting on Day 5 may interfere with the use of LH kits (ovulation predictor tests). If an elevation in LH occurs immediately following the last pill, a false-positive result will occur. Patients will think they "ovulated" when they have not. This could lead to inappropriate timing for coitus, post coital tests, or inseminations. An alternative approach consists of beginning clomiphene on Day 2 or 3 of the patient's cycle. This allows for earlier recruitment of the dominant follicle and typically increases the time from the last pill to the time of the LH surge. Decreasing the number of days and increasing the dosage, such as 3 pills for 3 days starting on Day 3, can accomplish the desired result while decreasing the amount of medication and unpleasant side effects.

Indications

Ideally, patients who have a recognizable hormonal imbalance should use clomiphene citrate. Clinically, these patients are World Health Organization (WHO) group 2 anovulatory individuals who are estrogenized and have normal gonadotropins. Typically, these patients may also have hyperandrogenism and/or insulin resistance. Appropriate evaluation for these problems, along with examinations for thyroid abnormalities, pregnancy, hyperprolactinemia and adrenal disorders, should be carried out initially. Weight loss and the addition of an insulin sensitizer in these individuals help to limit the amount and duration of medication.

The age-related decrease in fecundity, the "biological clock," is a common problem for couples seeking fertility assistance. The clomiphene challenge test is used to evaluate decreased ovarian reserve. Serum FSH and estradiol levels are obtained on Days 3 and 10 of the patient's cycle. Clomiphene citrate (100 mg, two tablets) is given for 5 days starting on Day 5. If the FSH level on Day 3 or Day 10 is elevated, a problem with follicular recruitment can be expected. Occasionally, the use of clomiphene citrate in the perimenopausal patient may stimulate a better response than injectable medications by using the patient's own stimulated endogenous gonadotropins.

☆*Change History:* December 2015. J Gianfortoni updated the text and further readings to this entire article.
This article is an update of Joseph G. Gianfortoni, Ovarian Stimulation: Clomiphene Citrate, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 467–469.

The natural continuum of follicular development results in the formation of a single mature dominant follicle. In the in vitro fertilization setting, it is hoped that additional follicles will develop so that a reasonable number can be retrieved for fertilization and transfer. Clomiphene citrate has been used with variable success compared to injectable menotropins. It is a less expensive means of stimulation and has a decreased risk of ovarian hyperstimulation. Unfortunately, fewer follicles develop. Another difficulty is the development of a spontaneous LH surge causing premature oocyte release and luteinization. The use of newer GnRH antagonists may help resolve this problem.

Clomiphene citrate is most commonly used, and abused, by patients who have an undetermined etiology of their infertility. This includes the group of patients who report difficulty conceiving, leading the physician to treat them prior to completing a thorough evaluation. This occasionally works if subtle endocrinopathies are corrected by the development of multiple follicles.

Clomiphene citrate has also been suggested for treatment of a luteal-phase defect. Theoretically, the increase in follicle number produces increased levels of estrogen and progesterone, thereby stimulating better endometrial development. Paradoxically, the estrogen antagonistic effect on the endometrium can diminish endometrial thickening and receptivity. Other indications for its use include better timing of inseminations and the development of follicles on the side of a single functioning tube.

Side Effects

The side effects of clomiphene citrate are generally associated with their estrogenic antagonist properties. Alerting the patient to potential problems allows better adjustment to this therapy in an already stressful situation. Side effects can be seen within any organ that is estrogen sensitive. Thus, thickened hostile cervical mucus interfering with sperm mobility, dyssynchronous endometrial development leading to problems with implantation, vaginal dryness and hypothalamic changes (eg, hot flashes, headaches and visual changes) may be seen. Visual changes are the most frightening. The most frequently described are blurred vision and flashing lights. It is usually recommended that clomiphene be discontinued if these symptoms occur, although at lower doses they typically will not return.

Mood changes can occur with varying degrees of intensity. Because of its association with irritability and an altered sense of well-being, clomiphene has sometimes been called the patient's "mean pills."

Mature follicular cysts at the time of ovulation are larger than average when the patient is taking clomiphene. The change in diameter from a 2-cm follicle to a 3-cm follicle increases the volume from 4 to 13 cm^3. If several large follicles develop at the same time, it is understandable that the patient may have increasing pelvic pain. Once formed, these corpus lutea may persist into the next cycle. Evaluation prior to restarting clomiphene citrate is generally suggested. Although rare, hyperstimulation syndrome has been reported with the use of clomiphene citrate.

In the general population, the multiple birthrate is 1–2%, whereas it is 5–12% with clomiphene use. Although the vast majority are twins, higher order multiples have been reported.

Ovarian Cancer Risk

Clomiphene as associated with an increase in the rate of ovarian cancer in two early studies. Theoretically, increased ovarian activity would lead to additional epithelial changes, thereby elevating malignant neoplastic potential. Subsequent analysis and other studies failed to find similar results. During the past 40 years, the use of ovulation-stimulating agents has not resulted in an increase in the U.S. mortality rate for ovarian cancers. In contrast, the marketing of tobacco products to women during this same period has resulted in a dramatic increase in the rate of lung cancer. This killer has surpassed breast cancer as the leading cause of cancer deaths in women.

Alternatives

After correction for other endocrinopathies, such as hyperprolactinemia, hypo- or hyperthyroidism and hyperandrogenism, the addition of clomiphene citrate usually aids ovarian stimulation in anovulatory patients. For some WHO group 2 individuals, metformin has been shown to be of assistance with or without overt insulin resistance. The addition of injectable FSH after 5–10 days of clomiphene citrate treatment can assist in the continued maturation of an appropriate number of follicles while lowering the overall cost to the patient.

Tamoxifen and letrozole have proven to be successful alternatives for stimulating otherwise clomiphene-resistant patients. Injectable gonadotropins or the use of GnRH offer the best solution for WHO group 1 anovulatory women.

Ovulation Induction With Gonadotropins

Aude Bruyneel, Free University of Brussels, Brussels, Belgium
Ralph Papas, University of Balamand, Beirut, Lebanon
Anne Delbaere, Free University of Brussels, Brussels, Belgium

Introduction

Ovarian stimulation represents a major management tool used very commonly nowadays for many conditions in the field of reproductive medicine. Gonadotropins have been available for clinical use for >60 years and are essential for ovarian stimulation including for ovulation induction in anovulatory women as well as for multi-follicular recruitment necessary for assisted reproductive technology (ART) procedures. Multiple preparations of gonadotropins have been developed over the years and are currently widely available on the market for ovulation stimulation.

Historical Background

In this section, we will briefly review the major landmarks that lead to the understanding of the physiology and pharmacology of gonadotropins, as well as the pioneering works that created the wide use, range and availability of pharmaceutical gonadotropin preparations we have today.

Year	*Advancement*
1927–30	Aschheim and Zondek, two German gynecologists, were the first to identify the endocrine function of the pituitary gland and to discover the hormonal action on the human ovary of two forms of gonadotropins they labeled "prolans" A and B. The substances they identified were extracted from pregnant, postmenopausal women and castrated individuals' samples. Notably, they injected pregnant women's urine subcutaneously into immature female mice, causing the development of follicular cysts and hemorrhage into the ovarian stroma and this became known as the Aschheim Zondek pregnancy test. But they believed that the substance responsible for this originated from the anterior pituitary (Aschheim and Zondek, 1927)
1931	Fevold et al. confirmed the roles of the two hormones, and "prolan A" was labeled "follicle-stimulating factor" whereas "prolan B" became "luteinizing factor." The roles of gonadotropins FSH (follicle stimulating hormone) and LH (luteinizing hormone) in being responsible for the rhythmic function of the ovary, and in turn controlling the proliferation and function of the endometrium in preparation for an eventual implantation of a fertilized oocyte, were identified at this point (Fevold *et al.*, 1931)
1937	Cartland and Nelson were the first to extract a purified version of gonadotropins from urine. Their material was stable and sterile enough to initiate use in laboratory and clinical research (Cartland and Nelson, 1937)
1941	Mazer and Ravetz introduced the concept of a "two-step protocol," where anterior pituitary gland extracts are used during the follicular phase for ovarian stimulation followed by urinary pregnancy extracts for ovulation induction. They were the first to report on the resumption of menstrual flow in previously amenorrheic patients, the concept that ovarian response to exogenous gonadotropins is based on individual ovarian receptivity, as well as the first to describe three cases of iatrogenic ovarian hyperstimulation syndrome (OHSS) in regularly menstruating women (Mazer and Ravetz, 1941)
1943	Seegar-Jones et al. were the first to confirm that one of the "prolans" described by Aschheim and Zondek had a placental origin and became known as human chorionic gonadotropin (hCG) (Lunenfeld, 2004; Seegar-Jones *et al.*, 1943)
1945	Hamblen et al. were the first to publish on the use of gonadotropins in a physiologic temporal sequence form of the "two-step protocol" followed by planned intercourse that was compatible with fertility and that resulted in multiple pregnancies (Hamblen *et al.*, 1945)
1949	Until the early 1940s, most of the available gonadotropin extracts were of animal origin. At the end of the 1940's, gonadotropins started to be extracted from urine of post-menopausal women. Multiple methods have been reported and improved over the years, including the early works of Bradbury et al. in 1949 and later Albert in 1955, which were used by many laboratories for years to extract material from large pools of human urine to produce gonadotropins (Bradbury *et al.*, 1949; Albert, 1955)
1950	The method of urinary extraction was further perfected and introduced for clinical use which led to the extraction of purified forms of FSH and LH at the final stages of production (Donini et al., 1964, 1966)
Late 1950s–early 1960s	The first successful inductions of ovulation leading to pregnancies were reported in hypogonadotropic anovulatory women (Lunenfeld, 1963)

 doi:10.1016/B978-0-12-801238-3.65169-3

	Extraction of gonadotropins for clinical use from human pituitary glands (hPG) was developed and compared to urinary extraction with the increasing demands for pharmaceutical gonadotropins. However, hPGs were later removed from the market in the 1980s with the appearance of cases of dementia and death secondary to Creutzfeldt-Jacob disease (Gemzell *et al.*, 1958; Buxton and Hermann, 1961; Lazarus, 1985)
Early 1970s	Technological advances have permitted the development of highly purified "third generation gonadotropin" FSH preparations with <0.1 IU of LH activity and <5% of unidentified urinary proteins (Lunenfeld, 2004). The enhanced purity equated to only a very small amount of protein becoming required for injection, therefore permitting highly purified FSH preparations to be injected subcutaneously. Also, with the batch-batch variability having been almost excluded at this point, new ovulation induction regimens have started to emerge with lower doses, lower dose increments, as well as more consistent and predictable responses (Lunenfeld, 2004)
1975–76	Rathnam and Saxena were the first to describe the amino-acid sequence of the alpha and beta subunits of FSH (Rathnam and Saxena, 1975; Saxena and Rathnam, 1976)
1977	Steptoe and Edwards' pioneering work from the UK led to the birth of the world's first baby conceived by IVF, Louise Brown on 25 July 1978. This work was awarded a Nobel Prize in 2010 and contributed heavily to the wide use of gonadotropins
1980s	Howard W. Jones and Georgeanna Seegar Jones from the Eastern Virginia Medical School in Norfolk incorporated the use of urinary gonadotropins for ovarian stimulation for IVF purposes. This became known and widely utilized worldwide as "controlled ovarian hyperstimulation" (COH), with the addition of pituitary down-regulation with GnRH agonists in the 1980s that can prevent a premature LH surge and ovulation during gonadotropin stimulation
Late 1980s–90s	With the advent of recombinant DNA technology, human FSH was successfully expressed in a Chinese hamster ovary (CHO) cell line in 1988 (Keene *et al.*, 1989). This first recombinant FSH (follitropin alpha) was first used in the clinic in 1991 (Mannaerts *et al.*, 1991). Another similar recombinant form of FSH (follitropin beta) was later introduced and marketed in 1996 (Olijve *et al.*, 1996)
2000–01	Recombinant human LH (lutropin alpha) was released, and with the launch of recombinant hCG (choriogonadotropin alpha) in 2001, the full recombinant gonadotropin range became available
2010	An analogue of FSH with long-acting activity, corifollitropin alpha was introduced on the market. The molecule product labeled is a fusion molecule of recombinant human FSH and the C-terminal peptide of the beta subunit of hCG, which allows for a prolonged absorption and a longer half-life for up to a week with a single subcutaneous injection in women undergoing controlled ovarian stimulation (Croxtall and McKeage, 2011)
2016	A new form of human recombinant FSH, follitropin delta was derived from a human fetal retinal cell line (Arce *et al.*, 2014). Due to differences in glycosylation profile, it has a lower clearance and induces a higher ovarian response than follitropin alpha when administered at equal doses of biological activity (Arce *et al.*, 2014). An individualized dosing algorithm was developed for follitropin delta incorporating body weight, which influences drug exposure and pretreatment anti-müllerian hormone (AMH) levels, which predict ovarian response (Nyboe Andersen *et al.*, 2017)

Choice Considerations for Pharmaceutical Gonadotropins

Multiple gonadotropin preparations have been developed over the years and are currently on the market.

The three main types of urinary gonadotropin extracts used for ovarian stimulation are human Menopausal Gonadotropins (menotropins or HMGs), purified FSH preparations (urofollitropins or FSH-P), and highly purified FSH preparations (FSH-HP). The older preparations used to contain >95% protein impurities and varying amounts of FSH, LH, and hCG, but improvements in purification techniques resulted into a standardization of the FSH and LH activities to 75 IU for each type of gonadotropin, although <5% extraneous urinary proteins still exist even in today's hMG products. It is important to underline that the LH-activity in hMG derives primarily from the hCG component (Practice Committee of American Society for Reproductive Medicine, Birmingham, Alabama, 2008).

Different forms of pure recombinant FSH gonadotropin preparations have been developed for ovarian stimulation: follitropin alpha, beta, and, more recently, follitropin delta (Arce *et al.*, 2014). Lutropin alpha is the only pure recombinant LH preparation available on the market. A combined preparation of recombinant FSH and LH (follitropin alpha and lutropin alpha) is available in a single injection.

Corifollitropin alpha is the only long-acting recombinant FSH analogue available, which allows for a half-life of up to 1 week with a single subcutaneous injection. Corifollitropin alpha is only used for IVF protocols because a single dose can initiate and sustain multifollicular growth, whereas other urinary and recombinant FSH can be used for both ovulation induction and IVF.

Ovulation triggering and induction of final oocyte maturation is performed with hCG, which binds the same receptor as LH.

Efficacy

Treatment of hypogonadic hypogonadal patients, characterized by low gonadotropin and low estrogen levels, requires exogenous LH activity in addition to FSH. In these patients, because of low LH levels, treatment with FSH alone leads to follicular development but not pregnancy (Schoot *et al.*, 1992). Until recently, the only option was hMG (which contains equivalent amounts of FSH and LH IU), but the recent development of recLH and rechCG offered new possibilities of treatment.

For all other indications, several systematic reviews compared recombinant gonadotropins with urinary gonadotropins (HMG, purified FSH, and highly purified FSH) for ovulation induction as well as for controlled ovarian hyper-stimulation for ART. Concerning ovulation induction, a recent Cochrane review found no evidence of a difference in live birth rates among women with polycystic ovary syndrome (PCOS) and CC resistance, between urinary-derived preparations and recombinant FSH. Evidence for all outcomes was, however, still considered to be of "low or very low quality" by the authors (Weiss *et al.*, 2015). For IVF/ICSI, the latest Cochrane review included 28 trials and the meta-analysis showed no evidence of a statistically significant difference in terms of live birth rate when comparing recombinant FSH to any of the other gonadotropins, irrespective of the down-regulation protocol used (van Wely *et al.*, 2012). The authors also mention in their conclusion that "further research on these comparisons is unlikely to identify substantive differences in effectiveness" among the different preparations.

Regarding the effectiveness of co-administrating recombinant LH to recombinant FSH during ovarian stimulation for IVF and ICSI cycles, no evidence of statistical difference in pregnancy outcomes exists with the addition of recombinant LH (Broekmans *et al.*, 2006).

Principles of Ovarian Stimulation With Gonadotropins

Ovarian stimulation encompasses ovulation induction in anovulatory patients and ovarian hyperstimulation, often used to treat ovulatory women in a context of subfertility or infertility. While ovulation induction is intended to induce a monofollicular ovulation in order to restore fertility in anovulatory women, ovarian hyperstimulation aims at inducing a multifollicular ovulation to increase a couple's chance of conception. Before timed intercourse, ovarian hyperstimulation aims at inducing the development of two or three follicles in order to enhance the overall chance of conception. The same principle of ovarian hyperstimulation can be combined with intra-uterine insemination (IUI), whereby a sperm preparation is brought into proximity of two to three oocytes. In the case of in vitro fertilization (IVF), conventional protocols of ovarian stimulation aim at multi-follicular development in order to maximize oocyte yield, thereby increasing the number of embryos and the subsequent cumulative pregnancy rate.

Whatever the indication, it must be emphasized that no stimulation should be administered without a careful infertility work-up including ovarian function assessment, verification of the fallopian tubes permeability, and a sperm exam.

Ovulation Induction in Anovulatory Patients

Anovulatory disorders account for around 25% of causes of infertility (Hull *et al.*, 1985). According to serum levels of gonadotropins and estrogens, they can be classified in one of the three categories of the World Health Organization (WHO) classification. Low gonadotropins and low estradiol refer to WHO class 1 anovulation encompassing disorders at the hypothalamic or pituitary level. The WHO class 2 anovulation is characterized by normal estradiol and FSH levels. The vast majority of patients in this last category have PCOS. The last category, WHO class 3, is characterized by high gonadotropins and low estradiol levels associated with ovarian insufficiency.

Ovulation induction with gonadotropins applies to WHO classes 1 and 2, while it is not effective in patients with ovarian failure (WHO class 3).

Indications

Women with class 1 anovulation who have an intact pituitary function can be treated with pulsatile GnRH therapy or exogenous gonadotropins. However, it should be emphasized that for many of these patients, hypothalamic anovulation is functional and results from stress-inducing conditions such as excessive dieting or intense exercise training. Increased caloric intake or reducing exercise in order to match caloric intake to energy expenditure should be considered before using pharmacological agents. Pulsatile GnRH therapy is highly efficient in restoring the periodic release of FSH and LH. Compared to gonadotropins, it has a reduced risk of multiple folliculogenesis, multiple pregnancies, and ovarian hyperstimulation syndrome (OHSS) (Martin *et al.*, 1993). However, it has the disadvantage of being administered through a portable mini-pump that has to be worn during the whole period of stimulation, which can extend up to several weeks.

The vast majority of women with WHO class 2 anovulation have PCOS, which is the most common endocrine disorder among reproductive-aged women and the main cause of infertility due to anovulation. In 2003, a consensus workshop between the European Society for Human Reproduction and Embryology and the American Society for Reproductive Medicine in Rotterdam indicated PCOS in the presence of two of the following three features: oligo- and/or anovulation, clinical and/or biochemical signs of hyperandrogenism, and polycystic ovaries at ultrasound and exclusion of other endocrinopathies (such as hyperprolactinemia, Cushing syndrome, 21α hydroxylase deficiency) (Rotterdam ESHRE/ASRM-Sponsored PCOS consensus workshop group, 2004).

Obesity is common in women with PCOS and can lead to or exacerbate insulin resistance, which plays a key role in the pathogenesis of ovarian dysfunction in many PCOS patients. Obesity is also associated with an absence of response to all

pharmacological agents used to induce ovulation. Weight loss is therefore recommended in all obese women with PCOS because it leads to higher spontaneous ovulation rates (Legro *et al.*, 2015) and natural conception rates (Mutsaerts *et al.*, 2016).

Anti-estrogen therapy with clomiphene citrate (CC) is generally considered as the first-line treatment in women with anovulation due to PCOS.

However, a recent systematic review and meta-analysis aiming at comparing the effectiveness of alternative first line treatments of ovulation induction for women with WHO class 2 anovulation concluded that letrozole (aromatase inhibitor) was more efficient than CC in terms of ovulation, pregnancy, and live birth rates (Wang *et al.*, 2017). Insulin-sensitizing agents as metformin can be used alone or as adjuvant therapies for ovulation induction. The meta-analysis concluded that the combination of CC and metformin was superior to CC alone in terms of ovulation and pregnancy, but that there was no evidence of an improved live birth rate with the combined treatment, which could be related to the reduced sample size of studies reporting live births (Wang *et al.*, 2017). Although letrozole and the combination of CC and metformin appear superior to CC alone as first-line treatment of ovulation induction in terms of ovulation and pregnancy, it must be emphasized that neither letrozole nor metformin are approved for the treatment of anovulation in many countries, and continue to be used off-label (Vitek *et al.*, 2015; Usadi and Merriam, 2015). As a result, CC remains the front-line agent to induce ovulation and achieve pregnancy in patients with PCOS. Around 25% of PCOS women will not respond at all to CC and are considered to be CC resistant (White *et al.*, 1996).

Women with PCOS who fail to ovulate or conceive following ovulation induction with anti-estrogens or aromatase inhibitors can be offered ovarian stimulation with gonadotropins or laparoscopic ovarian diathermy as a second-line treatment (Balen *et al.*, 2016). In the absence of pregnancy after 6–9 ovulation cycles with CC or letrozole, however, it is appropriate to offer the couple IVF, taking into consideration the age and resources of the patient (Balen *et al.*, 2016).

Treatment Regimens

The aim of the treatment is to restore normal ovulation and promote monofollicular development, while avoiding major side-effects such as high-order multiple pregnancies and OHSS. Whatever the indication, it is therefore essential to perform a strict monitoring of the cycle by measuring serum estradiol levels and assessing the number and size of developing follicles by repeated transvaginal ultrasounds.

Initial protocols used to start with a dose of 75 IU FSH incremented every 5–7 days, but they were associated with multiple follicular development resulting in an unacceptable incidence of multiple pregnancies (Homburg and Howles, 1999). Several investigators have attempted to reduce the rate of complications of multiple follicular development by proposing a stepwise administration of gonadotropins to achieve the FSH threshold required for initiation and maintenance of follicle growth (Brown et al., 1978), without exceeding the individual threshold requirement of the ovary (Seibel *et al.*, 1984; Polson *et al.*, 1987; Buvat *et al.*, 1989). Different studies have shown that chronic low-dose regimens could induce ovulation while considerably reducing multifollicular development compared to conventional regimen (Homburg and Howles, 1999). The current standard protocol is the low-dose step-up protocol (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008). For the first cycle, it is recommended to use low starting doses of FSH of 37.5–50 IU/day (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008) and to increase the dose very progressively in order to reach the adequate threshold. In overweight patients (BMI $\geq$ 25 kg/m^2) a starting dose of 75 IU/day can be used (Yildizhan *et al.*, 2008). The dose is increased by 50% if, after 14 days, no response is observed on echography and estradiol monitoring (no follicle $\geq$10 mm, no increase in plasma estradiol level). As a follicle reaches the size of 10 mm, the ongoing dose is maintained until the dominant follicle reaches the size of at least 17 mm, when ovulation can be triggered by the administration of hCG (5000 IU of hCG or 250 μg of recombinant hCG). The threshold dose or a dose slightly below can be used as the starting dose in subsequent cycles (Homburg and Howles, 1999) (**Fig. 1**).

Overall, low-dose step-up regimens result in a monofollicular ovulation rate in approximately 70% of the cycles, a pregnancy rate of 20%, and a multiple live birth rate of about 6% (Homburg and Howles, 1999).

In order to mimic more closely the events of the normal ovulatory cycle, with a decrease in FSH during the late follicular phase allowing follicular dominance, decremental dose regimen have been proposed starting with a FSH dose of 150 IU continued until a follicle $\geq$10 mm is observed. The dose is then lowered to 112.5 IU/day followed by a later decrease to 75 IU/day 3 days later, which is continued until ovulation is triggered with hCG (Schoot *et al.*, 1995; van Santbrink *et al.*, 1995). Preliminary studies reported that both step-up and step-down regimens achieved similar high rates of monofollicular development (van Santbrink

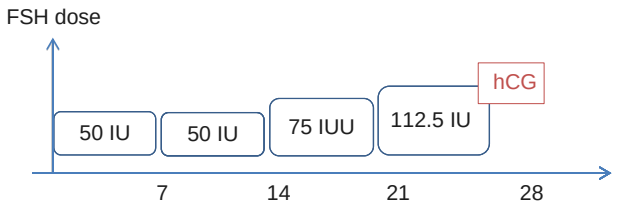

Fig. 1 Chronic low-dose step-up regimen.

and Fauser, 1997). However, it has been subsequently shown in larger series that the step-down protocol was associated with a higher rate of multifollicular development, multiple pregnancies, and a higher incidence of OHSS (Christin-Maitre *et al.*, 2003). A combined approach of sequential step-up and step-down regimens has been shown to help reduce the risk of over-response observed in step-down regimen (Hugues et al., 1996, 2006). It is generally accepted that the step-down regimen should be used only after the response threshold has been established in one or more previous stimulation cycles with a low-dose step-up regimen.

Adjunction of insulin-sensitizing agents to gonadotropins as potential adjuvant therapy has been addressed in several studies for PCOS patients. In a recent Cochrane review, metformin co-treatment during ovulation induction with gonadotrophins was associated with a higher cumulative live birth rate when compared with FSH alone (odds ratio (OR) 2.31, 95% confidence interval (CI) 1.23–4.34), but the conclusion was considered to be based on low-quality evidence (Bordewijk *et al.*, 2017). There was insufficient evidence to show an effect of the adjunction of metformin to FSH on multiple pregnancy rates and adverse events (Bordewijk *et al.*, 2017).

In hypogonadic hypogonadal patients, a dose of 75 IU of recLH in addition to daily FSH was observed to be the right dose to induce follicular development and pregnancy (Burgués and Spanish Collaborative Group on Female Hypogonadotrophic Hypogonadism, 2001).With an LH-like activity driven by hCG, HMG appears to be as effective as the combination of recFSH and recLH in ovulation induction in WHO class 1 anovulation infertility (Carone *et al.*, 2012).

Monitoring

Intense ovarian response monitoring is required in all cases of ovulation induction with gonadotropins. Strict adherence to the chronic low-dose regimen of FSH should markedly reduce the likelihood of multiple follicular development and hence high-order multiple pregnancies and OHSS. The multiple birth rate has been shown to increase from 5% in the presence of one follicle $\geq$16 mm to 20% in the presence of three follicles $\geq$16 mm and to 50% if more than three follicles $\geq$16 mm were observed (Homburg and Howles, 1999). It is advised to cancel the cycle and to ask the patient to refrain from sexual activity or to use a barrier contraception in the presence of more than two follicles $\geq$16 mm and two additional follicles $\geq$14 mm, in order to minimize the risk of multiple pregnancies in women with a history of anovulation, under the age of 38, and without any other infertility factor (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008). It is in any case mandatory to inform the patient about the risks associated with multiple pregnancies following ovulation induction with gonadotropins.

Ovarian Stimulation in Intra-Uterine Insemination

IUI is a simple assisted reproductive technology procedure in which semen is prepared in the laboratory and inserted in the uterine cavity using a small catheter at the time of ovulation. IUI can be performed with or without ovarian stimulation. It is the first-line therapy for moderate male factor (asthenospermia), cervical factor (malformations, cervical conization), mild endometriosis, and unexplained infertility. It can also be considered after failed ovulation induction cycles with gonadotropins in women with dysovulation, although if pregnancy has not occurred after six ovulatory cycles, the patient may be offered IVF (Balen *et al.*, 2016).

Before starting ovarian stimulation in the presence of unexplained infertility (attempt of conception for at least 1 year with a fertility work-up showing patent fallopian tubes, ovulatory menstrual cycles, and a normal semen analysis), it is important to consider the likelihood of spontaneous pregnancy and expectant management (Hunault *et al.*, 2004; van Eekelen *et al.*, 2017). Ovarian stimulation in this context aims at inducing the development of two or possibly three follicles in order to enhance the overall chance of conception. In the case of unexplained infertility, the efficacy of ovarian stimulation with gonadotropins followed by programmed intercourse has not been demonstrated and IUI is usually proposed from the outset (Veltman-Verhulst *et al.*, 2016). The place of IUI in combination with ovarian hyperstimulation for unexplained infertility is, however, still a matter of debate, the main concern being the increase in multiple pregnancy rate. A recent Cochrane review confirmed the increase in live birth rate after IUI in stimulated cycles versus natural cycles (Veltman-Verhulst *et al.*, 2016). However, in cycles with three or four dominant follicles, the multiple pregnancy rate increases without a substantial gain in overall pregnancy rate (van Rumste *et al.*, 2008). Therefore, IUI with ovarian stimulation should ideally aim for no more than two follicles (van Rumste *et al.*, 2008). One mature follicle should be the goal if safety is the primary concern, whereas two follicles may be accepted after careful patient counseling. However, the age of the patient, the duration of infertility, and the number of previous failed IUI cycles should also be taken into account.

Exogenous gonadotrophin administration is usually started around day 2–4 of a menstrual cycle at daily dose of 50–75 IU FSH per day. Careful cycle monitoring should be performed by ultrasound and estradiol measurement, and in the presence of an excessive number of follicles, the cycle should be canceled or supernumerary follicles should be punctured transvaginally before insemination (Albano *et al.*, 2001). Monitoring is also necessary for correct timing of the insemination by assessing preovulatory luteinizing hormone rise in blood or urine. In stimulated cycles, ovulation is often induced by an injection of hCG, which improves timing possibilities.

The live birth rate is around 10%–15% per IUI. It is recommended to limit IUI treatment to 6 cycles (Collège National des Gynécologues et Obstétriciens Français (CNGOF), 2010; National Institute for Health and Care Excellence (NICE) guideline,

2013), in line with reduced pregnancy rates with increasing IUI rank (Custers *et al.*, 2008). Nevertheless, the woman's age should be taken into account to optimize the duration of the IUI treatment and ensure timely transfer to IVF if indicated.

