As testosterone may increase hemoglobin concentrations (Fernandez-Balsells *et al.*, 2010), untreated polycythemia needs to be evaluated and managed prior to considering testosterone therapy. Conversely anemia, whether related to nutrient deficiency, chronic inflammation or renal disease or of uncertain etiology, is more prevalent in elderly compared to younger or middle-aged men (Guralnik *et al.*, 2004). Testosterone therapy in the T-Trials increased hemoglobin concentrations and improved anemia in those older men (Roy *et al.*, 2017). Thus an increase in hemoglobin concentration may be an ancillary benefit of testosterone therapy in elderly men with low–normal hemoglobin concentrations. Obstructive sleep apnoea may itself result in symptoms of fatigue and obesity is a risk factor for both sleep apnoea and lower testosterone concentrations (Wittert, 2014). Testosterone therapy only transiently worsens the severity of obstructive sleep apnoea (Hoyos *et al.*, 2012; Killick *et al.*, 2013) therefore the presence of untreated severe obstructive sleep apnoea can be regarded as a precaution rather than an absolute contraindication to testosterone therapy (**Table 3**). Given the ongoing debate over the effects of exogenous testosterone on the cardiovascular system and the possible concerns over adverse effects in older men, cardiovascular risk factors and disease should be adequately managed and stabilized prior to consideration of testosterone therapy. Desire for fertility and occupational drug testing are less likely to be of concern to elderly men.

As with any medical intervention, potential adverse effects of treatment need to be considered. Polycythemia and elevation in PSA are recognized adverse effects of testosterone therapy (Fernandez-Balsells *et al.*, 2010; Yeap *et al.*, 2016b). Appropriate safety monitoring for hemoglobin concentration, hematocrit, and PSA should be undertaken. A small reduction in high-density lipoprotein cholesterol may be noted (Fernandez-Balsells *et al.*, 2010). Gynaecomastia, male pattern balding, weight gain, changes in mood or libido, difficulty passing urine, muscle pain, priapism and increased blood pressure are recognized potential adverse events (Yeap *et al.*, 2016b). Postinjection cough due to pulmonary oil microembolism is an uncommon but recognized side effect of depot intramuscular testosterone injections (Middleton *et al.*, 2015), and some men report pain following injection (Sartorius *et al.*, 2010). Men using transdermal formulations must be educated on appropriate steps to prevent inadvertent transfer of residual medication to others by skin contact.

In elderly men testosterone therapy can be monitored clinically by improvement in symptoms and signs of androgen deficiency, and also by measurement of testosterone concentrations achieved on treatment. Generally trough testosterone concentrations are assessed prior to the next injection of long-acting depot testosterone, or in the morning prior to the next application of daily transdermal formulations (Yeap *et al.*, 2016b). Given that higher starting doses of testosterone have been associated with adverse events in men $\geq$65 years with limited mobility (Basaria *et al.*, 2010), these should be avoided when treating elderly men. In an epidemiological study of men aged 70–89 years, there was a U-shaped association of endogenous circulating testosterone with mortality with optimal survival seen in men with testosterone concentrations in the middle of the range (9.8–15.8 nmol/L) (Yeap *et al.*, 2014b). Ideally RCTs should be conducted to test the longer term efficacy and safety of different dosing regimens of testosterone in elderly men. Pending the availability of such information, it seems prudent to maintain testosterone concentrations within the physiological range for elderly men, likely with trough concentrations toward the lower part of that range. Excessive doses that might result in elevated concentrations of testosterone should be avoided.

Conclusions and Priorities for Future Research

In men, circulating testosterone concentrations decline with age. In elderly men, nonspecific symptoms such as lethargy, fatigue, decreased energy, decreased sexual activity, and the presence of sarcopenia or osteoporosis are not uncommon and may or may not be due to androgen deficiency. Careful clinical assessment is warranted including evaluation for systemic illnesses and medication use. Biochemical confirmation of androgen deficiency should be via early morning blood sampling and measurement of testosterone concentrations using an accurate assay, preferably mass spectrometry where available. Age-appropriate reference ranges should be used to interpret testosterone results in conjunction with LH and SHBG. Men with the clinical syndrome of androgen deficiency due to underlying hypothalamic, pituitary or testicular disease merit appropriate investigation and treatment. Testosterone therapy should be considered in such men and age alone is not a barrier to treatment. Expected benefits of testosterone therapy are resolution of symptoms androgen deficiency, and an increase in lean mass and bone mineral density. Prior to commencing testosterone treatment, elderly men should be screened for underlying prostate disease and have management for cardiovascular risk factors and disease optimized. Ongoing monitoring for efficacy and safety of testosterone therapy should be undertaken.

In elderly men, low testosterone concentrations predict poorer health outcomes including frailty, osteoporosis and cardiovascular events. However, the role of testosterone therapy in elderly men with low testosterone concentrations compared to younger men in the absence of hypothalamic, pituitary or testicular disease remains uncertain. The T-Trials have shown a modest benefit of testosterone therapy for sexual function, and improvements in bone density and anemia, in men aged $\geq$65 years with baseline testosterone $<$9.5 nmol/L with symptoms consistent with but not diagnostic of hypogonadism. These results do not provide an indication for testosterone therapy, as further evidence needs to be provided regarding longer term benefits and risks. Priorities for future research are to clarify the longer term benefits and risks of testosterone treatment in elderly men in the absence of hypothalamic, pituitary or testicular disease, particularly whether in this context testosterone therapy has a beneficial, neutral or adverse effect on the cardiovascular system.

Introduction

The Encyclopedia Britannica defines aging as "progressive physiological changes in an organism that lead to senescence or a decline of biological functions and of the organism's ability to adapt to metabolic stress" (https://www.britannica.com/science/aging-life-process). In fact, for evolutionary biologists aging is an inevitable process that results in a progressive structural and functional decline from the cellular level to the whole organism to adapt to environmental stress and changes. This leads, finally, to an increased age-specific mortality rate (i.e., a decrease in survival rate), along with a decrease in age-specific reproductive rate (Flatt, 2012). Hence, among the age-dependent or age-progressive decline in intrinsic physiological function there is the reduced ability to cope with stressors and to reproduce.

In most eukaryotic species, sexual reproduction is the leading strategy to allow reproduction and it is essentially based on sexual activity. Sexual activity consists of those physiological, anatomical, behavioral, and psychological functions that favor the union of male gamete to the female one, thus ensuring continuation of the species. Although it is not essential for individual survival, it is pivotal for species survival. The World Health Organization (WHO) recognizes that sexuality and reproduction are fundamental components of being healthy and human (World Health Organization, 2006). According to the WHO, sexual health is a state of physical, mental, and social wellbeing in relation to sexuality (World Health Organization, 2006). It requires a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences (World Health Organization, 2006). Considering that the aging population is growing worldwide, understanding senescence-associated modification in the sexual and reproductive attitudes represents a relevant task for the sanitary systems. In fact, sexual wellbeing is an often neglected dimension that may contribute directly and indirectly (via physical and emotional health) to successful aging.

Andropause Does Not Exist

In most mammalian species studied so far, there is a diminution of reproductive functioning during mid-through late-life (Packer *et al.*, 1998). In mammals, ovary and testis are the key actors orchestrating reproductive and sexual processes. These two endocrine glands secrete sexual hormones and produce mature germinal cells in a time- and gender-specific way. Ovary and testis are, however, very different since an early stage of fetal development and remain different lifelong. A palindromic gender translation of reproductive or sexual problems from one gender to the other is not a product of sexual revolution, that is, a change in the cultural perception of sexual morality and sexual behavior, but a mere medical mistake. A good example of this medical mistake is the exportation of the concept of the female menopause to male andropause. In the female, the number of germinal cells is determined prenatally, and during the post pubertal life, the continuous oocyte cell death is irreplaceable, finally leading to a true ovarian (germinal and endocrine) failure paralleled by the termination of menstruation (i.e., the menopause) well before it is reached the maximum lifespan of the species. This is not the case in males. In fact, in the testis, gametogenesis and steroidogenesis

do not abruptly stop and, in the large majority of cases, does not stop at all. Hence, andropause does not exist (Wu *et al.*, 2008; Perheentupa and Huhtaniemi, 2009). In fact, some men remain reproductively competent at ages approaching the maximum lifespan of the species. These biological differences might underpin some of the differences in the aging-associated modification in sexual life between genders. In this article, we will focus on sexual function in the aging men.

Testis Physiology and Aging

The male gonad, the testis, can be considered as a factory exporting two distinct groups of locally derived products: sex steroids and sperms. Sex steroids and spermatozoa are produced into two distinct areas within the testis (although in close proximity and in continuous cross talk): Leydig cells and seminiferous tubules. Active testicular production is stimulated by intra-testicular factors (including testosterone; T) and tuned by extra-testicular trophic hormones secreted by the pituitary, the gonadotrophins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). LH and FSH secretion from anterior pituitary is finely regulated by inhibitory influences coming from the testis itself (sex steroids and inhibin B) and stimulated by the secretion in the portal vessels of the pituitary stalk of a hypothalamic decapeptide, the gonadotropin-releasing hormone (GnRH). Among sex steroids produced by the testis, T is exported into the bloodstream in relatively high concentrations (10–30 nmol/L), mainly bound to a protein: sex hormone binding globulin (SHBG). Free T (FT) is the SHBG unbound fraction of total T (TT) and it represents its bioactive fraction. In target tissues, T bioactivity is increased by its reduction to dihydrotestosterone (DHT), through two distinct 5α reductase (5αR) isoforms, 5αR type 1 (SRD5A1), which is androgen-independent, and a more tightly androgen-controlled one, 5αR type 2 (SRD5A2). More recently, with the development of genome-wide profile analyses for gene expression, a third 5αR (SRD5A3) gene was identified, with a not yet characterized biological function. A small fraction of TT is converted to estrogen, through the action of P450 aromatase. T, either directly or through its effectors (DHT estrogens), exerts different actions throughout male life. In the fetus, T stimulates the differentiation of the Wolffian duct into male internal genitalia (epididymis, vas deferens, and seminal vesicles) and of the urogenital sinus in male external genitalia. At puberty, it induces the development of libido, enlargement of the vocal cords, muscle and bone mass, penile growth, and the initiation of spermatogenesis. During adult life, its main role is maintaining some of the aforementioned functions, however without resulting of vital relevance. In fact, lifespan of castrated individuals is not shorter from their eugonadal counterpart (Min *et al.*, 2012).

Male hypogonadism (HG) is the failure of the testis to produce sperm, sex steroids (T and, to a lower extent, estrogen), or both, because of a distant (pituitary/hypothalamus) or a local (testicular) failure. However, a HG-like syndrome can also derive from an impaired action of the sex steroids, as in the case of a resistance to androgens or estrogens, because of alterations in receptor sensitivity or in free hormone bioavailability. Based on these considerations, male HG can be classified in three main forms: primary HG (testis failure), secondary HG (hypothalamic/pituitary failure) or impaired androgen action (biological action failure). The most common form of impaired androgen action is due to increased level of SHBG (Rastrelli *et al.*, 2017).

Recently, HG has been also classified according to its reversibility and to the demonstration of an organic perturbation to the hypothalamus–pituitary-testis (HPT) axis (Grossmann and Matsumoto, 2017). When the latter condition is verified, HG is termed "organic"; otherwise, HG is considered "functional." In particular, functional HG is characterized by "no recognizable structural intrinsic HPT axis pathology" and by the lack of "pathologic aetiologies" (Grossmann and Matsumoto, 2017). Hence, it a diagnosis of exclusion. Because of its functional nature, it may be reversible (Grossmann and Matsumoto, 2017). Functional HG is often due to a deterioration of the HPT activity, due to morbidities impairing HPT axis function or to aging (Corona *et al.*, 2016; Grossmann and Matsumoto, 2017). In contrast to HG orchestrating its effect during prenatal life or puberty, HG with an exordium in late life (late onset HG, LOH), shows a scanty symptomatology, with a phenotype almost superimposable to that of eugonadal men. Symptoms and signs associated to LOH could be physical (weakness, decreased muscle mass, visceral obesity, osteoporosis), psychological (depression, fatigue, impaired memory) or sexual (decreased libido and impaired spontaneous or sex-related erections). In a cross-sectional survey of the European general population (the European Male Aging Study; EMAS), only a triad of sexual symptoms (low libido and reduced spontaneous and sex-related erections) syndromically associates with decreased T levels, whereas other proposed HG symptoms did not segregate with androgen deficiency (Wu *et al.*, 2010). This has been confirmed in a longitudinal extension of the same study, where it was demonstrated that worsening or development of sexual symptoms was associated with incipient secondary (Rastrelli *et al.*, 2015) or primary (Ahern *et al.*, 2016) HG. According to these and previous results (Rastrelli *et al.*, 2015; Ahern *et al.*, 2016) almost all the andrology Scientific Societies recommend the presence of sexual symptoms, along with the biochemical demonstration of low T, to define a clinically relevant LOH (Wang *et al.*, 2009; Bhasin *et al.*, 2010; Khera *et al.*, 2016).

By using ultrasonography, a recent retrospective research on 147 relatively healthy subjects indicate that testis volume decreased by only 2.8% from the fourth to seventh decade (Yang *et al.*, 2011). Accordingly, even if a T decline as a function of aging has been described in several longitudinal studies (Corona *et al.*, 2013a), this is relatively modest and clinically insignificant. In the European general population, an annual age trend of TT decrease was estimated of 0.09 nmol/L year (Wu *et al.*, 2008; Camacho *et al.*, 2013). Paternal aging is associated with a decrease in both the quality and quantity of spermatozoa, along with genetic and epigenetic changes in sperm structure (Gunes *et al.*, 2016). However, although some semen parameters decrease with age, no clinically significant alterations in the fertilizing capacity have been described in aging men (Perheentupa and Huhtaniemi, 2009). A detailed description of testicular alteration according to aging is behind of the scope of this review.

Sexual Activity in the Aging Couple

Although there is the common belief that a physiological sexual inertia characterizes the elderly state, epidemiological studies indicate that this is not always the case. The prevalence of sexual activity, behaviors, and problems in relation to aging was recently reinvestigated (Waite *et al.*, 2009; Lindau and Gavrilova, 2010) from two previously published US datasets: the national social life, health and aging project (NSHAP) and the national survey of midlife development in the United States 1995–96. The former is a national probability sample of 3005 adults (1550 women and 1455 men) 57–85 years of age (Lindau *et al.*, 2007), while the latter reports data from 3032 adults aged 25–74 (1561 women, 1471 men) (Lindau and Gavrilova, 2010). From the analysis of the two cohorts it was found that men were more likely to be sexually active than women at all ages. In particular, among the 75–85 year old group: 38.9% of men compared with 16.8% of women were sexually active, being sexual activity strongly associated with a reported very good or excellent health. In NSHAP (Lindau *et al.*, 2007), the most common sexual dysfunctions in aging men were erectile dysfunction (ED; 37%), lack of interest (28%), and inability to climax (27%). Conversely, the most prevalent sexual problems among women were low desire (43%), difficulty with vaginal lubrication (39%) and inability to climax (34%).

The Wisconsin longitudinal study is a study of the life course from late adolescence through the early to mid-1960s in a random sample of 10,317 men and women who graduated from Wisconsin high schools in 1957 (Syme *et al.*, 2013). In a case-control analysis Syme *et al.* (2013) reported that approximately two-thirds (64.2%) of subjects aged from 63 to 67 years had sex from once a month or less to once a day or more with males being more active than females. The latter data are in line with the aforementioned evidence suggesting that many older adults continue to enjoy, value, and engage in sexual activity.

The successful aging evaluation study is a population-based study on 606 community-dwelling adults in San Diego County, aged 50–99 years and who had a partner (Wang *et al.*, 2015). Over 80% of respondents had engaged in sexual activity in the past year, over 70% engaged in sexual activity weekly or more than once a week, and over 60% were somewhat or very satisfied with their sex lives. No sex differences were evident on dimensions of sexual health except for a higher rate of rejection of sexual overtures by women. Depressive symptoms were negatively associated with all assessed aspects of sexual health even after adjusting for confounders (Wang *et al.*, 2015).

In conclusion, aforementioned epidemiological evidence suggest that a large number of elderly men and women remain sexually active throughout their lives, although self-reported sexual activity is indeed more common in men, regardless of marital status and age. The validity of self-reported measures is however to be regarded with caution because quite often men over- and women under-estimate their sexual attitudes.

Sexual Problems in the Aging Man

The Krimpen study, a population-based study involving 1688 men enrolled in a Dutch municipality near Rotterdam, found the prevalence of ED increased from 3% in men aged 50–54 to 26% in men aged 70–78.25 (Blanker *et al.*, 2001). Similarly, the percentage of men who reported being sexually active declined with increasing age and was lower in men with ED and ejaculatory dysfunction and in those without a partner. In sexually active men, 17%–28% did not have normal erections, indicating that with advancing age, normal erections are not an absolute prerequisite for having sexual activity (Blanker *et al.*, 2001).

A more recent European survey (Corona *et al.*, 2010a) confirms that sexual problems are progressively increasing as a function of age, including ED (**Fig. 1**), low sexual desire and dissatisfaction with orgasm (**Table 1**). In the oldest age group (>70 years) two out of three men reports ED of moderate/severe entity. However, in the same age band, 49% report at least one sexual intercourse, 24% autoeroticism, 58% petting, and 75% thinking about sex. Hence, it is confirmed that valid erection are not a prerequisite for the continuation of sexual activity. In the same study, it was reported that only a fraction of men with ED has concerns about this sexual problem (**Fig. 1**). Interestingly, this fraction was higher at mid-life, declining thereafter and involving only a quarter of men over 70. In conclusion, whereas ED is a common problem in the aging male, only a minority is worried and, therefore, potentially asking for a medical consultation. In the EMAS study, the risk of ED was clearly associated to comorbidities, including organic (cardiovascular diseases, diabetes, obesity, lower urinary tract symptoms) and psychological (depression) disturbances (Corona *et al.*, 2010a). In the same survey, it was also found that relational factors, including satisfaction in the dyadic sexual relationship and partner's health, increase the risk of ED (Corona *et al.*, 2010a). Organic factors are less relevant for the other sexual complaints, while depression has a negative impact in all the aspect of sexuality of the aging male, including sexual desire, orgasm, and intercourse frequency.

Considering that ED is the most common form of sexual dysfunction but only for a minority of subjects, ED represents a bothering issue, it will be useful to describe the correlates of ED in subjects consulting an andrology service for ED.

Correlates of ED in the Aging Man Consulting for Sexual Dysfunction

SIEDY (Structured Interview for Erectile Dysfunction) is a structured interview we developed 15 years ago for the assessment of the components concurring with ED (Petrone *et al.*, 2003). It is a 13-item interview, with three factor analysis-derived scales, which

Data adapted from Corona, G., Lee, D.M., Forti, G., et al. (2010a). Age-related changes in general and sexual health in middle-aged and older men: Results from the European male ageing study (EMAS). *The Journal of Sexual Medicine* **7**, 1362–1380.

Table 1 Prevalence of decreased sexual desire and related concern as a function of age in the European Male Ageing Study population

	Age bands			
	40–49 (n = 796)	*50–59 (n = 904)*	*60–69 (n = 839)*	*> 70 (n = 830)*
Thinking about sex less than once weekly	8.2% ($n = 64$)	17.5% ($n = 154$)	33.5% ($n = 273$)	52.8% (410)
Concerned about decreased sexual thoughts	14.1% ($n = 9$)	14.3% ($n = 22$)	18.3% ($n = 50$)	10.2% ($n = 42$)
Dissatisfied about timing of orgasm	4% ($n = 34$)	5% ($n = 45$)	10% ($n = 68$)	16% ($n = 82$)
Concerned about timing of orgasm	11.8% ($n = 4$)	42.2% ($n = 19$)	27.9% ($n = 19$)	19.5% ($n = 16$)

Data adapted from Corona, G., Lee, D.M., Forti, G., *et al.* (2010a). Age-related changes in general and sexual health in middle-aged and older men: Results From the European Male Ageing Study (EMAS). The Journal of Sexual Medicine 7, 1362–1380.

measure the organic (Scale 1), relational (Scale 2), and intrapsychic (Scale 3) components of ED. These three factors are often simultaneously present in ED patient and mutually contribute to the pathogenesis of ED. It is noteworthy that, in contrast with previously described instruments, scales of SIEDY were identified through factor analysis, and not predetermined by the authors Petrone *et al.* (2003). The ability of each scale in detecting organic, relational and intrapsychic problems in ED subjects was validated in subsequent studies (Boddi *et al.*, 2012; Corona *et al.*, 2012).

In a previous analysis on the contribution of the three scales in explaining ED as a function of aging, we found that both organic (Scale 1) and relational (Scale 2) issues were progressively increasing as a function of aging, whereas intrapsychic problems were more relevant in mid-life but declining thereafter (Corona *et al.*, 2013a). **Fig. 2** represents, as an error bar graph, the variation of each scale scoring (represented as percentage of maximal score) as a function of age bands, in a largest series of subjects than before. It is evident that organic (Scale 1) and relational (Scale 2) factors are the most relevant issues associated to ED in the elderly. However, in a previous study (Corona *et al.*, 2013a), we demonstrated that in the oldest tertile (60–88 years old) of the population referring for ED, the most relevant factor is Scale 1, that is, the organic component. Hence, we will focus on it.

Fig. 2 shows an impressive age-dependent decrease of penile blood flow, as assessed at penile color Doppler ultrasound, after PGE_1 (prostaglandin E_1) stimulation (dynamic peak systolic velocity, D-PSV) in our population. In fact, in the oldest age band, D-PSV is almost one half than in the youngest band. Considering that penile erection is a neurovascular phenomenon, this indicates that an objectively observed vascular impairment is orchestrating its effect in age-associated ED.

Age-dependent accumulation of morbidities could explain the high score of Scale 1 and the decrease of D-PSV that characterize male senescence. As shown in **Fig. 3**, in the European general population (EMAS study), the number of morbidities is progressively increasing as a function of age, being adverse cardiovascular conditions the most represented morbidities of the elderly (Corona *et al.*, 2010a). The link between organic ED and cardiovascular diseases (CVD) has been apparent since long time; however, only in the last 20 years ED has been recognized as a harbinger of underlying CVD, representing, therefore, a valid marker of risk for incident major adverse cardiovascular events (MACE) (Corona *et al.*, 2010b; Rastrelli *et al.*, 2014). It has been hypothesized that ED becomes evident earlier than MACE because the smaller penile arteries reach critical narrowing, with insufficient blood flow, earlier than larger vessels (Montorsi *et al.*, 2006).

We have collected longitudinal information regarding CVD in a subset of the previous population, attending our unit for ED for the first time between 2000 and 2007 (consecutive series of 1687 patients). The main characteristics of this study have been

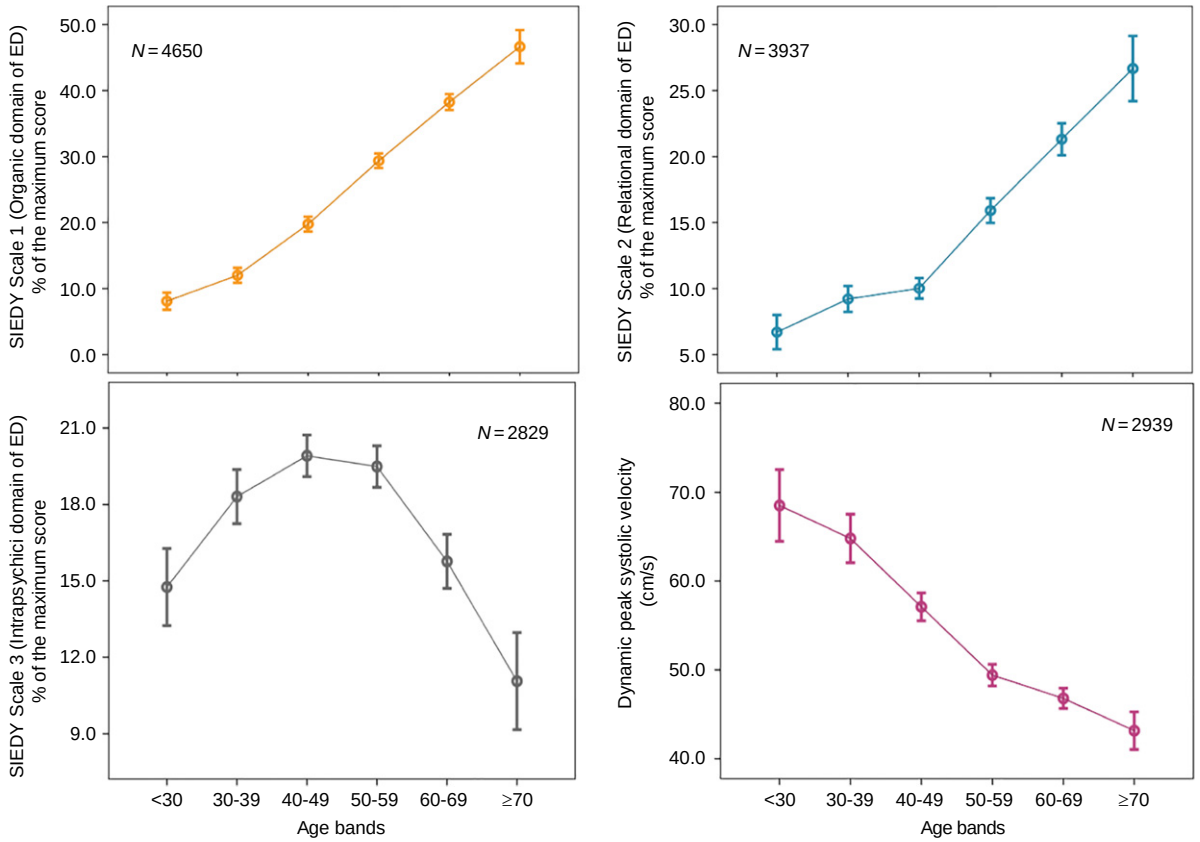

Fig. 2 Age related change in SIEDY scales and dynamic peak systolic velocity at penile color Doppler ultrasound in a population of men seeking medical care for sexual dysfunction at the Sexual Medicine and Andrology Unit of the University of Florence. The Structured Interview on Erectile DYsfunction (SIEDY) includes three scales, which quantify the organic (Scale 1), relational (Scale 2), and intrapsychic (Scale 3) pathogenic components of erectile dysfunction. The components are more important in erectile dysfunction pathogenesis as the scales increase.

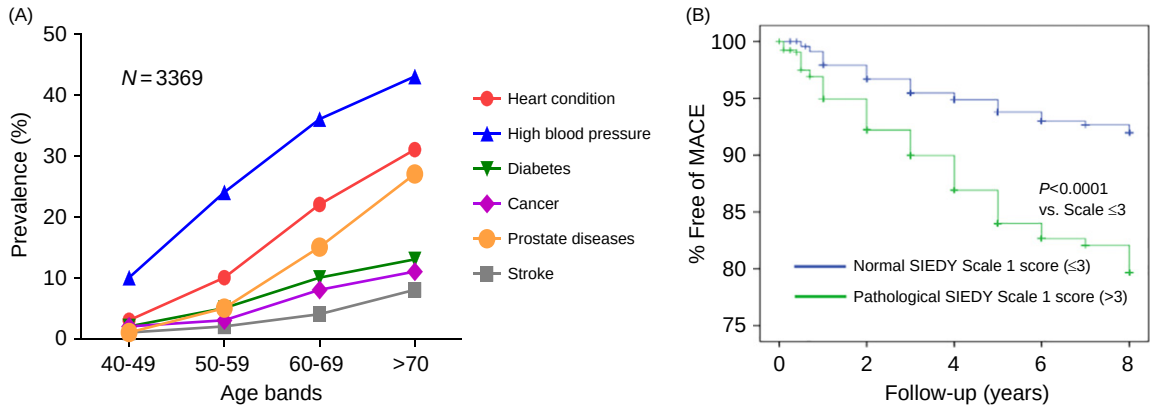

Fig. 3 (Panel A) Prevalence of several morbidities as a function of age in the European male aging study population. (Panel B) Percentage of men free from MACE (major adverse cardiovascular events) according to SIEDY Scale 1 score (organic pathogenic component of erectile dysfunction) in a population of 1687 men seeking medical care for sexual dysfunction followed-up for 4.3 ± 2.6 years. SIEDY: Structured Interview on Erectile Dysfunction. Data adapted from Corona, G., Lee, D.M., Forti, G., et al. (2010a). Age-related changes in general and sexual health in middle-aged and older men: Results from the European male ageing study (EMAS). *The Journal of Sexual Medicine* **7**, 1362–1380.

previously reported (Corona *et al.*, 2013a). Events were identified through the regional hospital discharge system and the City of Florence Register Office. Information on mortality up to 31 December 2007, including causes of death, was obtained from the City of Florence Registry Office, which contains complete and updated records of all persons living within city boundaries. During a mean follow up of 4.3 ± 2.6 years, 139 MACE, 15 of which were fatal, were observed, with a yearly rate of 0.23%. **Fig. 3** also

shows that, when the ED population was categorized according to a pathological score in Scale 1 (i.e., >3), the presence of an organic component of ED was associated with an increased risk of MACE.

Andro-Pause or Lean-Pause?

Low T represents another putative determinant of an impaired sexuality in the aging male. Two recent meta-analyses on the effect of T therapy (TTh) on sexual symptoms in randomized controlled trials (RCTs) involving HG subjects indicate that TTh significantly improved erectile function, libido, intercourse satisfaction, orgasm, and overall sexual satisfaction. This was evident when the effect of T on sexual function was explored in RCTs through different self-reported measures (Corona *et al.*, 2014) and when RCTs strictly using the International Index of Erectile Function (IIEF-EFD, i.e., the most frequently used validated tool to assess erectile function) was scrutinized (Corona *et al.*, 2017). We found that, on the average, TTh was able to improve IIEF-EFD score of 2.31 [1.41; 3.22] points, suggesting efficacy of clinical significance, at least in the milder ED form. Patients with more severe HG (TT <8 nmol/L) reported greater improvement in IIEF-EFD score when compared with those with a milder T deficiency. In addition, the effect of TTh on IIEF-EFD was less apparent in obese and diabetic subjects (Corona *et al.*, 2017), but not affected by age (Corona *et al.*, 2014). Conversely, TTh was completely without effect on ED when studies involving eugonadal subjects were selected (Corona *et al.*, 2014). These results indicate that, although TTh can be proposed at any age, it is meaningful only when an overt T deficiency is present and when other metabolic disturbances, such as diabetes and obesity, are absent, most probably because these morbidities are per se associated to ED, independently from low T.

Fig. 4 shows the age-dependent decline of TT in a large series ($n = 4883$) of subjects consulting our Center for sexual dysfunction. A stepwise decrease in TT is evident from the youngest age bands until mid-life. Thereafter, there is a more smoothed T decline. However, considering that SHBG is progressively increasing, the resultant fraction of unbound FT is linearly decreasing as a function of age also in the more aged individuals. In youngest subjects, the age-dependent T decline is not associated with a concomitant rise of LH, suggesting a central deficiency. Only in subjects older than 60 years there are evidence for a LH surge, indicating a testicular deficiency. Hence, it is possible to conclude that a mixed form of HG—due to a central and peripheral defect in T production along with an impairment of T bioactivity—is more often present in the aged male. However, several considerations should be done concerning aging and T deficiency. First, as shown in Fig. 4, the age-associated T decline never reaches, on average, a true pathological value and only approaches it in the oldest subjects, when calculated FT (cFT) is considered. Second, such a decline is not apparent when only obese individuals were considered. In fact, in nonobese individuals we observed a small, but significant, decrease in TT of 0.07 nmol/L per year, while in the obese

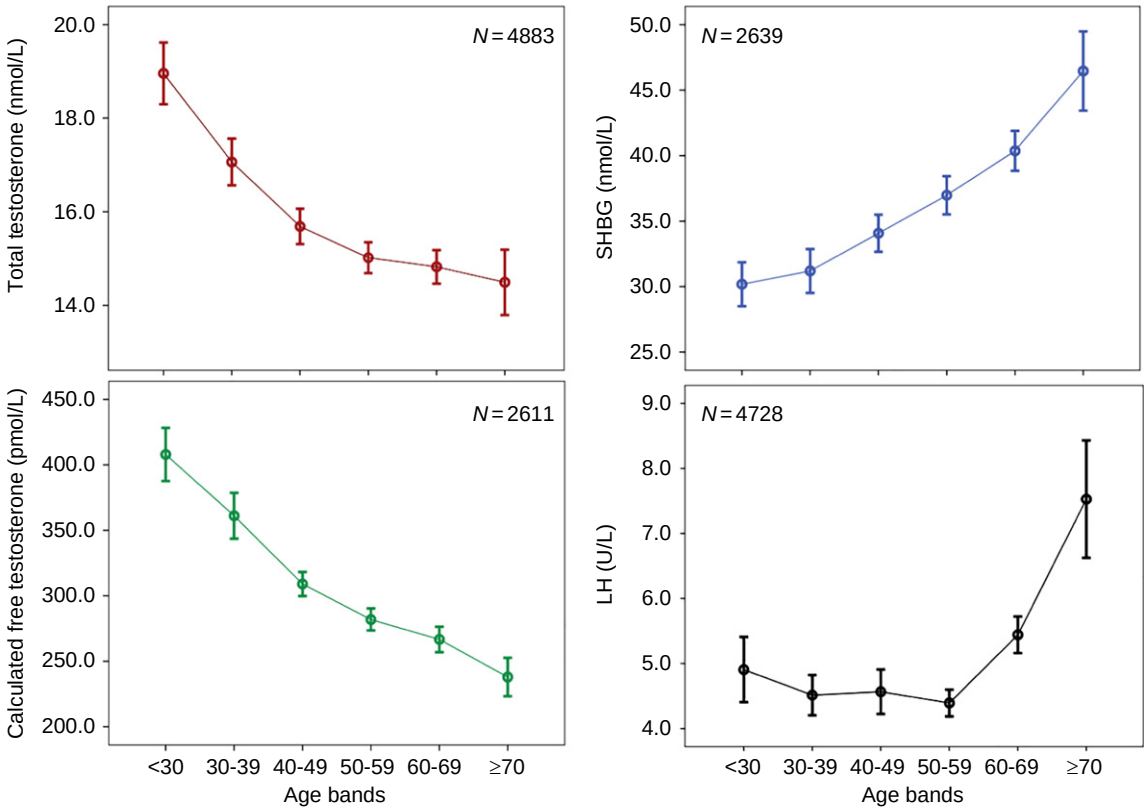

Fig. 4 Age related change in total and free testosterone, sex hormone binding globulin (SHBG) and luteinizing hormone (LH) in a population of men seeking medical care for sexual dysfunction at the Sexual Medicine and Andrology Unit of the University of Florence.

counterpart the regression line is almost flat with an annual decline of 0.02 nmol/L. This is tantamount to say that an obese young individual at the age of 20 years has a lower T than a lean subject at the age of 80 (13 vs. 14.3 nmol/L). This is even more evident when subjects were categorized according to waist circumference (102 cm). Hence, it is possible to say that more than an andropause the lean-pause is the real problem underlying T deficiency in the aging male. Considering that obesity, and in particular visceral obesity, is an age-dependent growing phenomenon (see **Fig. 5**), shifting from the regression line of obese individuals to that of lean subjects will greatly help to age more safely and with higher T levels. Intervention studies strongly support this point. A meta-analysis on the effect of low calorie diet (LCD) on TT indicates that LCD can induce an average increase of 2.87 (1.68–4.07) nmol/L (Corona *et al.*, 2013a,b). A greater T increase can be achieved through bariatric surgery, which results in an average increase of 9.19 (6.75–11.64) nmol/L and 88.85 (62.99–114.72) pmol/L in TT and cFT, respectively. The increase in T was accompanied by an increase in gonadotropin levels of more than one unit per liter (Corona *et al.*, 2013b), thus suggesting that weight loss partially restores HPT axis. This effect might be related to the decrease in circulating estradiol (on average 23 pmol/L), which could result in a decreased negative feedback on the axis (Corona *et al.*, 2015a,b). In obese men, also physical activity, in particular moderate-intense aerobic exercise, induces an increase in TT and cFT levels (Ari *et al.*, 2004; Hayes *et al.*, 2017; Kumagai *et al.*, 2017). Although reported by only one study, this was associated with an improvement in sexual functioning (Khoo *et al.*, 2013). The effect of physical activity on T seems to be greater than LCD (Kumagai *et al.*, 2016). Hence, lifestyle changes are strongly suggested as the first intervention in subjects with age-associated T decline, particularly in those with obesity.

Conclusions

A consistent fraction of aged males still consider sexuality as an important issue, although sexuality in the elderly might have behavioral, social and intrapsychic paradigms that differ from those typical of reproductive age. For instance, penetrative sexual intercourse might not necessarily reflect the hope and the need of aged individuals that can easily consider other forms of intimacy in their relationships. A fountain of youth does not exist, however for thirsty individuals to halt the senescence-associated degeneration of sexual function the only applicable formula is exercise more, eat less and adopt a healthier lifestyle.

Osteoporosis in the Oldest Old

Evelien Gielen, Center for Metabolic Bone Diseases, UZ Leuven, Leuven, Belgium

Epidemiology of Osteoporosis and Osteoporotic Fractures in Old Age

Osteoporosis is a systemic skeletal disease characterized by low bone mass and micro-architectural deterioration of bone tissue, with a consequent increase in bone fragility and fracture risk (Cosman *et al.*, 2014). The incidence of osteoporotic fractures increases with age, and osteoporosis in old age is a challenge because of the extent of the problem and the major burden in terms of morbidity and mortality. Today, the cumulative incidence of hip and vertebral fractures in women at the age of 80 years is close to 30% and more than 40% respectively, and women over the age of 80 account for more than 30% of all osteoporotic fractures and for even more than 60% of all non-vertebral fractures (Cooper *et al.*, 1992; Grados *et al.*, 2004; Seeman *et al.*, 2010). In future, the burden of osteoporosis will only increase because of the aging of the population.

Thus, age is one of the main determinants of the absolute risk of fracture. It is also one of the main determinants of the type of osteoporotic fracture. Between the ages of 55 and 75, women are most at risk of vertebral fractures, but beyond the age of 75, they become increasingly at risk of nonvertebral fractures, such as hip fractures (Sambrook and Cooper, 2006).

Elderly Persons With Osteoporotic Fractures Are Frail

Osteoporosis and osteoporotic fractures tend to occur in a frail subset of the older population (Boonen *et al.*, 2004a). Indeed, elderly with osteoporotic fractures are not "average" elderly, but frail elderly with a high prevalence of underlying comorbidities and at risk of disabilities (Gielen *et al.*, 2012). This frailty is reflected in the poor postfracture outcomes of these patients. For example, 1 year after a hip fracture, 40% of the patients is still unable to walk independently, 33% is institutionalized or totally dependent and mortality is about 20% (Leibson *et al.*, 2002; Schnell *et al.*, 2010). Similar observations have been made in elderly with other types of nonvertebral fractures and even vertebral fractures (Gielen *et al.*, 2011). In hip fracture patients, the excess mortality is not only observed within the first year after the fracture but continues to be observed in the years thereafter because of the underlying comorbidities of these frail elderly (Haentjens *et al.*, 2010).

Diagnosis of Osteoporosis and Intervention Thresholds in Old Age

Despite the high prevalence and significant burden of osteoporosis in the elderly, this condition continues to be underdiagnosed and undertreated, even in those admitted to the hospital with documented fractures. This is particularly so in women over the age of 80 (Feldstein *et al.*, 2003).

Yet, the operational definition of osteoporosis also applies to the very elderly. The World Health Organization (WHO) defines osteoporosis as a bone mineral density (BMD) value at the lumbar spine or the proximal femur of at least -2.5 standard deviations (SD) below the peak bone mass of a young healthy individual (Kanis *et al.*, 1994). Dual energy X-ray absorptiometry (DXA) has, however, low sensitivity for fracture as the majority of fractures occurs in persons with a T-score above -2.5. This indicates that factors other than BMD contribute to fracture risk (Thomas-John *et al.*, 2009). In particular, an existing osteoporotic fracture is the most significant predictor of future fracture risk, doubling fracture risk compared to persons without previous fractures. Also age independently increases fracture risk, with, over a four SD interval of BMD ($+1$ to -3 SD), a 14-fold increase in hip fracture risk at the age of 50, but a 145-fold increase at the age of 80 (Melton *et al.*, 1999; Kanis *et al.*, 2001). Therefore, tools based on age and other clinical risk factors are increasingly being used to target osteoporosis therapy. Among these is the FRAX-algorithm, developed by the WHO Collaborating Centre for Metabolic Bone Disease at Sheffield, UK, which integrates the weight of various clinical risk factors for fractures, with or without femoral neck BMD, to estimate the 10-year probability of hip fracture and major osteoporotic fracture (clinical spine, forearm, hip or shoulder fracture) (FRAX ®). The objective of FRAX is to identify individuals at higher fracture risk who qualify for osteoporosis treatment. Three approaches can be distinguished, which, especially in the elderly, differ in the threshold above which treatment is recommended.

Fixed FRAX Intervention Threshold (National Osteoporosis Foundation (NOF), USA)

According to the NOF guidance, treatment is recommended in individuals with a prior hip or vertebral fracture and for those with osteoporosis (T-score ≤ -2.5) at the femoral neck, total hip or lumbar spine. In persons with osteopenia (T-score between -1.0 and -2.5), the 10-year fracture probability should be calculated and a fixed intervention threshold is recommended for all ages and both genders (Cosman *et al.*, 2014). This fixed intervention threshold is based on the 10-year hip fracture probability at which

 doi:10.1016/B978-0-12-801238-3.64969-3

treatment becomes cost-effective (Kanis *et al.*, 2013; Tosteson *et al.*, 2008). Among women, this 10-year hip fracture probability ranges from 2.5% at the age of 50 to 4.7% at 75 years and among men from 2.4% at 50 years to 4.9% at 75 years. Thus, the intervention threshold slightly increases at older age, which can be explained by the increased competing mortality risks from other disorders at higher age (Tosteson *et al.*, 2008). The NOF guidance recommends treatment in a person with osteopenia and a 10-year probability of a major fracture of ≥20% or a hip fracture of ≥3% (Rizzoli *et al.*, 2014; Cosman *et al.*, 2014). Importantly, these specific intervention thresholds are valid in the United States but not in other regions of the world because of differences in the epidemiology of fracture risk, the health care budget, health economic considerations, practice guidelines and reimbursement criteria (Kanis *et al.*, 2016). Therefore, the thresholds need to be country-specific, although several national osteoporosis guidelines just recommend the thresholds for hip (≥3%) and major osteoporotic fractures (≥20%) of the NOF (Kanis *et al.*, 2013, 2016).

Age-Dependent FRAX Intervention Threshold (National Osteoporosis Guideline Group (NOGG), UK)

The position of the NOGG is to start osteoporosis treatment in an individual when his or her fracture probability exceeds the FRAX intervention threshold, defined as the age-specific fracture probability of a men or women with a previous fragility fracture, no other risk factors, an average BMI (24 kg/m^2) and without knowledge of BMD (Compston *et al.*, 2013; McCloskey *et al.*, 2015). The rationale is that, in general, a person with a previous fragility fracture is considered to qualify for treatment. Therefore, at any age, an individual with the same fracture probability, but without previous fracture, should also be eligible (Kanis *et al.*, 2016). Thus, the intervention threshold is the age-dependent "fracture threshold," and, by consequence, rises with age.

Hybrid FRAX Intervention Threshold

The age-dependent intervention threshold of the NOGG is designed to avoid under-prescription of treatment in young patients as well as over-prescription in older patients that could arise from a fixed threshold such as the intervention threshold of the NOF. The NOGG guideline, however, induces inequalities in access to therapy especially at older age, depending on the presence or absence of a prior fracture (McCloskey *et al.*, 2015; Kanis *et al.*, 2016). An age-dependent threshold indeed requires, for older persons without a previous fracture to be qualified for treatment, a higher fracture risk as compared to those qualifying for treatment because of a previous fracture (Johansson *et al.*, 2012). Therefore, an alternative threshold using a hybrid model has been proposed. According to this model, the threshold rises with age, but remains constant from the age of 70, being at 20% for a major osteoporotic fracture and 5.4% for a hip fracture (Kanis *et al.*, 2016; McCloskey *et al.*, 2015).

Treatment of Osteoporosis in the Oldest Old

In this section, we will evaluate the efficacy and safety of the treatment options for osteoporosis in the oldest old (≥80 years). Both non-pharmacological and pharmacological interventions will be discussed. Osteoporosis treatment should be proven to be effective in the elderly, not only against vertebral fractures but even more so against non-vertebral fractures, as these account for most of the morbidity and mortality. Treatment should also be safe in elderly who are frail, with underlying comorbidities and at increased risk of adverse events.

Physical Exercise Therapy in Old Age

Whether physical exercise reduces the incidence of osteoporotic fractures has, so far, not been assessed in well-designed randomized controlled trials (RCTs) with fractures as the primary end point. Limited evidence, however, suggests that physical exercise is associated with reduced fracture risk. In a meta-analysis of 10 trials (randomized or not), physical exercise significantly reduced overall but not vertebral fracture risk (RR = 0.49; 95% CI 0.31–0.76 and RR = 0.56; 95% CI 0.30–1.04 respectively) (Kemmler *et al.*, 2013). Another meta-analysis of 13 prospective cohort studies showed that moderate-to-vigorous physical activity is associated with reduced hip fracture risk in men and women (RR = 0.55; 95% CI 0.44–0.69 and RR = 0.62; 95% CI 0.56–0.69 respectively) (Moayyeri, 2008). It should be noted that both meta-analyses included young individuals (>45 and >40 years respectively) and did not focus exclusively on (very) elderly.

Physical exercise therapy may reduce the risk of fractures by increasing BMD and by improving sarcopenia, the age-related loss of muscle mass and function.

Physical exercise therapy increases BMD from childhood into old age

Reaching an optimal peak bone mass at the end of the critical period of bone accrual in childhood and young adulthood is an essential part in the prevention of fractures later in life. Physical exercise in *children* and *young adults* may be of major importance to reach this optimal peak bone mass (Gunter *et al.*, 2008; Magkos *et al.*, 2007; Martyn-St James and Carroll, 2010). After the critical period of bone accrual, physical exercise remains important in maintaining and even increasing BMD. Indeed, several meta-analyses have been published about the effect of physical exercise, such as impact exercises with mixed loading, walking or high-intensity resistance training, on BMD in *postmenopausal women* (Martyn-St James and Carroll, 2006, 2008, 2009; Ma *et al.*, 2013).

The most recent Cochrane review on this topic showed a relatively small, but statistically significant effect of physical activity on BMD in postmenopausal women (Howe *et al.*, 2011). The most effective interventions were a combined exercise program for lumbar spine BMD and progressive resistance training for femoral neck BMD. In 2012, the first systematic review with meta-analysis of physical exercises focusing on *older adults* has been published (Marques *et al.*, 2012). This meta-analysis includes 1577 subjects in 19 RCTs, with a median value for mean age of 69 years and a mean age ranging from 65 to 83 years. Exercises of mixed loading impact were associated with significant increases in BMD at the lumbar spine (weighted mean difference [WMD] = 0.011 g/cm^2, 95% CI 0.003–0.020; $P = .007$) and femoral neck (WMD = 0.016 g/cm^2, 95% CI 0.005–0.027; $P = .004$), while impact exercises combined with resistance training were effective at the lumbar spine (WMD = 0.016 g/cm^2; 95% CI 0.002–0.036; $P = .028$) (Marques *et al.*, 2012). Although these findings support the role of exercise to increase BMD at the lumbar spine and femoral neck in older adults with a mean age around 70 years, evidence in the *very elderly* is, to our knowledge, still very limited. In frail community-dwelling elderly with a mean age of 83 years, a 9-month exercise training program consisting of exercises to improve balance, flexibility and coordination as well as progressive resistance training and endurance exercises did not significantly increase BMD at the lumbar spine and proximal femur (Villareal *et al.*, 2004). There was, however, a trend toward reduction in BMD in the control group who only performed the balance, flexibility and coordination exercises. Several limitations, such as insufficient power, may, at least partly, explain the lack of significant results of this RCT (Villareal *et al.*, 2004). Thus, more research is needed to determine the effect of physical exercise on BMD in very old, frail individuals.

Effect of physical exercise therapy on sarcopenia

Physical exercise therapy may not only decrease fracture risk by increasing BMD, but also by decreasing the propensity to falls in the elderly, which is due, among other factors, to sarcopenia and impaired balance.

Numerous studies have shown that progressive resistance training is an effective intervention to improve muscle mass, muscle strength and functional limitations, even in the elderly (Liu and Latham, 2009; Peterson *et al.*, 2011). That even frail elderly may benefit from resistance training is clear from a randomized placebo-controlled trial of Fiatarone *et al.* (1990). 10 frail, institutionalized elderly aged 90 $\pm$1 years who undertook an 8-week progressive resistance training program improved their muscle strength by 174% ($\pm$31%) and muscle mass by 9.0% ($\pm$4.5%), while their mean gait speed improved by 48%. The training program consisted of three times a week three series of eight repetitions with a resistance of 80% of 1 repetition maximum (RM, the maximum weight that can be lifted). Progressive resistance training has also been reported to improve *balance performance*. In a systematic review of 29 RCTs, totalizing 2174 participants with a mean age of $\geq$60 years, 14 studies reported improvements -significantly greater than controls- in balance performance after progressive resistance training (Orr *et al.*, 2008).

In conclusion, physical exercise may increase BMD and improve sarcopenia and balance control, also in the (very) elderly. This supports the recommendation of physical training in order to, ultimately, reduce fracture risk. Although more research is needed to establish the optimal training schedule, the general recommendation is to perform a combination of aerobic exercise and resistance training, both targeted to sites predominantly affected by osteoporotic fractures. High-impact bone loading activities on 3 days a week have to greatest potential to increase BMD, but low to medium weight-bearing exercises on 5 days a week are recommended for those not used to exercising and those over 50 years. The intensity of resistance training should be moderate to high (60%–80% of 1 RM) in order to minimize the risk of injuries as well as to ensure a sufficient strength-building stimulus (Nelson *et al.*, 2007; Chodzko-Zajko *et al.*, 2009).

Calcium and Vitamin D Supplementation in Old Age

Notwithstanding some controversy about the threshold level of 25-hydroxyvitamin D (25OHD), vitamin D deficiency is commonly defined as a serum level of 25OHD below 20 ng/mL (50 nmoL/L) (Rosen *et al.*, 2012). Low levels of 25OHD occur in all age groups, but elderly are at increased risk of hypovitaminosis D because of low dietary intake and decreasing capacity of the skin to produce vitamin D_3, together with less outdoor activities and sun exposure (Lips, 2001; Holick *et al.*, 1989). Therefore, especially frail elderly and those in institutions have lower levels of 25OHD, with a gradual decline of 25OHD from healthy adults over independent elderly to hip fracture patients and institutionalized persons (Lips, 2001).

Calcium and vitamin D deficiency is one of the main determinants of bone loss and fracture risk in old age, and poor vitamin D status may also increase fracture risk by increasing the risk of falling through an effect on muscle strength (Scott *et al.*, 2010). Adequate calcium and vitamin D status is therefore essential in the prevention of bone loss and osteoporotic fractures. There is, however, much controversy about the threshold level of serum 25OHD for optimal bone health. The Task Force of the Endocrine Society recommends a serum 25OHD level above 30 ng/mL (75 nmoL/L), while the Institute of Medicine (IOM) recommends a daily intake of 800 IU of vitamin D for ages $\geq$71 years in order to achieve, in at least 97.5% of the population, a serum 25OHD level of 20 ng/mL (Holick *et al.*, 2011; Ross *et al.*, 2011; Institute of Medicine, 2011). A serum 25OHD level above 20 ng/mL is indeed sufficient to normalize surrogate endpoints of bone health such as 1.25-dihydroxyvitamin D ($1,25(OH)_2D_3$), parathyroid hormone (PTH), intestinal calcium absorption and BMD (Bouillon *et al.*, 2013).

There is, however, an ongoing intense debate whether vitamin D, in combination with calcium, does reduce the risk of osteoporotic fractures (Bolland *et al.*, 2014; Bischoff-Ferrari *et al.*, 2014). A recent meta-analysis for example found that vitamin D coadministered with calcium reduces hip fracture risk in institutionalized but not in community-dwelling elderly (Bolland *et al.*, 2014). This and other meta-analyses and individual RCTs may have failed to demonstrate a reduction in fracture risk with calcium

and vitamin D because of an insufficient dose of supplementation, therapeutic incompliance or lack of targeting of supplementation to persons at risk of vitamin D deficiency or a negative calcium balance (Jackson *et al.*, 2006; Grant *et al.*, 2005; Boonen *et al.*, 2006b; Bouillon *et al.*, 2013). Calcium and vitamin D supplementation indeed needs to be directed to persons with documented or at risk of calcium and/or vitamin D deficiency, which is, as mentioned before, highly prevalent in osteoporosis patients, home-bound frail elderly and institutionalized persons (Lips, 2001).

Thus, combined supplementation with calcium and vitamin D has become an essential component to reduce bone loss and fracture risk in elderly individuals. Osteoporosis treatment, on top of calcium and vitamin D, should be considered in elderly with osteoporosis and osteoporotic fractures.

Pharmacological Osteoporosis Treatment in Old Age

Issues concerning drug therapy in the elderly include reduced intestinal absorption, metabolism and excretion of drugs as well as polypharmacy, therapeutic incompliance and concomitant disorders (Rizzoli *et al.*, 2014). Aging is, for example, associated with a decline in renal function. Since $\pm$50% of the bisphosphonates are excreted by the kidneys, impaired renal function may result in accumulation of these drugs, which potentially affects efficacy and safety (Vondracek and Linnebur, 2009). In this section, the evidence in the oldest old about the efficacy (**Table 1**) and safety of the currently available osteoporosis treatment options will be discussed. This evidence is mostly based on subgroup analyses of the landmark osteoporosis trials that have been published in recent years.

Alendronate

Originally, the efficacy of Alendronate was established by the Fracture Intervention Trial (FIT) in postmenopausal women. The FIT Vertebral Fracture Arm (FIT I) included women with a prevalent vertebral fracture, while the FIT Clinical Fracture Arm (FIT II) included women with a T-score ≤ -1.6 at the femoral neck (mean age 70.8 years and 67.7 years, respectively) (Black *et al.*, 1996; Cummings *et al.*, 1998).

Two sub-analyses of the FIT trials have been undertaken to determine the anti-fracture efficacy and safety of Alendronate in the oldest old. A post hoc analysis of FIT I has evaluated the efficacy of Alendronate in postmenopausal women with the highest fracture risk, including a subgroup of women aged $\geq$75 years (range 75–82 years) (Ensrud *et al.*, 1997). After 3 years, Alendronate significantly reduced the risk of vertebral fracture by 38% (RR = 0.62; 95% CI 0.41–0.94) in women aged $\geq$75 years, compared to 51% in the younger population (RR = 0.49; 95% CI 0.35–0.68). To prevent one new vertebral fracture, eight women aged $\geq$75 years needed to be treated compared with nine women aged $<$75 years. In another analysis, based on pooled data from both FIT arms, age-specific fracture rates by treatment group (55 to $<$65 years, 65 to $<$70 years, 70 to $<$75 years and 75 to 85 years) were calculated (Hochberg *et al.*, 2005). Relative risk reductions for hip (RR = 0.47; 95% CI 0.27–0.81; $P < .01$) and vertebral (RR = 0.55; 95% CI 0.37–0.83; $P < .01$) fractures were constant among age groups, with an even greater absolute risk reduction as age increases, which can be explained by the age-related increase in fracture risk in the placebo group (Hochberg *et al.*, 2005).

Finally, a more recent study showed that Alendronate treatment in patients with a mean age of 82.4 $\pm$ 8.3 years and a prior fracture was associated with a reduced hip fracture risk (HR = 0.72; 95% CI 0.61–0.85; $P < .001$) (Axelsson *et al.*, 2016). The reduction in hip fracture risk was maintained across all age quartiles and the absolute risk reduction after 5 years increased substantially by quartile of age.

The post hoc analysis of FIT I and the pooled analysis from both FIT arms did not report safety data in the very elderly (Ensrud *et al.*, 1997; Hochberg *et al.*, 2005). In the more recent trial in fracture patients, adverse events such as esophagitis, dyspepsia or acid reflux were not more common in the higher than in the lower age quartiles (Axelsson *et al.*, 2016). These data indicate that Alendronate is a safe treatment option in the elderly, with proven vertebral and hip fracture reduction, and also indicates that elderly, who have a higher baseline fracture risk, benefit even more from osteoporosis treatment than younger persons.

Risedronate

The VERT (vertebral efficacy with risedronate therapy)-trials (VERT-NA and VERT-MN) have demonstrated the efficacy of risedronate to prevent vertebral and non-vertebral fractures in postmenopausal women with one or more prevalent vertebral fractures (mean age $\pm$70 years) (Harris *et al.*, 1999; Reginster *et al.*, 2000). In addition, the HIP-trial has investigated the effect of Risedronate on hip fracture risk in two different arms, of which the first arm included postmenopausal women with a mean age of 74 years (McClung *et al.*, 2001).

To determine the efficacy of risedronate in the very elderly, the second arm of the HIP-trial included 3886 women, aged $\geq$80 years (mean age 83 years). These elderly women were included based on the presence of a low BMD at the femoral neck or at least one nonskeletal risk factor for hip fracture (e.g., poor gait or a propensity to fall) (McClung *et al.*, 2001). After 3 years, no significant reduction in the risk of hip fractures was observed (RR = 0.8; 95% CI 0.6–1.2; $P = .35$). Importantly, the majority (58%) of the participants was included solely on the basis of a nonskeletal risk factor, while only 16% was included based on low BMD. A second analysis focusing on the elderly was a pooled analysis of the VERT-NA, VERT-MN and HIP-trials (Boonen *et al.*, 2004b). This analysis included 1392 women aged $\geq$80 years (mean age 83 years) with osteoporosis (T-score < -2.5 or at least one vertebral fracture). The risk of vertebral fractures was reduced by 44% (HR = 0.56; 95% CI 0.39–0.81; $P = .003$) after 3 years. For nonvertebral fractures, the incidence was not significantly different in the treatment group and the placebo group ($P = .66$).

Table 1 Relative risk (95% CI) of new vertebral, hip and nonvertebral fractures compared with placebo in very elderly women receiving currently available osteoporosis treatments

	RCT	*Included participants*	*N*	*Mean age (years)*	*Vertebral fractures*	*Hip fractures*	*Nonvertebral fractures*
Alendronate	Post hoc analysis FIT I (3 years) (Ensrud et al., 1997)	Women aged 75–82 y	539	Not specified	*RR = 0.62; 95% CI 0.41–0.94; P < .05* $p_{interact} < 75$ & ≥ 75 y NS	–	–

Table, with permission, adapted from Gielen, E., Bergmann, P., Bruyere, O. *et al.* (2017). Osteoporosis in frail patients: A consensus paper of the Belgian Bone Club. Calcified Tissue International.

This difference in benefit for vertebral vs. nonvertebral fractures in both analyses in the very elderly might be explained by the fact that bisphosphonates impact on BMD, proven by the significant reduction of vertebral fractures (McClung *et al.*, 2001; Boonen *et al.*, 2004b). Bisphosphonates, however, do not impact on the nonskeletal risk factors of fractures such as gait disturbances, impaired balance and fall risk. These nonskeletal factors are of particular importance in the occurrence of non-vertebral fractures, such as hip fractures, in the elderly, who are more prone to falling (Tom *et al.*, 2013). In contrast, vertebral fractures are often atraumatic, thus less influenced by these nonskeletal risk factors. An additional explanation for the discrepancy between the older and younger population in preventing nonvertebral fractures might be insufficient statistical power in the older age group (Boonen *et al.*, 2004b).

Women aged ≥80 years in the HIP trial had a slightly higher incidence of death, other serious adverse events and withdrawal due to adverse events as compared to younger women (McClung *et al.*, 2001). However, the overall frequency and types of adverse events, including those involving the upper gastrointestinal tract, were similar in the Risedronate and placebo group, regardless of age. Also in women aged ≥80 years in the pooled analysis of the VERT-NA, VERT-MN and HIP trials, adverse events were similar in the Risedronate and placebo group (Boonen *et al.*, 2004b). Even in the very elderly with active gastrointestinal tract disease at baseline or on aspirin, nonsteroidal antiinflammatory drugs (NSAIDs) or proton pump inhibitors (PPIs), the incidence of adverse events was the same in both treatment groups.

Thus, according to the safety data of both Alendronate and Risedronate, oral bisphosphonates are well tolerated in the very elderly, and, even in those at risk of gastrointestinal events, not associated with an increased risk of adverse events as compared to placebo. However, in clinical practice, treatment with oral bisphosphonates may be challenging, as the stringent intake instructions (e.g., to stay upright for at least 30 min after the intake) may be difficult for physically or cognitively impaired elderly. Inappropriate administration, however, increases the risk of adverse events (Vondracek and Linnebur, 2009; Cryer and Bauer, 2002). Furthermore, oral osteoporosis medication increases the pill burden in the elderly, which contributes to low compliance. Indeed, almost 50% of those who have been prescribed an oral bisphosphonate, have discontinued treatment after 1 year (Lo *et al.*, 2006).

Zoledronic acid

An intravenous bisphosphonate, such as Zoledronic acid, is an alternative in elderly that cannot tolerate or adhere to oral bisphosphonates (Boonen *et al.*, 2010). The Health Outcomes and Reduced Incidence with Zoledronic Acid Once Yearly Pivotal Fracture Trial (HORIZON-PFT) has shown that Zoledronic acid significantly reduces the risk of vertebral, hip and nonvertebral fractures in postmenopausal women with osteoporosis (mean age 73 years) (Black *et al.*, 2007). Also in a subsequent analysis in patients with surgical repair of a low-trauma hip fracture (mean age 74.4 years), the HORIZON-Recurrent Fracture Trial (HORIZON-RFT), Zoledronic acid significantly reduces the risk of new vertebral and nonvertebral fractures (Lyles *et al.*, 2007).

A post hoc pooled analysis of the HORIZON-PFT and HORIZON-RFT focused on the elderly, by including postmenopausal women aged ≥75 years (mean age 79.4 years) with osteoporosis (T-score ≤ −2.5 at the femoral neck or ≥1 prevalent vertebral or hip fracture) (Boonen *et al.*, 2010). After 3 years, the incidence of vertebral and nonvertebral fracture was significantly lower in the Zoledronic acid group compared to the placebo group (HR = 0.34; 95% CI 0.21–0.55; $P < .001$ and HR = 0.73; 95% CI 0.6–0.9; $P = .002$ respectively). This benefit was comparable with the relative risk reduction in subjects younger than 75 years in the HORIZON-PFT and HORIZON-RFT, presenting Zoledronic acid as an effective treatment option for the prevention of vertebral and non-vertebral fractures in the elderly. However, in patients aged ≥75 years, the incidence of hip fractures was lower with Zoledronic acid, but this did not meet statistical significance (HR = 0.82; 95% CI 0.56–1.2; $P = .297$), contrary to the statistical significance that was obtained in patients <75 years. Possibly the sample size was not statistically powered to detect hip fracture risk reduction in this older age group. An alternative explanation is the greater influence of nonskeletal risk factors for hip fractures with increasing age (Boonen *et al.*, 2004b, 2010).

In the post hoc analysis of the HORIZON-PFT and RFT trial in women aged ≥75 years, the incidence of adverse events and postdose symptoms occurring within 3 days of the infusion (pyrexia, myalgia and influenza-like illness) was higher with

Zoledronic acid than with placebo (Boonen *et al.*, 2010). However, the incidence of serious adverse events and death were similar in the two treatment arms. An increased risk of atrial fibrillation, suggested in the HORIZON-PFT, which could be a concern in the elderly, was not observed in the very elderly on Zoledronic acid (Boonen *et al.*, 2010).

Denosumab

Denosumab has been established as an effective intervention by the FREEDOM trial, with a significant reduction in the risk of vertebral, hip and non-vertebral fractures in postmenopausal women (mean age 72.3 years) (Cummings *et al.*, 2009).

A post hoc analysis of the FREEDOM trial has evaluated the effect of Denosumab in high risk populations, among which women aged ≥75 years (Boonen *et al.*, 2011). In this age group (mean age 78.2 years), Denosumab significantly reduced the risk of hip fractures by 62% (2.3% placebo vs. 0.9% denosumab; $P < .01$). This risk reduction in elderly patients is comparable with the risk reduction in the overall study population of the FREEDOM trial. Another analysis of the FREEDOM trial confirmed that Denosumab reduces the risk of vertebral fractures to the same extent in subjects aged ≥75 years (RR = 0.36; 95% CI 0.25–0.53) as in subjects <75 years (RR = 0.30; 95% CI 0.22–0.41, interaction *p*-value 0.482) (McClung *et al.*, 2012). Also the effect on non-vertebral fractures was similar in persons older (RR = 0.84; 95% CI 0.63–1.12) and younger than 75 years (RR = 0.78; 95% CI 0.63–0.96, interaction p-value 0.642). In addition, the FREEDOM Extension trial showed that, also in women aged ≥75 years at baseline, Denosumab for up to 6 years was associated with a persistently low incidence of new vertebral, hip and nonvertebral fractures, with a fracture incidence similar to that observed after 3 years (Papapoulos *et al.*, 2012).

Denosumab is thus effective to prevent vertebral *and* hip fractures in the elderly (McClung *et al.*, 2012; Boonen *et al.*, 2011). This is in contrast to the bisphosphonates where no significant reduction in hip fracture risk could be shown for Risedronate and Zoledronic acid in the elderly, although, as mentioned, this might be explained by lack of statistical power in these subgroup analyses (Boonen *et al.*, 2010; Ensrud *et al.*, 1997; Hochberg *et al.*, 2005). However, it is tempting to speculate that this observation of hip fracture reduction with Denosumab is due to the mechanism of action of Denosumab, different from the mechanism of action of bisphosphonates, with distinct effects on cortical bone (Genant *et al.*, 2013). Cortical porosity is indeed one of the main determinants of non-vertebral fracture risk, including hip fracture risk.

In general, Denosumab was well tolerated in postmenopausal women in the FREEDOM trial (Cummings *et al.*, 2009). In the post hoc analysis in women aged ≥75 years, no significant differences were noted in the safety profile between placebo- and Denosumab-treated subjects, and the incidence of the reported adverse events was similar to those in the overall FREEDOM population (Boonen *et al.*, 2011). Importantly, the efficacy of Denosumab is not affected by renal function, so elderly with renal impairment will experience the same anti-fracture efficacy as patients with normal renal function (Jamal *et al.*, 2011). However, since the use of Denosumab is associated with a high rate of severe hypocalcemia in patients with advanced chronic kidney disease, close monitoring and replacement of calcium and vitamin D is required to avoid hypocalcemia in these patients. Finally, Denosumab, but also the bisphosphonates, may be associated with very rare but severe adverse events, such as atypical femoral fractures and osteonecrosis of the jaw. To our knowledge, there is no evidence that these events are independently associated with age (Low, 2012).

Strontium ranelate

The anti-fracture efficacy of Strontium ranelate, which has a dual mode of action of increasing bone formation and reducing bone resorption, was established by the spinal osteoporosis therapeutic intervention (SOTI) trial (mean age 69.3 years) and the TReatment Of Peripheral OSteoporosis (TROPOS) (mean age 76.7 years) (Meunier *et al.*, 2004; Reginster *et al.*, 2005).

In a preplanned pooled analysis of both SOTI and TROPOS in women aged ≥80 years (mean age 83.5 years), Strontium ranelate significantly reduced the risk of both vertebral and nonvertebral fractures (Seeman *et al.*, 2006, 2010). However, the finding of an increased risk of cardiac events, including myocardial infarction, in additional clinical studies in male osteoporosis and osteoarthritis, led the European Medicines Agency (EMA) to recommend a change in the indication of Strontium ranelate (European Medicines Agency, 2013). It remained a useful option in elderly with severe osteoporosis and unable to take other osteoporosis treatments, but contraindicated in case of uncontrolled hypertension, established, current or past history of ischemic heart disease, peripheral arterial disease and/or cerebrovascular disease (Reginster, 2014). Due to this restricted indication leading to a continuous decrease of patients treated with Strontium ranelate, the worldwide and permanent cease of marketing of Strontium ranelate became effective starting from August 2017 (Servier, 2017).

Teriparatide

Daily subcutaneous injections of teriparatide, a biosynthetic parathyroid hormone analog, reduces the risk of vertebral and nonvertebral fractures, as shown in the fracture prevention trial (FPT) in postmenopausal women with a prior vertebral fracture (mean age 69.5 years) (Neer *et al.*, 2001).

A prespecified subgroup analysis of the FPT-study was undertaken to investigate the effect of Teriparatide in persons aged ≥75 years after 19 months of treatment (mean age 78.3 years) (Boonen *et al.*, 2006a). 5.2% of elderly in the Teriparatide group and 15.1% in the placebo group had a new vertebral fracture (RR = 0.35, $P < .05$). Treatment-by-age interaction was not significant ($P = .99$), indicating that the effect of Teriparatide was not statistically different in younger versus older patients. Likewise, 3.2% of the elderly women in the Teriparatide group and 4.2% in the placebo group had a new non-vertebral fracture (RR = 0.75; $P = .661$). The treatment- by-age interaction was again not significant ($P = 0.42$). The nonsignificant effect on nonvertebral fracture risk in the very elderly can be explained by the small number of nonvertebral fractures in the older subgroup.

As a result, this analysis was not sufficiently powered to show a statistically significant reduction in the risk of nonvertebral fractures in women aged ≥75 or to detect small differences in the relative treatment effect on nonvertebral fractures in the younger and older subgroups (Boonen *et al.*, 2006a). Hip fracture incidence was not a primary endpoint in this trial. So, age does not affect the efficacy of Teriparatide in preventing vertebral and non-vertebral fractures.

In the post hoc analysis of the FPT trial in women aged ≥75 years, there was no increase in adverse events in women treated with Teriparatide compared to placebo (Boonen *et al.*, 2006a). On the contrary, back pain, cataract and pruritus were significantly less common in those treated with Teriparatide. Treatment-by-age interaction (≥75 vs. <75 years) was not significant for the important adverse events. Only diarrhea was reported more frequent, while cataract, deafness, pruritus and weight loss were reported less frequent in the older compared to the younger age group. Thus, in the elderly, the safety profile of Teriparatide is, in general, comparable to placebo. In clinical practice, the major disadvantages of Teriparatide are the cost and the daily subcutaneous administration which may be a burden for older patients.

Conclusion

Osteoporosis is one of the most common age-associated conditions and a major cause of fracture risk. In old age, osteoporosis and osteoporotic fractures tend to occur in a frail subset of the population. Treatment of osteoporosis is of particular concern in the elderly because of the substantial burden of osteoporotic fractures in terms of morbidity, mortality and economic cost.

It is never too late to treat osteoporosis, not even in elderly patients with the most severe degree of osteoporosis and not even in those who have already sustained an osteoporotic fracture. Calcium and vitamin D supplementation is an essential but not sufficient component in the management of osteoporosis in old age. Adding osteoporosis treatment reduces the risk of fractures even more, at least in older individuals with documented osteoporosis and at least for vertebral fractures and possibly also for hip fractures. In frail elderly with documented osteoporosis, osteoporosis treatment may even be more effective than in younger patients, with more fractures averted and lower numbers needed to treat. Nonpharmacological interventions such as physical exercise therapy may contribute to reduce fracture risk by increasing BMD and improving muscle mass and function.

Data in the very elderly show that currently available osteoporosis therapies are relatively safe, with no significant differences in the incidence of most adverse events in the treated group compared to the placebo group. The incidence of adverse events in the very elderly is also similar to that reported in the general population. In real life, specific issues such as comorbidity and polypharmacy should be taken into account in the elderly and may influence the choice of therapy. However, all together, these efficacy and safety data in the elderly indicate that age in itself is no reason to withhold osteoporosis treatment in very elderly with osteoporosis or at high fracture risk.

Aging and the Thyroid Gland☆

Leonidas H Duntas, University of Athens, Athens, Greece

Introduction

The aging process may affect the hypothalamic–pituitary–thyroid (HPT) axis and increase the prevalence of thyroid disorders. Moreover, the comorbidities and polypharmacy that typically accompany aging often complicate the diagnosis and treatment of thyroid dysfunction in this population. These two factors strongly point to the need for a specialized and individualized approach. The aim of the present critical review, which includes the most relevant studies of the last few years, is to highlight the effects of age on thyroid function, thus offering a concise update to clinicians on the epidemiology, pathogenesis and challenges in diagnosing and treating thyroid disease in aging persons.

Aging and the Hypothalamic–Pituitary–Thyroid Axis

Advancing aging is associated with decreasing synthesis, secretion pattern and activity of thyrotropin-releasing hormone (TRH), the core regulator of the HPT axis. Consequently, thyrotropin-stimulating hormone (TSH) secretion rate and its nocturnal peak slowly decline with age in a manner dependent upon sex, body composition, stress, drugs, nutrition, exercise and comorbidity (Veldhuis, 2013). The changes become prominent by the eighth decade of life, with a tendency, this being more evident in women than in men, towards higher basal TSH as well as to appearance of thyroid autoantibodies. In addition, taking into consideration that TRH is a trophic factor for the diencephalon and that it acts as a neuroprotectant against oxidative stress and glutamate toxicity, decreasing TRH may be involved in the development of dementia in long-standing hypothyroidism (Daimon *et al.*, 2013).

Thyroid function in aging is usually sufficient to sustain normal serum thyroid hormone levels, which is also supported by reduced thyroxine degradation rates. On the other hand, evaluation of the HPT axis in aged patients may often be challenged by non-thyroid illness (NTI), malnutrition and medication(s) used, all of them resulting in altered 5′-iodothyronine deiodination and impaired thyroid function test (low to normal T4, low T3, high reverse T3 and inappropriately normal or low TSH) (Lado-Abeal, 2015). The pathogenesis of long-term NTI is multifactorial, marked by the suppression of TRH, resulting in persistently reduced secretion of TSH despite low plasma thyroid hormone levels (Fliers *et al.*, 2015). In some cases distinguishing between NTIS and severe hypothyroidism can be challenging. In patients with NTI, infusion of hypothalamic-releasing factors can reactivate the thyroid axis (Fliers *et al.*, 2015).

With regard to medication, a number of drugs may interfere with thyroid testing by affecting the binding of thyroid hormone (TH) to binding proteins, or can displace TH from binding sites, impair T4 conversion to T3 or decrease TSH secretion (Table 1).

Thyroid Disease in the Elderly

Overt and Subclinical Hypothyroidism

The prevalence and incidence of hypothyroidism increase with aging and contribute to total morbidity in the old. However, it has been shown that among the elderly, a thyroid disorder may be underdiagnosed due to less obviously manifested symptoms and comorbidities in conjunction with the confounding effects of medications, this finding strongly supporting the concept of targeted screening for those above 65 years old. Notably, a very recent population-based study carried out in young and older hypothyroid patients investigated to what extent a high prevalence of symptoms predicts overt hypothyroidism in these two cohorts. The results demonstrated that while applying a hypothyroid symptom score was useful in diagnosing hypothyroidism in the young (<50 years), it failed to indicate hypothyroidism in older (>60 years) patients (Carlé *et al.*, 2016). As mentioned above, thyroid function test interpretation may often be difficult due to the presence of NTI which can bring about alterations in the metabolic clearance of thyroid hormone, drug interactions and potential adverse reactions (Kim, 2000–2014).