Ovarian Stimulation in In Vitro Fertilization

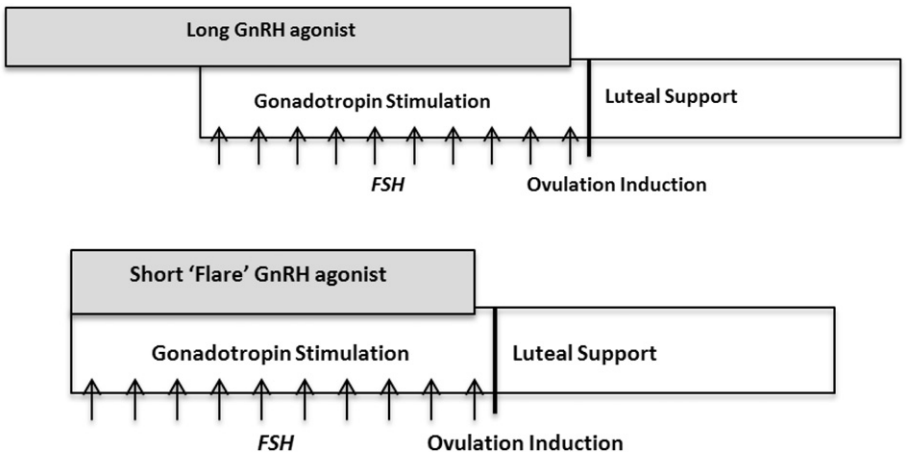
Ovarian stimulation for IVF aims at multi-follicular development in order to maximize oocyte yield, thereby increasing the number of embryos and the subsequent cumulative pregnancy rate. The advent and addition of pituitary down-regulators (GnRH agonists since the 1980s and GnRH antagonists since 2001) that can prevent a premature LH surge and ovulation during gonadotropin stimulation cycles contributed heavily to a wider use of gonadotropins for IVF purposes. Indeed, before the addition of GnRH agonists, the risk of premature LH rise occurred in about 20% of the cycles. The premature LH surge used to occur secondary to the positive feedback triggered by a high serum estrogen level in the mid-follicular phase. Pituitary inhibition is therefore part of the large majority of ovarian stimulation protocols for IVF.

GnRH Agonist Protocols

When the GnRH agonist is used, a phenomenon of initial positive "flare" in pituitary response is observed, followed by down-regulation through clustering and internalization of pituitary GnRH receptors. Making use of the latter part of this phenomenon, the so-called "long down-regulation protocol" of gonadotropin stimulation with a preliminary and continuous GnRH agonist administration has been established in IVF practice since the late 1980s, and has contributed significantly in reducing the rate of cycle cancellation and improving outcomes because of its practically nullified risk of premature LH surge. The "long protocol" requires the GnRH agonist to be started in the luteal phase of the run-in cycle or at the first day of the menstrual cycle and to be continued until the ovulatory hCG trigger. Gonadotropin stimulation is typically started about 10–14 days later, when pituitary down-regulation is established. An important advantage of this protocol relies on the flexibility it provides in the scheduling of egg retrieval (Hayden, 2008). Some women will experience hypo-estrogenic side effects of varying severity secondary to pituitary down-regulation; however, the major disadvantage of this protocol is its relatively prolonged duration with additional costs secondary to increased consumption and injections of gonadotropins, as well as hormonal and ultrasound follow-up measurements.

The "short" or "flare" protocol is another frequently used protocol of ovarian gonadotropin stimulation for IVF purposes that employs a GnRH agonist. Indeed, it makes use of the GnRH agonist-induced positive flare of endogenous FSH pituitary secretion, in addition to the exogenous gonadotropin administration. The agonist is typically started on day 2 of the menstrual cycle while gonadotropin stimulation is initiated on day 3. Follicular growth and maturation take about 10–12 days to occur, which gives enough time for adequate pituitary down-regulation to be established in order to prevent a premature LH surge. Therefore, a shorter duration of treatment and decreased amounts of gonadotropins and injections are required compared to the "long protocol." However, one disadvantage is the reliance on the lowered scheduling flexibility encountered with this approach, given that the start of stimulation is dependent on the start of menses.

A 2015 Cochrane review compared short and long protocols IVF outcomes, and found "no conclusive evidence of a difference in live birth and ongoing pregnancy rates, but there was moderate quality evidence of higher clinical pregnancy rates in the long protocol group" (Siristatidis *et al.*, 2015).

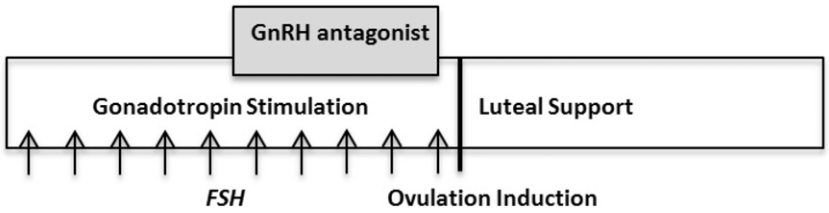


GnRH Antagonist Protocol

It took a considerable amount of time and research to generate clinically useful GnRH antagonists. The current third-generation compounds, Ganirelix and Cetrorelix, can competitively and reversibly bind to GnRH receptors in the pituitary gland, therefore inducing immediate pituitary suppression and subsequent rapid recovery of function, which makes them particularly useful. Indeed, this property allows for a more patient-friendly GnRH antagonist protocol compared to the GnRH agonist protocols, as it requires pituitary down-regulation injections that can be restricted only to the days when a premature LH surge is likely to occur (Duijkers *et al.*, 1998; Felberbaum *et al.*, 1995; Huirne *et al.*, 2007). Typically, multiple small daily doses are used from cycle day 6 as a fixed order, or when the leading follicle reaches 14 mm of diameter, and continued until the day of ovulation induction.

The antagonist protocol offers clear advantages that increase its favor with IVF patients, including a more compact total treatment length that is also physiologically confined to a single month as well as a more favorable side-effect profile. More importantly, the risk of hospital admission due to OHSS is reduced with the GnRH antagonist protocol. In fact, in 2016 a Cochrane review compared the use of the GnRH antagonist with long GnRH agonist protocols and found moderate-quality evidence of a substantial reduction in OHSS with the use of the antagonist without a reduction in the likelihood of achieving live birth.

The main disadvantage of the GnRH antagonist is the lowered flexibility for scheduling that is encountered given that the start of stimulation is dependent on the start of menses. One way to bypass this problem is to use pretreatment with estrogen, which does not compromise the IVF outcome (Cédrin-Durnerin *et al.*, 2012). Another way of programming antagonist cycles is to use the combined oral contraceptive pill to manipulate the length of the follicular phase of the menstrual cycle preceding IVF.



Correct individualization of the gonadotropin's starting dose is a critical decision that clinicians usually make according to multiple clinical criteria including the patient's characteristics like age and BMI, objective markers of ovarian reserve like follicular phase FSH level, antral follicular count (AFC), and anti-Mullerian hormone (AMH), as well as previous history of outcomes of recent ovarian stimulation cycles (La Marca and Sunkara, 2014; Fauser *et al.*, 2008; Alviggi *et al.*, 2012). AMH levels and AFC have been found to be the most reliable examination tools for the measurement of the potential ovarian reserve (Broekmans *et al.*, 2006; La Marca *et al.*, 2010; Nelson et al. 2007). AMH is a glycoprotein secreted into the circulation by primary, pre-antral, and small antral ovarian follicles. Its serum levels correlate strongly with antral follicles as counted by ultrasound, and with the number of retrieved oocytes in IVF cycles where it has been commonly used (La Marca *et al.*, 2010).

Risks and Counseling Issues

Multiple Pregnancies

With the advent of ART, the incidence of multiple gestation has increased drastically. Indeed, while only 1%–2% of all births result from naturally conceived twin pregnancies (ESHRE Capri Workshop Group, 2000), up to 26% of ART-related live births in the USA (Kissin *et al.*, 2015) and 18% in Europe are multiple gestations (Calhaz-Jorge *et al.*, 2017).

Perinatal outcome is known to be severely affected in multiple gestations as the risks for prematurity and low birth weight are elevated in such instances. Many reports have shown fetal mortality to be increased four- to seven-fold in twin gestations and as much as 20 times in triplet gestations (Fauser *et al.*, 2008; Nugent *et al.*, 2000; Verberg *et al.*, 2007).

In IVF, multiple gestation can be easily controlled for and practically eliminated by limiting the number of embryos transferred. Over the past decade, multiple studies have shown that repeated single embryo transfer (SET) was as efficient as the replacement of 2–3 embryos in terms of cumulative pregnancy rates, but was associated with a significant decrease in the incidence of multiple pregnancies (Gerris *et al.*, 1999; Martikainen *et al.*, 2001; Thurin *et al.*, 2004; Pandian *et al.*, 2013). In some European countries like Belgium and Sweden, SET has even become mandatory in good prognosis couples. These guidelines are also increasingly being adopted worldwide as new technologies for embryo selection and successful embryo preservation through freezing were developed and are becoming widely available.

Since this option is not available after timed-intercourse and IUI, monofollicular recruitment through rigorous ultrasound monitoring should remain the goal for those cases.

OHSS

The development of OHSS is mainly an iatrogenic side effect secondary to the use of exogenous gonadotropin for ovarian stimulation. It is unusual with other stimulation agents like CC (Delvigne and Rozenberg, 2002).

Patients at the highest risk of OHSS are typically the young and lean PCOS patients (Navot *et al.*, 1992) who display elevated results on ovarian reserve testing with AMH levels and AFC, and present a hyper-response to ovarian stimulation (Tarlatzi *et al.*, 2017).

OHSS can be classified into mild, moderate, or severe states. Truly clinically relevant instances of OHSS, that is, moderate and/or severe cases, occur at an estimated rate of 3%–8% of ART cycles (3%–6% moderate and 0.5%–5% severe forms) (Delvigne and Rozenberg, 2002; Golan *et al.*, 1989; Schenker and Ezra, 1994). Milder forms of OHSS are more common, of less clinical importance, and occur in an estimated 20%–33% of ART cycles (Mourad *et al.*, 2016).

In the milder presentation of OHSS, women experience mild abdominal pain and bloating in addition to mild nausea and vomiting, and ascites present mainly around the ovaries. However, when the condition progresses to severe OHSS, massive ascites are observed in addition to increased fluid in the pleural and pericardial spaces, concomitant with intravascular volume depletion, hemoconcentration, hypoalbuminemia, and electrolyte imbalances. Severe OHSS can be associated with severe morbidity including thromboembolic events (Kligman *et al.*, 1995), respiratory distress, and liver and/or renal failure. Very rarely, when untreated or inefficiently managed, OHSS can rapidly progress to potentially lethal complications (Braat *et al.*, 2010).

Human chorionic gonadotropin plays a crucial role in the development of the syndrome as severe forms are restricted to cycles with exogenous hCG (to induce ovulation or as luteal phase support) or with endogenous pregnancy-derived hCG (Delbaere *et al.*, 2004).

Avoiding endogenous and exogenous exposure to hCG in the stimulated cycle at risk can be performed by using a GnRH antagonist protocol with a GnRH agonist to trigger ovulation and freezing all embryos for later use. The development of this stimulation strategy in patients at risk has drastically decreased the incidence of OHSS with only anecdotal reported cases (Devroey *et al.*, 2011; Banker *et al.*, 2015).

Cancer

The issue of a potential risk of cancer has been addressed in several studies. However, these concerns have not been validated objectively, since all published reviews and meta-analysis that focused on such issues have consistently found a lack of convincing causal relationship between ART fertility drugs and cancers whether in the breasts, ovaries, or uterus (Siristatidis *et al.*, 2012; Li *et al.*, 2013; Saso *et al.*, 2015; Sergentanis *et al.*, 2013; Salhab *et al.*, 2005; Rizzuto *et al.*, 2013).

A possible increased risk of borderline ovarian tumors in subfertile women treated with IVF has been reported (Rizzuto *et al.*, 2013). However, this is still questioned since infertility itself was found to be an independent risk factor for ovarian malignancy, therefore possibly explaining the above mentioned observation (Venn *et al.*, 1995; Ness *et al.*, 2002; Brinton *et al.*, 2004).

Conclusions and Future Perspectives

Ovarian stimulation with gonadotropins encompasses different clinical situations aiming at increasing the chance of conception whether by restoring ovulation in anovulatory women or by increasing the follicular recruitment in subfertile patients in association with timed intercourse, IUI, or IVF. Whatever the indication, it is associated with complications, particularly multiple pregnancies, which can be drastically reduced by a strict monitoring and cancellation policy in ovulation induction cycles and controlled by a SET policy in IVF. OHSS is another complication that can be largely minimized by proper monitoring in ovulation induction or in the case of empirical treatment of unexplained infertility. The incidence of OHSS is much more frequent in IVF cycles, but recent therapeutic approaches and individualized algorithms have nearly eliminated this potentially life-threatening complication. Controlled ovarian hyperstimulation and assisted reproduction should not become a substitute for ovulation induction for anovulatory patients, as this first-line treatment offers good live birth rates with fewer complications. In the future, gonadotropins could be taken orally and replace the injectable forms currently available, which would contribute to increased comfort for the patient.

Ovarian Hyperstimulation Syndrome

Basil C Tarlatzis, Julia K Bosdou, and Efstratios M Kolibianakis, Aristotle University of Thessaloniki, Thessaloniki, Greece

Abbreviations

ARDS	Adult respiratory distress syndrome
CC	Clomiphene citrate
E2	Estradiol
FSH	Follicle stimulating hormone
GnRH	Gonadotropin-releasing hormone
HES	Hexaethyl starch
hCG	Human chorionic gonadotropin
IVF	In vitro fertilization
LH	Luteinizing hormone
OHSS	Ovarian hyperstimulation syndrome
PCOS	Polycystic ovarian syndrome
RCTs	Randomized control trials
VEGF	Vascular endothelial growth factor

Introduction

Ovarian hyperstimulation syndrome (OHSS) is the most serious iatrogenic complication associated with ovulation induction or multifollicular development for in vitro fertilization (IVF) (Abramov *et al.*, 1999b). OHSS is triggered by the exogenous administration of human chorionic gonadotropin (hCG), used for induction of final oocyte maturation and/or by its endogenous production in cases of pregnancy. Depending on the timing of onset, OHSS is characterized as either early, occurring within 10 days from oocyte retrieval (Mathur and Jenkins, 2000), or late, occurring after that initial 10 day period, usually in patients who become pregnant (Fiedler and Ezcurra, 2012). Most OHSS cases occur during ovarian stimulation for IVF. However, OHSS is also possible in patients undergoing ovulation induction or enhancement of ovulation.

Incidence of OHSS

Europe Versus United States

Based on data provided by the European IVF-Monitoring Consortium, the incidence of OHSS (for which, however, no definition is given) in Europe is estimated to be 0.78% (95% CI: 0.74–0.82) of all stimulated IVF cycles (Kupka *et al.*, 2016). On the other hand, the incidence of severe OHSS in the United States is reported to be 0.28% (95% CI: 0.25–0.31) (Kawwass *et al.*, 2015).

Ovulation Induction and OHSS

In anovulatory women, such as those with polycystic ovarian syndrome (PCOS), several approaches exist in order to induce monofollicular growth (Birch Petersen *et al.*, 2016). The most common ones are clomiphene citrate (CC) and aromatase inhibitors, while less frequently low-dose gonadotropins have also been used (Kar, 2012; Melo *et al.*, 2015). The incidence of OHSS with the use of both CC and aromatase inhibitors is very rare (Franik *et al.*, 2014). However, the incidence of OHSS in PCOS patients with the use of low-dose recombinant follicle stimulating hormone (FSH) is reported to be 2% (95% CI: 1–3) (Weiss *et al.*, 2015).

Enhancement of Ovulation and OHSS

CC, aromatase inhibitors, as well as low-dose gonadotropins have also been used for enhancement of ovulation in women with unexplained infertility. However, since in these patients the target of ovarian stimulation is to allow the development of two to three follicles in order to increase the probability of conception, CC and aromatase inhibitors are less frequently used. No cases of OHSS after CC administration for unexplained fertility were reported in meta-analyses of relevant randomized control trials (RCTs) comparing CC with aromatase inhibitors (Liu *et al.*, 2014). On the other hand, based on data reported in a meta-analysis of RCTs where low dose gonadotropins were used for the treatment of women with unexplained infertility, male infertility or mild endometriosis, the incidence of OHSS (for which, however, no definition was given) was 2% (95% CI: 0–3) (Cantineau *et al.*, 2011).

Ovarian Stimulation for IVF and OHSS

Based on published meta-analyses of RCTs comparing gonadotropin-releasing hormone (GnRH) agonists with antagonists (Al-Inany *et al.*, 2011b) and recombinant daily FSH versus corifollitropin alfa (Tarlatzis *et al.*, 2012), the incidence of OHSS varies from 1.3% to 20.3% according to the characteristics of the patients treated and the type of IVF protocol used (**Table 1**).

Table 1 The incidence of OHSS according to the characteristics of the patients treated and the type of IVF protocol used

Protocol	*Population*	*Source*	*Incidence %*	*95% CI*
GnRH agonists	All women	Al-Inany *et al.* (2011b)	9	7.7–10.5
	PCOS		20.3	16–25.5
GnRH antagonists	All women	Al-Inany *et al.* (2011b)	3.2	2.6–4
	PCOS		4.8	2.9–7.9
Corifollitropin alfa	Normal responders	Tarlatzis *et al.* (2012)	1.8	1.1–2.8
rFSH			1.3	0.7–2.2

Pathophysiology of OHSS

The pathophysiology of OHSS has been related to increased vascular permeability, caused by the extensive production of several vasoactive substances secreted by the ovaries, such as vascular endothelial growth factor (VEGF), angiotensin II, insulin-like growth factor 1, interleukins, and tumor necrosis factor-alpha, following the luteinization of granulosa cells (Goldsman *et al.*, 1995; Tollan *et al.*, 1990; Ata and Tulandi, 2009).

The key factor for OHSS occurrence is hCG, which is administered to simulate endogenous luteinizing hormone (LH) surge for triggering final oocyte maturation. HCG is thought to increase serum VEGF levels, leading to fluid shift in the third space (Ata and Tulandi, 2009). Unlikely to LH, hCG is characterized by a longer half-life, stimulating the existing corpora lutea, enhancing ovarian angiogenesis, and triggering vascular permeability in ovarian vessels (Neulen *et al.*, 1995; Pellicer *et al.*, 1999).

Clinical Presentation of OHSS

The symptoms of OHSS are not specific and the clinical diagnosis has been classified into different grades based on its severity as mild, moderate, severe, or critical (Navot *et al.*, 1992). Clinical presentation of OHSS includes abdominal distension, due to accumulation of intraperitoneal fluid, nausea, vomiting, diarrhea, and abnormal laboratory values (Mathur and Jenkins, 2000; Golan and Weissman, 2009).

As OHSS severity increases, a further increase in vascular permeability and aggravation of ascites lead to hypovolemia, hemoconcentration, oliguria, thromboembolism, and electrolyte disturbance. At that point, enlarged ovaries with multiple large follicles can be detected by ultrasound. In critical cases, patients may present with tense ascites, pericardial effusion, hydrothorax, severe dyspnea, and even adult respiratory distress syndrome (ARDS) (Abramov *et al.*, 1999b; **Fig. 1**).

Management of OHSS

The management of OHSS depends on its severity and the presence or absence of pregnancy. Mild and moderate OHSS do not require specific treatment and patients can be treated symptomatically on an outpatient basis (Practice Committee of the American Society for Reproductive Medicine, 2016). On the other hand, severe OHSS usually requires patient hospitalization since it might lead to serious complications.

Outpatient Management of OHSS

Women undergoing outpatient management of OHSS should be appropriately counseled and provided with information regarding fluid intake and output monitoring. Nonsteroidal antiinflammatory agents should be avoided, as they may compromise renal function (Royal College of Obstetricians and Gynaecologists, 2016). In women with severe OHSS ultrasound-guided paracentesis has been suggested as a safe alternative to hospitalization for the management of OHSS in an outpatient setting (Practice Committee of the American Society for Reproductive Medicine, 2016; Royal College of Obstetricians and Gynaecologists, 2016). In this case thromboprophylaxis is required.

Hospitalization for OHSS

In patients hospitalized with severe OHSS, assessment of severity usually involves physical examination, recording of vital signs, body weight, abdominal circumference, ultrasound examination, and laboratory tests such as hemoglobin, hematocrit, serum creatinine, electrolytes, liver enzymes, and coagulation (Mathur and Jenkins, 2009). Since underlying symptomatic moderate or severe OHSS is a hypovolemic state, treatment involves fluid administration, supportive care, paracentesis, and prophylactic anticoagulation (Royal College of Obstetricians and Gynaecologists, 2016).

There are no trials on the optimum method for maintaining fluid balance in women with severe OHSS (Mathur and Jenkins, 2009). Women with hemoconcentration and dehydration may need more intensive initial rehydration and may benefit from

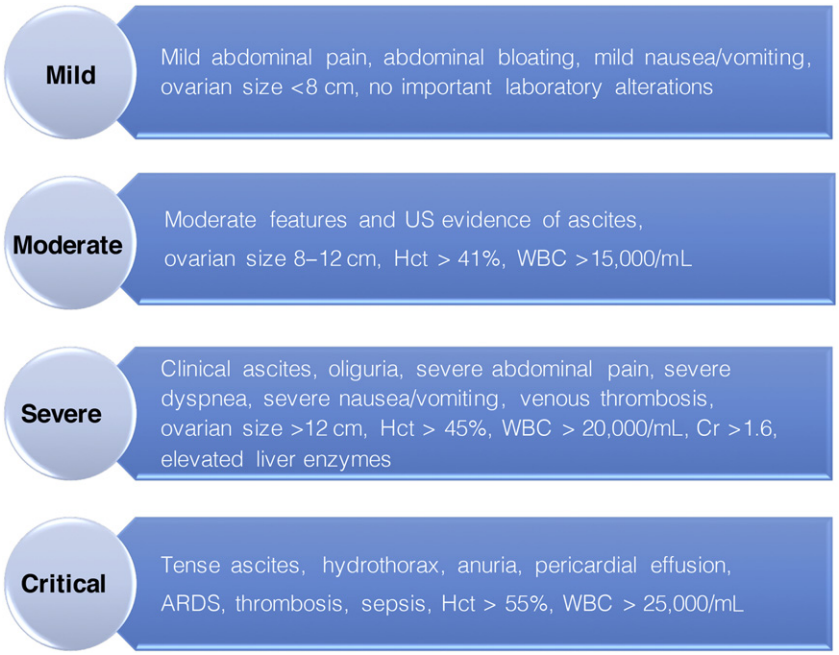

Fig. 1 Classification of OHSS into different grades based on its severity (Abramov et al., 1999b; Mathur and Jenkins, 2000; Golan and Weissman, 2009).

colloids such as human albumin and hexaethyl starch (HES) (Practice Committee of the American Society for Reproductive Medicine, 2016). Paracentesis under ultrasound guidance should be carried out for patients with severe discomfort, abdominal pain, respiratory distress, or oliguria due to the large amount of ascites (Royal College of Obstetricians and Gynaecologists, 2016). Symptomatic hydrothorax persisting despite abdominal paracentesis may be drained directly (Mathur and Jenkins, 2009).

All patients hospitalized with OHSS should be provided with prophylactic anticoagulation to avoid potentially serious thromboembolism. The duration of thromboprophylaxis should be individualized according to patient risk factors and outcome of treatment (Royal College of Obstetricians and Gynaecologists, 2016; Practice Committee of the American Society for Reproductive Medicine, 2016). Since the risk of adnexal torsion or ovarian rupture appears to be increased in women with OHSS, particularly in the presence of pregnancy, surgery is indicated as a treatment option in these patients (Royal College of Obstetricians and Gynaecologists, 2016; Practice Committee of the American Society for Reproductive Medicine, 2016).

Complications of OHSS

OHSS may result in significant morbidity and mortality due to life-threatening complications including renal insufficiency, ARDS, thromboembolism, and hemorrhage from ovarian rupture (Braat *et al.*, 2010; Zosmer *et al.*, 1987; Abramov *et al.*, 1999a; Al Omari *et al.*, 2011).

Mortality rates due to OHSS are difficult to be estimated due to inadequate reporting. Thus, currently reported mortality rates are likely to represent an underestimation of the real problem. Three deaths from OHSS have been reported out of 100,000 IVF cycles performed in the Netherlands during the period 1984–2008 (Braat *et al.*, 2010). Moreover, four deaths, three of which maternal, were reported in 100,000 women following IVF, according to the Confidential Enquiry into Maternal and Child Health in the period 2003–2005 in the United Kingdom (Lewis, 2007), while no maternal deaths due to OHSS in more than 200,000 IVF/ICSI cycles were reported later in the 2011 triennial report of the Confidential Enquiries into Maternal Deaths in the period 2006–2008 (Cantwell *et al.*, 2011).

Prevention of OHSS

Identification of Risk Factors

In recent years, the introduction of GnRH antagonists led to a substantial decrease in the incidence of severe OHSS as compared to GnRH agonists. Although the incidence of severe OHSS is significantly decreased in GnRH antagonist as compared to GnRH agonist cycles based on the latest meta-analysis by the Cochrane group (Al-Inany *et al.*, 2011a), severe OHSS is still possible even with the use of GnRH antagonists, especially in patients at high risk, such as those with PCOS.

Prevention of OHSS can be attempted at different time points during patients' evaluation and treatment but preferably it should be performed before initiation of ovarian stimulation. This is feasible by identifying known risk factors for its occurrence and by classifying patients accordingly. For this purpose, important variables to consider include history of OHSS, assessment of antral follicles count and of

anti-Mullerian hormone. Following assessment of OHSS risk, selection of appropriate stimulation protocols, dose individualization, and tight monitoring of ovarian stimulation are essential. Alarming signals for the occurrence of OHSS during ovarian stimulation are a rapid rise of estradiol (E2) levels, very high E2 levels, or an excessive number of developing follicles. In an attempt to predict high-risk patients for developing severe OHSS, a cut-off value for ≥ 19 follicles of ≥ 11 mm on the day of triggering final oocyte maturation has been proposed, yielding a sensitivity of 74.3% and a specificity of 75.3% (Griesinger *et al.*, 2016). In a more recent retrospective cohort study performed in consecutive IVF/ICSI cycles, a cut-off value for ≥ 15 follicles of ≥ 10 mm on the day of triggering final oocyte maturation appears to offer high sensitivity (89.5%) and specificity (82.9%) for the prediction of severe OHSS (Tarlatzi *et al.*, 2017).

Post hCG Strategies

Several strategies have been suggested to minimize the risk of severe OHSS after hCG administration, including co-administration of dopamine agonists, intravenous administration of albumin, HES, low-dose aspirin, ketoconazole, corticosteroids, metformin, "coasting," continuation of GnRH agonist administration after HCG combined with embryo cryopreservation, or reduction of the hCG dose used to trigger final oocyte maturation. The use of these strategies can only decrease the incidence of severe OHSS but not result in its elimination (Aboulghar and Mansour, 2003).

Replacement of hCG With GnRH Agonist

The use of GnRH antagonists for suppressing premature LH surge has made feasible the substitution of hCG for final oocyte maturation with GnRH agonists. This has changed dramatically clinical practice in assisted reproductive technologies, resulting in the virtual elimination of severe OHSS and in an increased safety of ovarian stimulation (Devroey and Adriaensen, 2011). The replacement of hCG with a GnRH agonist for triggering final oocyte maturation avoids the sustained hCG stimulation for 10 days of corpora lutea. With the use of GnRH agonist triggering, the endogenously elicited LH lasts only 24–36 h, decreasing in this way the occurrence of severe OHSS as compared to hCG. However, the absence of corpora lutea stimulation results in low steroids levels and is associated with a decreased probability of pregnancy after fresh embryo transfer (Tarlatzis *et al.*, 2017).

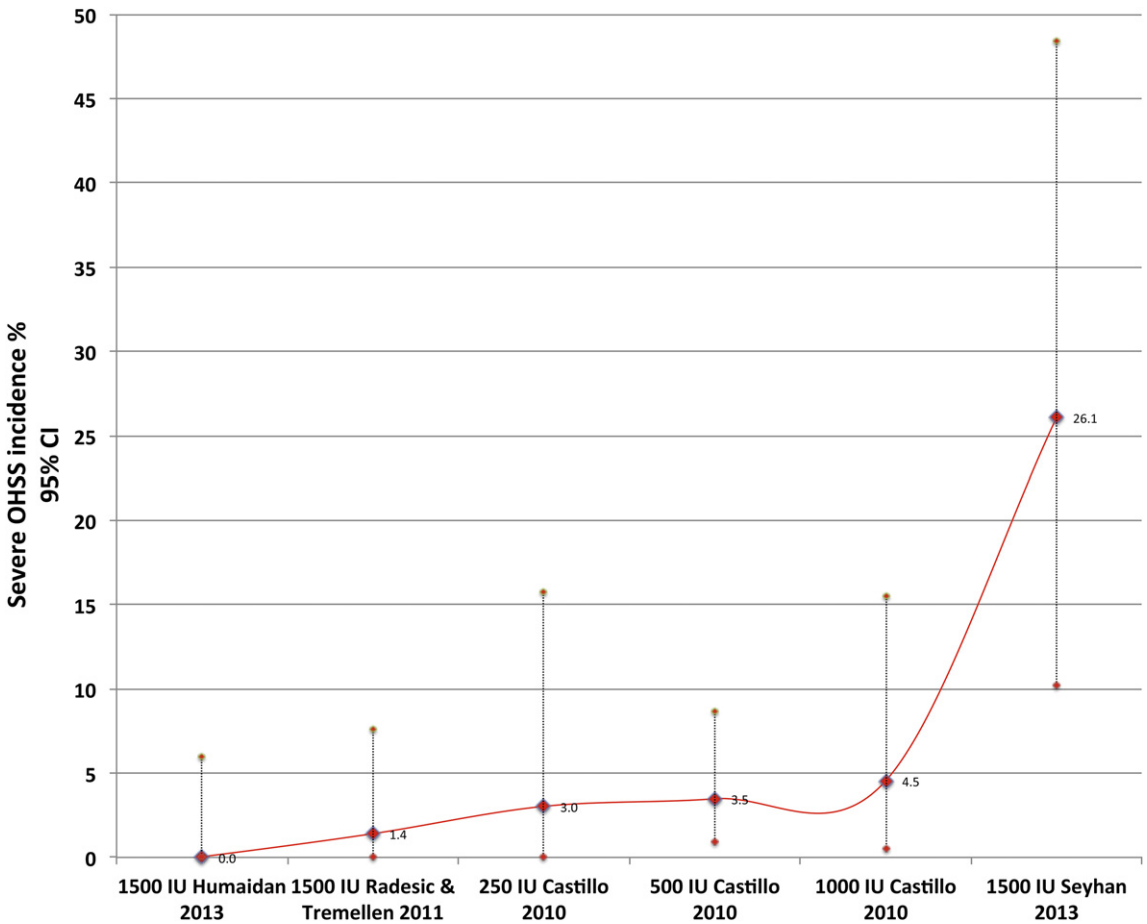

Fig. 2 Incidence of severe OHSS in studies evaluating hCG supplementation in the luteal phase after triggering with GnRH agonist.