Subclinical hypothyroidism (SCH) is defined as elevated TSH with normal levels of free thyroxine (FT4) and triiodothyronine (T3). SCH is classified into a minimal disease with TSH levels between 4.0 and 6.0 mU L^{-1}, a mild form with TSH levels between 6 and 10 mU L^{-1} and a severe form with TSH >10.0 mU L^{-1}. SCH is a common condition in the elderly at a rate of up to and over 15%, the majority of individuals with SCH having a TSH between 4.5 and 6.9 mU L^{-1}. The rates of reversion to euthyroidism or progression to overt hypothyroidism depend on baseline TSH and antithyroid peroxidase antibody (TPOAb) positivity (Somwaru

Table 1 Drugs that interfere with thyroid hormone (TH) tests, by variably acting at different levels of the pituitary thyroid axis, and with thyroid hormone metabolism

Drugs	*Interference*
Estrogens	TBG[a] ↑
Tamoxifen	TBG ↑
Fluorouracil	TBG ↑
Anabolic Steroids	TBG ↓
Salicylates and NSAD (Fenclofenac)	TH displacement
Heparin	TH displacement
Diuretics (Furosenide)	TH displacement
Amiodanone	Decrease T4:T3 conversion
Iopanoic acid	Decrease T4:T3 conversion
B-blockers (propranolol)	Decrease T4:T3 conversion
Glucocorticoids	Decrease T4:T3 conversion
Dopamine	TSH ↓
Somatostatine and its analogues	TSH ↓
Glucocorticoids	TSH ↓
Ferroursulfate	LT4 absorption ↓
Cholestiramine	LT4 absorption ↓
Soy bean	LT4 absorption ↓

Drugs	*Interference*	
Antiepileptics	*TSH*	*FT4*
Valproate	↑	↓
Phenobarbital	↑	↓
Carbamazepine	↑	↓
Retinoids	↓	
Metformin (diabetes/insulin resistance)	↓	
Tyrosine kinase inhibitors (TKIs)	Hepatic metabolism T4	↑

[a]TBG, thyroxine binding globulin.

et al., 2012). Thus, a reversion to euthyroidism at 2 year was more common, up to 46%, for those with a TSH of 4.5–6.9 mU L^{-1} as compared to about 10% in subjects with a TSH between 7 and 9.9 mU L^{-1} and only 7% of those with a TSH at 10 mU L^{-1}, which latter is also independently associated with progression to overt hypothyroidism.

TSH levels within the population reference range are not associated with risk of CHD events or CHD mortality, suggesting that subtle differences in thyroid function are not likely to influence the risk of CHD. In the elderly, age-specific population-derived normal TSH reference ranges are not commonly used to identify thyroid dysfunction, thus rendering an upper limit of normal TSH inappropriate in diagnosing SCH in persons older than 65 years (Hennessey and Espaillat, 2015). Consequently, this may lead to overestimation of SCH in the elderly and premature or unnecessary initiation of treatment. In a recent study in community-dwelling men, 3885 men aged 70–89 years were analyzed according to the 2.5th and 97.5th centiles (Yeap *et al.*, 2016). It was shown that the reference interval for TSH in older men moves upward, to 0.64–5.9 mIU L^{-1}, whereas the reference interval for FT4 is compressed, at 12.1–20.6 pmol L^{-1} (0.94–1.60 ng dL^{-1}, compared with the conventional reference ranges (Yeap *et al.*, 2016)). Thus, the application of the conventional reference interval in older patients may result in misinterpretation of results, classifying patients as having overt or subclinical thyroid disease when in fact this is not the case.

Should the disease, however, be left untreated, the consequences of SCH in the elderly are, in the absence of a consensus, controversial, while it is most likely that the effects vary depending on age, duration of disease and gender. Accordingly, some data show an increased risk for hip fracture in men and for Alzheimer's disease in women, while there are conflicting results as to cardiovascular risk (Somwaru *et al.*, 2012; Biondi, 2008). Nevertheless, in a meta-analysis of 10 studies including 14,449 participants investigating risks associated with SCH (2134 CHD events and 2822 deaths), it was estimated that SCH is associated with a modestly increased risk for CHD (Ochs *et al.*, 2008). In another study, the association of subclinical thyroid disease and mortality was evaluated in 17,440 individuals older than 65 years and followed up over a decade (Grossman *et al.*, 2016). Of the 17,440 individuals, 1956 had SCH [11.2%], 538 had subclinical hyperthyroidism (SCHyP) [3.1%], while 14,946 were normal euthyroid [85.7%]. Both SCH and SCHyP were associated with significantly increased mortality, which was persistent following multivariate analysis (Grossman *et al.*, 2016). Importantly, crude mortality was elevated at 1 (the most significant association), 2 and 5 years, but this association is likely to decrease as time from initial evaluation increases. The highest mortality rate was associated with TSH levels above 6.38 mIU L^{-1} in patients with SCH, whereas no threshold for increased mortality was identified in SCHyP.

SCH has been associated with dyslipidemia, although the pathogenesis is complicated, while high TSH levels, even within the reference levels, have been linked to modestly higher levels of blood pressure and serum lipids (Asvold *et al.*, 2013). The SCH-lipids

association is likely to be influenced by age and gender, as younger women show more detrimental effects of high TSH on lipids than those in menopause and men. Meanwhile, the reported connection with atherosclerosis is not as yet fully understood from a pathogenetic point of view. In this regard, the recent findings of increased LDL peroxidation, according to plasma concentrations of hydroxy-octadecadienoic acids (HODEs) and hydroxy-eicosatetraenoic acids (HETEs) in patients with overt (OH) and SCH warrant further investigation to elucidate the issue (Zha *et al.*, 2015). In this line of evidence, high homocysteine levels were reported in OH and SCH, resulting in decreased concentrations of apolipoprotein A-I (Apo-AI) and high density lipoprotein cholesterol (HDL-C) (Yang *et al.*, 2016). These effects may substantially contribute to development of atherosclerosis and cardiovascular disease (CVD). By inhibiting Apo-AI, SCH deranges its antioxidant capacity and mitigates oxidative stress (Yang *et al.*, 2016). Moreover, hyperhomocysteinemia propagates insulin resistance and impairs endothelial function in patients with hypothyroidism and arterial hypertension, thereby appreciably contributing to CVD. It is also noteworthy that women with SCH display higher remnant lipoproteins (RLP) levels. These however rapidly and significantly decrease following replacement therapy with levothyroxine (Brenta *et al.*, 2016), a possible mechanism behind this response being the increased hepatic lipase activity observed after levothyroxine treatment.

Subclinical thyroid dysfunction has been considered as a risk factor for cognitive impairment in aging patients. The association between subclinical thyroid dysfunction and cognition was investigated in the PROspective Study of Pravastatin in the Elderly at Risk (PROSPER) (Winkler *et al.*, 2015), a aged 70–82 years ($n = 5154$ patients) with pre-existing vascular disease. SCH and SCHyP were registered in 65 and 161 participants, respectively, but no consistent association was established of SCH and/or SCHyP with impaired cognitive performance, compared to euthyroid participants.

In contrast, an analysis was made of a population-based study, including 2563 euthyroid participants (aged 50–80 years) from the second examination of the population-based Heinz Nixdorf Recall study, to investigate the gender-specific association of low- and high-normal TSH association with mild cognitive impairment (MCI) (Wijsman *et al.*, 2013). The results did not show any association with low-normal TSH concentration in women, and no association of either low- or high-normal TSH concentration with MCI in men, thus indicating that women with high-normal TSH concentration ($TSH > 4.50$ mU L^{-1}) might be at higher risk of MCI.

Also of note, an observational cohort study based on the records of a number of Danish health registers disclosed that patients with hypothyroidism are at increased risk of being diagnosed with a psychiatric disorder and being treated with antidepressants, antipsychotics and anxiolytics both before and after the diagnosis of hypothyroidism (Thvilum *et al.*, 2014). Therefore, considering the several objective and practical difficulties, as enumerated above, in diagnosing hypothyroidism among the elderly, it seems clear that even a small clinical sign should lead to monitoring (Carlé *et al.*, 2014).

Indications for treatment of SCH remain controversial. While treatment of SCH may improve lipid profile, there is however no evidence that it is associated with decreased cardiovascular or all-cause mortality in elderly patients. In patients above 70 years with a high risk of progression from SCH to overt disease close monitoring should be considered as the best practice. Treatment of the elderly aged 70 years and over should be recommended when serum TSH is > 10 mU L^{-1} (repeatedly measured), independent of the presence of symptoms and signs of hypothyroidism: this is of particular importance in females, and especially in those with positive TPOAB, dyslipidemia, diastolic arterial hypertension and/or MCI. In cases with $TSH < 10$ mU L^{-1} an individual approach is advocated.

Overt and Subclinical Hyperthyroidism

Hyperthyroidism is usually oligosymptomatic in the elderly, this being due to alterations of thyroid hormone production, metabolism and action and, importantly, to the fact that hyperadrenergic symptoms are largely absent in older patients with hyperthyroidism (Engels *et al.*, 2015). This notion was confirmed by an experimental study in which euthyroid mice that were rendered hyperthyroid were seen to undergo age-dependent changes in thyroid hormone transporter mRNA expression (Engels *et al.*, 2015).

The most common physiological causes of hyperthyroidism in the elderly are Graves' disease and toxic multinodular goiter. Hyperthyroidism is a serious clinical condition among older subjects, associated as it is with high morbidity, and it is moreover a disorder that is frequently challenging to diagnose due to the confounding effects of drugs and NTIs, as mentioned earlier, on the interpretation of thyroid function tests (Samuels and Franklyn, 2000–2015).

There is also the problem of iatrogenic hyperthyroidism. Notably in this respect, the increased risk of atrial fibrillation (AF) in older patients prescribes the use of amiodarone or administration of iodinated contrast agents, which, however, can disrupt thyroid function and often induce hyperthyroidism (Samuels and Franklyn, 2000–2015). Meanwhile, there is the problem arising from the presence of SCHyP, defined as normal thyroxine (FT4) levels with decreased TSH, since its management is a debatable subject in the old due to the lack of symptoms. Among the elderly, however, it is linked to an increased risk of total mortality, coronary heart disease (CHD) mortality, heart failure and AF, particularly in patients with suppressed TSH levels < 0.10 mIU L^{-1} making it particularly dangerous for this age group. This fact was demonstrated by a systematic review of pooled data collected from more than 70,000 participants carried out in order to arrive at a precise estimation of the risks of CVD outcomes that were linked to subclinical thyroid dysfunction (Gencer *et al.*, 2013). Prospective cohort studies, including thyroid function data and ensuing fractures, have also been analyzed to evaluate the association between subclinical thyroid dysfunction and hip, spine, or any fractures (Blum *et al.*, 2015). SCHyP was associated with an increased risk of hip and other fractures, again among those with TSH levels of less than 0.10 mU L^{-1} and those with endogenous SCHyP (Blum *et al.*, 2015). In a prospective multicenter study, thyroid hormones and thrombophilic biomarkers were evaluated 1 year after acute venous thromboembolism (VTE) and it was found that in elderly patients, SHyP may be associated with lower rVTE risks (Segna *et al.*, 2016).

In summary, the above findings are of considerable importance to physicians and clinicians since, by establishing a firm basis of estimated risk of clinical outcomes and of potential TSH thresholds (TSH < 0.10 mU L^{-1}), they considerably facilitate decision-making for initiation of treatment.

Epicrisis

Both SCH and SCHyP are common and on the rise in the elderly. This is due to the increasing aging population, to more frequent screening as well as to possibly adverse environmental factors. Because the diagnosis can be hampered by non-specific or mild symptomatology and by confounders, it should be made with special care. Treatment should be seriously considered in patients with a TSH > 10 mU L^{-1}, while in elderly patients with TSH < 10 mU L^{-1} as well as in older patients with a TSH between 0.1 and 0.4 mU L^{-1} an individualized approach is strongly recommended.

Introduction to Endocrine Toxicology and Endocrine Disruption

Jorma Toppari, Institute of Biomedicine, Research Center for Integrative Physiology and Pharmacology, University of Turku, Turku, Finland and Department of Pediatrics, Turku University Hospital, Turku, Finland

The World Health Organization defines an endocrine disruptor as "an exogenous substance or mixture that alters function(s) of the endocrine system and consequently causes adverse health effects in an intact organism, or its progeny, or (sub) populations". In 2017 European Union adopted this definition for the basis of scientific criteria to identify endocrine disruptors in the field of plant protection products. This was considered an important step towards greater protection of citizens from harmful substances. However, there are also other definitions for endocrine disruptors, for example, Endocrine Society uses an operational working definition of an endocrine disrupting chemical as "an exogenous chemical, or mixture of chemicals, that interferes with any aspect of hormone action" (Zoeller et al., 2012; Gore et al., 2015). The important difference between the definitions is, whether the effect of the chemical needs to be "adverse" to make it endocrine disruptor. According to WHO any chemical with an effect on the endocrine system is a potential endocrine disruptor. The distinction is significant from the regulatory point of view.

Several scientific societies have published their opinions, reviews, and analyses on endocrine disruptors during the recent years: the American College of Obstetricians and Gynecologists (ACOG), the American Society for Reproductive Medicine, Endocrine Society, European Society of Endocrinology, European Society for Paediatric Endocrinology, Pediatric Endocrine Society, The International Federation of Gynecology and Obstetrics (FIGO), the Royal College of Obstetricians and Gynecologists. These reviews present a comprehensive picture of the environmental problems that we face in endocrinology.

The list of endocrine disruptors is enlarging and includes now more than 1000 chemicals. However, only a small percentage of the more than 100,000 chemicals that are currently produced have been studied for their endocrine disrupting activity. Endocrine disruption can occur at several levels. Receptor interference is the simplest and easiest to analyze of the effects. Multiple receptor assays are available for all hormones. Quantitative structure–activity relationship (QSAR) analyses can be done with computer modeling, which has helped to recognize putative receptor interactions without wet laboratory work. However, endocrine disruption is not limited to receptor interactions. Hormone biosynthesis or metabolism can be affected, as well as hormone transport and elimination. The endocrine system is built with several feedback and feedforward circuits that are fine-tuned by paracrine and autocrine regulation. Disconnecting these circuits also leads to endocrine disruption, which explains the complex dose–effect relationships of endocrine disruptors. In contrast to many classical toxicological models that appear to follow the Paracelsus paradigm, according to which "dose makes the poison," the dose responses are often nonlinear in endocrinology. Therefore no adverse effects in experiments with high doses do not rule out effects at low doses. An example of nonlinear exposure–outcome relationship comes from the effects of testosterone treatment: a low testosterone dose does not interfere with spermatogenesis, but higher doses inhibit sperm production by blocking LH secretion from the pituitary, which leads to decline in intratesticular testosterone concentration. If testosterone dose is further increased, sperm production starts again, because the exogenous testosterone now fully replaces testicular hormone. The dose–response curve in this case is U-shaped. Animal experiments are still needed to cover the complex metabolism and interactions in testing of the chemicals.

Hormones guide organogenesis and growth, and therefore developmental endocrine disruption is particularly devastating. Exposure to an endocrine disruptor at a fragile stage of development can be much worse than the same exposure in later life. Critical developmental windows are known, and organogenesis during the first trimester of fetal life is the most vulnerable time. During the last decades we have learned about developmental origin of adult diseases, which is based on the programming events occurring during early development. Much of our current burden of noncommunicable diseases appears to have a connection to fetal dysregulation where endocrine disruptors may play an important role.

Endocrine toxicology started to gain more attention in the 1990s when the term endocrine disruptor was coined. The focus was first on estrogenic compounds, since the adverse effects of developmental exposure to diethylstilbestrol (DES) were shown both in rodents and humans, and many of the mouse findings were recapitulated in the analyses of old randomized controlled trials. The appearance of clear cell adenocarcinoma of vagina in teenager girls who had been exposed to DES in utero caused an alarm that led to the ban of DES in the 1970s. Although this tumorigenic effect was not occurring in mice, similar structural anomalies in the reproductive tract of both male and female were evident in humans and experimental animals. Furthermore, DES adversities were observed also in the second generation after exposure, suggesting epigenetic inheritance. At the same time, estrogenic effects in wildlife fish became evident. High levels of estrogen-induced vitellogenin in male fish and a high proportion of intersex fish in English rivers pointed to pollution of water with estrogenic compounds, such as alkylphenols and traces of human contraceptives. Alkylphenols were used for example in textile industry and their release to waste water was soon regulated when the hormonal activity was identified. Yet another concern was raised, when the unknown estrogenic activity released from polycarbonate plastic flasks in laboratories was identified as bisphenol A (BPA). The activity was weak but caused problems in experiments where blank controls showed clear hormonal activity. Ever since bisphenol A has been one of the most studied endocrine disruptors raising a lot of controversy. In many countries baby bottles are not allowed to contain any bisphenol A, and industry has started to advertise bisphenol A-free products. In the United States, a large research program CLARITY is on-going to solve the open questions concerning endocrine toxicity of BPA. In this Encyclopedia, there are plenty of examples of endocrine disrupting effects of BPA for

 doi:10.1016/B978-0-12-801238-3.64328-3

example, in the pancreatic beta cells (Alonso-Magdalena et al., 2018), hypothalamus (Fudvoye et al., 2018), adipose tissue (Willner and Blumberg, 2018), and control of behavior (Arambula and Patisaul, 2018).

Increased incidences of hormone-related cancers, such as testicular, prostate, and breast cancer raised the question, whether endocrine disrupting chemicals had contributed to the increase. Developmental origin of cancers was intensively studied and for testicular cancer a lot of evidence accumulated showing its fetal origin. When the incidence of congenital birth defects, such as hypospadias and cryptorchidism had also increased, and semen quality had declined, an obvious question was, whether these had something to do with each other. Indeed, they do, since all of them can have the same cause, for example, defective androgen production or androgen receptor mutation. Male reproductive health problems turned endocrine disruptor research also to antiandrogens. The list of these compounds has grown long. One of the first was *p,p′*-DDE, the most persistent congener of DDT, an old pesticide that was banned in the developed world because of its ecotoxicity, extinction of birds at the high level of food chain. DDE was shown to be an androgen receptor antagonist (Kelce et al., 1995). Many others followed, including procymidone and vinclozolin, two fungicides. The latter did not bind androgen receptor itself, but its two metabolites were receptor blockers. Systematic research on antiandrogens demonstrated also that their effects were additive, even when the mechanism of action varied, that is, receptor antagonists and inhibitors of hormone synthesis worked together accumulating the effect. Although estrogenic compounds were in the forefront of male reproductive toxicology first, studies have switched almost totally to antiandrogens during this century.

Research on endocrine disruptors has been hampered by political agendas. Chemical industry has tried to defend its markets by denying many early warnings of adverse effects associated to its products. On the other side, some non-governmental organizations have been ready to ban chemicals at the first sign of any danger. Argumentation has often deviated from scientific rigor to naming of the opposite site with phrases like “green humbug” or “fake science.” Nevertheless, European Union, United States, and Japan have aimed at better identification and proper regulation of endocrine disruptors. Although the progress has been slow, REACH (Registration, Evaluation, Authorisation, and Restriction of Chemicals) legislation in EU gave some basis for that work. Clinical endocrinologists have also become aware of the problem, and the endocrine societies are now actively involved in advocating research on endocrine disruptors. Since human experimentation with endocrine disruptors is usually not possible, except for some compounds used in pharmaceutical products, we have to base our evaluation of the chemicals on their physicochemical characteristics, in silico, in vitro and in vivo testing, ecotoxicology and epidemiology, which together form the weight of evidence basis to our decisions.

The impact of endocrine disruptors can be also measured in money. Leo Trasande and coworkers (2015) made a series of health economic analyses of the expenses caused either directly or indirectly by endocrine disruptors and inaction in their regulation in EU. The overall estimate was 157 billion euro per year. By far the highest costs derived from adverse effects on neural development by thyroid disruptors. Thomas Adams stated already 1618: “Prevention is better than healing, because it saves us from the trouble of being sick”. Thus, identification and elimination of the endocrine disruptors should be our aim. European Union chemical legislation took a step to this direction when REACH (Registration, Evaluation, Authorization and Restriction of Chemicals) was launched, but it is only the beginning.

Encyclopedia of endocrine diseases presents now for the first time a section on environmental disruption of different endocrine systems. Endocrine disruption is not limited only to these endocrine systems but affects all our endocrine organs. In the future endocrine disruptors should always be considered when solving problems in endocrine diseases.

Toxic Effects of Common Environmental Pollutants in Pancreatic β-Cells and the Onset of Diabetes Mellitus

Paloma Alonso-Magdalena, Eva Tudurí, Laura Marroquí, and Ivan Quesada, Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain
Robert M Sargis, University of Illinois at Chicago, Chicago, IL, United States
Angel Nadal, Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

The Endocrine Pancreas

The endocrine pancreas constitutes 1%–2% of the total human pancreatic weight and involves multicellular structures, called the islets of Langerhans, that are dispersed throughout the pancreas (In't Veld and Marichal, 2010). Each islet ranges in size from 100 to 300 μm and is comprised of 1000–3000 cells across different endocrine populations: glucagon-secreting α-cells, insulin-secreting β-cells, somatostatin-releasing δ-cells, pancreatic polypeptide PP cells, and ghrelin-releasing ε-cells. About 90% of the islet is composed of α- and β-cells. In mouse, pancreatic β-cells constitute 65%–80% of the islet, while α-cells represent about 15%–20%. However, the α-to-β-cell ratio is increased in human islets (Cabrera *et al.*, 2006). The major function of these two cell types is to regulate glucose homeostasis. When plasma glucose levels decline, α-cells secrete glucagon, which mainly induces hepatic glucose output by activation of gluconeogenesis and glycogenolysis. In contrast, when plasma glucose levels rise, pancreatic β-cells secrete insulin, which activates glucose uptake by skeletal muscle and adipose tissue and inhibits hepatic glucose production. This feedback loop allows for the maintenance of plasma glucose within physiological limits. The extensive microvasculature of the islet facilitates rapid sensing of ambient glucose by islet cells and their prompt hormone release into the circulation (In't Veld and Marichal, 2010). In addition to nutrients and hormones, islet cells are also regulated by sympathetic, parasympathetic, and sensory nerves (Rodriguez-Diaz and Caicedo, 2014). Among the different islet cell types and hormones, the pancreatic *β*-cell and the secretion of insulin play a key role in the pathophysiology of diabetes.

The Pancreatic β-Cell

The insulin-secreting pancreatic β-cell is an electrically excitable cell that acts as a glucose sensor (Rorsman *et al.*, 2011; Rorsman and Braun, 2013). Glucose enters the β-cell cytosol via plasma membrane glucose transporters, increasing metabolic activity. Considered the molecular sensor of the β-cell, glucokinase phosphorylates glucose molecules and is a rate-limiting step for glycolytic flux. In the pancreatic β-cell, glucose is efficiently metabolized by the mitochondrial pathway, increasing the cytosolic ATP/ADP ratio. This rise induces closure of ATP- sensitive K^+ (K_{ATP}) channels. The resting membrane potential of the pancreatic β-cell (about -70 to -75 mV) is mainly due to the opening of these channels. In the presence of stimulatory glucose concentrations, the cytosolic rise in the ATP/ADP ratio blocks the K_{ATP} channel, inducing plasma membrane depolarization until a threshold at which voltage-operated Ca^{2+} channels are activated (Rorsman *et al.*, 2011; Rorsman and Braun, 2013; Yang *et al.*, 2014). Ca^{2+} entry through these channels raises cytosolic Ca^{2+} concentration that activates the exocytosis and extracellular release of insulin secretory granules. Thus, extracellular changes in plasma glucose are sensed via β-cell metabolism and translated into electrical activity and calcium signals that induce insulin secretion. In addition to calcium, other intracellular messengers such as NADPH, glutamate, and cAMP among others potentiate and/or amplify the secretory process by increasing the transport and exocytosis of secretory vesicles (Yang *et al.*, 2014). In vivo glucose-induced insulin secretion is biphasic with a transient rapid peak of insulin release (first phase) followed by gradual secretion towards a plateau (second phase).

The regulation of insulin biosynthesis in the pancreatic β-cell is also critical to maintain an adequate insulin content and secretory response to the different stimuli and physiological situations (Fu *et al.*, 2013). Insulin transcription is regulated by numerous transcription factors that interact with the promoter region of the insulin gene, establishing numerous pathways that sensitively respond to nutrients and hormones. The insulin gene encodes the preproinsulin protein that is further processed to proinsulin via the endoplasmic reticulum and Golgi. This highly efficient process facilitates insulin synthesis in response to physiological demands, but may lead to endoplasmic reticulum stress in pathological conditions. Finally, proinsulin is sorted into the secretory vesicles and converted to insulin by prohormone convertases during granule maturation (Fu *et al.*, 2013). Thus, all these highly regulated processes are necessary of β-cells to satisfy insulin demand.

Diabetes Mellitus

Diabetes mellitus is a chronic metabolic disease with a high prevalence worldwide. Diabetes occurs either when the pancreas does not produce enough insulin, or when the body cannot effectively use the insulin it produces. According to the World Health

Organization (WHO), this disease has already reached the status of a global epidemic and has grown in almost all social strata and niches, especially in low- and middle-income countries where more than 80% of diabetes deaths occur. The 2016 WHO global report on diabetes estimated that approximately 422 million individuals have diabetes worldwide (prevalence of 8.5%) with this number projected to reach 552 million by 2030, making diabetes the 7th leading cause of death (WHO, 2016). Diabetes is therefore considered one of the most serious current public health problems, making understanding its pathophysiology essential for improving societal health.

The WHO classifies diabetes into the following types: type 1 diabetes (T1D, previously known as insulin-dependent, juvenile or infantile); type 2 diabetes (T2D, previously known as noninsulin dependent or adult), and gestational diabetes (GDM).

T1D (5%–10% of cases) is a tissue-specific, chronic autoimmune disease characterized by severe impairments in insulin synthesis resulting from immune-mediated β-cell death (Herold *et al.*, 2013). Genetic predisposition and environmental factors are the main known contributors to T1D onset. The interaction between these two factors induces the activation of several signaling pathways and transcription factors in the *β*-cells, leading to the production and secretion of cytokines and chemokines, expression of major histocompatibility complex (MHC) class II antigens, and eventually β-cell apoptosis (Morgan and Richardson, 2014; Op de Beeck and Eizirik, 2016).

T2D is the most prevalent type of diabetes accounting for approximately 90%–95% of cases. Insulin resistance resulting from the combination of obesity and low-grade, chronic inflammation in metabolic tissues, such as skeletal muscle and adipose tissue, is an important mechanism underlying the development of T2D. In addition, T2D is also considered a complex multifactorial polygenic disease, with a strong genetic component (Gregor and Hotamisligil, 2011; Bonnefond and Froguel, 2015). During its initial phase, pancreatic β-cells compensate for increased peripheral insulin resistance by progressively increasing insulin secretion (hyperinsulinemia). However, if insulin resistance persists for years, especially in genetically predisposed individuals, β-cell secretory capacity gradually deteriorates, leading to a progressive increase in fasting glucose levels and, consequently, hyperglycemia (DeFronzo *et al.*, 1992; Kahn, 2001).

Additionally, persistent metabolic stress leads to a decrease in β-cell mass (around 30%–60%) in patients with T2D. This is mainly due to an increase in apoptosis resulting from chronic exposure to free fatty acids and high glucose (glucolipotoxicity), and/or islet amyloid deposits. Furthermore, local, mild inflammation has been observed in pancreatic islets during the course of T2D. Similarly to T1D, the presence of immune cells (e.g., macrophages) surrounding β-cell contributes to β-cell dysfunction and, therefore, apoptosis (Velloso *et al.*, 2013; Marchetti, 2016).

In recent years there has been a generalized global increase in diabetes prevalence that cannot be explained by genetic factors. Regarding the development of T2D, dietary changes (i.e., consumption of high energy foods), sedentary lifestyles and, subsequently, a rise in the incidence of obesity cannot explain the rapid increase in T2D prevalence. Thus, other environmental factors likely contribute to this alarming rise in the number of diabetes cases.

Epidemiological, cellular, and animal studies indicate that chemical pollutants, including endocrine disrupting chemicals (EDCs), affect β-cell function and should be considered diabetes risk factors (Heindel *et al.*, 2016; Mimoto *et al.*, 2017; Neel and Sargis, 2011; Alonso-Magdalena *et al.*, 2011). In the current article, we will focus on the effects of widespread chemical pollutants on pancreatic β-cells in in vitro cellular models and in vivo animal models. The alterations that these chemicals induce in this critical cell type should advance understanding of their impact on glucose regulation and diabetes risk.

Nonpersistent Pollutants

This group of pollutants includes chemicals that do not strongly accumulate in fat and are generally rapidly metabolized and excreted in urine or feces within approximately 24 h. However, many of these chemicals are used in a wide variety of commonly used products resulting in extensive exposure that results in a high percentage of the human population having detectable levels in urine and/or serum.

Phthalates

Phthalates and phthalate esters are a group of EDCs commonly named plasticizers since they have been extensively used to impart flexibility and elasticity to rigid plastics such as polyvinyl chloride (PVC). They are not covalently bound to the plastic matrix so they can easily leach and be released into the environment. These chemicals are commonly used in the production of many consumer products including medical devices (intravenous tubing and containers for blood, dialysis or nutrients), toys, vinyl flooring materials, building materials, cosmetics, and food containers. Of note, European Union has banned the use of phthalates in toys for children under 3 years of age and in cosmetics. Human exposure is widespread via ingestion, inhalation, and dermal contact (Halden, 2010). In their fourth National Report on Human Exposure to Environmental Chemicals, the Centers for Disease Control and Prevention (CDC) reported detectable urinary concentrations of 13 phthalate metabolites, including mono-benzyl phthalate (MBzP), mono-isobutyl phthalate, mono-ethyl phthalate (MEP), mono-(2-ethylhexyl) phthalate (MEHP), and mono-butyl phthalate (MBP) among others (Centers for Disease Control and Prevention (CDC), 2015).

Initial concerns about phthalates focused on their developmental and reproductive effects. Human and animal studies suggested a correlation between phthalate exposure and increased risk of male reproductive abnormalities such as hypospadias, low

sperm count, or shorter anogenital distance (Meeker *et al.*, 2009). More recently, phthalates have been linked to T2D and associated disorders, including increased waist circumference, overweight, and insulin resistance (Stahlhut *et al.*, 2007; Gore *et al.*, 2015; Heindel *et al.*, 2016; Kuo *et al.*, 2013). Nevertheless, the underlying mechanisms contributing to metabolic complications are still unresolved. In an attempt to unravel this phenomenon a number of studies have explored the possibility that phthalates disrupt glucose metabolism by altering pancreatic β-cell function.

In vitro studies have evaluated the effects of the high volume phthalate di-(2ethylhexyl) phthalate (DEHP) on the rat pancreatic β-cell line INS-1. At micromolar concentrations (100–400 μM), DEHP decreased cell viability in INS-1 cells treated for 24 h. This was associated with an increase in the production of reactive oxygen species (ROS) and a decline in the activity of the antioxidant enzymes superoxide dismutase and glutathione peroxidase. In addition, altered lysosomal membrane permeability and a reduction in the mitochondrial membrane potential were reported. Overall these data suggest that both oxidative stress and lysosome-mitochondrial damage could be responsible for DEHP effects (She *et al.*, 2017). This reduced cellular viability was also found in studies performed by Sun and collaborators who observed that INS-1 cells treated with DEHP (25, 125, or 625 μM) for 24 h showed significant oxidative damage and activation of ER stress response that ultimately promoted increased apoptosis and decreased glucose-stimulated insulin secretion (GSIS) (Sun *et al.*, 2014). The phthalate metabolites, monoisobutyl phthalate (MiBP), mono-*n*-butyl phthalate (MnBP), and mono-(2-ethylhexyl) phthalate (MEHP) have also been reported to impair GSIS and cell viability (Weldingh *et al.*, 2017). In contrast, other studies did not find any effect of DEHP on GSIS but did report a decline in basal insulin secretion (Hectors *et al.*, 2013).

Curiously, in the human pancreatic β-cell line 11B4, 72 h treatment with monoethyl phthalate (MEP) (1–1000 nM) augmented cellular proliferation and insulin content after glucose induction with enhanced expression of the transcription factor PDX-1 (Guven *et al.*, 2016).

Animal studies have shown that in utero exposure to DEHP may disrupt pancreatic β-cell function in the offspring. Treatment with DEHP (1.25 and 6.25 mg/kg/d) throughout gestation and lactation provoked the development of glucose intolerance in the female offspring at 27 weeks of age. This was accompanied by lower insulin release in response to glucose as well as reduced pancreatic β-cell mass and degranulation (Lin *et al.*, 2011). Similarly, perinatal administration of DEHP, at doses between 1 and 100 mg/kg/d, resulted in glucose intolerance with decreased insulin secretion and content at postnatal day 60. Interestingly the changes were associated with an increment of global DNA methylation that led to a downregulation of several genes involved in pancreatic β-cell function and differentiation such as Pdx-1, Pax-4, and Pax-6 (Rajesh and Balasubramanian, 2014).

Bisphenol-A

Bisphenol-A (BPA) is a widespread EDC that has been extensively used as the base compound in the production of polycarbonate plastics and the resin lining of food and beverage cans. It is commonly found in a variety of plastic items including plastic dinnerware, water bottles, children's toys, medical and dental devices, dental sealants, and household electronic equipment among others. It is also relatively abundant in thermal paper cash register receipts (Schecter *et al.*, 2010; Lopez-Cervantes and Paseiro-Losada, 2003; Hehn, 2016). BPA has been detected in 93% of urine samples in the United States (Calafat *et al.*, 2008). It has been found to be present in urine, amniotic fluid, neonatal blood, placenta, cord blood, and human breast milk at levels that are known to be biologically active (Vandenberg *et al.*, 2010, 2007). Levels found in urine range from 2.38 to 4.32 μg/g creatinine (Centers for Disease Control and Prevention (CDC), 2015). General population exposure to BPA occurs via ingestion but also by dermal contact and inhalation (Vandenberg *et al.*, 2010; Zalko *et al.*, 2011). Nowadays BPA is accepted as a contributing factor in the increasing incidence of diabetes and obesity worldwide (Gore *et al.*, 2015; Alonso-Magdalena *et al.*, 2011; Casals-Casas and Desvergne, 2011). The mechanisms for the diabetogenic effects of BPA are multifactorial but mounting evidence suggests that the disrupting effects of BPA on pancreatic β-cells is key. This has been demonstrated in a series of in vitro and in vivo studies.

In the rat β-cell line INS-1, BPA effects are variable depending on the dose. INS-1 cells cultured in the presence of BPA (1–100 nM) showed increased basal insulin release but no alteration in GSIS (Hectors *et al.*, 2013). On the contrary BPA (100 and 1000 nM) increased both basal secretion and GSIS in the TC-6 β-cell line leading to ER stress as indicated by the activation of Hsp70 (Makaji *et al.*, 2011). Effects into the micromolar range (0.0020–2 μM) have also been explored in the INS-1 cell line. At a dose of 0.002 μM, BPA increased GSIS (Lin *et al.*, 2013), while higher doses (0.2, 2 μM) had the opposite effect (Lin *et al.*, 2013; Weldingh *et al.*, 2017). Similar directional changes in insulin gene and protein expression were observed (Lin *et al.*, 2013). Furthermore, BPA treatment has been observed to decrease cell viability and augment apoptosis while reducing expression of some genes essential for β-cell metabolism and mitochondrial function (Lin *et al.*, 2013). In another study BPA was shown to increase ROS production and DNA damage (Xin *et al.*, 2014). Another mechanism by which BPA may promote β-cell failure in the INS-1 cell line is via human islet amyloid aggregation coupled with an enhancement of the cytotoxic properties of this peptide (Gong *et al.*, 2013).

In vitro experiments have also shown that BPA can disrupt the function of isolated pancreatic islets. In a rapid manner BPA (100 pM–10 nM) provoked closure of the pancreatic β-cell K_{ATP} channels, increasing the frequency of $[Ca^{2+}]_i$ oscillations, which in turn resulted in a rapid increase in insulin secretion. This effect has been demonstrated to be mediated by the activation of extranuclear estrogen receptor β (ERβ) (Nadal *et al.*, 2000; Soriano *et al.*, 2012). Longer exposures to BPA promoted insulin gene transcription and biosynthesis after extranuclear binding to the estrogen receptor α (ERα) (Alonso-Magdalena *et al.*, 2008). At higher doses in the micromolar range, BPA effects on insulin secretion and content exhibited an inverted U-shape with an

augmentation at lower doses (0.1–2.5 μM) followed by a significant decline at higher concentrations (25 and 250 μM) (Song *et al.*, 2012). In contrast, other reports have observed a monotonic response with similar augmentation at 10 and 100 μM (Adachi *et al.*, 2005).

Animal studies have largely demonstrated that maternal exposure to BPA during gestation, or gestation and lactation, have profound effects on glucose homeostasis and pancreatic *β*-cell function in the offspring (Alonso-Magdalena *et al.*, 2010; Wei *et al.*, 2011; Liu *et al.*, 2013; Angle *et al.*, 2013; Garcia-Arevalo *et al.*, 2014) while paternal exposure may not have any effect (Ding *et al.*, 2014).

Male offspring of mice exposed to BPA at a dose of 10 μg/kg/d from day 9 to 16 of gestation displayed glucose intolerance and insulin resistance at 6 months of age. Pancreatic β-cells from these animals were more sensitive to extracellular glucose with enhanced GSIS that could be a compensatory mechanism in response to insulin resistance (Alonso-Magdalena *et al.*, 2010). Similar results were observed at the BPA dose of 50 μg/kg/d with augmented pancreatic β-cell mass (Wei *et al.*, 2011). At later stages of life, insulin secretion has been reported to decrease in BPA-treated offspring (Liu *et al.*, 2013). Importantly, the impairment of glucose and lipid metabolism was exacerbated by combining prenatal BPA exposure with later feeding of a high fat diet (HFD). On a HFD, BPA exposure led to diminished insulin secretory response to glucose suggesting that the compensatory changes in the islets could not overcome insulin demands (Garcia-Arevalo *et al.*, 2014; Wei *et al.*, 2011).

BPA has also been shown to alter pancreas development. A recent study has demonstrated that exposure to low doses of BPA during gestation led to increased pancreatic β-cell mass and area (Garcia-Arevalo *et al.*, 2016) and to a higher number of islet-cell clusters (Whitehead *et al.*, 2016) within the early life of the offspring. These early changes were associated with a rise in cell division, decreased apoptosis, and marked hyperinsulinemia (Garcia-Arevalo *et al.*, 2016). Increased insulin secretion leading to excessive insulin signaling has been proposed to be responsible for the alterations in the adult offspring glucose homeostasis previously described (Garcia-Arevalo *et al.*, 2016).

Transgenerational effects from early developmental exposures to BPA have also been reported. F0 maternal exposure to BPA provoked an impairment of insulin secretion, epigenetic changes in islets (hypermethylation of Igf 2), and reduced β-cell mass in the F2 offspring through the male germ line (Mao *et al.*, 2015).

Of note, metabolic abnormalities were observed not only in the offspring but in the mother. BPA-exposed pregnant females develop glucose intolerance, impaired pancreatic β-cell function, and decreased β-cell mass 7 months after delivery (Alonso-Magdalena *et al.*, 2015).

In adults, BPA exposure at a dose of 100 μg/kg for 4 days increased insulin content and insulin release favoring hyperinsulinemia and insulin resistance (Alonso-Magdalena *et al.*, 2006). Conversely, longer treatments (20 days) resulted in decreased insulin secretion, enhanced apoptosis, and lower gene expression of Glut 2, Pdx1 among others (Ahangarpour *et al.*, 2016). In animal models of T1D (i.e., NOD mice) BPA treatment exacerbated insulitis and hyperglycemia (Bodin *et al.*, 2013).

Alkylphenols

Alkylphenols are synthetic surfactants found in detergents, cleaning products, pesticides, antistatic agents, lubricants, hair care products, solubilizers, and as additives in plastics such as PVC, and polystyrene. 4-*n*-Nonylphenol (NP) and 4-*n*-octylphenol (OP) are some of the most common. Human exposure to these compounds may occur through ingestion of contaminated food and drinking water as well as from contact with some personal care products and detergents (Soares *et al.*, 2008). Biomonitoring studies, based on the representative subsamples of National Health and Nutrition Examination Survey (NHANES) 2005–10, have reported urinary detectable levels of OP in the North American population (Centers for Disease Control and Prevention (CDC), 2016).

Very few studies have explored the potential alterations in the pancreas arising from alkylphenol exposure. Rat islets cultured for 24 h in the presence of OP or NP at doses of 25 and 250 μg/L showed increased basal insulin secretion as well as insulin content (2.5 μg/L), while higher doses (250 μg/L) decreased insulin content (Song *et al.*, 2012). In a similar manner, 24 h islet treatment with NP (0.1–1000 μg/L) increased insulin secretion in response to stimulatory glucose concentration (16.7 mM) (Adachi *et al.*, 2005).

Persistent Organic Pollutants (POPs)

POPs are organic chemicals of significant concern because of their physical and chemical properties: they resist chemical and biological degradation so they remain intact for extremely long periods of time, they have high lipid solubility that promotes accumulation in the fatty tissue of living organisms, they bioaccumulate in ecosystems and they are transported far from their original sources resulting in worldwide distribution. The most commonly encountered POPs are organochlorine pesticides (aldrin, dieldrin, chlordane, *o,p′*-dichlorodiphenyltrichloroethane (DDT), endrin, heptachlor, mirex, toxaphene), industrial chemicals (polychlorinated biphenyls (PCBs), hexachlorobenzene (HCB)) and unintended chemical by-products (polychlorinated dibenzo-*p*-dioxins and polychlorinated dibenzofurans (PCDD/PCDF)). More recently other compounds such as polyfluoroalkyl compounds (PFCs) and flame retardants have been added to the list of POPs under the Stockholm convention (Convention, 2008).

Due to the large number of compounds classified as POPs we will focus on those whose effects on pancreatic β-cell are best studied.

Dioxins

Dioxins mainly consist of polychlorinated dibenzodioxins (PCDDs), the polychlorinated dibenzofurans (PCDFs), certain polychlorinated biphenyls (PCBs), and other related compounds. They are mainly by-products of industrial processes including chlorine bleaching of paper pulp, incineration of chlorine-containing substances such as polyvinyl chloride (PVC) and the manufacturing of some pesticides and herbicides. They can also result from natural processes like volcanoes and forest fires (EPA, 2017). The PCDD 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) is the most studied and toxic of all dioxins. It was a major contaminant in the industrial accident in Seveso, Italy, and during the Vietnam War. The main toxic effects, sources of exposure, and reference doses are described in reviews by the Environmental Protection Agency (EPA) (EPA, 2012) and CDC (Centers for Disease Control and Prevention (CDC), 1984).

In vitro studies have evaluated the effect of TCDD on pancreatic β-cell physiology although the conclusions are somehow discrepant. A significant increase of cytosolic calcium influx via T-type channels as well as enhanced insulin secretion at basal glucose concentrations (2.8 mM) were observed on INS-1E cells cultured in the presence of TCDD (50 and 100 nM) (Kim *et al.*, 2009). On the contrary, lower doses of TCDD (0.05–1 nM) have been shown to severely impair GSIS and to dose-dependently decrease cell survival (Piaggi *et al.*, 2007). The toxicity of TCDD on this cell line was prevented by epigallotacatechin-3-gallate, an inhibitor of the aryl hydrocarbon receptor (AhR) (Martino *et al.*, 2013). In primary islets TCDD did not alter insulin secretion; however, a significant reduction of insulin content was observed at all doses tested (0.1–100 nM) (Kurita *et al.*, 2009).

Few animal studies have evaluate TCDD effects on glucose homeostasis but they all indicate that TCDD exposure in adult mice promote an impairment of GSIS and insulin content (Kurita *et al.*, 2009; Novelli *et al.*, 2005), decreased plasma insulin levels (Kurita *et al.*, 2009; Ebner *et al.*, 1988) and transient hyperglycemia (Ebner *et al.*, 1988). Importantly, the impaired insulin secretion following TCDD administration has been proposed to be mediated by AhR (Kurita *et al.*, 2009).

Polychlorinated Biphenyls (PCBs)

PCBs are a subset of the synthetic organic chemicals known as chlorinated hydrocarbons that have been produced on an industrial scale from the late 1920s until they were banned in 1979. Despite being banned they remain widespread. They have been commonly used in a variety of materials as insulators in transformers and capacitors, as heat exchange fluids and as plasticizers in paints, plastics and rubber products as well as in carbonless copy paper, adhesives, and inks. A total of 209 possible PCB congeners exist (Fisher, 1999; Gore *et al.*, 2015). Biomonitoring information of each of them can be found in the Fourth CDC report (Centers for Disease Control and Prevention (CDC), 2015).

The effects of two PCB congeners (2,2′,4,4′-tetrachlorobiphenyl and 2,2′,4,4′,5,5′-hexachlorobiphenyl (PCB153)) and the commercial PCB mixture Aroclor-1254 have been examined in the rat β-cell line RINm5F. Treatment with each of these agents (5–10 μg/mL) increased insulin release in a calcium-dependent mechanism, which required the activation of a calcium/calmodulin-dependent kinase II (Fischer *et al.*, 1996, 1999).

In vivo intranasal PCB126 exposure (10 μg/kg) for 15 days in male rats induced insulin resistance, hyperinsulinemia, and hypertriglyceridemia together with increased oxidative stress on the islets of Langerhans. The analysis of the proteomic profile of the islets revealed that PCB126 exposure modified the expression of some proteins related to oxidative stress (Loiola *et al.*, 2016). In addition, PCB126 (2–5 nM) altered pancreas morphology during development in zebrafish. These included hypomorphic islets, altered islet migration, the appearance of ectopic β-cells, and islet fragmentation (Timme-Laragy *et al.*, 2015). Other PCBs have also been studied. For example perinatal exposure to PCB 153 in mice (0.09–1406 μg/kg/d) resulted in decreased pancreas weight in the female offspring and enhanced glucagon levels; however, no differences in glucose tolerance or insulin sensitivity were observed (van Esterik *et al.*, 2015). In contrast, chronic exposure to Aroclor 1254 (0.5, 5, 50, and 500 μg/kg) in adult mice caused a significant increment of pancreatic β-cell mass and reduced α-cell mass together with hyperinsulinemia, glucose intolerance, and hyperglycemia (Zhang *et al.*, 2015).

p,*p*′-Dichlorodiphenyltrichloroethane (DDT)

DDT is an organochlorine insecticide with a long half-life that was commonly used in the United States until 1972 when it was banned. It is still used in certain countries of Africa, South America, and Asia mainly to control malaria (EPA, 2016b).

Little is known about the direct effects of this compound on the pancreatic β-cell. In a recent study the effects of DDT and DDE, a metabolite of DDT (0.1, 1, and 10 μM), have been explored in the human pancreatic β-cell line NES2Y. Prolonged exposure to these pollutants decreased cellular viability at the highest concentration, and downregulated expression of some cytoskeletal and glycolysis-involved proteins (Pavlikova *et al.*, 2015).

Polyfluoroalkyl Compounds (PFCs)

Polyfluoroalkyl compounds (PFCs) is the collective name for a series of synthetic fluorinated organic compounds widely used in a range of industrial applications and the manufacture of products including nonstick cookware, coatings of some food packaging as well as components of fire-fighting foam. They are generally hydrophobic and lipophobic and will not tend to accumulate in fatty tissues; however, they can bind noncovalently to plasma proteins and distribute throughout the body. Among PFCs, perfluorooctane sulfonate (PFOS), and perfluorooctanoic acid (PFOA) have been the most extensively produced and studied. They are very stable to metabolic and environmental degradation (EPA, 2016a). Using data from CDC's 2003–2004 NHANES, four PFCs (PFOS, PFOA, PFHxS, or perfluorohexane sulfonic acid, and PFNA or perfluorononanoic acid) have been detected in over 98% of the serum samples collected (Calafat *et al.*, 2007). The mean levels found in serum for PFOA was 2.08 μg/L for PFOA and 6.31 μg/L for PFOS (Centers for Disease Control and Prevention (CDC), 2015).

Exposure of mice to PFOA in the range of 0.5–5 mg/kg/d for 7 days led to oxidative damage in pancreas and liver which was manifested by increased lipid peroxidation. An upregulation of several antioxidant pancreatic genes (Sod1, Sod 2, Gpx2, and Nqo1) was observed as a compensatory mechanism to alleviate oxidative stress. Interestingly accumulation of PFOA was observed not only in the serum but also in the liver and pancreas (Kamendulisa *et al.*, 2014). PFOS has been shown to disrupt pancreas organogenesis in zebrafish. Embryos exposed to micromolar concentrations of PFOS during development exhibited decreased islet area and size as well as pancreas length following a U-shaped dose response curve (Sant *et al.*, 2016, 2017).

Organotins

Organotins are a diverse class of ubiquitous environmental contaminants widely used in agriculture and industry as biocides, fungicides, molluscicides, rodent repellents, algaecides, wood preservatives, antifouling paints as well as stabilizer additives in PVC products. So far, major attention has been given to the organotin tributyltin chloride (TBT) because of its exceptional toxicity to aquatic life. It constitutes one of the first examples of endocrine disruption: TBT was shown to induce irreversible sexual abnormalities in female marine gastropods, a phenomenon known as imposex. Other organotins such as triphenyltin chloride (TPTC) have also been shown to be highly toxic biocides (Appel, 2004; Anastasiou *et al.*, 2016). The major route of human exposure to these pollutants comes from consumption of contaminated drinking, beverages, fish, and seafood. There is scarce information on levels of human exposure to organotins. A few studies have established dietary exposure levels of 2–5 μg/d, although levels can be as high as 375 μg/d in some demographic groups (Grun, 2014).

Acute exposure to TBT (0.1–0.2 μM) in the β-cell line RIN-m5F resulted in an increment of Ca^{2+} concentration, GSIS as well as elevated levels of ROS production; an effect that was abrogated in the presence of a protein kinase C (PKC) inhibitor. The same results were obtained in mouse and human islets (Chen *et al.*, 2017). The in vivo effects of TBT on the endocrine pancreas were variable depending on the dose, gender, and duration of treatment. Male mice treated with TBT for 45 days at doses of 0.5, 5, and 50 μg/kg/d showed morphological changes in the pancreas with increased apoptosis and reduced proliferation of islet cells. This caused a reduction in the relative islet area at day 60 of treatment. At this time point important metabolic alterations were observed, including glucose intolerance, decreased plasma insulin and glucagon levels as well as increased fasting glucose levels (Zuo *et al.*, 2014). Shorter exposures in female rats (0.1 μg/kg/d) resulted in a very mild glucose intolerance, hyperinsulinemia, and a greater number of islets (Bertuloso *et al.*, 2015).

A single oral dose of triphenyltin fluoride (TPTF) (100 mg/kg) in rabbits was shown to promote lower insulin release in response to glucose, glucagon or arginine. In addition, the animals showed higher fasting plasma glucose levels with lower basal insulin levels, likely due to reduced pancreatic insulin secretion. However, few abnormalities of the insulin secretory granules in pancreatic β-cells were observed by electron microscopy (Manabe and Wada, 1981). Similarly, decreased GSIS was observed after oral administration of triphenyltin chloride (TPTC) in hamsters with no change in the morphology of the pancreas (Miura and Matsui, 1987; Matsui *et al.*, 1984; Ogino *et al.*, 1996). This has been proposed to occur due to a diminution of Ca^{2+}-influx through voltage-gated Ca^{2+} channels promoted by reduced Na^{+} permeability via a protein kinase A-dependent mechanism as well as by a reduction of NAD(P)H and ATP production in pancreatic islets (Miura *et al.*, 1997, 2012; Miura and Matsui, 2006).

Heavy Metals

Heavy metals are defined as metallic chemical elements with relatively high density and atomic weight that are toxic or poisonous at low concentrations. Although they are found naturally on the earth, most environmental contamination and subsequent human exposure result from anthropogenic activities.

Multiple epidemiological reports have shown evidence suggesting that certain heavy metals exhibit diabetogenic characteristics (Gonzalez-Villalva *et al.*, 2016; Menke *et al.*, 2016; Hectors *et al.*, 2011). We summarize below the studies that reveal effects of heavy metals on glucose homeostasis with regard to metabolic function of pancreatic islets and, more specifically, insulin-secreting β-cells.

Arsenic

Because of its high degree of toxicity, arsenic is ranked first on the priority list of hazardous substances by the Agency for Toxic Substances and Disease Registry (ATSDR) (2017). Natural arsenic sources include numerous mineral species and volcanos, which release it into water, air, and soil. Of these different sources of exposure, ingestion is the major one within the general population. Arsenic levels in soil range from about 1 to 40 parts of arsenic to a million parts (ppm) of soil, with an average of 3–4 ppm. EPA reduced the maximum contaminant level (MCL) standard for arsenic in drinking water from 50 to 10 μg/L (Agency for Toxic Substances and Disease Registry (ATSDR), 2007a).

Research conducted in rodent pancreatic islets and single β-cells suggests that arsenic may contribute to the development of T2D by impairing β-cell function. Numerous in vitro studies have observed inhibition of insulin secretion after either acute (90 min) (Ahangarpour *et al.*, 2017) or prolonged (48–72 h) (Douillet *et al.*, 2013; Diaz-Villasenor *et al.*, 2006) arsenic exposure at 100 and $\leq$5 μM, respectively. Apart from reporting reduced GSIS (Diaz-Villasenor *et al.*, 2006; Douillet *et al.*, 2013; Fu *et al.*, 2010), some of these studies also detected diminished insulin release at basal glucose concentrations (Ahangarpour *et al.*, 2017; Diaz-Villasenor *et al.*, 2006). The mechanisms by which insulin secretion is inhibited include, among others, reduced intracellular Ca^{2+} oscillations and decreased Ca^{2+}-dependent calpain-10 proteolysis of SNAP-25 (Diaz-Villasenor *et al.*, 2008). Insulin synthesis is also impaired in single rat β-cells exposed to 5 μM arsenic for 72 h (Diaz-Villasenor *et al.*, 2006) and in islets exposed to methylarsenite (MAsIII) and dimethylarsenite (DMAsIII) at $\leq$1 μM for 48 h (Douillet *et al.*, 2013). In contrast to the findings described in primary cultures, Fu *et al.* described elevated insulin secretion at 3 mM glucose after exposure of the β-cell line INS-1 (832/13) to arsenic, likely due to increased insulin mRNA and protein levels (Fu *et al.*, 2010). Other studies performed in β-cell lines have also associated arsenic exposure with enhanced mitochondrial mass (Fu *et al.*, 2010), autophagic β-cell death (Zhu *et al.*, 2014), increased caspase-3 activity and apoptosis (Yen *et al.*, 2007; Yao *et al.*, 2015), augmented antioxidant levels (Yen *et al.*, 2007; Fu *et al.*, 2010), and increased reactive oxygen species (ROS) content (Yen *et al.*, 2007; Zhu *et al.*, 2014) as well as decreased intracellular ATP levels (Yen *et al.*, 2007). Hence, numerous arsenic-induced effects may blunt β-cell function.

In mice, the exposure to 3 mg/L arsenic in drinking water for 16 weeks increased plasma insulin (Liu *et al.*, 2014), whereas 10 mg/L increased plasma insulin at early stages and reduced it from week 5 to week 12 (Yen *et al.*, 2007). Other symptoms observed following arsenic exposure include pancreatic inflammation, decreased Irs1 and Glut4 as well as increased Adipoq mRNA levels (Liu *et al.*, 2014), and islet damage due to mild accumulation of inflammatory cells in the pancreas (Yen *et al.*, 2007). In parallel, in diabetic leptin deficient (*db*/*db*) mice, prolonged arsenic exposure caused increased fasting blood glucose, reduced plasma insulin, impaired glucose handling and insulin sensitivity as well as pancreatic inflammation (Liu *et al.*, 2014).

Cadmium

Cadmium is a metal of considerable health concern due to its high toxicity. Natural sources involve emissions from volcanic eruptions or forest fires, among others. It is present in the earth's crust at approximately 0.1–0.5 ppm, commonly associated with other metals, and its levels in ocean water have been reported between $<$5 and 110 ng/L (Agency for Toxic Substances and Disease Registry (ATSDR), 2012). It is frequently used in industrial processes including the production of alkaline batteries, stabilizers for plastics, nonferrous alloys and pigments. Cadmium bioaccumulates in the food chain, and consumption of cadmium-contaminated food is a major source of human exposure. In addition, smoking is a significant and potentially modifiable source of human cadmium intake (Agency for Toxic Substances and Disease Registry (ATSDR), 2012).

In vitro experiments revealed that cadmium impairs GSIS in both MIN6 cells (1 μM) and primary mouse islets (0.1 μM) following 48 h exposure (El Muayed *et al.*, 2012). Although neither cell death nor oxidative stress seemed to be responsible for the decrease in insulin release (El Muayed *et al.*, 2012), a different study showed augmented generation of intracellular ROS and malondialdehyde (MDA) production after cadmium exposure of the rat β-cell line RIN-m5F, which contributed to mitochondrial dysfunction (Chang *et al.*, 2013). In addition, the authors reported JNK-MAPK activation and apoptotic-related signals that led to β-cell death (Chang *et al.*, 2013). Thus, cadmium exposure, and its subsequent accumulation within β-cells (El Muayed *et al.*, 2012; Chang *et al.*, 2013), causes cellular toxicity and β-cell dysfunction.

Numerous studies conducted in animal models confirmed the development of hyperglycemia after oral (Merali and Singhal, 1980; Trevino *et al.*, 2015) and parenteral (Ithakissios *et al.*, 1975; Merali and Singhal, 1976, 1975; Bell *et al.*, 1990; Kanter *et al.*, 2003; Edwards and Prozialeck, 2009) cadmium administration. In addition to increased blood glucose levels, cadmium also produced impaired glucose tolerance (Merali and Singhal, 1975; Chang *et al.*, 2013), reduced plasma insulin levels (Ithakissios *et al.*, 1975; Kanter *et al.*, 2003; Edwards and Prozialeck, 2009; Chang *et al.*, 2013), and decreased in vivo insulin release in response to a glucose load (Merali and Singhal, 1976), although one study observed hyperinsulinemia accompanied by hyperglycemia after cadmium administration (Trevino *et al.*, 2015). Further ex vivo research showed that both isolated islets (Merali and Singhal, 1980) and perfused pancreas (Ithakissios *et al.*, 1975) from cadmium-treated rats secreted less insulin in response to high glucose concentrations compared to controls. In addition, oral cadmium administration increased proinflammatory cytokines (TNF-α, IL1β, and IFN-γ) and cleaved caspases levels, and reduced cellular defense protein levels (Nrf2 and HO-1) as well as glucose transporters (GLUT2 and GLUT4) in rat pancreas (Bashir *et al.*, 2016). Moreover, cadmium exposure produced morphological changes in the pancreas that include degranulation, degeneration, and necrosis (Demir *et al.*, 2006; Kanter *et al.*, 2003), and possible loss of cell–cell adhesion (Edwards and Prozialeck, 2009).

Lead

Lead is a toxic metal and considered a major public health risk due to its widespread use; it is actually the second most toxic compound according to the Agency for Toxic Substances and Disease Registry (ATSDR) (2017). Despite the fact that it occurs naturally, anthropogenic sources are mostly responsible for the 1000-fold increase in environmental lead levels that have occurred over the past three centuries (Agency for Toxic Substances and Disease Registry (ATSDR), 2007b). Lead has multiple industrial and domestic applications and it is found in plumbing pipes, leaded gasoline, lead-based paints, and storage batteries among other uses. The main sources of human exposure are inhalation of lead-contaminated dust particles and ingestion of lead-contaminated water and food. EPA limited the concentration of lead in breathed air to 1.5 $\mu g/m^3$ averaged over 3 months, and to 0.015 mg/L in drinking water (Agency for Toxic Substances and Disease Registry (ATSDR), 2007b).

Mouse isolated islets exposed to lead (1–10 mM) ex vivo displayed reduced cell viability and GSIS, and exhibited potentiated glycogen synthase kinase-3 beta (GSK-3β) activity and ROS levels (Mostafalou *et al.*, 2015), thus indicating that lead exposure impairs β-cell viability and function.

The administration of lead (0.05% and 0.2%, for 32 days) in drinking water slightly increased blood glucose levels, and potentiated fasting insulin levels, and HOMA-IR in rats (Mostafalou *et al.*, 2015). While these findings suggest an effect on insulin responsive tissues, the lack of studies in the pancreas restricts knowledge of whether in vivo lead exposure also impairs islet function as part of the mechanisms by which it dysregulates glucose homeostasis.

Mercury

Mercury occurs naturally, and it is mainly present in three forms: metallic mercury, inorganic mercury salts, and organic mercury compounds. Methylmercury, mainly produced from methylation of inorganic mercury by microorganisms, is among the most common natural forms of mercury. It is of particular concern because methylmercury is linked to several health disorders. The major sources of mercury accumulation in the general population result from the ingestion of methylmercury-contaminated fish or seafood, and from dental amalgam fillings containing metallic mercury (Agency for Toxic Substances and Disease Registry (ATSDR), 1999). The limits set by EPA and Food and Drug Administration (FDA) are 2 parts of inorganic mercury per billion (ppb) parts of water in drinking water, and 1 part of methylmercury in a million parts (ppm) in seafood products (Agency for Toxic Substances and Disease Registry (ATSDR), 1999).

In vitro exposure of β-cell derived HIT-T15 cells (Chen *et al.*, 2006a,b, 2010) and mouse islets (Chen *et al.*, 2006a,b) to both organic (methylmercury) and inorganic mercury inhibited GSIS. Moreover, these mercuric compounds triggered ROS generation (Chen *et al.*, 2006a,b), activation of PI3K and Akt phosphorylation (Chen *et al.*, 2006b), disruption of the mitochondrial membrane potential and activation of caspase-3 (Chen *et al.*, 2006a). In addition, mercury decreased cell viability (Chen *et al.*, 2006a, 2010) and increased both apoptosis and necrosis in the β-cell line (Chen *et al.*, 2010).

In agreement with the outcomes reported in vitro, the oral administration of mercuric compounds from 2 to 6 consecutive weeks raised blood glucose (Chen *et al.*, 2006b, 2012; Maqbool *et al.*, 2016), reduced plasma insulin (Chen *et al.*, 2006b, 2012; Maqbool *et al.*, 2016), and C-peptide (Maqbool *et al.*, 2016) levels, produced glucose intolerance (Chen *et al.*, 2012, 2006b; Maqbool *et al.*, 2016), insulin resistance (Maqbool *et al.*, 2016), and plasma lipid peroxidation (Chen *et al.*, 2006b; Maqbool *et al.*, 2016), and increased plasma MDA levels (Chen *et al.*, 2012, 2006b) in rats. Further research conducted in pancreas from mercury-treated animals detected increased ROS levels and apoptotic cells within the islets (Chen *et al.*, 2012). In line with these findings, gene expression studies revealed increased p53, caspase-3, and caspase-7 (apoptotic genes) and decreased Bcl-2, Mcl-1, and Mdm-2 (antiapoptotic genes) and Nrf2, GPx, and NQO1 (antioxidant genes) mRNA levels within the islets (Chen *et al.*, 2012). Altogether, these results indicate that mercuric compounds induce oxidative stress and cause apoptosis and islet dysfunction.

Nickel

Nickel is a naturally occurring element, found in all soil, water, and air, primarily in combination with oxygen and sulfur. Nickel is frequently alloyed with iron, copper, chromium, and zinc, which are later used in making metal coins, jewelry, valves, or heat exchangers (Agency for Toxic Substances and Disease Registry (ATSDR), 2005). Humans are exposed to nickel from air and polluted food and drinking water. Common amounts of nickel in soil are between 4 and 80 ppm, and between 2 and 4.3 ppb in drinking water in the United States (Agency for Toxic Substances and Disease Registry (ATSDR), 2005).

Various animal studies have reported hyperglycemia following nickel administration (Cartana and Arola, 1992; Alvarez *et al.*, 1993; Gupta *et al.*, 2000; Horak *et al.*, 1978; Horak and Sunderman, 1975). In fact, just a single intraperitoneal injection of 12–85 μmol/kg body weight (Horak and Sunderman, 1975; Horak *et al.*, 1978; Gupta *et al.*, 2000; Cartana and Arola, 1992) is sufficient to significantly and transiently raise blood glucose levels within 30 min. Further research suggested that nickel-induced hyperglycemia could be associated with hyperglucagonemia (Horak *et al.*, 1978; Cartana and Arola, 1992; Horak and Sunderman, 1975; Alvarez *et al.*, 1993), hypoinsulinemia (Cartana and Arola, 1992; Alvarez *et al.*, 1993) caused by α-adrenergic activation (Alvarez *et al.*, 1993), and increased inducible nitric oxide synthase (iNOS) protein in the pancreas (Gupta *et al.*, 2000). A decrease in insulin release following nickel exposure was also observed in isolated islets stimulated at both low and high glucose concentration (Dormer *et al.*, 1974).

Conclusion

Diabetes is a common terrible problem with a multifactorial origin. Pollutants are likely contributors to its etiology and, therefore, understanding the mechanisms by which EDCs promote diabetes is important to develop therapies for exposed individuals. In addition, improved environmental regulations are essential for mitigating environmental drivers of diabetes risk.

Endocrine Disruptors and Obesity

Sigal A Willner and Bruce Blumberg, University of California Irvine, Irvine, CA, United States

Introduction

Obesity, defined as a BMI greater than 30 kg/m^2, is an epidemic disease in children and adults around the world (reviewed in Heindel *et al.*, 2017; Hales *et al.*, 2017; Flegal *et al.*, 2016; Janesick and Blumberg, 2016; Legler *et al.*, 2015). The incidence of obesity in U.S. adults has increased over the past four decades from 13% to 35% (Flegal *et al.*, 2016). The most recent statistics from the period 2015–2016 put this number at 39.8% for U.S. adults and 20.6% in youths (Hales *et al.*, 2017). Obesity is linked not only to accumulation of adipose tissue, but also to many components of the endocrine system including the gastro-intestinal tract, pancreas, muscle, liver, and brain (reviewed in Heindel *et al.*, 2017). Obesity is associated with a wide variety of other comorbidities, including diabetes, metabolic syndrome, hypertension, coronary heart disease, gall bladder disease, and cancer. There is a strong correlation between an increase in childhood obesity and an increase in diagnoses of type 2 diabetes in children and adolescents (Dabelea *et al.*, 2014). Moreover, obesity is a risk factor for many components of type 2 diabetes and other metabolic diseases particularly when visceral fat is increased (Despres, 2012). Remarkably, nearly 40% of all cancers are diagnosed in overweight or obese people in the United States (Steele *et al.*, 2017). Together, the diseases associated with obesity are not only dangerous to individual health, but also very costly to society (Legler *et al.*, 2015; Attina *et al.*, 2016).

The current clinical paradigm for obesity is one of energy intake versus energy expenditure (Hall *et al.*, 2012), with clinical management of obesity consequently focused on diet and exercise (Hill and Peters, 1998). Other well-studied risk factors implicated in obesity include genetics (Herbert, 2008; Li *et al.*, 2010), smoking during pregnancy (Behl *et al.*, 2013; Power and Jefferis, 2002), and stress (Garruti *et al.*, 2008; Torres and Nowson, 2007). A provocative recent paper based on analysis of data derived from the U.S. National Health and Nutrition Examination Study (NHANES, 1971–2008) showed that leisure time physical activity has increased 47%–120% between 1988 and 2006, rather than having decreased as is often stated (Brown *et al.*, 2016). Moreover, for an equivalent amount of caloric intake, macronutrient intake, and leisure time physical activity, average adult BMI was up to 2.3 kg/m^2 higher in 2006 than in 1988 (Brown *et al.*, 2016). This paper makes two strong points. The first is that exercise is increasing, rather than decreasing. The second is that changes in diet and exercise are not adequate to explain the increase in BMI between 1988 and 2006 (Brown *et al.*, 2016). Together, these results cast serious doubt on the sufficiency of the energy balance model of obesity and strongly implicate the importance of other risk factors in obesity (Brown *et al.*, 2016).

Obesity is also largely intractable once established. More than 83% of obese individuals who lost substantial amounts of weight gained it back within a few years (Fildes *et al.*, 2015; Fothergill *et al.*, 2016; Kraschnewski *et al.*, 2010). The obesity epidemic is not limited to humans—it also affects animals living in close proximity to humans. These include domestic dogs and cats, feral rats living in cities, and, crucially, primates and rodents living in research colonies where diets are carefully controlled (Klimentidis *et al.*, 2011). It is difficult to argue that all of these animal populations suffer from inappropriate lifestyle choices. Rather, it is clear that it is counterproductive to frame the issue of obesity in terms of a single cause, energy balance. Regulation of body weight is complex and regulated by a variety of hormones that modulate glucose homeostasis, metabolism, energy balance, appetite and satiety, as well as the development of adipose tissue itself (reviewed in Heindel *et al.*, 2017). Considering the ever-increasing rise in the incidence of obesity and its broad contribution to adverse health outcomes, it is crucial to identify and understand the variety of factors that contribute to obesity beyond the simplistic energy balance model.

The Developmental Origins of Health and Disease Hypothesis

David Barker's eponymous "Barker Hypothesis," also known as the Fetal Origins Hypothesis, proposed that prenatal nutrition is an important factor in determining whether a child will be more or less vulnerable to metabolic diseases and cardiovascular disorders later in life (Barker, 2007; Hales and Barker, 2001). He proposed that prenatal malnutrition led the fetus to become adapted to a nutritionally poor environment and that if the environment was nutrient rich, instead, the child would be more susceptible to chronic diseases later in life, such as type 2 diabetes, high blood pressure, heart disease and obesity due to this mismatch. His hypothesis suggests that there are critical periods of development during which environmental factors can cause changes in phenotype that can lead to permanent biological dysfunctions and increased susceptibility to diseases later in life (Barker, 2007; Hales and Barker, 2001). Gluckman and Hanson recognized that the critical period was not restricted to fetal development and extended the fetal origins model, renaming it as "The Developmental Origins of Health and Disease" (Gluckman and Hanson, 2004; Gluckman *et al.*, 2009; Hanson and Gluckman, 2015).

The Thrifty Phenotype

James Neel first proposed the "thrifty gene" hypothesis, which suggested that particular gene variants evolved to favor efficient use of nutrients in the calorie-limited environment in which humans evolved, but that promote obesity and type 2 diabetes in the

 doi:10.1016/B978-0-12-801238-3.65207-8

modern, calorie-rich environment (Neel, 1962). However, none of the common obesity-related gene variants yet identified were judged to confer any properties or traits that could be considered to provide a survival advantage (Wang and Speakman, 2016). At the same time, it is quite clear that there is a "thrifty phenotype" (Hales and Barker, 2001). A large number of studies in animals and humans linked poor prenatal nutrition with subsequent predisposition to disease, including obesity later in life and in subsequent generations (Barker, 2007; Hanson *et al.*, 2011). Essentially, prenatal programming is thought to adapt the fetus to poor, but not plentiful nutrition later in life. Despite considerable study, there are very few concrete details on the molecular mechanisms that promote a thrifty phenotype, although, there are some indications that leptin resistance (Friedman, 2014) and epigenetic mechanisms are involved (Godfrey *et al.*, 2011; Lillycrop, 2011).

Endocrine System and EDCs

The endocrine system strongly influences obesity because many endocrine organs and hormones work together to regulate metabolism and, in turn, weight. For example, insulin and glucagon are produced in the pancreas and act to modulate affect glucose uptake and usage; ghrelin and cholecystokinin affect metabolism in the gastrointestinal tract; and glucagon, insulin, and fibroblast growth factor 21 (FGF21) act in the liver to control metabolism, hunger, and satiety. Sex hormones such as estradiol also contribute to energy metabolism and obesity by affecting food intake, body weight, fat distribution, the balance of glucose and insulin, lipogenesis, and lipolysis (reviewed in Heindel *et al.*, 2017). The brain acts as an endocrine organ that contributes to obesity through its food reward mechanisms which are affected by hormones, growth factors, and neurotransmitters (Jager and Witkamp, 2014; Schellekens *et al.*, 2012; Volkow *et al.*, 2013). Hormones and growth factors also contribute to fat accumulation by affecting appetite, satiety, and energy (reviewed in Heindel *et al.*, 2017).

Furthermore, there are many ways in which the endocrine system acts directly on adipocytes to contribute to obesity. Growth factors and hormones, including estrogens, androgens, glucocorticoids, insulin, and thyroid hormones, play a part in controlling the number and content of adipocytes. Adipose tissue development and function is affected by steroid hormones including estrogens, androgens, and glucocorticoids, and is connected to the immune system through the function of adipokines (reviewed in Heindel *et al.*, 2017). Adipocytes, themselves, secrete over 20 endocrine, paracrine, and autocrine chemicals; and metabolism in adipocytes is affected by hormones such as glucagon, insulin, and FGF21 (reviewed in Heindel *et al.*, 2017). In this way, the endocrine system may have a direct effect on development of obesity by affecting the functioning of adipocytes within the body.

Endocrine Disrupting Chemicals

According to the Endocrine Society, an endocrine disrupting chemical (EDC) is "an exogenous chemical, or mixture of chemicals, that can interfere with any aspect of hormone action" (Zoeller *et al.*, 2012). While the original definition of EDCs focused on estrogens, antiandrogens and thyroid disruptors, it is now recognized that any endocrine signaling system can be disrupted by exogenous chemicals that target various places in endocrine signaling pathways (Gore *et al.*, 2015). EDCs can alter the rate of production and metabolism of hormones, affect the way hormones are transported to their target tissues and the action of the specific receptors for individual receptors (reviewed in Diamanti-Kandarakis *et al.*, 2009; Gore *et al.*, 2015). Most recently, Jun Kanno has introduced the concept of "signal toxicity," which proposes that essentially any receptor-based cellular signaling system can be disrupted by chemicals that act on the receptor (Kanno, 2016). A key feature of this model is that such chemicals act on receptors and without the receptor, there is no "toxicity." Rather than eliciting toxicity by damaging cellular components, chemicals that cause signal toxicity do so by interfering with signaling itself (usually by acting on the receptor). Such signaling disruptors are expected to act at low doses and not to exhibit threshold effects—both of which are characteristics of EDCs (Vandenberg *et al.*, 2012).

Currently, there are approximately 1000 known chemicals that are considered to be EDCs, although no systematic analysis of chemicals for endocrine disrupting effects has yet been undertaken (reviewed in Diamanti-Kandarakis *et al.*, 2009; Gore *et al.*, 2015). These chemicals are used in a wide variety of consumer products. They have been found in food packaging, building materials, pesticides, clothing, upholstery, detergents and cleaning agents, plastics, thermal paper, and medical equipment (Zoeller *et al.*, 2012; Vandenberg *et al.*, 2012; Gore *et al.*, 2015; Diamanti-Kandarakis *et al.*, 2009; Hormann *et al.*, 2014; Bergman *et al.*, 2013). EDCs also contaminate food, air, and water, due to their use in food production and industrial processes. EDCs can make their way into the body orally, through dermal contact, through inhalation, or in the case of contamination of medical equipment, intravenously or subcutaneously (reviewed in Diamanti-Kandarakis *et al.*, 2009; Gore *et al.*, 2015). Often, only low levels of EDCs are necessary to affect the endocrine system and the effects often do not scale linearly with dose, that is, are nonmonotonic (Vandenberg *et al.*, 2012). This means that even limited exposure to these EDCs may lead to significant effects later in life.

The Obesogen Hypothesis

In 2006, we proposed the existence of endocrine disrupting chemicals that could influence adipogenesis and obesity and be important, yet unsuspected players in the obesity epidemic. These "obesogens" are functionally defined as chemicals that promote

obesity. Obesogens can act directly to increase the number of fat cells and/or the storage of fat into existing cells. Obesogens can act indirectly by changing basal metabolic rate, by shifting energy balance to favor calorie storage, and by altering hormonal control of appetite and satiety (reviewed in Janesick and Blumberg, 2011; Heindel *et al.*, 2017). Evidence has accumulated linking EDCs to obesity, and obesogens have been detected in humans (Stahlhut *et al.*, 2007; Hatch *et al.*, 2008; Trasande *et al.*, 2012; Li *et al.*, 2013; Tang-Peronard *et al.*, 2011) and animals (Newbold *et al.*, 2009; Vom Saal *et al.*, 2012; Grun *et al.*, 2006; Hines *et al.*, 2009). Because these chemicals are pervasive in the environment, it is crucial to understand how they disrupt developmental programming, predisposing individuals to obesity and related disorders

EDC exposure during development can cause lasting changes in physiology, similar to the case with early life nutrition in the DOHaD model. EDCs alter hormonal levels and function; hormones and growth factors are of utmost importance in development, as they affect gene expression, number of cells, cell location, and the balance between cell types. Moreover, EDCs that affect organ structure and endocrine signaling between cells can cause increased susceptibility to disease and organ dysfunction in the developed organism (reviewed in Heindel *et al.*, 2017; Lughetti *et al.*, 2015). Thus, obesogenic EDCs work by affecting nuclear factors or other endocrine pathways during development in ways that lead to obesity later in life. Indeed, exposure to EDCs during critical periods of development, such as when cells are differentiating into adipocytes, has been shown to contribute to diseases such as obesity in adulthood (reviewed in Heindel *et al.*, 2017).

Adipogenesis

Adipose tissue, comprised of white, brown, and beige fat, is a source of energy and an important regulator of energy balance and homeostasis in the body (reviewed in Heindel *et al.*, 2017). It aggregates in depots located subcutaneously, viscerally, and intrathoracically (reviewed in Heindel *et al.*, 2017). White adipose tissue develops in humans by the 14th week of gestation (Poissonnet *et al.*, 1984). A second period during which more adipose cells are developed occurs after birth and continues through adolescence (Spalding *et al.*, 2008). After this second period of adipose tissue development, the minimum number of white adipose cells (which store energy as triglycerides) in the body is thought to be fixed (Rosen and Spiegelman, 2014), but fat can continue to accumulate within those cells, increasing total fat mass in the body, into adulthood.

The development of adipocytes starts with mesenchymal stem cells (MSCs), which first must commit to the adipocyte cell lineage. Commitment is followed by differentiation into mature adipocytes (reviewed in Rosen and Spiegelman, 2014). Commitment of MSCs to the adipocyte cell lineage is mediated by transcription factors Zfp423, Zfp467, Schnurri2, Tcf7l1, and the mTORC1 effector S6K1 (Gupta *et al.*, 2010; Quach *et al.*, 2011; Carnevalli *et al.*, 2010; Cristancho and Lazar, 2011). One effect of these genes in contributing to adipogenesis is promoting the expression of the gene PPARγ, the master regulator of adipogenesis (reviewed in Rosen and Spiegelman, 2014; Tontonoz and Spiegelman, 2008). Other genes that contribute to adipocyte differentiation and development include Runx2 and CCAAT-enhancer-binding proteins -α, -β, and -δ (Siersbaek and Mandrup, 2011; Tontonoz and Spiegelman, 2008; James, 2013). Most recently, it was shown that activation of the nuclear receptor, RXR, commits MSCs to the adipose lineage by decreasing genome-wide expression of the repressive histone mark, histone 3, lysine 27 trimethylation (H3K27me3), in proximity to that regulate adipose commitment (Shoucri *et al.*, 2017). This "primes" the genes for subsequent activation by PPARγ and differentiation into adipocytes.

How Do Obesogens Act?

Although about 50 obesogens or potential obesogens have been identified, there is little mechanistic understanding of how most function. We know the most about Tributyltin (TBT). TBT is widely used in industry and triphenyltin (TPT) in agriculture. Human exposure occurs through dietary sources from contaminated seafood and shellfish, from organotin use as fungicides and miticides on food crops, in wood treatments, and industrial water systems. TBT contaminates plastics (e.g., polyvinyl chloride) and house dust (Antizar-Ladislao, 2008; Fromme *et al.*, 2005; Kannan *et al.*, 2010). TBT is a nanomolar affinity ligand that activates the so-called "master regulator" of adipogenesis, peroxisome proliferator activated receptor gamma (PPARγ) and its heterodimeric partner, 9-cis retinoic acid receptor (RXR) to promote adipogenesis and alter lipid homeostasis (Le Maire *et al.*, 2009; Grun *et al.*, 2006; Kanayama *et al.*, 2005). Human and mouse mesenchymal stem cells (MSCs) and preadipocytes are induced to differentiate into adipocytes via a PPARγ-dependent pathway after exposure to TBT at environmentally-relevant (nanomolar) levels or to PPARγ agonists such as rosiglitazone (ROSI) (Li *et al.*, 2011; Kirchner *et al.*, 2010). Importantly, TBT exposure during pregnancy can to lead to obesity in the F1 offspring and in F2 and F3 generations without additional exposure (Chamorro-García *et al.*, 2013). Three other groups have shown that TBT induces obesity in mice in both sexes when treated at any age (Bo *et al.*, 2011; Penza *et al.*, 2011; Zuo *et al.*, 2011; He *et al.*, 2014). Others showed similar effects in rats (He *et al.*, 2014), goldfish (Zhang *et al.*, 2016), and zebrafish (Riu *et al.*, 2014; Tingaud-Sequeira *et al.*, 2011). Therefore, the obesogenic effects of TBT exposure, both developmentally and in adulthood, are well-supported in the literature across model systems.

In vivo experiments identified several other chemicals as known obesogens. Exposure to the fungicides triflumizole (Li *et al.*, 2012), tolylfluanid (Regnier *et al.*, 2015) or the plasticizer diethylhexyl phthalate (Hao *et al.*, 2013) also led to obesity later in life. Triflumizole was shown to act through PPARγ (Li *et al.*, 2012), whereas tolylfluanid is thought to act via the glucocorticoid receptor (Regnier *et al.*, 2015). It is not known which receptor diethylhexyl phthalate acts through, but it may be PPARγ.

Other potential obesogens have been identified that are known to act on preadipocytes or MSCs to promote adipogenic differentiation (Janesick *et al.*, 2016). These include the agricultural chemicals quinoxyfen, spirodiclofen, fludioxonil, tebupirimfos, flusilazole, forchlorfenuron, acetamaprid and pymetrozine (Janesick *et al.*, 2016). It remains to be shown which of these chemicals are capable of inducing fat accumulation and obesity, in vivo, but one might reasonably expect that at least some will turn out to be bona fide obesogens.

As previously mentioned, only low levels of EDCs are necessary to alter development. This may be the case because protective mechanisms that exist in a developed organism—such as the ability to repair DNA, a competent immune system, detoxifying enzymes, liver metabolism, the blood–brain barrier, and a normal (slower than fetal) metabolic rate—may not yet be developed (reviewed in Heindel *et al.*, 2017; Newbold *et al.*, 2007). However, it is postulated that more instances of EDC exposure, occurring postdevelopment, also contribute to obesity in adulthood (Legler *et al.*, 2015; Heindel *et al.*, 2017).

Direct vs. Indirect Mechanism of EDCs

While some EDCs directly affect commitment and differentiation of MSCs and preadipocytes, others act indirectly to affect obesity by altering other parts of the endocrine system. For example, the brain hormone kisspeptin and its receptor KISS1R play a role in regulating glucose homeostasis, insulin secretion, food intake, and body composition (Song *et al.*, 2014). Studies in rodents have shown kisspeptin to be a potential target of EDCs. EDCs were shown to affect timing of pubertal onset, estrous cycles, and sociosexual behaviors (Anderson *et al.*, 2013; Mueller *et al.*, 2015; Panzica *et al.*, 2011), and it is possible that these chemicals can, in turn, affect the development of obesity. Moreover, while exposure to EDCs affects cells and development at a genomic level, effects are often not seen until later in life, "when the system is challenged by over-nutrition and/or lack of exercise" (reviewed in Heindel *et al.*, 2017).

Transgenerational Effects of Obesogen Exposure

More evidence that EDCs function by altering genes during development comes from the observation that obesogenic effects can be passed from generation to generation, from F0 through F3 and beyond, the latter having not received any direct exposure to the EDC (Chamorro-García *et al.*, 2013). For example, one study showed that exposure to low doses of TBT in mice led to a reprogramming of MSCs to differentiate into adipocytes, as well as a consequent increase in fat depot size (Kirchner *et al.*, 2010). These effects were seen through the F3 generation (Chamorro-García *et al.*, 2013). As a result, F1 through F3 generations of mice were all predisposed to obesity later in life (Chamorro-García and Blumberg, 2014; Chamorro-García *et al.*, 2013)

In order to elicit transgenerational effects, EDC exposure must make permanent changes in the genome, or epigenome (Janesick *et al.*, 2014b; Ozgyin *et al.*, 2015; Szyf, 2015; Walker and Ho, 2012; Skinner, 2015). EDCs are hypothesized to affect DNA methylation, histone methylation (reviewed in Chamorro-García and Blumberg, 2014; Janesick *et al.*, 2014b; Skinner, 2015; McCarrey *et al.*, 2016) and higher order chromatin structure (Chamorro-García *et al.*, 2017). One model for the transgenerational inheritance of obesity holds that altered DNA methylation is passed from one generation to the next. However, considering that there are at least two waves of demethylation and remethylation that occur during germ cell development, an important unanswered question is just how EDC-elicited changes in methylation are propagated to subsequent generations. The general thinking is that these EDC-dependent changes in methylation enable the altered methylation marks to evade germline reprogramming (McCarrey *et al.*, 2016; Skinner *et al.*, 2015) but the underlying mechanisms remain unclear. It is clear that DNA methylation is changed in subsequent generations after F0 exposure to EDCs (Haque *et al.*, 2016; Manikkam *et al.*, 2013; Nilsson *et al.*, 2012; Skinner *et al.*, 2013, 2015; Tracey *et al.*, 2013).

A recent study provides a potential answer to this dilemma. It showed that exposure of F0 dams to 50 nM TBT throughout pregnancy and lactation (but not in any subsequent generation) predisposed F4 male offspring to become obese and this was exacerbated by a moderate increase in dietary fat (Chamorro-García *et al.*, 2017). Moreover, the ancestrally TBT exposed group was not able to mobilize fat as well as controls during fasting, suggesting that these animals store more of the calories they consume as fat and resist mobilizing this fat when needed (Chamorro-García *et al.*, 2017). A detailed genomic analysis showed that TBT group showed persistent changes in DNA methylation that were associated with alterations in the expression of metabolic genes, including the satiety hormone, leptin (which was over-expressed). Overexpression of leptin together with obesity is clinically presumed to indicate a state of leptin resistance. Ancestral exposure to the EDC, TBT, can thus alter metabolic set points making the exposed individual more likely to gain weight and retain this weight on the same diet as unexposed controls, the classic "thrifty phenotype."

Surprisingly, instead of being associated with particular promoter sequences, the methylation changes observed in this study were located in blocks of DNA in which methylation was all in the same direction (over- or under-methylated compared with controls). These were denoted as isoDMBs and represent regions of large-scale changes in genomic structure and chromatin accessibility because they are also associated with regions of biased GC content already known to be associated with higher order chromatin structure (Chamorro-García *et al.*, 2017). In this model, EDC exposure leads to genome-wide changes in chromatin accessibility that alter the ability of DNA methylases and demethylases to modify cytosine bases (Chamorro-García *et al.*, 2017). Intriguingly, these changes in chromatin structure are associated with regions of highly biased GC sequence composition that also contain a much higher number of metabolic genes than would be expected by chance (Chamorro-García *et al.*, 2017). Thus, EDC

exposure alters chromatin structure and accessibility which secondarily alters DNA methylation to regulate gene expression and this disproportionately affects genes involved in metalism. The altered chromatin structure is what is inherited, rather than specific changes in DNA methylation.

In addition to our studies with TBT (Chamorro-García *et al.*, 2013, 2017). heritable effects of several environmental chemicals on obesity have been demonstrated, albeit at relatively high doses. Plastic components such as BPA, diethylhexyl and dibutyl phthalates (Manikkam *et al.*, 2013), the pesticide methoxychlor (Manikkam *et al.*, 2014), a mixed hydrocarbon mixture (jet fuel JP-8) (Tracey *et al.*, 2013) and the once widely used pesticide, DDT (Skinner *et al.*, 2013) all induce transgenerational obesity in rats. Thus, there is strong experimental support for transgenerational effects of environmental chemicals on obesity, which may be highly relevant for humans. There is evidence that altered DNA methylation may be transmitted across generations (Hanson and Skinner, 2016; Skinner *et al.*, 2015), but the underlying mechanisms remain unclear and the phenomenon controversial (Iqbal *et al.*, 2015; Whitelaw, 2015).

Effects of Exposure to Specific EDCs During Perinatal Period

Many studies in animals, investigating specific EDCs, have shown that exposure to these chemicals during the perinatal period (during gestation or early life) leads to obesity later in life. Below we summarize what is known about the effects of various classes of EDCs on obesity and point the reader to other recent reviews for a more detailed elaboration of this subject (Heindel *et al.*, 2015, 2017; Janesick *et al.*, 2014a). While the strength of evidence varies for different chemicals, together, they support the notion that exposure to obesogenic EDCs during development leads to obesity later in life.

Fungicides

A variety of fungicides have been shown to act as EDCs, leading to obesity. Discussed previously, TBT is a well-studied obesogenic EDC found in fungicides. It works as an agonist of RXR and PPARγ, which work together to promote adipogenesis. In multiple studies, TBT was shown to stimulate adipogenesis in preadipocytes in vitro (Heindel *et al.*, 2017; Grun *et al.*, 2006; Kanayama *et al.*, 2005; Pereira-Fernandes *et al.*, 2014; Watt and Schlezinger, 2015). In vivo, studies in mice have shown that prenatal exposure to TBT increases lipid accumulation and adipose tissue mass in adulthood (Grun *et al.*, 2006; Kirchner *et al.*, 2010), effects which are passed down to multiple generations (Chamorro-García and Blumberg, 2014; Chamorro-García *et al.*, 2013, 2017). TBT is one chemical with strong evidence of obesogenic properties in animal models, yet human biomonitoring is lacking. Furthermore, TBT not only promotes adipocyte accumulation by acting on nuclear receptors, but also has been shown to lead to hepatic steatosis, hyperglycemia with reduced circulating insulin and increased islet cell apoptosis, and reduced cellular proliferation—all aspects of metabolic dysfunction (Zuo *et al.*, 2014).

Triflumizole is another fungicide, used on food crops, known to promote obesity. Like TBT, it works through activating PPARγ which, in turn, promotes adipocyte differentiation. In 3T3-L1 cells, triflumizole was shown to induce adipogenesis, even at nanomolar concentrations. Downstream, it induced adipogenic target genes including FABP4 and ADIPOQ expression (Li *et al.*, 2012). In contrast, tolylfluanid is a commonly used fungicide, especially in Europe. Rather than acting through PPARγ activation, it works to induce preadipocyte differentiation by activating the glucocorticoid receptor (Sargis *et al.*, 2010). In mice, tolylfluanid exposure led to increased weight gain after 35 days of exposure, with increased perigonadal, perirenal, and mesenteric fat pad weight (Regnier *et al.*, 2015). These mice also experienced disruption to their adipokine profile, with increased leptin to adiponectin ratio. Moreover, genes important for fatty acid oxidation were downregulated by tolylfluanid in mice, including two isoforms of acetyl-coA dehydrogenase (Regnier *et al.*, 2015).

BPA

BPA is an obesogenic EDC to which we are commonly exposed through polycarbonate plastics, epoxy resins lining food and beverage cans, and thermal papers such as cash register receipts. BPA has been shown to promote fat accumulation and weight gain after developmental exposure in rats and mice (reviewed in Heindel *et al.*, 2017). Mice treated with BPA showed a substantial increase in weight gain and a significantly higher perigonadal fat pad weight as compared with nonexposed mice by 28 weeks (Garcia-Arevalo *et al.*, 2014). BPA treated mice also tended to have an impaired glucose tolerance as compared to controls, linking the effects of BPA exposure to not only obesity, but potential development of type 2 diabetes. Expression of genes involved in glucose and lipid metabolism in BPA-treated mice also supported the correlation between BPA exposure and adiposity. In white adipose tissue, BPA-treated mice had significantly higher levels of expression of *Strebp1c*, which is involved in regulation of lipid biosynthesis and lipogenic enzyme expression. *Pparα* expression, a gene associated with lipid detection and hypolipidemic effects, was decreased in WAT, as was expression of *Cpt1β*, which important for fatty acid oxidation. *Cd36*, a gene involved in fatty acid uptake, also showed decreased expression. In the liver of BPA-treated mice, *Pparγ* levels were increased (Garcia-Arevalo *et al.*, 2014).

In humans, prenatal exposure to BPA was shown to be associated with increased fat mass index (FMI) and body fat percentage in children at 7 years of age (Hoepner *et al.*, 2016). Prenatal BPA exposure has also been shown to correlate with BMI and waist

circumference in children at 4 years of age (Valvi *et al.*, 2013), as well as with an increase in postnatal growth without affecting BMI in children ages 2–5 (Braun *et al.*, 2014). Diet may be a confounding factor in these studies because BPA is found in food packaging; therefore, a higher food intake, especially of processed, packaged foods could be associated with both a higher caloric intake and a higher intake of BPA (Hoepner *et al.*, 2016).

Phthalates

Phthalates are obesogenic EDCs, found in many plastics such as tubing and vinyl flooring, as well as in household and personal care products, fragrances, and food packaging (reviewed in Heindel *et al.*, 2017). The EU has already taken steps to reduce the use of certain phthalates (such as DEHP). Phthalates work by activating PPARs as well as causing antiandrogenic affects, both of which can lead to obesity (Kim and Park, 2014). Indeed, multiple studies in animals, testing various phthalates, showed that phthalate exposure led to increases in body fat and. For example, diethyl-hexyl-phthalate (DEHP) was shown to induce expression of genes associated with adipogenesis, including PPARγ, C/EBPα, and Srebf1. In vivo, perinatal exposure to DEHP led to increased adipose tissue deposition, serum lipids, glucose, levels, and body weight in offspring (Hao *et al.*, 2013). Mono-(2-ethylhexyl)-phthalate (MEHP), a metabolite of DEHP, was shown to activate PPARG, the protein product of the PPARγ gene, and its downstream target genes including PPARγ. In this way, MEHP promoted preadipocyte differentiation and adipogenesis. In the liver, MEHP was shown to activate PPARG and induce its downstream targets, including aP2, LPL, and FAS. Together, these genes stimulate fatty acid uptake and TAG synthesis (Hao *et al.*, 2012a). Studies in humans have shown varied effects associated with adipogenesis and obesity, including one finding that phthalate exposure during pregnancy was associated with elevated triglyceride levels in cord blood with increased body mass at 3 months, in boys (Kim *et al.*, 2016). Levels of phthalate metabolites are associated with waist diameter, insulin resistance and BMI in humans (Hatch *et al.*, 2008; Stahlhut *et al.*, 2007). Overall, studies suggest an association of phthalate exposure with weight gain in humans (reviewed in Heindel *et al.*, 2017).

Polycyclic Aromatic Hydrocarbons (PAHs)

PAHs are another well-studied group of chemicals that act as obesogenic EDCs. They are byproducts of fossil fuel burning, found in diesel exhaust, cigarette smoke, and general air pollution (reviewed in Heindel *et al.*, 2015). PAHs are have lipophilic properties, so they accumulate in organs such as the liver, kidney, and fat cells. They alter expression of PPARγ, fatty acid synthase, and adiponectin mRNAs after prenatal exposure in mice. These mice experienced increased weight and fat mass (Yan *et al.*, 2014). A mouse-model study using benzo[*a*]pyrene, a high molecular weight PAH, showed that the PAH impaired adipose tissue lipolysis, leading to increased weight gain and fat mass (Irigaray *et al.*, 2006). Other studies in mice have also been conducted, with results indicating an association between PAH exposure and obesity, but varying with experimental design (Heindel *et al.*, 2017). Some studies in humans show an association between exposure to PAHs and childhood obesity. Scinicariello and Buser (2014) showed an association between childhood exposure to low-molecular weight PAHs and obesity, as measured by BMI and waist circumference (Scinicariello and Buser, 2014). Rundle *et al.* showed a link between maternal exposure to PAHs and childhood obesity (Rundle *et al.*, 2012). PAHs not only induce obesity, but also have been shown to promote insulin resistance and inflammation in adult mice on a high fat diet (Bolton *et al.*, 2014; Strakovsky *et al.*, 2015). They may function in the endocrine system by acting like estrogens (Scinicariello and Buser, 2014; Wenger *et al.*, 2009).

Diethylstilbestrol (DES)

DES is an obesogenic EDC that promotes weight gain in females, at puberty, after exposure during development (Newbold *et al.*, 2008, 2009). One study in mice showed that DES works to increase obesity by increasing the number of adipocytes in gonadal fat pads (Angle *et al.*, 2013). Studies in humans have shown that prenatal exposure to DES promoted childhood obesity at age 7 (Jensen and Longnecker, 2014), and that at low doses, it promoted obesity in adult women (Hatch *et al.*, 2015). As with other obesogens, DES has been shown to work through PPARγ activation and resultant preadipocyte differentiation; as well as through activation of glycerol-3-phosphate dehydrogenase (GDPH), a lipid biosynthesis enzyme (Hao *et al.*, 2012b).

Persistent Organic Pollutants (POPs)

POPs are a broad class of chemicals that act as obesogenic EDCs. POPs are persistent in the environment because they resist degradation. Many are lipophilic and, as such, accumulate in adipose tissue (Jackson *et al.*, 2017). POPs include pesticides such as HCB and DDT, as well as industrial chemicals such as PCBs (Heindel *et al.*, 2017). Prenatal exposure to POPs HCB, βHCH, and PCB-138 and -180, was shown, in each case, to lead to increased BMI in children (Agay-Shay *et al.*, 2015). These, along with many other POPs, have been studied in humans, consistently showing that prenatal exposure is associated with obesity later in life (Heindel *et al.*, 2017; Vafeiadi *et al.*, 2015; Tang-Peronard *et al.*, 2014; Valvi *et al.*, 2012; Mendez *et al.*, 2011). Interestingly, while many studies confirm an association between prenatal POP exposure and obesity, there is little understanding of the underlying mechanisms.

Future Investigations

Many chemicals have been shown to have obesogenic properties in vitro, or in vivo. Some have been heavily studied in animals, but human data are sparse. For example, animal studies have shown that TBT may be an EDC that contributes to the obesity epidemic; yet the data regarding exposure levels in the human population (Kannan *et al.*, 1999) and the potential effects of these exposures in human longitudinal studies are few (Rantakokko *et al.*, 2014, 2008). Longitudinal studies of EDCs in human populations are the gold standard for linking results in animal studies with potential effects on humans (Trasande *et al.*, 2015; Attina *et al.*, 2016; Legler *et al.*, 2015).

The study of chemical obesogens is still in its infancy and many important gaps in our knowledge remain. For example, while we and others have shown that TBT exposure leads to increased adiposity in mice, rats and zebrafish, our recent study on the effects of altered diet on male F4 descendants of TBT treated animals is the first to test the interactions between diet and obesogen exposure (Chamorro-García *et al.*, 2017). Thus, there is an important gap in our understanding of how current or ancestral obesogen exposure interacts with diet, which could be very significant for human health. We have shown that some effects of obesogen exposure on MSCs (Shoucri *et al.*, 2017; Kirchner *et al.*, 2010) and on mice (Chamorro-García *et al.*, 2013, 2017) are likely to be epigenomic, yet relatively little is known about the underlying mechanisms. How are effects of maternal TBT exposure transmitted to offspring and to subsequent generations? How does maternal TBT exposure lead to a transgenerational thrifty phenotype? How does TBT exposure elicit large-scale changes in chromatin structure apparently only in the male germline? Why are effects in females more prominent in the F1 generation? At least one paper shows that TBT at high doses can also modulate the estrogen receptor, in vivo (Penza *et al.*, 2011). Which molecular targets mediate the effects of TBT on metabolic programming, in vivo? TBT exposure appears to "whiten" brown adipose tissue (BAT), in vivo, and exposure to the EDC obesogen, DDT, impairs thermogenesis in rats (La Merrill *et al.*, 2014). Do TBT and other EDCs impair thermogenesis, in vivo and if so, through what mechanisms?

Conclusion

EDCs are pervasive in our diets and environment. Obesogenic EDCs act to promote obesity, and can function by altering levels of hormones and consequently the action of their receptors during development. Some EDCs act directly on adipocytes, creating developmental changes that lead to increased propensity for obesity later in life. EDCs can also act indirectly to promote fat accumulation and obesity, by acting on other endocrine pathways (such as those in the brain and liver) (reviewed in Heindel *et al.*, 2017). A very conservative estimate of the impact of three obesogens on the cost of obesity and type 2 diabetes in the EU put the cost at $18 billion Euro per year (Legler *et al.*, 2015). The estimated cost in the United States was lower (Attina *et al.*, 2016), but this was primarily due to the dearth of longitudinal studies in humans that could be used to link animal experiments with human outcomes. We know very little about the extent to which a confirmed obesogen such as TBT impacts the human obesity epidemic in the United States and worldwide?

There is an urgent, unmet need to understand the mechanisms underlying the predisposition to obesity and related disorders. Obesity adds more than $200 billion to US healthcare costs (Cawley and Meyerhoefer, 2012) and the number of obese individuals continues to increase (Ogden *et al.*, 2014; Hales *et al.*, 2017). Evidence implicating environmental influences continues to mount, but the study of environmental factors in obesity remains in the early stages, and the mechanisms of environmentally initiated obesity (i.e., other than by foods or lifestyles) remain largely unknown. Recent results show that ancestral TBT exposure exacerbates the effects of increased dietary fat on fat accumulation in the F4 generation and renders the animals resistant to fasting-induced fat mobilization (Chamorro-García *et al.*, 2017). This suggests that descendants of obesogen-exposed individuals may respond to calories differently—they will store proportionately more calories as fat than nonexposed individuals and will resist losing this fat, even when calories are restricted as in dieting or fasting. This is similar to the "dieter's lament"—gaining weight despite not eating as much as others and resisting losing this weight even with dieting. We predict that these observations may have important implications for understanding how to treat obesity in humans.

Endocrine Disruptors and Thyroid Function

Josef Köhrle, Charité - Medicine University Berlin, Berlin, Germany, Humboldt University of Berlin, Berlin, Germany; and Berlin Institute of Health, Institute of Experimental Endocrinology, Berlin, Germany

Nomenclature

ADRA2	α2-Adrenergic receptor
AKT	serine/threonine kinase protein kinase B
ATC	Anaplastic thyroid carcinoma
Dehal	Dehalogenase
DIO	Deiodinase
DUOX	Dual oxidase
EDC	Endocrine disrupting compounds
FTC	Follicular thyroid carcinoma
IGF1	Insulin-like growth factor 1
K_m	Michaelis–Menten constant
LAT	L-type amino acid transporter
MCT8	Monocarboxylate transporter 8
MTC	Medullary thyroid carcinoma
NIS	Sodium-iodide symporter
OATP	Organic anion transporter
ODC	Ornithine decarboxylase
PCB	Polychlorinated biphenyls
Pi3K	PI3-kinase
PTC	Papillary thyroid carcinoma
PTEN	Phosphatase and tensin homolog, tumorsuppressor gene
PTU	6-n-Propyl-2-thiouracil
RET	Proto-oncogene tyrosine-protein kinase receptor
RXR	Retinoic acid receptor
TAAR	Trace amine-associated receptor
TBG	Thyroxine-binding globulin
Tg	Thyroglobulin
TPO	Thyreoperoxidase
Tetrac	Tetraiodothyro-acetic acid
TH	Thyroid hormone (T4,T3)
THM	Thyroid hormone metabolites
Triac	Triiodothyro-acetic acid
T4	3,3′,5,5′-Tetraiodo-L-Thyronine (Thyroxine)
T3	3,3′,5-Triiodo-L-Thyronine
rT3	3,3′, 5′-Triiodo-L-Thyronine (reverse T3)
3,5-T2	3,5-Diiodo-L-Thyronine
3-T1 AM	3-Iodo-thyronamine
T1Ac	3-Iodo-thyroacetic
TR	T3 Receptor
TRAK	TSH receptor stimulating antibodies
TRH	Thyrotropin releasing hormone
Triac	3,3′,5-Triiodothyro-acetic acid
TRPM8	Transient receptor potential cation channel subfamily M member 8
TSH	Thyrotropin, thyroid stimulating hormone
TTR	Transthyretin

Glossary

Iodothyronines Iodinated derivatives of the thyroid hormones (TH) 3,3′,5,5′-Tetraiodo-L-Thyronine (T4) and 3,3′,5-Triiodo-L-Thyronine (T3) that are formed by sequential deiodination of T4 and T3 or that are sulfated or glucuronidated metabolites. Apart from T3, the other iodothyronines, including T4, do not bind to the nuclear T3 receptor in vivo and therefore are not thyromimetically active. 3,5-T2 also exerts thyromimetic activity probably via mitochondrial mechanism of action and at high concentrations via T3 receptors.

Thyroid hormone The thyroid produces and secretes T4 and T3, which are iodinated derivatives of the amino acid tyrosine. T4 is considered as prohormone that acts primarily after 5′-deiodination to T3, the active TH. Most TH, that is, T3, actions are mediated by its binding to T3 receptors (TR) TRα and TRβ, which are encoded by different genes. TR are members of the nuclear receptor family, which modulate transcription of nuclear and mitochondrial T3-responsive genes as ligand-activated transcription factors. Recently, also "nonclassical" T3 actions have been demonstrated, which are rapidly initiated by TR interactions with intracellular kinase signaling cascades. Some rapid T4 effects may be exerted via binding and activation of $\alpha v\beta 3$ integrin receptors at the plasma membrane. TH regulate the development, differentiation, growth, energy, and structural metabolism of higher vertebrates, including humans. TH act in a permissive way in close cooperation with other hormonal, neuronal, and nutritive signals. Deficiency of iodine or TH during pregnancy leads to severe impairment of the development of the central nervous system and growth (cretinism) and impairment of many metabolic functions in the adult organism.

Thyroid hormone metabolites This term comprises the classical TH T_4 and T_3, their deiodinated metabolites and their recently re-discovered decarboxylated metabolites, the thyronamines 3-iodo-thyronamine and the iodine-free thyronamine, as well as the oxidized metabolites of the latter two compounds, that is, 3-iodo-thyroacetic acid and thyroacetic acid, all of which show various pharmacological actions distinct from those of the classical THs T_3 and T_4.

The Thyroid, the largest human endocrine gland, is located in front of the larynx and trachea below the thyroid cartilage. Shaped like a butterfly with two lobes connected by an isthmus it weighs between 18 g (female) and 25 g (male) and may grow to form a goiter under conditions of nutritional iodine deficiency, exposure to nutritional goitrogens or by autoantibody stimulation during Graves' disease (Basedow goiter). The main vital function of this highly vascularized gland is to accumulate the trace element iodine from blood and to generate, store and release the iodine-containing thyroid hormones (TH) L-thyroxine (3,3′,5,5′-Tetraiodo-L-thyronine, T4) and L-T3 (3,3′,5-Triiodo-L-thyronine). TH synthesis occurs in the angiofollicular units (**Fig. 1**), which comprise a tightly sealed epithelial monolayer of polarized thyrocytes and are organized in microspheres with diameters up to 1 mm, all of them completely surrounded by a microcapillary network. Its endothelial cells connect to each follicular cell, thus delivering iodide anions and nutrients to the follicles and disposing TH, released by follicular cells, to their target tissues and cells via the bloodstream. The follicular lumen, the site of TH synthesis and storage of the TH precursor protein thyroglobulin (Tg), contains the colloid, mainly composed of semisolid, polymerized, highly concentrated iodinated Tg, the major protein of this extracellular space. The thyroid gland is drained by lymphatic structures and receives sympathetic and parasympathetic nerval signals. The close location of the thyroid to the recurrent laryngeal nerve is a major challenge during thyroid surgery.

Regular development, migration and function of this gland and its adequate production of TH are essential for normal fetal and perinatal development as well as for healthy growth and adult life. Genetic disorders caused by mutations of several transcription factors, relevant for fetal thyroid development, migration of the thyroid anlage to its final destination, growth and proper function of the gland or mutations of genes coding for the individual components of TH biosynthesis, storage, and secretion may lead to major developmental delays and impairments known as cretinism. Developmental disorders affecting the thyroid may present with ectopic location (e.g., sublingual gland), hemiagenesis, too small size or even complete athyreosis. Cretinism may also result from inadequate maternal, fetal or postnatal iodine intake, still a problem affecting two thirds of the world population today! However, such adverse outcome can efficiently and completely be prevented by neonatal and life-long supplementation with adequate doses of the TH T4 to the newborn starting during the first week of life. Worldwide screening (by measurement of thyrotropin [TSH] or T4 concentration in neonatal heel prick blood) for this condition of congenital hypothyroidism, which is the most frequent but also preventable congenital endocrine disease occurring in ca. 1:3000 live births, has been successfully introduced around 1980. Affected adequately treated individuals have normal brain and physical development and body functions. Thyroid function may also be impaired by several nutritional and environmental factors leading to goiter formation similar to iodine deficiency. Among those goitrogens, several of them characterized by bitter taste, are various secondary metabolites of Brassicacea plants and cruciferous vegetables (goitrin, genistein, (iso-)flavones), especially if such food is inadequately prepared and cooked. In addition, environmental disrupting compounds (EDC, such as perchlorate, nitrate, thiocyanate and several other components of tobacco smoke), synthetic chemicals with properties of endocrine disruptors (flame retardants, plasticizers, PCBs) and a high number of pharmaceuticals used as routine drugs also directly interfere with the function of thyroid gland or the action of its hormones.

As the lifelong TH synthesis fully depends on adequate availability of the essential trace element iodine, proper organization of the angiofollicular units of the gland, as well as normal function and regulation of the complex biochemical and structural

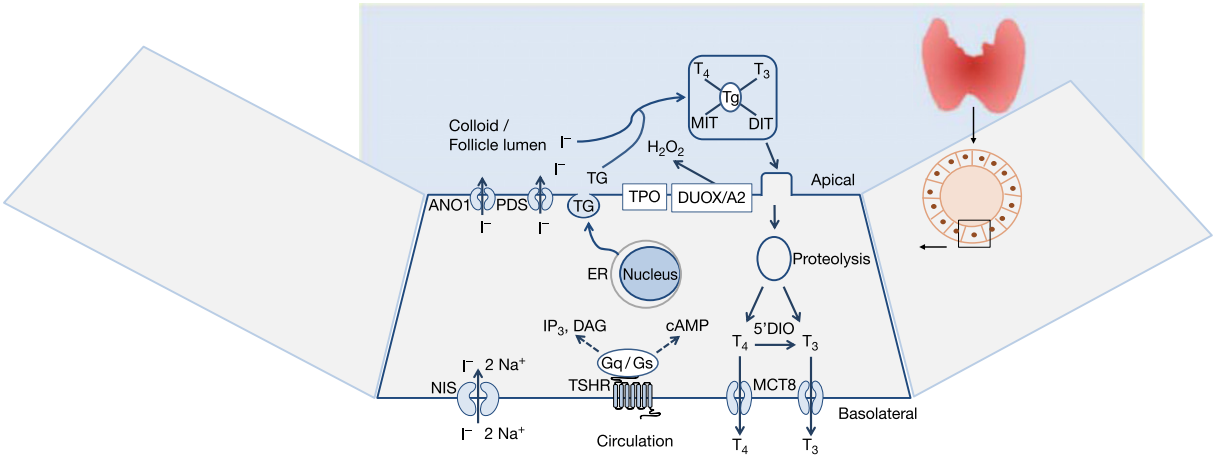

Fig. 1 The thyroid is composed of the angiofollicular units, where synthesis, storage, and secretion of thyroid hormones occurs. The complex sequence of reactions generating TH and depending on iodide uptake from blood, organification of oxidized iodine species and TH synthesis on thyroglobulin, stored in the colloid lumen, and secretion of proteolytically released TH T_4 and T_3 into the circulation is described in the text. Abbreviations: 5'-DIO, 5'-Deiodinase; cAMP, cyclic AMP; DAG, Diacylglycerol; DIT, diiodotyrosine; DUOX/A2, Dual oxidase/Activator 2; ER, endoplasmic reticulum; Gq/Gs, G-proteins; H_2O_2, hydrogen peroxide; I^-, iodide; IP_3, Inositol trisphosphate; MCT8, Monocarboxylate transporter 8; MIT, monoiodotyrosine; NIS, Sodium-iodide symporter; PDS, Pendrin; ANO1, Anoctamin1; TG, Thyroglobulin; TPO, thyreoperoxidase; T_4, 3,3',5,5'-Tetraiodo-L-Thyronine (Thyroxine); T_3, 3,3′,5-Triiodo-L-Thyronine; TSHR, thyroid stimulating hormone receptor.

machinery of the cascade of TH synthesis, storage and secretion, every defect or malfunction of this potentially "dead end street" may result in a congenital or postnatally acquired hypothyroid condition with its fatal sequelae, however treatable by T4 supplementation. The first step of TH biosynthesis (Fig. 1) is the accumulation of iodide from the blood against a concentration gradient via the sodium–iodide symporter (NIS), located in the basolateral membrane of thyrocytes and importing one iodide anion together with two Na^+ cations into the thyrocyte cytosol. Energy required for this symporter comes from ATP-driven Na^+, K^+–ATPase, which exports the excess Na^+ for K^+ import. Thus, inhibitors of Na^+,K^+–ATPase such as ouabain as well as inhibitors of NIS can interfere with adequate iodide uptake. Perchlorate, an environmental EDC released from fireworks, rockets, airbags, etc. and contaminating drinking water, rivers and lakes, is a potent competitor of NIS-dependent iodide uptake. Perchlorate is also used in medical practice for acute treatment of hyperthyroidism or blockage of the thyroid gland. Accumulated iodide immediately leaves the thyrocyte via apical ion channels (Pendrin, Anoctamin 1) into the follicular lumen. A fraction of this iodide may be "organified" and bound to unsaturated fatty acids forming iodolipids and iodolactons in thyrocyte membranes. The main protein synthetized by thyrocytes is Tg, a dimeric large glycoprotein ($2 \times 330{,}000$ Da) secreted into the thyrocyte lumen and representing the key synthesis and storage protein for TH. Tg is a cysteine-rich (ca. 120 cysteine residues) and tyrosine rich protein (60–120 tyrosine residues depending on species) with a domain structure containing four "hormonogenic" sites, three of them generating T4 at the N-terminus and one C-terminal site generating T3. Of the 66 tyrosines in the human Tg protein sequence around 15 are mono- or di-iodinated (monoiodotyrosine [MIT], diiodotyrosine [DIT]) while still being part of the polypeptide sequence of the huge protein. Iodination of the Tg tyrosine residues is an enzymatic reaction catalyzed at the luminal extracellular surface of the apical thyrocyte membranes by the multifunctional hemoprotein thyreoperoxidase (TPO). TPO is anchored in the apical membrane with its active site facing the lumen where it receives oxidized "iodine species" as cosubstrate for iodination of tyrosyl-residues of Tg. TPO also oxidizes iodide to I^0 or iodonium using H_2O_2 as oxidizing agent. This H_2O_2 is generated from H_2O by the integral apical membrane enzyme dual oxidase (DUOX), a Ca^{2+}-regulated, NADPH-dependent oxidase, which requires a maturation factor DUOXA protein as coregulatory subunit. The relay-type organization of this peculiar reaction sequence catalyzed by this multienzyme-complex has been termed "thyroxisome" based on observations, that several fine-tuned interactions are required for efficient Tg-iodination and TH biosynthesis. The third step influenced by TPO is the coupling of iodinated tyrosine residues resulting in iodothyronines, which are still part of the iodinated Tg polypeptide protein chain. Head-to-tail coupling of two DIT residues in the N-terminal hormonogenic domains generates T4, while coupling of one DIT with one MIT residue in the C-terminal hormonogenic site generates T3. One DIT or the MIT residues migrates under formation of the diphenyl-ether-ring structure of the newly formed iodothyronines producing a dehydroalanine residue at its former polypeptide sequence position. Iodinated Tg, containing MIT, DIT, T3 and T4-residues in its still intact protein sequence is deposited, oligomerized and polymerized forming compact solid globules (up to 500 μm size) in the colloid lumen at the highest protein concentration (up to 600 mg/mL) so far known for human tissues. Details of these polymerization and the depolymerisation reactions subsequently required for mobilization, degradation and cellular uptake of deposited Tg colloid content are less well studied. Probably, selenoproteins such as glutathione peroxidase 3, also secreted by thyrocytes into the apical luminal space together with several secreted cathepsins are required, which solubilize and degrade Tg in redox-regulated manner. Oligomeric Tg is then engulfed by micropinocytosis at the apical thyrocyte membrane, secondary lysosomal vesicles are formed and contained iodinated and hormone-containing Tg undergoes complete proteolysis mainly catalyzed by members of the cathepsin protease family. MIT and DIT residues liberated hereby are immediately routed towards the active site of the apical membrane associated dehalogenase enzyme, which regenerates the essential iodide to be channeled into the apical space for another round of Tg iodination and TH biosynthesis. During the lysosomal degradation of one Tg unit also up to four T4 and one T3 molecules are liberated and released into circulation via the monocarboxylate transporter 8 (MCT8), a transmembrane TH transporter located in the basolateral thyrocyte membrane. Thyrocytes not only produce a certain fraction of the active TH T3 in the C-terminal T3-hormonogenic site of Tg but also express high levels of the type 1 and type 2 5′ deiodinase (DIO1,2) selenoproteins which generate T3 from T4 inside the thyrocytes. Recent evidence suggests that the relative fraction of T3 produced during TH biosynthesis in Tg and also by DIO activities are higher under conditions of iodine deficiency and TSH stimulation. The complete process of iodide uptake, oxidation, H_20_2 generation as well as Tg secretion, iodination, storage, proteolysis, that is, TH biosynthesis, is under control of the anterior pituitary glycoproteohormone thyrotropin (TSH). TSH binds and activates the G-protein coupled TSH receptor at the basolateral thyrocyte membrane. TSH receptor signals both via Gs, activation of adenylate cyclase and protein kinase A to stimulate thyroid proliferation and TH release by the angiofollicular units and also via Gq, activation of protein kinase C and elevation of cytosolic Ca^{2+} to enhance H_20_2 production and the various steps required for Tg iodination and TH biosynthesis. Thus, TSH and its receptor are key regulators of thyroid function. Apart from TSH also the high concentrations of the pregnancy hormone human chorion gonadotropin, also a glycoproteohormone, bind and activate the TSH receptor during the first trimester of pregnancy, hereby securing maternal thyroid function and adequate fetal T4 supply during the first trimester, when fetal thyroid has not yet developed. TSH receptor stimulating autoantibodies (TRAK) represent the third type of activating ligands for the TSH receptor. TRAK, the hallmark of Graves' disease (M. Basedow), circulating in the blood of affected patients (mainly females) and entertaining continuous stimulation of the angiofollicular units and TH production, are generated by B-lymphocytes, which in contrast to the hypothalamus pituitary axis are not under negative feedback regulation of TH. Antithyroid drugs, surgical removal of the thyroid gland or its destruction by radioactive iodine isotope (radioiodine therapy) may cure this hyperthyroid disease state. Apart from the above mentioned NIS competitor perchlorate currently only two antithyroid drugs are available to treat hyperthyroidism, the thiouracil based agents 6-n-Propyl-2-thiouracil (PTU) or methimazol and its prodrug carbimazol. These agents are potent inhibitors of the hemoprotein TPO. To limited extent lithium cations are also clinically used as inhibitors of TH

release, which however may exert adverse effects as antidepressants at higher concentrations. Apart from TRAK-induced Graves' disease hyperthyroidism might originate from very rare germ line or more frequent somatic acquired activating mutations of the individual components of the TSHr signaling cascade. This might lead to the rare form of neonatal (e.g., germ line activating mutation of TSH receptor or Gs protein) or postnatal hyperthyroidism with development of autonomous ("hot") nodules in the progeny of those mutated angiofollicular units that gain proliferative and functional advantage over the rest of the thyroid gland due to the growth and functional stimulation of components of the TSH receptor signaling cascade. Autonomous nodules are preferably removed by surgery or radioiodine therapy. On the other hand several inactivating mutations of components of the TSH receptor signaling cascade are known to impair or prevent the complex process of TH biosynthesis and release, thus causing hypothyroidism, which can be efficiently treated with lifelong T4 supplementation similar to congenital hypothyroidism. A more prevalent cause of hypothyroidism is an autoimmune thyroid disease (AITD) slowly destroying thyroid structure and function. This form of hypothyroidism may present with lymphocytic infiltration of the gland (Hashimoto thyroiditis) and typically antibodies directed against TPO and Tg and measurable in the blood are formed as epiphenomenon of the slow ongoing thyroid destruction process. Again life-long treatment with T4 is required and this disease also mainly affecting women in their reproductive age is the main reason why T4 ranks among the top 5 of medical prescriptions world-wide. The underlying primary causes of both autoimmune thyroid diseases are still unknown.

Apart from these benign thyroid related diseases the thyroid is also affected by malignant alterations and thyroid cancer is the most frequent cancer of the endocrine system, again with higher prevalence in females compared to males. Four main variants of thyroid cancer originating from thyrocyte cells are known, which can be distinguished according to their molecular, morphological and clinical features: follicular carcinoma, follicular variant of papillary carcinoma, papillary carcinoma and anaplastic undifferentiated thyroid cancer. The latter variant has a very poor prognosis, while papillary thyroid cancer meanwhile is not a deadly disease anymore. Molecular basis of thyroid cancer has been partially identified during the last two decades and several mutations of oncogenes (e.g., BRAF V600E and RAS point mutations or RET-translocations) and tumor suppressor genes (P53, PTEN) involved in the carcinogenic process are known and targets for personalized treatment with selective inhibitors or anticancer drugs. The known tumor causing mutations lead to aberrant activation of mitogen-activated protein kinase and phosphoinositide 3-kinase-PTEN-AKT signaling, some aspects of which can be targeted with novel antitumor drugs. Thyroid cancer and metastases which still accumulate iodide can be effectively treated with radioiodide therapy and some current treatment attempts are directed towards pharmacological restoration of NIS function ("redifferentiation therapy"), which again allows application of efficient and long-established radioiodide therapy.

Apart from the essential trace element iodine, which plays the key role in thyroid-related biology and function, two other essential trace elements are also required for efficient synthesis, metabolism and action of TH, that is, iron and selenium. Iron is the central atom of the prosthetic heme group of TPO, which catalyzes the three steps of iodine oxidation, iodination of Tg tyrosyl-residues and the coupling of iodinated tyrosyl-residues to form iodothyronines in the Tg polypeptide chain. Iodine utilization and TH biosynthesis is more efficient with adequate iron supply. Nutritional deficiency of iron, more frequent in women during their reproductive years due to iron loss during menstruation as well as in underdeveloped regions with low intake of animal protein sources, is associated with inadequate TH production and resulting goitrogenesis. The third essential trace element required of adequate function of the TH axis and cellular action TH is selenium. Selenium deficiency alone or in combination with iodine deficiency and/or concomitant exposure to goitrogenic agents is involved pathogenesis of two forms of endemic cretinism, myxedematous or neurological cretinism, which can be prevented by adequate iodine intake, followed by selenium supplementation and avoidance of goitrogen exposure. The essential and beneficial role of adequate nutritional selenium intake has been attributed to its key function in several indispensable selenocysteine-containing proteins, which are involved in cellular redox control (e.g., thioredoxin reductases), antioxidant function (glutathione peroxidases), quality control of ribosomal protein biosynthesis, cellular signaling and enzymatic deiodination of TH (all three deiodinase isoenzymes). Remarkably, most of these selenoproteins are highly expressed in the thyroid and this gland also retains its selenium content even under nutritional selenium depletion. It has been hypothesized but not yet formally proven, that the lifelong production of H_2O_2 in the angiofollicular units, starting after week 12 in utero, requires an efficient antioxidative and redox-control system to maintain the vital function of this organ for TH production. Thus it does not come as a surprise, that selenium supplementation is also applied as adjuvant but not curative medication in the two autoimmune diseases described above.

Another major influence on thyroid follicular growth and function is exerted by the insulin/growth hormone/IGF-1 signaling cascades. Enhanced thyroid proliferation and goiter growth are well known from acromegaly patients and insulin and IGF-1 receptor signaling is markedly enhanced under conditions of low iodine supply. Probably, iodinated lipids and iodolactones, mentioned above, exert an inhibitory effect on this thyroid growth pathway, thus representing a local autoregulatory loop depending on adequate iodine intake and organification.

Finally, a further hormone producing cell type located in the thyroid gland needs to be considered, that is, the calcitonin-producing C-cells or parafollicular cells, which are found scattered between but not as integral part of the angiofollicular units. C-cells also drain their hormone into the microcapillary network of the gland and they originate from progenitor cells different from those of thyrocytes. C-cells are of clinical importance as they may evolve to medullary thyroid carcinoma (MTC), a rather aggressive, highly metastasising cancer, which already may develop during early childhood. Activating point mutations of the RET oncogene with clinically important genotype-phenotype relationships have been identified as driver mutations of this tumor. Several drugs inhibiting this RET-dependent mitogen-activated protein kinase and phosphoinositide 3-kinase-PTEN-AKT signaling or early complete thyroidectomy may cure this

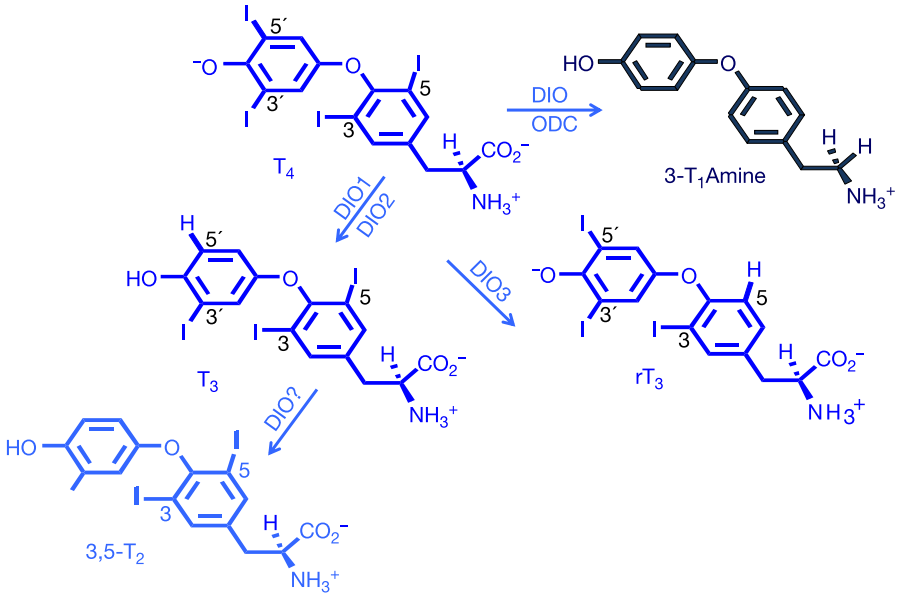

Fig. 2 Structures of the main biologically active thyroid hormones secreted by the thyroid gland (T4, T3) or generated extrathyroidally by deiodinase selenoenzymes (DIO) and ornithine decarboxylase (ODC). Tyrosine-derived iodinated thyroid hormones are charged molecules, which pass cellular membranes via various TH transmembrane transporters and act via several cellular receptors.

cancer if detected before its metastasis. Interestingly, the "hormone" calcitonin is an evolutionary dispensable relict in humans (but not in aquatic life forms). Calcitonin must not be replaced after complete thyroidectomy that does not disrupt calcium-phosphate homeostasis. However, calcitonin administration is a valuable treatment option in osteoporosis.

Thyroid Hormones

The term thyroid hormones (TH) typically comprises the two main secretory products of the angiofollicular units of the thyroid gland, that is, T_4 and T_3 (Fig. 2). Recently some more TH metabolites (THM) need to be included into this term. Two further THM are enzymatically generated outside the thyroid gland in peripheral target tissues/cells. (i) 3,5-diiodo-L-thyronine (3,5-T_2) also exerts rapid thyromimetic effects similar to the classical TH T_3, while (ii) 3-iodo-thyronamine (3-T_1AM) exhibits a spectrum of pharmacological actions quite distinct and mostly antagonistic to that of the thyromimetic T_3. A third class of THM with hormonal activity comprises the acetic acid side chain metabolites of iodothyronines and thyronamines, that is, 3,3′,5,5′-tetra-iodo-thyroacetic acid (Tetrac), 3,3′,5-tri-iodo-thyroacetic acid (Triac), and 3-iodo-thyroacetic (T_1Ac). T4 is the main secretory product (ca. 90–110 µg/day) of the normal thyroid gland under adequate iodine intake. Approximately 10–20 µg of T_3 are directly secreted by the thyroid per day, while extrathyroidal type 1 and type 2 deiodinase activities contribute another 30–40 µg of T_3 per day via enzymatic deiodination of the "prohormone" T_4 in target tissues including the brain. Molecular details of enzymatic formation of the minor THM 3,5-T_2 are not yet unraveled and 3,5-T_2 may represent a THM mainly generated and acting intracellularly on mitochondria and at higher concentrations also via the classical intracellular T_3 receptors. Remarkable are the efficient antisteatotic actions of 3,5-T_2 in obese rodent experimental animal models.

3-iodo-thyronamine (3-T_1AM) is a recently re-discovered THM circulating in nanomolar concentration in human blood. 3-T_1AM is generated from TH via deiodination in combination with decarboxylation by the enzyme ornithine-decarboxylase. One site of production during absorption of orally ingested TH might be the gastrointestinal mucosa. 3-T_1AM exhibits a remarkably broad spectrum of actions after its pharmacological administration (i.p., i.v., i.c.v.) to rodents and other experimental animals. Among those are effects, in part antagonizing those of thyromimetic T3, on the heart, body temperature, learning, memory, pain and other sensory functions. Which of these effects can also be exerted by endogenous 3-T_1AM, remains to be established by further studies. 3-T_1AM effects are not mediated by classical T3 but by cell membrane receptors such as members of the families of trace amine associated receptors (TAAR), G-protein coupled alpha-adrenergic receptors (ADRA2A), and transient receptor potential cation channel subfamily M member 8 (TRPM8).

Similarly, enzymes generating the acetic acid THM metabolites have not been characterized, albeit Tetrac and Triac are well known compounds circulating in blood and acting either via $\alpha v\beta 3$ integrin receptors at the cell membranes (Tetrac) or via the intracellular T3 receptor (Triac). Compared to the classical TH T_4, T_3 and 3,5-T_2 the acetic acid THM metabolites have very short half-lives as they exhibit low affinity to TH distribution proteins in the blood. Thus, Triac is used as thyromimetic drug to suppress elevated TSH in the conditions of TH resistance caused by inactivating mutations of TRβ and for amelioration of some hyper-metabolic aspects of tissue-specific hyperthyroidism in the X-chromosome linked Allan–Herndon–Dudley syndrome caused by inactivating mutations of the TH cell membrane transport protein MCT8.

Neuroendocrine Disruption of Reproduction

Introduction: Peripheral Versus Central Effects of Endocrine Disrupting Chemicals on Reproduction

Reproductive functions involve the coordinated action of different central and peripheral structures including the hypothalamus, pituitary gland, gonads, uterus, vagina, breast, prostate, etc. Several studies have shown that exposure to endocrine disrupting chemicals (EDCs) is associated with reproductive disorders such as alteration of the timing of puberty, infertility, abnormal cyclicity, premature ovarian failure, testicular cancer or adverse pregnancy outcome (Gore *et al.*, 2015). Some of those disorders have been shown to involve direct effects of EDCs on the gonads and other peripheral tissues. For instance, studies have reported that early exposure to bisphenol A altered fetal ovarian steroidogenic gene and microRNA expression in sheep (Veiga-Lopez *et al.*, 2013; Rivera *et al.*, 2011) and inhibited germ cell nest breakdown (Wang *et al.*, 2014). Prenatal exposure to diesthylstilbestrol (DES) leads to an increased expression of the homeobox A10 gene in the uterus through epigenetic mechanisms (Bromer *et al.*, 2009). The testis is also directly targeted by EDCs during early human life, as indicated by intratesticular anomalies described in the testicular disgenesis syndrome in human (Skakkebaek *et al.*, 2001) which are very similar to testicular anomalies described in rodents after early exposure to phthalates (Sharpe *et al.*, 1995). Central endocrine disruption initially received relatively less attention but increasing evidence during the past decade has shown that the neuroendocrine system is also targeted by EDCs (Gore, 2001; Bourguignon *et al.*, 2010; Frye *et al.*, 2012). This article will summarize the data illustrating the effects of EDCs on sexual differentiation of the brain as well as the hypothalamic control of puberty and reproduction.

Neuroendocrine Disruption of Sexual Differentiation of the Brain

Sex steroids such as estradiol or testosterone organize the sexual differentiation of the brain during critical developmental windows (Schwarz and McCarthy, 2008; Gore, 2008). This early organization at the hypothalamic level allows the coordination of sex appropriate reproductive physiology and sexual behavior. Sexual differentiation of the brain is mostly dependent on the action of fetal and maternal hormones on steroid hormone receptors, but other factors participate to the establishment of the sex differences. The aromatization of testosterone into estradiol by the enzyme p450 aromatase (present in specific brain regions during critical periods of perinatal development) is one of the mechanisms whereby testosterone acts to organize and sexually differentiate brain structures and chemistry in males (Roselli *et al.*, 2009). Alpha fetoprotein is another factor involved in the sexual differentiation of the brain. This circulating protein is produced by the fetal liver and binds estrogens with high affinity. In addition to its known neuroprotective role, it specifically delivers estrogens to target brain cells to ensure female differentiation as described in rodents (Bakker and Baum, 2008). Although most of the sex differences in the brain are established during the prenatal and neonatal periods, it appears that pubertal hormones also contribute to the addition of new cells in the sexually dimorphic regions (Ahmed *et al.*, 2008).

Two hypothalamic regions play a crucial role in the regulation of sexually dimorphic reproductive physiology: the anteroventral periventricular hypothalamic nucleus (AVPV) and the sexually dimorphic nucleus of the preoptic area (SDN-POA). The AVPV volume is sexually dimorphic: the region has been described as larger in female than in male rats. Testicular androgens, after aromatization into estrogens, appear to be responsible for this defeminisation/masculinization of the AVPV (Wright *et al.*, 2010). AVPV neurons project onto and directly stimulate GnRH neurons in the preoptic area. In rodents, AVPV plays a well-established role in the control of the preovulatory LH surge (Wiegand *et al.*, 1982; Ronnekleiv and Kelly, 1986). The SDN-POA is approximately fivefold larger in male than in female rats (Gorski *et al.*, 1978, 1980). The volume of the SDN-POA is increased by estradiol aromatized from testicular androgens perinatally. It is thought to play a role in male reproductive behavior and mate choice (Rhees *et al.*, 1999).

Because those nuclei express nuclear hormone receptors (Estrogen receptor alpha, Estrogen receptor beta, androgen receptor, and progesterone receptor) (Chakraborty *et al.*, 2003; Orikasa *et al.*, 2002; Mann and Babb, 2005; Simerly *et al.*, 1990; McAbee and DonCarlos, 1999; Quadros *et al.*, 2002, 2007), they are potential direct targets of endocrine disrupting chemicals. Initial studies illustrated the effects of early exposure to phytoestrogens on sexually dimorphic nuclei in the hypothalamus. Phytoestrogens are naturally occurring plant compounds structurally or functionally similar to oestrogens. Isoflavones are the most hormonally active and most characterized phyto-oestrogens. They are found in soy beans but also in berries, wine, grain, nuts, and soya-fortified foods (Kurzer and Xu, 1997). Most isoflavones bind nuclear estrogen receptors (ER) and act as partial agonists. They appear to have a higher affinity for estrogen receptor beta (ERβ) (Kuiper *et al.*, 1998) which could explain varying activity depending on the tissue since ERβ expression varies across cell types and is sexually dimorphic (Cao and Patisaul, 2011, 2013). Some isoflavones such as genistein have been shown to bind to GPR30 (Thomas and Dong, 2006). Recent data suggests that isoflavones can also

alter DNA and histone methyltransferases as well as other modifiers of chromatin structure (Shanle and Xu, 2011; Li and Tollefsbol, 2010). While not always in accordance, several studies have reported an effect of isoflavones which is consistent with an estrogenic effect with an increased volume of the POA in males. For instance, genistein administered prenatally until adulthood leads to an increased volume of the POA in exposed males but not females (Scallet *et al.*, 2004). When the exposure is shorter, this increase is not observed or not maintained (Lewis *et al.*, 2003). Neonatal exposure to genistein increased tyrosine hydroxylase immunoreactivity in the male anteroventral periventricular nucleus (Patisaul *et al.*, 2006, 2007), indicating that genistein leads to a demasculinization of the AVPV through interference with endogenous estrogens. Genistein has also been shown to decrease kisspeptin fiber density in the female anteroventral periventricular nucleus and arcuate nucleus (Losa *et al.*, 2011).

Synthetic endocrine disrupting chemicals have been shown to affect sexual differentiation of the brain as well. Rubin *et al.* (2006) have shown that perinatal exposure to low doses of bisphenol A (BPA) reduced the sex differences in the population of tyrosine hydroxylase (TH) neurons in the AVPV, primarily through a decline in the number of labeled neurons in females. Another study from McCaffrey *et al.* showed a defeminization of the female AVPV (evaluated through a decrease of TH positive cell numbers) after perinatal exposure to a wide range of BPA doses (McCaffrey *et al.*, 2013). Evidence of a demasculinization of the male SDN-POA (reduced volume as labeled by calbindin) was also observed after such exposure (McCaffrey *et al.*, 2013). The volume of the sexually dimorphic nucleus of the preoptic area is larger in males exposed perinatally to low doses of BPA but not in female, suggesting a sex specific effect of BPA exposure on SDN-POA volume (He *et al.*, 2012). However, a study from Kwon *et al.* has yielded discordant results since perinatal administration of BPA did not produce detectable effects on the SDN-POA volume (Kwon *et al.*, 2000). Differences among results may be due to differences in the age of analyses, the timing of exposure, the route of exposure or the chosen doses of EDCs.

Neuroendocrine Disruption of Pubertal Timing

Secular Trend in Age at Puberty and Environment

Puberty is a life period characterized by the maturation of the hypothalamic- pituitary-gonadal axis. It involves both physiological and behavioral changes that ultimately lead to the achievement of reproductive capacity. Puberty results from the activation of a complex neuroendocrine machinery which leads to an increase in frequency and amplitude of gonadotropin-releasing hormone (GnRH) secretion in the hypothalamus (Herbison, 2016).

A reduction in menarcheal age has been reported between 1850 and 1960 in Scandinavian countries (Tanner, 1962) and further in many European countries and United States (reviewed in Parent *et al.*, 2003, 2015). These observations were thought to be the result of the improvement in health and nutritional status with the changes in socio-economical conditions. After a constant advance between 1850 and 1960, it appears that, in several countries with relatively stable and uniform condition of life, menarcheal age has shown only minor progression during the past decades while breast development seems to still be advancing (Parent *et al.*, 2015). Some studies have identified a secular trend towards early onset of puberty, irrespective of the level of BMI (Aksglaede *et al.*, 2009), suggesting the involvement of other environmental influences, among which endocrine disruptors chemicals. Detailed analysis reveals that the pattern of age distribution is affected both in boys and girls. This justifies a revision of the belief according to which current changes correspond to an advancement of pubertal timing in females. Current variations in pubertal timing actually involve a trend toward earliness for initial pubertal stages and toward lateness for final pubertal stages. This data suggests a role for environmental influences including nutrition, stress, and endocrine disruptors. This hypothesis is supported by some observations of association between early exposure to endocrine disrupting chemicals or other environmental factors and the age at onset of puberty as well as rodent data which will be described below.

Challenges in Demonstrating the Endocrine Disruption of Puberty Timing

Before discussing the available data linking exposure to EDCs and neuroendocrine disruption of pubertal timing, it is important to be aware of some challenges that we face in this area.

A growing body of evidence demonstrates that fetal and early postnatal life is a critical period of sensitivity to the effects of EDCs (Gore *et al.*, 2015; Fudvoye *et al.*, 2014). The capacity of environmental factors to shape the neuroendocrine system is thought to be maximal during fetal and early postnatal life and possibly less important when approaching the time of onset of puberty (Parent *et al.*, 2015). However, most studies on the role of environmental factors in triggering onset of puberty focused on the period immediately preceding puberty (Parent *et al.*, 2015). The current recommendations of the Organization of Economic Co-operation and Development (OECD) for testing effects of EDCs on rodent female puberty, define postnatal days 22–42 as the validated exposure period with timing of vaginal opening and increase in uterine weight as evidence of puberty. Those guidelines ignore the earlier period before 25 days that is critical for neuroendocrine maturation. The effects of environmental stressors on pubertal timing depend on the period of occurrence or exposure. For instance, prepubertal underfeeding may lead to delayed puberty (Biro *et al.*, 2005; Dunger *et al.*, 2006; Ong et al., 2004, 2006; Cheng *et al.*, 2012; Himes, 2006; Roa and Tena-Sempere, 2010)whereas intrauterine growth restriction is associated with early puberty (Ibáñez *et al.*, 2006, 2011). Likewise, psychosocial stress shortly before or during puberty may cause delayed menarche or amenorrhea (van Noord and Kaaks, 1991; Tahirović, 1998) whereas advancement of puberty has been described in girls who had experienced such stress in early postnatal life or infancy

(Moffitt *et al.*, 1992; Wierson *et al.*, 1993). Those data are consistent with the concept that environmental clues affect pubertal timing differently depending on the life period when they come into action. In the early phase of organization of adaptive mechanisms, adverse conditions can be interpreted centrally as a risk for species survival and are translated into need of early reproductive fitness. Reversely, in a period closer to puberty, similar adverse conditions can be interpreted as a risk for quality and outcome of pregnancy and are translated into a need for delayed reproductive fitness.

Another challenge comes from observations that are inconsistent with the classical toxicology perspective according to which there will be no effect of a chemical below a threshold of exposure. This principle implies that the dose–response relationship is linear. However, hormones have complex concentration-response patterns which lay the foundation for dose–response characteristics exhibited by EDCs (Gore *et al.*, 2015). We have shown that neonatal exposure to BPA for 2 weeks leads to a delayed maturation of GnRH secretion after a low environmentally relevant dose and advanced maturation after exposure to a higher dose (Franssen *et al.*, 2016). Opposing effects on male rat puberty have also been observed after exposure to lower or higher doses of phthalates (Ge *et al.*, 2007; Saillenfait *et al.*, 2008). In addition, low-dose mixtures, consistent with human exposure, can have effects not conforming to simple additive models (Kortenkamp, 2008; Christiansen *et al.*, 2012). However, most animal and human studies so far have focused on one or a single group of EDCs.

EDCs exposure, by modifying the hormonal environment, can affect pubertal timing either through central mechanisms, acting at different levels of the hypothalamic-pituitary system or through interaction with the peripheral target tissues such as the breast, uterus, testis or ovaries. Peripheral mechanisms can coexist with central mechanisms or secondarily facilitate them. Such a concept is supported by the dissociation between advancement in age at onset of breast development in Denmark, the Netherlands, and Belgium without parallel change in menarcheal age (Parent *et al.*, 2015). A single pubertal event can be influenced by different endocrine pathways. For instance breast development can be due to ovarian estrogen secretion under the stimulation by pituitary gonadotropins and/or estrogenic effects of EDCs independently of hypothalamic-pituitary maturation. Moreover, EDCs can interfere with the physiological inhibitory feedback mechanisms of sex steroids at the hypothalamic-pituitary level while they can also stimulate neuroendocrine maturation of GnRH secretion (Rasier *et al.*, 2006).

Disruption of the Hypothalamic Control of Puberty

Several animal studies have reported alterations of pubertal timing after exposure to EDCs. Some models allowed the identification of neuroendocrine mechanisms leading to such effects.

In females, the effects of EDCs on the timing of vaginal opening depend on the period of exposure (Parent *et al.*, 2015). When the animals are exposed to BPA during pregnancy only, age at vaginal opening is either not affected (Tinwell *et al.*, 2002; Murray *et al.*, 2007; Howdeshell *et al.*, 1999) or early (Honma *et al.*, 2002; Nikaido *et al.*, 2004). When exposure takes place between birth and 15 days of age, age at vaginal opening is either not affected (Adewale *et al.*, 2009; Losa-Ward *et al.*, 2012; Nagao *et al.*, 1999; Yu *et al.*, 2010) or early (Adewale *et al.*, 2009; Losa-Ward *et al.*, 2012; Fernández *et al.*, 2009; Nah *et al.*, 2011). A dose of 50 μg/kg causes advancement of puberty while 50 mg/kg has no effect, indicating a nonlinear dose–response relationship (Adewale *et al.*, 2009; Losa-Ward *et al.*, 2012). We also showed that a very low doses of 25 ng/kg/day from postnatal day 1–15 delayed maturation of GnRH secretion while a high dose of 5 mg/kg/day led to an accelerated maturation (Franssen *et al.*, 2016). Taken as a whole, those studies show that BPA effects depend markedly on the window of exposure and the dose, with possible nonlinear dose–response relationship. Several studies have provided evidence of neuroendocrine changes after early exposure to BPA in the female rat. These will be discussed further in the mechanistic article below. Most studies investigating the consequences of neonatal exposure to genistein led to equivocal conclusions since age at vaginal opening was either normal with no dose-related effect (Nagao *et al.*, 2001; Jefferson *et al.*, 2005; Kouki *et al.*, 2003) or early and dose- or duration-dependent (Lewis *et al.*, 2003; Kouki *et al.*, 2003) or even late and dose-dependent (Jefferson *et al.*, 2009). Using phthalates, the period of exposure appears crucial since prenatal exposure accounts for late vaginal opening (Salazar *et al.*, 2004) whereas postnatal exposure is associated with normal timing (Gray *et al.*, 2006; Moral *et al.*, 2007) or early vaginal opening irrespective of the dose (Hu *et al.*, 2013; Ma *et al.*, 2006). Polybrominated EDCs appear to cause either no change or delay in vaginal opening depending on the dose and irrespective of the period of exposure (Stoker *et al.*, 2004; Lilienthal *et al.*, 2006; Ceccatelli *et al.*, 2006).

In male rodents, balano-preputial separation is commonly used as a marker of puberty. With the exception of early balano-preputial separation after exposure to phthalates (Ge *et al.*, 2007; Saillenfait *et al.*, 2008), EDCs appear to cause either no effect or a delay of sexual maturation in the male rodent. BPA does not show any effect whatever the dose and the window of exposure (Tinwell *et al.*, 2002; Nagao *et al.*, 1999; Tan *et al.*, 2003; Ashby and Lefevre, 2000; Kato *et al.*, 2006). Similarly, using a very low dose of BPA neonatally for 5 days, we did not see any effect of exposure on balano-preputial seperation. However, when pulsatile GnRH secretion from hypothalamic explants is studied at 25 days in such exposed animals, GnRH pulse frequency is reduced, indicating a delayed maturation of GnRH secretion caused by BPA neonatally. This indicates that GnRH secretion could be extremely sensitive to disruption without being sufficient or lasting sufficiently to account for phenotypic changes. When similar doses of different EDCs are used at different periods of exposure in the male rodent, they are found to be effective in delaying puberty after postnatal (after weaning) exposure as opposed to no effect after prenatal exposure. Such findings are obtained using dichlorodiphenylichloroethylene (DDE), vinclozolin (Warner *et al.*, 2004) or diethylstilbestrol (DES) (Warner *et al.*, 2004; Mol *et al.*, 2002) suggesting that the fetus is less sensitive than the juvenile animal. The newborn rat can also be more sensitive than the fetus as found after exposure to DES (Warner *et al.*, 2004). Such a conclusion was also drawn in a review of several studies on BPA

effects in the female rat since gestational exposure has no effect on age at vaginal opening whereas neonatal exposure is followed by early puberty (Guo *et al.*, 2004). Importantly, both periods of exposure fall into the so-called "programming window" indicating that, even within this particular period, there may be differences in sensitivity to endocrine disruption. The dose of EDC however plays a critical role since, when investigated at a given period of life, higher doses appear to be more effective such as shown after prenatal exposure for DDE (Leijs *et al.*, 2008) and phthalates (Denham *et al.*, 2005; Den Hond *et al.*, 2002), or after lactational exposure for DDE, vinclozolin or DES (Warner *et al.*, 2004) or following exposure after weaning for DDE (Grandjean *et al.*, 2012; Warner *et al.*, 2004), vinclozolin (Warner *et al.*, 2004; Adgent *et al.*, 2012), DES (Warner *et al.*, 2004; Kim *et al.*, 2011), phthalates (Deng *et al.*, 2012; Strom *et al.*, 2001), and polybrominated diphenyl ethers (PBDE) (Giampietro *et al.*, 2004). It is noteworthy that in two studies using phthalates, opposing effects are observed since lower doses are associated with early puberty and higher doses with delay (Deng *et al.*, 2012; Denham *et al.*, 2005). Interestingly enough, we have reported similar opposing effects using DES neonatally in the female rat (Fernandez-Rhodes *et al.*, 2013).

Neuroendocrine Disruption of Ovulation

Ovulation is under the control of GnRH secretion which is tightly regulated by the positive and negative feedbacks of gonadal steroids. In both males and females, GnRH secretion is suppressed by the negative feedback taking place at the level of the arcuate nucleus. The positive feedback of estrogens is mediated by the AVPV and potentiates the surge in GnRH and subsequently luteinizing hormone (LH) that precedes ovulation. In rodents, the sexual differentiation of this positive feedback takes place during the perinatal period and is particularly sensitive to disruption by hormones and EDCs. It has been shown that the administration of testosterone or estradiol benzoate during the neonatal period can alter the positive feedback by estradiol (Padmanabhan and Veiga-Lopez, 2014). Such data suggests that early exposure to EDCs could alter the programming of the preovulatory LH surge. In addition, exposure to EDCs during adulthood could alter the central control of ovulation. This article will summarize the effects of neonatal or adult exposure to EDCs on the hypothalamic control of ovulation. As discussed above for puberty, it is sometimes difficult to differentiate the effects of EDCs on the central versus the ovarian control of ovulation. Some animal models can help to shed light upon such aspects.

The sheep offers a good model for studying the effects of EDCs on the neuroendocrine control of ovulation thanks to the availability of noninvasive approaches to monitor follicular dynamics as well as surgical approaches to obtain hypophyseal portal blood (Padmanabhan and Veiga-Lopez, 2014). Prenatal exposure of female sheep to excess androgens has been shown to lead to adult reproductive disorders with LH excess, multifollicular ovarian morphology and corpus luteus dysfunction. Such early exposure to testosterone disrupted the estradiol negative feedback (Wood and Foster, 1998; Sharma *et al.*, 2002), estradiol positive feedback (Wood and Foster, 1998; Sharma *et al.*, 2002), and progesterone negative feedback (Robinson Forsdike and Taylor, 1999). Neonatal exposure to BPA leads to reproductive disorders similar to those found in testosterone exposed sheep with LH excess and severly dampened preovulatory LH surge (Savabieasfahani *et al.*, 2006).