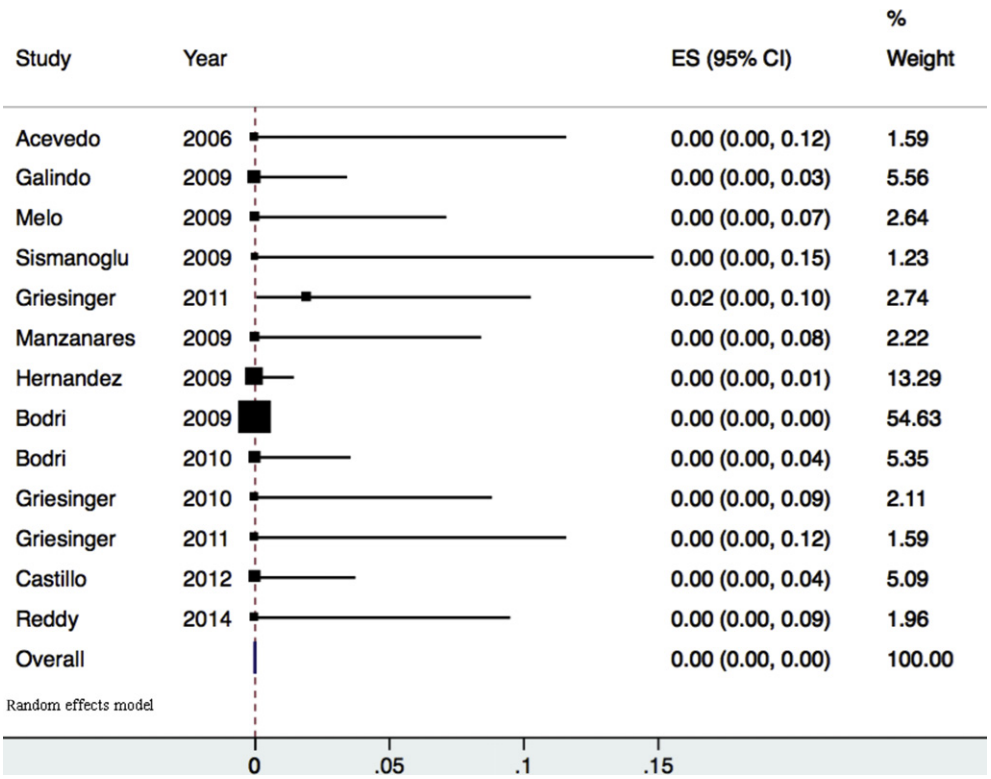

Fig. 3 Estimated probability of severe OHSS in patients triggered with GnRH agonist, by synthesis of the results from all available trials in which GnRH agonist was used for triggering final oocyte maturation and no luteal phase support was administered.

To manage the problem of the decreased probability of pregnancy after GnRH agonist triggering in ovarian stimulation for IVF, different approaches were proposed. These include luteal supplementation with recombinant LH after triggering with GnRH agonist (Papanikolaou *et al.*, 2011), the dual triggering of final oocyte maturation with the combination of GnRH agonist and hCG (Decleer *et al.*, 2014), the stimulation of endogenous LH levels with repeated GnRH agonist administration (Pirard *et al.*, 2006), the intensive luteal phase steroid supplementation after GnRH agonist triggering (Engmann *et al.*, 2008), or the administration of GnRH antagonist in the luteal phase and cryopreservation of all embryos (Lainas *et al.*, 2012; Lainas *et al.*, 2013). Although no severe OHSS cases were observed following these approaches, no firm conclusions regarding the incidence of severe OHSS can be drawn, due to the small number of both studies performed and of participants included (Tarlatzis *et al.*, 2017).

Currently several studies have been performed evaluating hCG supplementation in the luteal phase after triggering with GnRH agonist, in order to both decrease the incidence of severe OHSS and maintain the probability of pregnancy. However, this approach based on the revival of corpora lutea will inevitably lead to severe OHSS in a proportion of high-risk patients (Humaidan *et al.*, 2013; Seyhan *et al.*, 2013; Castillo *et al.*, 2010; Radesic and Tremellen, 2011; **Fig. 2**).

In order to eliminate OHSS, freezing of all embryos is the preferred approach. By synthesizing the results from all available studies until November 2015, prospective and retrospective (Bodri *et al.*, 2009, 2010; Castillo *et al.*, 2012; Hernandez *et al.*, 2009; Acevedo *et al.*, 2006; Galindo *et al.*, 2009; Melo *et al.*, 2009; Sismanoglu *et al.*, 2009; Griesinger *et al.*, 2011a; Griesinger *et al.*, 2011b; Reddy *et al.*, 2014; Manzanares *et al.*, 2010), in which GnRH agonist was used for triggering final oocyte maturation and no luteal phase support was administered (Tarlatzis *et al.*, 2017), the incidence of severe OHSS was 0% (95% CI: 0–0) (**Fig. 3**). In such a scenario, deferring embryo transfer to a subsequent cycle is mandatory and probably beneficial since subsequent embryo transfer will take place during a normal luteal phase. This is the basis of the so called "freeze all" approach after GnRH agonist triggering (Griesinger *et al.*, 2007).

Fertility and Pregnancy in Patients With 21-Hydroxylase Deficiency

Virginie Grouthier, Carine Courtillot, Jérôme Dulon, Philippe Touraine, and Anne Bachelot, Sorbonne University, Paris, France

Abbreviations

21OHD	21-Hydroxylase deficiency
CAH	Congenital adrenal hyperplasia
CVS	Chorionic villi sampling
DEX	Dexamethasone
FSH	Follicle stimulating hormone
GC	Glucocorticoid
HC	Hydrocortisone
LH	Luteinizing hormone
MC	Mineralocorticoid
NC-CAH	Nonclassic form of CAH
SV	Simple-virilizing form
SW	Salt-wasting form

Congenital adrenal hyperplasia (CAH MIM 201910) corresponds to a group of inherited autosomal recessive disorders that arise from defective steroidogenesis and results from a deficiency in one or several of the enzymes of cortisol biosynthesis. CAH due to 21-hydroxylase deficiency (21OHD) is the most common form of CAH, accounting for more than 95% of the cases and is one of the most common known autosomal recessive disorders (Auchus, 2015). The impaired glucocorticoid feedback inhibition via the classic negative feedback loop leads to increased secretion of adrenocorticotropic hormone (ACTH) and to subsequent adrenal hyperplasia and increased production of adrenal androgens and steroid precursors prior to the enzymatic defect (**Fig. 1**). 21OHD is the result of deletions or deleterious mutations in the active gene *CYP21A2* (Auchus, 2015). There are many mutations of the *CYP21A2* gene identified so far, which cause of varying degrees of impairment of 21-hydroxylase activity, and most patients are compound heterozygotes. The clinical phenotype, related to the less severe mutated allele, is classified as classic for the severe form, or nonclassic for the mild or late-onset form (Auchus, 2015). Classic CAH encompasses salt-wasting (SW) or simple-virilizing (SV) forms, depending on the degree of aldosterone deficiency. Increased production of adrenal-derived androgens and progesterone in CAH women interfere with their reproductive function and their fertility in many different ways, depending of the severity of the disease (**Fig. 2**).

Fertility and Pregnancy in Women With Classic Form of CAH

Classic 21OHD CAH is characterized by severe mutations in the *CYP21A2* gene, leading to cortisol deficiency, androgen and progesterone overproduction and virilization of the female external genitalia due to prenatal androgen excess (**Fig. 2**). Sexuality and fertility in women with classic CAH has been described form many years as impaired, especially for the patients with the SW form (Bachelot *et al.*, 2017). This results of several issues such as biological (poor hormonal balance), mechanical (related to surgeries), psychological factors.

Fertility in Women With Classic Form of CAH

One of the main factor implicated in the reduce fertility of the CAH women is the consequence of the childhood genital surgery (Wang and Poppas, 2017). In CAH, 46XX female fetuses are virilized in utero due to their increase exposure to androgens. Genital phenotype of 46,XX CAH patients at birth includes an increased development of the genital tubercle along with an increased length of the urethra, the opening of which is usually located on the ventrum of the genital tubercle. The vaginal cavity opens into the posterior wall of the urethra at a variable distance from the bladder neck. Aims of surgery are to restore functional genital anatomy to allow future penetrative intercourse, to facilitate future reproduction. Surgery can include clitoroplasty, vaginoplasty and labioplasty (Wang and Poppas, 2017). There are few long-term follow-up studies evaluating the outcome of surgery in CAH women, and most of those studies have small sample sizes. Urinary incontinence, vaginal stenosis and inadequate introitus, poor cosmetics, anorgasmia and painful intercourse have been reported in adults and currently remain relevant issues (Wang and Poppas, 2017). It is well established that there is a relationship between sexual activity and vaginal function, thus genital surgery may result in sexual dissatisfaction. Surgical techniques for genital feminization in female CAH patients have nonetheless evolved significantly over time. There are nowadays new surgical procedures which, for instance, preserve innervation and clitoral sensation in order to conserve erotic sensitivity and orgasmic capacity secondary to the clitoroplasty and improved vaginoplasty techniques. Moreover, to date, the choice of the timing of the surgery (early or late surgery) remains therefore a matter of debate. Unfortunately, there are few data in the literature about the outcomes of this surgery in terms of sexual function and the outcomes of the current techniques will take time to emerge. In a cohort study of 138 CAH patients, Arlt et al. have shown that 92 women had undergone genital reconstruction, 43% of who had more than one surgery, and 23% during adulthood (Arlt *et al.*, 2010). Among these patients, 46% have stated being unhappy about their sexual life. A French cross sectional study showed that, despite expert

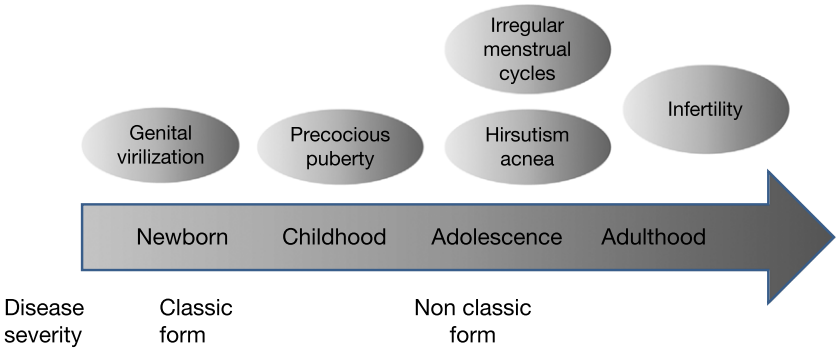

Fig. 2 Clinical aspects of classic and non-classic forms of 21-hydroxylase deficiency according to the age of the patients.

medical and surgical care by physicians dedicated to this rare disease, women with CAH still suffer major limitations in their sexual function and reproductive life. In this study, 37% of CAH women said they never had heterosexual intercourse with vaginal penetration, and for those who had, 81% experienced pain during vaginal penetration. Sexual functioning was much lower in CAH women than controls and lowest in CAH women with high Prader stages (Bachelot *et al.*, 2017). In a more recent review including 151 patients with genitoplasty, assessments of cosmetic results have shown that the majority of patients (between 60% and 94%) reported good or excellent outcomes (Wang and Poppas, 2017). When the physician was the person who assessed the cosmetic outcomes, 59%–94% reported satisfactory results (Wang and Poppas, 2017). Data on the youngest adult generation who may have benefited from improved insights in surgical methods are needed, especially with respect to adult sexual function and patient's satisfaction with the treatment. All these data also underscore the importance of psychological support in the treatment of children with CAH. Recent studies have shown that these women have normal sexual identification, and do not have gender identity confusion. Sexual preference has been studied, but the results are conflicting, with a large variability of heterosexuality and homosexuality rates probably due to the different methods of these studies (Bachelot *et al.*, 2017).

Another factor related to CAH female subfertility is related to the menstrual irregularities and anovulation, which are frequent in CAH women, affecting from 30% to 70% of women (Bachelot *et al.*, 2017). Menstrual cycle control represents therefore an important therapeutic target in these patients (**Fig. 3**). Several factors (androgen and progesterone overproduction, prenatal exposure to sexual steroid) are suspected to disturb the reproductive axis in CAH females (Bachelot *et al.*, 2017). Some authors have therefore suggested that high levels of fetal or perinatal androgens favor LH hypersecretion at puberty, leading to anovulation and polycystic ovaries (Bachelot *et al.*, 2012). However, the conclusions of these studies are almost all speculative, as there are not based on LH pulsatility study. More recently, LH pulsatility pattern has been described in women with classic CAH (Bachelot *et al.*, 2012), therefore highlighting the mechanism of anovulation in these women. It showed two different profiles in CAH women: one group of patients had LH pulsatility patterns similar to the controls; the other one had reduced LH pulses amplitude and frequency, and presented more frequently with menstrual cycle disturbances, higher 17OHP, testosterone, progesterone and androstenedione levels and lower FSH levels. LH pulsatility profiles, with reduced pulse frequency and amplitude, suggest progesterone action on the gonadotropic axis rather than androgen action. This was corroborated by the plot analysis of

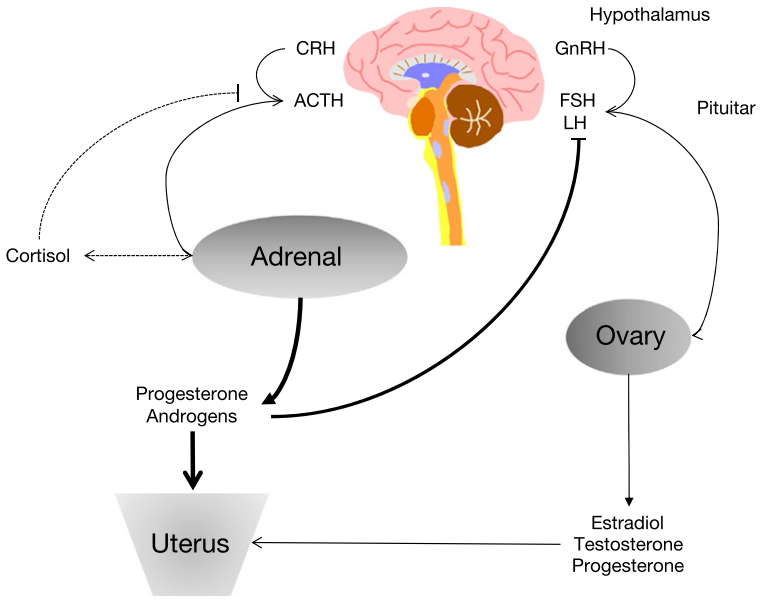

Fig. 3 Hormonal mechanism of female infertility in 21OHD. The impaired glucocorticoid feedback inhibition via the classic negative feedback loop leads to increased secretion of ACTH and to subsequent adrenal hyperplasia and increased production of adrenal androgens and steroid precursors prior to the enzymatic defect. Adrenal-derived androgens and progesterone interfere with gonadotropin pulse secretion. Adrenal progesterone prevent thickening of the endometrium, failure of endometrial breakdown and impermeability of the cervical mucus leading to infertility. *Dashed lines* indicate the absence of steroid production or feedback inhibition.

progesterone concentrations versus testosterone concentrations. None of CAH women exhibit polycystic ovarian syndrome like-LH pulse pattern, with elevated LH pulse levels and amplitude. This study thus demonstrated that hormonal control, especially progesterone overproduction control, is a key factor of gonadotrop function and therefore fertility in adult CAH women (Bachelot *et al.*, 2012). Optimized glucocorticoid (GC) and mineralocorticoid (MC) regimens during fertility monitoring should thus be thus an important concern in CAH women and in particular, suppression of serum progesterone concentrations during the follicular phase of the menstrual cycle should be a major objective in these patients, because it is probably responsible for reduced LH pulsatility and anovulation. Moreover, this elevated adrenal progesterone can prevent thickening of the endometrium in the follicular phase, failure of endometrial breakdown and impermeability of the cervical mucus leading to infertility (Bachelot *et al.*, 2017) (**Fig. 3**).

Analogous to testicular adrenal rest tumors, ovarian adrenal rest tumors have been described, but only in case reports (Bachelot *et al.*, 2017). It is very likely that ovarian adrenal rest tumors, if present, could impair ovarian function in CAH females by displacing normal ovarian tissue and by locally producing steroids, which interfere with normal ovarian function. Systematic study of ovarian adrenal rest tumors by pelvic ultrasonography and MRI was not able to detect them in any of the 13 CAH women studied, according to the diagnostic criteria derived from the imaging features of testicular adrenal rest tumors. This suggests that ovarian adrenal rest tumors in CAH females are rare, in contrast to the high prevalence of testicular adrenal rest tumors in CAH males.

Better fertility and fecundity in CAH women will be largely dependent on surgical advances in genital reconstruction, earlier treatment, optimized compliance to therapy, availability of psychological support, organization of transition from pediatric to adult specialist care, procuration of menstrual cycle control and sexual well-being. At last, considering that these women carrier two severe mutations and the high rate of heterozygotes for *CYP21A2* mutations in the general population, it is essential to genotype the partner of these women, to predict the risk of classical CAH in the offspring and offer genetic counseling.

Pregnancy in Women With Classic CAH

Fertility rate, that is, live births per woman, is significantly lower in CAH women than in the general female population (Bachelot *et al.*, 2017). The first large study has shown that among 25 women with SV form and adequate vaginal opening, fertility rate was 60%, meanwhile among the 15 women with SW form with adequate vaginal opening, fertility rate was only 7%. However, more recent data suggest that fertility rates have significantly improved, largely owing to earlier treatment of CAH, improvement of compliance with therapy and surgical advances in genital reconstruction leading to increased percentage of patients with sexual activity (Bachelot *et al.*, 2017). A recent study has presented for the first time the pregnancy rate as the proportion of women who were actively trying to conceive, and reported a near normal conception rate for women with classical congenital adrenal hyperplasia (Casteràs *et al.*, 2009). In this cohort of 103 CAH women among whom 25% wanted to conceive, the pregnancy estimate was 54% (Casteràs *et al.*, 2009). Pregnancies were most often spontaneous, obtained after a good hormonal control with

optimized GC and MC regimens. Indeed, to achieve pregnancy, they focused on combined suppression of serum progesterone concentrations in the follicular phase of the menstrual cycle and plasma renin activity. This was confirmed in a prospective cross-sectional study of adults with CAH attending specialized endocrine centers across the United Kingdom. In this cohort, 25% of classic CAH women had sought pregnancy. 28 of 47 CAH women reported 46 live births, including six conceived after fertility treatment. The success rate of CAH women seeking pregnancy was 54% (Arlt *et al.*, 2010). Recently, a large population-based epidemiological study on psychosocial outcomes in CAH patients was conducted in Sweden that showed that women with the SW form were less often married [OR 0.5 (0.2–1.1)] and had fewer partnerships compared with controls. CAH patients were less likely to have biological children than controls [OR 0.3 (0.2–0.3)] and when assessing women with the SW and SV forms, it was still significantly decreased [SW OR 0.05 (0.0–0.1); SV OR 0.4 (0.2–0.7)] (Bachelot *et al.*, 2017).

There are few empiric data concerning the management of GC doses in the pregnant CAH patient. There are recent guidelines from the Endocrine Society (Speiser *et al.*, 2010). Consideration may be given to increasing the dose of GC and/or fludrocortisone in advance of the development of clinical evidence of adrenal insufficiency in difficult to manage pregnant SW CAH patients. Symptoms of adrenal insufficiency, including postural hypotension, may rarely develop in pregnant women with classic CAH. GC and/or fludrocortisone doses should be increased if such signs and symptoms occur. During labor and delivery, stress doses of GCs should be given, but there are no controlled studies regarding optimal dosing. CAH women are at increased risk for gestational diabetes; thus, glucose tolerance should be monitored throughout pregnancy. Overall, the treatment of the pregnant CAH patient should be individualized.

Female Fertility in Women With Nonclassic Form of CAH

Contrasting with numerous data on classical CAH, fertility in NC-CAH has been rarely studied. Subfertility seems nevertheless to be relative in this population, based on the three main published cohort (Moran *et al.*, 2006; Bidet *et al.*, 2010; Eyal *et al.*, 2017).

Reproductive Axis of NC-CAH Women

In girls and women with nonclassic CAH, the excess of androgens is responsible for varying manifestations (**Fig. 2**). Hirsutism is the most common sign, ranging from 60% to 80% of the women (Bidet *et al.*, 2009; Livadas *et al.*, 2015). It usually appears in the pubertal period, while the need for cortisol increases. Other signs of hyperandrogenism such as acne and alopecia may occur. Clitoromegaly has been reported in 6%–20% of adult women with NC-CAH. Menstrual cycles irregularities has been reported in about 50% of the patients at diagnosis, are a reflection of these disturbances of the gonadotropic axis (Bidet *et al.*, 2009; Livadas *et al.*, 2015). These disorders of the cycle are variable, ranging from primary (8%) or secondary (4%) amenorrhea to oligomenorrhea (46%) in a large cohort of 190 patients (Bidet *et al.*, 2009). Women with NC-CAH may present with signs of hyperandrogenism suggestive of a diagnosis of polycystic ovary syndrome. It is therefore important for any polycystic ovary syndrome chart to eliminate non classic 21-hydroxylase deficiency, according to the Rotterdam criteria.

In the majority of the affected subjects with NC-CAH, ACTH production is normal (Bidet *et al.*, 2009). Cortisol response to ACTH may be normal or slightly impaired (Bidet *et al.*, 2009). However, adrenal androgens secretion is increased. These patients exhibit elevated adrenal androgens and testosterone levels, but within a wide range and similar to the levels found in PCOS patients (Bidet *et al.*, 2009; Livadas *et al.*, 2015). Other mechanisms may contribute to hyperandrogenism of NC-CAH patients including ovarian dysfunction, which may contribute to androgen excess in these women, as demonstrated by the improvement of clinical and biochemical hyperandrogenism after ovarian suppression. The overproduction of adrenal androgens appears to be the main disruptive factor of the gonadotropic axis. This may have a direct or indirect (via aromatization on estrogens) effect on ovary and gonadotrop axis function. This results in a loss of pulsatility of gonadotropin secretion, leading to anovulation or dysovulation. It has been also suggested that androgens may play a role in ovarian folliculogenesis via androgen receptors on granulosa cells. In addition, 21-hydroxylase deficiency can cause increased levels of progesterone. As it has been showed in women with classic 21-hydroxylase deficiency, increased adrenal progesterone production could disturb gonadotrop axis. The negative impact of elevated progesterone levels at the end of the follicular phase on embryo implantation rates has been shown in in vitro fertilization cycles. In addition, a "mini-pill" effect with inhibition of endometrial proliferation, a negative effect on cervical mucus and feedback on the gonadotropic axis may also occur. The inhibitory effect of adrenal androgens and/or progesterone overproduction on the pituitary-ovary axis is confirmed by the normalization of menstrual cycles subsequent to the suppression of adrenal androgen and progesterone oversecretion by glucocorticoid treatment in women with NC 21-hydroxylase deficiency. Indeed, Bidet et al. showed that menstrual cycle or ovulation disorders observed in NC-CAH women who consulted for infertility were in most cases corrected by hydrocortisone treatment, which led to simultaneous lowering of plasma testosterone and androstenedione levels and rapid occurrence of pregnancy (Bidet *et al.*, 2010).

Fertility in Women With NC-CAH Form

Subfertility is relative in NC CAH women. Indeed, only 10% and 30% of NC CAH women of reproductive age complain of infertility (Moran *et al.*, 2006; Bidet *et al.*, 2010). Anovulation was the main cause of subfertility in NC CAH women. In an

international retrospective study of 203 identified pregnancies, 138 (68%) occurred before CAH diagnosis and treatment (Moran *et al.*, 2006). Similarly, in a recent French study on a cohort of 190 women, only 11% of women consulted for infertility, including 2.6% for secondary infertility (Bidet *et al.*, 2010). This rate was comparable to rates reported in the general population. They described 187 pregnancies, 110 without and 77 with glucocorticoid treatment, occurred in 85 of the 95 women (90.5%) who wished pregnancy, leading to 141 births. These results are in agreement with previous reports (Moran *et al.*, 2006). The study of the cumulative incidence of pregnancies showed that 67% of women wishing to have conceived in the first 6 months and that 75.9% had conceived at 1 year. That is slightly less than in the general population (80 and 92%, respectively). However when considering the 85 patients who conceived, the cumulative incidences of all pregnancies (83.5%) and pregnancies resulting in birth (82%) at 1 year or less are similar to those in the general population (Bidet *et al.*, 2010). These reassuring data have been confirmed in a retrospective study included 75 women diagnosed with NC CAH who sought fertility, 72 women succeeded in conceiving (187 pregnancies) (Eyal *et al.*, 2017). The 96% pregnancy rate among this cohort of NC CAH females was similar to the 95% rate reported for the normal population. 17 pregnancies were achieved by glucocorticoid therapy after failure to conceive spontaneously.

Pregnancy in Women With NC-CAH Form

Apart to this relative subfertility, increase in the frequency of the occurrence of miscarriage has been described in NC CAH women, in the absence of glucocorticoid treatment (Moran *et al.*, 2006; Bidet *et al.*, 2010; Eyal *et al.*, 2017). In the French study, the rate of miscarriage in NC CAH women in the absence of glucocorticoid treatment was 19.4% when abortions are excluded. This rate is higher than the 10%–15% rate reported in the general population. Contrariwise, this rate was significantly lower in NC CAH women under glucocorticoid treatment (Bidet *et al.*, 2010). It seems therefore possible that this treatment is likely to improve the fertility of these patients and the prognosis of their pregnancies. Moran et al., (2006) observed also a markedly lower rate of miscarriages (25.4% vs. 6.2%) after NC CAH diagnosis among 107 patients and 206 pregnancies. However, in the study, some patients received glucocorticoid before NC CAH diagnosis and some others ovulation inducers after NC CAH diagnosis, which may dilute the specific glucocorticoid effect. The high percentage of miscarriages may therefore reflect the poor quality of ovulation and/or the existence of an inadequate corpus luteum with its hormonal consequences on the uterine environment. In a recent retrospective study, of 187 pregnancies, 38 (20.3%) ended in spontaneous miscarriages during the first trimester, but there was no significant difference in the rate of miscarriages between glucocorticoid-treated and untreated pregnancies, but the majority of pregnancies (68%) involved women who had been treated before conceiving (Eyal *et al.*, 2017). That difference might be due to differences in the sample sizes of this study and the others. Therefore, glucocorticoid drug therapy should be considered in hyperandrogenic women with NC CAH who have failed to conceived spontaneously and demonstrate overt or subclinical ovulatory dysfunction, as it has been demonstrated that it prevents infertility and recurrent miscarriages, by lowering adrenal androgen and progesterone secretion and normalizing menstrual cycles (Speiser *et al.*, 2010). Dexamethasone should be avoided during pregnancy, and glucocorticoids such as hydrocortisone and prednisone, which are easily metabolized by placental 11 beta-hydroxysteroid dehydrogenase type 2, must be use (Speiser *et al.*, 2010). Cortisol-binding globulin concentrations increase in pregnancy, and as hydrocortisone administered exogenously is bound by this globulin, hypothetically the dose of hydrocortisone should be increased in pregnant patients with NC-CAH. However, in actual practice there are no biochemical markers and few clinical markers that should be followed in pregnancy, and doses are rarely adjusted. Prospective controlled trials will be needed to determine the true benefit and the mechanism of action of glucocorticoid therapy on pregnancy outcome in NC CAH.

All studies suggest that using a physiological dose of glucocorticoids does not affect birth weight. There were also no differences in the rate of ectopic pregnancy, preterm birth, stillbirths, twins or multiple pregnancies (Moran *et al.*, 2006; Bidet *et al.*, 2010). The prevalence of NC CAH among children of NC CAH mothers (19.2%) was much higher than the predicted rate of 3%–5%. This finding is similar to that of Moran et al. (2006).

At last, considering that NC CAH women might carrier a severe mutation, with a frequency ranging from 9% to 60%, depending of the population, and the high rate of heterozygotes for *CYP21A2* mutations in the general population, it is essential to genotype the partner of nonclassic CAH patients carrier a severe mutation, to predict the risk of classical CAH in the offspring and offer genetic counseling (Moran *et al.*, 2006; Bidet *et al.*, 2010).

Prenatal Management of CAH

The aim of prenatal treatment is to avoid the need for surgery in the little girl and to relieve the emotional distress and anxiety of the parents that may be caused by an external genitalia anomaly in their child. Prenatal treatment was first introduced in the early 80's, using dexamethasone (DEX) which is a synthetic GC with a long half-life, not deactivated by the placental 11β-hydroxysteroiddehydrogenase type 2 and that crosses the placenta and becomes bioavailable to the fetus (review in Bachelot *et al.*, 2017). In the CAH fetus, DEX leads to ACTH suppression and reduction of androgen excess, which blocks the virilization of the external genitalia in female fetuses. The dose of DEX used is 20 μg/kg maternal body weight (preconception)/day, divided in two or three daily doses, without exceeding 1.5 mg/day. This dose corresponds to about six times the physiologic GC needs of the mother (Bachelot *et al.*, 2017). Studies with lower doses have not been performed, but some data show that the DEX dose could

probably be reduced when poorly tolerated in the mother (Tardy-Guidollet *et al.*, 2014). DEX must be initiated before the presumed date of genital sensitivity to androgens, at the latest at the 7th week of gestation (WG) or 9th week of amenorrhea and continued until birth in CAH females to ensure its efficacy (New *et al.*, 2001; Tardy-Guidollet *et al.*, 2014). The timing of DEX initiation seems to play an essential role in the genital morphology of CAH girls (New *et al.*, 2001; Tardy-Guidollet *et al.*, 2014).

Early DEX initiation before 7 WG, ideally at the latest at 6 WG, and its maintenance during the whole gestation have resulted in normal feminine genitalia in CAH girls in 80%–85% cases, failure being usually observed when treatment was started after 8 WG (New *et al.*, 2001; Tardy-Guidollet *et al.*, 2014). A recent small study from French surgeons has suggested that prenatal DEX therapy could potentially be limited to the period of the partitioning window, during the time of urogenital cleavage, which would both reduce total fetal exposure to DEX, yet still facilitate easier surgical correction. Enlargement of the genital tubercle continues to occur in late pregnancy without ongoing antenatal treatment, but it is generally responsive to postnatal treatment (Bachelot *et al.*, 2017.

Prenatal DEX exposure has decreased over the years. Circulating cell-free DNA in maternal serum allows fetal sex determination by detecting the Y chromosome (SRY test). It has recently been shown that the sensitivity of the SRY test was guaranteed just after 4 WG in 96% cases (Tardy-Guidollet, 2015). Moreover, trophoblast retrieval and isolation from the cervix was recently proven to be an approach that noninvasively and correctly identifies male fetal DNA in fetuses at risk for CAH as early as 5 WG. In addition, the development of chorionic villi sampling (CVS) performed earlier than amniocentesis and with a shorter response delay, has allowed minimizing DEX exposure of non-CAH females. Very interestingly, the first demonstration of non-invasive prenatal diagnosis of CAH using cell-free fetal DNA in maternal plasma, as early as 6 WG, has recently been published (Bachelot *et al.*, 2017). Even though large-scale prospective studies are needed, this technique offers the possibility to only treat the affected female fetus.

Prenatal DEX however continues to be a subject of debate. Rare adverse events have been reported in treated children, but no harmful effects have been documented that can be clearly attributed to this treatment (New *et al.*, 2001; Bachelot *et al.*, 2017). A large study on 600 CAH-affected pregnancies where infants were treated prenatally with DEX, reported no significant difference in head circumference, birth weight or length, compared to untreated affected siblings (Bachelot *et al.*, 2017). A recent large French retrospective study confirmed the absence of malformations and of growth restriction at birth (Tardy-Guidollet, 2015). Maternal side effects of prenatal DEX include weight gain, edema, mood change, sleep disturbance, acne and striae. But there has not been a confirmed association with major pregnancy complications such as hypertension, gestational diabetes, stillbirth or spontaneous abortions.

Concerns have been raised in regards to the GC effects on the fetal brain, which arise from studies of other conditions rather than direct studies on prenatal treatment of CAH. A small study from M. New's group described children prenatally exposed to DEX compared to untreated children from CAH at-risk pregnancies, and showed no significant differences in cognitive abilities but demonstrated an increase in internalizing behaviors, such as being more shy, more emotional and less sociable (Mercè Fernández-Balsells *et al.*, 2010). Another large study from the same group was unable to find any adverse effects of prenatal DEX on motor and cognitive outcome. Recently, the same American group published a large study evaluating the long-term effects of prenatal DEX in affected and unaffected CAH patients, and found no adverse effects such as increased risk for cognitive defects, disorders of gender identity and behavior or sexual function in adulthood (Mercè Fernández-Balsells *et al.*, 2010). Conversely, in a small-sample Swedish study of 26 children prenatally treated with DEX compared to 35 matched controls, the authors from S. Lajic's group found no effects on intelligence, lateralization, memory encoding, or long-term memory, but short-term treated CAH-unaffected children had significantly poorer performance than controls on a test of verbal working memory (Mercè Fernández-Balsells *et al.*, 2010). These patients also had lower questionnaire scores in self-perceived scholastic competence and social anxiety. However, parents described these children as more sociable than controls, without significant difference in psychopathology, school performance, adaptive functioning or behavioral problems. A large neuropsychological American study also found that subjects treated with short-term prenatal DEX actually performed better than controls in most areas of mental processing and memory performance; however, girls treated with DEX in the long-term had slower mental processing (Bachelot *et al.*, 2017).

Despite these inconsistencies, a meta-analysis has found no significant difference in neuropsychological outcomes of children treated prenatally with DEX, although only four eligible observational studies were identified, which in addition had low methodological quality (Mercè Fernández-Balsells *et al.*, 2010). Since the early 2000, several medical societies have issued opinions concerning prenatal treatment of CAH based on data presented above and agreed that it is experimental and should only be done in Institutional Review Boards-approved prospective research protocols, with written informed consent, and that this treatment is inappropriate for use in community practice (Speiser *et al.*, 2010). The Swedish group has stopped recruiting patients due to concerns regarding abnormal behavioral development in children exposed to prenatal DEX and notified the Regional Ethics Committee in Stockholm.

It is certain that DEX safety in children treated in utero remains controversial and needs to be better assessed. However, the review of the literature shows an overall efficacy of prenatal DEX. The actual perspective of only treating affected girls will be a major improvement in the care of these at risk pregnancies.

Conclusion

Better fertility and fecundity in classic CAH women will be largely dependent on surgical advances in genital reconstruction, earlier treatment, optimized compliance to therapy, availability of psychological support, organization of transition from pediatric to

adult specialist care, procuration of menstrual cycle control and sexual well-being. Contrasting with numerous data on classical CAH, fertility in NC-CAH has been rarely studied but subfertility seems nevertheless to be relative in this population. Glucocorticoid drug therapy should be considered in hyperandrogenic women with NC CAH who have failed to conceived spontaneously and demonstrate overt or subclinical ovulatory dysfunction, as it has been demonstrated that it prevents infertility and recurrent miscarriages. At last, considering that these women carrier one or two severe mutations and the high rate of heterozygotes for *CYP21A2* mutations in the general population, it is essential to genotype the partner of these women, to predict the risk of classical CAH in the offspring and offer genetic counseling. Recent years have brought new insights in the description of CAH reproductive function and fertility. The use of DEX during pregnancy remains another matter of debate. Its use to prevent or diminish the risk of virilization of the young girl has to be discussed taking account the potential long term use of such molecules on brain function or metabolism.

Glossary

Agonist Drug that has affinity for and stimulates physiological activity at cell receptors normally stimulated by naturally occurring substances.

Antagonist Substance that tends to nullify the action of another as a drug that binds to a cell receptor without eliciting a biological response.

Cryopreservation Maintenance of the viability of embryos or spermatozoa at extremely low temperatures.

Diagnostic ultrasound Use of ultrasound to obtain images for medical diagnostic purposes, employing frequencies ranging from 1.6 to approximately 10.0 MHz.

Donor gamete/embryo Eggs, spermatozoa, or embryos contributed from one person (or couple) to assist in establishing pregnancy in another couple.

Endometriosis Condition in which cells similar to those that form the inside of the uterus are found outside of the uterus; may cause internal bleeding, tissue inflammation, and subsequent scarring, pain, and infertility.

Hysterosalpingography Insertion of a small tube into the cervix followed by injection of dye; the resulting X-ray is inspected for evidence of blockage or irregularity of the uterus or fallopian tubes.

Laparoscopy Inserted through a small incision made just under the navel; looking through the scope, one can examine the ovaries, fallopian tubes, uterus, and other internal structures.

Meiosis Consists of two cell divisions that result in four cells, each of which contains half of the number of chromosomes found in somatic cells.

Ovarian hyperstimulation syndrome (OHSS) Side effect that can occur during infertility treatment with ovulation-inducing drugs; symptoms include ovarian enlargement, accumulation of fluid in the abdomen, and gastrointestinal disorders (e.g., nausea, vomiting, diarrhea).

Surrogate pregnancy Purposely established pregnancy in which the woman who bears the pregnancy does not intend to raise the child.

Unexplained infertility Diagnosis of exclusion when the standard investigation of both the female and male partners has ruled out other infertility diagnoses.

Introduction

In vitro fertilization (IVF) is an assisted reproductive technology (ART) used to treat infertility, to prevent the transmission of some genetic diseases, or to preserve and re-establish fertility potential after fertility-damaging treatments of diseases. IVF involves a number of complementary steps. In brief, oocyte retrieval (usually after controlled ovarian stimulation) and sperm collection, both required for the fertilization of oocytes outside the human body, are followed by the in vitro culture of embryos obtained under proper conditions. The whole process culminates into the transfer of selected embryos in the uterus to start a pregnancy.

History of IVF

During the late 19th century scientists began study of the physiology of mammalian fertilization (**Table 1**). Because there was limited technology for observing events at a cellular level, study of mammalian fertilization did not progress further until after 1930 when Pincus began to study rabbit eggs and sperm under the binocular microscope. In 1944, Rock and Menkin reported in vitro fertilization of a human egg but did not intend to use the resulting embryo in an attempt to start a pregnancy. In 1967, Edwards and Steptoe began work on a technique for harvesting and fertilizing human eggs in vitro with the intention of treating infertile couples. Edwards reasoned that he could "simply pluck the egg from the ovary and fertilize it in the laboratory." In 1969, Edwards, Bavister, and Steptoe reported that they had achieved human fertilization in vitro. The first IVF human pregnancies were achieved in 1975, although they were not successful in reaching term. Then, on July 25, 1978, Louise Joy Brown was born by caesarian section at Oldham General Hospital in England. Her birth was the first to demonstrate that conception in the laboratory could result in the birth of a normal baby. The first IVF baby in the United States was born in 1980. Shortly thereafter, in response to patient demand, numerous clinics offering ART procedures were established all over the world, ushering in a new epoch in helping infertile couples to achieve pregnancy.

This article is an update of David H. Barad, In Vitro Fertilization (IVF), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 77–81.

Table 1 History of in vitro fertilization

Year	*Investigator(s)*	*Event*
1870–80	S. Schenk	Observed rabbit sperm stripping away cumulus cells from egg under the microscope
1890	Walter Heap	Successful transfer of fertilized rabbit oocytes flushed from donor rabbit to foster mother rabbit
1930	Gregory Pincus	Observed rabbit sperm penetrating the egg with binocular microscope
1934	Gregory Pincus and E. V. Enzmann	Mixed rabbit sperm and eggs and returned them to the fallopian tube with birth of young; fertilization not observed
1944	John Rock and Miriam Menkin	Harvested human eggs just before ovulation, combined them with human sperm, and observed the results
1954	Charles Thibault	Reported in vitro fertilization of rabbit eggs; first report of mammalian fertilization in vitro
1959	M. C. Chang	Fertilized rabbit eggs in vitro and transferred four-cell embryos with birth of healthy young
1969	Robert Edwards, Barry Bavister, and Patrick Steptoe	Human in vitro fertilization with embryo division
1971	Robert Edwards and Patrick Steptoe	First transfer of in vitro fertilization embryo with intent of establishing a pregnancy
1978	Robert Edwards and Patrick Steptoe	Birth of Louise Brown
1992	Gianpiero Palermo	Development of intracytoplasmic sperm injection

IVF Procedures

At first, most women treated with IVF procedures had damaged fallopian tubes. As confidence with the new technique increased, clinicians began to use IVF to treat other causes of infertility. Today, ART procedures are used to help women with damaged fallopian tubes, endometriosis, couples who are infertile because of low sperm count or poor sperm function, unexplained infertility, and some genetic disorders.

Ovulation Induction

Edwards and Steptoe obtained a single egg, which would become Louise Brown, with a retrieval timed just before her mother's natural ovulation. Today, most women are treated with follicle-stimulating hormone (FSH) to promote the maturation of multiple eggs before their retrieval. This treatment is known as "ovulation induction" or "controlled ovarian hyperstimulation." FSH treatment for ovulation induction is administered by daily injection for several days, beginning on the third day of menstrual bleeding. Many women are treated with gonadotropin-releasing hormone (GnRH) agonists, GnRH antagonists, or oral contraceptives to suppress their hypothalamic–pituitary–ovarian axis and, consequently, their reproductive cycle. Women undergo monitoring of their serum estradiol concentration and sonogram imaging to determine the growth of their follicles. When the largest follicle has a diameter of greater than 18 mm, the egg is approaching maturity. Final egg maturation is triggered by injection of human chorionic gonadotropin (hCG) or GnRH agonist administration to induce a luteinizing hormone (LH) peak. The clinician retrieves the eggs 34–37 h after this final injection.

Egg Retrieval

Until the late 1980s, laparoscopy was used as the primary method of egg retrieval. To achieve pregnancy, some women would undergo multiple laparoscopies in a single year. Laparoscopic egg retrieval required about 45 min of general anesthesia and was more difficult when pelvic scars covered the ovaries. Today, physicians use ultrasound imaging to guide a needle through the vaginal wall to the ovary. Introduction of ultrasound-guided egg retrievals during the mid-1980s eliminated the need for laparoscopy and a full operating room to complete egg retrievals, allowing ART services to be provided in outpatient settings. Using ultrasound, each follicle is imaged on the display. The retrieval needle is passed through the needle guide, which is parallel to the vaginal ultrasound probe. The needle passes through the vagina and into the peritoneal cavity. The follicles are punctured, and their fluid is suctioned through the needle to a sterile container. The follicular fluid is brought to the embryology laboratory, where the eggs are identified under low-power magnification. The eggs are removed from the fluid, carefully examined by the embryologist, and evaluated for maturation. An egg must have completed its first meiotic division to be successfully fertilized. After the eggs are inspected, the embryologist places each egg in a small bubble of media along with a suspension of washed sperm.

Embryology Laboratories

Embryology laboratories have evolved greatly over the years. Most successful embryology laboratories have protocols to ensure quality control and to maintain a sterile, toxin-free environment. Techniques have been developed in the embryology laboratories to assist in fertilization, embryo growth, and embryo selection and safe transfer.

Fertilization

Expansion of assisted reproductive indications to help couples with poor sperm production or function led to methods of gamete micromanipulation to improve the chance of fertilization in the laboratory. A clear shell called the zona pellucida surrounds human eggs. Zona drilling and subzonal insertion were techniques used to help spermatozoa pass the zona pellucida barrier and bind to the oocyte cell membrane. Working in Belgium in 1992, Palermo achieved fertilization of a human egg by injecting a sperm cell through the egg cell membrane into the cytoplasm, a procedure that became known as intracytoplasmic sperm injection (ICSI). Until then, many embryologists believed that intracytoplasmic injection of sperm would disrupt the basic mechanisms of fertilization. Palermo showed that an egg could be successfully fertilized by ICSI and that a healthy embryo and successful pregnancy could result.

Incorporation of ICSI techniques into the IVF procedures has allowed successful treatment of couples who in the past could only have been offered adoption or artificial insemination. A few living sperm cells retrieved from testicular biopsy or epididymal aspiration can be used for intracytoplasmic injection of oocytes. Use of laboratory techniques to overcome such natural barriers to fertility provoked concern that children resulting from these procedures might be adversely affected. Studies have shown that men with deletions or mutations of genes needed to produce spermatozoa are likely to pass on those traits when they have children by ART procedures. Some genetic traits associated with male infertility are closely linked to other inherited diseases such as cystic fibrosis. For these reasons, couples with severe male factor infertility are encouraged to seek genetic counseling as part of their preparation for infertility treatment.

Embryo Culture

Over the first 5 days after fertilization, the embryo grows rapidly from a single-cell zygote to a hollow ball of many cells, called a blastocyst. During this crucial interval, the embryo makes its transition from a metabolism based on maternal genes to its own genetic program. The media used for embryo culture is a simple solution of salts and nutrients. High-quality embryos can grow in this standard media with good implantation and pregnancy rates.

The metabolic needs of the embryo change as the embryo grows. Sequential culture uses media of different types depending on the stage of embryo development. These more complex media are used to respond to the changing metabolic requirements of the embryo.

Embryo Transfer

Over time, embryologists have learned to produce healthier embryos. In 1985, it was not unusual to transfer six to eight embryos in a single procedure. Today, to decrease the chance of multiple gestations, clinics commonly transfer no more than three high-quality embryos. Embryo transfer is typically done after 3 days of culture. In some cases, embryo culture may be extended to allow transfer of a single blastocyst. Some clinics will transfer more embryos if the overall embryo quality is poor. Embryos are transferred in a thin flexible straw that is threaded carefully through the cervix. The optimal transfer places the embryos in the mid-uterine cavity, together with a minimal amount of transfer media. The transfer is performed carefully to avoid uterine bleeding, which can decrease the chance of implantation. In most cases, the transfer procedure is painless. Embryo transfer may fail if the embryos become trapped in the cervical mucus or do not leave the transfer catheter. Each of these problems can be overcome by careful technique. Some clinicians use sonographic imaging to confirm intrauterine placement of the embryos.

A normal uterine cavity and endometrium will encourage implantation. A physician will often evaluate the patient's endometrial cavity with hysterosalpingogram or ultrasound imaging before the ART cycle begins. Endometrial polyps or fibroids inside the uterine cavity are frequently removed in preparation for treatment. Progesterone supplementation is used after embryo transfer to promote normal secretory endometrium. Embryo hatching is another way in which to assist implantation. Hatching is performed by making a slit in the zona pellucida just before the embryo is transferred. Hatching is thought to make it easier for the embryo to emerge from the zona and may improve signaling between the embryo and the endometrium.

Cryopreservation

As mentioned previously, to reduce the risk of a multiple pregnancy, most clinics transfer only two or three embryos. Because an average ART cycle produces more than three embryos, there are often healthy embryos left over after the transfer. It is possible to freeze the leftover embryos to preserve them. This process is called cryopreservation. If a couple does not achieve pregnancy after IVF, the partners can attempt pregnancy again by transfer of thawed embryos remaining from their first treatment cycle. Pregnancy rates after cryopreservation and thaw of human embryos are less than those following a fresh embryo transfer. The chance of pregnancy will depend on the quality of the embryos and on the maternal age at the time that the embryos were frozen. Live births have occurred after as long as 7 years of cryopreservation, although in most cases couples will use their frozen embryos within a short time.

More recently, progresses in cryobiology have led to vitrification techniques that have been applied to both oocytes and embryos with results surpassing conventional methods. Today, vitrified-thawed oocytes or embryos offer comparable results to fresh oocytes or embryos. This has open the possibility of vitrifying all embryos and delaying embryo transfer to improve uterine readiness for implantation.

Treatment Success and Risks

Even though ART is expensive and invasive when compared with other therapies, ample empirical evidence supports the use of ART procedures for treatment of infertility. Today, live birth rates per initiated cycle often surpass 35%. Chance of success is greatest with younger maternal age and evidence of normal ovarian function. Women over 40 years of age or with high concentrations of FSH early in the menstrual cycle have little chance of achieving a live born child. Multiple pregnancy rates after ART treatment average 25%–40% and can be as high as 60% in some series. The high rate of multiple pregnancy after ART treatment contributes to an increase in spontaneous pregnancy loss (25%), ectopic pregnancy (5%), and preterm delivery. Ovarian hyperstimulation syndrome (OHSS) occurs in 5% of cycles and is another significant consequence of ART treatment, although the use of new methods for ovulation triggering (in particular, GnRH agonists) have practically reduced this prevalence to zero.

Future Implications of Art Techniques

It is likely that we have only just begun to see the direction that these technologies can take us. ART techniques, combined with a growing knowledge of molecular and cell biology, will allow further development of preimplantation diagnosis and possible preimplantation gene therapy. The goal of helping to reverse the effects of aging on reproductive potential may one day be realized through the application of techniques borrowed from cloning and stem cell research. Further improvement in embryo culture technique and embryo selection should increase the number of established pregnancies, reduce the number of multiple pregnancies and pregnancy losses, and further increase the live birth rate per initiated ART cycle.

Ethical Concerns

Some have expressed concern that the expense and risks of ART may outweigh the benefit to the few couples who achieve successful live births. Further concern about expense, risk, and commercialization arises if an egg donor or gestational surrogate, who bears procreative risk in return for payment, is involved. There is consensus that surrogates and donors should be paid for their services but not paid so much that the participants are blinded to their potential risks. In many countries, ART procedures are available only to those who can afford them. Does a society have responsibility to provide infertility care to all of its members as it would to any individual suffering with disease? Some governments have dictated the maximum number of eggs to be retrieved and fertilized and the maximum number of embryos to be transferred per case in an effort to decrease the chance of a multiple gestation. Is this intrusion on the right of individuals to have control over their medical care justified by a concern for patients' safety and the safety of their potential fetuses? Do governments have a right to limit the types of reproductive services available to their citizens?

In July 1978, after Louise Brown was born, religious leaders complained that doctors did not have the right to "play god." Steptoe replied, "I don't know what the fuss is all about. I'm just glad we were able to help Mrs. Brown to have such a happy healthy baby." Today, because of ART, millions of couples and their physicians have had the joyful opportunity of echoing Steptoe's sentiment.

Ovarian Failure Treatment Strategies: Egg Donation☆

Pedro N Barri, University Hospital Quirón Dexeus, Barcelona, Spain

Glossary

Embryo transfer The process by which an embryo is placed into the uterine cavity. The embryo is loaded into a fine cannula that is placed into the uterine cavity. The location of the cannula may be identified by transabdominal ultrasonography. The embryo is expelled into the uterine cavity and the cannula is removed.

Endometrial receptivity The uterine endometrium undergoes continual remodeling. In the early luteal phase of the menstrual cycle, under the influence of progesterone, the endometrium is in a permissive state for the embryo to implant.

Gonadotropin A peptide hormone, follicle-stimulating hormone or luteinizing hormone, that is synthesized and secreted in the pituitary.

Ovarian reserve The extent of residual follicles in the ovary that determines the ovarian response to gonadotropin stimulation.

Superovulation The use of gonadotropin stimulation to increase ovarian follicle recruitment and development.

Window of implantation The limited period of time during which the endometrium is receptive for an embryo to implant.

Introduction

Improvements in life expectancy, obstetrical practice, and neonatal care and advances in assisted reproductive technology have enabled conception and successful childbirth in women with ovarian failure, the majority of whom are peri- and postmenopausal. Assisted reproductive techniques and ovum donation are essential for the establishment of pregnancy in the setting of ovarian failure.

The egg donor is identified and undergoes the process of superovulation and oocyte retrieval to obtain the egg. The egg is fertilized in vitro. Concomitantly, the endometrium of the woman with ovarian failure (recipient) is synchronized to a secretory endometrium receptive for implantation by the use of exogenous sequential estrogen and progesterone administration. When the embryo has cleaved and is ready for transfer, it is placed into the recipient's uterus, and exogenous hormone treatment with estradiol and progesterone is continued.

Pregnancy rates are in the range of 40%–50% per cycle; the highest rates are observed with in vitro fertilization (IVF) and are comparable to those seen with IVF in women of similar age to the egg donor. Even with improvements in antenatal care, obstetrical consequences of childbirth in women older than 40 years of age using egg donation include hypertensive complications and gestational diabetes, an increase in intrauterine fetal deaths, and at least a twofold greater likelihood of cesarean delivery. However, as demonstrated by the fertility and obstetrical outcomes of older women using egg donation, the aging uterus is not a limiting factor in reproduction, pregnancy, or successful delivery of a live-born infant.

Pregnancy rates in OD programs are 50%–60% and live birth rates are around 40%. However, these results are accompanied with high twin pregnancy rates (30%–35%). Multiple pregnancies, commonly associated with poor perinatal outcomes, are considered the most frequent complication of assisted reproductive technique (ART). According to the Spanish Fertility Society (SEF) registry, a remarkable decrease in triplet delivery in OD has been observed in recent years, reaching 0.5% in 2012, yet twin pregnancy rates remain high, being 27.8% in the same year.

Most oocyte donation programs consider a high clinical pregnancy rate as the most important outcome to be taken into account. Pressure to obtain good results, as well as the difficulty of the patients both emotionally and in economic terms in repeating cycles (e.g., advanced age, lack of donors), might explain that some centers do not take into consideration the costs and risks associated with complications caused by multiple gestations.

Natural Limits of Reproductive Capacity

Birth records in the United States and Great Britain prior to the current era of assisted reproductive technology indicate that the maximum recorded age for a successful pregnancy in a woman was 52 years, and only 1/20,000–60,000 births occur naturally past the age of 50. Peak fertility in women occurs between the ages of 20 and 25. After age 30, an insidious decline in fertility ensues

☆*Change History:* November 2017. PN Barri updated the text and further readings to this entire article.

This chapter is an update of Esther Eisenberg, Ovarian Failure Treatment Strategies: Egg Donation, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 457–460.

and becomes clinically evident after age 35. In reality, although the ovaries continue to produce steroids during the 10 years preceding menopause, effective gamete production decreases significantly during this time. The loss of ovarian sensitivity to gonadotropins heralds the cessation of reproductive capacity. A woman is born with all the ovarian follicles she will ever have. As a woman ages, follicle depletion occurs as a result of ovulation and follicular atresia within the ovary. Concurrently, the secretion of estradiol and inhibin from the ovarian granulosa cells declines. Subsequently, follicular growth becomes more infrequent despite increasing pituitary gonadotropin secretion, and ovulation occurs more erratically. Ultimately, menopause, the absence of ovulation and the cessation of menses, occurs.

When the numbers of follicles contained within the ovaries of similarly aged women but with differing menstrual status (regular cycles, perimenopausal, and postmenopausal) are compared, a marked depletion in the remaining follicles is evident in the perimenopausal ovary compared to the ovary of a woman who has been menstruating regularly. Loss of follicles accelerates prior to menopause, and the ovarian follicular reserve is practically expended in menopause. Oocyte chromosomal abnormalities are more common in aged women.

In addition to chronologic age, genetic and other factors such as endometriosis, previous ovarian surgery, systemic chemotherapy, or radiotherapy may affect the ovarian reserve and consequently the biologic response of the ovary. A biological marker of ovarian reserve is the basal follicle-stimulating hormone (FSH) level, obtained on menstrual cycle day 3. Other markers of ovarian reserve include. AMH levels and ultrasonographic evaluation of antral follicle count (AFC)

Egg Donation

Egg (ovum) donation is a process in which eggs (ova) provided by one woman (egg donor) are given to a recipient with the intent to establish a pregnancy in the recipient. The egg donor can be a friend, family member, or an anonymous donor. The donated eggs may be used solely by one recipient or shared by two recipients without reducing the chance of pregnancy. The process of obtaining eggs is similar to that for IVF.

Although the recommendations are based on fresh embryo transfer cycles advances in the methods of cryopreservation (vitrification) and increased survival of embryos vitrified at blastocyst stage will allow better results in the transfer cycles and thus, assumes that the accumulated rates are increasingly high. It will be necessary then that the recommendations designed to consider cumulative pregnancy rates and especially live birth rates.

Candidates for Egg Donation

Women who may consider egg donation include those who have reduced ovarian reserve and impaired folliculogenesis, those who have undergone menopause, those who have ovarian dysgenesis (Turner syndrome), or those who have ovarian failure related to radiation therapy or chemotherapy to treat a malignancy. Any woman who has a uterus but absent or nonfunctioning ovaries is a potential egg recipient. There are approximately 100,000 women in the United States who are unable to bear children due to their inability to produce eggs or whose eggs may not fertilize normally. The majority of women using egg donation are those of advanced reproductive age (>39 years) who are peri- or postmenopausal. Screening of the general health status of the recipient prior to the establishment of pregnancy is advised and should include a full physical examination, screening mammogram, and, in women older than age 40, a cardiac stress test. In addition, before initiating the process of egg donation, the recipient's uterus must be evaluated to exclude intrauterine pathology. Finally, a trial cycle of sequential hormone treatment to prepare the endometrium may be undertaken to determine whether adequate endometrial development occurs in response to estradiol and progesterone administration.

Appropriate preparation of the recipient's endometrium is achieved with the administration of exogenous estrogen in a stepwise fashion, followed by estrogen and progesterone administration synchronized with the timing of hCG administration to the ovum donor. If pregnancy occurs, exogenous administration of estrogen and progesterone is continued for 10 weeks until the placenta has grown sufficiently to produce an ample amount of progesterone (the luteal–placental shift of estrogen and progesterone production generally occurs at 9 or 10 weeks of pregnancy). In 2000, in the United States donor eggs were used in approximately 10% (10,389) of all assisted reproductive technology cycles. More than 70% of all IVF cycles used donor eggs among women older than age 46.

Requirements for an Egg Donor

An egg donor is generally 21–34 years old and has a satisfactory physical examination, including a normal Pap smear, a negative medical history, and genetic screening history, including karyotype negative screening tests for infectious agents, and satisfactory psychological screening and counseling. Appropriate screening of potential egg donors consists of a complete history and physical examination; detailed review of genetic and infectious diseases, including testing for syphilis, gonorrhea, chlamydia, HIV-1 and HIV-2, and hepatitis B surface antigen and hepatitis C antibody; psychological evaluation; and extensive counseling regarding the risks of the procedure prior to signing an informed consent form. If the egg donor is married, both she and her husband should

sign an informed consent. Compensation is provided for time and effort expended and varies depending on geographic area. Screening of the candidates was carried out as described in, incorporating the modifications established in RD-Law 9/2014. The genetic test of carrier of recessive and X-linked autosomal diseases (qCarrier test) was incorporated, based on the Next Generation Sequencing technique, which allows the detection of 240 genetic diseases (Abulí et al., 2016).

Pregnancy and Live Birth Rates

The pregnancy success rate for IVF when donor eggs are used is related to the age of the woman who donated the egg. Since egg donors are typically younger than age 30, the pregnancy rate of an egg donor cycle is approximately 40%–50% per cycle, comparable to that of a young woman undergoing IVF. The cumulative live birth rate is approximately 90% after four cycles. Although the rate of pregnancies conceived using embryos that developed from an egg provided by a donor is excellent, the live birth rate may differ slightly from that of a young woman because maternal factors, such as an increased rate of gestational diabetes and hypertension, contribute to the viability of pregnancy.

Whereas in naturally conceived pregnancies, an age-related increase in spontaneous abortion is observed with advancing age, the rate of spontaneous abortion in pregnancies conceived with egg donation is related to the age of the egg donor, who is generally younger than age 30. Thus, an increase in the spontaneous abortion rate is not an added risk for these older women. In addition, the age of the egg donor determines the risk of fetal chromosome abnormalities such as trisomies. Consequently, since the egg donor is typically a young woman, the risk of chromosomal abnormalities tends to be lower than that observed in women older than age 40.

Uterine Factors

The structure and function of the uterus are dependent on the ovarian production and secretion of estrogen and progesterone and the delivery of these hormones to the endometrium and myometrium via the uterine vasculature. After age 50, uterine weight decreases by $>50\%$, accompanied by changes in collagen and elastin. Because women in their 50s can conceive and carry pregnancies to viability with egg donation, structural changes in the uterus related to hormonal changes of ovarian failure or aging are likely reversible with the administration of exogenous steroid hormones in high doses or they are not of sufficient magnitude to prevent pregnancy.