Neonatal exposure to BPA in rodents has been shown to disrupt pubertal timing but also leads to premature anestrus and ovarian anomalies. As described for the sheep, these anomalies could result from disrupted organization at the level of the hypothalamus/pituitary or at the level of the ovaries. Adewale *et al.* have shown that alterations of estrus cycle caused by a relatively low dose of BPA was not accompanied by a reduction of the number of GnRH neurons expressing the immediate early gene c-fos suggesting that steroid-positive feedback was not defeminized by BPA. However, this study did not rule out the possibility that other regulation of the GnRH neurons could have been altered (Adewale *et al.*, 2009). Other studies suggest that neonatal exposure to BPA decreased basal and GnRH induced LH secretion and increased GnRH pulsatility in adult rats, suggesting a permanent effect on GnRH pulsatility and pituitary signaling (Fernández *et al.*, 2009). There is relatively less information on the neuroendocrine disruption of ovulation caused by EDCs other than BPA. Exposure to TCDD (2, 3, 7, 8-tetrachlorodibenzo-para-dioxin) has been associated with abnormal ovulation and premature ovarian failure (Gregoraszczuk and Ptak, 2013). While some studies showed that TCDD disrupted estradiol secretion in human ganulosa cells (Baldridge *et al.*, 2015), others have reported alteration of the hypothalamic-pituitary axis. Takeda *et al.* (2014) have shown that exposure of pregnant rats to TCDD led to decreased expression of gonadotropins in pups and LH and FSH levels appeared to be decreased in virgin female mice (Huang *et al.*, 2011). Tributyltin chloride is used as a biocide in antifouling paints which exposure has been associated with obesity. It has recently been shown to alter estrus cyclicity and cause decreased surge LH levels and GnRH expression (Sena *et al.*, 2017). Very few data are available regarding the effects of phthalates on estrus cyclicity and ovulation. One study showed that exposure to DEHP during adult life led to increased duration of estrus in mice (Hannon *et al.*, 2014).

Mechanisms of EDCs Effects on the Overall Neuroendocrine Control of the Reproductive System

The hypothalamic-pituitary-gonadal axis is responsible for the development of puberty and acquisition of the reproductive function. A subset of neurons in the anterior hypothalamus secrete gonadotropin-releasing hormone (GnRH) which, through its pattern of release, controls all aspects of reproductive function throughout life. The secretory activity of GnRH neurons depends on trans-synaptic and glial inputs mediated by neurotransmitters and cell–cell signaling molecules. New methods have provided more information regarding the dynamic coordination of network contributing to the central control of the pubertal process and

reproduction (Ojeda and Lomniczi, 2014). When studying the central mechanisms potentially involved in the neuroendocrine disruption of puberty or ovulation, GnRH neurons appear to be a potential target of exposure to endocrine disruptors. Using a murine model of neonatal exposure to dichlorodiphenyltrichloroethane (DDT), our team has confirmed the involvement of neuroendocrine disruption in the alteration of pubertal timing. Pulsatile GnRH secretion was accelerated after early exposure to DDT and this effect was followed by early sexual maturation (Rasier *et al.*, 2007). Further studies have indicated that such effects involve the estrogen receptor, the orphan dioxin (AhR, arylhydrocarbon) receptor and a subtype of glutamate receptor (Rasier *et al.*, 2008). Another study of our group showed that exposure to DES (10 μg/kg/day) during the first 5 days of life was associated with early vaginal opening while a dose of 1 μg/kg day was associated with delayed vaginal opening and delayed developmental increase in GnRH pulse frequency (Franssen *et al.*, 2014). DES is a potent synthetic estrogen which was prescribed to prevent miscarriages during the 1950s and 1960s. Its prescription was banned because of the increased risk of vaginal cancer after in utero exposure. DES is still used as a paradigmatic EDC in animal models. Our observations counteract the classical hypothesis that EDCs cause sexual precocity. Although precocity is indeed observed in several studies and possibly reflects both peripheral and central mechanisms, delayed female puberty after neonatal exposure to a potent oestrogenic EDC is a new finding that is likely to be of neuroendocrine origin. In addition, it appears that prenatal food restriction could have additive effects to neonatal DES exposure on the neuroendocrine effects of leptin. When females were exposed in utero to prenatal food restriction and postnatally to DES, the stimulatory effect of leptin on GnRH secretion in vitro was completely blunted (Franssen *et al.*, 2014). This reinforces the demonstration of a neuroendocrine disruption of GnRH secretion and illustrates the potential additive effects of different environmental stressors.

Other studies have shown effects of EDCs on GnRH secretion. Fernandez et al. demonstrated an increase of GnRH pulsatility in infantile rats after neonatal exposure to BPA (Fernández *et al.*, 2009). Interestingly, GnRH pulsatility remained disrupted in adult rats neonatally exposed to BPA (Fernández *et al.*, 2009). Losa-Ward *et al.* (2012) have reported morphological alteration of RFamide-related peptide-3 (RFRP3) neurons known to inhibit GnRH neuron activity after neonatal exposure to BPA. They showed reduced RFRP3 perikaria, fiber density and contacts on GnRH neurons, suggesting that BPA-induced premature puberty could result from decreased inhibition of GnRH neurons. GnRH neurons response to steroid-positive feedback, however, was not affected by neonatal exposure to BPA in the study from Adewale et al. (2009). More recently, our group has reported that the developmental increase in frequency of GnRH release at the time of puberty is delayed in female rats exposed neonatally to a low dose of BPA (25 ng/kg/day). Interestingly, the effects were opposite with a high dose of BPA (5 mg/kg/day). The mechanism involved respectively increased or reduced tone of γ-aminobutiric acidergic (GABAergic) neurotransmission which is known to play an inhibitory control on GnRH secretion (Franssen *et al.*, 2016).

Neuroendocrine disruption of reproduction can act through interference with the production or the action of brain neuropeptides which regulate GnRH secretion. Kisspeptin, encoded by the KISS1 gene, is known to stimulate GnRH secretion and plays a crucial role in the onset of puberty (Seminara *et al.*, 2003; de Roux *et al.*, 2003). Navarro et al. have shown a reduction in hypothalamic expression of *KiSS1* mRNA at puberty after neonatal exposure to a high dose of BPA as it was observed after exposure to estradiol benzoate (Navarro *et al.*, 2009). Similarly, Patisaul et al. found a reduction in kisspeptin immunoreactivity (estimated in term of fibers density) in the arcuate nucleus in adult female rats (Patisaul *et al.*, 2009) after neonatal exposure. Regarding the earlier vaginal opening that occurs after exposure to a high dose of BPA (Franssen *et al.*, 2016), those observations were unexpected since Kiss1 is considered as a major gatekeeper of puberty onset. The reduction in kisspeptin expression could then be part of a reactive mechanism to BPA exposure. Similarly, a study performed in the sheep showed a decrease of Kiss1 mRNA levels at the rostral, mid and caudal regions of the hypothalamus in fetus exposed in utero to a complex mixture of EDCs (Bellingham *et al.*, 2009). Such effects were not observed after adult exposure, supporting the hypothesis that the period of exposure is critical for such regulatory processes. Xi *et al.* (2011) showed that perinatal exposure to a high dose of BPA resulted in the upregulation of the expression levels of KiSS-1 and GnRH in both male and female pups. This observation was not replicated after postnatal exposure to BPA, highlighting once again the critical perinatal period for BPA affecting reproductive neural circuits in hypothalamus (Xi *et al.*, 2011). Acute infusion of BPA in the stalk-median eminence of mid to late pubertal female rhesus monkeys led to a suppression of GnRH and kisspeptin secretion for the highest doses while lower doses did not have any apparent effects (Kurian *et al.*, 2015).

GnRH neurons themselves express ERβ but also G protein coupled receptor 30 (GPR30) and estrogen-related receptor γ, all potential receptors for endocrine disrupting chemicals. Thus GnRH neurons could be directly targeted by EDCs. A recent study has shown that BPA significantly decreased calcium activity in GnRH neurons in explants. Blockade of GABAergic and glutamatergic input did not abrogate the inhibitory effect of BPA, suggesting a direct effect of BPA on GnRH neurons (Klenke *et al.*, 2016). Other studies in fish suggest that early exposure to BPA or bisphenol S could increase the number of GnRH3 neurons during development which suggests a broader effect of BPA and BPS on neurodevelopment (Qiu *et al.*, 2016).

Conclusion and Perspectives

The hypothalamus provides a unique site for finely tuned integration of endogenous and environmental factors influencing the control of puberty and reproduction. While initial studies focused on the effects of EDCs on peripheral organs, recent data have shown that the hypothalamic-pituitary control of reproduction can be targeted by environmental pollutants. While such effects are extremely difficult to study in humans, animal models play a crucial role in deciphering the neuroendocrine mechanisms of action

of such compounds. Neuroendocrine effects of EDCs can be opposing and involve different mechanisms depending on the dose or whether they take place early, during fetal and neonatal life or late during prepubertal life.

These last few years, the knowledge of molecular and genetic mechanisms controlling the pubertal process has accelerated considerably. Puberty results from coordinated changes in a multiplicity of genes organized into functional networks. Recent evidence suggests that a dual mechanism of epigenetic regulation affecting the transcriptional activity of neurons involved in stimulating GnRH release plays a fundamental role in the timing of puberty (Ojeda and Lomniczi, 2014; Lomniczi *et al.*, 2015). In addition, a multilayered microRNA-operated switch appears to be involved in the increase in GnRH expression during the prepubertal period (Messina *et al.*, 2016). Epigenetic repression and activation of gene transcription might be a mechanism by which environmental factors affect pubertal development and reproduction. Because EDCs have been recently shown to alter DNA methylation, histone modifications and microRNA expression (Gore *et al.*, 2015), further studies will be needed in order to explore the involvement of such mechanisms in the neuroendocrine disruption of reproduction.

Glossary

AGD Anogenital distance, the distance between anus and genitals.
ASD Anoscrotal distance the distance between anus and scrotum.
Cryptorchidism Undescended testis.
Hypospadias In hypospadias urethral opening is located on the ventral side of the penis due to incomplete formation of the urethra. This is often associated with an abnormal ventral penile curvature and the absence of the ventral foreskin.
TEQ WHO-recommended 2,3,7,8-TCDD equivalent.
Total-TEq WHO-recommended 2,3,7,8-TCDD equivalent for 17 dioxins and 12 dioxin-like PCBs.

Introduction

This article focuses on cryptorchidism, hypospadias, testicular germ cell cancer, and poor semen quality in humans and their associations with environmental exposure to endocrine disrupting chemicals (EDCs). These disorders have common risk factors [such as being born as small for gestational age (SGA)], they show heritability in families and some of them are also risk factors for each other (Trabert *et al.*, 2013; van der Horst and de Wall, 2017; Lee and Coughlin, 2001; Toppari *et al.*, 2010; Thorup *et al.*, 2014; Weidner *et al.*, 1999). According to the testicular dysgenesis syndrome (TDS) hypothesis, cryptorchidism, hypospadias, testicular germ cell cancer, and poor semen quality may have a common origin in fetal life and thus represent symptoms of testicular dysgenesis (Skakkebaek *et al.*, 2001). Also short anogenital distance (AGD) and impaired testosterone production are currently regarded as possible symptoms of TDS (**Fig. 1**) (Skakkebaek *et al.*, 2016). In the rat model fetal exposure to phthalates (which are antiandrogenic chemicals) during the masculinization programming window leads to cryptorchidism and hypospadias, reduced testicular and penile size, shortened anogenital distance, compensated Leydig-cell dysfunction and focal testicular dysgenesis (van den Driesche *et al.*, 2017). Exposure of the fetal testis to environmental factors such as EDCs is regarded as one of the strongest risk factors for male reproductive disorders of TDS (Skakkebaek *et al.*, 2016).

Cryptorchidism

Congenital cryptorchidism, that is, undescended testis, is one of the most common urogenital malformations of newborn boys. Thus, this congenital malformation has been investigated more frequently than other reproductive diseases in infancy. The descent of the testis from the abdomen to the scrotum has often been described to occur in two phases during fetal development (Hutson, 1985; Hutson *et al.*, 2015). The first, transabdominal phase, is according to animal studies dependent on the Leydig cell hormone insulin-like factor 3 (INSL3) (Nef and Parada, 1999; Zimmermann *et al.*, 1999; Gorlov *et al.*, 2002). The second, the inguinoscrotal

 doi:10.1016/B978-0-12-801238-3.64345-3

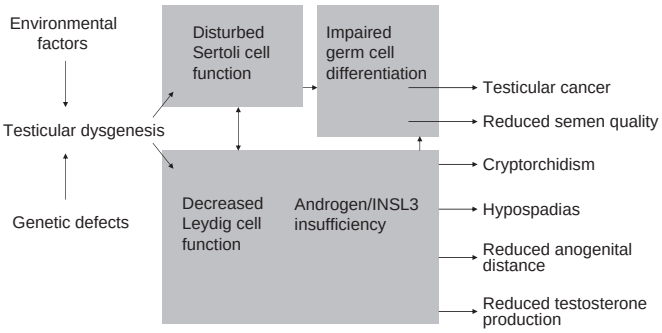

Fig. 1 Schematic presentation of testicular dysgenesis syndrome. Genetic factors and environmental endocrine disrupting chemicals can disturb fetal development of Sertoli cells and Leydig cells. This leads to impaired germ cell development and reduced Leydig cell hormone production. Testicular cancer, poor semen quality, cryptorchidism, hypospadias, reduced anogenital distance, and low testosterone levels are the possible outcomes of the developmental defect.

phase, is dependent on androgens (Hutson, 1986; Hutson *et al.*, 2015). Normally, testes have descended into the scrotum by the time of birth in a full-term baby (Hutson *et al.*, 2015). In prospective cohort studies the prevalence of congenital cryptorchidism has varied between 1% and 8% among full-term boys. The prevalence is higher among premature babies and in boys born as SGA (reviewed in Virtanen and Toppari, 2008). Cryptorchidism has been associated with shortened AGD (Thankamony *et al.*, 2014; Jain and Singal, 2013). Undescended testes often descend spontaneously during the first few months of life possibly due to temporary increase in reproductive hormone levels caused by the postnatal activation of the hypothalamus–pituitary–gonadal (HPG) axis (Raivio *et al.*, 2003; Suomi *et al.*, 2006; Virtanen and Toppari, 2008; Kuiri-Hänninen *et al.*, 2011). Referral for surgical correction (orchiopexy) is recommended if a testis in not descended by the age of 6 months and orchiopexy is to occur by the age of 12–18 months to preserve fertility (Ritzen *et al.*, 2007; Kolon *et al.*, 2014; Tekgül *et al.*, 2016). Early orchiopexy has been associated with improved testicular growth and development (Kollin *et al.*, 2007, 2012).

Some ecological and epidemiological studies have shown associations between cryptorchidism and the use of pesticides in the families' residence area, parental occupation in farming or gardening or parental occupational exposure to pesticides (Garcia-Rodriguez *et al.*, 1996; Kristensen *et al.*, 1997; Pierik *et al.*, 2004; Agopian *et al.*, 2013; García *et al.*, 2017; Weidner *et al.*, 1998; Andersen *et al.*, 2008). However, other studies have been published that did not find statistically significant positive associations (Carbone *et al.*, 2006, 2007; Restrepo *et al.*, 1990; Morales-Suárez-Varela *et al.*, 2011; Kurahashi *et al.*, 2005; Zhu *et al.*, 2006; Biggs *et al.*, 2002). Direct measurement of chemical exposure levels in biological matrices gives a much more specific information on possible exposure of an individual, but such studies are considerably more expensive and laborious to perform. Some of such case–control studies have suggested an association between levels of pesticides in maternal breast milk or in boy's adipose tissue and the risk of cryptorchidism (Damgaard *et al.*, 2006; Hosie *et al.*, 2000; Brucker-Davis *et al.*, 2008), but not all (Chevalier *et al.*, 2015). Other studies evaluating pesticide levels in maternal serum or in cord serum did not find a statistically significant positive association with cryptorchidism or remained inconclusive (Longnecker *et al.*, 2002; Trabert *et al.*, 2012; Bhatia *et al.*, 2005; Pierik *et al.*, 2007; Brucker-Davis *et al.*, 2008). Similarly, most studies evaluating association between levels of polychlorinated biphenyls (PCBs) in different matrices (breast milk, maternal serum, placenta, umbilical cord, cord serum, or boy's adipose tissue) and cryptorchidism have remained negative (Hosie *et al.*, 2000; Mol *et al.*, 2002; Brucker-Davis *et al.*, 2008; McGlynn *et al.*, 2009a; Virtanen *et al.*, 2012; Koskenniemi *et al.*, 2015; Chevalier *et al.*, 2015). Only one study evaluating colostrum levels of PCBs suggested a positive association with congenital cryptorchidism (Brucker-Davis *et al.*, 2008). The risk of cryptorchidism has been positively associated with the sum of dioxins and total-TEq levels [the WHO-recommended 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD) equivalent for 17 dioxins and 12 dioxin-like PCBs] in boy's adipose tissue, but not in placenta (Koskenniemi *et al.*, 2015; Virtanen *et al.*, 2012). Maternal hair and breast milk levels of flame retardants have shown positive associations with the risk of cryptorchidism (Main *et al.*, 2007; Goodyer *et al.*, 2017), whereas studies on other matrices (maternal serum, placenta) have remained negative (Main *et al.*, 2007; Small *et al.*, 2009). In a combined analysis of breast milk levels of 106 environmental chemicals, dioxins, and polybrominated diphenyl ethers (PBDEs) were found to be risk factors of cryptorchidism, whereas PCBs were associated with reduced risk of cryptorchidism (Krysiak-Baltyn *et al.*, 2012). These statistically significant associations were observed in the Danish, but not in the Finnish cohort (Krysiak-Baltyn *et al.*, 2012). Placenta levels of organotins showed a positive association with the risk of cryptorchidism in Denmark, whereas in Finland the association was negative (Rantakokko *et al.*, 2013). Studies evaluating levels of perfluorinated chemicals (PFCs) in amniotic fluid or cord blood found no significant association with cryptorchidism (Vesterholm Jensen *et al.*, 2014; Toft *et al.*, 2016). Some studies have evaluated associations between cryptorchidism and nonpersistent chemicals, such as phthalates and bisphenol A (BPA). For phthalates, a study evaluating levels in maternal urine during pregnancy suggested a positive association with cryptorchidism (Swan, 2008), but statistically significant positive associations were not found in studies evaluating levels in amniotic fluid, cord serum, or maternal breast milk (Jensen *et al.*, 2015; Main *et al.*, 2006; Brucker-Davis *et al.*, 2008; Chevalier *et al.*, 2015). Total BPA levels in boy's serum have been positively associated with cryptorchidism (Komarowska *et al.*, 2015), whereas studies evaluating free BPA levels in cord blood or boy's serum have not reported a statistically significant positive association (Fénichel *et al.*, 2012; Chevalier *et al.*, 2015; Komarowska *et al.*, 2015).

Different matrices may also give different results within the same chemical class. Furthermore, small studies are more prone to yield negative findings than large ones. However, a combined analysis of different studies has also been performed. A meta-analysis of 10 case–control studies evaluating different chemical classes [pesticides, PBB, PCBs, PFCs, phthalates] in different matrices (maternal serum, colostrum, cord blood, amniotic fluid) and countries reported a summary estimate of an odds ratio (OR) for congenital cryptorchidism of 1.03 (95%CI 0.72–1.47) (Bonde *et al.*, 2016). Available data was too limited to allow a meta-analysis of associations with specific chemicals. More data needs to be collected before more specific conclusions can be drawn. This may, however, be challenged by the declining levels of older chemicals (Bergman *et al.*, 2013). Furthermore, legislation leads to phasing out of some chemicals whilst new ones are introduced, which makes combination of old and new data difficult. No study has the possibility to analyze all the chemicals we are exposed to. EDCs may also predispose to cryptorchidism (and other disorders of male reproductive health) via affecting fetal growth (Wohlfahrt-Veje *et al.*, 2011).

Hypospadias

In hypospadias the urethral opening is located on the ventral side of the penis due to incomplete formation of the urethra during embryonic weeks 11–16 during which the urethral folds fuse to form the penile urethra (Blaschko *et al.*, 2012). The formation of the glanular urethra, the most distal part, is however, controversial (van der Zanden *et al.*, 2012). In the majority of hypospadias the urethral opening is located on the ventral side of the glans or the coronal sulcus (this is called an anterior or mild hypospadias). In more severe cases, the urethral orifice is located on the penile shaft (middle or moderate hypospadias) or at the scrotum or perineum (called posterior or severe hypospadias) (Carmichael *et al.*, 2012; van der Zanden *et al.*, 2012). Another classification divides hypospadias into only two classes: mild (distal) hypospadias (cases with preoperative urethral opening on the glans or distally on the penile shaft) and severe (proximal) hypospadias (all other cases) (van der Horst and de Wall, 2017). Hypospadias is often associated with an abnormal ventral penile curvature (chordee) and the absence of the ventral foreskin (Blaschko *et al.*, 2012; van der Horst and de Wall, 2017). Approximately 70% of cases have a mild type hypospadias. Although hypospadias is usually an isolated finding, it may be combined with cryptorchidism or micropenis (combination may be called microphallus), and hypospadias has also been associated with a shortened AGD (Thankamony *et al.*, 2014; van der Horst and de Wall, 2017). In animal models, several gene defects have been identified with abnormal embryonic development of the urethra (Blaschko *et al.*, 2012). However, the etiology of hypospadias in humans is unknown in most cases, but both genes and the environment are thought to play a role (Thorup *et al.*, 2014; van der Zanden *et al.*, 2012). According to registry data, the prevalence of hypospadias in Europe has been approximately 19 (range 5–37) per 10,000 total births (Bergman *et al.*, 2015) during this century. Surgical correction of hypospadias between the ages of 6 and 18 (24) months is currently recommended with the objective to obtain normal function and also to improve cosmetic appearance (van der Horst and de Wall, 2017; Tekgül *et al.*, 2016).

As for cryptorchidism, also for hypospadias associations with parental residential or occupational exposure to pesticides have been suggested. A meta-analysis reported an average risk ratio of 1.36 (95%CI 1.04–1.77) for maternal occupational exposure to pesticides and 1.19 (95%CI 1.00–1.41) for paternal occupational exposure (Rocheleau *et al.*, 2009). The suggested association of hypospadias with fetal exposure to pesticides has been supported by some more recent studies (García *et al.*, 2017; Kalfa *et al.*, 2015; Agopian *et al.*, 2013), but not all (Nassar *et al.*, 2010; Morales-Suárez-Varela *et al.*, 2011; Rocheleau *et al.*, 2011; Carmichael *et al.*, 2013). It has also been suggested that parental occupational exposure to heavy metals or parental exposure to any EDCs may be risk factors of hypospadias (Nassar *et al.*, 2010; Morales-Suárez-Varela *et al.*, 2011; Giordano *et al.*, 2010; Kalfa *et al.*, 2015; Haraux *et al.*, 2016).

Most of the studies evaluating the association between hypospadias and chemical levels (pesticides, PCBs, flame retardants, phthalates, or PFCs) in maternal serum or amniotic fluid have remained negative (Longnecker *et al.*, 2002; Bhatia *et al.*, 2005; Carmichael *et al.*, 2010; Trabert *et al.*, 2012; Small *et al.*, 2009; Jensen *et al.*, 2015; Toft *et al.*, 2016). A few studies have suggested a positive association between hypospadias and some pesticides or the sum of PCBs in maternal serum or in the boy's serum (Shekharyadav *et al.*, 2011; Giordano *et al.*, 2010; McGlynn *et al.*, 2009a; Rignell-Hydbom *et al.*, 2012). One study evaluated cryptorchidism and hypospadias together and suggested a positive association with placental levels of pesticides, BPA, and benzophenones (Fernandez *et al.*, 2007; Fernández *et al.*, 2016). The often small number of subjects and therefore limited statistical power has been a serious drawback in several hypospadias studies. However, as for cryptorchidism, also for hypospadias a combined analysis has been performed. In that meta-analysis, a summary estimate of an OR for hypospadias was 1.13 (95%CI 0.86–1.50) [10 case–control studies evaluating different chemicals (pesticides, PCBs, flame retardants, phthalates, PFCs) in different matrices (maternal serum, amniotic fluid) and in different countries] (Bonde *et al.*, 2016). Available data also allowed a meta-analysis of the association with specific chemicals—for 1,1′-dichloro-2,2′-bis(*p*-chlorophenyl)ethylene (DDE) the OR was 1.38 (4 studies, 95%CI 0.93–2.04) and for PCBs the OR was 1.11 (4 studies, 95%CI 0.61–2.01). Thus, no statistically significant associations were observed.

Testicular Cancer

Testicular germ cell tumors (TGCTs) represent the majority of testicular cancers and they are the most common cause of cancer in young men in developed countries (Rajpert-De Meyts *et al.*, 2016; Litchfield *et al.*, 2015; Trabert *et al.*, 2015). TGCTs of young

adults comprise seminomas and non-seminomas, both arising from germ cell neoplasia in situ (GCNIS). GCNIS is considered to develop from gonocytes that failed to mature to spermatogonia and transformed into malignant cells (Rajpert-De Meyts *et al.*, 2016). According to genome-wide association studies (GWAS) genes related to the *KIT*/*KITLG* signaling, male germ cell development/differentiation, telomerase function, microtubule assembly, and repair of DNA damage are associated with the TGCT risk loci (Litchfield *et al.*, 2015). Currently, no animal model for TGCT exists (van den Driesche *et al.*, 2017). The incidence of testicular cancer has been reported to be highest in Northern Europe (estimated age-standardized incidence rates of 12.5 per 100,000 in Denmark, and 12.7 per 100,000 in Norway) (Ferlay *et al.*, 2013) and an increasing incidence of testicular cancer has been observed in several countries worldwide during the last decades (Znaor *et al.*, 2014). The incidence has been predicted to also increase in several Southern European countries by the year 2025, whereas a plateau or a decrease in incidence is expected in historically high-risk European countries (Le Cornet *et al.*, 2014). Risks factor of TGCTs include cryptorchidism, hypospadias, inguinal hernia, and other genital malformations (Trabert *et al.*, 2013).

A follow-up of a U.S. pregnancy cohort observed that mothers of men with testicular cancer had a higher ratio of 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane (*p,p′*-DDT, primary component of commercial pesticide DDT) to *p,p′*-DDE (primary metabolite of *p,p′*-DDT) and lower levels of 1,1,1-tricholoro-2-(*o*-chlorophenyl)-2-(*p*-chlorophenyl)ethane (*o,p′*-DDT, low level contaminant of commercial DDT) than control mothers in postpartum serum samples (Cohn *et al.*, 2010). This suggests a higher historical exposure of case mothers to DDT or differences in the elimination of DDT (Cohn *et al.*, 2010). Other studies have evaluated differences between men with testicular cancer and controls or between case mothers and control mothers in serum chemical levels around the time of the cancer diagnosis, that is, in adulthood. In a Swedish case–control study men with testicular cancer had significantly higher serum levels of *cis*-nonachlordane, but for other chemicals (PCBs, pesticides and PBDEs) no significant differences were observed (Hardell *et al.*, 2003, 2004, 2006). However, mothers of cases had significantly increased levels of PCBs, hexachlorobenzene (HCB) and PBDEs (sum of 3 congeners) and *trans*- and *cis*-nonachlordanes, but not of *p,p′*-DDE when compared to control mothers. This suggested a possibly increased prenatal exposure of men with TGCT to PCBs and HCB, as these chemicals have very long half-lifes in humans (Hardell *et al.*, 2003, 2004, 2006).

Case control studies using serum samples taken before the diagnosis of testicular cancer have suggested an association between testicular cancer and exposure to some organochlorine pesticides, but the results regarding the association with exposure to PCB congeners have been conflicting (Purdue *et al.*, 2009; McGlynn *et al.*, 2008, 2009b). In addition, two studies in which serum samples of patients with testicular cancer were taken after diagnosis have given different results on the association between the exposure to organochlorine pesticides and testicular cancer (Giannandrea *et al.*, 2011; Biggs *et al.*, 2008).

A meta-analysis of eight case–control studies evaluating the association between exposure to endocrine disrupting chemicals and testicular cancer reported a summary estimate of an OR of 1.20 (95%CI 0.78–1.89) (Bonde *et al.*, 2016) and thus, found no significant association. Available data allowed a congener-specific meta-analysis for exposure to DDT and its metabolite DDE and also here no significant association was found (the respective ORs were 1.19 (95%CI 0.60–2.36) and 1.12 (95%CI 0.82–1.55)) (Bonde *et al.*, 2016).

Semen Quality

It has been suggested that sperm concentrations have been decreasing in the 20th century and at the beginning of 21st century in Western countries (Carlsen *et al.*, 1992; Swan *et al.*, 1997, 2000; Levine *et al.*, 2017). Also several, but not all, original studies published recently have suggested that the sperm concentration or total sperm counts are decreasing (reviewed in Virtanen *et al.*, 2017). However, significant geographical differences in sperm concentration have been observed in studies using similar study protocols (Virtanen *et al.*, 2017).

Several studies have evaluated associations between fetal or adult exposure to environmental chemicals and semen quality. Pre- or perinatal accidental exposure to high levels of persistent chemicals like PCBs and their pyrolytic products and to 2,3,7,8,-tetrachlorodibenzo-*p*-dioxin (TCDD) has been associated with reduced semen quality in adulthood (motility, morphology, sperm count, or concentration) (Guo *et al.*, 2000; Mocarelli *et al.*, 2011). In addition, exposure to TCDD during infancy after the Seveso accident has been associated with reduced semen quality (motility, concentration) (Mocarelli *et al.*, 2008). In a prospective Russian study, serum levels of TCDD and toxic equivalents for polychlorinated dibenzo-*p*-dioxins (PCDD TEQ) at the age of 8–9 years were associated negatively with sperm concentration, total sperm count, and total motile sperm count at the age of 18–19 years, although the TCDD levels were much lower than in the Seveso study (Mínguez-Alarcón *et al.*, 2017). Sums of PCDDs, polychlorinated dibenzofurans (PCDFs), coplanar-PCBs, or PCBs, and also toxic equivalents for PCDFs (PCDF TEQs), coplanar PCB TEQs, and total TEQs showed no significant associations with semen variables (Mínguez-Alarcón *et al.*, 2017).

Exposure to background levels of perfluoro-octanoic acid in utero has been associated negatively with semen quality (sperm concentration, total sperm count), whereas no such association has been described for perfluorooctanesulfonic acid, PCBs or *p,p′*-DDE (Vested *et al.*, 2013, 2014b). Prenatal exposure to nonpersistent phthalates has been associated negatively with semen volume in adulthood (Axelsson *et al.*, 2015b).

Meta-analyses and more recent studies have suggested that adult exposure to nonpersistent phthalates is associated adversely with semen quality (Cai *et al.*, 2015; Axelsson *et al.*, 2015a; Thurston *et al.*, 2015; Wang *et al.*, 2016). However, their role is likely to be small in determining classical sperm variables (sperm concentration, percent motile spermatozoa, and percent spermatozoa with normal morphology, total sperm count and total motile sperm count) (Thurston *et al.*, 2015). Some studies have suggested a

negative association between adult exposure to nonpersistent bisphenol A and semen quality, but the results are limited and inconclusive (reviewed in Mínguez-Alarcón *et al.*, 2016). Adult exposure to persistent chemicals has been associated negatively with semen quality (motility (PCBs) and morphology (perfluorinated compounds)) and with an increased time to pregnancy (PCBs and *p,p′*-DDE) (Vested *et al.*, 2014a; Buck Louis *et al.*, 2013). Some studies have suggested a negative association between *p,p′*-DDE exposure and sperm motility (Aneck-Hahn *et al.*, 2007; De Jager *et al.*, 2006; Toft *et al.*, 2006), but other studies did not find a significant association (Haugen *et al.*, 2011; Hauser *et al.*, 2003).

Anogenital Distance (AGD)

AGD in boys is measured as either the distance between the anus and scrotum (also called as anoscrotal distance, ASD) or as the distance between the anus and upper (or sometimes lower) base of the penis (Swan *et al.*, 2005; Salazar-Martinez *et al.*, 2004; Dean and Sharpe, 2013; Longnecker *et al.*, 2007). AGD is believed to reflect fetal exposure to androgens (Dean and Sharpe, 2013). Maternal urine phthalate levels during pregnancy have been associated negatively with AGD and anogenital index (AGI, AGD divided with weight) in their newborn and infant sons (Swan, 2008; Swan *et al.*, 2005, 2015; Suzuki *et al.*, 2012; Bustamante-Montes *et al.*, 2013; Bornehag *et al.*, 2015). Another study in a population with low exposure remained negative (Jensen *et al.*, 2016). Also a small study evaluating amniotic fluid phthalate levels remained negative (Huang *et al.*, 2009). The first trimester has been suggested to be the critical window of susceptibility for changes in AGD (Martino-Andrade *et al.*, 2016). Maternal serum levels of DDT and DDE showed no significant association with the anogenital distance of their sons (Bornman *et al.*, 2016; Longnecker *et al.*, 2007). Maternal plasma dioxin-like activity at delivery has been negatively associated with the AGD of their newborn sons (Vafeiadi *et al.*, 2013). Boys with cryptorchidism and hypospadias show a reduced AGD (Thankamony *et al.*, 2014; Hsieh *et al.*, 2012), and AGD has been positively associated with semen quality and testosterone levels in adult men (Mendiola *et al.*, 2011; Eisenberg *et al.*, 2011, 2012).

Hormone Levels

Chemical exposures have also been associated with changes in reproductive hormone levels. Free BPA levels in cord blood have shown negative associations with INSL3 levels, but associations with testosterone levels have been mixed (Fenichel *et al.*, 2012; Chevalier *et al.*, 2015). Maternal breast milk phthalate and PBDE levels have shown a positive association with LH levels and the LH:free testosterone ratio of infant boys at the age of 3 months, when the hypothalamus–pituitary axis is active (Main *et al.*, 2006, 2007). Exposure to TCDD perinatally after the Seveso accident was associated with an increased FSH level and decreased Inhibin B level in adulthood (Mocarelli *et al.*, 2011). Also in utero exposure level of PFOA (background levels) has shown positive associations with LH and FSH levels in adult men, whereas exposure levels of PFOS, PCBs or *p,p′*-DDE showed no association with reproductive hormone levels (Vested *et al.*, 2013, 2014b). Prenatal exposure levels of phthalates have shown positive association with LH and FSH levels in young adult men (Axelsson *et al.*, 2015b).

Combined Exposures and Human Risk Assessment

All manifestations of TDS can be seen in humans with genetic disorders of androgen production or action, such as 5alpha-reductase or 17beta-hydroxysteroid-dehydrogenase type 3 mutations, and androgen receptor mutations (Toppari *et al.*, 2010; Juul *et al.*, 2014; Ahmed and Rodie, 2010). Animal experiments show also similar adverse effects of exposure to antiandrogenic chemicals (Rider *et al.*, 2008; Christiansen *et al.*, 2008). Dioxins have a different mechanism of action but have similar effects to those of antiandrogens (Rider *et al.*, 2010). Furthermore, dioxins and antiandrogens have additive effects, and therefore even doses that are below the no-adverse-effect level (NOAEL) contribute to the toxicity (Rider *et al.*, 2010, Jacobsen *et al.*, 2010). This challenges human epidemiology where we typically analyze exposure-outcome associations chemical by chemical. Both nature examples of defects in androgen action and ample evidence from animal experiments point to potential risks of all antiandrogenic and dioxin-like compounds. In the absence of robust epidemiological evidence we have to rely on biological plausibility and animal experiments in the risk analysis (Hauser *et al.*, 2015).

Conclusions

In conclusion, despite clear evidence of adverse effects of antiandrogenic and dioxin-like chemicals on the male reproductive system, only few human studies have been able to detect associations between fetal exposure to EDCs and congenital cryptorchidism, hypospadias, testicular cancer, and reduced semen quality. Small study sizes due to time and budget constraints and the use of different biological matrices to measure exposure levels, which may not always be suitable, contribute to the divergence in observations. Furthermore, humans are exposed to a mixture of chemicals from conception to adult life making the

identification of specific chemicals with adverse effects difficult. Thus, future research challenges include further investigations of associations between cocktail exposures and male reproductive health.

Endocrine Disrupting Chemicals and Behavior

Sheryl E Arambula and Heather B Patisaul, North Carolina State University, Raleigh, NC, United States

Introduction

Inexorably connected, the endocrine system and nervous system work in tandem to regulate the development and expression of behavior. This relationship is best exemplified by the early actions of steroid hormones on the mammalian brain, which induce enduring changes in the brain that impact sexually dimorphic behavior (Cooke *et al.*, 1998; De Vries, 2004; Knudsen, 2004; McCarthy, 2008). Although brain development is a tightly regulated and orchestrated process, it is vulnerable to exogenous substances that interfere with the action of natural hormones.

Endocrine disrupting chemicals (EDCs) are a diverse group of exogenous compounds that have been found to interfere with the endocrine system and produce adverse health effects in exposed individuals or their offspring. Numerous classes of chemicals including plasticizers, flame-retardants, fungicides, pesticides, pharmaceuticals, heavy metals, and even naturally occurring compounds such as phytoestrogens are endocrine disrupting (**Table 1**). These and other EDCs dampen, block, or potentiate the action of endogenous hormones through a variety of direct and indirect mechanisms. For example, they may agonize or antagonize hormone receptors, interfere with hormone biosynthesis, or alter the number of hormone receptors (Gore *et al.*, 2015). The long-term consequences of EDCs depend on a variety of factors including the genetic susceptibility of the organism and the dose, duration, and developmental window of exposure.

Since the term was first coined nearly three decades ago, EDCs have received considerable attention from both the scientific community and the public (Hotchkiss *et al.*, 2008; McLachlan, 2016). While highly debated, endocrine disruption provides a plausible explanation for the global increase in the prevalence of sex-biased neurodevelopmental disorders, most notably attention-deficit hyperactivity disorder and autism spectrum disorder, which cannot be fully explained by genetic factors alone. Although the etiology of these disorders are not well understood, there is increasing concern that developmental exposure to EDCs may enhance risk by disrupting sexual differentiation of the brain. Indeed, extensive experimental and epidemiological evidence supports associations between early-life exposure to environmental contaminants and sex-specific neurobehavioral outcomes.

The goal of the current article is to examine the evidence for altered behavior as a consequence of EDC exposure. Although hundreds of suspected EDCs have been identified, bisphenol A (BPA) is arguably one of the most widely used and extensively studied. Thus for illustrative purposes, we will concentrate on the effects of early exposure to this notorious chemical.

BPA: A Landmark Endocrine Disrupting Chemical

Our focus on BPA is significant because this well recognized EDC is widely used as a component of polycarbonate plastics and epoxy resins and commonly incorporated into numerous household products. Human exposure occurs primarily from contaminated food and beverages (von Goetz *et al.*, 2010), and in industrialized countries, more than 90% of individuals are estimated to have detectable amounts of BPA in their bodies (Bushnik *et al.*, 2010; Calafat *et al.*, 2005, 2008; Casas *et al.*, 2013; LaKind and Naiman, 2015). Early-life exposure is of major concern because this period is characterized by rapid growth and has long been recognized as a critical window of vulnerability to the effects of neurotoxic and neuroendocrine disrupting agents. In humans, BPA has been detected in fetal plasma (Ikezuki *et al.*, 2002), amniotic fluid (Engel *et al.*, 2006), fetal liver (Nahar *et al.*, 2013), and placenta tissue (Schonfelder *et al.*, 2002), demonstrating the capacity for significant gestational exposure. Moreover, the fetal brain is particularly susceptible to environmental exposures because the blood–brain barrier is not fully formed, and thus provides limited protection (Adinolfi, 1985; Perera and Herbstman, 2011). Accordingly, levels of chemical exposures that have no obvious effects on the adult nervous system can pose a significant risk when exposure occurs developmentally.

A litany of studies provide evidence that developmental exposure to BPA results in neurobiological and mood-related behavioral consequences, even at doses below the current US Food and Drug Administration No Observed Adverse Effect Level (NOAEL) of 5 mg/kg body weight (bw)/day. It should be emphasized that despite an abundance of literature, there is a general lack of understanding concerning the specific cellular mechanisms by which BPA alters human neurodevelopment. Initially developed as a synthetic estrogen (Dodds and Lawson, 1936), BPA has long been considered weakly estrogenic. Until recently, BPA was primarily believed to exert its effects by engaging estrogen receptors (ERs). However, the binding affinity of BPA for both ERα and ERβ in cell culture assays is 10,000–100,000-fold lower than the endogenous estrogen (Blair *et al.*, 2000; Kuiper *et al.*, 1998; Waller *et al.*, 1996), making it improbable that BPA mediates its effects solely through classical ER-dependent nuclear pathways. In fact, BPA has also been demonstrated to have a low binding affinity for other steroid receptors (Rubin, 2011; Zoeller, 2005) and to have rapid, nongenomic actions via membrane-bound ERs (Belcher and Zsarnovszky, 2001; Thomas and Dong, 2006; vom Saal *et al.*, 2007). Most recently, studies have shown developmental BPA exposure can induce sex- and region-specific changes in DNA methylation patterns in the brain that are accompanied by decreased expression of ERs (Kundakovic *et al.*, 2013,

 doi:10.1016/B978-0-12-801238-3.65191-7

Table 1 Structures and potential sources of endocrine disrupting chemicals with published behavioral effects

EDC	*Structure*	*Potential sources of human exposure*
Bisphenol A (BPA)		• Food packaging • Medical devices • Thermal receipt paper • Epoxy resins and polycarbonate plastics
Chlorpyrifos		• Insecticide in agricultural and commercial settings • Residue on fruits and vegetables
Dioxins	 Tetrachlorodibenzo-*p*-dioxin	• High fat food (e.g., dairy products, animal fat, and eggs) • Industrial processes (e.g., municipal waste incineration)
Lead	 Triethyl lead	• Paint • Lead-based gasoline • Dust • Drinking water • Children's jewelry and toys
Methoxychlor (MXC)		• Insecticide used on pets, home gardens, crops, and livestock • Air, soil, water contaminant
Phthalates	 Benzyl butyl phthalate	• Plastics • Food packaging • Personal care products and pharmaceuticals • Vinyl flooring, wall covering, and carpet backing • High-fat foods (e.g., dairy products animal fat, and eggs)
Polybrominated diphenyl ethers (PBDEs)	 Pentabromodiphenyl ether	• Flame retardants • House dust contaminant • Fish, meat, and dairy products • Soil and sediments • Outdoor air
Polychlorinated biphenyls (PCBs)	 2,2',3,3',4-PCB	• High-fat foods (e.g., dairy products animal fat, and eggs) • Ground water contaminant • Electrical transformers, capacitors, and other industrial waste • Outdoor air
Vinclozolin		• Fungicide • Food and drinking water contaminant • Ground water • Outdoor air

2015). These alternative modes of action emphasize the complex, multimodal routes by which EDCs can impact brain and behavior across the lifespan.

Sexually Dimorphic Behaviors as Indicators of Endocrine Disruption

Sexual differentiation is the process by which the brain becomes structurally and functionally different between males and females. Sexual differentiation of the brain was once thought to hinge almost entirely upon gonadal hormones: generally, the brain develops as male in the presence of these hormones, and as female in their absence. However, recent evidence indicates this process is more nuanced and involves multiple sex-specific hormonal, genetic, and epigenetic factors that influence sexually dimorphic physiology and behavior thorough a variety of mechanisms (McCarthy and Nugent, 2013; McCarthy, 2016; Schwarz and McCarthy, 2008).

Disruption of sexually dimorphic behavior is a common outcome of developmental exposure to EDCs, particularly BPA. Indeed, sex-specific behavioral impacts of BPA have been demonstrated in numerous animal models and human epidemiological studies (Frye *et al.*, 2012; Inadera, 2015; Rochester, 2013). Considering their complex, multifactorial origin, it is not surprising that BPA has been found to decrease, eliminate, and even reverse behavioral sex differences. It is unclear, however, whether the differential effects of BPA in males and females are due to disruption of already existing behavioral dimorphisms or whether they reflect sex-specific vulnerability.

Evidence From Animal Models

The majority of experimental studies on neurobiological and behavioral consequences of developmental BPA exposure (gestational and/or neonatal) employ rodent models. Here we provide a summary of these findings and limit our discussion to studies that use BPA doses at or lower than the current FDA NOAEL (5 mg/kg bw/day).

Exploratory and Affective Behaviors

Experimental animal studies in rodents provide compelling evidence that developmental BPA exposure can increase the expression of anxiety-related and exploratory behaviors. However, effects vary across sex, animal model, and age at testing. Studies examining developmental BPA exposure in juveniles typically demonstrate sex-specific effects, but results are inconsistent. For example, two studies on juvenile C57BL/6J mice conclude that gestational and/or neonatal BPA exposure increased anxiety in males but had no effect in females (Cox *et al.*, 2010; Matsuda *et al.*, 2012), while another study with CD-1 mice reported the opposite (Gioiosa *et al.*, 2007). Additionally, a recent study in juvenile Sprague Dawley rats found no effects of perinatal BPA exposure on exploratory or anxiety activity, in either sex (Rebuli *et al.*, 2015).

Studies in adults are more consistent and in general, females display more robust anxiogenic effects following early-life BPA exposure compared to males (Gioiosa *et al.*, 2013; Hicks *et al.*, 2016; Ryan and Vandenbergh, 2006; Sullivan *et al.*, 2014). For example, neonatal exposure to 10 μg/kg of BPA was found to decrease exploratory-behavior and increase anxiety-like behavior in adult female CD-1 mice, resulting in a behavioral phenotype similar to that of adult control males (Gioiosa *et al.*, 2013). This is consistent with other studies that show developmental BPA exposure can decrease or eliminate sex differences typically observed in adult rodents, on a number of behavioral paradigms used to assess anxiety (Gioiosa *et al.*, 2007; Hicks *et al.*, 2016; Jones and Watson, 2012; Kubo *et al.*, 2003; Kundakovic *et al.*, 2013). Experiments using other animal models (including zebrafish, voles, and other alternative rodent species, and nonhuman primates) provide further evidence that developmental BPA exposure induces anxiety-related behaviors (Kinch *et al.*, 2015; Kundakovic *et al.*, 2013; Nakagami *et al.*, 2009; Patisaul *et al.*, 2012; Sullivan *et al.*, 2014). This consistency across studies and varying animal models prompted the World Health Organization to conclude that there is some concern about impacts of developmental BPA exposure on brain and behavior (FAO/WHO, 2011). While the underlying mechanisms remain unclear, this behavioral disruption is commonly associated with perturbation of ER-related gene expression in the hypothalamus and the amygdala (Arambula *et al.*, 2016, 2018; Cao *et al.*, 2012, 2013, 2014; Kundakovic *et al.*, 2013; Patisaul *et al.*, 2012; Rebuli *et al.*, 2014; Rebuli and Patisaul, 2015). Moreover, a recent study found that prenatal BPA exposure induced sex-specific effects on anxiety-like behaviors in adult BALB/c mice that corresponded to changes in DNA methylation and mRNA levels of ERα in the hypothalamus (Kundakovic *et al.*, 2013). These data provide intriguing evidence that BPA-induced disruption of anxiety behavior may be mediated through an epigenetic mechanism.

Other EDCs shown to alter anxiety-related and exploratory behaviors include phthalates (Carbone *et al.*, 2013; Quinnies *et al.*, 2017), polychlorinated biphenyls (thyroid disrupting) (Bell *et al.*, 2016; Gillette *et al.*, 2017), some flame-retardants (thyroid disrupting) (Baldwin *et al.*, 2017; Patisaul *et al.*, 2013), and vinclozolin (androgen disrupting) (Gillette *et al.*, 2014; Skinner *et al.*, 2008). Perhaps best characterized is the spectrum of adverse neurobehavioral outcomes associated with developmental lead exposure. Considerable and consistent research, in a variety of animal models including rodents, cats, and nonhuman primates, shows that developmental lead exposure can induce hyperactivity, impulsivity, and aggression (Burright *et al.*, 1989; Cervantes *et al.*, 2005; Delville, 1999; Hahn *et al.*, 1991; Holloway and Thor, 1987; Laughlin *et al.*, 1991; Li *et al.*, 2003). While not an EDC in

the classic sense, lead and other metals can be endocrine disrupting in some circumstances (Chen *et al.*, 2017; Henson and Chedrese, 2004; Hirsch *et al.*, 2010; Miao *et al.*, 2015).

Learning and Memory

Impairments in cognitive abilities have also been observed following developmental exposure to BPA. Under normal conditions, male rodents typically perform significantly better than females on spatial learning and memory tasks and, interestingly, early-life BPA exposure has repeatedly been shown to reduce this sex difference (Carr *et al.*, 2003; Jones and Watson, 2012; Xu *et al.*, 2007). Several studies in rats and mice suggest that gestational and/or neonatal exposure to BPA can negatively impact spatial memory in both juvenile and adult males (Kumar and Thakur, 2014; Kuwahara *et al.*, 2013; Liu *et al.*, 2016; Tian *et al.*, 2010; Xu *et al.*, 2007, 2010a,b). As an example, exposure to BPA (0.5 and 5 mg/kg bw/day) during the perinatal period significantly impaired spatial memory in juvenile and adult male ICR mice (Xu *et al.*, 2010b). In contrast, data on the effects of BPA on spatial learning and memory in females is sparse and mixed results have been reported (Carr *et al.*, 2003; Liu *et al.*, 2016; Xu *et al.*, 2007). Notably, the described changes in spatial memory were associated with BPA-induced alterations in dendritic spine density and morphology, as well as reduced expression of *N*-methyl-D-aspartic acid (NMDA) glutamatergic receptors and ERβ (Eilam-Stock *et al.*, 2012; Liu *et al.*, 2016; Tian *et al.*, 2010; Xu *et al.*, 2010a) in the hippocampus.

Experimental research also shows that dioxin (Kakeyama and Tohyama, 2003; Seo *et al.*, 1999), polychlorinated biphenyls (Eriksson and Fredriksson, 1996; Schantz *et al.*, 1995), polybrominated diphenyl ethers (PBDEs) (Costa and Giordano, 2007; Viberg *et al.*, 2003a), chlorpyrifos (Gomez-Gimenez *et al.*, 2017; Levin *et al.*, 2001), and other EDCs can result in altered learning and memory behaviors. As an example, perinatal exposure to PDBE slowed motor skill development in adolescent and adult CD-1 mice (Branchi *et al.*, 2002). Similarly, a series of experiments in mice found neonatal exposure to multiple PBDE congeners caused significant adult learning and memory deficits that corresponded to inhibition of the hippocampal cholinergic system (Viberg *et al.*, 2003b, 2006).

Paternal, Social, and Sexual Behaviors

In rodents, changes in parental, social, and sexual behaviors have been reported after developmental exposure to BPA, but evidence is sparse and inconsistent (Adewale *et al.*, 2009, 2011; Farabollini *et al.*, 2002; Hicks *et al.*, 2016; Jones *et al.*, 2011; Monje *et al.*, 2009; Picot *et al.*, 2014; Porrini *et al.*, 2005; Ryan *et al.*, 2010; Sullivan *et al.*, 2014; Wolstenholme *et al.*, 2011). To date only two studies have examined the relationship between developmental BPA exposure and subsequent maternal behavior. One of these found that prenatal exposure to BPA 10 μg/kg bw/day decreased the amount of time female CD-1 mice spent huddling over or nursing their offspring (Palanza *et al.*, 2002b). The second study, which was conducted in Wistar rats, reported similar effects of gestational and lifelong BPA exposure to 5 μg/kg bw (Boudalia *et al.*, 2014). The impact of developmental BPA exposure on paternal behavior is unknown. This is likely due to the fact that traditional rodent models used in toxicology do not display biparental care.

Evidence that developmental BPA exposure can alter behaviors related to sociality is limited and highly discordant, but existing literature suggests that female social behavior may be more sensitive to disruption than males. For example, exposure to 1.25 mg of BPA during the prenatal period increased male and female juvenile social play in C57Bl6J mice (Wolstenholme *et al.*, 2011). In contrast, another report perinatal exposure to 40 μg/kg BPA reduced social play in female juvenile Sprague–Dawley rats (males were not assessed) (Porrini *et al.*, 2005). A study in prairie voles, a more prosocial animal model than laboratory rats or mice, found sex- and age-specific effects on social behavior. Neonatal exposure to 5 and 50 μg/kg bw/day decreased social investigation in juvenile males and slightly inhibited partner preference formation in adult females. These behavioral outcomes were accompanied by sex-dependent changes in the number of dopaminergic-, oxytocin-, and vasopressin neurons in the paraventricular nucleus of the hypothalamus and dopaminergic neurons in the bed nucleus of stria terminals (Sullivan *et al.*, 2014).

Some published data suggests early-life BPA exposure can induce subtle changes in adult sexual behavior, but supporting evidence is mixed (Adewale *et al.*, 2009, 2011; Farabollini *et al.*, 2002; Jones *et al.*, 2011; Monje *et al.*, 2009; Picot *et al.*, 2014; Ryan *et al.*, 2010). Two studies in rodents have found a slight impairment in male sexual performance in terms of latency, intromission, and ejaculation (Farabollini *et al.*, 2002; Jones *et al.*, 2011), where others have found none (Picot *et al.*, 2014). Female data is similarly mixed but generally indicates female sexual behavior is unaffected by developmental BPA exposure. In rodents, female proceptive and receptive behaviors are often determined by hopping and darting and the lordosis response. Exposure to 0.05 mg/kg of BPA during the neonatal period decreased hopping and darting rate in adult female Wistar rats, while lordosis behavior was unaffected (Monje *et al.*, 2009). Another study, conducted in Sprague–Dawley rats, observed a modest increase in lordosis behavior in adult females following perinatal exposure to 40 μg/kg of BPA (Farabollini *et al.*, 2002). Other studies have observed no effects of developmental exposure on proceptive or receptive behaviors in females (Adewale *et al.*, 2009, 2011; Ryan *et al.*, 2010).

Animal data also indicates effects of developmental exposure to other EDCs including methoxychlor (Gray *et al.*, 1988; Palanza *et al.*, 2002a; Suzuki *et al.*, 2004), polychlorinated biphenyls (Simmons *et al.*, 2005; Steinberg *et al.*, 2007; Wang *et al.*, 2002), phthalates (Dalsenter *et al.*, 2006; Lee *et al.*, 2004), phytoestrogens (Patisaul and Adewale, 2009; Patisaul and Jefferson, 2010; Patisaul, 2017), and chlorpyrifos (De Felice *et al.*, 2015; Venerosi *et al.*, 2009, 2012) on parental, social, and sexual behaviors. For

instance, a number of studies in rodents provide evidence that PCBs can adversely impact sociosexual behavior and, in general, suggest that females may be more vulnerable to disruption than males. In rats gestational and neonatal exposure reduces receptive and proceptive sexual behaviors such as lordosis and likelihood to mate (Chung and Clemens, 1999; Steinberg *et al.*, 2007; Suzuki *et al.*, 2004).

Evidence From Epidemiological Studies

Although the health impacts of developmental BPA exposure remain controversial, during the last decade several epidemiological studies have reported adverse behavior in children developmentally exposed to BPA (Bellinger *et al.*, 2007; Braun *et al.*, 2009, 2011, 2017b; Casas *et al.*, 2015; Evans *et al.*, 2014; Harley *et al.*, 2013; Hong *et al.*, 2013; Maserejian *et al.*, 2012; Perera *et al.*, 2012; Roen *et al.*, 2015).

The first was a longitudinal cohort study (the Health Outcomes and Measures of the Environment Study; HOMES) in which maternal BPA urine concentrations were measured during pregnancy (gestational weeks 16 and 24) and around the time of birth. When the children were 2 years old, their behavior was evaluated using a questionnaire designed to assess adaptive and problem behaviors in community and home settings. In girls, but not boys, significant associations were found between higher levels of maternal BPA during gestation and increased externalizing behaviors, specifically hyperactivity and aggression (Braun *et al.*, 2009). In a follow-up study on the HOMES cohort, behavior and executive function were examined at 3 years of age. Higher levels of maternal BPA during gestation were correlated with increased anxiety, hyperactivity, and depressive behavior, particularly in girls (Braun *et al.*, 2011). Of note, two subsequent studies on the HOMES cohort found no associations between maternal levels of gestational BPA and autistic behaviors in children 4–5 years old (Braun *et al.*, 2014) or visual spatial ability in children 7 years old (Braun *et al.*, 2017a). This outcome highlights that while chemical exposures can be linked to measureable and meaningful decrements in behavior and cognition that can have life-long implications, manifestation of a clinically defined disorder, such as autism, is highly unlikely and would be notoriously difficult to prove.

Other longitudinal cohort studies have found stronger associations between prenatal urinary BPA levels and adverse childhood behavior in boys than in girls. In cohort of African-American and Dominican women and their children (Center for Children's Environmental Health Cohort; CCCEH), higher maternal urinary BPA concentration was associated with increased aggression and emotionally reactive behavior in boys at 3–5 years of age (Perera *et al.*, 2012). A follow-up study on the CCCEH cohort, found 7–9 year old boys exposed to higher concentrations of BPA during gestation had increased internalizing (symptoms of anxiety and depression) and externalizing (aggression and rule-breaking) problems (Roen *et al.*, 2015). Similarly, three additional cohort studies have reported positive correlations between higher gestational BPA concentrations and behavioral problems in boys at 6–10 years of age including increased symptoms of anxiety, depression, and inattention (Casas *et al.*, 2015; Evans *et al.*, 2014; Harley *et al.*, 2013). Lastly, the most recent epidemiological study found a relationship between maternal urinary BPA concentration during pregnancy and poorer working memory and increased internalizing behavior in boys at 3 years of age (Braun *et al.*, 2017b).

Collectively these epidemiological studies strongly suggest that developmental BPA exposure may have adverse neurobehavioral effects in children, which may differ between boys and girls. This conclusion is concordant with the abundant animal data although the mechanisms of action remain poorly understood. In general, the conclusions from the described studies are strengthened by their use of large mother–child cohorts, BPA measurements across several gestational time points, and multiple observed behavioral outcomes. However, it is important to recognize the limitations inherent to longitudinal cohort studies that may have contributed to the discrepant results, particularly demographic differences across cohorts. Additionally, differences in neuropsychological assessments and substantial within-person variation in urinary BPA concentrations may also contribute to the heterogeneity in the literature (Braun *et al.*, 2012; Thayer *et al.*, 2015).

Robust evidence from epidemiological studies support a relationship between early-life EDC exposure and neurobehavioral outcomes. Behavioral deficits, including impairments in learning, memory, and social skills, have been linked with developmental exposure to PCBs, numerous flame retardants, and other persistent organic pollutants (POPs). Of these, the evidence for PCB-related effects on neurodevelopment is particularly compelling. Several longitudinal cohort studies have observed associations between developmental PCB exposure and impairments in measures of executive functioning such as processing speed, verbal abilities, and visual recognition memory (Boucher *et al.*, 2009; Jacobson and Jacobson, 1996; Lai *et al.*, 2002; Ribas-Fito *et al.*, 2001). Similar impairments in executive functioning are also linked to developmental lead and methylmercury exposure (Grandjean and Landrigan, 2006; Winneke, 2011). Because humans are exposed to a complex cocktail of EDCs and other toxicants continuously, combined effects of multiple exposures are a significant and growing concern.

Conclusions

The experimental evidence summarized above supports the hypothesis that developmental exposure to BPA, even at doses below the current NOAEL, may interfere with some aspect of sexual differentiation of the nervous system, thereby resulting in disruption of both reproductive and nonreproductive behaviors. During fetal and child development, the brain is particularly susceptible to environmental stressors such as EDCs. A recent study found that children of parents who were concerned about EDCs had

decreased urinary concentrations of BPA, which suggests that by exercising precaution we may be able to reduce our exposure to chemicals (Pell *et al.*, 2017). While developmental exposure to BPA and other EDCs may contribute to neural disorders in children, it should be emphasized that available literature does not provide direct causal evidence. Further mechanistic and epidemiological studies are needed to clarify the relationship between EDC exposure and human health. Greater information is also needed about the effect of mixtures and repeated exposures over multiple critical periods.

Remaining Challenges and Future Directions

Accumulating evidence suggests that developmental EDC exposure is contributing to the rising rate of neurobehavioral disorders. However, there are many obstacles that make it difficult to establish direct causal relationships. First, the intervening period between neurodevelopmental insult and the manifestation of a resulting behavioral dysfunction can be very long. During this period, which may take years or decades in humans, behavior is concomitantly influenced by other factors including genetics, experience, and lifestyle. Consequently, ascertaining the contribution of single chemical exposure is extraordinarily difficult. Moreover, humans are exposed to varying amounts and mixtures of EDCs throughout their lifetime. Already an area of increased interest, modeling "real world" human exposure (i.e., chronic, low-dose mixtures) will greatly enhance the translational value of animal studies in the EDC field.

In humans, studies on the neurobehavioral changes following early-life EDC exposure are constrained by practical and ethical limitations. An obvious limitation is the relative inaccessibility of the human brain. Both in vivo and in vitro models can be used to identify peripheral biomarkers of EDC exposure and associated diseases, which can be incorporated into new and existing epidemiological studies. Reliable biomarkers could also have important implications for identifying at-risk populations.

Since the advent of the endocrine disruption concept nearly 30 years ago (Colborn *et al.*, 1993), the field has made substantial progress in identifying several unique mechanisms of EDC action on the brain but gaps remain in establishing direct relationships between changes in brain development and consequential changes in behavior. Improved understanding will require deeper investigation into the basic neural and molecular mechanisms underlying complex behaviors such as activity, sociability, and executive function. As understanding their biological origins grows, so does the capacity to more reliably predict and prevent injury from EDCs and other developmental neurotoxicants.

DEDICATION

Professor Luciano Martini, 1927–2017

The other Editor in Chief of the Encyclopedia, Professor Luciano Martini, passed away on July 13th, 2017. He was an internationally acclaimed authority in the field of endocrinology, in particular neuroendocrinology, a brilliant and imaginative scientist, and an impressive and erudite scholar.

Luciano achieved the venerable age of 90, and his long career was full of outstanding scientific achievements, leadership positions in academia and in scientific societies, academies, and committees.

Luciano received his MD degree from the University of Milan in 1950. He then rapidly progressed through junior academic ranks up to the position of Professor and Chairman of the Department of Pharmacology at the University of Perugia in 1968, and subsequently, in 1972, he returned to his *alma mater*, the University of Milan, as full Professor and Chairman of the Department of Endocrinology, a post he held until 2001. He served in Milan as director of the training and research program entitled Physiology of Reproduction for nearly 20 years and attracted to his team top-class Italian and foreign scientists to address his main research interests of neuroendocrine regulation of reproductive functions.

Scientific severity, ethical integrity, fine perception, and deep farsightedness describe best Luciano's character as a scientist. He created in his institute a scientific research group devoted to experimental endocrinology, which grew over the years in size and visibility and became widely recognized internationally. Luciano published more than 400 peer-reviewed and highly cited papers mainly in the fields of neuroendocrinology, endocrine oncology, physiology of reproduction, and steroid and energy metabolisms.

Luciano was a prolific editor of scientific books and journals, which include the two volumes of *Neuroendocrinology* and the nine biennial volumes of *Frontiers in Neuroendocrinology*. He was Editor in Chief of *Comprehensive Endocrinology* published in 12 volumes and the first Edition of *Encyclopedia of Endocrine Diseases*. He served as President in many national and international scientific societies including the International Society of Neuroendocrinology, the Italian Society of Endocrinology, the International Society of Endocrinology, and the European Federation of Endocrine Societies. For his scientific achievements Luciano received honorary doctorates in the universities of Liège, Santiago de Compostela, Pécs, and Milan, and he was the recipient of numerous scientific awards and invited academy memberships.

Luciano's portrait could not be complete if one forgets to mention his life-time passion for music. He was a well-trained and accomplished pianist, a passionate music listener, and an enthusiastic connoisseur of all types of music. He also was an amateur in visual arts and deeply interested in history.

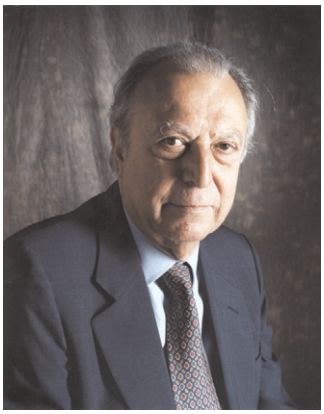
All of us who knew Professor Luciano Martini deeply mourn the loss of a great scientist and friend, the real "Il Maestro", teacher, colleague, and pioneer of modern neuroendocrinology. I trust Luciano would have been proud of this new edition of the Encyclopedia of Endocrine Diseases, and all of us having worked on its production would like to dedicate it to his memory.

Ilpo Huhtaniemi

Editor in Chief
Encyclopedia of Endocrine Diseases, 2nd edition

EDITORS IN CHIEF

Ilpo Huhtaniemi received his MD and PhD at University of Helsinki, Finland, did postdoctoral training in United States (UC San Francisco and NIH, Bethesda), and has been on sabbatical leave in Germany, United States and Scotland. In 1986–2002 he held the post of Professor and Chairman of Physiology at University of Turku, Finland. He moved in 2002 to UK to a Chair in Reproductive Endocrinology at Imperial College London, from which position he retired in 2015. He has received several national and international honors, amongst them a fellowship of The Academy of Medical Sciences, United Kingdom, and a Doctor Honoris Causa at the Medical University Łódź, Poland, and University of Szeged, Hungary. He was the Chief Managing Editor of *Molecular and Cellular Endocrinology* 1999-2017, has served in the Editorial Board of *Endocrinology and Endocrine Reviews* and is/has been the Editor or Editorial Board Member of several other scientific journals (e.g., *European Journal of Endocrinology*, *Clinical Endocrinology*, *Human Reproduction Update*, *Journal of Endocrinology*, *Molecular Human Reproduction*, *Reproduction*, *Asian Journal of Andrology*). He has extensive experience as Official of international scientific organizations (e.g., Past President of International Society of Andrology). His research interests include clinical and basic reproductive endocrinology, in particular the function of gonadotrophins and male reproductive endocrinology. He also has long-term interests in development of male contraception, hormone-dependent cancer, and the endocrinology of aging. He has authored about 700 peer-reviewed research articles and reviews, and his H-factor is 78.



Luciano Martini was born on May 14, 1927, in Milan, Italy. He obtained the degree of Medical Doctor "summa cum laude" on November 24, 1950, from the Faculty of Medicine of the University of Milan, Italy. He was Emeritus Professor of Pharmacology of the University of Perugia, Italy, and Emeritus Professor of Endocrinology of the University of Milan, Italy. He was Doctor Honoris Causa in Medicine of the Universities of Liège, Belgium, Santiago de Compostela, Spain, and Pécs, Hungary, and Doctor Honoris Causa in Biotechnological Sciences of the University of Milan, Italy. He was an author of more than 400 peer-reviewed scientific publications in the fields of endocrinology, neuroendocrinology, pharmacology, physiology of reproduction, steroid biochemistry, and basic oncology. He was elected member of the Accademia Nazionale dei Lincei (Italian National Academy) and of the American Academy of Arts and Sciences (Honorary Foreign Member).

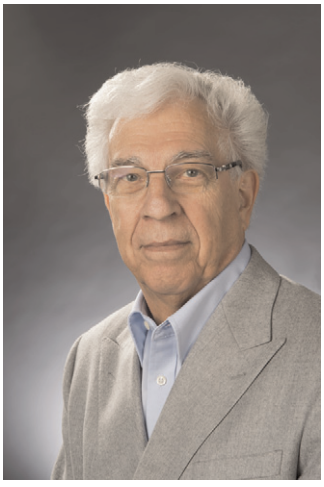
Luciano Martini acted as Editor in Chief of the journal *Frontiers in Neuroendocrinology* from 1990 to 2001, and was a Member of the Editorial Board of *Endocrinology* (Foreign Consulting Editor, 1961–65), as well as of several other speciality journals, such as *Experimental and Clinical Endocrinology*, *Biochemistry*, and *Steroids*. He has acted as Editor of several textbooks (e.g., *Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1966–67, and *Clinical Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1977–82) as well of a series of books under the name *Comprehensive Endocrinology* (13 volumes), Raven Press, New York, 1979–84. He acted as Editor in Chief for the first edition of *Encyclopedia of Endocrine Diseases* (4 volumes), Academic Press-Elsevier, San Diego, 2004.

EDITORIAL BOARD

SECTION EDITORS

Professor **Jean-Jacques Body** has been trained as an endocrinologist and a medical oncologist. He was Head of the Department of Medicine at University Hospital Brugmann in Brussels and Full Professor of Medicine (Internal Medicine) at the Free University of Brussels, (ULB), Brussels, Belgium. He was previously Head of the Internal Medicine Clinic at Institute J. Bordet (Cancer Center of ULB). He has also developed the "Supportive Care Dept" at the same Institute. His particular research interests are osteoporosis and bone metastases. He has a long-standing interest for bone metabolism and turnover in osteoporosis and tumor bone diseases. He has authored or co-authored more than 250 international peer-reviewed papers and he counts more than 200 invited lectures for international meetings.

Felipe F. Casanueva is Professor of Medicine at University of Santiago de Compostela and Head of Department of Endocrinology and Nutrition at University Hospital Santiago. He has been President of the scientific societes, such as: European Federation of Endocrine Societies (EFES), The Pituitary Society, International Society of Endocrinology (ISE) and, Sociedad Española para el Estudio de la Obesidad (SEEDO). Has written more than 50 chapters in international books and published more than 700 papers in international journals. He has received several awards for research at national and international level, such as: Rey Jaime I to the Medical Research, Geoffrey Harris Prize in Neuroendocrinology, Fundación Lilly of Bio-medical Research Clinic, Fundacion Danone – Professional Career – Dr Carlos Martí Hennberg, European Hormone Medal by the European Society for Endocrinology (ESE); he has been named Honorary Doctorate in Medicine of the University of Łódź, Erciyes, and Belgrade, and Honorary Member of the European Society of Endocrinology.



Dr. **Jean-Louis Chiasson** is currently Full Professor of Medicine at the University of Montreal. He is Head of the Research Group on Diabetes and Metabolic Regulation at the Research Center of the Centre hospitalier de l'Université de Montréal (CRCHUM).

Dr. Chiasson obtained his MD at Laval University in Quebec City in 1967. He did his specialty training in Internal Medicine at Laval Univesity and in Endocrinology at McGill University. He then did a research Fellowship in Diabetes at Vanderbilt University in Nashville, Tennessee. In 1974–76 and 1978–80, he was appointed Assistant Professor in the Department of Medicine and Physiology respectively at Vanderbilt University. In 1980, he returned to Montreal as Assistant Professor in the Department of Medicine at the University of Montreal and as Endocrinologist at Hotel-Dieu Hospital, now merged into the Centre hospitalier de l'Université de Montréal.

Dr. Chiasson's research interests include the regulation of carbohydrate metabolism in health and diabetes, as well as the development and evaluation of new strategies for the treatment and prevention of diabetes and its vascular complications. He has contributed over 250 scientific publications and lectures nationally and internationally on various topics on diabetes mellitus, its pathogenesis, its treatment, and its prevention. His scientific contribution puts him in the prestigious club of the 100 most cited publications in the world in the field of diabetes.

Sophie Christin-Maitre received her MD at University of Paris XI and her PhD at University Paris VI, Pierre and Marie Curie, France. She did a postdoctoral training in United States (Massachusetts General Hospital, Harvard University, Boston); she specialized in reproductive medicine. She holds the post of Professor of Endocrinology at University of Sorbonne, Paris, France. She has been the head of the Adult Endocrine Unit, in Hôpital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, since 2011. She is a member of the INSERM research unit UMR S_933, specialized in identifying new genes in reproductive disorders. Her interests include clinical and basic reproductive endocrinology, in particular the management of patients with Turner syndrome, patients with primary ovarian insufficiency, patients with hypogonadisms, and patients with abnormalities of sex development. She has authored approximately 150 peer-reviewed research articles and reviews.

Ulla Feldt-Rasmussen is Professor at Copenhagen University and Chief of Medical Endocrinology, National University Hospital. Her research interests involve the thyroid gland and autoimmunity, as well as pituitary and adrenal dysfunction.

She has published more than 410 papers in peer-reviewed journals on e.g., thyroid hormones and body composition, thyroid autoimmunity and cancer, cytokines as regulators of endocrine cells, influence of thyroid disrupting chemicals on thyroid cells, growth hormone deficiency related to body composition, bone metabolism and other pituitary axes, and transition from adolescent to adult care, as well as several aspects of Fabry disease. In recent years her group has embarked on studies on pituitary function after traumatic brain injury in a nationwide setting, and focusing on diagnostic accuracy of pituitary testing procedures. She has further authored numerous proceedings, textbook chapters, and other publications; as well as organized numerous international meetings and postgraduate courses, and has led several European projects and other collaborations within many areas of endocrinology.

Professor Feldt-Rasmussen reviews for international journals, and is an editorial board member of several endocrine journals. She belongs to many international professional organizations, including the Endocrine Society, ETA, ATA, ENEA, and GRS; she has served as Secretary-Treasurer of ETA and as President of the ETA Cancer Research Network.

Professor Feldt-Rasmussen serves on the advisory boards of several ad hoc endocrine committees, and has received many prestigious prizes including the Mayo Clinic's Haynes Lecturer's Award and ETA's Pinchera Research Prize.

Wouter W. de Herder M.D. Ph.D. (1960) is Professor of Endocrine Oncology at the Erasmus MC in Rotterdam, the Netherlands. In this University Hospital he is chairman of a multidisciplinary group for endocrine oncology (tumorwerkgroep endocriene tumoren) and he is head of the ENETS centre of excellence for neuroendocrine tumors. His major research interests are neuroendocrine and endocrine tumors.

Professor de Herder received his M.D. in 1985 and his Ph.D. in 1990 from the Erasmus University in Rotterdam, the Netherlands.

He is a member of several international and Dutch national societies, such as the Dutch Society for Endocrinology (NVE), the Endocrine Society (USA), the European Society of Endocrinology (ESE), European Neuroendocrine Tumor Society (ENETS) and the North American Neuroendocrine Tumor Society (NANETS). He served as a board member of the Dutch Society for Endocrinology (NVE) (2009–14). He served as chairman (2006–08) and vice-chairman of ENETS (2008–10) (European Neuroendocrine Tumour Society). He is member of the advisory boards of ENETS and NANETS.

Professor de Herder has (co-)published over 400 peer-reviewed papers and book chapters and is a reviewer for many international journals.

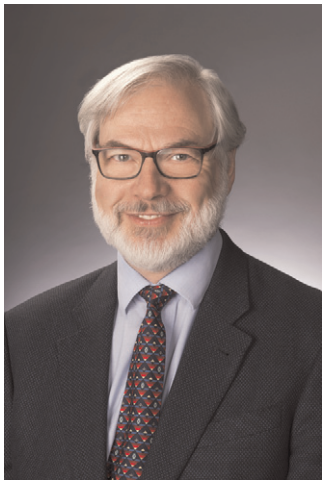
He is a member of the editorial boards of *Neuroendocrinology; Endocrinology, Diabetes & Metabolism Case Reports; Clinical Endocrinology*, and *Endocrine-Related Cancer*.