The effects of aging on the human uterus and consequently on conception, pregnancy course, and spontaneous abortion have not been fully explored. The best predictor of endometrial receptivity and successful implantation is full endometrial thickness as determined in the longitudinal plane by transvaginal ultrasound. As more data are obtained through clinical experience with ovum donation programs, transvaginal ultrasonographic measurements of endometrial thickness and uterine blood flow, and basic research on uterine function, identification, and modulation of critical uterine factors may improve pregnancy outcomes in all women.

Obstetrical Consequences of Delayed Childbearing

Obstetrical consequences of egg donation in women older than age 40 include antenatal medical complications, an increase in intrauterine fetal deaths, and at least a twofold greater likelihood of operative delivery. Medical complications, including hypertensive complications and gestational diabetes, occur with higher frequency in older women. Hypertension occurs 2–10 times more often in older women. In addition, cardiovascular, respiratory, renal, and autoimmune disorders and neoplasia result in more frequent hospitalizations in the older gravida, and when pregnancy is complicated by a medical problem, the complication tends to be more serious than in a younger parturient. According to the report of the ESHRE consensus meeting on "Risks and complications in assisted reproduction techniques" held in Maastricht in 2002, the success of assisted reproduction technology should be measured by the birth of one single healthy child, and multiple pregnancy should be considered as a major complication (Clua et al., 2010, 2016). For oocyte donation, most scientific societies recommend that the age of the donor should be used to determine the number of embryos for transfer. Since in Spain, Law 14/2006 establishes that all donors must be under 35 years of age, it would be logical to recommend single-embryo transfer (SET) in oocyte donation programs as long as good-quality embryos were available, similarly to the recommendation made for young IVF patients. In Spain, according to the SEF guidelines, it is advisable to transfer one or two embryos in oocyte donation recipients (Clua et al., 2012, 2015).

Malpresentation occurs more frequently during labor and delivery, as do placenta previa, uterine myoma, and multiple gestation. The presence of these conditions increases the likelihood of operative delivery. In addition, an increased incidence of labor abnormalities is observed, including prolonged latent phase, prolonged labor (slow active phase, active phase arrest, and prolonged second stage), and failure of decent. Labor abnormalities also contribute to the increased risk of operative delivery.

Perinatal Consequences in Women of Advanced Maternal Age

Age of the mother does not appear to affect birth weight or the incidence of preterm births in women in the United States. These outcomes are determined by social factors such as nutrition, socioeconomic status, smoking, and prior obstetrical history. There is

a three or fourfold increase in perinatal mortality with older maternal age. This is due primarily to an excess of fetal deaths (stillbirths) both before and during labor and not to neonatal deaths. Congenital anomalies, maternal hypertension, uteroplacental insufficiency including large placental infarcts, abruptio placenta, and placenta previa are contributing conditions. The contribution of age independent from having undergone egg donation is unknown. When obstetrical outcome in women who conceived with the assistance of IVF was compared to that of a control group matched by maternal age and multiplicity, an increased incidence of intrauterine growth retardation, placenta previa, and preterm delivery was found among IVF singleton pregnancies. As more women of various ages undergo egg donation, age-related factors influencing the course of pregnancy and delivery will be distinguished from IVF-related risk factors and will contribute to our understanding of the obstetrical consequences of both IVF and aging.

In the past century, medical advances have contributed to the reality of pregnancy in peri- and postmenopausal women. These include the development of IVF and related assisted reproductive technologies, the identification and synthesis of estrogen and progesterone, and their availability as pharmaceutical preparations that can be used to artificially prepare an endometrium for implantation, and developments in obstetrical and neonatal practice that have resulted in significant improvements in maternal health and neonatal outcome. In addition, improvements in overall general health status as reflected by increased life expectancy and decreased infant mortality in developed countries have made parenthood at an older age a feasible option as people live longer and healthier lives.

Introduction

Recent advances in fertility preservation (FP) techniques now allow to consider cryopreservation of oocytes, embryos, and ovarian tissue. Initially developed for patients suffering from cancer, FP has rapidly invaded others medical fields, and should be included in the management of all women of reproductive age diagnosed with diseases that could threaten fertility or having to receive gonadotoxic treatments. Thus, FP should now be discussed for non-oncological at risk for premature ovarian insufficiency (POI) due to gonadotoxic iatrogenic treatments, repeated ovarian surgery, auto-immune, endocrine or genetic disorders.

After a description of the existing techniques of FP, the main FP indications will be discussed.

Techniques for Fertility Preservation in Women

Among FP techniques, some are considered as well established such as oocytes or embryos cryopreservation after ovarian stimulation while others still remain experimental.

Oocyte/Embryo Cryopreservation After Controlled Ovarian Stimulation

Ovarian stimulation

Prior to embryos/oocytes cryopreservation, a controlled ovarian stimulation (COS) is commonly requires. It consists in the administration of exogenous FSH for 10–15 days to produce a multifollicular growth. The use of high doses of gonadotropins overrides the mechanism of follicle dominance and thereby achieves the growth of several large follicles up to the preovulatory stage (Verberg *et al.*, 2009). COS is usually performed using GnRH antagonist protocols until three to four follicles have reached 16–22 mm in diameter. Final follicular maturation is therefore triggered using hCG or GnRH agonist administration. Thirty-six hours later, oocytes are retrieved by transvaginal ultrasound-guided aspiration of follicular fluid from follicles. Mature oocytes obtained are frozen by vitrification. For PF patients, the objective is to yield a maximum number of oocytes while avoiding risk of ovarian hyperstimulation syndrome. Their use will require a thawed procedure and further in vitro fertilization (IVF) and embryo transfer.

GnRH antagonists have modified the way patients are stimulated, enabling a significant reduction in the duration of treatment. Indeed, in contrast to agonists, GnRH antagonists immediately suppress pituitary FSH and LH releases and do not require the 10–14 days of GnRH agonist administration before gonadotropins administration. Exogenous FSH is usually started on cycle day 2–3 and GnRH antagonists will be initiated when the lead follicle reaches 12–14 mm in diameter, at approximately day 6 of ovarian stimulation. As a result, the timing between the beginning of gonadotropins administration and oocytes pick-up will often not exceed 14 days on average. Numerous studies and meta-analyses have shown similar live birth rates with antagonist and agonist protocols (Toftager *et al.*, 2017). Antagonist protocol offers the advantage of reducing the risk of ovarian hyperstimulation syndrome (OHSS) especially with GnRHa ovulation triggering (Bodri *et al.*, 2009; Humaidan *et al.*, 2011).

Recently, new protocols have been developed offering the possibility to perform ovarian stimulation irrespective of the phase of the menstrual cycle ("random start" protocols) or to realize a double stimulation. Additionally, it is possible to use alternative stimulation protocols without exogenous FSH-related increase in serum estradiol levels or to carry out natural cycles. At least new procedures of ovulation triggering have almost canceled risks of severe ovarian hyperstimulation syndrome.

The "random start" protocol, starting gonadotropins administration regardless of the day in the menstrual cycle have been proposed and is especially interesting for patients having to initiate gonadotoxic treatment very soon (Sönmezer *et al.*, 2011; von Wolff *et al.*, 2009). The total number of oocytes recovered did not differ whatever the phase of the cycle at which ovarian stimulation was started. However, no data is currently available in this population regarding oocytes quality, pregnancy or live birth rates.

The concept of the double stimulation has recently emerged. Kuang *et al.* (2014), first showed, in infertile poor responders, the efficiency of a double stimulation during the same menstrual cycle for increasing the number of oocytes available for IVF. Further, this concept has been proposed for FP candidates.

The supraphysiologic estrogen serum levels (10–20-fold) induced by conventional protocols might have a detrimental effect on hormonal-sensitive diseases such as breast or endometrial cancers. The risk of cancer recurrence directly related to COS remains theoretical even though current available data remain reassuring (Azim *et al.*, 2008; Goldrat *et al.*, 2015). To reduce this risk as much as possible, innovative protocols of ovarian stimulation have been described, with a major objective: reducing estrogens production or action using tamoxifen or aromatase inhibitors (letrozole) (Oktay *et al.*, 2005).

The concomitant administration of letrozole and gonadotropins allows maintaining serum estradiol levels into the physiologic ranges, by preventing conversion of androstenedione and testosterone respectively to estrone and estradiol. In the absence of estrogenic negative feedback on the gonadal axis, FSH secretion is increased stimulating follicles growth (Oktay *et al.*, 2005, 2006). Despite lower serum estradiol levels on the day of ovulation triggering, the number of oocytes and embryos obtained with letrozole-FSH protocols did not differ when compared with conventional COS (Oktay *et al.*, 2005). Moreover, follow-up of breast cancer patients having undergone ovarian stimulation for FP with letrozole has not showed increased risk of recurrence or detrimental effect on short-term survival rates (Azim *et al.*, 2008; Oktay *et al.*, 2006, 2015a). Kim *et al.* (2016) confirmed in a recent prospective study the safety of controlled ovarian stimulation with letrozole prior to chemotherapy with 5-year follow-up after breast cancer diagnosis. Moreover, a recent investigation showed comparable pregnancy rates between patients having undergone ovarian stimulation with aromatase inhibitors and non-cancer patients included in conventional protocols (Oktay *et al.*, 2015). Finally, no increase in congenital malformations and chromosomal abnormalities was observed in newborns with letrozole protocols (Oktay *et al.*, 2015).

Tamoxifen is a competitive antagonist within the breast by competitive binding to estrogens receptors. Yet, tamoxifen, by inhibiting the negative feedback of estrogens over the hypothalamic-pituitary system, causes increase in GnRH secretion and further FSH release (Meirow *et al.*, 2014). In FP candidates, the detrimental effect of tamoxifen on endometrium is no longer relevant, since no fresh embryo transfer is planned. Oktay et al. first proposed a tamoxifen-FSH protocols for breast cancer patients. When compared with letrozole protocols, the use of tamoxifen yield significantly higher peak serum estradiol levels and is less effective in term of number of oocytes and embryos obtained (Oktay *et al.*, 2005).

At least, given the short half-life of GnRH agonist-induced endogenous LH surge, it is now recommended to use these drugs as an alternative to hCG in FP candidates stimulated with GnRH antagonist protocols. In cancer patients, GnRH agonists trigger have shown to be as effective as hCG, while reducing the risks of moderate/severe OHSS (Reddy *et al.*, 2014). Avoiding hyperstimulation complications is critical in order not to delay initiation of cancer treatment.

Natural-cycle IVF have been proposed as an alternative to conventional COS for poor responders (Lainas *et al.*, 2015; Pelinck *et al.*, 2002). However, it is now well established that the overall pregnancy rates achieved with modified natural-cycle IVF in patients >35 years are low, probably as a result of the poor oocyte quality. However, iterative natural cycles could be used for young FP candidates (excluding cancer indications) with already impaired ovarian reserve. The main limit for this strategy may be the high number of cycles required for obtaining a "sufficient" number of frozen oocytes, which may slow down the FP process.

Embryo cryopreservation

Cryopreservation of embryos using IVF is a well-established technique largely used worldwide for the last decades. Live birth rates are comparable with fresh and frozen embryos (Roque *et al.*, 2013). Most IVF outcomes appear comparable for cancer patients and age-matched controls (Cardozo *et al.*, 2015). However, cryopreservation of embryos requires a male partner or a sperm donor.

Oocyte cryopreservation

The first live birth obtained after thawing of a frozen embryo was published 30 years ago (Kuleshova *et al.*, 1999). Since then, improvement in cryopreservation techniques especially in vitrification has allowed the development of oocytes cryopreservation. With slow-freezing, survival rates of oocytes were about 65%. Vitrification consists in a rapid cooling, requiring a higher concentration of cryoprotectants and preventing formation of freezing crystals which can damage cell structures. This is especially important for egg freezing, since oocytes are large size cells with a high content of water. Vitrification has superior post-thaw survival and fertilization outcomes compared with oocytes that were slow-frozen (Rienzi *et al.*, 2017; Glujovsky *et al.*, 2014). Oocyte vitrification produces similar IVF outcomes compared with fresh oocytes and is not associated with further obstetrical or perinatal morbidity (Crawford *et al.*, 2017; Rienzi *et al.*, 2010). Moreover, concerning neonatals outcomes, no increase in chromosomal abnormalities or birth defects has been noted in children born from cryopreserved oocytes (Noyes *et al.*, 2009; Cobo *et al.*, 2014).

This safe and efficient technique is no longer considered as experimental according to the criteria by the ESHRE Special Interest Group "Ethics and Law" (Provoost *et al.*, 2014; ISFP Practice Committee *et al.*, 2012; Practice Committees of American Society for Reproductive Medicine, Society for Assisted Reproductive Technology, 2013; Loren *et al.*, 2013; Schmidt *et al.*, 2012).

Number of oocytes required

The minimal number of vitrified oocytes required to achieve a live birth remains unknown. Vaughan *et al.* (2017) observed that pregnancy rate was significantly higher when ≥15 oocytes were retrieved (41.3%) than <15 oocytes (36.5%). For Cobo *et al.* (2016), in adult women having frozen their gametes for nonmedical reasons, 10–15 eggs were associated with a 85% chances of live birth. Age at time of FP is a major factor influencing success rates: with 15 mature oocytes, the pregnancy rates were 40%, 36%, 27% and 16% in women <35, 35–37, 38–39 and >40 year-old, respectively (Sunkara *et al.*, 2011). More recently, in women having undergone autologous IVF-ET treatment using vitrified and warmed oocytes, the overall vitrified-

warmed oocyte to live birth efficiency was 6.4% (Doyle *et al.*, 2016). Based on these data, the authors recommend the cryopreservation of 15–20 or 25–30 mature oocytes in women aged <38 years or 38–40 years, respectively (Doyle *et al.*, 2016; Stoop *et al.*, 2014a). Thus, the higher the number of oocytes yields, the higher the probability to achieve a live birth after utilization (Drakopoulos *et al.*, 2016). Until now, after cancer treatment, <5% of patients returned to use their oocytes (Martinez *et al.*, 2014).

Ovarian Tissue Cryopreservation OTC

This technique consists in the removal of a part or an entire ovary during a laparoscopy. Then, small fragments of ovarian cortex containing primordial follicles are cryopreserved. The ovarian tissue can later be orthotopically transplanted into a peritoneal window or into one of the ovaries, with the purpose of restoring both endocrine and exocrine ovarian function with possibility of pregnancies natural or medically induced. Several transplantations may be performed successively in a single patient. Some heterotopically transplantations have been experienced (subcutaneous tissue of the abdominal wall, forearm or chest wall) with no result in terms of fertility.

The major issue with OTC is the great follicular loss due to ischemic events during the freezing and thawing procedures of cortical strips. As a consequence, the function of frozen-thawed ovarian tissue after grafting remains uncertain, even though the chances of restoring optimal ovarian function and fertility depend on the follicular density at the time of cryopreservation. Amount of ovarian tissue harvested (biopsies/cortical strips or whole ovary) is still debated. It may depend on the pathology, the expected gonadotoxicity of treatment, patient's age and ovarian reserve. Actually, partial or total oophorectomy automatically implies the irreversible loss of a part of the primordial follicular pool, possibly reducing the chance of natural pregnancies.

The first birth achieved with this technique was published more than 10 years ago by Donnez *et al.* (2004). To date, around 90 births have been reported worldwide (Jensen *et al.*, 2017) and OTC is performed in many countries.

Ovarian function, i.e., regular menstruation, was observed in two-third of transplantation cases (Van der Ven *et al.*, 2016). The mean duration of ovarian endocrine function after transplantation is about 5 years, offering a treatment of the negative effects of POI on quality of life such as osteoporosis, cardiovascular diseases and depression (ISFP Practice Committee *et al.*, 2012). Few complications are reported with those procedures. Live birth rates per transplantation are around 20% (Jensen *et al.*, 2017; Van der Ven *et al.*, 2016; Dittrich *et al.*, 2015; Donnez *et al.*, 2013). In a recent Belgian publication with more than 500 patients who underwent OTC between 1997 and 2013, <5% of patients underwent autotransplantation with 33% live birth rate per transplantation (Jadoul *et al.*, 2017). In the meta-analyze of Pacheco and Oktay (2017), with 309 ovarian tissue transplantations performed, cumulative live birth rate and endocrine restoration rate was 37.7% and 63.9% respectively.

The age limit to perform OTC still remains controversial. For many authors, OTC should not be proposed from women older than 35. However, pregnancies have been observed for women aged 36–39 (Meirow *et al.*, 2016). As a consequence, ovarian reserve and thus follicle density at the time of tissue cryopreservation may be a better criterion than age. OTC should be performed theoretically before chemotherapy. In some cases, tissue can be removed after gonadotoxic treatment and live births have been obtained among patient with IVF following transplantation of ovarian tissue removed after chemotherapy, nevertheless with apparently lower live birth rate than chemotherapy-naïve patients (Meirow *et al.*, 2016).

Moreover, some cancers might preclude transplantation owing to a high risk of reintroducing malignant cells (leukemia …) (Dolmans *et al.*, 2010). Some cases reported of leukemia survivors and transplantation after control of the absence of leukemic cells within the graft with no cancer recurrence observed (Meirow *et al.*, 2016). Authors highlight the fact that in hematologic malignancies, chemotherapy before OTC reduces the risk of malignant cells in the graft by clearing blood. At least, no methods can guarantee the absence of cancer cells in tissue.

Risks of surgery should be considered each time, especially in context of leukemia with potential platelet dysfunction and hemorrhagic complications.

After a large increase, the number of OTC procedures decreases with the improvement and spreading of oocyte vitrification. It remains hard to assess efficacy of OTC with only few publications concerning his effectiveness. This method still remains considered as experimental but with regard to recent results, OTC seems a viable option.

In Vitro Maturation of Oocytes

In vitro maturation consists in the retrieval of immature oocytes by transvaginal puncture under ultrasound guidance. Then, immature oocytes are put in a culture media for 24–48 h. Around 60% of maturation rate are observed (Shalom-Paz *et al.*, 2010) and allowed the obtaining of mature oocytes. This FP technique requires no ovarian stimulation and could be used without delay whatever the cycle phase, in case of emergency or when contraindications to ovarian stimulation exist.

The number of immature oocytes recovered is strongly correlated with the number of antral follicles visible into the ovaries and anti-Müllerian hormone (AMH) level (Sonigo *et al.*, 2016). As a result, IVM alone may not be suitable in patients with a low ovarian reserve.

The competence of an oocyte obtained from IVM is certainly reduced compared with one retrieved after in vivo maturation occurring during COS. And there are very few data concerning IVM for FP with only two pregnancies obtained after IVM practicing

during ovarian tissue removal (Prasath *et al.*, 2014; Uzelac *et al.*, 2015). However, data from thousands of children born from this technique realized for infertile women are promising especially with no increased congenital abnormalities (Buckett *et al.*, 2007).

GnRH Analogs

Some authors proposed the use of GnRH agonists (GnRHa) in order to prevent premature ovarian insufficiency induced by cytotoxic treatment. A monthly therapy leads to a reversible resumption of menses. The role of ovarian function suppression with use of GnRHa in terms of fertility preservation has remained controversial for years and is not recommended by numerous guidelines. GnRHa are used with the hypothesis that the drop induced in FSH levels will limit the growing initiation of follicles and thus avoid the destruction of growing follicles observed with exposition to cytotoxic drugs. Moreover, they could lead to an hypoperfusion of the ovary and thereby a lowered exposition to chemotherapy agents. At least, the sphingosine 1 phosphate up-regulation induced by GnRHa could have anti-apoptotic effects.

In most studies the primary endpoint analyzed was the resume of menses. The OPTION study provides evidence that GnRHa reduce the risk of POI (amenorrhea and elevated FSH) to 18.5% versus 34.8% in the control group ($P = 0.048$) (Leonard *et al.*, 2017). The meta-analyze of Lambertini *et al.* (2015), similarly observed a reduced risk of POI with agonist with a trend to an increase in pregnancy rate. In the POEMS study, administration of GnRHa during chemotherapy appeared to protect against ovarian failure and pregnancies occurred in more women in the GnRHa group than in the chemotherapy alone group (21% vs. 11%; OR: 2.45; 95% CI 1.09–5.51 $P = 0.03$) (Moore *et al.*, 2015).

However GnRHa do not provide long term protection on ovarian reserve after chemotherapy (Demeestere *et al.*, 2016). In the OPTION study, a marked fall in AMH was observed with no difference between groups (Leonard *et al.*, 2017). At least, concerning pregnancy rate, Yang *et al.* (2013) showed in a meta-analyze including 5 RCT and 528 breast cancers that GnRHa reduce the risk of POI chemotherapy-induced without improving live birth rate.

In conclusion, temporary ovarian suppression with GnRHa might reduce chemotherapy-induced gonadotoxicity and can be considered for women interested in preserving ovarian function and fertility, but not as an exclusive option.

FP Techniques in the Future

OTC and in vitro activation

Kawamura *et al.* (2013) demonstrated that the disruption of hippo signaling pathway in the ovary and acting on the AKT pathway leads to promotion of primordial follicle growth. Suzuki *et al.* (2015) proposed an in vitro activation (IVA) of residual follicles from the ovarian tissue before grafting, via stimulation of the AKT pathway, in order to improve the ovarian response to stimulation for women with POI. IVA allowed a successful production of mature oocytes among women with POI who as previously received ovarian stimulation with no follicular growth. Two successful live births have already been reported (Suzuki *et al.*, 2015).

In vitro folliculogenesis

In vitro culture of pre-antral follicles still remains a key challenge but could allow the utilization of primordial resting follicles (Telfer and Zelinski, 2013).

Germ line cells

Isolation of oogonial stem cells have been reported without data on their true role in the ovary. The utilization of germ line cells could represent an option in the future offering an unlimited source of primordial follicles.

Artificial ovary

The development of transplantable artificial ovary is on study. A team has recently demonstrated that isolated human pre-antral follicles embedded in fibrin formulations and xenografted into peritoneal pockets in nude mice are all viable after 1 week grafting. Fibrin seems to be a promising matrix for obtain an artificial ovary, supporting follicle survival and development (Paulini *et al.*, 2016). This could represent an option in pathologies with risk of re-introduction of malignant cells in disease free survivors with ovarian tissue transplantation.

Ovarian protective agents

Given that chemotherapy also triggers activation of dormant follicle growth, immune modulator that acts on the PI3K/PTEN/AKT follicle activation pathway and AMH, a negative regulator of follicle activation, are candidates to prevent depletion of the primordial follicles pool chemotherapy-induced (Kalich-Philosoph *et al.*, 2013; Roness *et al.*, 2016).

Oncological Indications

It is now well-established that all women in reproductive age facing with cancer should be referred early to reproduction specialist in order to discuss PF options before initiating gonadotoxic treatment. Fertility impairment could deeply affect cancer patients' long term quality of life. As a consequence, FP is considered as a fundamental part of cancer treatment. Numerous cancers are diagnosed in women in reproductive age, but breast cancers, lymphomas, leukemia or gynecologic malignancies represent the most encountered cancers.

Chemotherapy has detrimental effects on gonads and is associated with risk of POI for cancer survivors. Various mechanisms are implied (1) follicle stockpile destruction; (2) a "burn out" effect with increasing of growing follicle then undergoing atresia (3) vascular injuries and (4) ovarian fibrosis (Meirow *et al.*, 2001). Damages on the ovarian function depend on the drug employed, the dose, the association with other drugs or radiotherapy and above all, patient's age and ovarian reserve when initiating gonadotoxic treatment (Meirow *et al.*, 2010). Alkylating agents, such as cyclophosphamide, are highly gonadotoxic. Conditioning by busulfan or total body irradiation, used before hematopoietic stem cells transplantation (HSCT), is also highly gonadotoxic and causes impairment of fertility in most of cases.

The gonads are very sensitive to radiotherapy. The dose required to destroy 50% of the primordial follicles (LD50) is <2 Gy (Wallace *et al.*, 2003). Moreover, the dose of fractionated radiotherapy at which ovarian failure occurs was found to decrease with increasing age at treatment: at birth was 20.3 Gy; at 10 years, 18.4 Gy; at 20 years, 16.5 Gy; and at 30 years, 14.3 Gy (Wallace *et al.*, 2003). At least, radiotherapy causes reduction in uterine volume, myometrial fibrosis, vascular damages, and endometrial injury, which are behind the risk for pregnancy-related complications, including spontaneous miscarriages, preterm labor and delivery, low birth weight, and placental abnormalities (Meirow and Nugent, 2001).

When it is possible (i.e., sufficient delay before initiating treatment and no contra-indication to hormonal ovarian stimulation), oocytes cryopreservation after COS represents the technique of choice for female fertility preservation. In the literature, ovarian response to stimulation among cancer patients is matter to debate. In a recent study, it has been demonstrated that cancer patients have similar response to ovarian stimulation compared with controls of the same age and ovarian reserve parameters (Quinn *et al.*, 2017). Patients could also be candidate to a co-treatment by GnRHa. In case of emergency to initiate gonadotoxic treatment, OTC and/or IVM should be discussed.

Some cancers imply specific managements.

Breast Cancer

Breast cancer is the most encountered cancer among young women. Chemotherapy is often indicated. If surgery is first planned, ovarian stimulation with anti-aromatase in order to preserve oocytes could be proposed before chemotherapy. If neoadjuvant chemotherapy is proposed, OTC should be discussed considering the fact that data are reassuring concerning the risk of reintroducing malignant cells with grafting in this context. The possibility of BRCA 1 or BRCA 2 mutation (around 10% of young women with breast cancer) (Wang *et al.*, 2014) should be mentioned and that the graft of ovarian tissue is not suitable in these women at high risk. IVM represent another option in case of neoadjuvant therapy, alone or associated with OTC. At least, GnRHa is now recommended for breast cancer irrespective of hormone receptors status (Paluch-Shimon *et al.*, 2016; Lambertini *et al.*, 2017) but not as an alternative option to embryo/oocyte cryopreservation.

Ovarian stimulation is theoretically contra-indicated in breast cancer patients receiving neoadjuvant therapy. However, a single and recent study reported data for patients who underwent COS for FP before neoadjuvant chemotherapy (Chien *et al.*, 2017). Thirty-four women, with BC stage II–III, aged 35 on average, almost half with positive hormonal receptors, were stimulated and compared with controls. No significant difference was observed in terms of mean time from diagnosis to initiate chemotherapy, rates of pathologic complete response, recurrence and death between the two groups with a median follow-up of 79 months (Chien *et al.*, 2017).

For some authors, fertility preservation should be systematically proposed to women with BRCA mutations without cancer history, due to the high risk of breast cancer at a young age with gonadotoxicity of chemotherapy and duration of hormonotherapy with necessity to postpone pregnancy. Authors suggest an accelerated loss of primordial follicles and increased apoptosis in response to chemotherapy among those patients. Especially when considering the absence of risk due to stimulation in BRCA ½ carriers. Furthermore, recent studies showed that BRCA mutation carriers may have a lower ovarian reserve with higher risk of premature ovarian insufficiency and poorer reproductive outcomes. Moreover, some authors found poorer ovarian response to hormonal stimulation among BRCA mutations carriers with less oocytes recovered (Oktay *et al.*, 2010). Several studies show earlier menopause (Lin *et al.*, 2013; Finch *et al.*, 2013; Rzepka-Górska *et al.*, 2006) and lower AMH concentrations in BRCA mutations carriers (Wang *et al.*, 2014; Titus *et al.*, 2013).

Haematologic Malignancies

Chemotherapy is commonly indicated from low to high gonadotoxicitiy as before hematopoietic stem cells transplantation (HSCT) with risk of intensification.

For Hodgkin and non-Hodgkin lymphomas, oocytes and/or embryos cryopreservation is recommended when 10–12 days are available before initiating chemotherapy (ISFP Practice Committee *et al.*, 2012). OTC could be realized in case of emergency to start the chemotherapy or in case of highly gonadotoxic treatment, even when patients have already received chemotherapy. The risk of reintroducing cancer cell is considered as moderate (Dolmans *et al.*, 2010).

For women with leukemia, OTC is not recommended owing to the high risk of malignant cell reintroduction (Dolmans *et al.*, 2010). However, for very young women, OTC should be considered given the future advances in in vitro folliculogenesis, when a highly gonadotoxic chemotherapy is planned.

Other Gynecologic Cancers

Ovarian cancer is a rare cause of cancer among women of reproductive age. In stage 1, conservative surgery could be performed. Likewise, in Borderline tumors, conservative surgery should be offered if possible and ovarian stimulation is often possible after surgery in order to cryopreserve oocytes and/or embryos (Daraï *et al.*, 2013). OTC is not recommended owing to the risk of reintroducing malignant cells.

For endometrial cancer in early stage, fertility-sparing treatment using progestin could be introduced for women in reproductive age instead of radical surgery. Patients should follow-up with hysteroscopy and endometrial sampling. Then, patients could obtain pregnancy (spontaneous or medically assisted). When the parental plan is achieved, hysterectomy should be performed.

Pelvic Radiotherapy

Pelvic irradiation can be indicated in colo-rectal or cervix cancers. The option is oocytes and/or embryos freezing associated with ovarian transposition. This last procedure is hard to realize with stimulated ovaries. Ovarian transposition could only preserve endocrine function.

OTC should be discussed.

Patients must be informed that pelvic irradiation is associated with a high morbidity when pregnancy occurs (spontaneous miscarriages, preterm labor and delivery, low birth weight, and placental abnormalities).

For cervical cancer, in case of nonconservative surgery, patients should turn toward adoption or surrogacy. Uterus transplantation is an experimental technique with few live births reported worldwide and with high complications (Brännström *et al.*, 2015).

Medical Indications

Women at Risk of Premature Ovarian Insufficiency

Premature ovarian insufficiency is defined by resumption of cycle before the age of 40: primary or secondary amenorrhea >4 months with low level of estradiol (<50 pg/mL) and high level of gonadotrophins (FSH $>$ 25UI/L on two analysis spaced of 1 month). It concerns 1% of women (Nelson, 2009). Early exhaustion of ovarian follicle stockpile can be due to chromosomic, genetic, or auto-immune diseases as well as consequence of surgery, chemotherapy or radiotherapy. However, in <70%, POI appear idiopathic with no cause identified. Among chromosomal abnormality associated with POI, the most common is Turner syndrome.