Professor de Herder has given over 200 invited presentations at Dutch national and international meetings.

Ieuan Hughes is currently Emeritus Professor of Pediatrics at the University of Cambridge and Honorary Consultant Pediatrician at Cambridge University Hospitals NHS Foundation Trust and Cambridge Biomedical Campus. He is the author of more than 300 papers and chapters across the whole range of paediatric endocrinology. His particular expertise is in disorders of sex development for which he coordinated the International Consensus on the approach to the investigation and management of this broad topic. Research interests focus on steroid enzyme deficiencies and molecular mechanisms of androgen action.
Professor Hughes has served on the editorial boards of several journals, including *Clinical Endocrinology*, *Journal of Clinical Endocrinology*, and *Metabolism* and *Archives of Disease in Childhood* where he was also the Associate Editor. He is Past-Secretary and President of the European Society for Pediatric Endocrinology and a recipient of the highest award of the Society, the Andrea Prader Prize. Professor Hughes is a James Spence Medallist of the Royal College of Pediatrics and Child Health for outstanding contributions to paediatric knowledge. He is a Fellow of the Academy of Medical Sciences, a Council Member of the Learned Society of Wales and a Trustee of two charities. The chapter on Disorders of Sex Development in *Williams Textbook of Endocrinology* (now in its 14e) by Hughes and co-authors is considered to be a definitive and up to date regular review of this topic, specific and key to pediatric endocrinology.

Dr. **Gregory Kaltsas** MD FRCP (Lon) is Professor in General Medicine and Endocrinology at the National and Kapodistrian University of Athens, Greece. He was trained in General Medicine in Athens, Greece and London, UK, and in Endocrinology at the Middlesex and St Bartholomew's Hospital, London, UK. He developed a particular interest in neuroendocrinology (pituitary and neuroendocrine tumors) and adrenal physiology and diseases. Upon returning to Greece he established a neuroendocrine network and he is currently running the European Neuroendocrine Tumor Society (ENETS) Center of Excellence at Laiko Hospital in Athens, Greece. He has served as a member of the advisory board of ENETS and of the Executive Committee of the European Neuroendocrine Association (ENEA) and he has been elected in the Executive Committee of the International Society of Endocrinology. He has recently been elected as a representative of the European Society of Endocrinology in the ExCo of the International Society of Endocrinology. He has published more than 300 original papers, reviews, and chapters and serves on editorial boards and as associate editor in several endocrine journals.

Jean-Marc Kaufman obtained his MD and PhD degrees at the Ghent University, Belgium. He was a Senior Postdoctoral Research Fellow (1982–84) in reproductive physiology at the University of Texas Medical School at Houston. He is board certified in Endocrinology and in Nuclear Medicine. In 1985 he joined the staff of the Ghent University Hospital; he headed the department of Endocrinology from 2003 to 2014 and the Laboratory for Hormonology from 1995 to 2014. He was appointed in 1993 Professor of Medicine at the Ghent University (1993) and is past Chair of the Department of Internal Medicine at the Ghent University (2010–14). From October 1st 2014 he is Professor Emeritus at the Ghent University where he is pursuing clinical and research activities. Main research interests are in the assessment, regulation, and action of sex steroids with focus on their role in health, disease, and aging in men, and in osteoporosis in men. He is (co)author of over 300 publications in international peer-reviewed journals.



André Lacroix, MD FCAHS is Professor of Medicine, Division of Endocrinology at Centre hospitalier de l'Université de Montréal (CHUM). His areas of interest include the mechanisms of adrenal Cushing syndrome, primary aldosteronism, adrenal tumorigenesis, the role of aberrant adrenal hormone receptors in adrenal overfunction, as well as new drugs in the therapy of Cushing disease, primary aldosteronism and adrenocortical cancer.
He was trained at the University of Montreal followed by fellowships in Endocrinology and research at Vanderebilt University and National Institutes of Health, USA. He was Chairman of Medicine and Director of Academic Affairs at CHUM. Former President of the Canadian Society of Endocrinology and Metabolism, he is currently chairperson of the International Society of Endocrinology (2016–20), Editor, Adrenal Section of UpToDate and *Encyclopedia of Endocrinology*, Senior Editor of the *European Journal of Endocrinology*. Fellow of the Canadian Academy of Health Sciences since 2008 and Foreign member of the National Academy of Medicine of France since 2016.

Franco Mantero received his MD at the University of Padua, Italy, did postdoctoral training in Switzerland (Clinique Medicale Therapeutique, Hopital Cantonal, University of Geneva) and in United States (University of California, San Francisco), and has been on sabbatical leave in United Kingdom, United States, and France. He held a post of Associate Professor in Medicine at the Institute of Semeiotica Medica, University of Padua (1981–86). In 1986 he moved to the University of Catania to the Chair of Andrology and Endocrinology, in 1992 to the University of Ancona, and in 2000 to the University of Padua to the Chair of Endocrinology and Chief of the Endocrinology Unit of the Department of Medicine. He has received national and international honors, including a Doctor Honoris Causa at the Semmelweis University, Budapest, Hungary.
He has been Editorial Board Member of several scientific journals (e.g., *Clinical Endocrinology*, *Endocrinology*, *Journal of Hypertension*, *Journal of Endocrinology Investigation Steroids*)
He has served as Member of the Council of several international scientific societies (including International Society of Endocrinology, International Aldosterone Conference, Journee Klotz d'Endocrinologie Clinique, ENS@T) and one of the founders of the European Network for the Study of Adrenal Tumors. His research interests include clinical and basic endocrinology of the adrenal gland and endocrinology of hypertension, in particular pathophysiology of mineralocorticoids and primary aldosteronism. He has authored approximately 500 peer–reviewed articles and edited several books and proceedings.

Jorma Toppari, MD, PhD, is Professor of Physiology at the University of Turku and Chief Physician of Pediatric Endocrinology at Turku University Hospital, Turku, Finland. He is also Adjunct Professor in the Department of Growth and Reproduction at the University of Copenhagen, Denmark. He has served as chief editor of International Journal of Andrology (2001–09), and has been on editorial boards of several endocrinological journals, including currently *Endocrinology* and *Journal of Clinical Endocrinology and Metabolism*. He is the past President of the European Academy of Andrology. He has made numerous contributions to the studies on endocrine disruption in the past 20 years. He has published approximately 400 articles on endocrinology.

Jacquetta Trasler is a James McGill Professor in the Departments of Pediatrics, Human Genetics, and Pharmacology and Therapeutics at McGill University and a Senior Scientist at the Research Institute of the McGill University Health Centre (RI-MUHC). She received her MD and PhD degrees from McGill University followed by postdoctoral training in reproductive molecular biology at Tufts University in Boston. She has served as Director of the McGill University MD-PhD Program, Scientific Director of the Montreal Children's Hospital Research Institute (and simultaneously as Deputy Director/CSO of the RI-MUHC), President of the Canadian Fertility and Andrology Society, Member of the Institute Advisory Board for the Canadian Institutes of Health Research (CIHR) Institute of Genetics and currently serves on the CIHR Stem Cell Oversight Committee and College of Reviewers. Her research focuses on epigenetics and epigenomics to better understand the molecular and cellular targets for drug effects on germ cells with implications for the resulting offspring. She has been involved in scientific program organization for numerous meetings in the field of reproductive biology and medicine and is collaborating with national and international colleagues in clinical studies to examine how assisted reproductive technologies, infertility, drug treatment, and folate deficiency and supplementation impact the human epigenome including that of future generations.

Christina Wang, MD is Professor of Medicine, Assistant Dean at the David Geffen School of Medicine at UCLA, and Associate Director for Clinical and Translational Science Institute and a faculty member of the Division of Endocrinology, Department of Medicine, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, California.

Dr. Wang has been involved in many funded basic and clinical research studies. Her current clinical research studies include androgen replacement therapy, hormonal male contraceptive development, late onset hypogonadism, accurate assessment of serum androgens, and diet and androgen metabolism. Her basic research studies focus on the regulation of spermatogenesis and mitochondrial derived peptides in spermatogenesis.

She has authored over 300 peer-reviewed publications, 67 chapters and reviews mainly on male reproductive biology including characterization of the pharmacokinetics and efficacy of androgens in men, trials of hormonal male contraceptive, regulation of germ cell apoptosis, and reproductive aging. Dr. Wang served on the Executive Council, several committees and was the President of the American Society of Andrology (2006–07). She also served the International Society of Andrology as Secretary (2001–05) and Chair of the Program Organizing Committee (2005–09). She was President of the International Society of Andrology (2009–13). She is a member of the Research Group on Methods for the Regulation of Male Fertility of the World Health Organization since 1984 and Chairperson (1991–2002).

She has mentored many physician and scientist and is an advocate of young investigators. Dr. Wang has been invited speaker and distinguished lecturer at many national and international endocrinology, reproductive endocrinology, and andrology conferences.

LIST OF CONTRIBUTORS

Bo Abrahamsen
University of Southern Denmark, Odense, Denmark; and Holbæk Hospital, Holbæk, Denmark

Catarina Abreu
Hospital of Santa Maria, Lisbon, Portugal

O. Addison
University of Maryland School of Medicine, Baltimore, MD, United States

Zaida Agüera
Carlos III Institute of Health, Madrid, Spain; and University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Enrico Agabiti-Rosei
University of Brescia, Brescia, Italy

Carlo Aggiusti
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Veena Agrawal
University of Colorado, Aurora, CO, United States

James Ahlquist
Southend Hospital, Westcliff on Sea, United Kingdom

Syed Faisal Ahmed
Royal Hospital for Children, Glasgow, United Kingdom

Oluwaseun A. Akinseye
University of Tennessee Health Science Center, Memphis, TN, United States

Adriana Albani
Ludwig Maximilian University of Munich, Munich, Germany; and University of Messina, Messina, Italy

Maria Alevizaki
National and Kapodistrian University of Athens, Athens, Greece

Kristallenia Alexandraki
National and Kapodistrian University of Athens, Athens, Greece

Ahmad Alkhatib
Dasman Diabetes Institute, Dasman, Kuwait

Stefano Allasia
University of Turin, Turin, Italy

R.G. Allen
The Sally Balin Medical Center, Media, PA, United States

Jeremy Allgrove
Great Ormond Street Hospital NHS Foundation Trust, London, United Kingdom

Paloma Alonso-Magdalena
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Mazen Alsahli
Southlake Regional Health Center, Newmarket, ON, Canada; and University of Toronto Faculty of Medicine, Toronto, ON, Canada

Laurence Amar
Hôpital Européen Georges Pompidou, Paris, France; INSERM, UMR970, Paris, France; and Université Paris Descartes, Paris, France

L. Amar
Hôpital Européen Georges Pompidou, Paris, France; and Paris Descartes University, Paris, France

Gisah Amaral de Carvalho
Federal University of Paraná, Curitiba, Brazil

Ravinder Anand-Ivell
University of Nottingham, Nottingham, United Kingdom

Dana K. Andersen
National Institutes of Health, Bethesda, MD, United States

Niels H. Andersen
Aalborg University Hospital, Aalborg C, Denmark

Mikkel Andreassen
ENETS NET CoE, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Di Vincenzo Angelo
Center for the Study and the Integrated Treatment of Obesity – Bariatric Unit, University of Padua, Padua, Italy

Jean-Marie Antoine
Tenon Hospital, Paris, France; and Pierre et Marie Curie University, Paris, France

Athanasios Antoniou-Tsigkos
National and Kapodistrian University of Athens, Athens, Greece

Victor Appay
INSERM Centre d'Immunologie et des Maladies Infectieuses (CIMI-Paris), Paris, France

David Araújo-Vilar
UETeM, IDIS-CIMUS, University of Santiago de Compostela, Santiago de Compostela, Spain; and University Clinical Hospital of Santiago de Compostela, Santiago de Compostela, Spain

Sheryl E. Arambula
North Carolina State University, Raleigh, NC, United States

Jesús A. Araujo
University of California Los Angeles, Los Angeles, CA, United States

Leonardo Tadeu Araujo
University of Sao Paulo, Sao Paulo, Brazil

Teresa Arcidiacono
IRCCS San Raffaele Scientific Institute, Milan, Italy

Josephine Arendt
University of Surrey, Guildford, United Kingdom

Jesús Argente
Autonomous University of Madrid, Madrid, Spain; University Hospital Niño Jesús, Institute of Investigation La Princesa, Madrid, Spain; and Center for Biomedical Research in Network on the Pathophysiology of Obesity and Nutrition (CIBEROBN), Carlos III Health Institute, Madrid, Spain; and Madrid Institutes for Advanced Studies (IMDEA), Campus of International Excellence, Autonomous University of Madrid (CEIUAM), Madrid, Spain

Decio Armanini
University of Padua, Padova, Italy

David G. Armstrong
Manchester Royal Infirmary, Manchester, United Kingdom; and Southern Arizona Veterans Affairs Medical Center, Tucson, AZ, United States

Wilbert S. Aronow
New York Medical College, Valhalla, NY, United States

Pablo Arriagada
Gedeon Richter/Preglem S.A., Geneva, Switzerland

Sylvia L. Asa
University Health Network, Toronto, ON, Canada; University of Toronto, Toronto, ON, Canada; and Princess Margaret Cancer Centre, Toronto, ON, Canada

National and Kapodistrian University of Athens, Athens, Greece

Ashley Gearhardt
University of Michigan, Ann Arbor, MI, United States

Nori Geary
Weil Medical College of Cornell University, New York, NY, United States

Corinna Geisler
Universty of Kiel, Kiel, Germany

Andrea R. Genazzani
University of Pisa, Pisa, Italy

John E. Gerich
University of Rochester School of Medicine, Rochester, NY, United States

Willem J.M. Gerver
Maastricht University, Maastricht, The Netherlands

Sana A. Ghaznavi
Memorial Sloan Kettering Cancer Centre, New York, NY, United States

Ezio Ghigo
University of Turin, Turin, Italy

Mara Giacchè
Endocrine and Metabolic Medicine Unit, ASST Spedali Civili di Brescia, Brescia, Italy

Antonella Giampietro
Pituitary Unit, Catholic University of Sacred Heart, Rome, Italy

J. Gianfortoni
Life Source Fertility Center, Richmond, VA, United States

Andrea Giannini
University of Pisa, Pisa, Italy

Evelien Gielen
Center for Metabolic Bone Diseases, UZ Leuven, Leuven, Belgium

Céline Gillet
Free University of Brussels, Brussels, Belgium

Anne-Paule Gimenez-Roqueplo
Hôpital Européen Georges Pompidou, Paris, France; INSERM, UMR970, Paris, France; and Paris Descartes University, Paris, France

Véronique Gingras
Montreal Clinical Research Institute, Montreal, QC, Canada; and University of Montreal, Montréal, QC, Canada

Luca Giovanella
Ente Ospedaliero Cantonale, Bellinzona, Switzerland; and Oncology Institute of Southern Switzerland, Bellinzona, Switzerland

Marta Giralt
University of Barcelona, Barcelona, Catalonia, Spain; Sant Joan de Déu Research Institute, Esplugues de Llobregat, Spain; and CIBER Fisitopatología de la Obesidad y Nutrición, Spain

Andrea Giustina
San Raffaele Vita-Salute University, Milan, Italy

Nathalia L. Gomes
University of São Paulo, São Paulo, Brazil

Anne Gompel
Paris Descartes University, Port Royal, Paris

Louis Gooren
University of Florence, Florence, Italy; and VU Medical Center, Amsterdam, The Netherlands

Daniela-Brindusa Gorduza
Hôpital Mère-Enfant – Claude-Bernard University, Lyon, France

Monserrat Graell
University Hospital Niño Jesús, Institute of Investigation La Princesa, Madrid, Spain

Guido Grassi
University Milano-Bicocca, Monza, Italy

Claus H. Gravholt
Aarhus University Hospital, Aarhus C, Denmark

J.R. Grider
Virginia Commonwealth University, Richmond, VA, United States

Michael D. Griswold
Washington State University, Pullman, WA, United States

Virginie Grouthier
Sorbonne University, Paris, France

Simona Grozinsky-Glasberg
Hadassah-Hebrew University Medical Center, Jerusalem, Israel

Michael Grynberg
Service de Médecine de la Reproduction et Préservation de la Fertilité, Jean Verdier Hospital, Bondy, France; University Paris XIII, Bobigny, France; and Unité Inserm U1133, Paris-Diderot University, Paris, France

Federica Guaraldi
IRCCS, Istituto Scienze Neurologiche di Bologna, Bologna, Italy; and University of Bologna, Bologna, Italy

Gabriela Guercio
Hospital de Pediatría Garrahan, Buenos Aires, Argentina; and Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Argentina

Jenny E. Gunton
Westmead Hospital, Sydney, NSW, Australia; The Westmead Institute for Medical Research, The University of Sydney, Sydney, NSW, Australia; and Garvan

Institute of Medical Research, University of New South Wales, Darlinghurst, NSW, Australia

Mark Gurnell
University of Cambridge, Cambridge, United Kingdom; and National Institute for Health Research Cambridge Biomedical Research Centre, Cambridge, United Kingdom

Wolfgang Högler
Birmingham Women's and Children's NHS Foundation Trust, Birmingham, United Kingdom; and IMSR, University of Birmingham, Birmingham, United Kingdom

Abdelhadi Habeb
Prince Mohammed bin Abdulaziz Hospital for National Guard & Taibah University, Al-Madinah, Kingdom of Saudi Arabia

Joel F. Habener
Massachusetts General Hospital, Boston, MA, United States; and Harvard University, Boston, MA, United States

Béla Halász
Hungarian Academy of Sciences and Semmelweis University, Budapest, Hungary

Geoffrey L. Hammond
Life Sciences Center, Vancouver, BC, Canada

Daria Handkiewicz-Junak
Maria Sklodowska-Curie Memorial Institute–Cancer Center, Gliwice, Poland

Markolf Hanefeld
Technical University Dresden, Dresden, Germany

Fady Hannah-Shmouni
National Institutes of Health, Bethesda, MD, United States

Sabine E. Hannema
Leiden University Medical Centre, Leiden, The Netherlands

Anne Marie Hannon
RCSI Medical School, Dublin, Ireland; and Beaumont Hospital, Dublin, Ireland

Carsten Palnæs Hansen
ENETS NET CoE, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Inga Harbuz-Miller
University of Missouri, Columbia, MO, United States

Yenal I. Harper
University of Tennessee Health Science Center, Memphis, TN, United States

Nicholas C.W. Harvey
University of Southampton, Southampton, United Kingdom; University of Southampton and University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom; and WHO Collaborating Centre for Public Health Aspects of Musculoskeletal Health and Aging, Liège, Belgium

Annik Hauri-Hohl
Paediatric Endocrine Center Zurich (PEZZ), Zurich, Switzerland

L. Haynes
University of Connecticut Health Center, Farmington, CT, United States

Anthony P. Heaney
University of California Los Angeles, Los Angeles, CA, United States

Maka S. Hedrington
University of Maryland School of Medicine, Baltimore, MD, United States

Laszlo Hegedüs
Odense University Hospital, Odense, Denmark

J.M. Hershman
Division of Endocrinology, VA Greater Los Angeles Healthcare System, Los Angeles, CA United States

Lesley A. Hill
Life Sciences Center, Vancouver, BC, Canada

Barry T. Hinton
University of Virginia School of Medicine, Charlottesville, VA, United States

Angelica Lindén Hirschberg
Karolinska Institutet, Stockholm, Sweden; and Karolinska University Hospital, Stockholm, Sweden

Rikke Hjortebjerg
Aarhus University, Aarhus C, Denmark

Johannes Hofland
Erasmus University Medical Center, Rotterdam, The Netherlands

David W. Hogg
University of Toronto, Toronto, ON, Canada

Paul-Martin Holterhus
Christian-Albrechts University of Kiel (CAU), Kiel, Germany; and University Hospital of Schleswig-Holstein (UKSH), Kiel, Germany

Peter Holzer
Medical University of Graz, Graz, Austria

John W. Honour
University College London, London, United Kingdom

Nadine Hornig
Christian-Albrechts University of Kiel (CAU), Kiel, Germany; and University Hospital of Schleswig-Holstein (UKSH), Kiel, Germany

Christopher Houk
Augusta University Health Sciences, Augusta, GA, United States

Sasha Howard
Queen Mary University of London, London, United Kingdom

Ieuan Hughes
Department of Pediatrics, University of Cambridge, Cambridge, United Kingdom
Cambridge University Hospitals NHS Foundation Trust and Cambridge Biomedical Campus, Cambridge, United Kingdom

Mia Husic
University of Toronto, Toronto, ON, Canada

Vivian Hwa
Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States of America

Guido Iaccarino
University of Salerno, Baronissi, SA, Italy

Davide Iacuaniello
University of Naples Federico II, Naples, Italy

Antonio Ieni
University of Messina, Messina, Italy

I. Ilie
`Iuliu Hatieganu' University of Medicine and Pharmacy, Cluj Napoca, Romania

E.A. Iliescu
Queen's University, Kingston, ON, Canada

Frédéric Illouz
University Hospital of Angers, Angers, France

Frediano Inzani
Catholic University – IRCCS Fondazione Policlinico Universitario A. Gemelli, Roma, Italy

Richard Ivell
University of Nottingham, Nottingham, United Kingdom

Maitane Izaguirre
Metabolic Research Laboratory, University of Navarra, Pamplona, Spain

Jarmo Jääskeläinen
University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland

Niklas Rye Jørgensen
Rigshospitalet, Glostrup, Denmark; and University of Southern Denmark, Odense, Denmark

Martin B. Jørgensen
University of Copenhagen, Copenhagen, Denmark

Marie-Lise Jaffrain-Rea
University of L'Aquila, L'Aquila, Italy; and IRCCS Neuromed, Pozzilli, Italy

Ashish Jain
Montreal Diabetes Research Center, Montreal, QC, Canada; and CHUM-Research Center (CRCHUM), Montreal, QC, Canada

Andrzej Januszewicz
Institute of Cardiology, Warsaw, Poland

Barbara Jarząb
Maria Sklodowska-Curie Memorial Institute-Cancer Center, Gliwice, Poland

Ravi Jasuja
Translational Research and Discovery, Boston, MA, United States; Research Program in Men's Health: Aging and Metabolism, Boston, MA, United States; Boston Claude D. Pepper Older Americans Independence Center, Boston, MA, United States; and Brigham and Women's Hospital, Boston, MA, United States

Rebecca L. Jaworski
University of California San Diego, San Diego, CA, United States

Robert T. Jensen
National Institutes of Health/National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, United States

Susana Jiménez-Murcia
University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Dipesalema Joel
University of Botswana, Gaborone, Botswana

Fjola Johannesdottir
Beth Israel Deaconess Medical Center, Boston, MA, United States; and Harvard Medical School, Boston, MA, United States

Anders H. Johnsen
Copenhagen University Hospital, Copenhagen, Denmark

Pamela Jones
Massachusetts General Hospital, Boston, MA, United States

Nathalie Josso
Pierre and Marie Curie University, Paris, France

Emmanuel Jouanneau
Groupement Hospitalier Est, Bron, France

Anne Jouinot
Paris Descartes University, Paris, France

Anders Juul
University of Copenhagen, Copenhagen, Denmark

Josef Köhrle
Charité–Medicine University Berlin, Berlin, Humboldt University of Berlin, Berlin, Germany; Berlin Institute of Health, Institute of Experimental Endocrinology, Berlin, Germany

Agnė Kadusauskienė
Lithuanian University of Health Sciences, Kaunas, Lithuania

Gregory Kaltsas
National and Kapodistrian University of Athens, Athens, Greece

Archana Kamalakar
Emory University, Atlanta, GA, United States; University of Arkansas for Medical Sciences, Little Rock, AR, United States; and Texas A&M University, College Station, TX, United States

Chen Kan
Anhui Medical University, Hefei, China

Lixin Kan
Anhui Medical University, Hefei, China; and Northwestern University, Chicago, IL, United States

John A. Kanis
University of Sheffield Medical School, Sheffield, United Kingdom; and Catholic University of Australia, Melbourne, VIC, Australia

Vijayarangan G. Kannian
Oxford University Hospitals NHS Foundation Trust, Oxford, England

V. Kantorovich
University of Connecticut Health Center, Farmington, CT, United States; and National Institutes of Health, Bethesda, MD, United States

Kung-Ting Kao
Royal Hospital for Children, Glasgow, United Kingdom

Niki Karavitaki
Institute of Metabolism and Systems Research, College of Medical and Dental Sciences, University of Birmingham, Birmingham, United Kingdom; and Centre for Endocrinology, Diabetes and Metabolism, Birmingham Health Partners, Birmingham, United Kingdom

Gerard Karsenty
Columbia University, New York, NY, United States

Elena Kaschina
Charité—Medicine University Berlin, Berlin, Germany; and Berlin Institute of Health, Berlin, Germany

Rachel R. Kaspari
Yale School of Medicine, New Haven, CT, United States

Claudia Katschnig
Pediatric Endocrine Center Zurich (PEZZ), Zurich, Switzerland

Harshini Katugampola
Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom

Electron Kebebew
National Cancer Institute, Bethesda, MD, United States; and The George Washington University, Washington, DC, United States

Daniel M. Kemp
Massachusetts General Hospital, Boston, MA, United States; and Harvard University, Boston, MA, United States

Ivana Kholová
Tampere University, Tampere, Finland

Wieland Kiess
University of Leipzig, Leipzig, Germany

John Paul Kilday
Royal Manchester Children's Hospital, Manchester, United Kingdom

Andreas Kjær
Nuclear Medicine & PET, ENETS NET CoE, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Marianne Klose
Copenhagen University Hospital, Copenhagen, Denmark

Ulrich Knigge
ENETS NET Center of Excellence (CoE), Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Christian A. Koch
Technical University of Dresden, Dresden, Germany; and Medicover MVZ Oldenburg, Oldenburg, Germany

X. Kodji
King's College London, London, United Kingdom

Kamila Kolanska
Sorbonne University, Paris, France

Efstratios M. Kolibianakis
Aristotle University of Thessaloniki, Thessaloniki, Greece

Anne-Sophie C.A.M. Koning
Leiden University Medical Center, Leiden, The Netherlands

George Kontogeorgos
``George Gennimatas'' General Hospital of Athens, Athens, Greece; National and Kapodistrian University of Athens, Athens, Greece; and University of Toronto, Toronto, ON, Canada

John J. Kopchick
Ohio University, Athens, OH, United States

Márta Korbonits
Queen Mary University of London, London, United Kingdom

Yining Zhao
University Hospital Erlangen, Erlangen, Germany

Stephan Zipfel
Medical University Hospital Tübingen, Tübingen, Germany

PREFACE

The first Edition of the *Encyclopedia of Endocrine Diseases* was published in 2004. Because of the enormous development in the field it was found important to produce a completely revised and updated Second Edition of the Encyclopedia. The new Edition is a must-have one-stop reference covering every aspect of the physiological background, pathogenesis, clinical diagnostics, and therapeutic aspects of the wide array of endocrine and related metabolic diseases.

The functional balance of the body (homeostasis) is maintained by two regulatory circuits, i.e., the nervous and the endocrine systems. Among the most complex constructs in the body, the endocrine system comprises a group of glands that secrete hormones directly into the bloodstream, where they reach their specific receptors in other parts of the body, evoking specific intracellular signaling pathways leading to their biological effect. Many classically non-endocrine organs (e.g., the heart) have also turned out to have endocrine functions. The endocrine system maintains and regulates the body's homeostasis by using hormones to control metabolism, temperature, biological cycles, internal fluid volume, reproduction, growth, body composition, and development. The system is a marvel when functioning optimally, i.e., maintaining the body homeostasis. Unfortunately, there is a myriad of ways these processes, actions, and functions can go awry, resulting in various endocrine and metabolic diseases, which form the over-arching theme of the Encyclopedia.

The Encyclopedia is not meant as a primer on the subject of endocrinology, but instead intended to provide a comprehensive reference work on the extensive spectrum of diseases and disorders that can occur within the endocrine and metabolic system. The updated version of this groundbreaking encyclopedia is especially timely, as it covers the dramatic discoveries in the field of endocrinology and metabolism over the past 10 years, particularly with respect to novel diagnostic techniques and treatment approaches. In particular, there have been tremendous advancements in our understanding of the molecular basis of endocrine and metabolic diseases (mutations, epigenetics, signaling), as well as pathogenesis and therapy of the common forms of these diseases (e.g., diabetes, obesity, and endocrine malignancies).

The Encyclopedia offers a unique source of up-to-date information for the physicians and basic scientists working in the field. It is an essential resource for every clinician diagnosing and treating endocrine patients. The Encyclopedia also offers the prime source of information for students of medicine and science around the world, as well as basic research workers in academia, the pharma industry, and in other areas in need of information on endocrinology and metabolism. It also offers useful information for the lay public about normal and abnormal functions of hormones.

The Encyclopedia is intended to serve as a useful and comprehensive source of information spanning the many and varied aspects of the endocrine and metabolic system. The chapters have been written to be accessible to both clinical and nonclinical readers. The articles have been formatted in similar fashion and each is intended as a stand-alone presentation. Each article begins with a glossary list defining key terms that may be unfamiliar to the reader and are important for understanding the article. The body of the article begins with a brief introduction to the subject under discussion, bold headings lead the reader through the text, and figures and tables explain and illuminate most articles. The main text is followed by referenced citations to provide the reader with access to additional information on the topic, and cross-references lead the reader to related entries in the encyclopedia. The relatively short stand-alone articles have allowed us to recruit the best experts available for each topic.

Unlike the first Edition, where the articles were arranged in alphabetical order, the 2nd Edition is arranged in organ-based thematic order, where each organ-based group of diseases is presented as cluster of articles in the first four volumes. The fifth volume is a stand-alone compilation of all articles on pediatric endocrinology. The thematic organization gives the reader a better general view of the coverage of articles on a specific endocrine organ or disease type.

The Second Edition of the Encyclopedia builds of the first edition. Nevertheless, to bring a major reference work with such a broad scope from initial conception to final publication involved a great deal of planning and organization, together with the efforts of innumerable individuals. The authors of the first edition were invited to update their earlier texts. If this was not possible, the Section Editors invited another expert in the topic either to update the previous text or to write a de novo text; the latter happened in most of these cases. Hence, the Second Edition contains to a large extent totally new information, or at least the fluency of all texts has been scrutinized. Furthermore, all manuscripts have undergone peer-review arranged by the Section Editors.

Assembling a large volume of articles with the purpose to cover all essential topics of endocrine diseases posed multiple challenges. Coverage was a significant problem: on one hand some redundancy of the topics was almost impossible to avoid in places while, on the other, there were inevitable gaps. Some of these arose from late cancellations; others from oversights on our part. We can only promise to fill these gaps in future editions. We also note that as can be expected for a large multi-author compilation the individual articles do differ in detail and approach. We considered it more important to allow our experts substantial latitude in deciding how to present their topics than to apply rigid guidelines.

Most of the editing work of the Encyclopedia has been carried out by a highly competent board of 16 Section Editors, each of them internationally renowned experts in their respective field within clinical endocrinology. First, the broadest possible list of topics was compiled, aiming at the best possible coverage. Throughout the editorial process, the Section Editors supervised their subject area of expertise, recommended and corresponded with fellow editors and article contributors, reviewed the manuscripts, and continuously helped to refine the final list of topics. This has made the task of the Editor in Chief easy, mainly entailing the supervision of smooth progress of the project.

The Section Editors and their fields deserve being listed here: *Jean-Jacques Body* (Belgium, bone endocrinology), *Felipe F. Casanueva* (Spain, metabolism and obesity), *Richard N. Clayton* (United Kingdom, pituitary gland), *Jean-Louis Chiasson* (Canada, diabetes), *Sophie Christin-Maitre* (France, female reproduction), *Wouter W. de Herder* (The Netherlands, neuroendocrinology), *Ulla Feldt-Rasmussen* (Denmark, thyroid gland), *Ieuan Hughes* (United Kingdom, pediatric endocrinology), *Gregory Kaltsas*, Greece, and *Martin O. Weickert*, United Kingdom, (gastrointestinal hormones), *Jean-Marc Kaufman* (Belgium, endocrinology of aging), *André Lacroix* (Canada, adrenal cortex), *Franco Mantero* (Italy, adrenal medulla and endocrine hypertension), *Jorma Toppari* (Finland, endocrine disruptors), *Jacquetta Trasler* (Canada, endocrine epigenetics) and *Christina Wang* (United Kingdom, male reproduction).

The Elsevier editorial staff, *Will Smaldon*, *Laura Escalante Santos*, and *Kate Miklaszewska-Gorczyca*, have been of enormous help to the editors at every step during this long project. I admire the professionalism of everyone and am deeply indebted to all for their dedication and hard work to make the Encyclopedia the leading reference book of clinical endocrinology.

The authors of the individual chapters, more than 450 in total, were specifically selected by the Section Editors to represent the best available knowledge on the topic available. They all should be thanked for their dedication and the excellent quality of their contributions.

Ilpo T. Huhtaniemi
Editor in Chief

VOLUME 1 – General Principles of Hormone Production and Action, Diabetes, Lipid Metabolism and Atherosclerosis, Obesity, Gastrointestinal Hormones, Multi-Organ Endocrine Diseases, Endocrinology of Aging, and Endocrine toxicology and EDCs

General Principles of Hormone Production and Action

History of Endocrinology *Wouter W de Herder* 1
Statistics in Endocrinology: Meta-Analysis Advantages and Pitfalls *Olaf M Dekkers* 11
Evolution of Hormonal Mechanisms *Vincent Laudet and Gabriel V Markov* 16
General Principles of Endocrine Genetics *Constantin Polychronakos* 23
Endocrine Epigenetics, Epigenetic Profiling and Biomarker Identification *Virginie Bertrand-Lehouillier, Lisa-Marie Legault, and Serge McGraw* 31
Protein and Peptide Hormone Synthesis *Johannes Hofland and Frank H de Jong* 36
Protein and Peptide Hormone Action *Frank H de Jong and Johannes Hofland* 43
Roles of Plasma Binding Proteins in Modulation of Hormone Action and Metabolism *Geoffrey L Hammond, Lesley A Hill, and Phillip W Round* 51
Dynamic Endocrine Rhythms *Thomas J Upton and Stafford Lightman* 61
Growth Factors *Uxía Fernandez, Luisa M Seoane, and Ruben Nogueiras* 69

Diabetes

Normal Glucose Physiology *Mazen Alsahli and John E Gerich* 72
Glucose Metabolism and Hormonal Regulation *Keith Tornheim* 87
Insulin Secretion: Functional Biochemical Aspects *Willy J Malaisse* 95
Insulin Action; Post-Receptor Mechanisms *Ashok K Srivastava, Preeti Bajpai, and Ashish Jain* 100
Diagnosis and Classification of Diabetes Mellitus *Jean-Marie Ekoé* 105
Type 1 Diabetes *Bimota Nambam, William Winter, and Desmond Schatz* 110
Type 2 Diabetes *Susan L Samson and Alan J Garber* 116
Diabetes Mellitus and Pregnancy *Emily D Szmuilowicz, Charlotte M Niznik, and Boyd E Metzger* 122
Diabetes Mellitus; Diagnosis and Treatment in the Elderly *Odilia I Bermudez* 133

Carbohydrate Metabolism: Diabetes Mellitus, Genomic Aberrations *RK Semple* 141
Lifestyle Diabetes Prevention *Ahmad Alkhatib and Jaakko Tuomilehto* 148
Hyperglycemic Hyperosmolar State *J Maletkovic and A Drexler* 160
Hypoglycemia *Darleen A Sandoval, Elizabeth M Lamos, Lisa Younk, Maka S Hedrington, and Stephen N Davis* 163
Glycation- and/or Polyol Pathway-Inducing Complications *Naila Rabbani and Paul J Thornalley* 170
Hypertension and Diabetes *Atossas Niakan and William C Cushman* 180
Dyslipidemia in Diabetes *Savitha Subramanian and Alan Chait* 186
Ocular Manifestations Associated With Diabetes *S Lauhon, MS Stem, and PE Fort* 199
Kidney Disease in Diabetes *Stephanie Toth-Manikowski and Mohamed G Atta* 202
Diabetic Nerve Disease; Neuropathy *Jean-Marie Ekoe* 207
Neurological Disease and Diabetes, Autonomic *Aaron I Vinik, Tomris Erbas, M-L Névoret, and C Casellini* 210
Foot Disease in Diabetes *Jean-Marie Ekoé, Benjamin A Lipsky, and David G Armstrong* 216
Cardiovascular Disease in Diabetes *Marie-Eve Piché and Paul Poirier* 219
Treatment: Alpha Glucosidase Inhibitors *Markolf Hanefeld and Gabriele Mertes* 238
Insulin Pumps and Artificial Pancreas *Nadine Taleb, Véronique Gingras, and Rémi Rabasa-Lhoret* 245
Transplantation: Pancreatic and Islet Cells *Anissa Gamble, Antonio Bruni, and AM James Shapiro* 259
Hypoglycemic State, Nondiabetic *Pierre J Lefèbvre and André J Scheen* 270

Lipid Metabolism and Atherosclerosis

Classification of Hyperlipidemias and Dyslipidemias *Jesús E Millán Núñez-Cortes and Joaquín J Millán Pérez* 275
Atherosclerosis *Jesus A Araujo and Aldons J Lusis* 282
Atherogenesis *L Badimon and V Llorente-Cortés* 289
Epigenetics, the Vascular Wall, and Atherosclerosis *Gertrud Lund and Silvio Zaina* 303
Primary Mixed Dyslipidemias *Rafael Carmena* 314
Hypercholesterolemia *Sergio Martinez-Hervas and Juan F Ascaso* 320
Low HDL and High HDL Syndromes *Shizuya Yamashita and Yuji Matsuzawa* 327
Hypertriglyceridemias and Their Treatment *José T Real* 340

Obesity

Genetic Basis of Obesity *Dolores Corella and Oscar Coltell* 346
Gut Microbiota; Its Importance in Obesity *Araceli Muñoz-Garach, Isabel M Cornejo-Pareja, and Francisco J Tinahones* 353
Regulation of Food Intake *Albert Lecube and Carolina López-Cano* 363
Adipose Tissue *Xabier Unamuno, Gema Frühbeck, and Victoria Catalán* 370
Comorbidities of Obesity *Vettor Roberto and Di Vincenzo Angelo* 385
Hypothalamic Control of Food Intake and Energy Homeostasis *Luisa M Seoane, Miguel López, and Ruben Nogueiras* 393

Gastrointestinal Hormones and Their Regulation of Food Intake *Luca Busetto, Marco Rossato, and Roberto Vettor* 398

Body Composition *Manfred J Müller, Corinna Geisler, and Anja Bosy-Westphal* 406

Obesity and Food Addiction *Fernando Fernández-Aranda, Trevor Steward, Gemma Mestre-Bach, Susana Jiménez-Murcia, and Ashley Gearhardt* 414

Leptin *Rachel C Morgan and Robert V Considine* 420

Lifestyle and Nutrition *Dragan Micic and Snezana Polovina* 428

Physical Activity and Exercise *Federico Mallo Ferrer* 436

Treatment of Obesity with Bariatric Surgery *Maitane Izaguirre, Gema Frühbeck, and Victoria Catalán* 442

Metabolic Surgery; Indications and Outcomes *Lidia Castagneto-Gissey, James Casella-Mariolo, and Geltrude Mingrone* 459

Treatment: New Drugs *Silvia Garelli, Nicola Salituro, Giulia M Pontesilli, Luigi Ricciardiello, Valentina Vicennati, and Uberto Pagotto* 464

Binge-Eating, Bulimia, and Other Eating Disorders *Zaida Agüera, Núria Mallorquí-Bagué, María Lozano-Madrid, Andreas Stengel, Stephan Zipfel, and Fernando Fernández-Aranda* 473

Lipodystrophy *Marta Giralt, Francesc Villarroya, and David Araújo-Vilar* 482

Gastrointestinal Hormones

GI Hormone Development (Families and Phylogeny) *Anders H Johnsen* 496

GI Tract: General Anatomy (Cells) *George Kontogeorgos* 501

GI Hormones Outside the Gut: Central and Peripheral Nervous Systems *Graham J Dockray* 515

GI Tract: General Pathology of Neuroendocrine Growths *Guido Rindi, Frediano Inzani, and Enrico Solcia* 520

Gastrin *Graham J Dockray* 525

Cholecystokinin (CCK) *Nori Geary* 529

Pancreatic Polypeptide (PP) *Dana K Andersen and F Charles Brunicardi* 534

Peptide YY (PYY) *Peter Holzer and Aitak Farzi* 546

Glucagon and Glucagon-Like Peptides *Daniel M Kemp and Joel F Habener* 555

Glucagon Like Peptide 2 (GLP-2) *Georgios K Dimitriadis and Alexander D Miras* 561

Enterochromaffin-Like Cells *Apostolos V Tsolakis* 565

Substance P *Miguel Muñoz and Rafael Coveñas* 571

Gastrointestinal Hormones in Cancer *Inbal Uri, Kristallenia Alexandraki, and Simona Grozinsky-Glasberg* 579

Somatostatin Receptor Expression in Gastrointestinal Tumors *Eleftherios Chatzellis and Gregory Kaltsas* 587

Gastrointestinal Neuroendocrine Tumor Syndromes (GI NETS) *Robert T Jensen* 597

Gastrinomas *Robert T Jensen* 617

Pancreatic Islet Cell Tumors *Ulrich Knigge, Mikkel Andreassen, Birgitte Federspiel, Carsten Palnæs Hansen, Andreas Kjær, and Seppo W Langer* 626

Peptide Neurotransmitters and Smooth Muscle in the Gut *JR Grider, KS Murthy, and GM Makhlouf* 635

Multi-Organ Endocrine Diseases

Pituitary Tumors Associated With Multiple Endocrine Neoplasia Syndromes *Liliya Rostomyan, Adrian F Daly, and Albert Beckers* 642

Endocrinology of Aging

Aging and Longevity of Human Populations *Diana van Heemst* 648

Animal Models for Aging *EC-H Lee, B Rogina, L Haynes, and GA Kuchel* 653

Oxidative Stress and Aging *Arthur K Balin and RG Allen* 659

Immunology and Aging *Victor Appay* 664

Premature Aging Syndromes *Fabio Coppedè* 669

Hormonal Circadian Rhythms and Sleep in Aging *Georges Copinschi and Anne Caufriez* 675

Circadian Clock, Epigenetic Regulators (Sirtuins), and Metabolism *Mirella L Meyer-Ficca and Ralph G Meyer* 690

Somatotropic Axis in Human Aging *Sabrina Chiloiro, Antonio Bianchi, Antonella Giampietro, and Laura De Marinis* 700

Abnormalities in Water Homeostasis in the Elderly *Laura E Cowen and Joseph G Verbalis* 708

Body Weight, Body Composition, and Aging *Odessa R Addison and Alice S Ryan* 713

Lipid Disorders in the Elderly *Wilbert Aronow* 719

Gonadotropins and Testicular Function in Aging *Fiona Yuen, Peter Y Liu, Ronald Swerdloff, and Christina Wang* 723

Hypogonadism and Testosterone Therapy in Elderly Men *Bu B Yeap* 729

Sexual Function in Aging Men *Giulia Rastrelli, Giovanni Corona, and Mario Maggi* 739

Osteoporosis in the Oldest Old *Evelien Gielen* 748

Aging and the Thyroid Gland *Leonidas H Duntas* 758

Endocrine toxicology and EDCs

Introduction to Endocrine Toxicology and Endocrine Disruption *Jorma Toppari* 762

Toxic Effects of Common Environmental Pollutants in Pancreatic β-Cells and the Onset of Diabetes Mellitus *Paloma Alonso-Magdalena, Eva Tudurí, Laura Marroquí, Ivan Quesada, Robert M Sargis, and Angel Nadal* 764

Endocrine Disruptors and Obesity *Sigal A Willner and Bruce Blumberg* 776

Endocrine Disruptors and Thyroid Function *Josef Köhrle* 787

Neuroendocrine Disruption of Reproduction *Julie Fudvoye, Jean-Pierre Bourguignon, and Anne-Simone Parent* 793

Association of Endocrine Disrupting Chemicals With Male Reproductive Health *Helena E Virtanen, Katharina M Main, and Jorma Toppari* 802

Endocrine Disrupting Chemicals and Behavior *Sheryl E Arambula and Heather B Patisaul* 812

VOLUME 2 – Neuroendocrinology, Pituitary Gland and Diseases, Female Reproduction, and Male Reproduction

Neuroendocrinology

Corticotropin-Releasing Hormone (CRH) *Nicolas C Nicolaides and George P Chrousos* 1

Neurotensin *Arthur Shulkes* 10

Carcinoid Syndrome *Marina Tsoli and Gregory Kaltsas* 13

Catecholamines *Graeme Eisenhofer and Jacques WM Lenders* 21

Pineal Tumors *María-José Barahona and Susan M Webb* 25

Vasopressin *Aoife Garrahy and Christopher J Thompson* 29

Effects of Steroid Hormones on Brain *Anne-Sophie CAM Koning, Russell D Romeo, Bruce S McEwen, and Onno C Meijer* 36

Memory and Epigenetics: Role of Estrogen *Jennifer J Tuscher, Ashley M Fortress, and Karyn M Frick* 42

VIPoma, Glucagonoma, and Somatostatinoma *Wouter T Zandee and Wouter W de Herder* 52

Insulinoma *Wouter T Zandee and Wouter W de Herder* 58

Melatonin *J Arendt* 63

Overview of Neurotransmitters *Floyd E Bloom* 75

Pituitary Gland and Diseases

Anatomy of Hypothalamus *Béla Halász* 81

Pituitary Gland Anatomy and Embryology *Béla Halász* 90

Hypothalamic Disease *Sylvia L Asa and Shereen Ezzat* 97

Diabetes Insipidus *Gary L Robertson* 107

Growth Hormone (GH) *Rikke Hjortebjerg, Gerhard Baumann, and John J Kopchick* 116

Natural and Synthetic Growth Hormone Secretagogues *Giovanna Motta, Stefano Allasia, Marco Zavattaro, Ezio Ghigo, and Fabio Lanfranco* 127

Luteinizing Hormone (LH) *Livio Casarini, Daniele Santi, Gary R Marshall, and Manuela Simoni* 142

Follicle-Stimulating Hormone (FSH) *Daniele Santi, Livio Casarini, Gary R Marshall, and Manuela Simoni* 149

Prolactin: Regulation of Secretion and Action *Filippo Maffezzoni, Gherardo Mazziotti, and Andrea Giustina* 157

Molecular Pathogenesis of Pituitary Tumors *Shereen Ezzat and Sylvia L Asa* 165

Classification of Pituitary Neuroendocrine Tumors (PitNets) *Jacqueline Trouillas, Alexandre Vasiljevic, Emmanuel Jouanneau, and Gérald Raverot* 176

Genetic Causes of Familial Pituitary Tumors *Maria Manuel Costa and Márta Korbonits* 185

Clinical Features of Acromegaly *I Ilie and M Korbonits* 212

Diagnosis of Acromegaly *I Ilie and M Korbonits* 223

Therapy for Acromegaly *Philippe Chanson* 230

ACTH-Secreting Pituitary Tumors *Rosario Pivonello, Maria Cristina De Martino, Davide Iacuaniello, Chiara Simeoli, and Annamaria Colao* 248

TSH-Secreting Pituitary Adenomas *Olympia Koulouri and Mark Gurnell* 261

Surgery for Pituitary Tumors *Pamela Jones and Brooke Swearingen* 267

Clinical Features, Diagnosis, and Management of Nonfunctioning Tumors of Pituitary *Athanasios Fountas and Niki Karavitaki* 271

Surgical Treatment of Nonfunctioning Pituitary Tumors *Michael Buchfelder and Yining Zhao* 281

Pituitary Radiotherapy *Frederic Castinetti and Thierry Brue* 289

Diagnosis and Clinical Management of Aggressive Pituitary Tumors *Gerald Raverot, Emmanuel Jouanneau, and Jacqueline Trouillas* 294

Hypopituitarism, Causes, Diagnosis, Management and Mortality *Athanasios Fountas and Niki Karavitaki* 301

Diagnosis of Prolactinoma and Causes of Hyperprolactinemia *James Ahlquist* 314

Prolactinomas: Clinical Manifestations and Therapy *Anna Scholz and Dafydd Aled Rees* 319

Hypophysitis *Federica Guaraldi, Olivera Casar-Borota, and Marie-Lise Jaffrain-Rea* 325

Radiology of the Pituitary *Jane Evanson* 339

Hyponatraemia *Aoife Garrahy and Christopher J Thompson* 349

Pituitary Disorders Following Traumatic Brain Injury *Anne Marie Hannon and Christopher J Thompson* 365

Female Reproduction

Folliculogenesis *Danielle Monniaux, Véronique Cadoret, Frédérique Clément, Rozenn Dalbies-Tran, Sébastien Elis, Stéphane Fabre, Virginie Maillard, Philippe Monget, and Svetlana Uzbekova* 377

Human Menstrual Cycle *Sophie Christin-Maitre* 399

Implantation *Lechosław T Putowski and M Nowak* 404

Pregnancy Endocrinology *Stefano Palomba and Jessica Daolio* 408

Placental Epigenetics and Outcomes in Children *Patricia Fauque* 418

Endocrinology of Delivery *Silvia Vannuccini and Felice Petraglia* 425

Premenstrual Syndrome (PMS) *M Link* 432

Amenorrhea *Sophie Christin-Maitre* 436

Congenital Hypogonadotropic Hypogonadism in Females *Jacques Young* 439

Functional Hypothalamic Amenorrhea *Sarah L Berga* 444

Polycystic Ovary Syndrome *Stephen Franks* 451

Polycystic Ovary Syndrome: Implications for Cardiovascular, Endometrial, and Breast Disease *HF Escobar-Morreale* 456

Ovarian Androgen-Producing Tumors *Michael DiMattina and Callum Potts* 458

Sport and Menses *Angelica Lindén Hirschberg* 461

Primary Ovarian Insufficiency *Luca Persani* 471

Adult Care of Turner Syndrome *Claus H Gravholt, Mette Viuff, Kirstine Stochholm, and Niels H Andersen* 482

Initial Evaluation of the Infertile Couple *Jean-Marie Antoine and Jacqueline Mandelbaum* 490

Endometriosis *Alain Audebert* 498

Epigenetics of Endometriosis *Daniel Vaiman* 506

Uterine Fibroids and Infertility *Jacques Donnez, Olivier Donnez, Pablo Arriagada, and Marie-Madeleine Dolmans* 513

Environmental Factors and Female Reproduction *Patrick Fénichel and Charlotte Rougier* 525

Miscarriages *Hervé Fernandez and Perrine Capmas* 538

Obesity and Reproduction *Andrés E Ortiz-Flores and Héctor F Escobar-Morreale* 543

Developmental Epigenetics and the Contribution of Parental Diet to Offspring Outcomes *Oliver J Rando and Rebecca A Simmons* 553

Anti-Müllerian Hormone (AMH) in Adults *Agathe Dumont, Geoffroy Robin, Sophie Catteau-Jonard, and Didier Dewailly* 556

Ovarian Stimulation with Clomiphene Citrate *J Gianfortoni* 567

Ovulation Induction With Gonadotropins *Aude Bruyneel, Ralph Papas, and Anne Delbaere* 570

Ovarian Hyperstimulation Syndrome *Basil C Tarlatzis, Julia K Bosdou, and Efstratios M Kolibianakis* 581

Fertility and Pregnancy in Patients With 21-Hydroxylase Deficiency *Virginie Grouthier, Carine Courtillot, Jérôme Dulon, Philippe Touraine, and Anne Bachelot* 588

In Vitro Fertilization (IVF) *Renato Fanchin* 595

Ovarian Failure Treatment Strategies: Egg Donation *Pedro N Barri* 599

Fertility Preservation in Women *Julie Benard, Alexandra Benoit, Charlotte Sonigo, and Michael Grynberg* 603

Female Hormonal Contraception *Genevieve Plu-Bureau* 615

Progesterone Receptor Modulators: Current Applications and Perspectives *Kamila Kolanska, Axelle Pintiaux, Philippe Bouchard, Emile Daraï, and Nathalie Chabbert-Buffet* 622

Diagnosis of Menopause *Tommaso Simoncini, Marta Caretto, Andrea Giannini, and Andrea R Genazzani* 628

Menopausal Treatment *Anne Gompel* 634

Hormonal Treatment of Breast Cancer *Stéphanie Bécourt and Marc Espié* 646

Hormonal Treatment of Male to Female Transgender *Alessandra D Fisher and Louis Gooren* 656

Male Reproduction

Testes Embryology: Cellular Molecular Changes *T Svingen and LJ Pelliniemi* 664

Spermatogonial Physiology and Regulation of the Niche *Stefan Schlatt and Swati Sharma* 670

Male Germ Cell Differentiation *My-Thanh Beedle and Michael D Griswold* 678

Endocrine Control of Spermatogenesis *TM Plant, S Ramaswamy, and Karel De Gendt* 684

Gonadotropin-Releasing Hormone (GnRH) Development and Actions *Margaret E Wierman* 692

Genes and Gene Defects Affecting Gonadal Development and Sex Determination *Dagmar Wilhelm and Stefan Bagheri-Fam* 695

Mutations of the Gonadotropin-Releasing Hormone Receptor Gene *Alfredo Ulloa-Aguirre, Teresa Zariñán, and Saúl Lira-Albarran* 704

Androgen Biosynthesis and Gene Defects *Adina F Turcu and Richard J Auchus* 713

Reproductive and Nonreproductive Actions of Testosterone *Shalender Bhasin and Ravi Jasuja* 721

Hormone Replacement Therapy in Men *Cindy Pham, Christina Wang, and Ronald S Swerdloff* 735

Male Hormonal Contraception *Brian T Nguyen, Ronald S Swerdloff, Frederick CW Wu, and Christina Wang* 741
Estrogen and the Male *Agnė Kadusauskienė and Jonas Čeponis* 751
Gynecomastia *Glenn D Braunstein* 763
Male Sexual Dysfunction *Amarnath Rambhatla and Jacob Rajfer* 767
Androgens and Benign Prostatic Hyperplasia *Maritza Farrant and Stephanie T Page* 775
Prostate Cancer *Timothy McClure, Spyridon P Basourakos, Jaspreet S Sandhu, Peter N Schlegel, and James J Colt* 784
Insulin-Like Peptide 3 (INSL3) *Ravinder Anand-Ivell and Richard Ivell* 793
Epididymis *Maria Christina W Avellar and Barry T Hinton* 807
Fertility in Men With Spermatogenesis Abnormalities *Katherine Rotker and Mark Sigman* 814
Genetics of Male Infertility *Csilla Krausz and Francesca Cioppi* 821
Testicular Tumors *Ewa Rajpert-De Meyts* 831
Male Oncoinfertility *Bernard Robaire and Peter T Chan* 840

VOLUME 3 – Adrenal Glands and Hypertension

Adrenal Glands and Hypertension

Adrenal Cortex; Physiology *Fady Hannah-Shmouni and Christian A Koch* 1
Adrenal Cortex; Development *Typhanie Dumontet and Antoine Martinez* 8
Corticotropin-Releasing Hormone Peptide Family *David W Hogg, Mia Husic, and David A Lovejoy* 16
Regulation of POMC and ACTH Secretion *Dongyun Zhang and Anthony P Heaney* 27
ACTH, Melanocortin Receptors, and MRAP Accessory Proteins *Robert M Dores* 38
Adrenocorticotropic Hormone (ACTH): Physiology and Its Involvement in Pathophysiology *George Mastorakos and Athanasios Antoniou-Tsigkos* 48
Adrenal Steroidogenesis *Daniel B Martinez-Arguelles and Vassilios Papadopoulos* 56
Overview of Glucocorticoids *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 64
Stress and Endocrine Physiology *Nicolas C Nicolaides, Panagiota Pervanidou, and George P Chrousos* 72
Hypothalamic–Pituitary–Adrenal Suppression *Nicolas C Nicolaides and George P Chrousos* 83
Glucocorticoid Metabolism and Activation *Nantia Othonos and Jeremy Tomlinson* 90
Glucocorticoid Receptor *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 104
Glucocorticoids and Immunity *Karen E Chapman* 112
Corticotropin-Releasing Hormone and Inflammation *Markella Nezi, Evangelia Zapanti, and George Mastorakos* 121
Adrenal Insufficiency: Etiology and Diagnosis *Nicolas C Nicolaides and Evangelia Charmandari* 131
Primary Adrenal Hypoplasia and ACTH Resistance Syndromes *Ioannis Kyrou and Constantine Tsigos* 139
Impact of Glucocorticoid Receptor Polymorphisms on Glucocorticoid Action *Mesut Savas and Elisabeth FC van Rossum* 147

Glucocorticoid Resistance Syndromes and States *Nicolas C Nicolaides and George P Chrousos* 157

X-Linked Adrenoleukodystrophy/Adrenomyeloneuropathy *William B Rizzo* 166

Steroid Replacement in Adrenal Insufficiency *Joanne C Blair, Miguel Debono, and Richard Ross* 172

Management of Adult Patients With Congenital Adrenal Hyperplasia Due to 21-Hydroxylase Deficiency *Virginie Grouthier, Jérôme Dulon, Anne Bachelot, and Philippe Touraine* 185

Cushing Syndrome; Screening and Differential Diagnosis *André Lacroix and Lynnette K Nieman* 193

Molecular Genetics of Cushing Disease *Martin Reincke, Marily Theodoropoulou, and Adriana Albani* 205

Pituitary Surgery for Cushing Disease *Pamela Jones and Brooke Swearingen* 215

Evaluation and Follow-Up of Patients With Cushing Disease After Pituitary Surgery *Amandine Ferriere, Claire Cordroch, and Antoine Tabarin* 223

Medical Therapy of Hypercortisolism *Richard A Feelders* 232

Radiation Therapy in Patients With Cushing Disease *Nicholas A Tritos, Jay S Loeffler, and Beverly MK Biller* 237

Bilateral Adrenalectomy for Cushing Disease *Frederic Castinetti* 243

Cushing Syndrome—Unilateral Adrenal Adenoma *Guido Di Dalmazi* 249

Somatic β-Catenin Gene Mutations and WNT Signaling in Adrenal Tumors *Isabelle Bourdeau* 259

Adrenocortical Tumors and *gsp* Mutations *Maria Candida Barisson Villares Fragoso, Isadora Pontes Cavalcante, Leonardo Tadeu Araujo, Helaine Laiz Silva Charchar, Ingrid Quevedo Wanichi, Vania Balderrama, Amanda Meneses Ferreira, and Beatriz Marinho de Paula Mariani* 266

PPNAD, Carney Complex, and Other Micronodular Adrenal Hyperplasia *Stéphanie Espiard and Jérôme Bertherat* 271

Genetics of Familial Forms of Cortisol-Secreting Adrenal Tumors and Hyperplasias *Ludivine Drougat and Constantine A Stratakis* 283

Primary Bilateral Macronodular Adrenal Hyperplasia *André Lacroix* 293

Adrenal Incidentalomas *Massimo Terzolo, Soraya Puglisi, and Giuseppe Reimondo* 303

Adrenocortical Carcinoma: Diagnosis and Therapy *Massimo Terzolo, Soraya Puglisi, Paola Perotti, Mélanie Claps, Elisa Roca, and Alfredo Berruti* 308

Adrenocortical Carcinoma: Genetics and Molecular Markers *Anne Jouinot and Guillaume Assié* 317

Adrenal Surgery *Pavel Nockel, Mustapha El Lakis, and Electron Kebebew* 323

Long-Term Complications of Hypercortisolism *Rosario Pivonello, Davide Iacuaniello, Chiara Simeoli, Maria Cristina De Martino, and Annamaria Colao* 341

Effects of Glucocorticoids on the Brain *Alberto M Pereira, Susan M Webb, and Onno C Meijer* 360

Hypertension; Overview *Morton P Printz and Rebecca L Jaworski* 369

Neurogenic Hypertension *Gino Seravalle, Guido Grassi, and Giuseppe Mancia* 381

Renal Hypertension *Daniele Cusi* 383

Endocrine Hypertension *Inga Harbuz-Miller, Ryan Woodman, and Guido Lastra* 390

Resistant Hypertension *Robert M Carey* 402

Hypertension and Target Organ Damage *Maria Lorenza Muiesan, Anna Paini, Claudia Agabiti Rosei, Fabio Bertacchini, Carlo Aggiusti, Carolina De Ciuceis Damiano Rizzoni, and Massimo Salvetti* 406

Stroke *PCAJ Vroomen and GA Donnan* 415

Normetanephrine and Metanephrine *Jacques WM Lenders and Graeme Eisenhofer* 420

Adrenergic Mechanisms *Peter W de Leeuw and Abraham A Kroon* 425

Novel Insights in β-Adrenergic Receptor Signaling *Guido Iaccarino and Daniela Sorriento* 432

Baroreceptor Responses *AF Sved, EM Stricker, and SD Stocker* 440

Antiadrenergic Agents *Enrico Agabiti-Rosei* 443

Pheochromocytoma and Paraganglioma Syndromes *Vitaly Kantorovich and Karel Pacak* 449

Pheochromocytoma/Paraganglioma: Diagnosis and Treatment *Maurizio Castellano, Mara Giacchè, Luigi Mori, Alessandra Panarotto, and Carlo Cappelli* 455

Malignant Pheochromocytoma *Massimo Mannelli, Gabriele Parenti, Letizia Canu, Giuseppina De Filpo, and Elena Rapizzi* 460

Pheochromocytoma/Paraganglioma: Management, Genetics, and Follow-up *Anne-Paule Gimenez-Roqueplo and Laurence Amar* 469

Renin and Prorenin *Alberto Morganti* 478

Angiotensinogen and Angiotensins *Massimo Volpe and Speranza Rubattu* 483

Kininases *Randal A Skidgel, Ervin G Erdös, and Peter A Deddish* 490

Tissue Ace–Angiotensin–AT_1 Receptor Axis and Repair in the Heart *Yao Sun and Karl T Weber* 497

Hypertension and the Renin–Angiotensin–Aldosterone System *Elena Kaschina, Ulrike M Steckelings, and Thomas Unger* 505

Hyperreninemia *Pierre-François Plouin, Laurence Amar, and Michel Azizi* 511

Renal Vein Renin Measurement as a Diagnostic Tool *Gian Paolo Rossi* 516

Interference With the Renin–Angiotensin System (RAS): Classical Inhibitors and Novel Approaches *Katrina M Mirabito Colafella, Estrellita Uijl, and AH Jan Danser* 523

Aldosterone; Synthesis and Metabolism *John W Honour* 531

Aldosterone; Action and Function *Peter J Fuller and Morag J Young* 540

Aldosterone Receptors *Say Viengchareun, Marc Lombès, and Laetitia Martinerie* 546

Regulation of Potassium Homeostasis *Paola Russo, Fabio Lauria, and Alfonso Siani* 552

Salt-Sensitivity of Blood Pressure *Pasquale Strazzullo, Ferruccio Galletti, and Lanfranco D'Elia* 558

Endogenous Ouabain *Paolo Manunta and Marco Simonini* 564

Atrial Natriuretic Factor and the Family of Natriuretic Peptides *Tsuneo Ogawa and Adolfo J de Bold* 569

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Pathophysiology *John W Funder* 581

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Clinical Aspects *Ellen Marie Freel* 586

Primary Aldosteronism; Epidemiology and Screening *Michael Stowasser* 598

Primary Aldosteronism; Diagnosis and Treatment *Franco Mantero and Maria Verena Cicala* 607

Adrenal Venous Sampling for Primary Aldosteronism *Gian Paolo Rossi* 613

Genetics of Familial Hyperaldosteronism *Silvia Monticone, Martina Tetti, Isabel Losano, Franco Veglio, and Paolo Mulatero* 623

Aldosterone-Producing Adenomas; Genetics *Livia Lenzini, Sofia Zanin, and Gian Paolo Rossi* 631

Apparent Mineralocorticoid Excess *Padiporn Limumpornpetch and Paul M Stewart* 638

Licorice and 11β-Hydroxysteroid Dehydrogenase *Decio Armanini and Chiara Sabbadin* 644

Liddle Syndrome *Ermanno Rossi and Giovanni Maria Rossi* 652

Secondary Hyperaldosteronism *Aleksander Prejbisz and Andrzej Januszewicz* 664

Aldosteronism in Congestive Heart Failure *Yenal I Harper, Oluwaseun A Akinseye, Salem A Salem, Muhammad Shahreyar, and Karl T Weber* 668
Mineralocorticoid Receptor Antagonists *John W Funder* 674
Diuretics *Claudio Ferri and Rita Del Pinto* 681
Calcium Channel Blockers *Stefano Taddei and Rosa Maria Bruno* 689
Pseudohypoaldosteronism Type 1 *Fabio L Fernandes-Rosa* 696
Hyporeninemic Hypoaldosteronism *Shrey Purohit, Dalila B Corry, and Michael L Tuck* 703
Bartter and Gitelman Syndromes *Lorenzo A Calò and Verdiana Ravarotto* 714
Angiogenesis *Lindsay S Cooley and Andreas Bikfalvi* 722

VOLUME 4 – Calcium and Bone, and Thyroid Gland

Calcium and Bone

Bone Cells: Osteoblast/Osteoclast/Osteocyte *Nadia Rucci and Anna Teti* 1
Bone Remodeling *Susan M Ott* 10
Bone Structure and Biomechanics *Fjola Johannesdottir and Mary L Bouxsein* 19
Bone and Bone Marrow; Interactions *Delphine Spruyt, Céline Gillet, and Joanne Rasschaert* 31
Bone Muscle Interactions and Exercise *Jenny E Gunton* 40
Bone as an Endocrine Organ *Gerard Karsenty and Stavroula Kousteni* 47
Calcium Homeostasis in Humans *Roger Bouillon* 52
Calcium-Sensing Receptor *Giuseppe Vezzoli, Teresa Arcidiacono, Lorenza Macrina, Katia Maruca, and Stefano Mora* 58
Phosphate Metabolism, Hyperphosphatemia, and Hypophosphatemia *Seiji Fukumoto* 68
Vitamin D *Ian R Reid* 75
Nutrition and Bone *Peter Burckhardt* 82
Bone Development During Childhood and Adolescence: Peak Bone Mass *Jean De Schepper* 89
Bone Mass Measurement *Paul D Miller and Pierre JM Bergmann* 94
X-Ray Based Imaging Methods to Assess Bone Quality *Klaus Engelke* 102
Bone Turnover Markers *Etienne Cavalier, Richard Eastell, Niklas Rye Jørgensen, Konstantinos Makris, Samuel Vasikaran, and Howard A Morris* 116
Primary Hyperparathyroidism *Claudio Marcocci and Filomena Cetani* 128
Parathyroid Cancer *D Fink and Elizabeth Shane* 139
Parathyroid Surgery *EF Garner and H Chen* 151
Hypercalcemia: Other Causes than Primary Hyperparathyroidism *René Rizzoli* 160
Parathyroid Hormone Related Protein (PTHrP) *Archana Kamalakar, Charity L Washam, and Larry J Suva* 168
Physiology of Calcitonin and Its Therapeutic Uses *Sunil J Wimalawansa* 178
Hypoparathyroidism and Other Causes of Hypocalcemia *Bart L Clarke* 192
Calcitonin Gene-Related Peptide (CGRP) *AA Aubdool, X Kodji, and SD Brain* 204

Epidemiology of Fractures *Nicholas R Fuggle, Elaine M Dennison, and Cyrus Cooper* 213
Pathogenesis of Osteoporosis *Emma O Billington and Ian R Reid* 222
Role of Estrogens and Androgens in Osteoporosis *Michaël R Laurent* 233
Osteoporosis in Premenopausal Women *Serge Rozenberg* 246
Secondary Osteoporosis *Gregory R Emkey* 253
Osteoporosis; Prevention and Ca–Vitamin D Treatment *Bo Abrahamsen* 270
Osteoporosis Treatment: Bone-Forming Agents *Bente L Langdahl* 275
Osteoporosis Treatment: Sequential and Combination Therapy *Benjamin Z Leder and Joy N Tsai* 281
Osteoporosis: Treatment Gaps and Health Economics *Nicholas CW Harvey, Eugene V McCloskey, René Rizzoli, John A Kanis, Cyrus Cooper, and Jean-Yves Reginster* 288
Cancer Treatment-Induced Bone Loss (CTIBL) *Catarina Abreu, Maria R Dionísio, Joana C Silva, and Luís Costa* 296
Bone Metastases; Basic Aspects *Margaux Bernard, Paola Di Mauro, Caroline Reynaud, Chantal Diaz-Latoud, and Philippe Clézardin* 304
Bone Metastases; Clinical Aspects *Steven Wood, Azeez Salawu, Helen Kroening, Stella D'Oronzo, and Janet Brown* 310
Bone Metastases; Medical Treatment *Robert Coleman* 320
Multiple Myeloma Bone Disease *Evangelos Terpos and Maria Gavriatopoulou* 329
Diabetes and Bone *Peter Vestergaard* 341
Paget Disease of Bone *Stuart H Ralston* 350
Heterotopic Ossification and Calcification *Chen Kan, Na Ding, and Lixin Kan* 356
Kidney Stones *S Dizon, EA Iliescu, and A Ross Morton* 365
Pseudohypoparathyroid States *A Tsatsoulis, A Fountas, and E Laspa* 372

Thyroid Gland

Thyroid Gland: Anatomy and Physiology *Salvatore Benvenga, Giovanni Tuccari, Antonio Ieni, and Roberto Vita* 382
Thyroid Gland Development, Molecular Biology *Marina Muzza and Laura Fugazzola* 391
Hypothalamus–Pituitary–Thyroid Axis *Marco Bonomi, Biagio Cangiano, and Luca Persani* 398
Thyroid-Stimulating Hormone (TSH; Thyroptopin) *Leonidas H Duntas* 403
TSH Function and Secretion *Susan R Rose and Janet S Chuang* 408
TSH (Thyrotropin) Receptor *Yuji Nagayama* 416
Thyroid Hormone Metabolism *Josef Köhrle* 420
Sodium/Iodide Symporter (NIS) *Nancy Carrasco and Rachel R Kaspari* 429
Thyroid Peroxidase *Salvatore Benvenga and Roberto Vita* 433
Thyroglobulin *Marina Muzza and Laura Fugazzola* 439
Serum Thyroid Hormone-Binding Proteins *Luigi Bartalena and Eliana Piantanida* 442
Thyroid Hormone Receptors *Claire Briet, Frédéric Illouz, and Patrice Rodien* 448
Thyroid Hormone Action *Yui Watanabe and Roy E Weiss* 452
Resistance to Thyroid Hormone *Gisah Amaral de Carvalho, Tayane Muniz Fighera, and Roy E Weiss* 463

TSH-Producing Adenomas and Resistance to Thyroid Hormones *P Beck-Peccoz, L Persani, and A Lania* 473
Thyroid Function Tests *ER Christ and Albert G Burger* 477
Epidemiology of Thyroid Disease *Mark PJ Vanderpump* 486
Genetic Factors in Thyroid Disease *Marina Muzza and Laura Fugazzola* 496
Environmental Goitrogens *Veena Agrawal, Sana A Ghaznavi, and Ralf Paschke* 506
Iodine Deficiency *Peter Taylor, Onyebuchi Okosieme, Lakdasa Premawardhana, and John H Lazarus* 512
Nontoxic Goiter *Sana Ghaznavi, Kirstie Lithgow, Veena Agrawal, and Ralf Paschke* 524

Corticotropin-Releasing Hormone (CRH)

Nicolas C Nicolaides and George P Chrousos, National and Kapodistrian University of Athens Medical School, Athens, Greece and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Nomenclature

ACTH	Adrenocorticotropic hormone
AVP	Arginine vasopressin
CBP	CREB-binding protein
CRH	Corticotropin-releasing hormone
CRH-R	Corticotropin-releasing hormone receptor
DHEA	Dehydroepiandrosterone
HDAC1	Histone deacetylase-1
HPA axis	Hypothalamic–pituitary–adrenal axis
IL-6	Interleukin-6
MSH	Melanocyte-stimulating hormone
NF-κB	Nuclear factor kappa b
PACAP	Pituitary adenylate cyclase activating polypeptide
PVN	Paraventricular nucleus
POMC	Proopiomelanocortin
sAC	Soluble adenylyl cyclase

Glossary

Hypothalamic–pituitary–adrenal axis A set of stimulating and inhibitory signals between the hypothalamus, the anterior lobe of pituitary gland, and the adrenal cortex.

Receptor Protein molecules on the cell surface or inside the cell that recognizes a specific ligand or hormone.

Introduction

A hypothalamic factor that increases adrenocorticotropic hormone (ACTH) release from pituitary cells was discovered as an active principle in 1955 (Guillemin and Rosenberg, 1955; Saffran and Schally, 1955). In 1981, ovine corticotropin-releasing hormone (CRH) was isolated and sequenced (Vale *et al.*, 1981). Subsequently, a small peptide was isolated from rat hypothalami and was found to have 83% sequence homology to ovine CRH. Finally, 2 years later, the human CRH was identified with identical sequence to that of rat CRH (Rivier *et al.*, 1983; Vale *et al.*, 1983a,b).

CRH is a 41-amino acid peptide that is the major physiologic ACTH secretagogue (Rivier *et al.*, 1982; Vale *et al.*, 1983a,b). There is considerable sequence homology of CRH among species, particularly in the amino-terminal region, which is required for biologic activity. CRH belongs to a family of peptides that includes the nonmammalian sauvagine and urotensin I, the mammalian urocortins 1, 2 (stresscopin-related peptide, SRP) and 3 (stresscopin, SCP), the last three of which also are found in humans (**Fig. 1**) (Spiess *et al.*, 1981; Lederis, 1987; Donaldson *et al.*, 1996). All of these peptides have activities similar to but also distinct from those of CRH (Lederis, 1987).

CRH is processed from a prepro-CRH molecule (196 amino acids in humans) from which it is cleaved at flanking basic amino acid pairs (Shibahara *et al.*, 1983). The single human CRH gene is located on chromosome 8 (Arbiser *et al.*, 1988), those of human urocortins 1, 2, and 3 on chromosomes 2, 3 and 10, respectively (Donaldson *et al.*, 1996).

Synthesis, Regulation of Secretion, and Distribution of CRH

CRH is synthesized by neurons in the parvocellular (small cell) division of the hypothalamic paraventricular nuclei (PVN) (Swanson *et al.*, 1983). Their axons project to the median eminence, where CRH is secreted into the hypophysial portal blood. These neurons may also contain other ACTH secretagogues (e.g., arginine vasopressin (Kiss *et al.*, 1984) and cholecystokinin (Mezey *et al.*, 1986)), opioid peptides (e.g., met-enkephalin (Hökfelt *et al.*, 1983) and dynorphin-1-8 (Roth *et al.*, 1983)), and PHI-27, a prolactin secretagogue (Hökfelt *et al.*, 1983), particularly after adrenalectomy. In addition, CRH is synthesized by anterior pituitary corticotrophs and acts in an autocrine or paracrine manner to stimulate ACTH secretion (Giraldi and Cavagnini, 1998).