Turner syndrome

During Turner syndrome, primary or secondary POI is due to premature and accelerated exhaustion of the follicular stockpile. Various phenotypes are encountered owing to the possibility of mosaïcism. Natural pregnancies are observed among 5.6% of patients with 30% risk of miscarriages (Bernard *et al.*, 2016). Pregnancies with TS is associated with obstetrical complications (caesarian section, hypertension, pre-eclampsia, …) and fetal abnormalities (Hovatta, 2012). Pre-conceptional evaluation is needed in order to diagnose cardiovascular contra-indications to pregnancy. If pregnancy occurs, specialized follow-up is required.

Until now, egg donation was the most common option for TS women to achieve pregnancy. Given the noteworthy advances in FP, ovarian stimulation could be considered in order to cryopreserve oocytes for TS young women with spontaneous puberty. When ovarian reserve is already reduced with risk of ovarian unresponsiveness to hormonal stimulation, natural cycle could be planned. During childhood, when follicles are still present, ovarian tissue cryopreservation should be discussed (Oktay *et al.*, 2016).

Whatever the technique use, the patient and/or their parents should be informed of the lack of data concerning gametes or ovarian tissue competency in this context. Moreover, the utilization of gametes freezing will be function of the patient status.

FMR1 premutation

Females carrying a premutation do not present any sign of the classical Fragile X symptoms, but 20% of them will experience a primary ovarian insufficiency (POI) leading to infertility before the age of 40 (Sherman, 2000). FMR1 premutation is more often encountered in case of familial history of POI and the highest risk of POI is observed for premutation alleles in the range of about 80–100 repeats (Allen *et al.*, 2007). Oocyte vitrification after ovarian stimulation is possible for premutated women given the risk of POI. Pre-implantation diagnosis could be proposed to patients.

Others genes are associated with POI such as BMP15, SF1, NOBOX, FOXL2. Identifying mutations should lead to fertility counseling and discussion about FP options.

Congenital galactosemia

Congenital galactosemia is a rare metabolic disease causes by abnormalities of galactose metabolism. Despite diet without galactose, most girls will develop POI (Rubio-Gozalbo *et al.*, 2010), due to a reduced number of primordial follicle at birth and an accelerated loss of follicles (Rubio-Gozalbo *et al.*, 2010). Patients are encouraged not to postpone pregnancy. Moreover, oocyte vitrification should be discussed after puberty. In the same way as for TS girls, ovarian tissue preservation could be discussed for prepubertal girl before exhaustion of follicles stockpile.

Auto-Immune Diseases

The natural history of systemic disease such as systemic lupus erythematosus (SLE), antiphospholipid syndrome (APS), scleroderma, Sjögren syndrome, vascularitis often encounter fertility issues. Indication of FP is clearly established when a gonadotoxic treatment, most of the time alkylating agents, such as cyclophosphamide (CTX), is planned. The gonadotoxicity of CTX depend on dose and age at time of treatment (Carré-Pigeon and Schubert, 2007). Moreover, a delay of 6 months is necessary after the end of treatment and conception owing to the risk of congenital abnormalities. Other treatments like methotrexate or corticosteroids are not gonadotoxic and there is no data concerning monoclonal antibodies or anti-TNF.

Before initiating a treatment with CTX, patients should be counseled about the risk of ovarian insufficiency. The minimal dose sufficient should be employed and FP be discussed. Oocytes vitrification after ovarian stimulation is possible but could be contraindicated in case of antiphospholipid syndrome for example. It should be emphasized that FP in such a context often requires a multidisciplinary management.

If the indication to FP in case of alkylating treatment is well established, the use of FP technique for auto-immune disease is still debated. It is not clear if all systemic diseases per se lead to diminished ovarian reserve. Ovarian reserve exhaustion is mostly the consequence of alkylating agents. However, some disease such as lupus polyarthritis rheumatoid, Behçet disease and spondyloarthritis are associated with diminution of the ovarian reserve regardless of the treatment received. At least, sarcoidosis, granulomatosis vascularitis and histiocytosis could lead to hypogonadotropic hypogonadism due to hypophysis infiltration. Moreover, patients should be advised that the use of cryopreserved oocytes/embryos will be conditioned by evaluation of the risk of pregnancy obstetrical adverse outcomes.

Systemic lupus erythematosus

It is well known that infertility is associated with APS and SLE (Carp *et al.*, 2012) via ovarian failure, implantation failure and pregnancy losses. But, it is not proven that SLE per se is responsible for an exhaustion of primordial follicle stockpile (Andreoli *et al.*, 2017). Data on AMH levels in lupus women are conflicting, but many studies suggesting a lower ovarian reserve in those patients. AMH appeared to be reduced in pre-menopausal lupus patients during reproductive age compared to controls, even in women never treated with CTX and despite mild disease activity, suggesting a decreased ovarian function in lupus women regardless of a regular menstrual cycle (Lawrenz *et al.*, 2011; Ma *et al.*, 2013). Phenomenon of auto-immune ovaritis could be hypothetized. On the other hand, other authors found no difference in AMH between female patients and controls (Morel *et al.*, 2013). Recently, Gasparin *et al.* (2016) reported similar levels of AMH in 40 pre-menopausal women and 40 healthy controls, even after adjusting for age. It appears not clear whether SLE per se has a negative influence on ovarian reserve, regardless of the exposure to cytotoxic treatment. In a cross-sectional study on 216 lupus women, AMH levels were found to correlate with age and cumulative dose of CTX (Mok *et al.*, 2013).

To conclude, women with a diagnosis of APS and/or SLE should be properly counseled on fertility, especially on the negative impact of disease-unrelated factors as tobacco use, alcohol consumption and increasing age. According to EULAR recommendations, when multiple risk factors for impaired fertility coexist, ovarian reserve should be assessed in female lupus patients at a younger age than recommended for the general population (Andreoli *et al.*, 2017). If an alkylating agent is indicated, cryopreservation of oocytes/embryos is an option (Henes *et al.*, 2012). GnRH agonists could be introduced prior to initiation of CTX (Brunner *et al.*, 2015). IVF techniques with ovarian stimulation are safe and efficacy for women with quiescent SLE and/or APS (Orquevaux *et al.*, 2017; Bellver and Pellicer, 2009) with few flare of disease and thrombo-embolic events. In case of positive aPL, a prophylaxis should be initiated with low molecular weight heparin and/or low dose of aspirin and will be stop at least 12 h prior to oocytes pick-up (Andreoli *et al.*, 2017). Ovarian hyperstimulation should be avoided using antagonist protocol with GnRHa triggering. In case of active disease with contraindication to ovarian stimulation, IVM should be indicated avoiding any ovarian stimulation and its detrimental consequences.

Diseases Unresponsive to Immunosuppressive Therapy

It could concern hematological diseases such as sickle cell anemia, thalassaemia major or plastic anemia. When HSCT is indicated, oocytes vitrification must be proposed and/or OTC depending on the gonadotoxicity expected of the conditioning treatment. In case of ovarian stimulation, thrombosis risk must be evaluated due to the hyperestrogenia induced and a prophylaxis could be recommended.

Endometriosis and Benign Ovarian Disease

Endometriosis is a frequent hormone dependent disease encountered in around 5%–10% of women in reproductive age (Coccia *et al.*, 2010). Endometriosis can cause infertility, pain and premature ovarian insufficiency.

Various mechanisms can lead to infertility: (1) reduced number of antral follicle consequence of direct toxicity of endometriosis on healthy adjacent ovarian tissue occasioning burn out effect and mechanical distension, and iterative ovarian surgeries with the removal of healthy adjacent ovarian tissue because endometriomas are coherent to the ovary and it turns out to be hard to separate capsule and healthy ovarian tissue, (2) chronic pelvic inflammation, (3) adhesions and anatomic changes, (4) tubal alteration, (5) and adenomyosis often encountered during this disease (Vercellini *et al.*, 2014). As a consequence, several women with endometriosis will require ART to obtain pregnancy. This pathology tends to recur after surgical treatment (Donnez *et al.*, 2012a). The alteration of ovarian reserve manifests as a decrease in AMH level observed immediately after surgery when bilateral (Raffi *et al.*, 2012).

PF for women with endometriosis remains controversial. More and more teams include FP in endometriosis management but without existing consensus. According to Somigliana *et al.* (2015), women with bilateral endometriomas, recurrent cysts or iterative surgeries might benefit of PF especially for women more than 35 years or presenting risk factors for POI.

Elizur *et al.* (2009) reported the first case of oocytes cryopreservation in a young woman with endometriosis in 2009. Some authors have suggested to use ovarian tissue cryopreservation for endometriosis (Oktay and Oktem, 2010). In 2012, Donnez et al., have reported the first case of live birth after grafting of ovarian tissue retrieved during bilateral ovariectomy for endometriosis (Donnez *et al.*, 2012b). There is no data on the risk of disease recurrence when transplantation of ovarian tissue.

The first step of PF in the field of endometriosis consists in minimizing ovarian surgery with reasonable indication of surgical treatment in order to preserve ovarian reserve. When surgery is required, the intervention should be performed by experienced surgeons with minimal surgery energy preventing thermal injury during hemostasis procedure and when it is possible cystectomy should be performed rather than ovariectomy (Roman *et al.*, 2011).

Otherwise, oocyte vitrification should be discuss when it is possible. Realization of ovarian stimulation in order to cryopreserve oocyte should be undertaken when ovarian reserve is not too much compromise ovarian reserve. Indeed, ovarian response is diminished after preexisting ovarian surgery (Somigliana *et al.*, 2009). The presence of large endometriomas (≥ 5 cm) at time of IVF significantly decreases the number of oocyte retrieved compared with the contralateral healthy ovaries (Ferrero *et al.*, 2017). But, most of the time, women are referred too late with and ovarian reserve is yet reduced compromising de facto the efficacy of oocytes vitrification procedure. Several ovarian stimulations could be done in order to obtain a sufficient oocytes number but with increasing in both cost and impact of procedure.

Moreover, ovarian stimulation appear to be safe in endometriosis context with few complications, particularly no increased risk of ovarian abscess after oocytes harvesting in this context (Benaglia *et al.*, 2008). The risk of pain during hormonal treatment should be explained to women. Literature data are scarce but reassuring concerning complication occurring during ovarian stimulation in endometriosis context as well as the risk of recurrence (Coccia *et al.*, 2010).

To conclude, women with endometriosis diagnosis should be counseled about PF possibilities. Further studies should be done in order to evaluate the benefice of FP for endometriosis regarding cost-effectiveness aspect, impact on the use of egg donation, on the number of IVF performed for elderly women. It is important to define which group of endometriosis patient would benefit from PF.

Benign Gynecologic Diseases

Every pelvic surgery could lead to diminution of the follicular stockpile without alteration of oocytes quality. When a risk of recurrences exists (teratoma, endometriosis …), FP should be discussed. In case of single ovary, the risk of stimulation with ovarian torsion should be underlined. Oocyte vitrification could be indicated for women at risk to develop POI: bilateral cysts, unilateral with single ovary or recidive on remaining ovary. It could be performed before or after surgery depending on predictive response to ovarian stimulation and ovarian accessibility.

Gender Reassignment Procedures

A counseling about FP is recommended before starting hormone therapy or undergoing surgery to remove reproductive organs' even at a younger age (Martinez and International Society for Fertility Preservation–ESHRE–ASRM Expert Working Group, 2017). FP techniques should be undergone prior to puberty blockage in adolescents and before treatment with cross-hormones in both adolescents and adults (Committee on Adolescent Health Care, 2017). Currently, there is no data in prepubertal or pubertal adolescents who will never develop reproductive function in their natal sex.

Oocytes Banking for Anticipated Gamete Exhaustion

In many countries, oocytes vitrification is available for women wanting to postpone maternity due to the decline of follicle stockpile with aging. The goals are to bank oocytes and to anticipate gamete exhaustion (Stoop *et al.*, 2014b). The spreading of this "societal" FP could lead to a diminished use of egg donation.

Conclusion

Given recent improvements in terms of techniques and results, fertility preservation is now offered in numerous situations threatening ovarian reserve. Appropriate counseling by trained team should be provided to candidates for fertility preservation in order to support them in making decisions. Ethical issues should always been considered and further researches are warranted.

Female Hormonal Contraception

Genevieve Plu-Bureau, Paris Descartes University, Paris, France

Abbreviations

CHC	Combined hormonal contraceptives	**VTE**	Venous thromboembolism event
EE	Ethinyl-estradiol	**POC**	Progestin only contraceptives
IUD-LNG	Intra-uterin device with levonorgestrel	**OR**	Odd ratio
		IC	Confidence interval

Introduction

Female hormonal contraceptives are one of the most commonly proposed birth control methods, used by several million women worldwide (United Nations, 2013). The use of contraceptive methods aims to prevent the occurrence of an unwanted pregnancy during a given period and this, reversibly. The ideal contraception should be totally effective, acceptable, perfectly well tolerated, while preserving the subsequent fertility (United Nations, 2013). Despite a very wide choice of contraceptive methods currently available, such contraception does not exist.

Initially, combined hormonal contraceptives (CHC) delivered a daily dose of 150–100 μg of ethinyl-estradiol (EE) or mestranol and a progestin such as norethisterone acetate or norethindrone (Christin-Maitre, 2013). Due to results having early showed that these drugs increased the risk of cardiovascular disease, formulations of CHC have dramatically changed over the past 50 years (Bitzer and Simon, 2011). Subsequent developed newer-generation progestins have resulted in a stronger progestogenic activity and decreased androgenic effects such as acne, hirsutism and deleterious lipid changes (Sitruk-Ware and Nath, 2010). Finally, nonoral delivery methods represent a recent advancement in CHC, including the contraceptive vaginal ring and the transdermal contraceptive patch.

These different types of hormonal contraceptives have advantages and disadvantages. The main deleterious effect of combined estrogen/progestin contraception remains vascular effects. The impact on the risk of cancer is either protective or deleterious. Finally, noncontraceptive benefits are important in some clinical circumstances. After a review of classification of hormonal contraceptive, this article details these effects.

Classification of Hormonal Contraceptives

It is important to distinguish combined hormonal contraceptives (CHC) and progestin only contraceptive (POC), each with their indications, contraindications and potential side effects.

Combined Hormonal Contraceptives

Composition

These contraceptions combine two types of molecules: an estrogen (EE or estradiol) and a progestin. The latter is classically classified into generation (first, second, third) or "other progestins," depending on their date of commercialization and their pharmacological properties (**Table 1**). The estrogen-progestin balance depends on the dose and the type of the two hormones. This balance induces very different hormonal climates. The different indications and side effects derive directly from it. The early CHC consisted of high doses of synthetic estrogen (150 μg of EE or mestranol) and androgenic progestin such as norethisterone acetate or norethindrone. The contemporary CHC now deliver 50–15 μg per day of EE or 1–3 mg of estradiol or estradiol valerate (Bitzer and Simon, 2011). Progestogens used in combined hormonal contraception are mainly progestins derived from 19 nortestosterone (norsteroids). Derivatives of norethisterone, norethisterone acetate, lynestrenol, ethynodiol acetate or norethynodrel are the first generation and are no longer used. The currently available oral contraceptives are both 2nd and 3rd generation pills. Second generation pills contain norgestrel or levonorgestrel. Since the beginning of the 1980s, newer progestins (desogestrel and gestodene) consist of the 3rd generation pills (Sitruk-Ware and Nath, 2010). Norgestimate is a progestin, initially classified as 3rd generation but it is probably between 2nd and 3rd generation. These compounds have significantly reduced the EE dose due to their higher antigonadotropic activity. Moreover, their clinical use is theoretically associated with less androgenic adverse effects. Drospirenone, an aldosterone antagonist, and cyproterone acetate are molecules providing high-antiandrogenic effects and are classified as other generation pills with chlormadinone acetate and dienogest (Sitruk-Ware and Nath, 2010). These products have theoretically no androgenic properties and are antiandrogens for drospirenone and cyproterone acetate (Sitruk-Ware, 2004).

Classification according to generations is irrespective of EE doses and is thus debated. In January 2014, The EMA published a new classification depending on specific molecule of progestin and not on generation (EMA, 2014).

Table 1 Classification of different types of CHC

Types	*Molecules of estrogen*	*Molecules of progestin*	*Route of administration*
First generation	EE	Norethisterone	Oral
Second generation	EE	Norgestrel or levonorgestrel	Oral
Between 2nd and 3rd generation	EE	Norgestimate	Oral
Third generations	EE	Desogestrel	Oral
		Gestodene	
Others generations	EE	Drospirenone	Oral
		Cyproterone acetate	
		Chlormadinone acetate	
	Estradiol	Dienogest	Oral
	Estradiol valerate	Nomegestrol acetate	
	EE	Norelgestromin	Transdermal patch
	EE	Etonogestrel	Vaginal ring

Finally, hormonal contraceptives can be also classified according to the route of administration and include nonoral administered drugs such as the combined EE/norelgestromin transdermal patch and EE/etonogestrel vaginal ring. These two new methods provide continuous hormone dosing and simplify compliance.

Mechanism of action

The mechanism of action of these combined pills is mainly through the inhibition of ovulation, the antigonadotropic effect resulting in the absence of LH and FSH peaks. Moreover, the pill induces an inhibition of the follicular growth, a thickening of the cervical mucus by the progestin and an atrophy of the endometrium which becomes unfit for a possible implantation (Black *et al.*, 2015).

Progestin Only Contraception

Composition

Although the original development of oral contraceptives focused on progestin-only products, current POCs are less used than CHC because of its poorer uterine tolerance. Indeed, the menstrual cycle is less well controlled and bleeding such as spotting are common (Grimes *et al.*, 2013). However, POCs are contraceptives which may be an attractive option for women with contraindication for CHC. Several routes of administration are available. Four types of progestin-only contraceptives are currently available (**Table 2**):

- Progestin only pill that deliver low daily doses of progestin (Norethindrone, Levonorgestrel or desogestrel).
- Injectable 3-month contraceptives (depot medroxyprogesterone acetate [DMPA]) administered intramuscularly.
- Levonorgestrel implant or more recently etonogestrel single-rod implant which provide effective contraception for 3 years.
- Intrauterine system containing levonorgestrel (SIU-LNG), effective for 5 years or 3 years for the shorter device.

Mechanism of action

The contraceptive mechanisms are essentially peripheral action exerting an antimucus effect, antinidatory and by modification of tubal mobility (Black *et al.*, 2015). An atrophy of endometrium is associated with the use of SIU-LNG. An antigonadotropic effect is observed in some women using desogestrel only pill, but not all. The contraceptive implants (levonorgestrel or desogestrel) and the intra-uterine device delivering small doses of levonorgestrel, are called long acting reversible contraception. Its major advantage is perfect compliance and is therefore indicated in women who frequently forget their pill.

Efficacy of Hormonal Contraceptives

The effectiveness of a contraceptive method is measured by the Pearl index which corresponds to the ratio of the number of pregnancies per 100 women after 12 months of use. It is expressed in percentage of years. **Table 3** summarizes the Pearl indices for each method (Trussell, 2011).

Hormonal Contraceptives and Vascular Risk

Venous Thrombosis Risk

Venous thrombosis event (VTE) is a common disease, with an annual incidence of 1–4 per 1000 persons. Before menopause its incidence is low but strongly increases with age (Oger, 2000; Naess *et al.*, 2007). Among pill users, annual VTE incidence is 10 times more common than arterial events (Lidegaard *et al.*, 2009). Since early 1960s, it has been clearly shown that CHC increased

Table 2 Type of progestin-only contraceptives

Molecules	*Route of administration*	*Efficacy duration*	*Progestin doses (mg)*
Norethindrone	Oral	24 h	0.35
Levonorgestrel			0.03
Desogestrel			0.075
Etonogestrel	Subcutaneous implant	3 years	68
Levonorgestrel	Intrauterine	5 years	52
		3 years	13.5
Medroxyprogesterone	Intra muscular	3 months	150

Table 3 Efficacity of hormonal contraceptives

Methods	*Percentage of women experiencing an unintented pregnancy during the first year of use*	
	Typical use	*Perfect use*
No methods	85	85
Oral CHC, patch, vaginal ring or oral POC	9	0.3
Progestin implant	0.05	0.05
MPA injectable	3	0.3
SIU-LNG	0.2	0.2

the risk of VTE including deep vein thrombosis, pulmonary embolism or venous cerebral thromboembolism. Hormonal contraceptive use explains a substantial part of the venous thrombotic events among childbearing-aged women and VTE is the most important determinant of the benefit/risk profile of hormonal contraceptive. Several metaanalysis have evaluated the VTE risk according to the types of CHC and POC.

Oral combined hormonal contraception

The increase in thrombotic risk is the highest the first year of CHC use and 3rd generation pill use is associated with an increased VTE risk as compared to 2nd generation pill use (OR: 1.7; 95% confidence interval 1.4–2.0) (Plu-Bureau *et al.*, 2013; Stegeman *et al.*, 2013). Specific molecules combined with EE (drospirenone or cyproterone acetate) have been now investigated. Current users of drospirenone or cyproterone acetate containing CHC are at increased risk of VTE by around 1.5–2.2 compared with levonorgestrel users (Plu-Bureau *et al.*, 2013; Stegeman *et al.*, 2013). Many biological studies have consistently shown blood coagulation activation among pill users and thus providing a biological support to the increased thrombotic risk associated with the contraceptives use (Rosing *et al.*, 2001). The third generation progestins, drospirenone and cyproterone acetate in combination with EE appear to induce a resistance to activated protein C (APC) more pronounced than biological changes observed with 2nd generation pill use (Rosing *et al.*, 1999; Kemmeren *et al.*, 2004). Sex hormone-binding globulin (SHBG), which has been recently positively correlated to APC resistance among pill users (Odlin *et al.*, 2002; Raps *et al.*, 2012), would also be another useful marker to estimate the thrombotic safety of a CHC. Overall, estrogenic climate of a contraceptive pill could be estimated by plasma SHBG and could reflect the level of thrombotic risk associated with this pill use (Raps *et al.*, 2012; Gerstman *et al.*, 1991).

The risk associated with contraceptives containing norgestimate is debated (Plu-Bureau, 2015). Indeed, the level of risk seems similar to that of levonorgestrel. This is in accordance with metaanalysis of nine published studies regarding VTE risk associated with CHC containing norgestimate which shows no difference in risk as compared with levonorgestrel (Dragoman *et al.*, 2018). However, according to data on sex hormone binding globulin and activated protein C-resistance, similar VTE risks between norgestimate and levonorgestrel CHC are not biological plausible (Hugon-Rodin *et al.*, 2014), since studies on hemostasis markers show more deleterious changes in hemostasis among users of norgestimate than levonorgestrel. These discrepancies between epidemiological results and biological data need further research.

Nonoral combined hormonal contraception

Two methods of nonoral combined contraceptives are available such as the combined ethinyl-estradiol/norelgestromin transdermal patch and ethinylestradiol/etonogestrel vaginal ring. These contraceptives have recently been evaluated on thrombotic risk. In the context of contraceptive use, nonoral route of EE administration seems to be more thrombogenic than oral route. A recent metaanalysis shows an overall assessment of VTE risk with a significant OR of 1.5 (95% CI: 1.2–1.8), suggesting that contraceptive patch is associated with a higher thrombotic risk than CHC containing the same progestin (Plu-Bureau *et al.*, 2013; Lidegaard *et al.*, 2012; Tepper *et al.*, 2017). The vaginal ring delivering levonorgestrel seems to be also associated with an higher VTE risk as compared to 2nd generation pills that contain the same progestogen (pooled OR = 1.7; 95% CI: 1.3–2.3) (Plu-Bureau *et al.*, 2013). These results are in agreement with biological data. In a randomized cross-over study aimed to compared the impact of oral

and vaginal EE administration on haemostatic variables and estrogen-sensitive liver proteins, we showed that vaginal EE was associated with similar decreased activity of the coagulation inhibitory system and similar increased SHBG levels then oral route (Sitruk-Ware *et al.*, 2007). In addition, few years later, other studies found that APC resistance was higher among users of the vaginal ring than among users of contraceptives containing levonorgestrel (Fleischer *et al.*, 2009; van Vliet *et al.*, 2010; Kluft *et al.*, 2008).

Progestin only contraceptives

Progestin only pill is a good alternative of contraception for women with contraindication of estrogen use. By contrast, low doses of both oral progestin contraceptives and intra-uterine levonorgestrel could be safe with respect to VTE risk (Blanco-Molina *et al.*, 2012; Tepper *et al.*, 2016). A recent metaanalysis has shown no increase in VTE risk among users of oral POC as compared to nonusers (OR = 1.45; 95% CI: 0.92–2.26) (Blanco-Molina *et al.*, 2012). On contrary, the use of medroxyprogesterone acetate intramuscular contraception is associated with an increased VTE risk (OR 3.2; 95% CI: 1.8–2.7) (Plu-Bureau *et al.*, 2013). This increase in VTE risk could be consistent with deleterious glucocorticoid effect of MPA on vascular risk factors. The impact of levonorgestrel IUD has been investigated and pooled OR show a significant decrease in VTE risk as compared with nonuse (OR = 0.6; 95% CI: 0.4–0.8). Finally, the Danish study provided the first assessment of the VTE risk in relation to the etonogestrel implant use (Lidegaard *et al.*, 2012) but the low sample size (only 5 cases of confirmed VTE events occurred among 29,497 person-year) did not allow concluding that etonogestrel was not associated with an increased thrombotic risk (OR = 1.4; 95% CI: 0.58–3.38).

Women with biological thrombophilia

Congenital thrombophilia increases the risk of VTE. Two metaanalysis have evaluated the VTE risk associated with CHC use and biological thrombophilia. Compared to nonusers without thrombophilia, the risk of VTE among CHC users was 15.6 (95% CI: 8.7–28.1) for carriers of factor V Leiden, 12.6 (95% CI: 1.4–115.8) for antithrombin deficient, 6.3 (95% CI: 1.7–23.9) for protein C deficient and 4.9 (95% CI: 1.4–17.1) for protein S deficient. This comparison did not reach the significance for carriers of G20210A prothrombin mutation because of a too low sample size (OR = 6.1; 95% CI: 0.8–45.6) (Wu *et al.*, 2005). In the most recent metaanalysis, the VTE risk among carriers-CHC users was sixfold as compared with noncarriers-CHC users (Van Vlijmen *et al.*, 2016). Such observations have led international guidelines to advise against the use of CHC in women with known biological thrombophilia.

Arterial Risk

Combined hormonal contraceptives

Arterial disease is an uncommon disease among childbearing-aged women. Annual incidence of myocardial infarction (MI) is 2 per million among healthy women aged 30–34-year-old and rises to 20 per million between 40 and 44 year (Farley *et al.*, 1999). With respect to stroke, the annual incidence also increases with age (6 per million at age 20–24, 10 per million at age 30–34, and 16 per million at age 40–44) (Farley *et al.*, 1999). But given the potential consequences of these arterial diseases, these are an important determinant of the benefit/risk profile of hormonal contraception.

Most epidemiological studies have shown an increased risk of myocardial infarction and stroke in users of CHC. Overall, current use of oral combined contraceptives increased the risk of MI and ischemic stroke (pooled OR: 1.7; 95% confidence interval [95% CI]: 1.2–2.3 and OR: 1.8; 95% CI: 1.2–2.8, respectively), but was not associated with the risk of hemorrhagic stroke (Plu-Bureau *et al.*, 2013). The increase in ischemic arterial disease was higher among 1st generation pill users as compared to 2nd or 3nd generation pill users. By contrast, the risk of ischemic arterial disease among current users of 2nd or 3nd generation pill was similar for MI risk and for ischemic stroke. In conclusion, newer generation formulations of CHC as well as the nonoral hormonal contraceptive do not seem to be safer than 2nd generation hormonal contraceptives. Surprisingly, a more recent network metaanalysis (Roach *et al.*, 2015) with selected articles and including 24 studies show that CHC users were not at increased risk of myocardial infarction or ischemic stroke compared with nonusers (OR 1.0; 95% CI 0.9–1.0). The risks did not vary according to the generation of progestogen or according to progestogen type. However, when the authors stratified preparations according to estrogen dose, the risk of myocardial infarction or ischemic stroke seemed to increase with higher doses of estrogen. These two metaanalyses are not comparable because included studies are not the same. In our review, the included studies were set up after 1990 and only assessed preparations containing low doses of estrogen.

Progestin only contraceptives

Very few studies have evaluated arterial risk in relation to the use of progestin-only contraceptives. Two metaanalyses were performed on the risk of IDM and stroke. These do not show an increase in arterial risk associated with the use of this type of contraception (Chakhtoura *et al.*, 2011; Chaktoura *et al.*, 2009).

Arterial risk factor

Metabolic adverse effects include changes in the lipid profile, carbohydrate and blood pressure. The effect of combined contraception on lipids depends on the dose of estrogen and the type of progestogen used in its composition (Sitruk-Ware and Nath,

2013). If it is an estrogen-dominated pill, there is a larger increase in triglycerides compared to progestin-only pills. This increase still exists with the pills dosed at 20 μg EE, as well as an increase in HDL-cholesterol.

Some oral contraceptives may cause some degree of insulin resistance and hyperinsulinism. These are primarily oral contraceptives with a high dosage of estrogen and progestin derived from 19-nortestosterone. The contemporary contraceptives have limited effects on carbohydrate metabolism (Sitruk-Ware and Nath, 2013).

The frequency of arterial hypertension under estrogen/progestogens is poorly evaluated. However, there is a moderate increase in blood pressure by stimulation of renin in about 5% of cases (Tepper *et al.*, 2013). But there are large individual variations in this response. For some authors, oral contraceptives most often only reveal or aggravate a predisposed terrain. The risk of high blood pressure due to oral contraceptives increases with age, becoming of real concern only after age 35.

In practice, the evaluation of arterial risk factors is important. **Table 4** summarizes the risk factors to be assessed before prescribing any CHC.

Hormonal Contraceptives and Others Risks and Benefits

Risk of Cancers

Breast cancer is the most common cancer in terms of incidence, although events are very rare at the ages of use of CHC. Other cancers are also important to evaluate the benefit balance of hormonal contraception.

Breast cancer

The metaanalysis of the Collaborative Group on Hormonal Factors in Breast Cancer published in 1996 showed a slight increase in breast cancer risk associated with the use of CHC (OR 1.24; 1.15–1.33; 95% IC) (Collaborative Group on Hormonal Factors in Breast Cancer, 1996). Studies published after this metaanalysis showed overall similar results (Cibula *et al.*, 2010). The recently published Danish study evaluates contemporary contraceptives and provides valuable information on this level of risk (Morch *et al.*, 2017). The relative risk of breast cancer associated with all current and recent users of hormonal contraceptives was 1.20 (1.14–1.26; 95% IC). This risk varies between 1.0 and 1.6 according to the type of CHC. This risk is similar with the use of progestin only pills. This slight increase of risk must be put into perspective with the absolute risk. Thus for a woman younger than 35 years of age, the absolute increase in breast cancer would be 2 per 100,000 persons–year.

Others cancers

The use of combination pills would reduce the risk of endometrial cancer by approximately 50% (Collaborative Group on Epidemiological Studies on endometrial Cancer, 2015). In some studies, the greatest reduction in risk has been observed for women using highly progestin-only pills. Moreover, it should be noted that the use of oral contraception reduces the risk of ovarian cancer by about 40% (Collaborative Group on Epidemiological Studies of Ovarian Cancer *et al.*, 2008). This effect increases with duration of use and persists for several years after stopping oral contraception. Hormonal contraceptives are also associated with a decreased risk of colorectal cancers (Bosetti *et al.*, 2009).

Finally, a recent study have suggested that the global effect of the use of CHC for 5 years or longer is a slight reduction in the total risk of cancer (Bassuk and Manson, 2015).

Hormonal Contraceptives and Noncontraceptive Benefits

Hormonal contraceptives offer noncontraceptives benefits. Two recent reviews have evaluated the different clinical entities associated with a benefit impact of CHC or POC (Schindler, 2013; Bahamondes *et al.*, 2015). Clinical effectiveness of CHC has been shown for the treatment or the prevention of menstrual bleeding disorders. The use of SIU-LNG controls heavy menstrual bleeding

Table 4 Arterial and venous risk factors

Arterial risk factors	*Venous risk factors*
Age >35 years	Age >35 years
Dyslipidemia	Overweight-obesity
Smoking	Biological thrombophilia
Diabetes	Familial history of VTE
Overweight-obesity	
Hypertension	
Migraine with aura	
Familial history of myocardial infarction or ischemic stroke	

and the subsequent associated anemia. CHC is currently used for alleviating menstrual related pain symptoms (dysmenorrhea) and is the first choice treatment of endometriosis. Moreover, CHC are useful to improve symptoms of hyperandrogenia like that acne, hyperseborrhea, hirsutism, and some alopecia.

In Practice

Before the prescription of hormonal contraceptives, the research of vascular risk factor is the main key of the first medical consultation of contraception.

The clinical examination must include at least blood pressure measurement and body mass index calculation. The gynecological examination is not always necessary, in particular for the young woman.

The choice of contraceptive method suitable for each woman is possible given the wide choice of hormonal contraceptives available. The WHO publication of the medical eligibility criteria for contraception use allows help for the prescription of contraception in various clinical situations (WHO, 2015).

Progesterone Receptor Modulators: Current Applications and Perspectives

Kamila Kolanska, Sorbonne University, Paris, France
Axelle Pintiaux, Brussels University (ULB), Brussels, Belgium
Philippe Bouchard, Emile Daraï, and Nathalie Chabbert-Buffet, Sorbonne University, Paris, France

Introduction

The development of progesterone receptor modulators (PRMs) (**Table 1**) started in the early 80's, when mifepristone, the lead compound, allowed medical management of unwanted pregnancies (Christin-Maitre *et al.*, 2000). Further development in search for additional potential fields of application has been hampered for some time by political interferences (Bouchard, 2014; Bouchard *et al.*, 2011; Chabbert Buffet *et al.*, 2012; Ulmann, 2000; Ulmann *et al.*, 1990). PRMs are now used also for emergency contraception (since 2009 in Europe and United States) and treatment of myoma-related symptoms (since 2014). Further applications are currently under evaluation, and these compounds are likely to play a considerable role in Gynecology.

SPRMs Development and Mechanisms of Action

Initially synthesized in 1980 at Roussel Uclaf company, (RU 486 or mifepristone) for the treatment of depression, based on its antiglucocorticoid capacity, the antiprogesterone activity of mifepristone and its potential applications in obstetrics and gynecology was subsequently developed under the direction of Etienne Baulieu. Mifepristone was approved in France in 1988 in medical termination of pregnancy, in combination with a prostaglandin.

Progesterone (P) regulates uterine maturation for implantation and sustains pregnancy, but also exerts multiple roles in physiology through its nuclear receptor (PR) isoforms A and B (Bouchard, 2014; Bouchard *et al.*, 2011; Chabbert Buffet *et al.*, 2012). Progesterone can stimulate breast cell proliferation while it can exert antiproliferative effects in the uterus, preventing estradiol-induced endometrial growth.

It also regulates the GnRH pulse regulator by acting on KNDY neurones and the release of Kiss 1, the crucial regulator of GnRH pulse frequency (Bouchard, 2014; Ulmann *et al.*, 1990; Chabbert-Buffet *et al.*, 2000). While acute administration of P can trigger the release of GnRH, its continuous administration results is anovulation due to the slowing down of the GnRH pulse generator.

It became therefore tempting to study the effects of PRM into antagonizing progesterone known and unknown effects.

Table 1 Main PRMs and gynecology: in clinical use, currently or previously under development

Compound	*Therapeutic applications*	*Current status*
Mifepristone (RU-486)	Termination of pregnancy	Launched
	Emergency contraception	Phase III
	Long-term contraception	Phase II
	Uterine fibroids	Phase II
	Endometriosis	Phase II
	Endometrial cancer	Phase I
Ulipristal acetate (CDB-2914; VA2914)	Emergency contraception	Launched
	Uterine fibroids	Phase III
	Long-term contraception (vaginal ring)	Phase II
Asoprisnil (J-867)	Uterine fibroids	Withdrawn
	Endometriosis	Withdrawn
	Long-term contraception	Withdrawn
Telapristone acetate (CDB-4124)	Uterine fibroids	Phase III trials terminated
	Anemia	Phase I/II trial initiated
	Endometriosis	Phase III trials terminated
		Phase I/II trial initiated
		Phase II trials terminated
		Phase I/II trial initiated
Lonaprisan (ZK230211)	Breast cancer	Phase II
Onapristone (ZK98299)	Endometriosis	No development since the 1990s
	Cancer	
ORG-31710 & ORG-31806	Contraception	Preclinical; no development since the 1990s
	Cancer	

 doi:10.1016/B978-0-12-801238-3.64953-X

Current applications of PRMs include termination of pregnancy and management of preterm and term delivery, emergency contraception and medical treatment of uterine myomas.

PRMs Use in Pregnancy

The introduction of mifepristone in obstetrics and pregnancy termination has provided a safe medical method of first trimester pregnancy termination, which is a potential major progress especially in health-care resource-deprived areas, where abortion is a source of maternal mortality. In other countries it has allowed the development of the procedure in outpatients for very early pregnancy termination, reducing costs and improving patients comfort. Mifepristone is currently available in over 30 countries (Christin-Maitre *et al.*, 2000) for pregnancy termination.

Prostaglandins, used in association to mifepristone for pregnancy termination, induce uterine contraction, resulting in embryo expulsion, while mifepristone impairs two crucial functions of progesterone during early pregnancy, synchronization of the endometrium and the conceptus, and myometrial contractions inhibition. The antiprogestin activity may also act on endometrial blood vessels, and compromise embryo development.

A review of the Cochrane database (Kapp *et al.*, 2010) has analyzed the efficacy of the different available protocols showing that combined regimens associating mifepristone and PgE1 analogs are more effective even with the mifepristone dose reduced to 200 mg. Finally misoprostol, a prostaglandin analog, is efficient using the vaginal route, although this has been associated with very rare cases of fatal septic shocks related to Clostridium Sordellii in the United States and in Canada (Niinimaki *et al.*, 2017).

Mifepristone also causes cervical dilation and can be used in the management of fetal miscarriage (Baev *et al.*, 2017) and full term labor management (Singh Susheela *et al.*, 2009).

SPRMs for Emergency Contraception

Globally, 55‰ of pregnancies are estimated to be unintended in women aged 15–44 (Singh Susheela *et al.*, 2009), resulting in termination of pregnancy or unwanted birth, with their associated personal and social burden, especially in countries where abortion is not available. Emergency contraception (EC) offers women an important strategy to prevent unintended pregnancy after intercourse in cases of contraceptive misuse, nonuse or failure, as well as in situations of sexual violence (Jones *et al.*, 2002). Although use of EC is constantly increasing, it remains limited (KFF Foudation, 2003). Available data on the reduction of abortion rates since EC was developed, and made available over-the-counter, have not demonstrated a marked reduction in abortion rates (ESHRE CapriWorkshop group, 2015). However, this may be due to insufficient knowledge about pregnancy risk, inappropriate use of EC or a gap between the theoretical and practical efficiency of EC in current conditions.

In a strategy to increase access to and safety of EC, hormonal EC initially based on the administration of high doses of combined oral contraceptives (Jatlaoui *et al.*, 2016), was then replaced by levonorgestrel only administration, which does not increase thrombotic risk and could therefore subsequently be released over the counter.

PRMs share with levonorgestrel the advantage of low to null thrombotic risk. Mifepristone (Baird *et al.*, 1995), Ulipristal Acetate (UPA) (Glasier *et al.*, 2010) interrupt the LH surge and eventually follicular rupture. Further research has shown that PRMs remain highly active to prevent ovulation up to 120 h after unprotected intercourse, while levonorgestrel is only 50% active after 72 h (Brache *et al.*, 2013b). UPA is at least as safe as LNG when taken up to 72 h after sexual intercourse (Glasier *et al.*, 2010; Cheng *et al.*, 2012; Creinin *et al.*, 2006; Richardson and Maltz, 2012).

Today mifepristone, despite its proven efficacy as an EC (Cheng *et al.*, 2012), is available for this indication only in China, Vietnam, Russia and Armenia, while ulipristal acetate (EllaOne 30 mg) is available worldwide, over the counter. Tolerance of LNG and UPA is good (Thomin *et al.*, 2014), with side effects in 9% of cases and comparable (Creinin *et al.*, 2006), mainly headache, dysmenorrhea, intermenstrual bleeding and nausea. There are no contraindications to LNG or UPA use for EC, except for hypersensitivity to the compound or its excipient and ongoing pregnancy (Creinin *et al.*, 2006). No metabolic side effects have been demonstrated with UPA (Cameron *et al.*, 2015) or levonorgestrel.

Different aspects of hormonal EC still need improvement or evaluation however.

PRMs activity on ovulation is restricted to the preovulatory period, and disappears if the LH surge is already ongoing (Brache *et al.*, 2013b). Due to their action on progesterone receptors, interaction of PRMs with subsequent use of estroprogestins or progestins may require caution in patients taking ongoing contraceptive medication (Salcedo *et al.*, 2013). While UPA has been shown to have no impact on the efficacy of subsequent estroprogestin use in one study (Cameron *et al.*, 2015), recent data show that subsequent use of continuous desogestrel reduces the efficacy of UPA as an EC (Brache *et al.*, 2015). On the other hand, UPA did not appear to have an impact on desogestrel efficacy. Currently, the use of barrier contraceptives is advisable for 7 days after EC use. Some enzyme inducers may reduce the effectiveness of UPA or LNG, as well as certain drugs that increase gastric pH (Pohl *et al.*, 2013a,b). Body mass index (BMI) was shown to have a significant impact on EC efficiency as well (Glasier *et al.*, 2010, 2011). The impact of obesity appears more pronounced with LNG compared to UPA. In obese women, UPA may thus be recommended instead of LNG if possible; alternatively, the use of a copper intrauterine device (Cu-IUD) is recommended.

SPRMs for Myoma-Related Symptoms

Uterine myomas, present in 70%–80% of women by age 50, are the leading cause of hysterectomy (400,000 every year in the USA), and their main complication bleeding, is responsible for a severe alteration of quality of life (Stewart, 2015; Chabbert Buffert *et al.*, 2014a). They are benign clonal smooth muscle cell tumors (Bulun, 2013), and estradiol is considered as the leading growth signal.

The effects of PRMs in women with uterine myomas associate two independent characteristics: rapid control of uterine bleeding and sustained reduction in myoma volume as initially shown by Anna Murphy and SSC Yen with mifepristone in a short term study (Murphy *et al.*, 1993). K Chwalisz, a pioneer in the field of PRM, obtained similar results with the PRM asoprisnil (Chwalisz *et al.*, 2005). However, as mentioned initially by Murphy et al., the long term administration of these PRMs created some nonphysiological changes in endometrium morphology with a pattern initially described as glandular hyperplasia.

The development of UPA for uterine myoma treatment was subsequently achieved in several steps showing the rapid cessation of uterine bleeding and the decrease in uterine fibroids (Chabbert-Buffet *et al.*, 2007; Donnez *et al.*, 2012a,b; Williams *et al.*, 2012; Donnez *et al.*, 2014, 2015, 2016). Daily administration of 5 or 10 mg UPA in normal women volunteers studied in a randomized controlled study of 3 months, confirmed the cessation of menstrual bleeding in 90% of women, the absence of ovulation in 80% of volunteers. Interestingly, estradiol levels were not blunted (Chabbert-Buffet *et al.*, 2007).

Treatment of women with symptomatic uterine myomas using 5 mg UPA for 3 months was evaluated in a randomized trial versus placebo (Pearl I) showing the rapid cessation of bleeding, within 7 days in 90% of treated women. In addition, fibroid volume decrease reached 50% within the 3 months of the study, and was sustained for 6 months following cessation of treatment, while normal menstruation resumed within a month following cessation of treatment (Donnez *et al.*, 2012a).

The study Pearl II was a randomized controlled trial, comparing the effect of UPA and Leuprolide, a GnRH agonist (Donnez *et al.*, 2012b). This study confirmed the results of Pearl I and showed that the rapidity of the cessation of bleeding was shorter under UPA. The decrease in uterine volume was similar in both groups, but was not sustained in the GnRH-agonist group compared to the UPA group. Finally, the GnRH-agonist treatment induced estradiol deprivation symptoms as compared to UPA. As with Asoprisnil, the key issue was the interpretation of the endometrial changes observed following the treatment. They are now widely recognized as PAECs (Williams *et al.*, 2012): PRM associated endometrial changes. The endometrium histology shows altered glandular architecture including extensive glandular epithelium dilatation. The epithelium appeared essentially inactive with rare mitoses. Mild reversible thickening rarely occurred (Williams *et al.*, 2012) (**Fig. 1**).

These changes proved to be reversible following cessation of therapy and associated with no sign of proliferation. Curiously enough, PAECs are also observed in a significant number of untreated patients. Their significance is unknown (Williams *et al.*, 2012).

UPA was initially approved as a preoperative treatment (3 months). In Pearl III study and extension (Donnez *et al.*, 2014), each course of UPA was followed by a sequence of Progestin: Norethisterone Enanthate (10 mg daily for 10 days), in order to limit the development of PAEC, believed to be a consequence of unopposed estradiol effects. This study showed that the progestin course does not change the appearance of PAEC, which were confirmed to be benign aspects more frequent after PRM treatment and disappearing after cessation of treatment.

In Pearl IV study (Donnez *et al.*, 2015) intermittent courses of 3 months treatment with UPA were simply separated by sequences of 2 normal cycles in 451 women. Eight courses of 3 months 10 mg UPA daily were finally administered in 64 women. This study showed 9.1% of PAEC after cessation of the study, similar to what is observed in untreated women. All histological analysis showed benign lesions. Endometrial thickness usually did not exceed 7 mm after course 5–8. This lead to the authorisation for intermittent long term therapy using 3 month courses separated by 2 cycles interval. This strategy is particularly useful in women with fibroids near the menopausal transition (Donnez *et al.*, 2016). Seven hundred thousands women have been treated so far. Recently the European Medicine Agency is reviewing few cases of severe liver injury. Such cases were never observed, neither in animal nor in preclinical studies. This toxicity seems linked to probable prescriptions in women with liver disease. Recommendations will be provided by the EMA by June 2018.

Perspectives

Perspectives for PRMs use include new molecules, new routes of administration and new indications (**Table 1**).

Vilaprisan is a new steroid PRM currently in development for myoma treatment (Seitz *et al.*, 2017; Schultze-Mosgau *et al.*, 2017; Schütt *et al.*, 2016) with a very similar profile as compared to ulipristal acetate.

PRMs are currently evaluated in intrauterine systems or vaginal rings for contraception. Data on intrauterine systems have been published in primates (Heikinheimo *et al.*, 2007; Nayak *et al.*, 2007) showing a suppression of progesterone withdrawal induced bleeding and estradiol induced endometrial proliferation. However the latter remains to be confirmed in women, since the endometrial effects of systemic administration of PRM in primates also results in endometrial atrophy, while the aspect observed in women is specific as previously discussed. Prototypes of ulipristal acetate releasing IUS are being designed and developed for a preclinical toxicology study. The initial proof of concept study in users of the vaginal ring (Schütt *et al.*, 2016) has shown that the doses of ulipristal acetate had to be increased to reach pharmacologically effective circulating levels. These studies are currently undergoing. This form of vaginal ring could offer a convenient estradiol free contraceptive. The endometrial impact of such a system is unknown.

Fig. 1 Histological aspect of the PRM associated endometrial changes (PAECs). Cystic dilation of uterine glands is observes. The glandular epithelium shows a coexistence of apoptotic cells (*bold arrow*) and mitotic cells (*black arrow*), together with features of secretory differentiation (*white arrow*). Courtesy of Pr Pintiaux.

Finally, in addition to long term contraception, future indications may include dysfunctional uterine bleeding in the absence of myoma, adenomyosis and endometriosis. In addition the use of PRMs priori to IVF, to reduce myoma volumes and possibly improve IVF outcomes, is currently under evaluation, since successful pregnancies occurred in women with fibroids not requiring IVF after treatment with ulipristal acetate (Luyckx *et al.*, 2014).

Conclusion

Despite political interferences resulting in the slowing of their development, PRMs have allowed major improvements in women's health and comfort, such as medical termination of pregnancy, which is now doable at home, extended efficacy for emergency contraception, and finally medical treatment of myoma-related bleeding with the additional benefit of a very rapid cessation of bleeding and myoma shrinking, without estradiol deprivation. Development towards new molecules and application is actively ongoing.

Diagnosis of Menopause

Tommaso Simoncini, Marta Caretto, Andrea Giannini, and Andrea R Genazzani, University of Pisa, Pisa, Italy

Glossary

Amenorrhea Absence of menstruation—one or more missed menstrual periods.

Menopause The permanent cessation of menses due to the loss of ovarian follicular activity. The final menstrual period is retrospectively assigned after 12 months of amenorrhea, in the absence of other pathological or physiological causes.

Menopause may be spontaneous (natural menopause) or iatrogenic (secondary menopause). The latter can be induced earlier by medical intervention such as bilateral oophorectomy (surgical menopause) or iatrogenic ablation of ovarian function by chemotherapy, radiotherapy or treatment with gonadotrophin-releasing hormone analogues. In the absence of surgery, induced premature ovarian failure may be permanent or temporary.

The recently published NICE menopause guidelines recommends that diagnosis is made without laboratory tests: it's possible to diagnose in healthy women aged over 45 years with menopausal symptoms:

- perimenopause based on vasomotor symptoms and irregular periods;
- menopause in women who have not had a period for at least 12 months (who are not using hormonal contraception);
- menopause based on symptoms in women who have undergone hysterectomy (Sarri *et al.*, 2015).

For women aged over 45 years, laboratory tests, particularly follicle-stimulating hormone (FSH), do not help with the diagnosis because hormone levels fluctuate during the perimenopause. Knowing these levels will not change management (Roberts and Hickey, 2016).

Clinical Diagnosis

The menopausal transition marks a period of physiologic changes as women approach reproductive senescence. Evidence supports the clinical importance of the transition for many women as a period of temporal changes in health and quality of life (vasomotor symptoms, sleep disturbance, depression) and longer-term changes in several health outcomes (urogenital symptoms, bone, lipids) that may influence women's quality of life and the likelihood of healthy aging (Davis *et al.*, 2015). The 2001 Stages of Reproductive Aging Workshop (STRAW) proposed nomenclature and a staging system for ovarian aging including menstrual and qualitative hormonal criteria to define each stage. The STRAW staging system is widely considered the gold standard for characterizing reproductive aging through menopause. As a standardized staging system for reproductive aging, STRAW made a substantial contribution to women's health research by providing consistent classification of menopause status for studies of midlife women. Importantly, STRAW facilitated research that aimed to distinguish the health effects of ovarian versus somatic aging. The STRAW staging system also serves as a clinical tool for women and their healthcare providers to guide the assessment of fertility, contraceptive needs, and healthcare decision making.

As women progress to the late menopausal transition (STRAW Stage -2, characterized by variability in menstrual cycle length and increased levels of FSH; to -1, characterized by onset of skipped cycles or amenorrhea of at least 60 days and continued elevation of FSH), their menstrual cycle length increases to >60 days, anovulation becomes more likely and periods of time with little or no estrogen secretion occur. At this time, all of the commonly observed menopausal symptoms worsen acutely. Many symptoms peak in their intensity at this time, and women may require treatment (Harlow *et al.*, 2012) (**Table 1**).

A woman is considered postmenopausal when she is over the age of 45 and has gone at least 12 months without a spontaneous menstrual period (World Health Organization, 1996). No specific diagnostic testing is required unless the clinical presentation is atypical. Atypical presentations would include substantial mood changes, new-onset anxiety or fatigue, and arthralgia without flushes or sweats. Earlier ages of onset of prolonged amenorrhoea require consideration of other diagnoses such as polycystic ovary syndrome, secondary hypogonadotropic hypogonadism, hyperprolactinaemia, pituitary tumors or uterine problems such as Asherman syndrome. A menopausal woman who has undergone at least 12 months of amenorrhoea is unlikely to ever have another menstrual period, but it can occur in about 10% of women.

Menopausal Symptoms

Most women entering menopause experience vasomotor symptoms. The term vasomotor symptoms is often used to cover hot flashes and accompanying sweating.

Modified from Harlow, S. D., Gass, M., Hall, J. E., *et al.* (2012). Executive summary of the stages of reproductive aging workshop þ 10: Addressing the unfinished agenda of staging reproductive aging. Menopause (New York, NY) 19(4), 387–395.

A hot flush is a sudden episode of vasodilatation in the face and neck, which lasts 1–5 min and is accompanied by profuse sweating. Women experiencing hot flushes are reported to have a narrower thermo neutral zone, such that subtle changes of core temperature elicit thermoregulatory mechanisms such as vasodilatation, sweating or shivering. Declining levels of oestrogens and inhibin B, as well as increasing FSH levels, explain only part of the disturbed thermoregulation, which is associated with changes in brain neurotransmitters and peripheral vascular reactivity. Although initial studies reported that LH pulses occur during hot flashes in postmenopausal women, a causative link was never found. Learning more about the mechanisms of hot flushes may allow to identify novel therapeutic targets to better treat patients affected by these symptoms. It has recently emerged this hypothesis: kisspeptin, neurokinin B and dynorphin (KNDy) neurons, which project to the preoptic thermoregulatory area, regulate the hypothalamic GnRH pulse generator, most likely by mediating estrogen-dependent negative feedback of LH secretion. At postmenopause, KNDy neurons undergo hypertrophy, and the expression of the genes encoding neurokinin B and kisspeptin increases as a result of estrogen withdrawal, leading to increased signaling to heat dissipation effectors in the CNS and to GnRH neurons (Rance *et al.*, 2013).

Hot flushes usually occur in late perimenopause and the first postmenopausal years. Some women, however, may continue to experience vasomotor symptoms for many years after menopause. Occasionally, hot flushes occur in the late reproductive years, or several years after menopause. The occurrence and intensity of menopausal symptoms vary widely between women and depend on genetic, environmental, racial, lifestyle and anthropometric factors. Black race, smoking and overweight—in particular central obesity—increase the prevalence and severity of vasomotor symptoms (Sturdee *et al.*, 2017).

Sleep disturbances are also very common during the menopausal transition and they are mainly attributed to frequent arousals due to night sweats and occurring secondarily to psychological factors. Mood disorders such as depression and anxiety are not caused by menopause; vulnerable women, however, may have their first episode or a relapse during the transition. Muscle and joint pain is also part of the menopausal symptomatology and it is highly correlated with hot flushes and depressed mood (Davis *et al.*, 2015).

Genitourinary Syndrome of Menopause

The anatomy and function of the female lower genital tract is estrogen-dependent. Vulvovaginal atrophy and urinary tract atrophy, due to estrogen deficiency, are collectively called the genitourinary syndrome of menopause (GSM). With declining estrogen, the mucosa of the cervix, the epithelium of the vagina and vulva thin and become susceptible to injury. The vaginal rugae diminish, leading to a smoother appearing vaginal wall accompanied by diminished blood flow and a rise in pH (6–8). Together, these changes result in a pale appearance which may contain small petechiae and/or other signs of inflammation. The proportion of superficial to parabasal cells decreases with loss of glycogen and loss of lactobacilli (Panay, 2015). The loss of secretions leads to vaginal dryness and irritation. Women experiencing sexual and urinary symptoms due to vaginal atrophy should be diagnosed and treated without delay in order to avoid a cascade of events which do not resolve spontaneously. The diagnosis of GSM is often made on symptoms alone—many health-care professionals avoid examination of the patient, which is a mistake. There are other vulval and vaginal conditions which can produce similar symptoms such as vulval dermatoses, for example, lichen sclerosis, and vulval/vaginal malignancy. The diagnosis has been largely subjective with few objective measures used to confirm the diagnosis and monitor progression and response to treatment. The measurement of vaginal pH and the vaginal maturation index from vaginal smears provides some objective evidence. Although these measurements are commonly used in GSM studies, they are rarely used in day-to-day clinical practice. Unlike hot flushes and night sweats, which improve over time, symptoms of urogenital atrophy persist throughout postmenopausal life and may have a serious impact on sexual health and quality of life (QoL). Pain during intercourse, secondary to vulvovaginal atrophy, leads to diminished sexual desire, arousal difficulties, relationship problems, and diminished physical and emotional sexual satisfaction. Although the majority of women have signs of urogenital atrophy upon physical examination, less than half of the postmenopausal population report bothersome complaints. Age, sexual activity, ethnicity and attitudes towards menopause influence the occurrence and the severity of urogenital symptoms (Portman and Gass, 2014).

Assessment tools have been developed to facilitate the formal diagnosis and classification of the severity of GSM. One of the most commonly used tools for assessing vaginal health has been the Vaginal Health Index (Bachmann *et al.*, 1992). The user is asked to rate both the appearance of the vaginal mucosa and production of secretions on a scale from 1 to 5 (**Table 2**).

There has also been an attempt to introduce a quality-of-life impact modality (pain on intercourse) in this tool although the value of assessing only one modality is limited (The vulval health index, 2015) (**Table 3**).

A more comprehensive tool has recently been developed following the Consensus Group development of the term GSM. The GSM assessment tool consists of three general categories of elasticity, lubrication and tissue integrity, an anatomical section which includes vulval, vaginal and urethal anatomy, and two objective measures, vaginal pH and vaginal maturation. There is a score from 0 to 3 for each one of these seven components describing severity of symptoms (**Table 4**) to provide a semiobjective measure of vulval and vaginal atrophy. A numeric score is calculated by adding the individual scores to give a total out of 21 (0–7 mild atrophy, 7–14 moderate atrophy, and 14 severe atrophy) (Portman and Gass, 2014).

But, there is some inaccuracy in the tool assesses GSM. Both vulva health index and GSM tool still require validation and publication of clinical trial usage.

Biochemical Assessment

Reproductive aging coincides with endocrine changes which primarily originate from a diminished pool of follicles being recruited during each cycle. This leads to a reduction in produced estradiol, lower levels of inhibin B resulting in elevated FSH concentrations. Elevated FSH during the early follicular phase of a regular menstrual cycle, was traditionally considered a first sign of reduced ovarian reserve (Davis *et al.*, 2015). A more advanced stage of decrease in the amount of FSH-sensitive follicles results in

Table 2 Vaginal health index

	Score				
	1	*2*	*3*	*4*	*5*
Elasticity	None	Poor	Fair	Good	Excellent
Fluid volume (pooling of secretion)	None	Scant amount, vault not entirely covered	Superficial amount, vault entirely covered	Moderate amount of dryness (small areas of dryness on cotton tip applicator	Normal amount (fully saturates on cotton tip applicator)
pH	>6.1	5.6–6.0	5.1–5.5	4.7–5.0	4.6
Epithelial integrity	Petechiae noted before contact	Bleeds with light contact	Bleeds with scraping	Not friable–thin epithelium	Normal
Moisture (coating)	None, surface inflamed	None, surface not inflamed	Minimal	Moderate	Normal

Modified from Bachmann, G. A., Notelovitz, M., Kelly, S. J., *et al.* (1992). Long-term nonhormonal treatment of vaginal dryness. Clinical Practice in Sexuality 8, 12.

Table 3 Vulva health index

	Normal: 0	Mild: 1	Moderate: 2	Severe: 3
Labia majora	Normal	Mild loss	Moderate loss	Severe loss or disappeared
Labia minora	Normal	Mild loss	Moderate loss	Severe loss or disappeared
Clitoris	Normal size	Mild decrease in size	Moderate decrease in size	Severe loss or undetected
Introitus and elasticity	Normal	Mild decrease or stenosis	Moderate decrease or stenosis	Severe decrease or stenosis
Color	Normal	Mild pallor	Moderate pallor	Severe pallor
Discomfort and pain	None	Mild during intercourse	Moderate during intercourse	Severe during intercourse and any discomfort intensity beyond intercourse
Other findings (petechiae, excoriation, ulceration, etc.)	None	Mild	Moderate	Severe

Modified from Palacios, S. (2015). The vulval health index. Personal communication.