Hypothalamic CRH secretion is regulated by inputs from higher centers and is mainly influenced by the circadian pacemaker, stress and glucocorticoid negative feedback (**Fig. 2**). Glucocorticoid negative feedback inhibition occurs at both the pituitary and hypothalamic levels, and perhaps at higher centers, such as the hippocampus. Interestingly, at the level of the central nucleus of the amygdala, glucocorticoids stimulate rather than inhibit CRH secretion (Makino *et al.*, 1994). Although, in the anterior pituitary, glucocorticoids inhibit both ACTH secretion and POMC gene transcription (Lundblad and Roberts, 1988), these hormones decrease—to a lesser extent—CRH mRNA and peptide levels in the hypothalamic paraventricular nuclei (Davis *et al.*, 1986; Itoi *et al.*, 1987; Beyer *et al.*, 1988; Kageyama and Suda, 2009). Glucocorticoids also block the stimulatory effect of CRH on POMC gene transcription (Eberwine *et al.*, 1987) and acute ACTH release (Oki *et al.*, 1991), and inhibit anterior pituitary CRH receptor expression (Holmes *et al.*, 1987; Luo *et al.*, 1995). *CRH* gene expression is also influenced by several other factors. Pituitary adenylate cyclase activating polypeptide (PACAP) was demonstrated to increase CRH mRNA levels in the parvocellular region of the hypothalamic PVN. Moreover, interleukin (IL)-6, produced in the PVN, influences *CRH* gene expression in a direct and indirect fashion. Indeed, IL-6 stimulates directly the expression of CRH, while it is also involved in the PACAP-induced *CRH* gene transcription in an autocrine fashion (Nezi *et al.*, 2000–2015). Moreover, estradiol was found to increase the expression of CRH in response to stress (Kageyama and Suda, 2009). Furthermore, leptin, which inhibits adrenal glucocorticoid biosynthesis, may also

inhibit CRH secretion (Cherradi *et al.*, 2001). Since glucocorticoids stimulate leptin secretion, this may represent another feedback loop regulating hypothalamic–pituitary–adrenal function.

CRH is also present in some oxytocin-containing neurons in the magnocellular (large cell) division of the paraventricular nuclei that project to the posterior pituitary (Sawchenko *et al.*, 1984). In addition, CRH is widely distributed throughout the brain and spinal cord (Swanson *et al.*, 1983; Olschowka *et al.*, 1982) and in peripheral tissues, such as the adrenal medulla (Nicholson *et al.*, 1987), testis (Yoon *et al.*, 1988), ovaries (Mastorakos *et al.*, 1993), gastrointestinal tract (Nieuwenhuyzen Kruseman *et al.*, 1984; Suda *et al.*, 1984), pancreas (Petrusz *et al.*, 1983), skin (Slominski *et al.*, 2001), myometrium (Clifton *et al.*, 1998), endometrium (Di Blasio *et al.*, 1997), placenta (Grino *et al.*, 1987) and in inflammatory sites (Chrousos, 1995; Mastorakos *et al.*, 1994, 1995).

The presence of CRH and its two receptor types CRHR1 and CRHR2 (De Souza, 1987; Chen *et al.*, 1993; Potter *et al.*, 1994; Stenzel *et al.*, 1995) in the brain suggests that CRH functions as a neuromodulator. CRH also may have local autocrine or paracrine regulatory actions in other tissues. As an example, CRH inhibits chorionic gonadotropin-stimulated androgen production by the testis (Ulisse *et al.*, 1989) and facilitates embryo implantation in the endometrium. Furthermore, CRH may act as a hormone in the hypophysial portal system and as a systemic hormone in the pregnant woman (Makrigiannakis *et al.*, 2001).

Mechanism of Action

The pleiotropic biological effects of CRH are mediated by binding to both type 1 (a, b, c, d, e, f, g, h) and type 2-alpha, -beta, and -gamma CRH receptors and CRH-binding protein (Stenzel *et al.*, 1995; Lovenberg *et al.*, 1995; Potter *et al.*, 1992; Woods *et al.*, 1996; Kostich *et al.*, 1998). CRH-R2 are splice isoforms that differ in their amino-terminal sequences, tissue distribution, pharmacology (i.e., their relative affinities for CRH, sauvagine, urotensin, and the urocortins), and, presumably, their function (Hauger *et al.*, 2006). CRH-R2-beta and gamma are most abundantly expressed in the limbic system, for example, which suggests they may mediate the behavioral effects of CRH and the urocortins (Kostich *et al.*, 1998). CRH-R1 and CRH-R2 are members of the class B family of G-protein coupled receptors (Perrin and Vale, 1999). The *CRH-R1* gene is located on human chromosome 17q21, while the *CRH-R2* gene on human chromosome 7p14 (Vamvakopoulos and Sioutopoulou, 1994; Nezi *et al.*, 2000–2015).

CRH acts on the anterior pituitary corticotrophs by binding to CRH-R1 cell-surface receptors (Chen *et al.*, 1993; Millan *et al.*, 1987) and activating adenylyl cyclase, thereby increasing intracellular cAMP concentrations. Cyclic AMP activates cAMP-dependent protein kinase A, increasing the influx of extracellular calcium via L-type calcium channels and the production of lipoxygenase metabolites of arachidonic acid (Giguère *et al.*, 1982; Won and Orth, 1990, 1994; Oki *et al.*, 1991). This results in secretion of ACTH and other proopiomelanocortin (POMC)-derived peptides (Watanabe and Orth, 1987) and later in increased POMC gene transcription and POMC biosynthesis (Lundblad and Roberts, 1988). Although CRH-R1 activation results in increased levels of cAMP, the activated downstream effector molecules and the time course of the molecular response vary depending on the cell type. Interestingly, in hippocampal neurons and fibroblast-derived cell lines, the cAMP response may be sustained, whereas this signaling response may be transient in corticotroph cells (Inda *et al.*, 2017).

Research progress in CRH signaling has revealed an important role of β-arrestins in CRH-R internalization and termination of signaling. CRH-bound CRH-R1 was demonstrated to bind to both β-arrestin-1 and β-arrestin-2 (Oakley *et al.*, 2007), whereas activated CRH-R2 was shown to preferentially recruit β-arrestin-2 (Markovic *et al.*, 2008). In addition, accumulating evidence suggests that CRH-R1 continues to signal once internalized in endosomes, possibly through the newly identified soluble adenylyl cyclase (sAC) and/or the intracellular β-arrestin (reviewed in Inda *et al.*, 2017).

Chronic CRH stimulation causes corticotroph hyperplasia (Gertz *et al.*, 1987). Corticotroph CRH receptor number may modulate the ACTH response. CRH receptor messenger RNA and number are transiently reduced in the anterior pituitary, but not in the brain, by the administration of CRH and arginine vasopressin (AVP), whose effects are additive, by immobilization stress, and by adrenalectomy (Wynn *et al.*, 1985, 1988; Hauger *et al.*, 1987, 1988; Holmes *et al.*, 1987; Hauger and Aguilera, 1993; Pozzoli *et al.*, 1996).

The effects of adrenalectomy appear to be mediated at least in part by increased hypothalamic AVP and CRH secretion and are reversed by replacement doses of glucocorticoids. However, high doses of glucocorticoids suppress pituitary CRH receptor messenger RNA and number. These complex effects on pituitary CRH receptor expression help modulate the plasma ACTH response to stress on the one hand or adrenal insufficiency on the other.

CRH also stimulates pituitary intermediate lobe melanotrophs to synthesize POMC mRNA (Loeffler *et al.*, 1985) and secrete alpha-melanocyte-stimulating hormone (MSH) (Proulx-Ferland *et al.*, 1982).

CRH in Plasma

The contribution of hypothalamic CRH to peripheral plasma CRH concentrations is small; most of the plasma CRH presumably comes from nonhypothalamic sources (Orth, 1992; Sasaki *et al.*, 1987a,b; Bruhn *et al.*, 1987; Cunnah *et al.*, 1987). However, under certain circumstances, such as insulin-induced hypoglycemia or during major surgery, small increments in plasma CRH concentrations may reflect hypothalamic CRH release (Ellis *et al.*, 1990). Plasma CRH concentrations increase markedly during the third trimester in pregnant women because the placenta secretes CRH (Sasaki *et al.*, 1987a,b; Campbell *et al.*, 1987).

Binding Protein

CRH circulates in human plasma bound to a high-affinity binding protein (Orth and Mount, 1987; Potter *et al.*, 1991), which reduces its bioactivity and increases its clearance (Linton *et al.*, 1988). In women with complicated pregnancies, plasma CRH-binding protein concentrations may be reduced (Petraglia *et al.*, 1996) at the same time as plasma CRH concentrations are increased (Jeske *et al.*, 1990; Laatikainen *et al.*, 1991). Despite binding to this protein, the plasma half-life of CRH in humans is only 4 min (Schurmeyer *et al.*, 1984). A similar circulating binding protein has not been found in other species (Orth and Mount, 1987) except primates (Xu *et al.*, 2006).

Ovine CRH is used for most clinical studies because it does not bind to the binding protein (Orth and Mount, 1987), has a plasma half-life of 55 min and, consequently, a prolonged duration of action (Nicholson *et al.*, 1983; DeBold *et al.*, 1983). Thus, the specific binding of human CRH to CRH-binding protein may facilitate the removal of CRH from plasma (Woods *et al.*, 1994).

Effects on Pituitary Hormone Secretion

CRH increases the secretion of ACTH by the anterior lobe and of POMC-derived peptides by the intermediate lobe.

Anterior Lobe ACTH Secretion

Exogenously administered CRH produces a rapid, dose-dependent increase in plasma ACTH concentrations. This effect is specific; plasma concentrations of other anterior pituitary hormones, vasopressin, or catecholamines do not change (Schurmeyer *et al.*, 1984; Orth *et al.*, 1983). Human CRH is equipotent to ovine CRH, but because of its shorter circulating half-life, the duration of the elevation in plasma ACTH concentrations is shorter and the total amount of ACTH secreted is less (Schurmeyer *et al.*, 1984; Trainer *et al.*, 1995). However, the serum cortisol responses are similar because the plasma ACTH responses to both human and ovine CRH are maximally stimulatory for the adrenal cortex (Trainer *et al.*, 1995).

The ACTH released by CRH stimulates the secretion of cortisol and other adrenal steroids, such as dehydroepiandrosterone (DHEA) and, transiently, aldosterone (Conaglen *et al.*, 1984; Pavlov *et al.*, 1986). There is a very small if any sex or age difference in the plasma ACTH or serum cortisol response to CRH (Pavlov *et al.*, 1986; Sheldon Jr *et al.*, 1985; Ross *et al.*, 1986), but the serum DHEA response is reduced in elderly men and the serum cortisol response is blunted in obese subjects (Pavlov *et al.*, 1986; Kopelman *et al.*, 1988). As compared with white subjects, black subjects have greater plasma immunoreactive but not bioactive ACTH responses after CRH; as a result, the serum cortisol responses are similar in the two groups (Yanovski *et al.*, 1996).

The hour of day has little effect on the plasma ACTH response to CRH, but the response of serum cortisol is much greater in late afternoon or evening than in the morning (DeCherney *et al.*, 1985). In healthy persons a major factor influencing the magnitude of the plasma ACTH response to CRH is the serum cortisol concentration. The response to CRH varies inversely with the basal serum cortisol concentration (DeCherney *et al.*, 1985) due to glucocorticoid inhibition of CRH action on the corticotrophs (Vale *et al.*, 1983a, b). Thus, the ACTH response is increased during metyrapone-induced hypocortisolemia and reduced by glucocorticoid administration (DeBold *et al.*, 1989).

CRH-deficient knockout mice lack a normal diurnal serum corticosterone rhythm and have severely impaired adrenocortical response to stress (Muglia *et al.*, 2000). Pituitary POMC mRNA and ACTH levels and plasma ACTH concentrations are not increased. Pituitary POMC mRNA levels increase in adrenalectomized CRH-deficient mice, but plasma ACTH concentrations do not, indicating that CRH is required to stimulate ACTH release.

Intermediate Lobe POMC Peptide Secretion

A functional intermediate lobe exists only during fetal life and in late pregnancy in humans. Regulation of secretion of alpha-MSH, beta-endorphin (beta-END), and other POMC-derived peptides from the intermediate lobe differs from that in the anterior lobe. The secretion of these peptides is mainly under tonic inhibitory control by the hypothalamic neurotransmitter dopamine, and is not inhibited by glucocorticoids (Munemura *et al.*, 1980). Intermediate lobe hormone secretion is also inhibited by gamma-aminobutyric acid (GABA), another hypothalamic neurotransmitter (Tomiko *et al.*, 1983).

CRH and beta-adrenergic agonists stimulate alpha-MSH secretion through a cAMP-mediated mechanism, which is inhibited by dopamine. Dopamine also enhances the expression of intermediate lobe CRH receptors (Shiver *et al.*, 1992).

Extrapituitary Effects

CRH has several peripheral and central actions that may be mediated by binding to CRH-R1, CRH-R2 and CRH-binding protein (Stenzel *et al.*, 1995; Lovenberg *et al.*, 1995; Potter *et al.*, 1992; Woods *et al.*, 1996; Kostich *et al.*, 1998). Below, we discuss some representative examples of extrapituitary CRH effects:

- Increased activity of the hypothalamic–pituitary–adrenal axis may play a role in insomnia. Twenty-four-hour ACTH and cortisol secretion was increased in six young men and five young women with chronic insomnia (Vgontzas *et al.*, 2001a). The

greatest increase was during the evening and first half of the night. In 12 middle-aged men, intravenous CRH given after sleep onset caused more wakefulness and allowed less slow wave sleep than in young men (Vgontzas *et al.*, 2001b).

- Systemic administration of CRH causes mesenteric vasodilatation, which at high doses can result in hypotension and tachycardia (Orth *et al.*, 1983; Hermus *et al.*, 1987), and stimulates respiration through a central effect (Oppermann *et al.*, 1987).
- Intracerebroventricular injection of CRH activates the autonomic nervous system (Brown *et al.*, 1982), resulting in increased serum catecholamine, glucagon, and glucose concentrations, elevated blood pressure and heart rate, decreased gastric acid secretion (Lenz *et al.*, 1985) and behavioral changes in animals (Sutton *et al.*, 1982).
- CRH may modulate reproductive function, since it reduces sexual receptivity in female rats (Sirinathsinghji *et al.*, 1983), lowers serum luteinizing hormone concentrations by inhibiting the secretion of gonadotropin-releasing hormone (Petraglia *et al.*, 1987) and inhibits chorionic gonadotropin-stimulated testosterone production by cultured Leydig cells (Dufau *et al.*, 1989). In addition, CRH was demonstrated to promote blastocyst implantation and maintain early pregnancy by potentiating apoptosis of activated T-cells (Makrigiannakis *et al.*, 2001). A recent study examined human placental cytotrophoblasts and showed that glucocorticoids induces the expression of both CRH and COX-2, two key regulators of human parturition, through the noncanonical NF-κB pathway. The GR/RelB/p52 signaling crosstalk results in a dynamic histone 3 Lys9 acetylation and deacetylation (H3K9ac) of the *CRH* and *COX-2* gene promoters through recruitment of the histone acetyltransferase CREB-binding protein (CBP) and histone deacetylase-1 (HDAC1) (Di Stefano *et al.*, 2015; Zannas and Chrousos, 2015).
- CRH exerts multiple actions in gestation via binding to CRH type 1 receptors. It directly stimulates CRH-1 receptor synthesis and DHEA-S secretion by human fetal adrenocortical cells (Smith *et al.*, 1998; Sirianni *et al.*, 2005). It regulates placental blood flow and prostaglandin synthesis (Challis *et al.*, 1995), increases in myometrium during labor and potentiates oxytocin- and prostaglandin F2-alpha-induced myometrial contractility (Clifton *et al.*, 1998), and facilitates parturition (Challis *et al.*, 1995; Chang *et al.*, 1998).
- CRH and/or urocortin are secreted by a number of other peripheral tissues including spleen, thymus, synovial epithelial cells, inflammatory cells, and peripheral nerve endings and modulate the immune response via CRH type 1 and 2 receptors (Baigent, 2001; Jessop *et al.*, 2001; Radulovic and Spiess, 2001; McEvoy *et al.*, 2002). Urocortin, but not CRH, is present in gastric epithelial cells (Chatzaki *et al.*, 2003). Among their actions, CRH and urocortin modulate secretion of cytokines and proliferation of lymphocytes and macrophages and degranulation of mast cells (Radulovic and Spiess, 2001; Kempuraj *et al.*, 2004). CRH and urocortin also have potent cardiovascular actions (Parkes *et al.*, 2001).
- CRH and CRH-1 receptor are synthesized by human dermal fibroblasts and hair follicles; CRH and ACTH also stimulate cortisol production in the hair follicle and corticosterone production in dermal fibroblasts (Slominski *et al.*, 2005). CRH enhances lipid secretion from human sebocytes (Zouboulis *et al.*, 2002).
- CRH plays an important role in the initiation and and/or propagation of the local inflammatory response (Karalis *et al.*, 1991). In rats that were subcutaneously injected with carrageenan causing local aseptic inflammation, the intraperitoneal administration of rabbit antiserum to CRH resulted in suppression of the inflammatory process. CRH was locally found in the inflammatory site upon treatment with carrageenan but not in systemic circulation, suggesting an autocrine or paracrine, but not endocrine role in inflammation (Karalis *et al.*, 1991).

CRH in the Epigenetic Era

Several studies in animal models and humans have convincingly demonstrated that early environmental adverse experiences might have an important role in reprogramming the hypothalamic–pituitary–adrenal (HPA) axis activity via epigenetic modifications of genes encoding molecules participating in the stress response. More than three decades ago, the pioneer studies of M. Meaney and his colleagues showed that high maternal licking/grooming (LG) resulted in increased expression of glucocorticoid receptor in the hippocampus, leading to a less potent stress response via a higher negative feedback inhibition of hypothalamic CRH and pituitary ACTH (Meaney *et al.*, 1985). On the contrary, low maternal LG caused higher hippocampal cytosine methylation of the 1_7 promoter of the *NR3C1* gene, thereby reducing hippocampal expression of the glucocorticoid receptor and altering the adaptive stress response (Weaver *et al.*, 2004).

In addition to glucocorticoid receptor, recent studies revealed epigenetic alterations in the *CRH* gene associated with stress-related conditions, including hypersexual disorder and suicide attempts (Jokinen *et al.*, 2017, 2018). A genetic region 48 bp upstream of the transcription start site of the *CRH* gene was significantly hypomethylated in hypersexual male patients compared to healthy male volunteers (Jokinen *et al.*, 2017). Moreover, two CRH-associated CpG-containing sites were hypomethylated in a high-risk group of suicide attempters compared to a low-risk group (Jokinen *et al.*, 2018). Future studies will shed light on the role of epigenetic alterations of the *CRH* gene in human pathophysiology.

Neurotensin☆

Arthur Shulkes, University of Melbourne, Melbourne, VIC, Australia

Glossary

Ileum The distal three-fifths of the small intestine, where bile salts and many nutrients are absorbed.

messenger RNA (mRNA) An RNA molecule that specifies the amino acid sequence of a protein.

Peptide Any member of a class of compounds of low molecular weight that yield two or more amino acids on hydrolysis and that form the constituent parts of proteins.

Chemistry, Isolation, and Distribution

During the isolation of substance P from bovine hypothalami, S. E. Leeman and colleagues in 1973 isolated a 13-amino acid peptide that was termed "neurotensin" after its vasodilatory and cyanotic effects. Neurotensin was subsequently shown to have a widespread distribution in the central nervous system, pituitary, and intestine. Furthermore, neurotensin and neurotensin-related peptides are represented across the phylogenetic tree (Table 1). The C terminus, which is the bioactive core, is conserved, whereas the N-terminal peptide, NT (1–8), may be an inactive degradation product generated following cleavage at the dibasic arg^8–arg^8 residues. The ileum contains the highest concentration of neurotensin, with lesser amounts found in the jejunum and duodenum. The neurotensin is present in specific endocrine cells, in N cells, and in nerves predominantly in the myenteric plexus. Overall, the intestine contains more than 90% of neurotensin. Most of the remaining NT is in the brain, particularly the hypothalamus and pituitary. Neurotensin is synthesized and stored in neurosecretory cells in a number of hypothalamic areas, including the arcuate nucleus and the parvocellular paraventricular nucleus. The median eminence has a dense plexus of neurotensin-containing nerves arising predominantly from these nuclei. Anterior pituitary neurotensin is present in gonadotropes and thyrotropes.

Gene and Precursor Structure

Neurotensin is synthesized within a 170-amino acid precursor that also encodes the related peptide neuromedin N. These two peptides are located near the C terminus and are separated by basic residue pairs. The rat neurotensin/neuromedin N gene has 10.2 kb and is divided into four exons, with exon 4 containing the coding region for both neurotensin and neuromedin N. Two species of mRNA have been identified (1.0 and 1.5 kb), with the difference being the lengths of the 3′ untranslated tail. A similar pattern is seen in the human. The 1.0-kb form predominates in the intestine and pituitary, with equivalent amounts of the 1.0- and 1.5-kb forms in the brain and in tumors.

Secretion

Ingestion of fat is the most potent stimulant of gastrointestinal neurotensin release. However, the majority of neurotensin is rapidly metabolized into biologically inactive N-terminal fragments, predominantly NT(1–8), with the bioactive C-terminal

Table 1 The Neurotensin Family

Bovine/Human/Canine/Porcine/Rat NT	*pGlu*	*Leu*	*Tyr*	*Glu*	*Asn*	*Lys*	*Pro*	*Arg*	*Arg*	*Pro*	*Tyr*	*Ile*	*Leu*

fragment NT(9–13) being very rapidly metabolized. Thus, the increase in circulating bioactive neurotensin following a meal is quite modest and less than that required for a biological effect such as inhibition of acid secretion or gastric emptying. Nevertheless, neurotensin may function in concert with other regulatory peptides, such as cholecystokinin, to influence gastrointestinal functions. Neurotensin is also secreted from neurosecretory cells in the hypothalamus and nerve terminals in the median eminence, with elevated levels seen in hypophyseal–portal blood of the rat. In contrast, the neurotensin originating from the gonadotropes and thyrotropes of the anterior pituitary probably functions as paracrine/autocrine agents.

Receptors

Following the first demonstration of neurotensin-binding sites in rat brain synaptic terminals in 1977, there have been many biochemical and autoradiographic studies on the nature and distribution of neurotensin-binding sites. These have culminated with the cloning of three receptor subtypes, all of which recognize the C-terminal, biologically active part of neurotensin.

Neurotensin Type 1 (NTR1)

The cDNA clone was obtained from the rat brain cDNA library using an electrophysiological assay in Xenopus oocytes as the end point. The cDNA encodes a 424-amino acid protein (similar in size to that reported earlier by chemical isolation) and, as suggested by pharmacological studies, is a member of the G protein-coupled receptor family. The human receptor has been cloned from the colonic adenocarcinoma cell line HT29. The receptor has a high affinity (0.2 nm), is insensitive to levocabastine, and is expressed in the intestine and brain. Signal transduction mechanisms are primarily intracellular Ca and inositol 1,4,5-trisphosphate.

Neurotensin Type 2 (NTR2)

This is a low-affinity (5–7 nm) receptor that shares about 60% homology with NTR1 and is sensitive to levocabastine. Although it has the characteristics of a G protein-coupled receptor, the transduction mechanisms have not been completely characterized and appear to be system and species specific. Furthermore, neurotensin antagonists have paradoxical agonist functions in some species. The receptor is expressed mostly in the brain, but in a distribution pattern different from NTR1, so that there is rarely co-expression.

Neurotensin Type 3 (NTR3)

A third neurotensin-binding site was isolated by affinity cross-linking of brain extracts and following cloning shown to have 100% homology with the previously cloned human gp95/sortilin receptor. This protein has a large luminal domain, a single transmembrane domain, and a short cytoplasmic tail. The signal transduction mechanism and biological role remain to be determined.

Biological Effects

Neurotensin has a variety of biological effects, with more than 30 different *in vitro* and *in vivo* effects known. Peripheral effects include vasodilation, cyanosis, increased histamine release, stimulation of the endocrine and exocrine pancreas, effects on gastrointestinal tract smooth muscle activity and motility, stimulation of intestinal secretion, and inhibition of blood flow to adipose tissue. Centrally, neurotensin has hypothermic and antinociceptive effects, and it modulates brain dopamine systems, luteinizing hormone (LH), and prolactin release. Both central and peripheral administration of neurotensin inhibits food intake.

Gastrointestinal Effects

Neurotensin secretion is stimulated by a fat-containing meal and has been postulated as the mediator of many of the effects of fat ingestion. These include inhibition of gastric acid secretion and motility, stimulation of pancreatic and intestinal secretions, decrease in adipose tissue blood flow, and increase in small intestinal blood flow. Neurotensin potentiates the actions of secretin, cholecystokinin, and the vagus on pancreatic secretion and acts in concert with other enterogastrones, such as secretin, to inhibit gastric acid secretion. Neurotensin and its receptors have been implicated in the pathogenesis of intestinal inflammation and inflammatory bowel disease.

Central Effects

The neuroendocrine effects of neurotensin are extremely complex and dependent on the route of administration, the sex steroid status, and the species. Furthermore, there are outstanding issues of separating the physiological effects from the pharmacological effects and the mode of action (neurocrine, autocrine, paracrine, or endocrine). In this regard, the development of specific

receptors and the use of anti-neurotensin antiserum have been most useful. SR48692 blocks NTR1-mediated effects, such as potassium-evoked dopamine release and turning behavior but not analgesia or hypothermia. These latter effects appear to be mediated by the NTR2 and are blocked by R142948A, an inhibitor of both NT1 and NT2. However, recent studies using NTR1 knockout mice suggest that this receptor does contribute to the analgesic and hypothermic responses. Neurotensin has powerful analgesic effects but the requirement for injection has limited its usefulness.

There are intimate and multiple anatomical and functional relationships between neurotensin and dopamine throughout the central nervous system, often with reciprocal modulation of their activities. Neurotensin activates hypothalamic dopaminergic and noradrenergic activity in the basal state but not in the fasted state. Central administration increases plasma adrenocorticotropic hormone (ACTH) and corticosterone by enhancing the release of cortical-releasing factor (CRF) into the hypophyseal portal system. Studies with neurotensin antagonists implicate neurotensin in the stress-initiated activation of the hypothalamic pituitary adrenal axis. In ovarectomized animals (but not in male ones), injection of neurotensin in the preoptic area stimulates LH secretion, whereas injection of NT into the cerebral ventricular system inhibits LH secretion. However, no effect is seen in humans following intravenous administration.

As for gonadotropin release, the route of administration and the experimental conditions are critical in determining the effects of neurotensin on prolactin release. Intracerebroventricular administration decreases circulating prolactin, whereas intravenous administration increases prolactin concentrations. These effects appear to be specific in that they can be reversed by the administration of anti-neurotensin serum. Interestingly, estrogen increases neurotensin mRNA in specific regions of the hypothalamus, further implicating hypothalamic neurotensin in the estrogen-dependent prolactin secretion. In contrast, estrogen decreases anterior pituitary levels of neurotensin. Despite some conflicting data, studies comparing the effects of neurotensin and neurotensin antiserum administration are consistent with a stimulatory effect of neurotensin on thyroid-stimulating hormone (TSH) secretion via an autocrine or paracrine mode of action.

In summary, neurotensin regulates anterior pituitary function both by its release from the nerve terminal from the median eminence and by autocrine/paracrine effects from neurotensin synthesized within the anterior pituitary. The expression of hypothalamic and pituitary neurotensin is under the regulation of gonadal and steroid hormones.

Pathology

Pancreatic tumors producing neurotensin have been reported, but these tumors often produce excess amounts of other peptides, particularly vasoactive intestinal peptide. Because vasoactive intestinal peptide and neurotensin both stimulate intestinal secretion, it is difficult to assess the role, if any, of neurotensin in gastrointestinal symptoms of pancreatic tumors. No clinical syndromes that could be attributed to neurotensin were evident in patients with either lung or hepatic fibrolamellar tumors containing neurotensin as the only detected bioactive peptide. However, the presence of neurotensin in some types of tumors may be of some relevance given that, in experimental studies, neurotensin promotes gastric and colonic carcinogenesis and stimulates the growth of small cell lung cancer cell lines. Neurotensin antagonists inhibited basal and neurotensin stimulated small cell lung cancer growth. Neurotensin is absent from normal prostate but is synthesized and secreted from primary prostate cancers. Taken together it appears that neurotensin is oncogenic and that many of these oncogenic effects are mediated by NTR1. This receptor is over expressed in a number of tumors including lung and pancreas. The proliferative effect of neurotensin may be of theoretical benefit in patients who have atrophy of the bowel associated with long-term parenteral feeding. However, this has not been tested in the human. Neurotensin has been implicated in the pathogenesis of schizophrenia, and a subset of schizophrenic patients has low cerebrospinal fluid neurotensin concentrations that are restored by effective antipsychotic drug treatment. In a recent observational study by Melander and colleagues, fasting proneurotensin was significantly associated with the development of diabetes, cardiovascular disease and breast cancer. However a causal effect of proneurotensin or its end product, neurotensin has not been demonstrated.

Carcinoid Syndrome

Marina Tsoli and Gregory Kaltsas, National and Kapodistrian University of Athens, Athens, Greece

Introduction

Neuroendocrine neoplasms (NENs), previously known as carcinoid tumors, are considered to be rare neoplasms with an estimated incidence of 3–5 cases/100,000 inhabitants but their incidence has been rising over time as a result of improved sensitivity of currently employed diagnostic tools (Modlin *et al.*, 2008; Huguet *et al.*, 2017). NENs arise mainly in the gastrointestinal tract and bronchopulmonary system but in rare cases they can also occur in the ovaries, the urinary bladder and other organs (Yao *et al.*, 2008). NENs generally follow an indolent course but can develop metastatic disease whereas a subset can behave in an aggressive malignant manner. According to the WHO classification of 2000, the following types of NENs are recognized: (1) well-differentiated endocrine tumor, (2) well-differentiated endocrine carcinoma, (3) poorly differentiated endocrine carcinoma and (4) mixed endocrine-exocrine carcinoma (Solcia *et al.*, 2000; Kloppel *et al.*, 2014). In addition, NENs display significant heterogeneity according to their proliferative behavior. Thus, NENs are classified as grade 1 or 2 (G1 or G2) if their proliferative index (determined by immunohistochemical staining for nuclear ki-67 protein expression) is below 3% or between 3% and 20% respectively. NENS with a proliferative index higher than 20% are classified as grade 3 (G3) neuroendocrine carcinomas (NECs) (Klimstra *et al.*, 2010). Recently, the G3 tumors have shown heterogeneity that relies mostly on their degree of differentiation and are subdivided as G3 NETs (well differentiated) and G3 NECs (poorly differentiated) (Sorbye *et al.*, 2013; Basturk *et al.*, 2015).

NENs may be "functioning" or "nonfunctioning" based on the presence or absence of symptoms attributed to hypersecretion of metabolically active substances. However, some nonfunctioning tumors may be immunohistochemically positive for certain compounds without causing clinical syndrome or secrete substances that are metabolically inert. In addition, NENs that were considered initially nonfunctioning may acquire the ability to secrete substances and become functioning while functioning tumors may change their secretory component leading to a different clinical phenotype (Kaltsas *et al.*, 2004; Crona *et al.*, 2016).

NENs can secrete a variety of substances, peptides, amines or prostaglandins. Carcinoid syndrome (CS) is the constellation of symptoms resulting from the action of several humoral compounds secreted by NENs, the most prominent of them being serotonin, kallikrein, tachykinins, histamine and prostaglandins. Carcinoid syndrome is associated with acute and chronic complications that can impact on the quality of life and overall survival. The most important manifestations of CS are carcinoid crisis, fibrosis and carcinoid heart disease (CHD) that can be fatal if not correctly diagnosed and treated (Kaltsas and Grossman, 2006; Crona *et al.*, 2016).

Pathophysiology

Carcinoid syndrome is the result of synergistic action of tumor products entering the systemic circulation. NENs of the small intestine are the main cause of CS that occurs in 20%–30% of patients with liver metastases from these tumors (Kaltsas *et al.*, 2017).

The most prominent secretory products of neuroendocrine tumors considered to be related with CS are 5-hydroxytryptamine (5-HT, serotonin), histamine, tachykinins, kallikrein and prostaglandins. Serotonin is synthesized from tryptophan through its precursor, 5-hydroxytryptophan (5-HTP), by the enzyme aromatic acid decarboxylase and is involved in smooth muscle contraction, blood pressure regulation and neurotransmission. In normal subjects, 2% of dietary tryptophan is converted to serotonin and is stored in enterochromaffin cells of the gastrointestinal tract, in platelets and in serotoninergic neurons of central nervous system. The urinary breakdown metabolite of serotonin is 5-hydroxyindoleacetic acid (5-HIAA) which is excreted in the urine (Caplin *et al.*, 1998; Kulke and Mayer, 1999; Oberg *et al.*, 2017). In patients with CS there is a shift towards serotonin and 5-HIAA production. When 5-HT and other tumor products are secreted into the portal circulation they are metabolized and inactivated by the liver. However, when hepatic spread from a primary gastrointestinal NEN exceeds the hepatic degradation capacity, CS becomes evident. The syndrome is also occasionally developed in patients with large lymph nodes, peritoneal and ovarian lesions or bronchial carcinoids, where secretory products by-pass the liver via the thoracic duct or retroperitoneal venous collaterals or are released directly into the systemic circulation (Kulke and Mayer, 1999; Grozinsky-Glasberg *et al.*, 2015).

Some foregut NENs (gastric and bronchial) lack the aromatic amino acid decarboxylase and produce 5-HTP and histamine instead of serotonin. Hindgut (distal colon and rectum) and pancreatic neoplasms cannot convert tryptophan to 5-HT and other products and can rarely cause CS (Kaltsas *et al.*, 2004; Tsoukalas *et al.*, 2017).

The altered tryptophan metabolism may account for the majority of symptoms of CS. Serotonin acts via seven types of G-protein-coupled receptors and is considered to be involved in cell motility, fluid secretion and blood circulation in gastrointestinal and bronchopulmonary tract. In particular, serotonin stimulates intestinal motility and secretion and inhibits intestinal absorption accounting for the diarrhea of CS. Serotonin has also mitogenic effects in fibroblasts resulting in peritoneal and cardiac valvular fibrosis. The increased conversion of tryptophan to serotonin may lead to tryptophan deficiency with subsequent decreased protein synthesis, hypoalbuminemia and nicotinic acid deficiency leading to the clinical

symptoms of pellagra (skin rash, glossitis, angular stomatitis, mental confusion). However, serotonin is not directly associated with flushing, which is considered to be mediated by bradykinins, prostaglandins, tachykinins, substance P or histamine while bronchial constriction seems to be related to tachykinins and bradykinins (Caplin *et al.*, 1998; Kulke and Mayer, 1999; Kaltsas *et al.*, 2004).

Clinical Presentation

The principal symptoms of CS are diarrhea and flushing. Patients with the classic (typical) carcinoid syndrome develop cutaneous flushing (60%–85%), secretory diarrhea (60%–80%), intermittent bronchial wheezing (< 10%), venous telangiectasia, right heart valve fibrosis (in up to 20%) and pellagra. Typical flushing occurs suddenly, is of pink or red color, involves the face, neck and upper chest and lasts a few minutes (**Fig. 1**. It can be accompanied by increased heart rate and a burning sensation. Onset of symptoms may be spontaneous and occur several times a day or precipitated by alcohol and tyramine-containing foods (chocolate, bananas, walnuts), pharmacological agents and physical or emotional stress (Caplin *et al.*, 1998; Kulke and Mayer, 1999; Niederle *et al.*, 2016).

The diarrhea of CS is typically watery and nonbloody, sometimes explosive and frequently accompanied by abdominal cramping. Initially, diarrhea may be intermittent caused by secretory and dysmotility factors, but on later stages may become continuous caused by gut lymphangectasia and bacterial overgrowth. In contrast with other diarrhea causes, carcinoid syndrome leads to diarrhea that persists with fasting. It is considered to be the result of action of 5-HT, tachykinins, kallikrein, prostaglandins and histamine which result to increased gut peristalsis and secretion (von der Ohe *et al.*, 1993; Kaltsas *et al.*, 2004).

Bronchospasm occurs in patients with CS who present with wheezing and dyspnoea. Venous telangiectasia, primarily on the face and neck, appears late in the course of the disease due to prolonged vasodilatation. Due to the fact that dietary tryptophan is used for serotonin synthesis, patients with carcinoid syndrome develop pellagra which is characterized by angular stomatitis, glossitis, skin rash and mental confusion. In addition, poor protein synthesis may lead to hypoalbuminemia and muscle wasting (Caplin *et al.*, 1998; Kulke and Mayer, 1999; Kaltsas *et al.*, 2004).

Occasionally, an atypical syndrome is developed, which consists of purplish flush that is severe and prolonged and frequently leaves telangiectasia and hypertrophy of the skin of the face and upper neck but also of the limbs which may become acrocyanotic. Hypotension, headache, lacrimation, cutaneous oedema and bronchoconstriction may also develop. This variant of CS is associated with bronchial neuroendocrine tumors and is probably attributed to histamine production. Another rare type of histamine-mediated flush is a red, patchy and pruritic flush that develops in patients with gastric NEN (Caplin *et al.*, 1998; Kulke and Mayer, 1999; Kaltsas and Grossman, 2006).

Diagnosis

The diagnosis of CS is suspected when the patient reports suggestive symptoms, such as chronic diarrhea or flushing. The biochemical confirmation of diagnosis is based on measurement of 24-h urinary 5-HIAA levels. Consumption of certain drugs and

Fig. 1 Facial flushing from typical CS secondary to a small intestine NEN.

foods rich in tryptophan/serotonin can cause false elevated results and patients should collect urine with strict dietary restrictions. In addition, malabsorption syndromes (such as celiac disease, Whipple disease, cystic fibrosis) can lead to falsely increased 5-HIAA levels (Meijer *et al.*, 2000; Oberg *et al.*, 2017). 5-HIAA has a sensitivity of 100% and a specificity of 85%–90% for detecting CS and a specificity of approximately 100% for the diagnosis of a primary tumor in the small intestine (Feldman and O'Dorisio, 1986; Ardill and Erikkson, 2003). A low-level cut-off value (2,8 mmol/mol creatinine) yielded a specificity of 89%, while a high cut-off level (6,7 mmol/mol creatinine) improved specificity (98%) at the expense of a lower sensitivity (52%) (Meijer *et al.*, 2000). In certain cases, CS can be developed without increased 5-HIAA levels and this is attributed to secretion of biologically active molecules other than serotonin. Recent studies that examined the role of 5-HIAA levels as a prognostic factor show controversial results (Turner *et al.*, 2006; Formica *et al.*, 2007). Serum serotonin is less sensitive and specific while platelet serotonin is considered a sensitive test which however is not widely available (Niederle *et al.*, 2016). Recent studies have demonstrated high correlation of urine and serum 5-HIAA which could represent a useful diagnostic tool for CS in the future (Adaway *et al.*, 2016; Oberg *et al.*, 2017).

Serum chromogranin A (CgA) is a sensitive marker for neuroendocrine tumors irrespectively of primary origin and can be elevated in functional and nonfunctional NENs. In general, CgA levels increase in parallel with tumor burden. It is recommended to measure CgA in the same laboratory or with the same assay as it has been observed that CgA levels may differ significantly between different assays. However, CgA is a nonspecific marker as various clinical situations such as atrophic gastritis, chronic renal failure, liver cirrhosis, congestive heart failure or proton pump inhibitor use lead to CgA levels elevation. Specificity of CgA in the diagnosis of NENs depends on the tumor type and burden (100% specificities have been reported in patients with metastatic disease) and the cut-off values employed. Elevated CgA was found to be more sensitive than high urine 5-HIAA levels in patients with metastatic midgut lesions (87% vs. 76%, respectively) (Niederle *et al.*, 2016; Oberg *et al.*, 2017).

In general, when assessing a patient for CS, 5-HIAA is a specific marker while CgA levels are useful in case of established diagnosis to assess disease recurrence after complete surgical resection and disease response or progression during treatment.

Carcinoid syndrome is primarily associated with metastatic NENs that originate in small intestine while it can also develop in patients with ovarian, lung or gastric NENs. Multiphasic contrast-enhanced computed tomography (CT) and magnetic resonance imaging (MRI) of the abdomen are useful tools not only for tumor detection but also for following-up the response to treatment. Chest CT may be necessary to detect a bronchial NEN (Niederle *et al.*, 2016). Whereas liver metastases are easily detected, localization of primary tumor may be difficult. CT detects approximately half of the lesions when the size of the mesenteric mass exceeds 1.5 cm. For gastrointestinal NENs, MRI is able to detect around two-thirds of lesions. Typically, NENs appear as T1 hypointense and T2 hyperintense lesions. Similarly, hepatic metastases are well depicted on MRI and MRI is often used to further characterize lesions that are equivocal on CT. Like the primary lesions, hepatic metastases appear as T1 hypointense and T2 hyperintense (Tan and Tan, 2011). Transabdominal ultrasound (TAUS) may be used for screening of liver metastases (Dörffel and Wermke, 2008) but for primary tumor localization and long-term follow-up CT or MRI display higher sensitivity. Newer techniques such as contrast enhanced ultrasound (CEUS) and endoscopic ultrasound (EUS) are more advantageous methods of assessment of NENs especially for pancreatic, gastric and liver lesions (Tan and Tan, 2011).

Direct visualization with colonoscopy may be possible in tumors located in terminal ileum but for more proximal parts of ileum or for the jejunum more sophisticated techniques such as CT-water enteroclysis, video-capsule endoscopy or double-balloon enteroscopy may be required. These methods are especially suggested in case of metastatic NENs of unknown primary origin (Niederle *et al.*, 2016).

Many NENs express high levels of somatostatin receptors (SSTRs) and can therefore be detected with a form of the somatostatin analog octreotide which is linked with radionuclides that can be detected by somatostatin receptor scintigraphy (SRS, ^{111}Indium) or by positron emission tomography (PET, ^{68}Gallium). This technique has the advantage of whole body scanning which also allows detection of metastases outside of the abdominal region. SRS is considered to display an overall sensitivity of approximately 80%–90% in patients with gastrointestinal NENs. Normal uptake is seen in thyroid, spleen, liver and pituitary while bowel and kidney uptake can also be observed (Strosberg *et al.*, 2009; Tan and Tan, 2011). A recent study showed that ^{68}Ga-DOTATOC PET/CT is superior compared to ^{111}In-DTPA octreotide SPECT/CT when attempting to localize the primary tumor of metastatic disease or clinically suspected disease (Schreiter *et al.*, 2014).

Fluorodeoxyglucose (FDG) PET imaging is an imaging technique that addresses the high glucose metabolism of malignant tissues. ^{18}FDG-PET/CT has a low sensitivity for the detection of well-differentiated low-grade NEN but can identify NENs characterized by aggressive growth or behavior. New traces such as ^{11}carbon-5-hydroxytryptophane and ^{18}fluoro-dihydroxyphenylalanine (DOPA) have shown promising results but are not widely available and further studies are needed before recommending their standard use (Koopmans *et al.*, 2006; Tan and Tan, 2011).

Treatment

Somatostatin is a small peptide hormone that is present in human body in two molecular forms, consisting of 14 or 28 amino acids and has various biological effects in different tissues. These effects are mediated through specific SSTRS that are present in diverse tissues including the human gastrointestinal mucosa. Five different SSTR subtypes have been recognized. Somatostatin regulates the secretion of intestinal hormones, the gastrointestinal transit time and the resorption and secretion of intestinal fluid (Lamberts *et al.*, 1996; Kaltsas *et al.*, 2004).

As the majority of carcinoid tumors express SSTRs, very early it was observed that somatostatin ameliorated the symptoms of CS (Thulin *et al.*, 1978). Native somatostatin has a short half-life and synthetic structural analogues which mimic somatostatin action but display longer half-life have been synthesized. Octreotide was the first synthetic analogue and can be administered by multiple subcutaneous injections or continuous subcutaneous or intravenous infusion. It was shown that octreotide can result to symptomatic control of functioning NENs and also prevent the development of carcinoid crisis in patients with CS submitted to invasive procedures (Wood *et al.*, 1985; Kvols *et al.*, 1985). Also, a slow-release depot intramuscular formulation of octreotide (Sandostatin LAR) has been released and has to be administered once every 4 weeks. Another octreotide analogue, lanreotide, has also become available as a slow-release deep subcutaneous depot preparation (Somatuline Autogel) that has to be administered every 4 weeks (Rubin *et al.*, 1999; Modlin *et al.*, 2010). Octreotide and lanreotide have comparable binding profiles for SSTRs; octreotide binds with a high, low and moderate affinity to $SSTR_2$, $SSTR_3$ and $SSTR_5$ respectively (Hofland and Lamberts, 2003). In addition, a new synthetic analogue, pasireotide, with high affinity for all SSTRs except $SSTR_4$, has been observed to be efficacious in cases of inadequate control with octreotide LAR (Kvols *et al.*, 2012).

In patients with CS both diarrhea and flushing improve or even disappear after treatment with long acting somatostatin analogues (SSAs), usually within the first week. When SSAs are initiated, concomitant therapy with short-acting octreotide should be prescribed for the first 2–3 weeks. Frequent side effects of SSAs are nausea, diarrhea, steatorrhea, abdominal pain, biliary sludge or gallstone formation and rarely, hyperglycaemia and rash (Kaltsas *et al.*, 2004). Although SSAs are the best available treatment for CS, it has been observed that an escape phenomenon of tachyphylaxis may occur after a few months or years of treatment. The mechanism is related to either down-regulation of somatostatin receptors or an increase in tumor load. In this case, significant increase of dosage may be required while adding top-up doses of short-acting octreotide can also be useful (Kaltsas *et al.*, 2004; Strosberg *et al.*, 2014).

It has been observed that treatment with interferon-a (IFN-a) controls the symptoms of CS in 40%–70% of patients and exerts anti-tumor action. However, IFN-a has been associated with clinically significant adverse effects including flu-like symptoms, fatigue, auto-immune diseases and immunosuppression (Oberg, 2000; Kaltsas *et al.*, 2004). A newer agent, pegylated interferon, is considered to result to fewer side effects while a number of studies address the probable synergistic use of SSAs and lower doses of IFN-a (Fazio *et al.*, 2007).

Telotristat etiprate is an oral inhibitor of the enzyme tryptophan hydroxylase, the rate-limiting step in the conversion of tryptophan to serotonin. Telotristat does not have central nervous system side effects as it does not cross the blood–brain barrier and does not affect the serotonin levels in the brain (Pavel *et al.*, 2015). Recent studies have shown that addition of telotristat in patients with inadequate symptom control despite treatment with SSAs, results to significant reduction of bowel movements frequency and 5-HIAA levels while flushing episodes were also improved (Kulke *et al.*, 2017; Pavel *et al.*, 2015). Adverse events possibly related to telotristat are mild and include abdominal pain, nausea and a low rate of depression. It is thus suggested that telotristat can be used in patients with CS refractory to SSAs while further investigation needs the assumption that the decrease of serotonin levels might reduce the development of peritoneal and cardiac valvular fibrosis (Pavel *et al.*, 2015; Kulke *et al.*, 2017).

In NEN G1 or G2, surgery with the intention to cure can be considered even if liver or lymph node metastases are present. In patients with advanced disease, tumor debulking techniques such as hepatic artery embolization and palliative hepatic cytor-eductive surgery can decrease tumor load and result to symptomatic improvement of CS (Gupta *et al.*, 2003; Strosberg *et al.*, 2006). Peptide receptor radionuclide therapy (PRRT) can be used in patients with tumors expressing SSTRs and it has been observed that CS refractory to octreotide can be ameliorated (Bushnell *et al.*, 2010). Furthermore, treatment with octreotide therapy should be instituted before any manipulation in order to prevent carcinoid crisis (Kaltsas *et al.*, 2017).

Antidiarrheal medications such as loperamide and codeine can be useful in cases of refractory diarrhea while patients should avoid known precipitants of flushing and diarrhea (exercise, alcohol intake, consumption of spicy or tyramine-containing foods). Histamine-2 receptor antagonists may be proved useful agents as sometimes symptoms are related to histamine action. Furthermore, other causes of diarrhea should be considered and treated. In patients who have been submitted to distal bowel resection, bile acid loss and bacterial overgrowth can occur and treatment with cholestyramine or antibiotics may be required (Kaltsas *et al.*, 2004). In addition, pancreatic enzymes can be used to treat steatorrhea after pancreatic resection or due to therapy with SSAs while dehydration, electrolyte abnormalities and vitamin B deficiency should also be treated (Kaltsas *et al.*, 2004).

Carcinoid Heart Disease

Carcinoid heart disease (CHD, Hedinger syndrome) occurs in about 60% of patients with NENs and CS and typically involves the right side of the heart (Fox and Khattar, 2004). CHD develops more frequently in patients with NENs of the small bowel, followed by NENs of the lung, large bowel, pancreas, appendix or ovaries. In 18% of cases the primary tumor is unknown (Pellikka *et al.*, 1993).

The precise mechanism behind CHD remains unknown but it is generally thought to be mediated by serotonin, prostaglandins, histamine, bradykinin and other substances secreted by the tumor. Patients with CS and CHD have higher levels of 5-HIAA and other vasoactive substances (Pellikka *et al.*, 1993; Kulke and Mayer, 1999). In addition, serotoninergic drugs used in the treatment of obesity, migraine and Parkinson's disease lead to development of similar heart valvular fibrosis while it has been observed in cell cultures that serotonin has mitogenic effects on fibroblasts, smooth muscle cells and endothelial cells (Grozinsky-Glasberg *et al.*, 2015). 5-HIAA levels above 300 μmol/24 h and >3 episodes of flushing per day have been demonstrated to be predictors of CHD development or progression (Bhattacharyya *et al.*, 2011).

Heart lesions are characterized by plaque-like, fibrous endocardial thickening that leads to retraction and fixation of the valve leaflets. The most common lesions are tricuspid regurgitation followed by tricuspid stenosis, pulmonary regurgitation and pulmonary stenosis. Approximately 10% of patients develop left-sided heart disease because hormonal mediators are cleared or inactivated in the lungs. However, left sided lesions can be observed in case of patent foramen ovale, lung tumors or high tumor burden (Pellikka *et al.*, 1993; Kulke and Mayer, 1999).

Early in the disease course, the patients present with subtle symptoms, mainly fatigue and dyspnoea on exertion but ultimately they develop significant dyspnoea, anasarca and cardiac cachexia. However, some patients remain asymptomatic despite cardiac involvement (Dobson *et al.*, 2014).

The principal method of CHD diagnosis and follow-up is two dimensional echocardiography and Doppler examination. Typically, in the early stages thickening of tricuspid valve leaflets is observed which ultimately leads to tricuspid regurgitation and stenosis while all the heart valves can become progressively involved (**Fig. 2**). Regular echocardiographic screening of patients with carcinoid syndrome is recommended as mandatory for patients with CS (Grozinsky-Glasberg *et al.*, 2015). Cardiac MRI may be helpful but its usefulness has not been proven. N-terminal probrain natriuretic peptide (NT-proBNP), a neurohormone released by the atria and ventricles in response to increase in volume and pressure, has been shown to be a sensitive and specific marker for CHD prediction and be correlated with patient survival (Korse *et al.*, 2009). Thus, it is highly recommended to measure NT-proBNP levels for diagnosis and follow-up of CHD in patients with intestinal NENs and in all patients with CS (Grozinsky-Glasberg *et al.*, 2015; Niederle *et al.*, 2016). Furthermore, plasma activin A levels have been observed to be an independent predictor in advanced but also in early stages of CHD (Bergestuen *et al.*, 2010).

Treatment with SSAs and tumor debulking techniques may decrease the release of vasoactive agents and the development of heart failure but there is no evidence that can prevent CHD progression. Telotristat etiprate has been observed to improve diarrhea and reduce 5-HIAA levels and could be promising for patients with CHD. In addition, therapy for heart failure with loop diuretics, fluid and salt restriction and compression stockings should be introduced and may initially improve the symptoms of right heart failure (Grozinsky-Glasberg *et al.*, 2015). However, surgical valve replacement is the definitive treatment and is now performed earlier with low perioperative mortality. Median survival after valve replacement varies between 6 and 11 years (Moller *et al.*, 2005). In patients unsuitable for cardiac valve surgery, balloon valvuloplasty is an alternate technique for tricuspid or pulmonary stenosis but the clinical benefit is of short-term. Moreover, as a patent foramen ovale has been reported to coexist with CHD and may cause left-sided heart lesions, such a lesion should be ruled out and its closure should be considered prior to cardiac surgery (Grozinsky-Glasberg *et al.*, 2015). In the perioperative period, continuous infusion of octreotide is required to reduce complications and carcinoid crisis incidence (Kaltsas *et al.*, 2017).

Carcinoid Fibrosis

Midgut carcinoid tumors are commonly associated with large mesenteric lymph node metastases that are characterized by mesenteric fibrosis (**Fig. 3**). The release of growth factors and other substances from the metastatic lesions is considered to be the

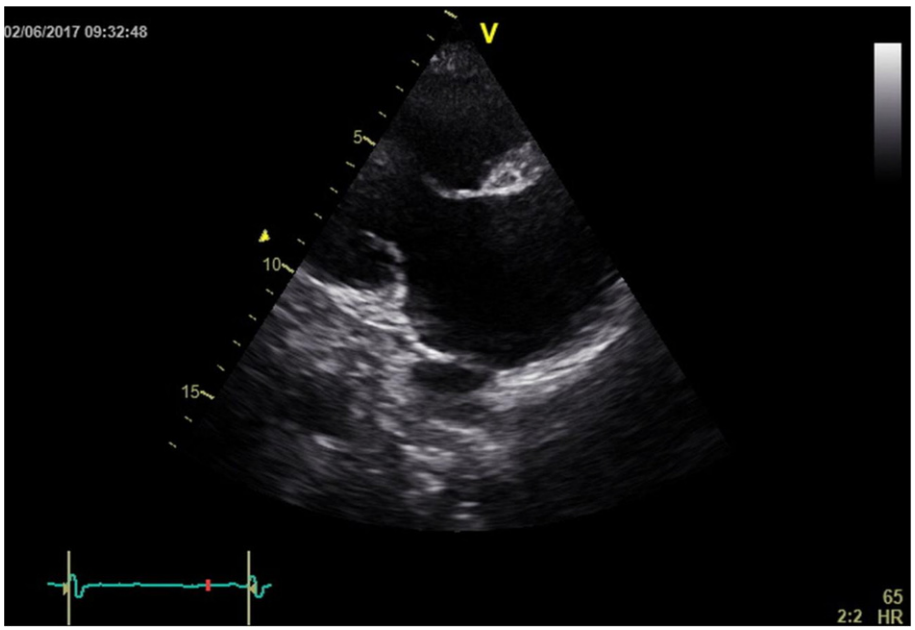

Fig. 2 Transthoracic echocardiogram showing thickened and rigid tricuspid valve leaflets in a patient with CS.

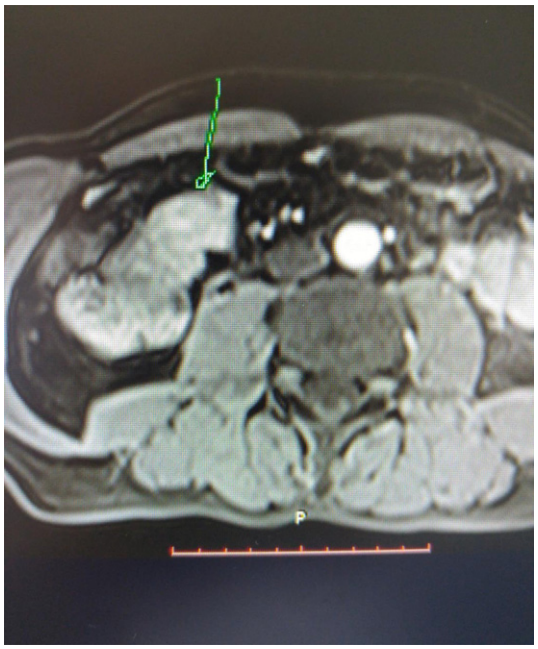

Fig. 3 Abdominal MRI showing desmoplastic reaction in a patient with CS secondary to a small intestine NEN.

cause of this fibrosis. Fibrotic tissue causes shrinkage and fixation of the mesentery and the mesenteric root to the retroperitoneum and may ultimately lead to partial or complete small bowel obstruction. Additional complications associated with carcinoid fibrosis are obstructive uropathy, mesenteric ischaemia, Peyronie's disease of the penis and carcinoid arthropathy. Surgical treatment with debulking of tumor mass from the mesenteric root preserving the vascular supply of intestine is required in order to avoid complications (Oberg, 1999; Kaltsas and Grossman, 2006).

Carcinoid Crisis

Carcinoid crisis is a life-threatening condition characterized by excessive flushing, bronchospasm, alterations in thermoregulation, hemodynamic instability mainly in the form of hypotension and tachycardia and central nervous system dysfunction. Some patients may develop hypertension provoked by excessive release of catecholamines. The carcinoid crisis can occur spontaneously or can be precipitated by severe emotional stress, anesthesia, surgery or other types of intervention and medication (chemotherapy or radiopharmaceuticals causing tumor lysis) that result to release of significant amounts of biologically active compounds in the systemic circulation. Sometimes, crisis presents with postoperative instability or fail to recover after surgery. CHD and high 5-HIAA levels have been observed to represent predictors of an emerging carcinoid crisis. Large tumor load and high CgA or 5-HIAA levels are associated with higher probability of developing a carcinoid crisis during surgery (Caplin *et al.*, 1998; Kulke and Mayer, 1999; Kaltsas *et al.*, 2017).

Pre- and perioperative treatment with intravenous octreotide is required during surgery or other minor interventions to prevent carcinoid crisis. Continuous octreotide infusion is administered 12 h before the procedure at a starting dose of 50–100 μg/h with gradual escalation until symptom control and continued for at least 48 h afterwards with dose titration as required; doses up to 500 μg/h may occasionally be required. Various schemes with subcutaneous administration of octreotide are also currently used by some centers but this approach is not considered safe (Kaltsas *et al.*, 2017). If patients are already on treatment with long-acting SSAs, these medications should be continued but a recent meta-analysis has suggested that these patients may require even higher doses to prevent carcinoid crisis (Seymour and Sawh, 2013). In case of atypical carcinoid syndrome, treatment with octreotide should be instituted but also antihistamines and corticosteroids may be required in order to decrease histamine release and its peripheral actions. In addition, it is strongly recommended to minimize the use of drugs that stimulate sympathetic nervous system or precipitate release of vasoactive products by the tumor (opioids, dopamine, d-tubocurarine) (Kaltsas *et al.*, 2017).

Conclusion

Carcinoid syndrome is a clinical entity attributed to the secretion of various humoral substances from NENs and is primarily associated with metastatic NENs of the small intestine while it can also develop in patients with ovarian, lung and gastric NENs. Flushing, diarrhea and bronchospasm are the most common manifestations of CS but an atypical CS can develop in patients with

bronchial and gastric NENs. Biochemical diagnosis is based in measurement of urine 5-HIAA levels and further investigation with imaging studies is required for tumor detection and follow-up. SSAs are the mainstay of treatment of CS while telotristat etiprate that reduces the production of serotonin is considered a promising option in cases of refractory CS. CS is associated with clinically significant and probably fatal complications the most important being carcinoid heart disease, fibrosis and carcinoid crisis that need to be timely diagnosed and treated. In addition, treatment with octreotide must be instituted before any manipulation in order to prevent carcinoid crisis.

Catecholamines☆

Graeme Eisenhofer, Technical University Dresden, Dresden, Germany
Jacques WM Lenders, Radboud University Medical Center, Nijmegen, The Netherlands and Technical University Dresden, Dresden, Germany

Glossary

Adrenal medulla It produces and secretes predominantly epinephrine.

Autonomic dysfunction Autonomic dysfunction comprise several disease entities including those characterized by orthostatic hypotension due to autonomic failure.

Catecholamines Catecholamines comprise norepinephrine, epinephrine and dopamine and are produced by the adrenal medulla and the central and sympathetic nervous systems. Catecholamines exert a wide array of physiological functions through adrenergic receptors, which are distributed in nearly all organs.

Catechol-*O*-methyltransferase This is an enzyme involved in the extraneuronal breakdown of catecholamines.

Monoamine oxidase It plays a pivotal role in the intraneuronal metabolism of norepinephrine.

Pheochromocytoma and paraganglioma Pheochromocytoma and paraganglioma are chromaffin cell tumors that produce excessive quantities of catecholamines leading to considerable cardiovascular morbidity and mortality if not diagnosed and treated in a timely manner.

Sympathetic nervous system Sympathetic nervous system produces exclusively norepinephrine, a neurotransmitter involved in the homeostatic modulation of numerous systems, but particularly the cardiovascular system.

Introduction

Long before first identification of the catecholamines, it were George Oliver and Edward Albert Schäfer who in 1895 were the first to demonstrate that administration of an extract of the adrenal medulla to a dog was able to increase blood pressure. In 1901 John Jacob Abel, Thomas Aldrich and Takamine isolated and identified epinephrine. It was then not until 1945 when norepinephrine was identified as the neurotransmitter of sympathetic nerves by the Swedish scientist Ulf von Euler. This was followed in 1952 by Arvid Carlsson's discovery of dopamine as a crucial neurotransmitter in the brain.

The naturally occurring catecholamines comprise norepinephrine, epinephrine and dopamine. These compounds have in common a catechol group consisting of a benzene ring with two hydroxyl groups at positions three and four and a connection to an ethylamine side chain. The distinct functional differences between these compounds reside in the ethylamine side chain (**Fig. 1**).

Whereas epinephrine is a hormone exclusively produced in the adrenal medulla, norepinephrine and dopamine act as neuromodulators or transmitters in central and peripheral nervous systems. However, most peripheral dopamine is produced in nonneuronal systems. All three are biologically active compounds, exerting their functions through adrenergic and dopaminergic receptors located in nearly all organs and tissues. Their different and varying physiological effects are not only determined by the intensity of secretory processes, but also by different affinities to receptors as well as different distributions or receptors in relation to different sources of catecholamines.

Catecholamines play a central role in the adaptation to stressful stimuli such as hypoglycemia, hypoxemia and emotions. They are also pathophysiologically involved in many diseases such as autonomic failure and pheochromocytoma. Pheochromocytoma is a neuroendocrine tumor characterized by excessive production of one or more catecholamines, exposing patients to a high risk of catastrophic complications. Reliable measurement of the *O*-methylated metabolites of catecholamines is instrumental for the diagnosis and posttreatment monitoring of these tumors.

Biosynthesis and Storage

The amino acid L-tyrosine is the precursor for the synthesis of catecholamines. Three enzymes are responsible for the final synthesis of norepinephrine: tyrosine hydroxylase (TH), aromatic-L-amino acid decarboxylase (LAAD) and dopamine-beta-hydroxylase (DBH) (Eisenhofer *et al.*, 2001). TH catalyzes the first rate-limiting step in catecholamine synthesis converting L-tyrosine to 3,4-dihydroxyphenylalanine (L-DOPA) (Nagatsu, 1995). By way of phosphorylation of serine residues TH can strongly and rapidly respond to various stimuli in order to speed up the production of norepinephrine when needed. After conversion of L-DOPA to dopamine by LAAD, dopamine is transported into the vesicular storage granules by vesicular monoamine transporters (VMAT). Within vesicles dopamine is

☆*Change History*: April 2018. Both G. Eisenhofer and J.W.M. Lenders have updated the chapter, including the change in figures.

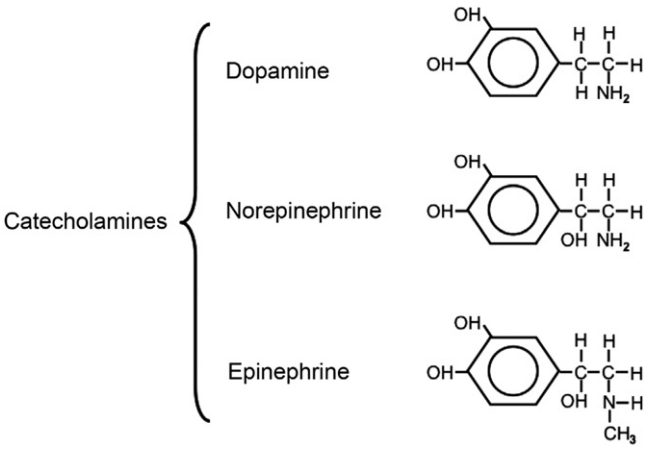

Fig. 1 The chemical structure of all three catecholamines.

hydroxylated to norepinephrine by DBH, requiring ascorbic acid and copper as cofactors. This biosynthetic pathway takes place in central and peripheral sympathetic neurons as well as chromaffin cells associated with the paraganglial chain and adrenal medulla.

Adrenomedullary cells uniquely express the enzyme phenylethanolamine *N*-methyltransferase (PNMT). This enzyme methylates norepinephrine, which leaks from storage vesicles into the cytoplasm, leading to production of epinephrine. Expression of PNMT is induced by the adrenocortical glucocorticoid, cortisol. Close proximity of the adrenocortical cells with centripetal blood flow from the cortex to the medulla guarantees continuous availability of cortisol. Following synthesis in the cytoplasm, epinephrine is actively translocated by VMAT into chromaffin storage granules.

Norepinephrine and epinephrine are stored in electron-microscopically distinct vesicles where they are available for secretion when required. These vesicles have varying size and appearance depending on the type of stored catecholamine. The ongoing dynamic exchange of stored catecholamines between granules and cytosol is based on active VMAT-dependent uptake from the cytosol and passive leakage from the vesicular granules back into the cytosol.

Regulation of Release

The secretory process of exocytosis takes place in terminal parts of sympathetic nerves (varicosities) and in the adrenal medullary cells. The storage granules containing catecholamines fuse with the plasma membrane, thus expelling catecholamines into the extracellular space. This fusing mechanism is a calcium-influx dependent regulated process, initiated by sympathetic nerve pulses or secretagogues. Since calcium channels may be affected by many other compounds such as peptides (e.g., angiotensin), many other stimuli than nerve pulses may contribute to or modulate exocytosis. Finally, under pathological (e.g., ischemia) and pharmacological conditions (e.g., tyramine), catecholamines can be secreted constitutively as a calcium-independent process. Neuronal release of catecholamines is also tightly regulated by catecholamines themselves through presynaptic adrenergic receptors by inhibition (alpha$_2$-adrenergic receptors) or stimulation (beta$_2$-adrenoreceptors) (Nagatsu and Stjarne, 1998).

Uptake and Metabolism

The human body possesses several defense mechanisms to protect against excessive catecholamine exposure (Eisenhofer *et al.*, 2004). The primary mechanism to discontinue quickly catecholamine action comes from cell membrane transporters. Nearly 90% of neuronally released norepinephrine is taken back up by the prejunctional norepinephrine transporters into the sympathetic neurons. Extraneuronal monoamine transporters play a minor role in terminating the actions of norepinephrine released by sympathetic nerves, but are more important than neuronal transporters for removal of circulating catecholamines. The rapid clearance of catecholamines from the circulation by these transport mechanisms results in a very short half-life for circulating catecholamines of about 2 min (Eisenhofer, 2001).

After neuronal reuptake, most norepinephrine is returned by VMAT in vesicular granules while a smaller proportion is metabolized to 3,4-dihydroxyphenylglycol (DHPG) in the cytosol by monoamine oxidase (MAO). Under resting conditions most DHPG is formed from norepinephrine passively leaking from storage vesicles. Similar processes occur in adrenal medullary cells where the additional presence of catechol-methyltransferase (COMT), leads also to production of *O*-methylated metabolites. Norepinephrine is converted to normetanephrine, epinephrine to metanephrine and dopamine to 3-methoxytyramine. Since COMT is not present in sympathetic neurons, metabolism of catecholamines produced from different locations results in different metabolic patterns.

COMT is also present at numerous extraneuronal sites, besides the adrenal medulla, where most *O*-methylated metabolites are deaminated to 3-methoxy-4-hydroxyphenylglycol (MHPG). Much of the DHPG produced in sympathetic neurons is also *O*-methylated at these sites leading also to production of MHPG.

The final end product of norepinephrine and epinephrine metabolism is vanillylmandelic acid (VMA), whereas homovanillylmandelic acid is the main end product of dopamine metabolism. Almost all VMA is produced in the liver through the actions of alcohol dehydrogenase on MHPG taken up into liver cells from the circulation. Additionally, all catecholamines and their metabolites except VMA are conjugated in various proportions by a specific sulfotransferase (SULT1A3) to sulfate conjugates. This enzyme is located in gastrointestinal tissues and serves as protection also against exogenous food derived amines. All metabolites, both free and conjugated are finally removed by urinary excretion. Due to their slow circulatory clearance the conjugated *O*-methylated metabolites of catecholamines are present in plasma at much higher concentrations than free metabolites, which are rapidly cleared by extraneuronal monoamine transporters.

Physiological Function

Catecholamines have profound physiological effects while almost all metabolites are biologically inactive. Even under baseline conditions without apparent stress plasma levels of catecholamines may vary considerably. Under stressful conditions, increased sympathoneural and adrenomedullary activity may induce extremely high circulating levels of plasma catecholamines. Catecholamines play an essential role in homeostasis and serve not only to adapt to such stressful conditions but also to protect vital organs. There are functional differences between catecholamines: in contrast to norepinephrine, which plays a pivotal role in cardiovascular regulation, epinephrine plays a more dominant role in many metabolic processes such as in glucose and lipid metabolism.

At the cellular level catecholamines exert their biological activity through interaction with cell membrane pre-, post-, and extrajunctional adrenergic receptors which can be classified into alpha-adrenergic receptors ($\alpha1_a$, $\alpha1_b$, $\alpha1_d$, $\alpha2_a$, $\alpha2_b$, $\alpha2_c$), beta-adrenergic receptors ($\beta1$, $\beta2$, and $\beta3$) and dopaminergic receptors (D1–D5) based on ligand-binding studies and responses to agonists and antagonists (Guimaraes and Moura, 2001). The resulting physiological effects depend on differences in affinity of receptors for different catecholamines, on the tissue distribution of the receptors and on the levels of catecholamines in plasma and in neuroeffector junctions. For instance, stimulating vascular $\beta2$-adrenergic receptors during stress in healthy subjects cause vasodilation. However, in a situation of extremely elevated plasma epinephrine levels such as in patients with an epinephrine secreting pheochromocytoma, vascular α-adrenergic receptors are stimulated, causing intense vasoconstriction, thus overriding the $\beta2$-adrenergic receptor mediated vasodilatory effects, and resulting in a severe increment in blood pressure.

Numerous classes of drugs exist that either block or stimulate adrenergic receptors. Typical examples are beta-adrenergic receptor blockers; these drugs result in reductions in heart rate, blood pressure and cardiac oxygen consumption and are commonly used in patients with cardiac ischemia. Beta2-adrenergic receptor agonists stimulate beta2-adrenergic receptors which are abundant in the bronchial tree, this resulting in bronchial dilation, which is the targeted therapeutic effect in patients with bronchial asthma. Some drugs have the potential to stimulate also central $\alpha2$-adrenergic receptors (such as clonidine), which results in a decrease in central sympathetic activity with an ensuing drop in vascular tone and blood pressure.

Understanding catecholamine physiology may also help in appreciating some side effects of drugs. Prejunctional located $\alpha2$-adrenergic receptors are supposed to have a constraining role in neuronal norepinephrine release. Blocking the $\alpha2$-adrenergic receptors by nonselective α-adrenergic blockers such as phenoxybenzamine will result in an increase in norepinephrine release, resulting in tachycardia, a well-known side effect of this drug. For a more detailed review of adrenergic receptors and their naturally and synthetic agonists and antagonists, we refer to previous reviews (Guimaraes and Moura, 2001).

Measurements Methods

The assay methodology for measurement of plasma or urinary catecholamines has evolved over the last three decades from spectrophotometric and radioenzymatic assays to liquid chromatography techniques with electrochemical detection. The latter technique, although superior to the earlier ones, requires preanalytical extraction and purification steps and suffered also from analytical interference by drugs. The latest development is liquid chromatography with tandem mass spectrometry (LC-MS/MS). The major advantages of LC-MS/MS over other methods are not only a higher and more rapid throughput of samples and a better signal-to-noise ratio but features in particular a higher analytical specificity. Immunoassays are still used in many places but suffer from inferior accuracy and analytical interference.

An essential aspect of measurements of catecholamines for obtaining reliable test results relates to how blood and urinary samples are collected and stored. As mentioned earlier plasma catecholamines are sensitive to sympathoadrenal activation, such as associated with stressful physical and mental stimuli. A typical example is the position of the patient when taking a blood sample; plasma catecholamines are nearly twice as high in the standing position as compared to the supine position due to an elevated sympathetic tone. It is therefore recommended that blood samples are drawn after supine rest for at least 20 min with an indwelling venous cannula. This minimizes stress-induced fluctuations and circumvents false-positive test results. Twenty-four hour urinary collections are less sensitive to stressful stimuli, but are inconvenient for the patient and the collections are not always

complete. Collecting night-time urine or spot urine may be provide better alternatives but should be normalized against urinary creatinine excretion.

Since catecholamines are sensitive to oxidative degradation, blood samples should be collected into tubes containing heparin or EDTA as anticoagulant and should be placed immediately on ice before centrifugation. For prolonged storage the samples should be kept frozen at $-80\ ^{\circ}C$. For urine samples it is advised to collect urine in containers that have hydrochloric acid to prevent degradation. For measurements of metabolites less stringent procedures are required.

Although analytical interference is minimal with LC-MS/MS there remains a risk of pharmacophysiological interference when drugs are used that may affect uptake transporter proteins, metabolizing enzymes or clearance of catecholamines. A typical example are the tricyclic antidepressants, which block the presynaptic norepinephrine uptake transporter mechanism, thus causing elevated plasma concentrations of norepinephrine and normetanephrine. Effects of drugs interacting with metabolizing enzymes or clearance are more relevant for metabolites of catecholamines such as metanephrines than catecholamines themselves.

Clinical Application

An increased secretion of catecholamines can be demonstrated in many clinical conditions in which the sympathoadrenal system is strongly activated. Typical examples are hypoglycemia (epinephrine), heart failure (norepinephrine), and acute cardiac ischemia. In these cases measurement of catecholamines has no significant diagnostic utility and is merely reflecting the severity of these conditions. There are other clinical conditions in which measurements of catecholamines and/or metabolites are indispensable for the diagnosis and clinical management. One main example is patients who are suspected to have a catecholamine-producing chromaffin cell tumor: pheochromocytoma, paraganglioma or neuroblastoma (Eisenhofer and Peitzsch, 2014). For many years, the diagnosis of pheochromocytoma or paraganglioma depended on measurements of catecholamines in plasma or urine. Due to a better diagnostic accuracy, measurement of metanephrines instead of catecholamines now provide the backbone for the biochemical diagnosis of these tumors (Lenders *et al.*, 2014). The underlying pathophysiological explanation for the superior diagnostic accuracy of metanephrines over catecholamines is the continuous intratumoral production of metanephrines, in contrast to the catecholamines, which may be released in paroxysms or in only relatively low amounts compared to the independent production of metanephrines.