Table 4 Genitourinary syndrome of the menopause assessment tool

	Normal: 0	Mild: 1	Moderate: 2	Severe: 3
Elasticity	Stretchable, elastic tissue	Slightly diminished elasticity	Moderately diminished	Absent, fibrotic
Lubrication	Normal secretions	Moisture slightly decreased moisture	Mostly dry, some moisture	Very dry
Tissue integrity	Intact epithelium, no friability or petechiae	Some friability with vigorous contact, no petechiae	Moderate friability or petechiae with some contact	Significant friability, bleeding, petechiae with minimal contact
Anatomy				
Introitus	3-Dimensional	Mostly 3-dimensional	Some contraction, stenosis, rather flat	Mostly contracted, stenotic, flat
Labia majora, minora	Normal for parity, coital activity, and anatomic variation	Most definition present	Some resorption, especially inferior aspect of labia minora	Significantly decreased size; minora mostly resorbed
Urethra	Normal size and position	Normal to slightly prominent	Moderately prominent urethral meatus	Eversion present; inner aspect protruding
Rugae	Normal	Present to slightly diminished	Moderately diminished but visible	Significantly diminished to absent
Color	Normal	Some faint pallor	Moderate pallor	Complete pallor
Supportive				
pH	<5		5–6.5	
Maturation index	No parabasal	Decrease in number of superficial cells, increase in number of parabasal cells	Cells fewer superficial cells, more parabasal cells	Few to no superficial cells, many parabasal cells

Modified from Portman, D. J., Gass, M. L. Vulvovaginal Atrophy Terminology Consensus Conference Panel. (2014). Genitourinary syndrome of menopause: New terminology for vulvovaginal atrophy from the International Society for the Study of Women's Sexual Health and the North American Menopause Society. Climacteric 17, 557–563].

increased menstrual cycle irregularity, and characterizes the menopausal transition. A combination of the menstrual cycle pattern, FSH serum levels and the antral follicle count (number of ovarian follicle-like structures assessed by transvaginal ultrasound) have been widely adopted in routine clinical practice to assess the current status of reproductive aging in women (Broekmans *et al.*, 2009). However, the capacity of these conventional measures to predict the course of reproductive aging over time—including timing of age at natural menopause (ANM)–is limited.

Although specific diagnostic testing for menopause is not recommended, clinical situations may arise in which it is beneficial to document primary gonadal failure. Usually, an increased FSH level will suffice to confirm this. Changes in FSH, oestradiol and inhibin B have been well documented in population-based samples of women undergoing observational research. Measurement of oestradiol during the perimenopause is not clinically useful. Inhibin B is the first hormone to decline, and its drop precedes a rise in FSH. The compensatory rise in FSH causes follicles to continue to grow and leads to a shortening of the follicular phase of the menstrual cycle. Eventually, the follicle pool becomes depleted and folliculo-genesis no longer occurs reliably. This juncture is when the late menopausal transition begins. Follicle failure is intermittent in the late transition and is eventually superseded by permanent amenorrhoea. After menopause has happened, oestradiol levels are expected to be consistently low (<20 pg mL^{-1}); progesterone is no longer produced. Anovulation leads to the loss of progesterone production. Of note, there is no acute change in testosterone levels in relation to the menopause transition. During the reproductive years, both ovaries and the adrenal glands contribute to circulating androgens. The postmenopausal ovary continues to contribute substantially to the circulating levels of testosterone for years, even if after menopause, the adrenals become the major source of androgen production. Serum

concentrations of adrenal androgens in midlife women might variably and transiently increase in the late menopausal transition. In particular, a rise in mean serum concentrations of dehydroepiandrosterone sulfate (DHEAS) occurs in most women between the early menopausal transition and early postmenopause stages. This changing hormonal environment produces a cascade of CNS-related and peripheral symptoms of variable severity for an unpredictable amount of time (McConnell *et al.*, 2012).

Over the past years extensive research has been performed regarding anti-Mullerian Hormone (AMH) as a predictor of ANM. AMH—formerly known as Mullerian-inhibiting substance (MIS)—has previously been studied extensively in the context of male gonadal differentiation. In the female fetus, the production of AMH commences around 36 weeks of gestation. AMH is a member of the transforming growth factor-β (TGFβ) superfamily of proteins, and is produced by granulosa cells within the follicles during the early stages of preantral and antral follicular development. Hence, AMH is a direct product of the growing cohort of follicles. Detectable serum AMH levels rise during early puberty up until they reach a plateau around the age of 20–25 years (Sowers *et al.*, 2008). Thereafter serum AMH levels gradually decline with advancing age, resulting in undetectable concentrations around 5 years prior to menopause. AMH might be useful for predicting the time of menopause. The development of a sufficiently sensitive AMH assay should be useful to help forecast the final menstrual period with better accuracy. Furthermore, several confounders which may influence AMH levels such as smoking, ethnicity, BMI, vitamin D and oral contraceptive pill usage, have been identified. AMH is currently also under investigation as a marker of ovarian function in a whole variety of clinical conditions, such as chemotherapy induced ovarian damage, premature menopause, ovarian endometriosis, ovarian surgery, polycystic ovary syndrome and many others (Daan and Fauser, 2015). Finally, AMH has recently been shown to predict the amount of exogenous FSH required for adequate ovarian stimulation for in vitro fertilization, allowing for individualized treatment regimens. Routine measurement of anti-Mullerian hormone (AMH) is not recommended to diagnose menopause in women over the age of 45, but may be helpful in women with suspected premature ovarian failure to assess ovarian reserve. However, while AMH has a relationship to age at menopause, the marked variability in levels needs further exploration and improved assay validity is required.

Diagnostic Imaging

Other measurements have also been proposed for forecasting the timing of permanent ovarian failure, including both antral follicle counts (assessed by transvaginal ultrasonography), recording of all follicles measuring $\leq$7 mm in diameter (usually done in the early follicular phase of the cycle), and functional ovarian reserve, which is ascertained by dynamic testing of the ovary with a stimulating agent (either clomiphene citrate or FSH). However, these methods are better predictors of the loss of fertility than they are of menopause per se. Transvaginal ultrasonography is a very useful method for assessing fertility status and can provide information about ovarian aging when appropriate. Measurement of the number of antral follicles can provide useful information about the likelihood of pregnancy in women who are of advanced reproductive age and wish to conceive. However, antral follicle counts have not been as useful in predicting menopause. Other ovarian measurements such as total ovarian volume and stromal thickness have also been proposed, but they currently lack the sensitivity and specificity to be clinically useful (Hansen *et al.*, 2012).

Differential Diagnoses of Menopausal Symptoms

If a woman is $>$50 years of age, has stopped menstruating and has classic estrogen deficiency symptoms, a diagnosis other than menopause is very unlikely. Other causes of amenorrhoea should be considered in younger women and in women aged $>$50 years who have atypical symptoms. Secondary amenorrhoea has to be investigated: progestin challenge, or progesterone withdrawal test is rarely used to evaluate amenorrhea. The test is performed by administering progesterone either as an intramuscular injection or oral medroxyprogesterone acetate. If serum estradiol is $>$40 pg/mL, withdrawal bleeding should occur 2–7 days after the progestin is withdrawn, indicating that amenorrhea is due to anovulation. However, if no bleeding occurs after progesterone withdrawal, then the patient's amenorrhea is likely to be due to either low serum estradiol, hypothalamic-pituitary axis dysfunction, a nonreactive endometrium or a problem with the uterine outflow tract, such as cervical stenosis or uterine synechiae (Asherman syndrome). In order to distinguish between hypoestrogenism or a uterine outflow tract problem/nonreactive endometrium, estrogen may be administered followed by a course of progestin in order to induce withdrawal bleeding (Ryosuke *et al.*, 1979). Pregnancy should always be considered in the setting of amenorrhoea: pregnancy needs to be excluded.

Other causes include thyroid disease, prolactinoma, severe depression or stress, and substantial weight loss. Each of these may be associated with vasomotor symptoms and mood changes. Other causes of vasomotor symptoms should be excluded if the presentation is atypical. Hormonal hot flushes do cause a significant rise in core temperature. If a woman records an increase in her oral temperature with flushing or night sweats, infective causes must be investigated. Thyrotoxicosis can mimic menopause, with women presenting with agitation and anxiety, sleep disturbance, overheating, sweating and palpitations. These symptoms may precede the classic thyrotoxic symptoms of weight loss and tremor. A careful medical and medication history should identify other possible causes. Serotonin-producing carcinoid tumors can present with nocturnal diarrhea and episodic flushing without sweating. Phaeochromocytomas release the catecholamines adrenaline and noradrenaline, and are characterized by persistent hypertension, flushing and profuse sweating (Lenders *et al.*, 2014). Measurement of thyroid stimulating hormone (TSH) and prolactin are also helpful in investigating menstrual irregularity. Estimates of the levels of luteinizing hormone, estradiol,

progesterone and testosterone are of no value in the diagnosis of ovarian failure, but may provide information about other menstrual cycle disorders. Some women may present with oligomenorrhoea and mood changes or depression (American Psychiatric Association, 2013). Perimenopausal depression needs to be differentiated from major depression and simple dysphoria. The diagnosis of major depression requires at least 2 weeks of depressed mood, or loss of interest or pleasure in nearly all activities for most of the day, nearly every day, accompanied by at least four of the following symptoms: change in appetite or sleep, fatigue, psychomotor agitation or retardation, feelings of worthlessness and/or guilt, diminished concentration or indecisiveness, and suicidal ideation. By contrast, perimenopausal depression is usually accompanied by irritability, hostility or agitation, and anxiety. Clinically, it resembles the mood changes of premenstrual syndrome, with negative mood, negative self-concept and less effective coping abilities. The lability of perimenopausal depression is a distinguishing feature, in contrast to the pervasive low mood that is seen in major depression.

In younger women with suspected premature ovarian failure or early menopause serial follicle-stimulating hormone (FSH) measurements should be undertaken. In menstruating women, measurement of FSH should be performed at the beginning of the follicular phase (days 2–5 of the cycle) to avoid ovulation-induced elevations of FSH.

Factors Hindering Diagnosis

Although one of the defining features of menopause is the cessation of the menstrual period, it more broadly encompasses the permanent cessation of ovarian reproductive function. Thus, the traditional definition is not useful in the setting of iatrogenic causes of amenorrhoea, such as hysterectomy, endometrial ablation or progestin intrauterine devices. Biochemical investigations may be warranted for women with iatrogenic amenorrhoea (notably, measurement of FSH and oestradiol) and for younger women (measurement of AMH). The latter is less useful in women >50 years of age, as most women will have low AMH levels by this time. Some women may report vasomotor symptoms when using combined oral contraception. In this instance, menopause can only be effectively diagnosed if the oral contraception is stopped for several weeks, after which menopausal status can be assessed both clinically and biochemically.

Menopausal Treatment

Anne Gompel, Paris Descartes University, Port Royal, Paris

Introduction

Definition: menopause is defined by the final menstrual period (FMP) and corresponds to the extinction of ovarian steroids secretion and loss of follicles.

Menopause is thus associated with a drastic decrease in estradiol secretion and its consequences at short and long terms. Mean age of Menopause is 51 years in the United States and France.

Menopause usually occurs after a period of menstrual irregularity and hormonal changes. This phase is called perimenopause or menopausal transition (MT).

Perimenopause and MT

Before the extinction of estradiol secretion by the ovary, occurs a period with cycle irregularity potentially associated with clinical symptoms. The first description of the pattern of menstrual cycles during the perimenopausal period was made by Treolar *et al.* (1967). The classical view is that the first stigma of perimenopause is a shortening of the follicular phase due to the decrease in follicular content and subsequently an increase in follicular stimulating hormone (FSH) levels which are associated with a more rapid growth of the dominant follicle. The cycles are still ovulatory but of a mean duration of 21–25 days. Then ovulation occurs less frequently and with alternate normal cycles and long anovulatory cycles. Then, approaching the menopause, number and length of anovulatory cycles increase. Estradiol secretion fluctuates and can be high or low according to time. FSH is also fluctuating and progressively increases as a signature of ovarian insufficiency.

Several recent studies have updated the descriptive analysis of cycle's abnormalities during this phase. Wide use of modern tools (antimullerian hormone (AMH) and follicular antral count) developed in infertile patients has shown ovarian insufficiency defined from fertility patterns to begin much earlier than cycles irregularity. A group of experts evaluated the data available for hormonal and cycle modifications occurring during the late reproductive stages and up to the postmenopause and published it as "Stages of Reproductive Aging Workshop (STRAW)" (Soules *et al.*, 2001). They proposed to classify the gonadal female activity in three periods, reproductive, MT, and postmenopause. The reproductive phase (RP) was described into three stages corresponding to early, peak, and late phase. The MT phase was divided into two stages, early and late and the postmenopause phase (PM) into two stages, early and late. The late phase of RP was characterized by regular menstrual cycles and increasing levels of FSH. Going through the subsequent stages, increased variability in menstrual cycle length and increased levels of FSH were observed (Soules *et al.*, 2001). Ten years later, the same group reanalyzed the data and included more specific description of hormonal events, including ovarian peptides as AMH and inhibin B (Harlow *et al.*, 2012). They proposed that in the late RP, initial hormonal features of perimenopause consist in low AMH and low follicular antral counts with no modification in length of cycles and FSH levels. Then a second later subphase is characterized by increasing values of FSH and shortened cycles (Harlow *et al.* 2012). In early MT the variability in menstrual cycle length was defined as a persistent difference of 7 days or more in the length of consecutive cycles with recurrence within 10 cycles of the first variable length cycle (Harlow *et al.*, 2012). The late MT is characterized by increased variability in cycle length, extreme fluctuations in hormonal levels, and increased prevalence of anovulation. FSH fluctuates but is higher during this phase than previously and can reach menopausal levels. The duration is estimated to be 1–3 years and climacteric symptoms are frequently present. A recent study gave few more insights from data collected from the Study of Women's Health Across the Nation (SWAN) (Santoro *et al.*, 2017). SWAN is a multiracial/multiethnic observational study of the MT among 1455 women enrolled at seven US sites. Among them, a population of middle-aged women with normal cycles collected their urines every day, 1 month year^{-1} until the FMP or 10 years after inclusion. The results mostly confirmed what was already known from smaller studies. Ovulation persisted up to 5/4 years before the FMP in most of the patients and then its frequency declined rapidly up to 1 year before the FMP where only 23% of the cycles were still ovulatory. Obese women displayed much more anovulation and menstrual cycle irregularity. The menstrual cycles remained regular up to 5 years before FMP (Santoro *et al.*, 2017). Curiously in this study the shortened cycles were not observed. The methodology of this study and/or the selected population can explain this discrepancy with the rest of the literature and our clinical experience. One of the consequences is to reaffirm the necessity of contraception up to the LMP.

Clinical consequences of MT can be important. It is a period when progesterone secretion decreases, estradiol levels can be rather high, and thus endometrial and uterine diseases can occur. Menorrhagia and metrorrhagia are frequently observed. Benign uterine diseases such as myoma, adenomyosis, polyps, and endometrial hyperplasia are more frequent than endometrial cancer but abnormal breakthrough bleeding always needs a rigorous evaluation by echography ± hysteroscopy (Goldstein and Lumsden, 2017). Mastalgia, premenstrual syndrome, and dysmenorrhea can also reappear or worsen. Climacteric symptoms can preexist to

 doi:10.1016/B978-0-12-801238-3.64947-4

menopause which can start far beyond the menopause as demonstrated by several longitudinal studies. A systematic study analyzing 66 papers on climacteric symptoms all over the world reported hot flushes in 3%–86% of premenopausal women, with a median of 21.5% (Freeman and Sherif, 2007). In the perimenopausal women, the prevalence was between 40% and 60% and remained stable in early menopause (Freeman and Sherif, 2007). The prevalence of symptoms was different according to the regions of the world. More recently, three big longitudinal studies also reported on the prevalence of climacteric symptoms during MT. The US Penn Ovarian Aging Study from a 9-year longitudinal, population-based cohort study of 403 women was studied from pre- to postmenopause (Freeman *et al.*, 2007). Hot flushes, vaginal dryness, sleep disorders, aches, joint pain, and stiffness, and depressed mood were observed before and across MT. The most prevalent symptoms were aches, joint pain, and stiffness and hot flushes. They increased during the late transition phase and the early postmenopause from about 30% of the patients up to 75% in MT and PM; whereas depression was more frequent in MT than after and poor sleep and vaginal dryness were not significantly associated with menopausal stages (Freeman *et al.*, 2007). This study demonstrated that even more prevalent after menopause, several symptoms can be present and severe far beyond FMP. SWAN study among the 1455 women enrolled reported on early onset of climacteric symptoms in 247 of them (Tepper *et al.*, 2016). The Australian Longitudinal Study on Women's Health (Mishra and Dobson, 2012a) also described symptoms through early, late MT and menopause in a sample of 5295 Australian women. Eleven percent of women had an early severe profile (according to a score for vasomotor symptoms (VSM)) while still premenopausal and in addition to them, some other reported moderate or mild symptoms before FMP (Mishra and Dobson, 2012a).

MT can be associated with metabolic pejorative features. Changes in fat distribution, with predominant abdominal fat, are associated with reduction in lean mass, all of which can contribute to insulin resistance. Waist circumference (WC) or WC/hip circumference ratio correlates with cardiovascular (CV) and breast cancer (BC) risks. Women often complain of gaining weight without modifying their nutrition. Actually, reduction of energy expenditure, insulin resistance, and modifications in orexigens are features of E2 loss, at least well demonstrated in mice. But these alterations usually occur few years before LMP, and are less clearly explained in the human. Overweight/obesity, dyslipidemia, hypertension, metabolic syndrome, and possibly diabetes are more prevalent in the perimenopausal period and after menopause. These metabolic dysfunctions contribute to the risk of CV events and have to be taken into account. Thus lifestyle recommendations on nutrition and regular exercise are the first line of management of women at this period of life (Khan *et al.*, 2014; Baber *et al.*, 2016). If menorrhagia/metrorrhagia are present, levonorgestrel-releasing intrauterine system (norg-IUS) is an interesting option after eliminating a cause which should necessitate a specific treatment (submucous myoma, polyp) (Lethaby *et al.*, 2015).

Management of Perimenopause

The management of symptoms in this period is different from what it is after menopause. Imbalance between estrogens and progesterone is responsible for the various symptoms and consequences of target organs. In addition, contraception is mandatory in women without tubal ligation or equivalent. Combined estro–progestin contraception is associated with increased risk of CV events and their use is not recommended in women with any risk factor for arterial or venous disease. Age is a factor increasing the risk of both events. Given the frequency of metabolic, endometrial, and uterine disorders, there is a place for treatment by IUS or progestins. If mastalgia or fibrocystic diseases or premenstrual syndrome occur, then antigonadotropic progestins could help. These agents can help to prevent endometrial cancer and breakthrough bleeding. However they can also be associated with VMS. When approaching the menopause, in periods of long cycles if contraception can be taken over by barrier contraceptives, then 10 days months^{-1} of progesterone can help to alleviate VMS, improve sleep disorders and irritability, and provide regular menstrual cycles up to the FMP.

Menopause

Menopause is associated with a drastic decline in ovarian steroids secretion and its consequences at short and long terms. Since menopause is associated with aging, it is somehow difficult to discriminate between the specific consequences of estradiol deficiency and natural senescence since they can also synergize on certain endpoints.

Diagnosis of Menopause

As previously mentioned, the diagnosis of menopause relies on clinical evaluation as the last menstruation. The classical definition for menopause is 1 year without menstruation with a FSH level above 40 UI mL^{-1}. This definition is somehow awkward or at least theoretical. Indeed in the clinical practice it is not worthy to recommend women consulting with various complains to wait 1 year before getting a medication to relieve their VSM. As stated by several textbooks including menopause management (Bricaire and Sitruk-Ware, 1998; Speroff, 2010), the best clinical practice to diagnose menopause is to administrate 10 days of progestin. If bleeding occurs, then this treatment has to be continued as long as bleeding follows the end of the 10 days treatment. Indeed, this treatment can prevent endometrial dystrophies (Gambrell *et al.*, 1980) which occur frequently in the MT as reported earlier. The

benefit of the treatment by progesterone/progestin treatment is also as mentioned earlier to alleviate VSM during this period and even after (Prior and Hitchcock, 2012; Loprinzi *et al.*, 2006).

The short-term consequences are onset or aggravation of climacteric symptoms. In addition to VSM symptoms, and joint pains, urogenital symptoms increase also in prevalence. The longitudinal studies cited earlier have shown that these symptoms can last several years after the menopause; severity of symptoms and their duration vary according to patients with some having early and severe symptoms which can last for long, and some others moderate or mild symptoms with long- or short-term duration (Mishra and Dobson, 2012b; Freeman *et al.*, 2011; Avis *et al.*, 2015). In the SWAN study, median total VMS duration was 7.4 years, but women who experienced early frequent VMS had more than 11.8 years of symptoms (Avis *et al.*, 2015).

Long-term consequences of menopause consist in osteoporosis, CV diseases, urogenital symptoms, sexual difficulties, and decrease in cognitive functions.

Osteoporosis affects about 30% of women in Europe and the United States (International Osteoporosis Foundation, 2017) with increasing risk of vertebral, wrist, and cervical fractures as aging is increasing. The role of estrogens is clearly demonstrated on osteoporosis, whereas its efficacy in CV prevention is less clear.

CV diseases are the first cause of mortality according to (WHO 2017). Men are at higher risk than women before menopause, but after menopause women have an increasing prevalence of CV events. There are myriad of preclinical and animal data showing that estradiol is protective against atherosclerosis (Morselli *et al.*, 2017). If most of observational studies including women treated by menopause hormonal treatment (MHT) have shown a significant decrease in CV events, randomized data are less favorable. One of the explanations is that estrogen administration close to menopause acting on vessels containing estradiol receptors can be protective but with aging, ERs are progressively lost, and estrogens cannot longer exert their effects or be deleterious (Clegg *et al.*, 2017). In the observational studies, women were mostly young postmenopausal whereas in the women health initiative (WHI) they were far from menopause in their great majority. This leads to the concept of "window of opportunity or intervention." A further explanation could be that the women treated had less risk factors than the women in the WHI study, thus this selection suggests "a healthy bias." During MT, metabolic disorders become prevalent and another beneficial effects of estrogens are to maintain insulin sensitivity and secretion and thus decrease prevalence of metabolic syndrome and diabetes (Hevener *et al.*, 2015).

Urogenital symptoms directly associated with a lack of E2 can associate vaginal itching, vaginal discharges, urethritis, and urinary incontinence. Incontinence can be urgent incontinence, stress incontinence, or mixed incontinence. Their prevalence increases with aging. Women are not always reporting them spontaneously and they have to be searched for systematically. Similarly, sexual dysfunctions increase with aging and have to be asked for. Loss of libido is frequent as well as dyspareunia because of vaginal dryness; if systemic treatment is not fully efficient on libido, topical treatment can help to improve sexual intercourses (see following). Androgens have positive effects on libido in some studies, but with controversial results according to the type of treatment. The patch no more available was the most effective treatment (Shifren and Davis, 2017). Australia is the only country to have approved for use a 1% testosterone cream with the recommended dose being 0.5 g day^{-1} gel of testosterone (Shifren and Davis, 2017). Androgens are not recommended in most of countries because of a lack of long-term safety data.

Cognitive disorders are the consequences of aging. They are a frequent complain of women during MT and after menopause, especially memory loss (Maki and Henderson, 2016). In preclinical studies in the animal, estradiol or progesterone can exert neuroprotection. Observational studies have suggested that an early MHT could protect against Alzheimer but randomized control trials (RCT) did not demonstrate any beneficial effect; furthermore, more dementia were observed in the WHI (Shumaker *et al.*, 2003, 2004). The negative impact can be interpreted as deleterious vascular effects of the treatment on the brain in relatively old patients. Similarly to a beneficial effect on CV events, MHT can have some benefits on cognitive disorders if administered during a window of opportunity that is to say early after menopause. There is, however, no proof of any protective effect of MHT on Alzheimer (Maki and Henderson, 2016).

Principles of MHT

In women with a uterus, the most efficient treatment on climacteric symptoms is an estrogen combined with a progestin. In women without a uterus estrogen only is recommended (Stuenkel *et al.*, 2015a).

Type of estrogen, progestin, and regimen of administration may vary, but all have proven their high efficacy to alleviate climacteric symptoms and increase quality of life in symptomatic women. In addition, RCTs and observational studies have consistently shown a benefit of MHT on fractures. The side effects however can be modulated by the choice of specific regimens (see further).

- It is now recommended by most of drug agencies (FDA, EMEA, HAS) (Office of the Commissioner, 2017; Haute Autorité de Santé—Traitements Hormonaux de La Ménopause, 2017). MHT should be administered at the "lower dose for the shortest period of time, according to symptoms, in symptomatic women" and that reevaluation of the need of MHT should be made regularly. Scientific societies of Endocrinology involved in menopause have regularly reevaluated the benefit/risk balance of the treatment and have somehow a different view. In addition to alleviate climacteric symptoms and prevent osteoporosis, they all agree on benefit over risk in women 50–60 years old or at <10 years since menopause (Stuenkel *et al.*, 2015b; Baber *et al.*, 2016; Lumsden *et al.*, 2016; The NAMS 2017 Hormone Therapy Position Statement Advisory Panel, 2017). The benefits can decrease in women over 60 years but still if women have no specific CV and BC risks if they are symptomatic continuation of

MHT can be discussed. If a woman is willing to take MHT after full information on benefits and risks, then MHT can be prescribed (Stuenkel *et al.*, 2015a).

Results From the Main RCTs, the WHI Trials

Until 2002, when the first publication from the randomized trial WHI was released (Rossouw *et al.*, 2002), MHT was considered as beneficial on climacteric symptoms but also on endpoints such as osteoporosis and CV protection. The view supported by numerous observational studies as well as preclinical data was that administration of estrogens should prevent the deleterious effects of the decline in the ovarian secretion on CV events. The successive publications from the WHI combined E + P trial (combined Hormone therapy, CHT) and the corresponding one using estrogens alone (ET) in postmenopausal hysterectomized women (Anderson *et al.*, 2004) have fully transformed the scope of MHT and as a consequence the management of climacteric symptoms and long-term consequences of E2 loss. These RCT were designed to follow women during 10 years after the inclusion by randomization between the active treatment and placebo. In order to get a low rate of dropout were included women far from menopause as they were less often symptomatic. The treatment consisted in conjugated equine estrogens (CEE) at the dose of 0.625 mg day^{-1} irrespective of the age of the patients and with or without medroxyprogesterone acetate (MPA) at 2.5 mg day^{-1} orally and continuously. The results were evaluated as primary outcome coronary heart disease (CHD) (fatal and nonfatal myocardial infarction) and BC as the primary adverse effect; a global index of morbidity, including, BC, pulmonary embolism, colorectal cancer, endometrial cancer, hip fractures, and death from other causes, was also followed (Rossouw *et al.*, 2002). In the CHT, 16,608 women of a mean age of 63.3 years were included; after a mean follow-up of 5.2 years, the study was stopped because of risks exceeding benefits (Rossouw *et al.*, 2002). Only 33% of the population had less than 60 years and more than 20% were over 70 years old. More than 30% were obese and 36% had hypertension. The ET trial included 10,739 hysterectomized women with a mean age of 63.3 years and an average follow-up of 6.8 years (Anderson *et al.*, 2004). Similarly to the CHT trial, 30% of the women were below 60 years and more than 25% were above 70 years. Even a bigger proportion of women was obese (40%) and had hypertension (53%). The main results of the CHT study were an increase in CHD, stroke, venous thromboembolism (VTE), and BC incidence and a decrease in colorectal cancers and osteoporotic fractures (**Table 1**). These outcomes were significantly using nominal confidence intervals (CI) but only the risk of VTE remained significantly using adjusted CI (Rossouw *et al.*, 2002). In the ET trial, there was an increase in stroke and VTE but not in BC. Several subsequent publications from the WHI reanalyzed these data according to the categories of age of the patients and time since menopause. Indeed, these studies have some important limitations: the ages of the included women do not correspond to the real life where MHT is indicated primarily to alleviate climacteric symptoms in recent postmenopausal women.

More recent analysis from the WHI, as shown in **Table 1**, reported a decrease in global mortality in women aged 50–59 years old (Manson *et al.*, 2013, 2017). Furthermore, it showed that expressed—in terms of excess risk or benefit—1.45 (−6.6 to +4.2) fewer CV events occurred per 1000 women per 5 years of treatment in the ET trial and 3.9 (0.15–8.0) more events per 1000 patients per 5 years in the CHT trial (Rossouw *et al.*, 2007). Furthermore, there were less BC in the ET group. In the CHT trial, the hazard ratio (HR) for BC was 1.24 (1.01–1.53) and increased with duration whereas in the ET trial, the HR was 0.79 (0.61–1.02) with no effect of time since inclusion (Manson *et al.*, 2013). CV events were significantly increased only in women over 70 years. The venous and arterial events were observed only in current users. The increase in CV events and VTE was more important the first year of treatment as it is in all procoagulant hormone-dependent events. Women with CV risk factors had an increased chance of events (Bassuk and Manson, 2014). BC risk as detected after at least 5 years of treatment increased with duration and decreased progressively after last use. This is interpreted as a promoter effect on preexisting lesions (Gompel and Santen, 2012). It is mostly ER-positive BC including lobular which are promoted by MHT. About 30% of the women in the CHT had previously used an HT. Only these women had a significant increase in the risk of BC after at least 2 years of previous use of CHT and an additional use of at least 3/5 years (Anderson *et al.*, 2006). The relative risk (RR) of BC was increased in women with mastalgia and high breast

Table 1 Health outcomes in the WHI RCT during treatment (from Manson *et al.*, 2013) expressed as difference in number of events per 10,000 person-years

	CEE + MPA		*CEE*	
	Total	*50–59 years*	*Total*	*50–59 years*
CHD	6	5	−3	−11

Endometrial cancer	−1	0	NA	NA
Hip fracture	−6	−3	−6	3
All cause mortality	−1	−10	3	−11

CHD, coronary heart disease; *BC*, breast cancer; *DVT*, deep vein thrombosis.

density (Crandall *et al.*, 2012; Byrne *et al.*, 2017).

Other endpoints were analyzed in the WHI trials; as an important benefit of MHT, significant less diabetes type 2 were observed in the CHT and ET trials (Manson *et al.*, 2013). Gallbladder disease and urinary incontinence were worsened by the systemic treatment whether ET or CHT (Manson *et al.* 2013). As stated earlier, more dementia were observed in a substudy of the WHI, the women's health initiative memory study (WIMS) which addressed specifically cognitive disorders (Shumaker *et al.*, 2003, 2004).

Differences Between CEE ± MPA and Other Available Treatments in Terms of Side Effects

The route of estrogen administration matters for the CV risk