An other clinical area in which measurements of catecholamines may be useful are specific causes of autonomic dysfunction such as is the case in patients with autonomic failure. In such cases, the disordered production of catecholamines is of pathogenic relevance. Common examples are patients with autonomic failure due to multiple system atrophy (MSA), less commonly patients with pure autonomic failure (PAF) and very rarely patients with genetically determined DBH deficiency. In all three groups a core clinical feature is orthostatic hypotension. Measurement of plasma catecholamines can be instrumental for distinguishing between these three orthostatic hypotensive groups. A correct diagnosis is pivotal for both prognosis and choice of treatment. In the first group of MSA patients plasma catecholamines may be normal but respond inadequately to sympathetic activation (e.g., supine to upright posture). The second group of PAF patients shows reduced plasma catecholamine levels at rest due to sympathetic nerve degeneration. In the last group of DBH deficient patients, plasma norepinephrine and epinephrine are not measurable while plasma dopamine is elevated. This pattern of catecholamines is pathognomonic for DBH deficiency, a genetically inherited syndrome with multiple other clinical features (Biaggioni *et al.*, 1987). There are additional genetic syndromes in which synthesis or metabolism of catecholamines is affected such as in Menke's disease (Kaler *et al.*, 1998). In this disease a gene coding for a copper-transporting ATP is mutated. As copper is a cofactor for DBH, this results in less activity of the enzyme DBH with an ensuing decreased conversion of dopamine to norepinephrine. Thus, measurements of catecholamines in addition to clinical features may be very helpful for the differential diagnosis of patients with syndromes of autonomic dysfunction.

Pineal Physiology

The pineal gland is innervated mainly by sympathetic nerve fibers which inform the gland of the prevailing light–dark cycle and acts as a neuroendocrine transducer; it is located behind the third ventricle in the center of the brain and is a highly vascular organ formed by neuroglial cells and parenchymal cells or pinealocytes; the latter synthesize melatonin, as well as other indoleamines and peptides.

The main pineal hormone melatonin (*N*-acetyl 5-methoxy-tryptamine) exhibits an endogenous circadian rhythm, reflecting signals originating in the suprachiasmatic nucleus; environmental lighting entrains the rhythm, by altering its timing. Independently of sleep, pineal melatonin is inhibited by light and stimulated during darkness. Melatonin deficiency may produce sleeping disorders, behavioral problems, or be associated with precocious or delayed puberty in children, while chronically elevated melatonin has been observed in some cases of hypogonadotropic hypogonadism (Macchi and Bruce, 2004).

Pineal Tumors

The main clinical problem related to the pineal gland is that of pineal tumors (**Table 1**). They are rare, 10 times more common in children than in adults, and mainly derive from the following three types of cells (Brat et al., 2008; Louis et al., 2007; Osborn et al., 2012):

1. Astrocytic tumors (20%).
2. Pineal parenchymal tumors (15%–30%): The 2016 WHO classification grades them from I (pineocytomas, being mostly benign) to IV (pineoblastomas, highly malignant) (**Table 2**). However, most parenchymal tumors show intermediate differentiation (WHO grades II and III, **Table 2**) (Nazato *et al.*, 2016).
   - Pineocytomas (grade I) present more often in adults with a mean age of 43 years, with a male to female ratio of 0.6/1, evolve slowly locally, do not invade contiguous tissue or seed the cerebrospinal fluid (CSF); the major prognostic factor is the extent of surgery.
   - Pineoblastomas (grade IV) typically appear before the age of 20 years, most often in young children, with a slight male preponderance, being more rapidly progressive and of shorter duration (interval between initial symptoms and surgery may be less than a month). Median postsurgical survival varies from 24 to 30 months. They are locally invasive and prone to disseminate through the CSF, often fatal. They may occur in familial bilateral retinoblastoma known as trilateral retinoblastoma syndrome, or in patients with familial adenomatous polyposis. They may also present in patients with *DICER1* germline mutations (Nazato *et al.*, 2016). Negative prognostic predictors are disseminated disease at diagnosis, young patient's age, and partial surgical resection.
   - Intermediate grades II and III represent different degrees of differentiation and prognosis (**Table 2**).
   - Papillary tumors of the pineal region were included as a new entity in the 2007 WHO classification. They are very rare neuroepithelial tumors, macroscopically indistinguishable from pineocytomas, combining papillary and solid areas; however, microscopically, these tumors are easily distinguished. The biological and clinical behavior of these tumors is variable and may correspond to WHO grades II or III, but definite histological grading criteria remain to be defined. The median age at diagnosis is 35 years, but may affect children and adults, with no sex predilection (Fauchon *et al.*, 2000; Fevre-Montange *et al.*, 2010; Jouvet *et al.*, 2000; Mena *et al.*, 1997; Patel *et al.*, 2012; Riis *et al.*, 2013; Schild *et al.*, 1993; Nazato *et al.*, 2016). Local recurrences are common, especially if resection is incomplete, but spinal dissemination is rare. Gross total resection and younger age are associated with overall survival, while radiotherapy and chemotherapy have no significant impact. Higher Ki-67 proliferation index (>10%) or >3 mitoses per 10 high-power fields have a shorter progression-free survival (Nazato *et al.*, 2016).

☆*Change History*: August 2017. María-José Barahona and Susan M Webb updated the text and references.

This chapter is an update of Susan M. Webb, María-José Barahona, Pineal Tumours, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 615-623.

Table 1 Classification of pineal tumors

Neuroglial cells (20%)
– Low-grade astrocytomas (juvenile pylocytic)
– Intermediate diffuse and anaplastic astrocytomas
– High-grade malignant glioblastomas
Parenchymal tumors (15%–30%) (see **Table 2**)
Germ cell tumors (80% in Japan, 30%–50% in Western Europe and United States)
– Germinomas
– Nongerminomatous germ cell tumors
– Embryonal carcinoma
– Yolk sac tumor
– Choriocarcinoma
– Teratomas
– Benign teratomas
– Immature
– Mature
– Teratoma with malignant transformation
– Mixed germ cell tumors

Table 2 Parenchymal pineal tumor classification (WHO 2016 grades; Nazato et al., 2016)

Pineocytoma	I
Pineal parenchymal tumor of intermediate differentiation	II or III
Pineoblastoma	IV
Papillary tumor of the pineal region	II or III

3. Germ-cell tumors (30%–50%), with more (teratomas) or less differentiation (germinomas), as well as intermediate degrees (yolk sac tumors). An increased risk of intracranial germ cell tumors has been associated with Klinefelter syndrome, Down syndrome, and neurofibromatosis type 1.

Clinical Presentation

Clinical presentation of pineal tumors depends on age at onset and histology (Bailey *et al.*, 1996; Chang *et al.*, 1995; Gaillard and Jones, 2010). Over 90% present with raised intracranial pressure, often with obstructive hydrocephalus; initial symptoms are frequent headaches, nausea, vomiting, and decreased vision; 50%–70% of patients refer visual signs like diplopia, cranial nerve palsies, papilledema and ptosis, or Parinaud syndrome (failure of upward gaze, pupillary dilatation, and diminution of pupillary light reflex) due to pressure on the pretectal region. Compression on the brain, cerebellum, hypothalamus, and pituitary may cause paralysis of other cranial nerves, ataxia, diabetes insipidus, and hypopituitarism. Pineal tumors may interfere with puberty, due to either pressure of the tumor on the hypothalamic centers, which govern gonadotropin secretion, excessive melatonin secretion by pinealocyte tumors causing delayed puberty in adolescents, or reduction of the potential antigonadotropic effect of melatonin, which, together with beta-hCG secretion by destructive germ cell tumors, could explain precocious puberty in prepubertal children.

Diagnosis

An appropriate tissue specimen for accurate histological diagnosis and determining tumor type is critical to optimize subsequent management. Serum alpha fetoprotein (synthesized mainly by yolk sac tumors, and teratomas) and beta-hCG (in choriocarcinomas or germinomas) concentrations are of diagnostic utility if markedly elevated in serum and/or CSF. Measurement of these markers in CSF for initial staging, and if positive, for follow-up is useful. CSF cytological examination should be delayed at least 2 weeks after surgery to increase the chance of reflecting true dissemination of viable tumor rather than postoperative tumor spillage. If these markers are clearly raised, histological verification may not be required.

Biopsies may be obtained by classical surgical routes (posterior interhemispheric transcallosal, suboccipital transtentorial, and infratentorial-supracerebellar routes) or by microsurgical techniques, with significantly reduced perioperative mortality rates ($<2\%$); a neuroendoscopic or stereotactic biopsy is reasonably safe and well tolerated, in experimented hands, but the diagnosis of mixed or intermediate tumors may be difficult without extensive tissue sampling (Oi *et al.*, 2000). In any case, operative risk

Table 3 Treatment guidelines for pineal tumors

Tumor type	*Radiotherapy*	*Chemotherapy*[a]	*Surgery*
Glial origin			
Juvenile pylocytic astrocytoma	No	No	Complete resection
Intermediate/diffuse/anaplastic/ astrocytomas/glioma	Local	No	Debulking
Malignant glioblastoma	Local	No	Debulking
Parenchymal tumors			
Pineocytoma	Local	No	Biopsy
Intermediate or mixed tumor	Local ± craniospinal	Yes in more undifferentiated tumors	Biopsy
Pineoblastoma	Local Routine craniospinal not always indicated Age <5 years: Lower dose, after initial chemotherapy	Yes (role on final outcome unclear)	Biopsy
Papillary tumors	Local	No	Complete resection
Germ cell tumors			
Germinoma	Local + craniospinal (unless convinced of negative staging)	Yes (alone not curative)	Biopsy
Non-germinatous tumors	Local + craniospinal	Yes (pre- or post-surgery)	Resection as much as possible, without increased morbidity

[a]Chemotherapy includes cisplatin, etoposide, and cyclophosphamide or isofosfamide.

Surgery for histologic biopsy and subtyping, and if necessary CSF diversion (ventriculoperitoneal shunt or ventriculostomy) should always be performed, with the possible exception of germ cell tumors with diagnostically elevated tumor markers.

should be balanced with the risk of not obtaining an accurate histological diagnosis, with prognostic implications. In cases of nondiagnostic or equivocal biopsies or indicative of a benign tumor (mature teratoma, meningioma), surgery is recommended.

Imaging

An MRI will disclose the size and extension of the tumor and possible metastases, but cannot accurately identify the histological nature, which relies on biopsy or serum/CSF tumor markers. In the more malignant tumors (pineoblastomas, germinomas, teratomas) the spine as well as the brain should be imaged, since spread into the subarachnoid space and the spine are frequent.

Treatment

Surgery, chemotherapy, and radiation are used in the treatment of pineal region tumors (Cohen *et al.*, 1995; Echevarría *et al.*, 2008; Jackacki *et al.*, 1995). Surgery, either open, stereotactic, or endoscopic, is used to obtain a biopsy, mandatory in the majority of cases to obtain a definite histological diagnosis. Morbidity and cure rates have improved over the last years thanks to a greater understanding of the nature of the different tumors, more accurate neurosurgical experience, selective use of chemotherapy, and the introduction of modern irradiation techniques. However, the rarity of pineal tumors makes the obtaining of large prospective multicenter international studies to define their optimal management difficult.

Treatment depends on histology obtained after surgery, which apart from the biopsy can resolve intracranial hypertension with a ventricular shunt (atrial or peritoneal) and perform partial debulking of the tumor if possible; total resection is rarely possible. The use of radiotherapy and chemotherapy depends on the type of tumor (**Table 3**).

The optimal treatment for papillary tumors of the pineal region remains controversial, as no definitive treatment strategy exists for this lesion. It has been described that a minimally invasive strategy (radiotherapy or stereotactic radiosurgery) resulted in a favorable response to treatment, avoiding the risks of aggressive surgical removal. However, incomplete resection tended to be associated with decreased survival and with recurrence. In an updated retrospective series of 44 patients, only gross total resection and younger patient age were associated with overall survival; radiotherapy and chemotherapy had no significant impact (Nazato *et al.*, 2016).

Vasopressin

Aoife Garrahy and Christopher J Thompson, Beaumont Hospital/RCSI Medical School, Dublin, Ireland

Introduction

Vasopressin is a small, nonapeptide hormone, synthesized in the hypothalamus, and released into the circulation from the posterior pituitary gland. The main physiological stimulus to vasopressin secretion is rising plasma osmolality, though significant reductions in arterial blood pressure and blood volume can also stimulate vasopressin secretion, by unloading of arterial baroreceptors. Although historically named as a result of its potent vasopressor actions, these actions only occur when plasma vasopressin is present in the plasma in supraphysiological concentrations. The most important action of vasopressin is its antidiuretic action on the collecting ducts of the kidney. Vasopressin binds to V2 receptors on the cell surface of tubular cells, initiating an intracellular cascade which results in the generation of the water channel, aquaporin-2. Preformed aquaporin-2 also migrates and inserts into the luminal membrane of the tubule cells, where it acts a conduit for water to be reabsorbed from the urine, through the cell, and back into the circulation. This leads to a decrease in renal free water clearance, concentration of urine, and a reduction in urine volume. The net effect is the reabsorption of water into the blood, which, along with thirst-generated water intake, leads to normalization of plasma osmolality.

Regulation of vasopressin secretion and action thus represents a key homeostatic process which protects the osmotic milieu of the body, allowing normal cellular function. In this chapter we will review the synthesis, secretion and action of this crucial hormone.

Synthesis and Secretion of Vasopressin

Vasopressin is synthesized in the ribosomes of the cell bodies of the magnocellular neurones of the supraoptic and magnocellular nuclei, in the hypothalamus. Once the pre-pro-hormone complex of vasopressin, copeptin and neurophysin II (**Fig. 1**) is synthesized, it is packaged in granules, for axonal transport to the posterior pituitary. The pre-pro-hormone, which has a molecular weight of approximately 20,000 Da progresses down the axons of the magnocellular neurones. During axonal transport, the large molecule is enzymatically cleaved into the three component parts; vasopressin, neurophysin II and copeptin. Copeptin is thought to modulate the three dimensional unfolding of vasopressin into the functioning molecule (Acher et al., 2002). The secretory granules, which contain all three component molecules are then stored in secretory granules at the neuronal terminals in the posterior pituitary, in preparation for secretion into the circulation, in response to osmotic, baroregulatory, or other stimuli. Stimulatory neural inputs, from the osmoreceptors in the anterior hypothalamus, or from the baroreceptors in the arterial circulation, lead to electronic impulses along the magnocellular neurones, and depolarisation of the cell membrane, releasing vasopressin and its copeptides into the systemic circulation.

Some of the vasopressin-containing neurosecretory neurones, mainly from the paraventricular nucleus, terminate in the median eminence (Zimmerman, 1981). Depolarisation of these neurones causes secretion of vasopressin into the portal blood supply to the anterior pituitary gland. Vasopressin is known to augment the CRF-dependent release of ACTH from the anterior pituitary gland (Scott and Dinan, 1998). Other vasopressinergic neurones from the paraventricular nuclei terminate throughout the nervous system, in the lateral and third ventricles, the medulla and the amygdala.

Osmoregulation of Vasopressin Secretion

The principle physiological determinant of plasma vasopressin secretion is plasma osmolality. Rises in plasma osmolality are detected in specialized osmoreceptor cells in the anterior hypothalamus, located in the subfornical organ (SFO) and the organum vasculosum lamina terminalis (OVLT) (Thrasher et al., 1982; Ferguson and Kasting, 1986) (**Fig. 2**). It has been hypothesized that fenestrations in the blood brain barrier in the region of the anterior hypothalamus allows plasma access to these magnocellular neurones, and when plasma osmolality rises, its causes depolarisation of the neurones in the SFO and OVLT. The osmoreceptors for vasopressin release and thirst are situated in close anatomical proximity in this area, so that it is usual for lesions in this area to affect both modalities simultaneously.

Physiological studies in healthy humans has shown that there is a close linear relationship between plasma osmolality and plasma vasopressin concentrations (Robertson et al., 1976; Thompson et al., 1986). Higher experimental rates of rise in plasma osmolality may alter the relationship to a curvilinear vasopressin response, but in physiological conditions, vasopressin rises in a linear fashion (**Fig. 3**, panel A). Experimental studies also confirm that there is a linear response between plasma osmolality and thirst ratings, as measured by a well validated linear analogue scale (**Fig. 3**, panel B) (Thompson et al., 1986; Phillips et al., 1984). When linear regression analysis is applied to the results of osmotic stimulation of thirst and vasopressin release, using hypertonic

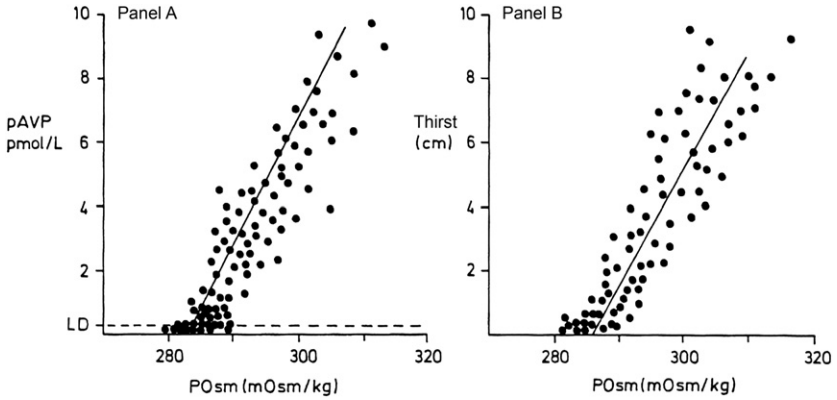

Fig. 3 The relationship between plasma osmolality and plasma vasopressin in healthy man is shown in panel A, and is described by the regression line pAVP = 0.43 (pOsm—284.3), $r = +0.92$, $P < .001$. LD represents the limit of detection of AVP, 0.3 pmol/L (Rooke and Baylis, 1982). Panel B shows the relationship between plasma osmolality and thirst and is defined by the regression line Thirst = 0.39 (pOsm—285), $r = +0.95$, $P < .001$. From Thompson, C. J. (1989). Polyuric states in man. *In:* Baylis, P. H. (ed.) *Baillieres Clinical Endocrinology and Metabolism: Water and salt homeostasis in health and disease.* 1989/08/01 ed. London: Bailliere Tindal & Cox.

saline infusion, it can be demonstrated that the osmotic threshold at which onset of thirst and release of vasopressin begin, are similar in healthy man (Phillips et al., 1984; Thompson et al., 1986). The relationship between plasma osmolality, expressed as both the slope (sensitivity) or the abscissal intercept (osmotic threshold) of the linear regression line seem highly reproducible within an individual, although there is significant interindividual variation (Thompson et al., 1991). Twin studies have shown that there is a high degree of concordance in both slope and intercept of the osmoregulatory line in monozygote, but not dizygote, twins (Zerbe, 1985), suggesting that the characteristics of the osmoregulatory relationship between plasma osmolality and vasopressin release are strongly genetically determined.

The original osmoregulatory studies showed that although the hypothalamic nuclei are osmotically sensitive, they do not respond in a similar way to all osmolytes; in other words they are solute specific. The osmolyte with the most powerful vasopressin secretagogue properties is sodium; urea is less powerful, whereas glucose seems to have little capacity to cause release of vasopressin except in the presence of insulin deficiency (Zerbe and Robertson, 1983; Thompson et al., 1988; Thompson et al., 1989). The inability of acute hyperglycaemia to provoke either thirst or vasopressin secretion is interesting, and perhaps suggests that the thirst associated with uncontrolled diabetes is due to volume depletion, rather than hyperglycaemia. The osmoregulatory relationship between plasma osmolality and vasopressin can also be altered by blood volume, in that the vigor of the vasopressin response to osmotic stimulation is enhanced by volume depletion (Dunn et al., 1973). Teleologically this would represent a

greater need for water conservation, and perhaps additional vasoconstrictor effects, when blood volume or blood pressure is compromised, and therefore it points to a positive adaptive response.

Lowering plasma osmolality has the opposite effect of hyperosmolarity, in that vasopressin and thirst are suppressed. Once plasma osmolality falls below the osmotic threshold indicated by regression analysis—usually around 284–286 mOsm kg^{-1}—plasma vasopressin concentrations become undetectable, even on the most sensitive radioimmunassays, though ultrasensitive cytochemical assays are still able to document low concentrations of vasopressin in the plasma (Baylis et al., 1986). The appearance of a hypotonic aquaresis at low plasma osmolalities does demonstrate that the theoretical concept of an osmotic threshold for vasopressin secretion has clinical relevance however. Although osmotic suppression of vasopressin secretion and thirst occurs, careful experimental studies also suggest an important role for neuroinhibitory reflexes, initiated by the act of drinking. Healthy volunteers allowed unlimited access to water show an immediate switch off of thirst appreciation and vasopressin secretion almost immediately after drinking, while plasma osmolality remains in the elevated range (Seckl et al., 1986; Thompson et al., 1987). Studies in the dog show a similar rapid fall in plasma vasopressin concentration soon after drinking; if water is instilled directly into the stomach via nasogastric tubes, this inhibitory effect does not occur, suggesting that the inhibition of vasopressin occurs more proximally, in the oropharynx (Thrasher et al., 1987). Rat studies, in which dehydration is followed by sham rehydration, suggest that preabsorptive reflexes regulate the activity of vasopressinergic neurones (Knight et al., 2010); Stricker and colleagues concluded that oropharyngeal signals inhibiting vasopressin were dependent upon the volume of the ingested fluid (Stricker and Hoffmann, 2007).

Nonosmotic Stimulation of Vasopressin Secretion

Baroregulation of vasopressin secretion in response to hypovolemia or hypotension is by far the most important of the nonosmotic stimuli. A considerable decline in blood pressure, in the order of 15%–20% is necessary to stimulate significant baroregulated vasopressin. This assumes homeostatic importance in shock, when the drop in blood pressure unloads the baroreceptors, leading to massive release of vasopressin from the posterior pituitary, at plasma concentrations sufficient to cause compensatory vasoconstriction. Baroreceptors are of two main types; low pressure receptors in the left atrium and high pressure receptors in the sino-aortic area. The high pressure receptors send inhibitory signals to the SON and PVN, but when blood pressure or blood volume drop significantly, these receptors are unloaded, and the inhibition of vasopressin secretion is removed. This is a very powerful stimulus to vasopressin secretion which produces plasma concentrations significantly higher than those produced by dehydration. Baroreceptors also modulate the vasopressin responses to osmotic stimuli, with higher plasma vasopressin concentrations per unit rise in plasma osmolality, when blood volume reduction is present (Baylis and Thompson, 1988).

Hypoglycemia (Baylis et al., 1981) causes modest elevations in plasma vasopressin concentrations. Although this could be interpreted as a homeostatic response to hypoglycemia, it is unlikely to be significant, as activation of glycogen breakdown and elevation of blood glucose concentration, has only been demonstrated at plasma vasopressin concentrations many times higher than that achieved by experimental hypoglycemia (Spruce et al., 1985). Nausea is a powerful vasopressin secretagogue.

Actions of Vasopressin

Vasopressin has various actions throughout the body which are mediated by binding to action-specific receptors on the cell surface. The subtypes and tissue-specific actions are shown in **Table 1**.

V1 Receptors

V1 receptors are found in high density on the cell surface of vascular smooth muscle cells, and vasopressin/receptor bindings generates intracellular calcium, via the phosphatidyl-inositol intracellular cascade. This leads to vasoconstriction, though this effect

Table 1 Subtypes and tissue specific actions of vasopressin receptors

Receptor	*Gene*	*Anatomical distribution*	*Intracellular signaling*	*Physiological action*
V1	AVPR1	Vascular smooth muscle Platelets, hepatocytes, myometrium	G-protein coupled phosphatidylinositol and calcium	Vasoconstriction Platelet aggregation Glycogenolysis Uterine contraction Cardiac hypertrophy
V2	AVPR2	Renal collecting duct Vascular endothelium Vascular smooth muscle	Adenyl cyclase and cAMP	AQP-2 synthesis Migration of preformed AVP into luminal cell membrane Secretion of von Willebrand factor and factor VIII
V3	AVPR3	Anterior pituitary gland	G-protein coupled phosphatidylinositol and calcium	ACTH release

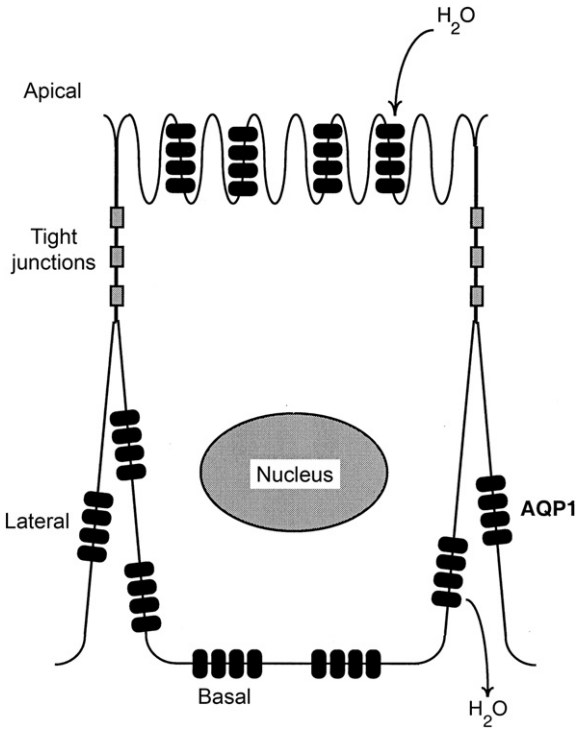

Fig. 4 Diagram representing transcellular water permeation of proximal tubule cell via AQP1. From Agre, P. (2000). Aquaporin water channels in kidney. *Journal of the American Society of Nephrology*, **11**, 764–777.

is not significant when vasopressin is present in the circulation at physiological concentrations. V1 receptors are also located on the cell surface of platelets and receptor binding induces thrombotic effects.

V2 Receptors

V2 receptors are found on the basolateral surface of the cells of the collecting tubules. Activation of these receptors initiates the key homeostatic action of vasopressin, namely water reabsorption from the urine. Binding of vasopressin to the cell surface V2 receptor initiates an intracellular cascade, which activates adenyl cyclase and generates cAMP and protein kinase A. This leads to the increased gene expression, and synthesis of, the Aquaporin water channel AQP-2 (Fushimi et al., 1993; Agre, 2000). In addition, it stimulates the movement of preformed AQP-2 vesicles to the apical cell membrane, where AQP-2 is inserted into the membrane, from which position it allows passage of water from the urine into the interior of the cells (**Fig. 4**). With reabsorption of water from the urine, urine volume falls, free water clearance is reduced, and urine osmolality increases. Failure of AVP/receptor binding, or failure to generate AQP-2, causes inability to concentrate urine, leading to nephrogenic diabetes insipidus. Genetic mutations of the V2 receptor, or, less commonly, mutations in the gene that encodes for AQP-2 production, can produce renal resistance to vasopressin, or congenital nephrogenic diabetes insipidus (Bichet, 2009). Acquired nephrogenic diabetes insipidus also occurs relatively commonly in patients on chronic lithium therapy (Moeller et al., 2013).

There is a sigmoid relationship between plasma vasopressin concentration and urine osmolality. When plasma osmolality has been lowered to below the osmotic threshold for vasopressin secretion and plasma vasopressin is undetectable on conventional radioimmunoassays, urine osmolality is low, usually at <100 mOsm/kg. As plasma vasopressin concentrations rise, there is a progressive urine concentration, with urine osmolalities rising to >800 mOsm/kg (**Fig. 5**). Urine osmolality therefore acts as a sensitive bioassay for the presence of circulating vasopressin. This is used in the diagnosis of SIAD, where urine concentration inappropriate for the low plasma concentration, represented by urine osmolality >100 mOsm/kg, is one of the key diagnostic criteria.

V3 Receptor

The V3 receptor is located in the anterior pituitary and vasopressin binding to this receptor stimulates ACTH secretion. Although in experimental conditions, vasopressin can independently stimulate ACTH secretion, in physiological conditions the role of vasopressin is to augment the secretagogue effect of CRF.

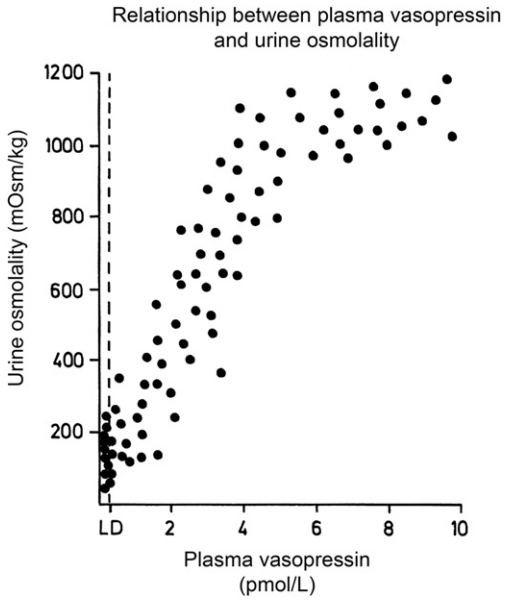

Fig. 5 The relationship between plasma vasopressin and urine osmolality in healthy volunteers during water loading and various stages of water deprivation. LD represents the limit of assay detection for AVP, 0.3 pmol/L (Rooke and Baylis, 1982). From Thompson, C. J. (1989). Polyuric states in man. *In:* Baylis, P. H. (ed.) *Baillieres Clinical Endocrinology and Metabolism: Water and salt homeostasis in health and disease.* 1989/08/01 ed. London: Bailliere Tindal & Cox.

Measurement of Vasopressin

The original experiments of VB Verney proposed the existence of an endogenous antidiuretic substance, after he demonstrated that the intracarotid injection of hypertonic saline into the conscious dog caused a prompt antidiuresis (Verney, 1947). However it was only with the subsequent development of antibodies to arginine vasopressin, which allowed the development of radioimmunoassays for vasopressin (Robertson et al., 1973; Rooke and Baylis, 1982), that the functional characteristics of vasopressin in health and in disease states, could be defined. However, despite the development of these early, highly sensitive radioimmunoassays, there are considerable logistic difficulties in the routine measurement of vasopressin, as either a research tool, or as an adjunct to clinical practice.

Vasopressin is a small molecule, which is present in minute quantities in physiological states. This is particularly difficult in humans, in whom social drinking suppresses vasopressin concentrations to close to the limit of even the most sensitive of assays. It is therefore very difficult to distinguish between physiological plasma concentrations and biologically suppressed concentrations; many of the commercial antibodies available for the development of radioimmunassays are completely unable to measure basal hormone levels with any degree of accuracy. The low plasma concentrations of vasopressin mean that the hormone must be extracted from plasma prior to assay, and the delicate nature of the hormone means that samples must be flash frozen in a $-70^{\circ}C$ freezer. Finally the assay is ponderous, time consuming and only available in a few highly specialized laboratories where it is principally used as a research tool.

This has led to interest in the measurement of copeptin as an alternate to vasopressin. Copeptin is a 39 amino acid peptide, which is a larger molecule, with a longer half life than vasopressin (Fenske et al., 2018). It is cosecreted into the plasma with vasopressin, and although it has no intrinsic biological activity, it offers a surrogate for plasma vasopressin concentrations, which is quicker, easier and cheaper to measure (Szinnai et al., 2007). Although it has been proposed that measurement of copeptin may be of value in the differential diagnosis of hyponatraemia (Fenske et al., 2009), it is unlikely that this will be of clinical value, as plasma vasopressin concentrations are elevated in almost all cases of hyponatraemia, and measurement of plasma vasopressin concentration does not constitute an important component of the diagnostic process. There has been far more interest in the use of copeptin in the differential diagnosis of polyuric states (Balanescu et al., 2011; Christ-Crain and Fenske, 2016); suppressed plasma levels in diabetes insipidus correlate with undetectable plasma vasopressin concentrations, though both hormones rise during osmotic stimulation in patients with primary thirst disorders. Given that copeptin can be readily measured in most competent laboratories, measurement of this peptide is likely to replace the occasional measurement of vasopressin in clinical practice.

Disorders of Vasopressin Secretion

Subnormal or absent vasopressin secretion gives rise to the passage of high volumes of hypotonic urine, a condition known as diabetes insipidus. A wide variety of neoplastic, inflammatory, vascular and infective conditions in the hypothalamo-pituitary area

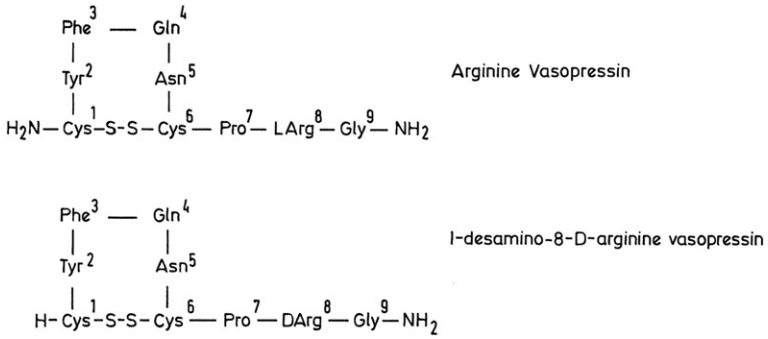

Fig. 6 Structures of arginine vasopressin and the structural analogue 1-desamino-8-D-arginine vasopressin.

can impair vasopressin secretion and produce central diabetes insipidus. In addition, genetic defects of the vasopressin V2 receptor, and a number of metabolic abnormalities, as well as lithium therapy, can cause insensitivity to the antidiuretic actions of vasopressin, leading to nephrogenic diabetes insipidus.

Conversely, abnormal or exaggerated secretion of vasopressin leads to reduction in free water clearance, accumulation of extracellular water, and the development of hyponatraemia.

These conditions are covered in depth in the relevant chapters of this textbook.

Clinical Uses of Vasopressin

The pressor properties of vasopressin are used to treat hypotensive shock, particularly due to bleeding oesophageal varices. Because the V1 receptors are widespread in the circulation, vasoconstriction is not confined to bleeding areas, and therapeutic use of intravenous vasopressin may lead to mesenteric and coronary artery vasoconstriction, leading to abdominal cramps or angina.

Because of the short half life of endogenous vasopressin (approximately 5 min), the native molecule has to be altered to make it useful for long-term treatment of diabetes insipidus. Desmopressin (ddAVP) is synthesized with two modifications to the molecular structure of native vasopressin; the amino group in the cysteine has been removed to prolong the plasma half life (Sawyer et al., 1974b) and D-arginine has been substituted for L-arginine to minimize pressor activity (**Fig. 6**) (Sawyer et al., 1974a). Desmopressin is available in intranasal and oral form. The most common side effect of therapy is dilutional hyponatraemia, occurring in 27% of ambulatory blood samples in patients with diabetes insipidus, and causing admission with hyponatraemia in 5.8% of patients with normal thirst appreciation (Behan et al., 2015). Dilutional hyponatraemia can be effectively prevented by delaying taking desmopressin once or twice weekly; this allows an aquaresis to occur, which prevents accumulation of water reabsorbed by the antidiuretic actions of desmopressin. Alternatively patients can delay every dose of desmopressin until clinically needed to prevent polyuria, though this method often leads to unacceptable disruptions to life routines.

Summary

This article explores the physiology of vasopressin synthesis, secretion and action, in order to provide the basis for the disorders of secretion and action which will be described in later articles. Vasopressin is a unique hormone; despite the small molecular weight, it has a fundamental role in maintaining cellular homeostasis.

Glossary

Dendrite Branching neurites that emanate from the neuronal cell body.
Dendritic spine A small protrusion of the cell membrane of the dendrite that receives excitatory input.
Glucocorticoids Steroid hormones released from the cortex of the adrenal gland such as cortisol and corticosterone.
Neurogenesis The production of new neurons.
Sex steroids Steroid hormones released from the gonads such as androgens, estrogens, and progestins.
Steroid hormones A family of hormones derived from cholesterol and characterized by their three six'carbon rings and one five'carbon ring.

Introduction

The brain receives a rich supply of blood and is constantly in contact with circulating hormones in the bloodstream. Thus, it is not surprising that the brain is influenced and modulated by hormones. One major class of hormones is the steroid hormones, which gain access to the brain because of their hydrophobic chemical structure that allows them to pass across the blood–brain barrier. Steroid hormones have a wide range of effects on the brain. For instance, steroids help to shape the brain during perinatal development and continue to modulate the structure and function of the central nervous system (CNS) into adulthood and throughout the life span. Specifically, steroids can influence factors such as neuronal survival, neurogenesis, neurite outgrowth, synaptogenesis, receptor expression, RNA synthesis, and neuronal excitability. These effects at the cellular level affect many aspects of mood, cognition and behavior. The effects of the steroid hormones on the development, structure, and function of the brain are the focus of this article.

The Mechanisms of Steroid Hormone Action in the Brain

Steroid hormones can be classified into the gonadal sex steroids (androgens, estrogens, progestins) and the adrenal corticosteroids. Corticosteroids in turn are either mineralocorticoids involved in salt homeostasis (e.g., aldosterone), or the glucocorticoid stress hormones (e.g., cortisol). During pregnancy, the placenta also produces steroid hormones. The biosynthesis of all steroid hormones starts with enzymatic cleavage of cholesterol. All endocrine organs can convert cholesterol to pregnenolone inside mitochondria and further convert pregnenolone to progesterone in the endoplasmic reticulum. Further enzymatic reactions are performed by tissue specific enzymes that are expressed only in some of the endocrine organs (Hanukoglu, 1992). For example, testosterone is produced in the gonads by a series of enzymatic reactions that convert cholesterol to progesterone, and then via other intermediates to testosterone (Payne and Hales, 2004). Testosterone can be converted to estrogen by the aromatase enzyme in a reaction called aromatization. Although testosterone is considered the "male sex steroid" and estrogen is considered the "female sex steroid," it is important to note that testosterone and estrogen are found in both males and females. In fact, estrogen formed locally in the brain of males by the aromatization of testosterone is responsible for masculinization of the male brain and plays a major role in activating male sexual behavior during adulthood. Such pre-receptor metabolism also occurs for glucocorticoids, that may be inactivated or regenerated by the 11β-hydroxysteroid dehydrogenase 1 or type 2 (11β-HSD1/2). 11β-HSD1 is highly expressed in the hippocampus converting inactive cortisone into active cortisol. Conversely, 11β-HSD2 converts active cortisol into inactive cortisone to exclude cortisol from binding the mineralocorticoid receptors in, for example the kidney and a limited number of brain areas to enable aldosterone rather than cortisol to bind the mineralocorticoid receptor (Seckl and Walker, 2001).

Localisation

The steroid hormones bind to specific receptors located throughout the brain. All steroid hormones can bind to cognate nuclear receptors; intracellular receptor that can bind to DNA to regulate gene expression. This allows for both the "activational" effects

☆*Change History*: December, 2017. Anne-Sophie CAM Koning, Russell D Romeo, Bruce S McEwen and Onno C Meijer updated the text and added new references.

This chapter is an update of Russell D. Romeo, Bruce S. McEwen, Brain, Effects of Steroid Hormones, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 414–418.

 doi:10.1016/B978-0-12-801238-3.95781-7

within hours of activation and "organizational" effects during development that are very long lasting. The structure of the different steroid receptors is very similar, with the two estrogen receptors (ER) ERα and ERβ being a bit more distant from the androgen, progesterone, glucocorticoid, and mineralocorticoid receptors. Each of the six classical steroid receptors has a unique expression pattern in the brain, and this allows for a large number of steroid effects, that may show considerable region specificity even for a particular steroid (Mahfouz *et al.*, 2016).

The gonadal steroid progesterone binds to the progesterone receptor (PR), which has two isoforms that are derived from the same gene: PRA and PRB. Both PRA and PRB are expressed in the hypothalamus, hippocampus, and cortex. In addition, progesterone binds to a G-protein coupled seven transmembrane receptor (GPCR) known as 7TMPR or mPR. mPR has three isoforms α, β and γ, of which the γ isoform is specifically expressed in neural tissues (Brinton *et al.*, 2008). Also estrogen can activate a classical GPCR, GPR30, adding to the signaling repertoire of the steroids (Prossnitz *et al.*, 2008). High expression of the classical ERα and ERβ is found in amygdala, hypothalamus, prefrontal cortex, hippocampus, thalamus, and cerebral cortex (Hara *et al.*, 2015). The other gonadal steroid testosterone binds to the androgen receptor (AR), which is expressed in the brain both in hypothalamus and in higher brain regions, such as the hippocampus (Beyenburg *et al.*, 2000).

Cortisol can, in the brain, bind two types of receptors: the glucocorticoid receptor (GR) and the mineralocorticoid receptor (MR) (Reul and de Kloet, 1985). Aldosterone also binds to the MR, but is outcompeted by corticosterone (in rats and mice) and cortisol unless these are enzymatically degraded (Wyrwoll *et al.*, 2011; Funder, 2005). In the brain most MRs are cortisol preferring. Cortisol has a higher binding affinity for MR than GR. As a consequence, at low cortisol levels MRs are activated and with high cortisol levels, for example after stress, GRs get activated. MR is abundantly expressed in limbic neurons, most notably the principal neurons of the hippocampus, while GR is expressed in neurons and glial cells throughout the brain. In the hippocampus, MR and GR are co-localized and can mediate opposite effects of cortisol. Given its high affinity and pre-stress occupancy, MR is important in the onset of the stress response and in appraisal of stimuli, while GR is involved in memory storage (de Kloet *et al.*, 2005). More effects of the individual steroids hormones will be discussed later in this article.

Signaling Mechanisms

There are three mechanisms through which steroid hormones exert their actions on neurons: genomic, indirect genomic, and nongenomic. The various mechanisms of steroid hormone action are presented in **Fig. 1**. The fastest, but least understood mode of action is non-genomic. They may be mediated by dedicated membrane type receptors in case of the sex steroids, but also by membrane associated variants of the classical nuclear receptors. For instance, steroids have been shown to bind to receptors located in the plasma membrane of neurons, and rapidly affect synaptic (re-)activity, for example, spontaneous glutamate release in the hippocampus (Karst *et al.*, 2010). Extranuclear estrogen receptors were found in axon terminals and spines of hippocampal CA1 pyramidal cells of the female rat. Various mRNAs for synaptic proteins and translation machinery have been localized in spines, suggesting that translation of such proteins can occur locally in the dendrite. Thus, estrogens may act directly on the synaptic apparatus and mRNAs to affect synaptic function and synaptogenesis. These non-genomic effects of steroids become manifest within minutes after receptor activation.

Eventually, events at the cell membrane may also via activation of second messenger pathways lead to the activation of transcription factors in the cell nucleus. The "classical" and slower genomic mechanism of steroid hormone action begins by the hormone diffusing through the plasma membrane of the neuron and binding to its intracellular receptor located in either the cytoplasm or the nucleus. This hormone–receptor complex then undergoes a conformational change allowing the hormone–receptor complex to migrate, dimerize, and bind to particular hormone response elements (HREs) on the DNA. Once the hormone–receptor complex binds to its HRE, it subsequently binds co-activators or co-repressors to activate or repress gene transcription, ultimately affecting the production of proteins that may alter the functioning of the neuron, or glia cell. This mode of signaling allows cross talk between different steroid receptors, as MR, GR, AR, and PR recognize (in part) the same HRE elements (Falkenstein *et al.*, 2000).

Steroids receptors may also interact with other, non-receptor, transcription factors. For example, GR may interact with other, non-receptor, transcription factors. For example, GR may interact with AP-1, where only the latter factor is bound to the DNA. Genome wide analysis of GR and MR binding at the chromatin for now indicates that direct HRE binding of the receptors is the dominant mode of action in the rodent hippocampus (van Weert *et al.*, 2017).

Organization Versus Activation

Steroid hormones not only allow for the activation of certain behavioral and physiological events during adulthood but also shape the nervous system during development. During perinatal development, the brains of males and females are exposed to different hormonal milieus that ultimately lead to many of the sex differences observed in the brain and behavior of males and females during adulthood. For instance, males experience increases in testosterone production and secretion during both prenatal and early neonatal development. This, on conversion in the brain to estradiol via the aromatase enzyme, organizes the brain in a masculine fashion. This early masculinization of the brain then allows the hormonal stimulation received during adulthood to act on these organized neural pathways to activate the appropriate male behaviors. In the perinatal female, the estrogen produced by the mother and the prenatal ovary does not masculinize her brain because this estrogen is bound by alpha fetoprotein and is

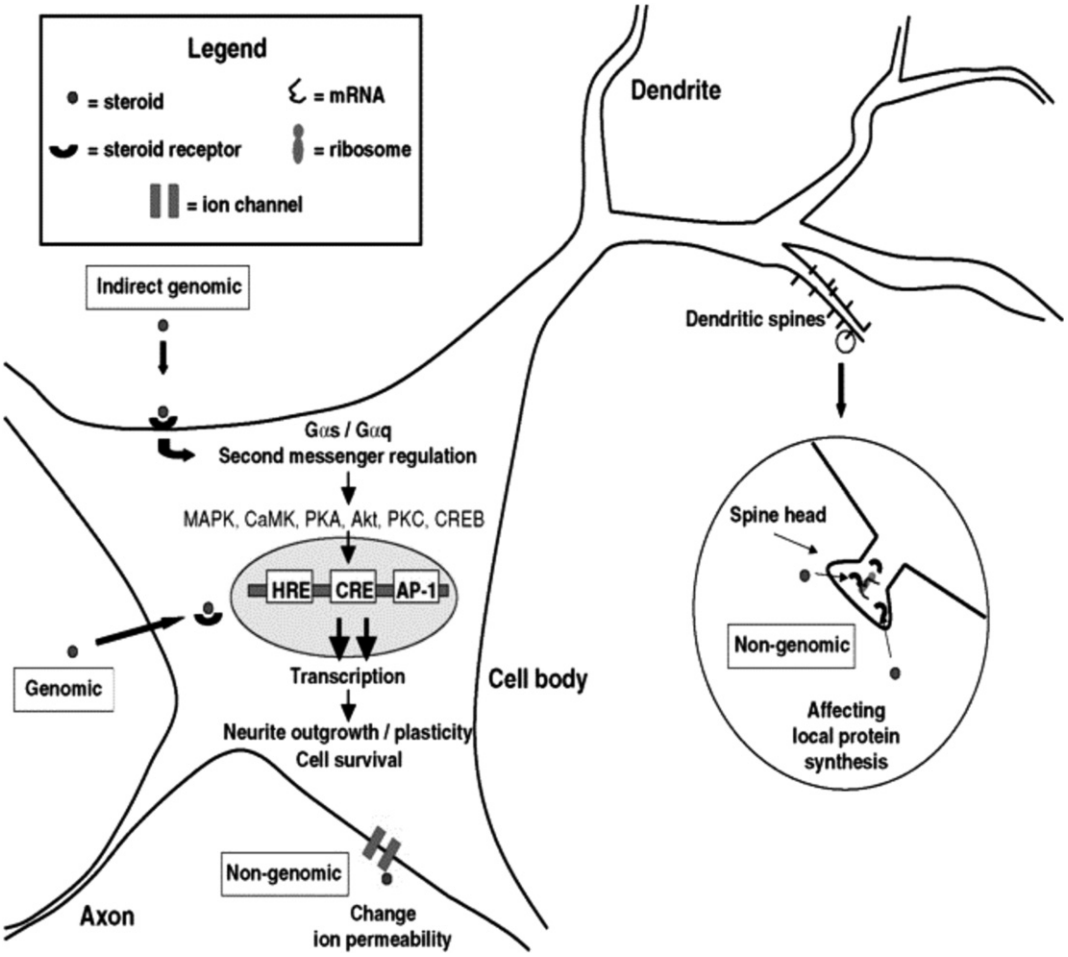

Fig. 1 The genomic, indirect genomic, and nongenomic mechanisms of steroid hormone action on neurons. Indirect genomic mechanisms include the activation of steroid receptors linked to second messenger cascades that activate gene transcription through DNA-binding domains such as cAMP response element (CRE) and activator protein-1 (AP-1), ultimately altering neuronal function. In the genomic mechanism, the steroid binds to the intracellular form of the receptor, permitting the steroid–receptor complex to translocate to the nucleus. This steroid–receptor complex then binds to the hormone response element (HRE), activating transcription of the genome and altering neuronal function. Nongenomic mechanisms of steroid action include the ability of steroids to influence ion permeability and possibly to affect local protein synthesis in the spine head. This later mechanism presumably would allow for the rapid regulation of spine-specific mRNAs and proteins. *Akt*, protein kinase B; *CaMK*, Ca^{2+}/calmodulin-dependent protein kinase; *CREB*, cAMP response element-binding protein; *Gαs and Gαq*, guanosine triphosphate (GTP)-binding proteins; *MAPK*, mitogen-activated protein kinase; *PKA*, protein kinase A; *PKC*, protein kinase C.

unable to cross the blood–brain barrier. Indeed, the feminized brain appears to be the default pattern of development in that a brain that does not receive androgenic and estrogenic stimulation during development results in a feminized brain.

The organizing influences of steroid hormones on the perinatal brain and the resulting morphological and functional differences between the sexes can be profound. Indeed, the organizing effects of steroids result in certain sexually dimorphic nuclei in the nervous system that may be as much as five times larger in one sex than in the other. Likewise, early life stress (during the first weeks of life in the rodent) can have long lasting consequences for the organization of brain circuits. However, in these cases the role of the actual steroid exposure is less well understood, as there are many other mediators activated upon stress. The effects of steroids on the adult brain are much more subtle than these organizing effects during perinatal development. However, steroids are still capable of shaping the adult brain in important ways (Becker *et al.*, 2002).

Effects of Steroids Hormones During Adulthood

Steroid hormones allow for the activation of certain behavior and psychological events during adulthood. For example in rats, female sexual lordosis behavior does not occur in absence of estrogens, but can be primed by a single estrogen treatment 2 h before the encounter with a male rat (Becker *et al.*, 2002). Sex steroids do not only affect reproduction but also other mental domains, such as testosterone effects on aggression. In male mice, aggression is positively correlated with increased circulating testosterone levels and castration of male mice show decreased aggressive behavior (Book *et al.*, 2001).

The stress hormone cortisol has substantial effects on behavior. Cortisol binding to the MR influences emotional and cognitive processes, such as memory retrieval, appraisal of potentially stressful situations and the response to stress. Binding to GR will lead to behavioral adaptation and memory storage, and can effect domains as different as reward, eating behavior, anxiety and mood, decision making and sleep (Meijer and de Kloet, 2017). These immediate effects of cortisol are beneficial, but chronic stress with long-term exposure to high cortisol levels has negative effects, such as impaired learning, disturbed anxiety and aggression regulation, increased risk for depression, cardiovascular problems, osteoporosis and obesity (de Kloet *et al.*, 2005). The negative effects of chronic exposure to high levels of cortisol are underscored by the many psychiatric and cognitive complaints in Cushing's disease patients, some of which can persist for many years (Andela *et al.*, 2013).

Steroid-Induced Neuronal Plasticity During Adulthood

Sex steroids have been shown to affect the density and morphology of dendritic spines. Spines are membranous protrusions emanating from dendrites and are sites of synaptic contact between neurons. Neurons receive excitatory input via these dendritic spines, which contain various types of glutamate receptors, scaffolding proteins, and signaling molecules. Spines come in various sizes and shapes that may be indicative of their maturity. Different steroids can affect the growth and development of spines, thereby modulating excitatory neuronal signaling.

The hypothalamus was the first brain area in which sex steroids were shown to influence synapse formation and spine maturation. Ovariectomized females have significantly fewer synaptic contacts in their ventromedial nucleus (VMN) than do ovariectomized females treated with estrogen. Furthermore, females in the proestrous stage of their estrous cycle (i.e., when estrogen levels are high) have a greater spine density than do females in diestrus (i.e., when estrogen levels are relatively low). The VMN is a fundamental component of the neural circuit that mediates the expression of female reproductive behavior. Thus, it is not surprising that estrogenic stimulation that activates female mating behavior would also promote spine density and, hence, increase excitatory input to the VMN. In males, VMN spine density increases after castration, whereas estrogen-treated males exhibit a relatively low number of spines, similar to the density observed in intact males. Thus, the effect of estrogen on VMN spine density in males is opposite that in females.

Similar effects have been observed in the arcuate nucleus (ARC) of the hypothalamus, which plays an important role in mediating the release of the gonadotropins from the anterior pituitary. The dendrites of these neurons in hormone-dependently females have twice as many spines than males, and presumably the greater excitatory input to the female ARC, may help to modulate the luteinizing hormone surge that causes ovulation in females.

Interestingly, such estrogen effects also occur in the hippocampus, and may in this way affect the organism's ability to remember. In females with higher estrogen levels significantly greater numbers of these dendritic spines were found compared with low estrogen levels. Additional studies have shown that this increased spine density is accompanied by an increased synaptic input to the apical dendrites of the hippocampal CA1 pyramidal cells. These structural alterations are paralleled by physiological and behavioral changes as well. Specifically, adult female rats experiencing high levels of estrogen show enhanced hippocampal long-term potentiation (LTP), a putative electrophysiological correlate of learning and memory, and improved memory retention on a hippocampal-dependent spatial memory task.

Whether estrogen increases hippocampal spine formation in humans is unknown, but estrogen replacement therapy has been shown to promote cognition in postmenopausal women (Bean *et al.*, 2014; Hara *et al.*, 2015). It also has been suggested that estrogen may aid in the prevention or amelioration of neurodegenerative diseases such as Alzheimer's disease. Another study has shown that estrogen can induce greater spine density in the prefrontal cortex of nonhuman primates. Given that the prefrontal cortex of primates is involved in many aspects of cognitive function, it is possible that the memory-enhancing effects of estrogen are mediated, at least in part, by its actions on both the hippocampus and the cortex.

Males do not show the same increase in spine density in response to estrogen. However, testosterone has been shown to increase the number of spines on the CA1 pyramidal cells of males. In addition, it was shown that neural AR deletion selectively impairs hippocampal LTP (Picot *et al.*, 2016).

Cortisol daily rhythmicity helps to sustain a normal rate of spine turnover. However, in contrast to the spine-promoting effects of estrogen and testosterone, high levels of corticosterone induced by repeated stressors, have been shown to decrease the branching of hippocampal CA3 pyramidal cells and to cause dendritic atrophy. Animals experiencing chronic stress also tend to perform more poorly on learning and memory tasks than do non-stressed animals. It is important to note that low to intermediate levels of "stress hormones" enhance performance on learning and memory tasks. Studies have found that high levels of corticosterone suppress LTP, whereas intermediate levels enhance plasticity. In general, MRs and GRs activation lead to behavioral adaptation, but with chronic stress MR and GR gene expression seem to adapt (de Kloet *et al.*, 2005). Both animal studies, and genetic variants in humans point to GR overactivation as a risk factor for mood disorders. Interesting, the MR gain of function genetic variant consistently protects against depression in several studies (Meijer and de Kloet, 2017). However, more research is needed to establish and explain the causal link.

Another mechanism that can alter MR and GR response is glucocorticoid medication. Use of synthetic glucocorticoids, like dexamethasone, can cause severe adverse effects, especially when high dosage is used. Severe neuropsychiatric consequences like psychosis, mania, depression, suicide (attempt), delirium, panic disorder and confusion or disorientation are reported (Judd *et al.*, 2014). In addition, cognitive and memory impairments, changes in mood and sleep disturbances (Meijer and de Kloet, 2017; Judd

et al., 2014). Normally, MR and GR activation is balanced, but glucocorticoid medication can disturb this balance. For example, dexamethasone is highly selective for GR and high dosage will lead to a suppressed cortisol production, depleting the MR of its ligand and resulting in a GR MR imbalance. It is thought that co-administration of cortisol with dexamethasone might prevent these adverse effects, since MR is re-activated and this way restoring the GR MR balance (Meijer and de Kloet, 2017).

Neuronal Protection and Neurogenesis

As discussed above, steroids can have profound influences on the structure and function of neurons early in development and into adulthood. In addition to these influences, steroids can alter the survival and production of new neurons, even in the adult brain. For instance, at high concentrations, estrogen can protect neurons by working as an antioxidant. Estrogen has also been shown to diminish the neural damage induced by stroke and reduced blood flow to the cortex. These neurotropic effects after stroke may be through the antioxidant properties and/or through the influence of estrogen on growth factor synthesis and receptor expression.

Steroid hormones have also been shown to affect neurogenesis. Estrogen has been demonstrated to increase the production of new neurons in the dentate gyrus of the female hippocampus. Conversely, animals experiencing high levels of corticosterone show less cellular proliferation in the dentate gyrus than do animals experiencing low levels of corticosterone. This corticosterone-induced decrease in neurogenesis suggests that high levels of corticosterone not only promote atrophy (and even loss) of neurons in the hippocampus but also slow the production of new neurons that may be needed to replace the lost cells.

Conclusion

Steroid hormones secreted from the gonads and adrenals act on the brain and are known to influence diverse functions such as reproduction and learning and memory. These hormones can act on neurons through a genomic, an indirect genomic, or a nongenomic mechanism of action. The sex steroids have been shown to organize the male and female perinatal brain so that the proper physiology and behavior can be activated by these hormones during adulthood. Furthermore, steroids continue to shape the adult brain by affecting factors such as synaptogenesis, spine maturation and growth, neuronal branching, neuroprotection, and neurogenesis. Therefore, steroids not only contribute to the development of the nervous system but also continue to influence neuronal structure and function throughout the life span.

Memory and Epigenetics: Role of Estrogen

Jennifer J Tuscher*, University of Wisconsin-Milwaukee, Milwaukee, WI, United States
Ashley M Fortress*, VA Pittsburgh Healthcare System, Pittsburgh, PA, United States
Karyn M Frick, University of Wisconsin-Milwaukee, Milwaukee, WI, United States

Introduction

Evidence that hormones could regulate behavior was first demonstrated in 1849 when Arnold Berthold showed that castration and reimplantation of the testes in roosters affected normal male development, sexual desire, and aggression. However, only in the last 30 years has it been demonstrated that sex steroid hormones are poised to mediate memory formation. Some of the first evidence supporting this notion came from the discovery of estrogen receptors in the dorsal hippocampus and the entorhinal cortex (Loy *et al.*, 1988; Maggi *et al.*, 1989) and from seminal work demonstrating that spine density in the CA1 region of the hippocampus could be regulated by estrogens, including the potent 17β-estradiol (E_2), and progesterone in female rats (Gould *et al.*, 1990; Woolley *et al.*, 1990; Woolley and McEwen, 1992, 1993). In the nearly three decades since the initial demonstration that ovarian hormones regulate CA1 dendritic spine density, preclinical research has provided evidence that E_2 can enhance learning and memory in adults of a variety of species, including songbirds, rodents, nonhuman primates, and humans (for reviews see Maki, 2012; Hammond and Gibbs, 2011; Frick, 2009, 2012; Schlinger and Remage-Healey, 2012; Bimonte-Nelson *et al.*, 2010). Recent work has demonstrated that E_2 employs numerous cellular and molecular mechanisms, including epigenetic processes, to influence memory formation, and these epigenetic mechanisms will constitute the focus of this review. A general overview of the beneficial effects of E_2 on memory will first be described below, followed by a discussion of the epigenetic mechanisms through which E_2 exerts these effects.

The Role of E_2 in Cognitive Function

Estradiol and Cognitive Function in Humans

Clinical studies investigating the estrogenic regulation of memory have focused largely on the effects of estrogens in the context of aging (i.e., as it relates to menopause), or changes in performance in cognitive tasks across the menstrual cycle. With respect to aging, numerous studies have shown that ovarian hormone loss due to natural or surgical menopause impairs various aspects of cognitive function, including verbal and spatial memory (Sherwin and Henry, 2008) (**Fig. 1**). Menopausal women are also at increased risk of Alzheimer's disease relative to men, even when accounting for women's longer lifespans (Dye *et al.*, 2012; Launer *et al.*, 1999). Indeed, longer periods of lifetime estrogen exposure are significantly and negatively correlated with the likelihood of

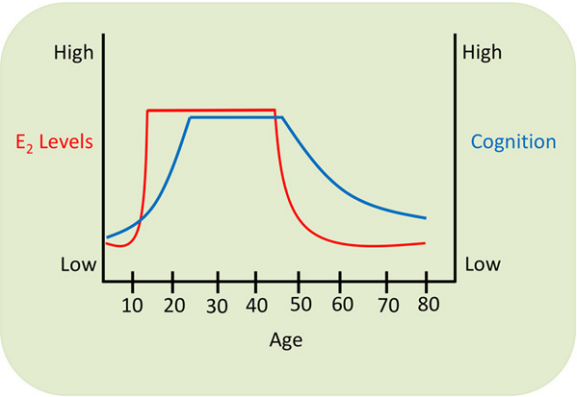

Fig. 1 Schematic illustration of changes in estradiol (E_2) levels and cognitive abilities across the life span in women. E_2 levels surge upwards at puberty and remain elevated (although fluctuating across the menstrual cycle) during the reproductive years. In the early 50's, E_2 levels drop substantially at menopause. Cognitive function reaches adult levels in the early-mid 20s and then remains relatively stable until middle-age, at which point certain aspects of cognitive function (e.g., episodic memory, divided attention, spatial navigation) decline gradually with age.

* JJT and AMF contributed equally to this work.

 doi:10.1016/B978-0-12-801238-3.64551-8

developing Alzheimer's disease in women (Fox *et al.*, 2013). The deleterious effects of menopause on cognition and risk of Alzheimer's disease can be reduced by E_2 therapy (Rocca *et al.*, 2007, 2011), suggesting not only that E_2 loss at menopause contributes to memory dysfunction, but also that maintaining E_2 levels at menopause may help prevent Alzheimer's disease and reduce age-related cognitive decline.

Evidence also indicates that E_2 fluctuations across the month-long menstrual cycle in premenopausal women impacts certain aspects of cognitive function. For example, women experiencing high E_2 levels during the midluteal phase of the cycle perform better in tests of verbal fluency, fine motor, and perceptual speed than women experiencing low E_2 levels during the menstrual phase (Hampson, 1990; Maki *et al.*, 2002). Some evidence suggests that visual memory is also poorer during the menstrual phase (Phillips and Sherwin, 1992). High levels of E_2 do not always correlate with better performance on cognitive tasks, however, as women's performance appears to be best in tasks in which men traditionally outperform females (e.g., those related to spatial ability) when E_2 levels are low (Hampson, 1990; Maki *et al.*, 2002).

In addition to its role in regulating normal cognitive function, E_2 has also been implicated in several disorders that disproportionately affect women relative to men, including Alzheimer's disease, posttraumatic stress disorder (PTSD), and certain aspects of addiction. Although beyond the scope of this article, reviews on the role of E_2 in Alzheimer's disease (Dye *et al.*, 2012), PTSD (Albert *et al.*, 2015; Milad *et al.*, 2010), traumatic brain injury (Asl *et al.*, 2013; Day *et al.*, 2013b), and substance abuse (Becker, 2016) provide important insights into the ways in which sex-steroid hormones may impact disorders characterized by memory dysregulation, and suggest directions for future research to better understand underlying neural mechanisms.

Animal Models Demonstrate the Importance of E_2 in Cognitive Function

Basic scientific research conducted in animal models is critical for mechanistic investigations into the role of E_2 in cognitive function. E_2-mediated actions in brain regions that support cognition, such as the hippocampus, are complex and impacted by numerous factors, including dose, duration of treatment, age, length of ovarian hormone deprivation prior to treatment, type of cognitive task, timing of administration relative to testing, task difficulty, and reproductive history (Acosta *et al.*, 2009, 2010; Luine, 2014; Daniel, 2006; Frick, 2009). However, some generalizations can be drawn, particularly among studies utilizing rodent models. The majority of rodent studies support the conclusion that E_2 facilitates learning and memory in behavioral tasks that require the hippocampus (Packard and Teather, 1997; Fader *et al.*, 1998; Daniel *et al.*, 1999; Luine *et al.*, 2003; Walf *et al.*, 2008; Fernandez *et al.*, 2008; Lewis *et al.*, 2008; Zhao *et al.*, 2010; Daniel, 2006; Fan *et al.*, 2010); see (Daniel, 2006; Tuscher *et al.*, 2015) for review. For example, young adult female rodents treated with exogenous E_2 exhibit enhanced spatial memory in the object placement, Morris water maze, radial arm maze, and T-maze tasks (Sandstrom and Williams, 2004; Luine *et al.*, 1998; Fader *et al.*, 1998, 1999; Daniel *et al.*, 1997; Bowman *et al.*, 2002; Bimonte *et al.*, 2002). E_2 can also facilitate memory in a number of nonspatial tasks, as demonstrated in object recognition (Fernandez *et al.*, 2008; Fortress *et al.*, 2013; Boulware *et al.*, 2013), social recognition (Phan *et al.*, 2012), inhibitory avoidance (Singh *et al.*, 1994; Rhodes and Frye, 2004), fear conditioning (Lebron-Milad and Milad, 2012; Chang *et al.*, 2009; Barha *et al.*, 2010; Zeidan *et al.*, 2011; Milad *et al.*, 2010), and trace eyeblink conditioning (Leuner *et al.*, 2004). Collectively, these studies provide evidence that E_2 treatment can benefit hippocampal memory in numerous behavioral tasks. The molecular mechanisms through which E_2 exerts these beneficial effects will be discussed in greater detail below.

Estrogen Receptor Expression and Cell-Signaling Mechanisms

Protein synthesis is an essential component of memory formation, and E_2 regulates the synthesis of new proteins through at least two different estrogen receptor (ER)-mediated mechanisms: the classical genomic pathway and the rapid nonclassical activation of cell-signaling pathways. Many of the brain regions that support memory formation express classical intracellular ERs (ERα and ERβ), which are found within the cytoplasm and nucleus of the cell. Both ERα and ERβ have their own distinct patterns of expression in the cerebral cortex, basal forebrain, amygdala, prefrontal cortex, and hippocampus in a variety of species, including mouse, rat, nonhuman primates, and humans (Gillies and McArthur, 2010). The classical "genomic" action of E_2 is initiated once the hormone diffuses through the target cell's outer membrane and binds ERα or ERβ within the cytoplasm (Nelson, 2000). Once the E_2-ER complex is formed, it translocates to the nucleus, where it binds to estrogen response elements on the DNA. Here, the complex acts as a transcription factor, and can initiate the transcription of E_2-sensitive genes that help maintain the neural circuitry that ultimately influences behavior (Heldring *et al.*, 2007; Jensen, 1962). Changes in gene expression elicited by such nuclear ER-hormone interactions via the genomic mode of action occur slowly (on the scale of hours—days) and are thought to yield long lasting changes.

E_2 can also influence cell function in a nonclassical manner by binding to membrane-associated ERs (mERs; e.g., GPER, Gq-mER; Srivastava and Evans, 2013), classical ERs located near the membrane (Boulware *et al.*, 2005, 2013), or by interacting with neurotransmitter receptors (e.g., mGluRs, NMDARs; Lewis *et al.*, 2008; Boulware *et al.*, 2005, 2013) to rapidly activate intracellular signaling pathways on the order of seconds to minutes (Gillies and McArthur, 2010). Although these mechanisms are often referred to as "nongenomic," this designation should not be taken literally, as activation of mERs can ultimately influence gene transcription. Rather, it should be thought of as way to distinguish between the effects of mERs and classical nuclear ER activation.

Work in our own lab has focused on the cell-signaling pathways through which E_2 regulates function in the dorsal hippocampus (DH) and medial prefrontal cortex, brain regions critical for learning and memory and whose function is compromised in various neuropsychiatric disorders and during aging (Small *et al.*, 2011; Maillet and Rajah, 2013; Sampath *et al.*, 2017). Rapid activation of cell-signaling cascades in these regions allows for acute modulation of cellular function in response to an experience (i.e., learning). Several pathways previously identified in studies focused on memory modulation in male rodents, such as extracellular signal-regulated kinase/mitogen activated protein kinase (ERK/MAPK), phosphatidylinositol 3-kinase (PI3K), protein kinase A (PKA), calcium calmodulin kinase II (CaMKII), and mammalian target of rapamycin (mTOR) (Adams and Sweatt, 2002; Horwood *et al.*, 2006; Impey *et al.*, 1998; Silva *et al.*, 1992; Hoeffer and Klann, 2010) are also regulated by E_2 in ovariectomized females. E_2-mediated activation of these pathways has been linked to changes in neuronal excitability (Woolley, 2007), long-term potentiation (LTP) (Smith and McMahon, 2005), spinogenesis (Tuscher *et al.*, 2016a), and memory enhancement (Fernandez *et al.*, 2008; Fan *et al.*, 2010; Fortress *et al.*, 2013) in ovariectomized females. Specifically, E_2 infusion directly into the DH rapidly activates cell-signaling cascades like ERK, PI3K, PKA and mTOR within 5 min of DH infusion (Fernandez *et al.*, 2008; Fan *et al.*, 2010; Fortress *et al.*, 2013). Further, activation of ERK, PI3K, PKA, and mTOR are all required for the beneficial mnemonic effects of E_2 in hippocampus-dependent tasks, as pharmacological inhibition of any of these pathways prevents the memory-enhancing effects of E_2 in ovariectomized female mice (Fernandez *et al.*, 2008; Fan *et al.*, 2010; Fortress *et al.*, 2013) (**Fig. 2**). As will be discussed below, E_2-mediated activation of certain pathways, such as ERK, can also alter gene transcription by regulating downstream epigenetic modifications such as DNA methylation and histone acetylation. Before addressing these data, the next section will first review the major epigenetic mechanisms that regulate hippocampal memory.

Epigenetic Modifications Related to Synaptic Plasticity and Memory

The term "epigenetics" refers to the idea that the expression of genes can be regulated "above the gene" by altering accessibility to genes rather than the genetic code itself (Crick, 1984; Holliday, 1999). Chromosomes are comprised of DNA tightly coiled around nucleosome subunits. Each nucleosome consists of an octamer containing eight histone (H) proteins, two each of H2A, H2B, H3, and H4 (**Fig. 3**). Each histone protein has a N-terminal tail that can be altered through posttranslational modifications such as acetylation, methylation, phosphorylation, ubiquitination, and SUMOylation (Rothbart and Strahl, 2014) (**Fig. 3**). Chromatin is formed from the supercoiling of adjacent nucleosomes which are connected by the linker protein H1 (Mazzio and Soliman, 2012).

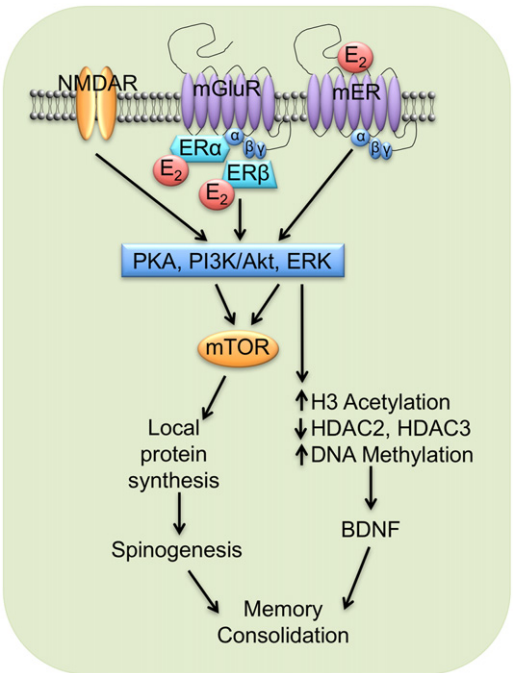

Fig. 2 Schematic representation of the cellular mechanisms through which E_2 regulates memory in ovariectomized mice. In the dorsal hippocampus, E_2 interacts with intracellular ERs (ERα and ERβ), mERs, and neurotransmitter receptors to rapidly activate PKA, PI3K/Akt, ERK, and mTOR cell signaling, which then triggers spinogenesis via local protein synthesis. Similarly, phosphorylation of ERK can enhance gene transcription via alterations in H3 acetylation, HDAC protein levels, and DNA methylation. These changes all contribute to the memory-enhancing effects of acute dorsal hippocampal E_2 infusion on memory consolidation. Abbreviations: *NMDAR*, *N*-methyl-D-aspartate receptor; *mGluR*, metabotropic glutamate receptor; *mER*, membrane estrogen receptor, *PKA*, protein kinase A; *PI3K*, phosphatidylinositol 3-kinase; *mTOR*, mammalian target of rapamycin; *H3*, histone 3; *HDAC*, histone deacetylase; *BDNF*, brain derived neurotrophic factor.

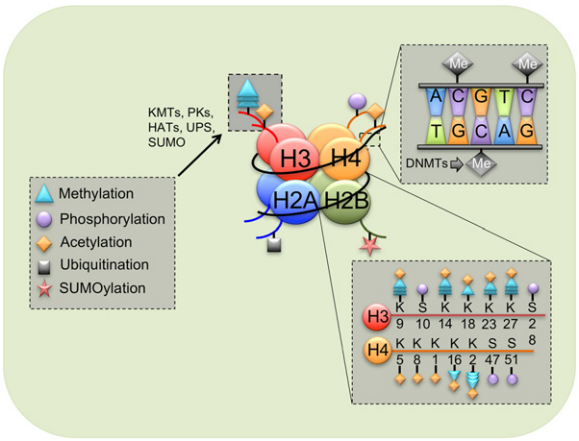

Fig. 3 Diagrammatic illustration of the nucleosome and common epigenetic alterations. The histone octamer consists of two each of histones H2A, H2B, H3, and H4. Abbreviations: *K*, lysine; *S*, serine; *KMTs*, lysine methyltransferases; *PKs*, protein kinases; *HATs*, histone acetyltransferases; *UPS*, ubiquitin proteasome system; *SUMO*, small ubiquitin-like modifier; *Me*, methyl group; *DNMTs*, DNA methyltransferases. Adapted from Fortress, A. M. and Frick, K. M. (2014). Epigenetic regulation of estrogen-dependent memory, *Frontiers in Neuroendocrinology*, **35**(4), 530–549.

The ability of a certain segment of chromatin to be modified depends on the posttranslational modification state of its histone tail, which controls how tightly wound the chromatin structure is and, therefore, whether the 3D structure is permissive to binding factors that regulate transcription. Each major modification and its individual role in memory are reviewed elsewhere (Fortress and Frick, 2014). Histone acetylation, phosphorylation, and methylation, along with DNA methylation, are summarized briefly below.

Histone modifications

Histone modifications can alter accessibility of DNA to the transcriptional machinery required for regulating the expression of genes, including those relevant to neuroplasticity and cognition. Histones are primarily modified at the N-terminal portion of their tails that extends beyond the nucleosome. The histone tail can interact with regulatory proteins, as well as neighboring histones and the DNA itself (Tsankova *et al.*, 2007; Marmorstein, 2001). A number of alterations are possible including methylation, phosphorylation, ubiquitination, SUMOylation, and acetylation. Of these, acetylation is perhaps the most well characterized in the neuroepigenetic literature. Acetylation is carried out by histone acetyltransferase (HAT) enzymes, which facilitate the transfer of an acetyl group from acetyl-CoA to lysine residues present on histone tails. In the majority of cases, acetylation of histone tails yields a transcriptionally active state, conferring open euchromatin that is accessible to transcriptional machinery (Tsankova *et al.*, 2007). Conversely, hypoacetylation generally has the opposite effect, largely because replacement of hydrogen with an acetyl group reduces the net positive charge of the histone, reducing its interaction with the negatively charged DNA backbone and increasing the likelihood of nucleosome displacement (Carrozza *et al.*, 2003). This displacement opens up the chromatin, making it readily accessible to transcriptional machinery and regulatory factors that can influence transcription and, thereby, regulate gene expression.

As mentioned earlier, activation of signal transduction pathways can facilitate epigenetic changes such as histone acetylation, which may be a mechanism contributing to the precision and the stability of a memory. One example is the ERK/MAPK signaling pathway, which stimulates CREB binding protein (CBP), a transcriptional coactivator with intrinsic HAT activity (Ait-Si-Ali *et al.*, 1999). Evidence that histone acetylation can influence learning was first demonstrated in rodents using the conditioned taste aversion paradigm. Using this task, mice that developed a conditioned taste aversion had increased ERK/MAPK activation and histone acetyltransferase activity in the insular cortex 48 h later (Swank and Sweatt, 2001). Further evidence for the role of histone acetylation in memory was determined in mice with reduced levels of CBP ($cbp^{+/-}$mice), which exhibit impaired long-lasting-LTP, as well as deficits in hippocampus-dependent object recognition memory and contextual fear conditioning (Alarcón *et al.*, 2004). Similar behavioral results were obtained in mice with an inducible dominant-negative system to turn off intrinsic CBP-mediated HAT activity. Interestingly, a histone deacetylase inhibitor rescued memory deficits in these mice, suggesting that reduced histone acetylation could underlie memory deficits in numerous disorders (Korzus *et al.*, 2004). Indeed, mice overexpressing the histone deacetylase HDAC2, which removes acetyl groups from histones, have poor hippocampus-dependent spatial memory and reduced synaptic plasticity (Guan *et al.*, 2009). The behavioral deficits induced by overexpressing HDAC2 were reversed by administering an HDAC2 inhibitor, suggesting that memory disorders accompanied by elevated HDAC2 levels could be treated by HDAC2 inhibitors (Guan *et al.*, 2009). Cellular mechanisms responsible for histone acetylation in the hippocampus were determined using contextual fear conditioning in rats. In a series of studies, it was demonstrated that ERK/MAPK signaling, acting upstream of mitogen and stress-activated protein kinase 1 (MSK1), is necessary for the acetylation of H3 (Levenson *et al.*, 2004; Chwang *et al.*, 2007). This evidence collectively suggests that rapid cell-signaling events can lead to changes in epigenetic modifications, such as histone acetylation, to regulate gene transcription and memory.

In addition to histone acetylation, histone phosphorylation is another posttranslational modification poised to regulate memory formation. Protein Serine/Threonine phosphatase 1 (PP1), which dephosphorylates proteins, has been implicated in hippocampal memory impairment and reduced plasticity in rodents (Genoux *et al.*, 2002). In general, phosphorylation is associated with the activation of proteins responsible for a sequence of events that promotes memory and, therefore, interfering with phosphorylation processes could disrupt memory formation. In support of this notion, mice with inducible deficiency of forebrain PP1 demonstrated enhanced long-term memory in the object recognition, object placement, and Morris water maze tasks. This enhanced memory performance coincided with an increase in total phosphorylation of histone H3 on Serine 10 (phospho-H3S10) in addition to increased phospho-H3S10 at the CREB promoter (Koshibu *et al.*, 2009). In addition to its role in regulating histone acetylation, ERK/MAPK signaling can also mediate histone phosphorylation. Activation of the upstream ERK/MAPK regulators PKC and PKA, as well as contextual fear conditioning training, all increased phospho-H3S10 in the hippocampus of rats (Chwang *et al.*, 2006). Further, inhibition of ERK/MAPK prevented phosphorylation of H3S10, suggesting that ERK/MAPK signaling is necessary for H3S10 phosphorylation and contextual fear memory consolidation (Chwang *et al.*, 2006). Notably, H3S10 phosphorylation is also increased in the hippocampus following both retrieval of a fear memory and the phosphorylation of ERK/MAPK (Besnard *et al.*, 2014). Although site-specific dephosphorylation on histone tails has not been demonstrated as a cause of memory impairment, these studies collectively suggest that histone phosphorylation contributes to memory formation.

Whereas histone acetylation and histone phosphorylation are associated with a permissive transcriptional state, histone methylation can be transcriptionally permissive or repressive depending on the residue and number of sites affected. The most commonly examined residue is lysine, which can be mono-(me), di-(me2), or tri-methylated (me3) (Ng *et al.*, 2009). Methyl groups are added to residues by histone (lysine) methyltransferases, which are specific to the residue they modify (Black *et al.*, 2012) and are removed by lysine demethylases. For example, unmethylated lysine9 on H3 (H3K9) is converted to H3K9me1 and H3K9me2 by the G9a methyltransferase, but only the MLL methyltransferase can convert H3K4 to H3K4me3 (Jarome and Lubin, 2013). H3K4me3 and H3K9me2, associated with transcriptional activation and repression, respectively, are both increased in the hippocampus following contextual fear conditioning (Gupta *et al.*, 2010). In support of the role of H3K9me2 in memory formation, inhibition of the G9a methyltransferase with BIX01294 impairs contextual fear memory formation (Gupta-Agarwal *et al.*, 2012). The importance of the H3K4 MLL methyltransferase in memory has been demonstrated in two independent studies in which mice deficient in *Mll1* exhibited selective impairments in hippocampus-dependent contextual fear memory (Gupta *et al.*, 2010), and mice deficient in *Mll2* displayed impaired hippocampus-dependent object recognition and object placement memory (Kerimoglu *et al.*, 2013). Although these studies suggest that methylation can affect histones in a site-specific manner, future studies will need to investigate the extent to which demethylation is site-specific.

DNA methylation

DNA methylation occurs when a methyl group is added to cytosine residues predominantly within cytosine-guanine (CpG, where 'p' refers to the phosphodiester bond) dinucleotides by a methyl donor (e.g., *S*-adenosyl methionine; SAM). CpG dense areas are referred to as CpG islands, (Mastroeni *et al.*, 2011). DNA methylation typically represses transcriptional activity when it occurs within the promoter region of a gene, although this is not always the case (Chahrour *et al.*, 2008). The addition of methyl groups results in the recruitment of corepressor complexes to the DNA, inducing a repressive state by conferring a state of tightly packed heterochromatin that prevents binding of transcription factors and molecules necessary for the initiation of transcription (Tsankova *et al.*, 2007). This often includes the recruitment of histone deacetylases (HDACs), which can act concurrently to affect the acetylation state of neighboring histones, further compacting the chromatin and reducing transcriptional activity. The addition of methyl groups occurs with the aid of DNA methyltransferases or DNMTs (**Fig. 3**), of which at least two types have been identified. Maintenance methylation, which preserves DNA methylation patterns throughout cellular replication, is catalyzed by DNMT1 (Chouliaras *et al.*, 2010). De novo methyltransferases DNMT3a and DNMT3b are responsible for methylation throughout development regardless of previous methylation status (Okano *et al.*, 1999). DNMT2 is not involved in DNA methylation, but instead plays a role in the methylation of aspartic acid transfer RNA (Chouliaras *et al.*, 2010). Together, these enzymes influence transcription and the expression of a number of genes that are critical for neuroplasticity and memory formation (Miller and Sweatt, 2007; Day *et al.*, 2013a). The dysregulation of these enzymes can lead to detrimental changes in gene expression, which may impair neuronal function and contribute to any number of neuropsychiatric disorders.

Early demonstration for the role of DNA methylation in memory came from evidence showing that contextual fear conditioning increased *Dnmt3a* and *Dnmt3b* mRNA in the hippocampus of rats 30 min after training, and that infusion of a DNMT inhibitor into the hippocampus impaired consolidation of contextual fear memory (Miller and Sweatt, 2007). Interestingly, the increase in methylation was at least partially due to hypermethylation of the memory suppressing *PP1* gene (resulting in a net decrease in expression of *PP1*). The persistence of contextual fear memories were later determined to be maintained through DNA methylation in the dorsomedial prefrontal cortex, a brain region important for long-term memory storage (Miller *et al.*, 2010). Additional evidence for the role of DNA methylation in regulating memory consolidation came from work linking contextual fear memory with expression of brain derived neurotrophic factor (BDNF), a neurotrophin well known to promote synaptic plasticity and memory (Cowansage *et al.*, 2010). The *Bdnf* gene is unique in that it has multiple exons that can be independently and differentially regulated. Contextual fear conditioning increased the mRNA expression of exon IV, which was associated with hypomethylation at CpG islands corresponding to exon IV (Lubin *et al.*, 2008). Similarly, treatment with a DNMT inhibitor was sufficient to impair memory, increase methylation of the *Bdnf* gene, and decrease *Bdnf* gene transcription (Lubin *et al.*, 2008). These findings support the conclusion that manipulation of DNA methylation is yet another method of regulating memory.

Estrogenic regulation of histone modifications and effects on memory

As mentioned earlier in this chapter, the ability of a dorsal hippocampal E_2 infusion to enhance hippocampal memory consolidation depends on the rapid activation of numerous cell-signaling cascades, including ERK/MAPK, in the hippocampus (Fernandez *et al.*, 2008; Fortress *et al.*, 2013). Activation of ERK in the hippocampus leads to an increase in the acetylation and phosphorylation of the histone protein H3, and these increases are associated with memory formation (Levenson *et al.*, 2004; Chwang *et al.*, 2006). Thus, our laboratory reasoned that E_2 might enhance memory by triggering ERK-mediated histone alterations. Indeed, direct infusion of E_2 into the DH increases HAT activity in the DH within 15 min and increases DH H3K9,14 acetylation within 30 min (Zhao *et al.*, 2010, 2012). However, E_2 infusion into the DH does not affect acetylation of H2BK12 or H4K12 (Zhao *et al.*, 2010, 2012), suggesting an effect specific to H3K9,14. Additionally, DH infusion of an ERK inhibitor impaired memory and blocked the E_2-induced increase in H3K9,14 acetylation (Zhao *et al.*, 2010), suggesting that H3 acetylation is critical for estrogenic regulation of hippocampal memory consolidation. To determine the extent to which histone acetylation is necessary for E_2 to enhance memory, the HAT inhibitor garcinol was coinfused with E_2. Garcinol prevented DH-infused E_2 from elevating H3K9,14 acetylation and enhancing object memory consolidation (Zhao *et al.*, 2012), demonstrating that H3 acetylation is necessary for the estrogenic enhancement of object memory formation.

E_2 may regulate histone acetylation in the long term by altering the expression of HDAC proteins. Four hours after DH infusion, E_2 significantly decreases levels of HDAC2 and HDAC3 protein (Zhao *et al.*, 2012; Fortress *et al.*, 2014), both of which have been implicated as negative regulators of hippocampus-dependent memory (Guan *et al.*, 2009; McQuown *et al.*, 2011; Graff *et al.*, 2012). E_2-induced downregulation of HDAC2 protein expression was blocked by garcinol (Zhao *et al.*, 2012), suggesting that HAT activity regulates expression of this memory repressing HDAC. Collectively, these findings suggest that E_2 may exert its beneficial effects on memory by increasing H3 acetylation and reducing the expression of negative regulators of memory such as HDAC2 and HDAC3 (**Fig. 2**).

Many of the specific gene targets affected by E_2-mediated H3 acetylation remain to be defined, although genes involved in neuroplasticity are likely candidates. One such example is the neurotrophin BDNF, which has an established role in regulating spine density, synaptic plasticity, and memory (Scharfman *et al.*, 2003; Heldt *et al.*, 2007; Spencer *et al.*, 2008; Luine and Frankfurt, 2013). Recent evidence demonstrates that E_2 infusion directly into the DH specifically increases H3 acetylation at *Bdnf* promoters pII and pIV 30 min after infusion in both young and middle-aged ovariectomized mice (Fortress *et al.*, 2014). These alterations in H3 acetylation at pII and pIV precede a significant increase in BDNF and pro-BDNF protein levels that occurs in the DH 4 and 6 h after infusion. Thus, one potential mechanism through which E_2 exerts its beneficial mnemonic effects is via epigenetic regulation of BDNF in the hippocampus. However, many genes are involved in memory formation, so additional research is needed to elucidate how histone alterations may impact the expression of other genes that contribute to the beneficial effects of E_2 on memory.

Estrogenic regulation of DNA methylation and effects on memory

DNA methylation can also be modified by E_2 treatment. For example, infusion of E_2 directly into the DH significantly increases *Dnmt3a* and *Dnmt3b* mRNA levels 45 min later, however, only DNMT3b protein levels were significantly elevated 4 h later (Zhao *et al.*, 2010). Protein and mRNA levels of the maintenance enzyme DNMT1 remained unaffected after direct DH infusion of E_2. Interestingly, E_2-mediated increases in DNMT3b protein were blocked by coadministration of the HAT inhibitor garcinol (Zhao *et al.*, 2012), suggesting that histone acetylation is required for E_2-mediated changes in DNMT3b protein. This finding is consistent with other research demonstrating that interactions between DNA methylation and histone acetylation are critical for modulating cognition and neuroplasticity (Miller *et al.*, 2008). The E_2-mediated enhancement of object memory consolidation is also blocked by a DH infusion of the DNMT inhibitor 5-aza-2′-deoxycytidine (Zhao *et al.*, 2010), suggesting that DNA methylation is also critical for the memory-enhancing effects of E_2 (**Fig. 2**). However, the specific genes and CpG sites methylated by E_2 in the DH remain unknown and this is an area ripe for future research.

Gaps in Knowledge and Implications for Future Studies

Understanding the mechanisms through which E_2 can orchestrate epigenetic processes to regulate memory is important for understanding cognitive function in both health and disease. Thus far, these mechanisms have only begun to be elucidated as outlined in this chapter. The extent to which E_2 regulates other posttranslational modifications such as histone phosphorylation, ubiquitination, methylation, or SUMOylation in the hippocampus through various cell-signaling mechanisms remains to be identified. Further, only very few gene targets important for memory whose expression is epigenetically regulated by E_2 have been identified to date. Thus, understanding which epigenetic modifications are regulated by E_2 and the downstream transcriptional and translational consequences of these modifications will be critical next steps. Finally, understanding the functional implications of estrogenic regulation of neuroepigenetics will be imperative to better understanding the etiology of disease and improving the design of drugs for reducing memory dysfunction in the future.

It's also important to consider that it is very unlikely that the epigenetic effects of E_2 on memory are restricted to the hippocampus. Parallel evidence for estrogenic regulation of epigenetic processes exists in other brain regions outside of the hippocampus, including the amygdala and the prefrontal cortex. For example, both the prefrontal cortex and the amygdala are actively being investigated for sensitivity to epigenetic modifications in neuropsychiatric disorders, including PTSD (Pizzimenti

and Lattal, 2015). E_2 facilitates extinction learning following fear conditioning, which corresponds to decreased activation in the amygdala and increased activation in the ventromedial prefrontal cortex in rats (Zeidan *et al.*, 2011). Although a necessary role for E_2 in regulating epigenetic mechanisms in the fear memory circuitry has not been tested, a necessary role of histone acetylation in fear memory consolidation was demonstrated using direct infusion of the HAT inhibitor garcinol into the lateral amygdala, which impaired fear memory consolidation in rats (Maddox *et al.*, 2013). Mice that were in the metestrus phase of the estrous cycle (low estrogen state) or were ovariectomized exhibited increased *Hdac4* mRNA in the amygdala following cued fear conditioning, suggesting a potential mechanism through which low levels of E_2 could impair processing of cues related to PTSD (Maddox *et al.*, 2017). These findings suggest that E_2 may promote fear memory consolidation by increasing histone acetylation in the other brain areas, however direct evidence has not been provided.

Finally, the role of de novo neurosteroidogenesis in regulating the epigenetic processes that govern memory formation remains unknown and is an area of increasing clinical relevance. All sex steroid hormones, including E_2, are synthesized in the brain, including the hippocampus, and suppressing endogenous E_2 synthesis with aromatase inhibitors prevents memory formation in female mice and male song birds (Bailey *et al.*, 2013; Tuscher *et al.*, 2016b). Similarly, clinical studies suggest that aromatase inhibition may negatively impact cognitive function in human females. Aromatase inhibitors such as letrozole are used to treat hormone-receptor positive forms of breast cancer (Geisler *et al.*, 2002; Puddefoot *et al.*, 2002), and some findings suggest that such treatments compromise working memory, concentration, and performance in verbal and visual memory tasks (Collins *et al.*, 2009; Bender *et al.*, 2007, 2015). Epigenetic regulation of the aromatase enzyme and downstream epigenetic changes in E_2-mediated memory in response to aromatase inhibitors have yet to be identified, but may prove to be important given increasing evidence that aromatase inhibition leads to memory impairment in females.

Summary

The past 30 years has provided exciting new information about the molecular mechanisms underlying memory formation and dysfunction. In particular, neuroepigenetic studies have illuminated the complexities of gene regulation and revealed a multitude of ways in which epigenetic processes can alter behavior without changing the genetic code. Combined with behavioral neuroendocrinology, neuroepigenetics is advancing our understanding of how hormones regulate the epigenetic processes that influence behavior. Such regulation could explain how environmental, chromosomal, and psychological factors determine individual responses to specific situations. Although information on E_2-mediated epigenetic alterations in the brain remains limited, there is ample potential to explore how sex-steroid hormones modulate behavior and disease in numerous brain regions with implications across a spectrum of disorders. It is our hope that this is where the future will take us and other investigators.

VIP Vasoactive intestinal polypeptide

Vipoma

Vasoactive intestinal polypeptide (VIP) derives its name from the splanchnic vasodilatory effect of VIP after systemic administration (Said and Mutt, 1970). It was first hypothesized that VIP is secreted by endocrine cells, but VIP is now known to be found in the (central) nervous system and thus VIP is a neurotransmitter (Fahrenkrug, 1989). Peripherally, VIP has been localized in neurons in the intestine, lung, adrenals, pancreas, and liver (Larsson *et al.*, 1976). In the gastrointestinal tract, VIP stimulates contraction of enteric smooth muscle cells, pancreatic exocrine secretion, gastrointestinal blood flow and inhibition of gastric acid secretion (Holst *et al.*, 1984; Robberecht *et al.*, 1976; Barbezat and Grossman, 1971). In the circulation VIP has a half-life of less than 1 min and concentrations are normally very low (0–190 pg/mL). This concentration reflects the overflow of VIP from the nerves into the circulation. A VIPoma is a neuroendocrine tumor secreting VIP, significantly increasing the overflow of VIP in to the circulation. The combination of elevated plasma VIP concentrations and symptoms reflecting the actions of VIP (see clinical presentation) is named the VIPoma syndrome.

History

The first two patients with a VIPoma were described by the US physician John V. Vermer Jr. and the Irish-US pathologist Ashton B. Morrison (1922–2008) in 1958. They presented a 67-year-old male and a 19-year-old male with the typical symptoms of VIPoma: watery diarrhea and hypokalemia. Both patients died of arrhythmias secondary to refractory hypokalemia and autopsy revealed pancreatic tumors (Verner and Morrison, 1958). Through this case report the two acronyms for the syndrome of VIP hypersecretion arose: Verner–Morrison syndrome, after the first to discover the syndrome or watery diarrhea hypokalemia achlorhydria (WDHA)-syndrome. It took until 1970 to isolate VIP from pigs' small intestines. This enabled Steve Bloom and colleagues to develop a specific radioimmunoassay to demonstrated elevated plasma VIP levels in patients with the VIPoma syndrome and for positive immunohistochemistry for VIP in the pancreatic tumor (Bloom *et al.*, 1973). Finally a proof of principle was provided by Kane in 1983. Injecting five healthy subjects with porcine VIP, resulting in levels resembling VIPoma patients, resulted in profuse diarrhea in all patients within 4 h (Kane *et al.*, 1983).

Clinical Presentation

The incidence of VIPomas is estimated to be 1–2 per 10 million per year (Halfdanarson *et al.*, 2008). Patients with a VIPoma experience symptoms which are in line with the action of VIP, which are mainly gastro-intestinal. When the tumor is small, and thus secretion is still limited, symptoms are often temporary. Patients suffer only from intermittent diarrhea. However, with tumor growth and increasing VIP secretion, the complaints become more frequent and severe. In severe cases, diarrhea becomes profuse and patients lose over 6–8 L of watery, tea-colored stools per 24 h. The diarrhea is of the secretory type, indicating it will persist even when the patient is fasting. Eventually the diarrhea will lead to electrolyte disturbances. Patients lose large amounts of bicarbonate and potassium in the stools and then often require intravenous supplementation of these electrolytes. Other symptoms include facial flushing and, inhibition of gastric acid secretion. Around 50% of patients have hypercalcemia but the mechanism of action is unknown.

VIPomas are mostly diagnosed in a work-up for diarrhea and the differential diagnosis includes all kinds of secretory diarrhea. This is mainly infectious colitis or laxative abuse, but also other neuroendocrine syndromes like gastrinoma, medullary thyroid carcinoma and the carcinoid syndrome.

Diagnosis and Clinical Work-Up

The diagnosis of a VIPoma is made on the combination of the clinical presentation and elevated plasma VIP levels. One measurement showing a non-elevated plasma VIP concentration does not exclude a patient from having a VIPoma since especially small tumors can secrete VIP intermittently. On the other hand, a marginally elevated plasma VIP level should be confirmed by a second measurement.

 doi:10.1016/B978-0-12-801238-3.64340-4

A VIPoma is either localized in the pancreas (75%), or in the sympathetic ganglia (Soga and Yakuwa, 1999c). As 80% of the pancreatic VIPomas are larger than 2 cm they can easily be detected with a magnetic resonance imaging (MRI)-scan or a CT-scan. Smaller lesions can be detected with an endoscopic ultrasound. Functional imaging includes a somatostatin-receptor scintigraphy or PET–CT with gallium-labeled somatostatin analogues (Nikou *et al.*, 2005; Virgolini *et al.*, 2005).

Treatment and Prognosis

The first goal in patients with a VIPoma is to correct the fluid and electrolyte disturbances, for which often intravenous supplementation is required. Diarrhea can be effectively reduced by intermediate, or long-acting somatostatin analogues and should be started as soon as possible in all patients (Song *et al.*, 2009). In the acute setting octreotide can be administered subcutaneous three times daily, or octreotide can be given as a continuous iv infusion. All patients presenting with a VIPoma should be considered for curative surgery, if disease is localized or all metastases are accessible for resection. If resection is not feasible several therapeutic options are available in the palliative setting. As VIPomas are rare all therapies are either based on case series or extrapolated from other, more common pancreatic neuroendocrine tumors. When diarrhea is well controlled a patient can be switched to long-acting depot somatostatin analogues, like lanreotide autosolution, or octreotide LAR. In patients who do not respond to somatostatin analogues debulking can be considered with surgery, embolization (bland- or radioembolization), or peptide receptor radiotherapy (PRRT) with radiolabeled somatostatin analogues (Kwekkeboom *et al.*, 2008; Moug *et al.*, 2006; Peng *et al.*, 2004). The tyrosine kinase inhibitor Sunitinib has also been described in some patients to effectively decrease diarrhea (de Mestier *et al.*, 2014).

The prognosis of patients with a VIPoma is highly dependent on the stage. Patients with a localized VIPoma have an average 5-year survival of 94% but this declines to 60% in metastatic VIPoma (Soga and Yakuwa, 1999c).

Glucagonoma

Glucagon is a peptide hormone, secreted from alpha cell of the pancreas and it has a major role in glucose regulation. It is one of the many hormones which can increase plasma glucose levels. The glucagon receptor can be found in the liver, brown and white adipose tissue, brain, heart, kidney and gastrointestinal tract. Increase of glucagon levels results in increased hepatic glucose output, lipolysis of adipose tissue and satiety.

In the non-fasting state, alpha cells only secrete low levels of glucagon. In response to hypoglycemia glucagon secretion increases and this counteracts the metabolic effects of insulin, restoring euglycemia. Through this effect it can also be used as a drug in patients with hypoglycemia due to a (relative) overdose of insulin (Campbell and Drucker, 2015). Glucagonomas present a rare kind of pancreatic NETs characterized by the hypersecretion of glucagon.

History

The first studies on the endocrine function of the pancreas were performed in the early 1920 when dogs were pancreatectomized and were found to develop diabetes mellitus. However, in 1922 *John R. Murlin* discovered that certain peptides from the pancreas were also able to increase glucose levels in dogs and rabbits (Kimball and Murlin, 1923). It took until the 1950s to isolate glucagon and to report the complete amino acid sequence (Staub *et al.*, 1953). The typical skin lesions associated with glucagonomas were then already described by S. William Becker in 1942 (Becker *et al.*, 1942). The skin eruption was thereafter linked to a metastatic pancreatic tumor by Mcgavran *et al.* (1966). This female patient presented with diabetes mellitus, anemia, and skin eruptions. She was diagnosed with a metastatic pancreatic tumor and later in the course of the disease strongly elevated glucagon levels were measured. The UK dermatologist Darrell Wilkinson was the first to name the typical skin lesions "necrolytic migratory erythema" in 1971(Wilkinson, 1971).

Clinical Presentation

The hypersecretion of glucagon associated with glucagonomas has several distinct clinical features. In a majority of patients there is either a new onset, or worsening of diabetes mellitus. This is accompanied by significant weight loss trough the catabolic effect of glucagon in 70%–80% of patients. Also, cheilosis, glossitis and stomatitis can occur in 30%–40% of patients and glucagomas are highly associated with thromboembolic events (Kaltsas *et al.*, 2004; Soga and Yakuwa, 1999a). But the most distinct feature remains the typical skin manifestations named necrolytic migratory erythema. The rash can start as an erythema or dermatitis-like lesion, but in later stages bullae can form with secondary infections. (**Fig. 1**A–C) Necrolytic migratory erythema usually starts in the groin and perineum but can spread over the entire body in severe cases (Wermers *et al.*, 1996). The cause of the skin lesions is unknown, but it is thought to be associated with zinc, fatty acid, and amino acid deficiency. In patients with a glucagonoma, plasma glucagon is often increased over 1000 pmol per liter (Soga and Yakuwa, 1999a). Hyperglucagonemia can also be found in

Fig. 1 (A–C) Necrolytic erythema and glossitis caused by glucagonoma.

patients with diabetes mellitus, insufficiency of glucagon catabolism (renal or liver failure) or serious disease with catabolism, however in these conditions plasma glucagon is rarely higher than 500 pmol per liter (Bloom and Polak, 1987). The incidence of glucagonomas is low, and only around 2% of all pancreatic NETs.

Diagnosis and Clinical Work-Up

A glucagonoma is diagnosed when a patient is found to have (part of) the previously described clinical syndrome in combination with an elevated plasma glucagon level and a histological diagnosis of a neuroendocrine tumor (preferably with a pancreatic lesion on imaging). Fasting plasma glucagon levels have been described to be 4–150 times elevated in patients with a glucagonoma, but are usually more than 10–20 times elevated (Stacpoole, 1981). A biopsy should always be taken for the histopathological diagnosis and grading.

Imaging of the primary tumor in the pancreas is best performed with an MRI, CT or an endoscopic ultrasound (**Fig. 2**). In metastatic disease, somatostatin-receptor scintigraphy or PET-CT with gallium-labeled somatostatin analogues has a high probability of detecting glucagonomas and their metastatic spread (Eldor *et al.*, 2011; Kindmark *et al.*, 2007).

Treatment and Prognosis

First step in treatment of patients with a glucagoma is correction of diabetes mellitus, mineral deficiencies and the catabolic state of the patient often requiring insulin treatment and intravenous supplementation of minerals and amino acids (Doherty, 2005). Administration of somatostatin analogues can result in weight increase and large reductions of skin lesions and is therefore advised in all patients. Also treatment with low-molecular-weight heparins should be started to prevent thrombosis. After improving the clinical condition of the patient, surgical resection should be considered if a radical resection seems feasible. However as around 50%–80% of patients have metastatic disease at diagnosis this is often not feasible (Soga and Yakuwa, 1999a; Stacpoole, 1981).

For unresectable glucagonomas, palliative treatment with lanreotide autosolution or octreotide LAR should be commenced, because of the reduction in glucagon secretion and thus symptoms. It is likely that somatostatin analogues also have an

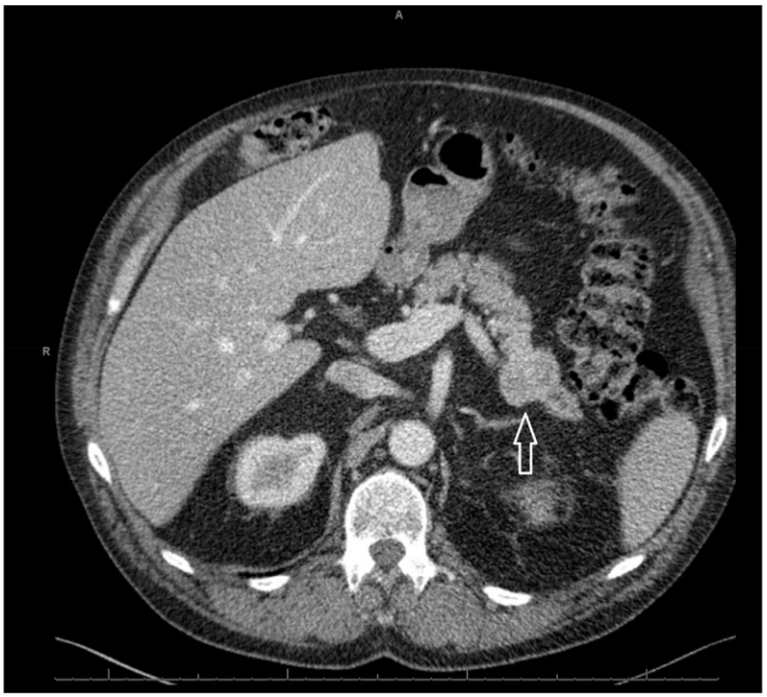

Fig. 2 CT scan demonstrating a pancreatic neuroendocrine tumor. From Müller, R., Gravert, M., Kern, T., Madl, T., Peschek, J., Sattler, M., Groll, M. and Buchner, J. (2013). High-resolution structures of the IgM Fc domains reveal principles of its hexamer formation. Proceedings of the National Academy of Sciences of the United States of America **110**, 10183–10188.

anti-proliferative effect in glucagomas, but because of the low incidence of glucagonomas there is no evidence for this. In high-grade glucagonomas, treatment with chemotherapy can be considered. PRRT with radiolabeled somatostatin analogues has also been successfully used in the treatment of glucagonomas (Eldor *et al.*, 2011). Futhermore, Everolimus and Sunitinib have been successfully tried. Prognosis is excellent in patients after surgical resection, however in patients with metastatic glucagonomas 5-year survival is around 50%–70% (Soga and Yakuwa, 1999a; Chu *et al.*, 2003, Kindmark *et al.*, 2007).

Somatostatinoma

Somatostatin is a regulatory peptide found throughout the central nervous system and in most large organs. There are two major sub-forms of somatostatin, namely somatostatin-14 and somatostatin-28. Somatostatin-14 is found in hypothalamus and has an inhibitory effect on neurotransmitter release as well as growth hormone and thyroid stimulating hormone secretion from the pituitary. Luteinizing hormone, follicle-stimulating hormone, and adrenocorticotropic hormone (ACTH) secretion are not inhibited in healthy subjects, but interestingly ACTH secretion can be inhibited by somatostatin in patients with Cushing's disease (ACTH-secreting pituitary adenoma). In the gastro-intestinal tract somatostatin can be secreted form the delta cells in the bowel mucosa or pancreas, but also in specific bowel neurons. Somatostatin inhibits the secretion of insulin and glucagon in the pancreas, inhibits gall bladder and bowel movement, but also inhibits the exocrine secretion of bile and gastric acid.

There are five subtypes of somatostatin receptors (SSTRs). Pituitary tumors mainly express the subtypes 2 and 5 while neuroendocrine tumors mainly express the SSTR subtype 2. The inhibitory effect of somatostatin on varies physiological processes led to development of drugs targeting this effect. Somatostatin itself only as a half-life of 3 min and therefore varies analogues where developed. Octreotide was the first analogue to be developed (half-life: 1.5 h) and later the slow release analogues lanreotide autogel and octreotide LAR were developed. These drugs are mainly used for the treatment of acromegaly and neuroendocrine tumors (Oberg and Lamberts, 2016; Patel, 1999).

A somatostatinoma is a neuroendocrine tumor arising from the delta-cells in the pancreas or bowel.

History

The somatostatinoma syndrome has a relative short history. Krulich and McCann, in 1968, were the first to describe the effect of a hypothalamic extract inhibiting the secretion of growth hormone (Krulich *et al.*, 1968). The exact nature and structure of the extract was discovered later. The group of Roger Guillemin was the first to isolate somatostatin from sheep hypothalami and for this work the Frenchman received the Nobel Prize in 1977 (together with Andrew Scally "for their discoveries concerning the

peptide hormone production of the brain") (Brazeau *et al.*, 1973). In that same year the first cases of somatostatinoma were described by Om Ganda as well as Lars-Inge Larsson, followed by the publication of the full description of the syndrome by Günter Krejs in 1979 (Larsson *et al.*, 1977; Ganda *et al.*, 1977; Krejs *et al.*, 1979).

Clinical Presentation

The syndrome of somatostatin hypersecretion is well defined in the WHO guidelines. It consist of markedly elevated somatostatin levels in the plasma and/or tumor, diabetes mellitus of recent onset, decreased gastric acid secretion, cholelithiasis, steatorrhoea, and anemia/weight loss (Bosman and World Health Organization, 2010). All these symptoms are the result of the inhibitory effects of somatostatin. However, this distinct presentation is very rare, with only 10% of patients presenting with the somatostatinoma syndrome (Garbrecht *et al.*, 2008; Soga and Yakuwa, 1999b). Abdominal pain as presenting symptom is more common in 50% of patients. Many of these patients are diagnosed as somatostatinoma based on positive immunohistochemical staining for somatostatin, without the corresponding syndrome and this makes the diagnosis somewhat controversial. This contributes to the rare nature of somatostatinomas with an estimated incidence of only 1 per 40 million persons per year.

Diagnosis and Clinical Work-Up

Somatostatinomas are most often localized in the pancreas (60%) or in the duodenum (40%). Pancreatic somatostatinomas tend to be larger with an median size of 43 mm compared to duodenal tumors of 15–20 mm (Soga and Yakuwa, 1999b). The diagnosis is (as in VIPoma and glucagonoma) based on the clinical picture of the somatostatinoma syndrome, elevated plasma somatostatin and the histopathological diagnosis of a neuroendocrine tumor. The pancreatic and duodenal lesions can best be visualized with CT, MRI or endoscopic ultrasound. Despite of elevated plasma somatostatin levels, somatostatinomas can still be visualized with functional imaging with somatostatin receptor scintigraphy or gallium-labeled somatostatin PET–CT scans.

Treatment and Prognosis

Surgery is the only curative treatment for somatostatinomas and should always be considered if a radical resection can be performed. In metastatic disease treatment with somatostatin analogues can result in decrease of plasma somatostatin levels (Angeletti *et al.*, 1998). Due to the rare character of somatostatinomas no evidence is available for treatment with PRRT or immunotherapy. Prognosis is excellent after radical resection and 5 year survival was 59.9% in metastatic disease (Soga and Yakuwa, 1999b).

Insulinoma

Wouter T Zandee and Wouter W de Herder, Erasmus MC – University Hospital Rotterdam, Rotterdam, The Netherlands

Glossary

MEN-1 Multiple endocrine neoplasia-1.

PRRT Peptide receptor radionuclide therapy.

Introduction

Plasma glucose levels need to be maintained within a narrow range for the proper functioning of several body functions. There are several hormones that increase plasma glucose (growth hormone, cortisol, epinephrine, and glucagon), but only insulin directly decreases plasma glucose. The pancreas has an important role in glucose regulation, mainly through the islets of Langerhans. Insulin is secreted from β-cells located in these islets together with the glucagon secreting α-cells and the somatostatin-secreting δ-cells. After the ingestion of glucose or carbohydrates there is a subsequent rise in plasma glucose, but the swift secretion of insulin from the β-cells keeps plasma glucose within narrow margins in healthy subjects. In the fasting state plasma glucose levels are mainly regulated by the insulin/glucagon ratio in the portal vein of the liver: insulin secretion decreases at plasma glucose levels lower than 4.5 mmol/L and plasma insulin should be immeasurable at plasma glucose levels under 2.5 mmol/L. Glucagon and epinephrine are secreted when plasma glucose levels drop below 3.8 mmol/L and with this defense mechanism hypoglycemia's only rarely occur. One specific cause of hypoglycemia is an insulinoma: a neuroendocrine tumor arising from the pancreatic β-cells causing hypoglycemia through hypersecretion of insulin (Cryer and Gerich, 1985; Kittah and Vella, 2017).

History

Paul Langerhans was the first to describe the pancreatic islets in 1869 and with that discovery the islets where named after this German pathologist (Langerhans, 1869). Several years later, Lane from Chicago first described the different α- and β-cell within the islets (Lane, 1907). The peptide insulin was then first isolated by the Canadian group of, Frederick Banting and Charles Best, James Collip and John MacLeod (Banting and Best, 1922). During one of their experiments they removed the pancreas in dogs and they observed all symptoms of diabetes and increase of plasma glucose. Administering to these dogs a pancreatic extract (then named "isletin") reversed hyperglycemia, thereby identifying the important role of the pancreas in glucose regulation. John MacLeod and Frederick Banting were awarded the Nobel Prize for Physiology in 1923 for this discovery. However, Nicolae Paulescu from Rumania actually discovered insulin a year before the Canadian group but was never credited for this fact (Paulescu, 1921).

The first case of a patient with hypoglycemia caused by an insulinoma was described by the surgeon Harris and William Mayo operated this patient but found a unresectable pancreatic tumor with multiple metastases. In this case, extracts of the liver nodules were said to cause hypoglycemia in rabbits and thus must have been producing insulin (Wilder *et al.*, 1927). The first to cure a patient with an insulinoma was the Roscoe Graham, a surgeon from Canada (Howland *et al.*, 1929). An excellent case series on insulinomas was later published by the surgeon Allen Whipple in 1935 describing the symptoms on which we currently still base our diagnosis of hypoglycemie (Whipple's triad) (Whipple, 1938).

Clinical Presentation

Since an insulinomas is a neuroendocrine tumor arising from the pancreatic β-cells, hypoglycemia caused by hypersecretion of insulin by the β-cells, is its main symptom. The diagnosis can be very challenging because the symptoms can be aspecific and very prevalent while insulinomas only occur rarely. In some cases patients suffer from seizures or abnormal behavior and only after long neurological or psychiatric treatment the insulinoma is diagnosed.

The symptoms of hypoglycemia start with the so-called autonomic symptoms secondary to catecholamine release and activation of the cholinergic system when plasma glucose drops below 3.3 mmol/L (60 mg/dL). The adrenergic symptoms due to catecholamine release include tremors, palpitations and anxiety. Among the cholinergic symptoms are sweating, hunger and nausea. When plasma glucose drops below 2.8 mmol/L (50 mg/dL) cognitive dysfunction can occur with symptoms as weakness, behavioral changes, confusion, amnesia, lethargy and in severe cases coma or seizures. A patient with an insulinoma typically experiences weight gain because of the increased appetite to prevent hypoglycemic episodes and the anabolic effect of insulin. Hypoglycemia occurs during fasting, but patients can also experience hypoglycemia after a meal because of the overshoot of insulin secretion. Some patients also present with a pancreatic incidentaloma found to be a neuroendocrine tumor and hypoglycemia occurs only later in the course of the disease.

 doi:10.1016/B978-0-12-801238-3.65228-5

The estimated incidence of insulinomas is around 4 per million person years. Approximately 10% of insulinomas is associated with MEN-1 and about 5% is metastatic (Service *et al.*, 1991).

Diagnosis and Clinical Work-Up

The first step in diagnosis of an insulinoma is the diagnosis of endogenous hyperinsulinemia, meaning an inappropriately elevated insulin during hypoglycemia. The hypoglycemia should fulfill Whipple's triad: symptoms or signs of hypoglycemia at which time a low plasma glucose is measured and symptoms should resolve when euglycemia is restored (Whipple, 1938; Cryer *et al.*, 2009). It is important to first rule out any drugs that can cause hypoglycemia. These drugs are mainly antihyperglycemic drugs like insulin or sulfonylurea derivatives used to treat diabetes. But is also important to look for other comorbidities like severe sepsis, adrenal insufficiency or liver failure that can cause hypoglycemia. If these factors seem unlikely testing for endogenous hyperinsulinemia should be performed (Cryer *et al.*, 2009).

If a spontaneous hypoglycemia occurs one can always draw blood for the required measurements but often a 72-h fast is required to provoke a hypoglycemia. In this test a hypoglycemia is defined as plasma glucose below 2.2 mmol/L (40 mg/dL) in the presence of Whipple's triad. Some guidelines define hypoglycemia as plasma glucose below 3.0 mmol/L (54 mg/dL), but this will decrease specificity with more false positive results (Service, 1995; de Herder *et al.*, 2006). Almost all patients with an insulinoma develop hypoglycemia during this test. A majority even develops the hypoglycemia within the first 12–24 h and at 48 h the sensitivity is already near 100% (Hirshberg *et al.*, 2000; Service and Natt, 2000; van Bon *et al.*, 2009; Dizon *et al.*, 1999). When hypoglycemia occurs blood should be drawn to test for plasma insulin, C-peptide, pro-insulin, beta hydroxybutyrate and a screening for hypoglycemic drugs should be performed. Thereafter hypoglycemia should be corrected with intravenous glucagon or glucose. Patients with an insulinoma typically have elevated plasma insulin (>18 pmol/L) and C-peptide (>0.2 nmol/L). Occasionally an insulinoma secretes pro-insulin instead of insulin. The combination of laboratory assessments helps to differentiate between the causes of hypoglycemia (**Table 1**).

If no hypoglycemia occurs after 72 h the fast is ended. Some advocate that at that time glucagon should be administered to test the hepatic glycogen stores, as in hyperinsulinemia the hepatic glycogen stores are preserved during fasting and a higher increase in glucose will be seen.

After the demonstration of endogenous hyperinsulinemia the next step is to find a neuroendocrine tumor in the pancreas. The first step is often conventional imaging with a MRI- or CT-scan. A transabdominal ultrasound is not sensitive, only detecting 34.4% of insulinomas, while an abdominal CT-scan is able to detect the insulinoma in around 30%–85% of patients and the MRI detects 85%–95% of insulinomas (**Fig. 1**) (Mehrabi *et al.*, 2014; de Herder *et al.*, 2006). In case these scans are negative or if additional imaging is needed for localization an endoscopic ultrasound can be used: it allows for a transducer to be placed very close to the pancreas in the duodenum and can thereby detect lesions as small as 5 mm. The endoscopic ultrasound alone has a sensitivity of around 95%, but sensitivity is lower in detecting lesions in the tail of the pancreas. In combination with CT, the endoscopic ultrasound is able to detect hardly all insulinomas (de Herder *et al.*, 2006).

Nuclear imaging can also be very useful in detecting insulinomas. The somatostatin scintigraphy or PET-CT has only limited detection rates in localized insulinoma, most probably because the low expression of somatostatin receptors in localized insulinoma (Mehrabi *et al.*, 2014). There is however high expression of the glucagon-like peptide 1 (GLP-1) receptor making it an excellent target for radiolabeled exendin4. This radiolabeled GLP-1 receptor agonist was shown to be superior than CT, MRI or somatostatin receptor imaging detecting 95% of insulinomas (Christ *et al.*, 2013). In metastatic insulinoma, the expression of somatostatin receptors is usually more prevalent and therewith the sensitivity of the somatostatin scintigraphy or PET-CT increases (**Fig. 2**) (Wild *et al.*, 2011). It seems that GLP-1 receptor imaging is superior in localized insulinoma and the somatostatin receptor imaging in metastatic insulinoma.

Table 1 Patterns of results during 72 h fast

Cause	*Insulin (pmol/L)*	*C-peptide (nmol/L)*	*Proinsulin (pmol/L)*	*Beta-hydroxybutyrate (mmol/L)*	*Circulating oral hypoglycemic drugs*	*Antibody to insulin*
Exogenous insulin	$\gg 18$	<0.2	<5	≤ 2.7	No	No
Endogenous hyperinsulinemi[a]	≥ 18	≥ 0.2	≥ 5	≤ 2.7	No	No
Oral hypoglycemic drugs	≥ 18	≥ 0.2	≥ 5	≤ 2.7	Yes	No
Insulin auto-immune	$\gg 18$	$\gg 0.2$	$\gg 5$	≤ 2.7	No	Yes
IGF-mediated	<18	<0.2	<5	≤ 2.7	No	No

[a]Endogenous hyperinsulinemia: nesidioblastosis, post-gastric bypass hypoglycemia.

IGF: Insulin-like growth factor.

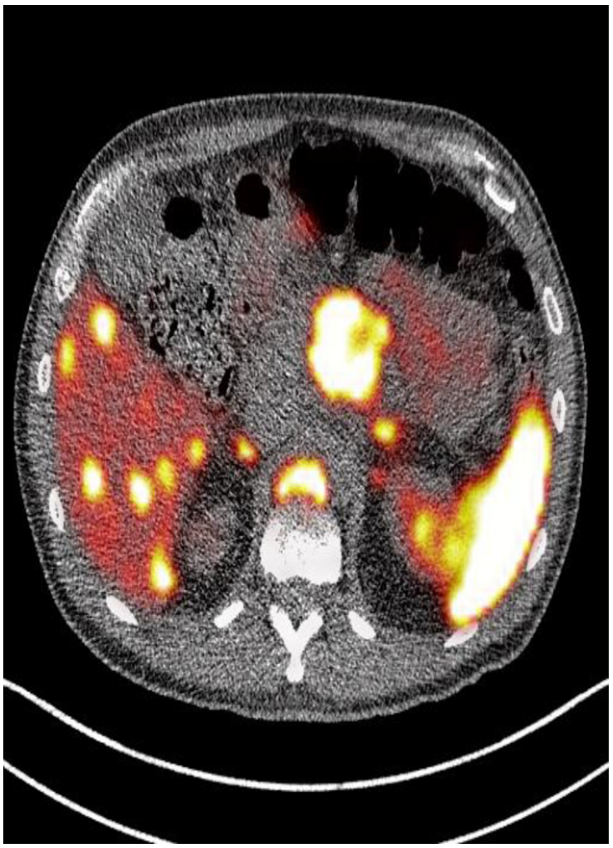

Fig. 2 68-Gallium-DOTATATE PET/CT showing intense uptake in pancreatic tumor and multiple liver metatstases. Physiologic uptake in the spleen.

In patients with negative imaging noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS) can be considered. The disease caused by hypertrophy of pancreatic islet can be distinguished from an insulinoma with angiography combined with calcium stimulation and transhepatic portal venous sampling. Hypersecreting β-cells release insulin upon stimulation with calcium where normal functioning β-cells do not. This results in an increase of insulin measured in the portal vein. Through selective catheterization of an artery a specific anatomical part of the pancreas can be stimulated. An insulinoma will typically only

secrete insulin upon stimulation of one region while NIPHS reacts to stimulation of the entire pancreas (Jackson, 2005). In children a F-DOPA-PET can be used to diagnose nesiodioblastosis (Stanley, 2016).

Treatment and Prognosis

Surgery is the first line treatment of patients with a localized insulinoma. In 90% of patients the insulinoma is smaller than 5 cm and restricted to the pancreas. After enucleation or (partial) pancreatectomy overall survival and curation rates are often near 100% (Mehrabi *et al.*, 2014; Tsutsumi *et al.*, 2013).

In patients with a metastasized insulinoma surgery should be considered if the primary tumor and all metastasis can be resected. In other cases treatment is aimed at preventing hypoglycemia and stabilizing tumor growth.

Hypoglycemia can be prevented with diazoxide which activates the ATP-sensitive potassium channels of the β-cells and reduces insulin secretion (Altszuler *et al.*, 1977). The most common side effect are fluid retention (well treatable with diuretics) and hirsutism (Gill *et al.*, 1997). Octreotide or the longer acting analogs lanreotide and octreotide LAR can also be used in metastatic insulinoma. They require adequate expression of somatostatin receptor subtypes (preferably the SSTR2 subtype and SSTR3 and SSTR5 subtypes) on the tumor to reduce insulin secretion but, if somatostatin receptor subtype-expression is low these drugs can also paradoxically increase hypoglycemias by decreasing glucagon secretion, relatively more than they decrease insulin secretion. A short clinical trial with short-acting octreotide is, therefore, recommended when starting with somatostatin analogues (de Herder *et al.*, 2011). Lanreotide and octreotide LAR can also potentially increase progression-free survival as has been demonstrated in non-functioning neuroendocrine tumors (Caplin *et al.*, 2014).

As a second-line treatment, when tumor progresses or hypoglycemias persist, Peptide Receptor Radionuclide Therapy (PRRT) with radiolabeled somatostatin has been shown to be highly effective. Patients are usually treated with four doses of PRRT with radiolabeled somatostatin and this has been reported to result in long lasting euglycemia and progression-free survival (van Schaik *et al.*, 2011). Also, everolimus was shown to be effective in preventing hypoglycemia in metastatic insulinoma (Bernard *et al.*, 2013; Kulke *et al.*, 2009). In high-grade insulinoma the chemotherapy combination with streptozotocin and 5-fluorouracil can be considered (Moertel *et al.*, 1980).

The prognosis of metastatic insulinoma has not been studied in the current era with contemporary treatment options. Older series report a median survival of approximately 2–3 years, but survival of over 30 years has been described in single patients (Danforth Jr. *et al.*, 1984; Hirshberg *et al.*, 2005; Starke *et al.*, 2005). It is however likely that survival is currently in the same range as non-functioning pancreatic neuroendocrine tumors: approximately 6–8 years (Martin-Perez *et al.*, 2013).

Melatonin☆

J Arendt, University of Surrey, Guildford, Surrey, UK

Glossary

Circadian Occurring or recurring about (latin-circa) once per day (dian). Biological circadian rhythms are internally generated and, in humans, have a period which is usually slightly longer than 24 h.

Period The duration of one complete cycle of a rhythmic variation.

Phase A distinct stage in a process of change, in this case a circadian rhythm.

Photoperiod Strictly the length of the light phase of a particular light–dark cycle, but may be used to describe the whole light–dark cycle.

Photoperiodism The response of an organism to changes in the lengths of the daily periods of light.

Introduction

The discovery of melatonin (N-acetyl-5-methoxytryptamine) in 1958 by Lerner and colleagues was the major stimulus for an enormous amount of work. Research on this small molecule has led to much current knowledge, not only concerning the function of the molecule itself as an internal hormonal time cue (the 'hormone of darkness'), but also to our fundamental understanding of rhythmic functions in species as diverse as microorganisms and humans. Substantial therapeutic benefits of melatonin treatment, particularly in the field of rhythm-related sleep disorder, are emerging.

Lerner and colleagues were searching for an amphibian skin lightening factor known to be present in the cow pineal gland. He and colleagues collected hundreds of thousands of cow pineal glands from abattoir material and processed the tissue through a series of extractions and other separation procedures. The skin lightening activity was monitored by an amphibian skin lightening bioassay. Two years of effort were necessary before a few micrograms of pure material were isolated. Chemical synthesis led to N-acetyl-5-methoxytryptamine (Fig. 1) which proved to be the most potent skin lightening substance ever tested.

It is now evident that melatonin is a hormone, synthesised from tryptophan (Fig. 1) and secreted, in mammals, largely by the pineal gland. In a normal environment secretion takes place essentially during the dark phase of the light dark cycle in virtually all species (including unicellular organisms). The evening increase and morning decline of melatonin serve to define 'biological night.' Its primary function in mammals is to convey information concerning the length of the night for the organisation of daylength dependent functions, and in consequence it has been called the 'darkness' hormone. Other sites of synthesis exist, for example the retina and the gut, however pinealectomy leads to undetectable or very low circulating levels at all times of day and night. Thus other sites of synthesis contribute very little to circulating melatonin (in mammals).

Synthesis and Metabolism of Melatonin

Melatonin synthesis in rodents and humans is initiated through noradrenergic stimulation of adrenergic beta1 receptors within the pineal, potentiated by alpha1 receptor stimulation. Administration of beta receptor antagonists such as propanolol and atenolol will suppress melatonin production in humans. In most circumstances the rate limiting step in synthesis (Fig. 1) is the activity of serotonin-N-acetyltransferase (arylalkylamine N-acetyl transferase, AA-NAT) with a major increase (7–150 fold) in the activity during the dark phase. Serotonin availability may also play a role. The rhythm of melatonin production is endogenous, being generated by clock genes in the suprachiasmatic nuclei (SCN), the major central rhythm-generating system or 'clock' in mammals (the pineal gland itself, and also the retina are self sustaining 'clocks' in some if not all lower vertebrates). The rhythm is synchronized to 24 h primarily by the light–dark cycle acting via the retina and the retinohypothalamic projection to the SCN (Fig. 1 and 2).

The cDNAs encoding both AA-NAT and the O-methylating enzyme hydroxyindole-O-methyl transferase (HIOMT) (Fig. 1) have been cloned. It is likely that the human enzyme is regulated primarily at a post transcriptional level, whereas in rodents the key event appears to be cyclic AMP-dependent phosphorylation of a transcription factor that binds to the AA-NAT promoter. Rapid decline in activity with light treatment at night appears to depend on proteasomal proteolysis.

In humans and rodents melatonin is metabolized to 6-sulphatoxymelatonin (aMT6s), primarily within the liver, by 6-hydroxylation, followed by sulphate conjugation. A number of minor metabolites are also formed, including the glucuronide

☆*Change History:* August 2014. J Arendt added an abstract, text on melanospin, some text to receptors section, a new paragraph to agonists section, a new paragraph to melatonin actions in the pars tuberalis, a new paragraph on melatonin and diabetes, text on cardiovascular disorder and autism, a new paragraph on light at night, cancer and melatonin, otherwise minor corrections and eight new references. Added Fig. 1, 5, 7(a) and 7(b), correct Figure 7(a), added 9(a) and 9(b) and 11. Note new numbering of most figures and updating of old figures.

This article is an update of Josephine Arendt, Melatonin, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 228-237.

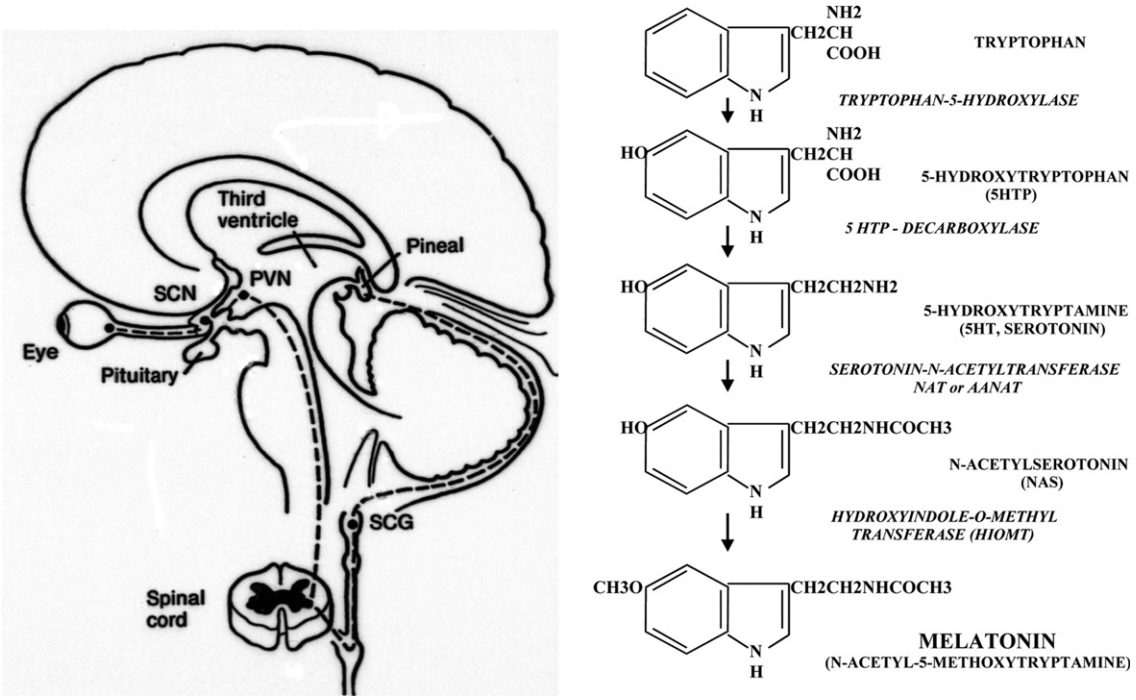

Fig. 1 Melatonin synthesis and the principle neural pathways innervating the pineal gland. SCN, suprachiasmatic nucleus; PVN, paraventricular nucleus; SCG, superior cervical ganglion. Left panel from Tamarkin, K., Baird, C.J., Almeida, O.F.X. (1985) Melatonin: a coordinating signal for mammalian reproduction. Science, 227, 714–720.

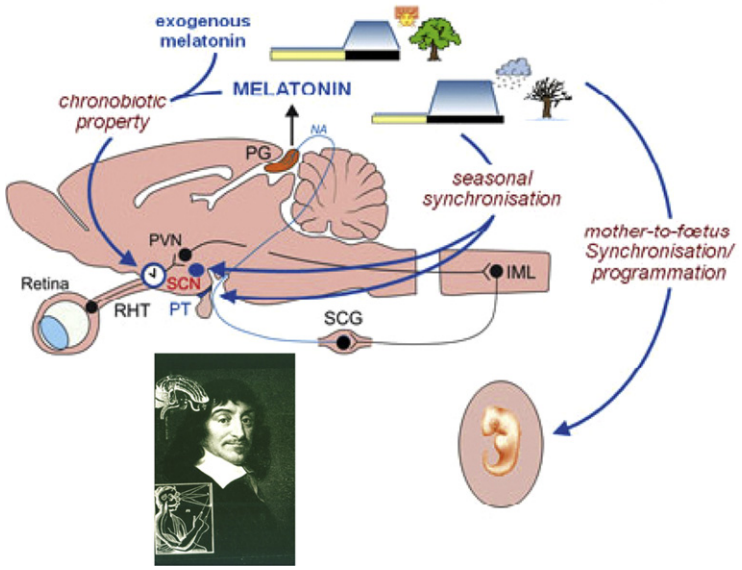

Fig. 2 A summary of the major effects of melatonin and the control of its secretion. The French philosopher Descartes considered, during the 17th century, that the pineal (PG) was controlled by light input from the eyes, and today we know that light does indeed regulate the timing of the pineal melatonin rhythm by its synchronizing effects on the activity of the central circadian clock in the suprachiasmatic nucleus (SCN), as well as its ability to suppress melatonin secretion depending on intensity and spectral composition. Light (daylength) also regulates the duration of melatonin secretion at night: long duration in short photoperiod and vice-versa. This daylength signal is used to time seasonal events in photoperiodic species. Prenatal maternal melatonin can influence postnatal circadian rhythmicity (rodents) and the timing of pubertal development (sheep). Endogenous and exogenous melatonin influence the timing of sleep and other circadian rhythms as well as having a direct influence on sleep propensity in humans. In many lower vertebrates, the pineal is effectively a 'third eye,' registering overall illuminance and acting itself as a central circadian clock. RHT, retinohypothalamic tract; PT, pars tuberalis; PVN, paraventricular nucleus; SCG, superior cervical ganglion; IML, intermediolateral column of the spinal cord. Adapted from an original diagram by Valerie Simonneaux, CNRS, Strasbourg, France, by permission.

conjugate. Exogenous oral (fast release) or intravenous melatonin has a short metabolic half-life (20–60 min, depending on author and species), with a large hepatic first-pass effect and a biphasic elimination pattern.

Very large interindividual variations in melatonin and aMT6s production are seen with intra-individual stability of both amplitude and timing. This stability leads to the extensive use of melatonin in plasma or saliva, and aMT6s in urine, as marker rhythms for circadian phase, for example in the investigation of sleep disorders, and evaluating adaptation to abrupt phase shifts as in shift work and jet lag. The large individual variations have been ascribed to the size of the pineal gland rather than to variations in enzymic activity.

Physiological Role of the Pineal Gland

The pineal is essentially part of the visual system. Probably the most famous of ancient texts on the pineal is that of the influential French philosopher Descartes. In 1662 Descartes considered that by movements, the pineal controlled the flow of 'animal spirits' into motor nerves and thus influenced movements of the body. He thought that the stimulus for pineal function came from visual input to the retina. The latter is a most remarkable insight, as effectively this is true today. It is usually Descartes to whom is attributed the concept of the pineal as the seat of the soul, although this idea probably derives from Herophilos. In lower vertebrates it is directly photoreceptive and often functions as a 'third eye' measuring overall illuminance in the environment for the organisation of circadian and seasonal functions. Pineal glands of lower vertebrates are innervated by both afferent and efferent fibres. In reptiles and birds the gland has a mixed photoreceptor and secretory function. Direct neural connections to the brain exist in mammals, but the sympathetic nervous system provides the main input (**Fig. 1** and **2**). Mammalian pineals consist largely of pinealocytes and glia.

The mammalian pineal is secretory and has lost its capacity for direct photoreception. Remnants of its ancient visual role remain in the presence of, for example, opsins in pinealocytes. However light indirectly controls mammalian melatonin production via the retino-hypothalamic projection (RHT) and the SCN.

Melatonin Secretion Characteristics

In the absence of time cues, for example light–dark alternation, the melatonin rhythm, like all circadian rhythms, 'free-runs' i.e. it assumes a period which is individually variable and genetically determined, usually somewhat longer than 24 h (on average about 24.2–24.3 h). Time cues synchronise or 'entrain' the rhythm to 24 h. The most potent time cue is the light dark cycle, and many blind people with no light perception at all show 'free-running' melatonin and other rhythms (e.g. sleep, cortisol, core temperature) in a normal environment (**Fig. 3**).

In addition to entraining the rhythm, daylength (photoperiod) determines the duration of night time secretion both by direct suppression of melatonin and by determining the length of the signal emitted by the SCN. Light of suitable intensity, duration and spectral quality, suppresses melatonin production at night, short wavelengths (ca 480 nm) are most effective, acting via a novel opsin–melanopsin-in directly photosensitive retinal ganglion cells. Short wavelengths are also most effective for entrainment of the rhythm, and indeed other circadian rhythms, to 24 h.

In mammals melatonin is secreted into the bloodstream and also probably into the CSF. CSF concentrations are reported to be higher than those of plasma in some species. In humans the evening melatonin onset is usually about 2100–2200 h, it peaks around 0300–0500 h, and declines to daytime values by about 0800–0900 h (**Fig. 4**). The effective cessation of secretion is earlier according to various models of the secretion characteristics. The melatonin onset and offset correspond to a number of important events related to biological dawn and dusk, including the evening increase in sleep propensity and decline in core body temperature. In winter, particularly in high latitudes and polar regions, the timing of the rhythm may be delayed compared to summer and this has been attributed to the weaker light dark cycle in winter. The melatonin rhythm is extensively used as a marker for the timing of the circadian system (**Fig. 5**).

Melatonin Receptors

Melatonin receptors have now been cloned and three subtypes were initially named Mel 1a, Mel 1b and Mel 1c. The Mel 1a receptor gene has been mapped to human chromosome 4q35.1. Its primary expression is in the pars tuberalis of the pituitary and the SCN. Mel 1b has been mapped to chromosome 11q21-22 and its expression is in the retina and the brain. Mel 1c is not found in mammals. Two cloned mammalian receptors (Mel 1a, Mel 1b) have been renamed MT1 and MT2. They are a new family of G protein coupled receptors, have high affinity (Kd 20–160 picomolar) and inhibit forskolin-stimulated cyclic AMP formation. Using gene knockout technology and pharmacological manipulations, the results to date suggest that the phase shifting receptor is MT2, whilst MT1 is associated with acute suppression of SCN electrical activity in addition to its actions within the pars tuberalis. However there is apparent overlap of function in some studies. Many other

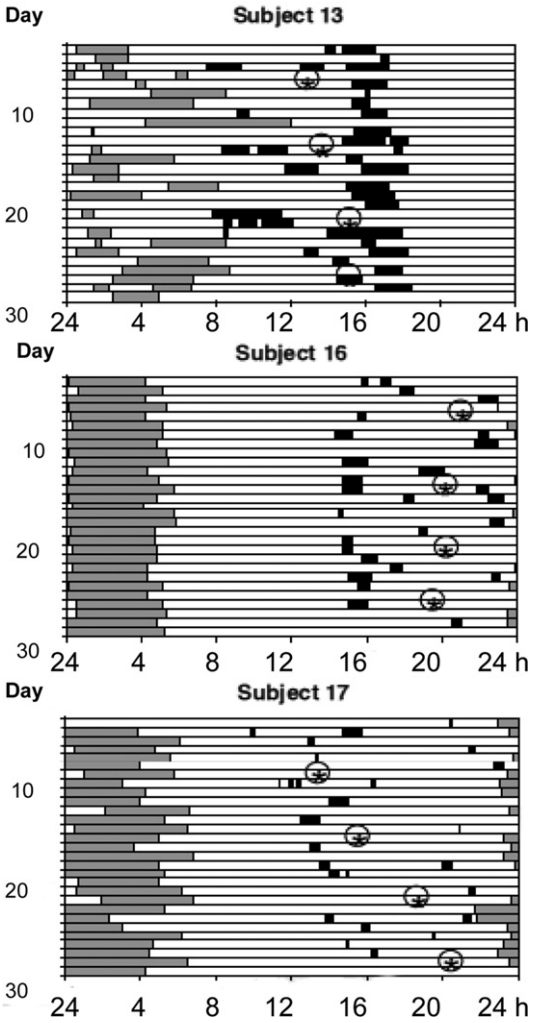

Fig. 3 Three blind subjects (no perception of light) showing abnormal sleep and melatonin rhythms. Subjectively recorded sleep is shown by the grey bars and naps (classified as such by the subjects) by the black bars. Melatonin was assessed as 6-sulphatoxymelatonin (aMT6s) in sequential urine collections for 48 h weekly and the asterisks indicate the calculated peak time (acrophase) of the aMT6s rhythm. Note the abnormal timing of aMT6s which normally peaks between 2400 and 0600 h, and the association of naps with daytime melatonin production. Subject 17 is clearly 'free-running' i.e. showing endogenous periodicity, with a steady daily delay of the aMT6s rhythm. Blind subjects with no eyes have all shown this phenomenon to date. Subject 16 is synchronized to 24 h but with an abnormal phase position. Cortisol and core body temperature rhythms show similar abnormalities to melatonin. These and other observations in the blind underline the importance of light for synchronizing rhythms and the association of daytime melatonin production with poor night time sleep and daytime naps. From Lockley, S.A., Tabandeh, H., Skene, D.J., Buttery, R., Bird, A.C., Defrance, R. and Arendt, J. (1995) Daytime naps and melatonin rhythms in blind people. Lancet, 346, 1491, by permission.

physiological responses have been ascribed to MT1 and MT2 receptors, including (MT1) melatonin-mediated potentiation of adreneregic vasoconstriction and (MT2) modulation of dopamine release in the retina. Mel1c, renamed MT3, belongs to the family of quinone reductases.

Melatonin Agonists and Antagonists

Large numbers of putative and actual melatonin agonists together with some antagonists have now been described. The most interesting have similar effects to melatonin on rhythm physiology in both rodents and humans. The primary indication is sleep disorders. A therapeutic role for the agonist agomelatine (valdoxan) in depression has emerged. Importantly this particular agonist acts as an antagonist at $5HT_{(2c)}$ receptors as well as via MT1 and MT2 receptors.. It appears to have both anti-depressant and chronobiotic effects. At the moment of writing, the marketing application for another agonist ramelteon (rozerem) has been withdrawn in Europe 'in patients best interests.' The latest agonist tasimelteon has just been approved by the FDA for use in non-24 h sleep-wake disorder, common in totally blind individuals. A recent review summarises melatonin receptor pharmacology.

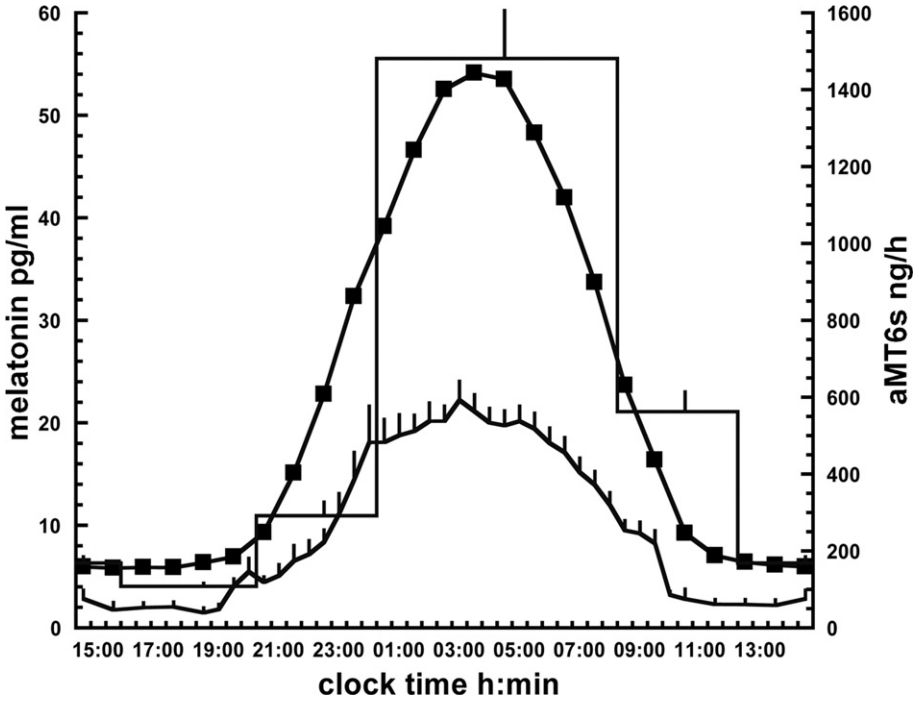

Fig. 4 Average concentrations + SEM of melatonin in plasma (squares, average N = 133, error bars within the symbol), saliva (no symbol, average N = 28) and 6-sulphatoxymelatonin (aMT6s) in urine (histogram, average N = 88), all measurements by radioimmunoassay values (healthy men and women over 18 years of age) from the author's laboratory.

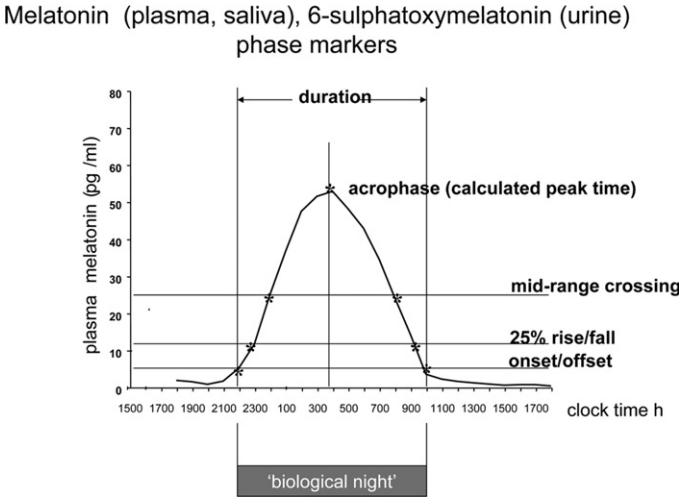

Fig. 5 The markers used to characterize melatonin and aMT6s (6-sulphatoxymelatonin) rhythms are illustrated diagrammatically. Area under the curve or total 24-h excretion (aMT6s) is used to assess total secretion. At present, there is no standard definition of onset-offset (and hence duration). The evening rise is often referred to as the dim light melatonin onset (DLMO) and the morning decline as the DLMOff, but these have variable definitions.

Physiological Role of Melatonin in Mammals

Photoperiodism

In all species studied melatonin appears to act as a timekeeping hormone. It has receptors both within and without the central nervous system and can modify gene expression in certain target organs. Pinealectomy abolishes the ability to respond to

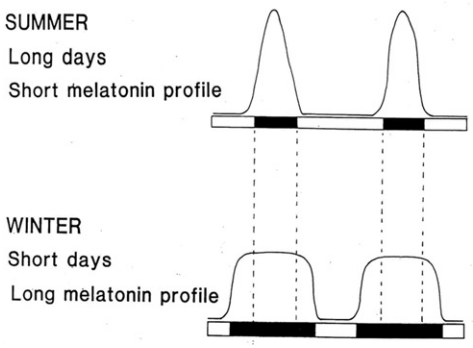

Fig. 6 The duration of melatonin secretion changes with daylength providing an internal time cue for the organisation of daylength dependent seasonal functions in photoperiodic species. This changing duration can be seen in humans if they are maintained in different durations of total darkness, however domestic intensity light at night is sufficient to greatly diminish or eliminate this photoperiodic response.

changing daylength in photoperiodic seasonal breeders. In mammals the primary role of melatonin is to provide information about photoperiod for the timing of seasonal functions in daylength dependent (photoperiodic) seasonal species. These functions include timing of breeding, of pubertal development, seasonal changes in coat growth, behaviour and body weight. The critical signal for the timing of photoperiodic events is the changing duration of melatonin secretion according to daylength, together with previous photoperiodic history (Fig. 6). Artificial generation of winter (long night) melatonin profiles in summer is equipotent with artificial long nights in changing the timing of seasonal functions. Melatonin implants (which are 'read' as long nights) are used in agriculture to time the season of birth of, for example, lambs and the growth of winter coat of cashmere goats and mink.

Melatonin influences production of gonadotrophins and gonadal hormones via actions within the hypothalamus. There is recent evidence for a molecular mechanism within the pars tuberalis of the pituitary, which links the short duration, long day melatonin signal to a hypothalamic increase of triiodothyronine (T3) through a thyroid-stimulating hormone/deiodinase2 paracrine mechanism.The local synthesis of type 2 deiodinase (Dio2) promotes triiodothyronine (T3) production and summer biology, whereas type 3 deiodinase (Dio3) promotes T3 degradation and winter biology. However melatonin controls seasonal variations in prolactin by a direct action on the pars tuberalis of the pituitary. This structure is the major site of melatonin receptors (MT1) in most species. Photoperiod-dependent gene expression in the pars tuberalis (PT) is directly modified by melatonin (Fig. 7(a) and 7(b)). The PT directly controls seasonal variations in prolactin secretion via the effects of melatonin on clock genes. In the PT, melatonin onset at dusk activates cryptochrone (Cry1) gene expression and melatonin offset at dawn activates period (Per1) gene expression, reflecting the photoperiod. It is proposed that the melatonin signal is decoded through circadian clock genes. Multiple effects of melatonin on clock genes have been reported in the PT and reports continue to accumulate of effects on clock genes in other tissues.

Role in the Mammalian Circadian System

Pinealectomy in mammals leads to subtle effects on circadian rhythms. The speed of adaptation to forced phase shift is enhanced and the activity-rest cycle becomes fragmented in continuous light in rodents. There is good evidence for the importance of the maternal melatonin rhythm in setting circadian phase in neonatal rodents. This may be the most important role for melatonin in the mammalian circadian system since an essential physiological role in adult mammals remains to be defined. The effects of pinealectomy in humans remain to be clarified: confounding factors are the possible concomitant damage of surrounding structures during surgery. However suppression of melatonin by the beta-adrenergic antagonist atenolol leads to an enhanced rate of phase shift to applied light.

The peak night time levels of melatonin are temporally associated with the nadir in core body temperature (cBT), maximum sleepiness/fatigue, lowest alertness, increased blood lipid (triacylglycerol), glucose, and possibly insulin (Fig. 8). These are correlative associations, however in the case of cBT and sleep propensity there is good evidence that melatonin contributes to the night time decline and increase respectively. Light suppression of melatonin at night leads to an increase in cBT and alertness. The increase in alertness correlates to the degree of melatonin suppression, but evidence for the quantitative contribution of endogenous melatonin to these effects is lacking. Exogenous melatonin clearly influences sleep. Possibly the best evidence for a causal role of melatonin in human sleep comes from studies in free-running blind subjects. When they are out of phase, i.e. when melatonin is secreted during the daytime, the peak levels are strongly associated with an increase in daytime napping (Fig. 3). In general melatonin reinforces functions associated with darkness. In nocturnal animals its production is associated with activity not sleep.

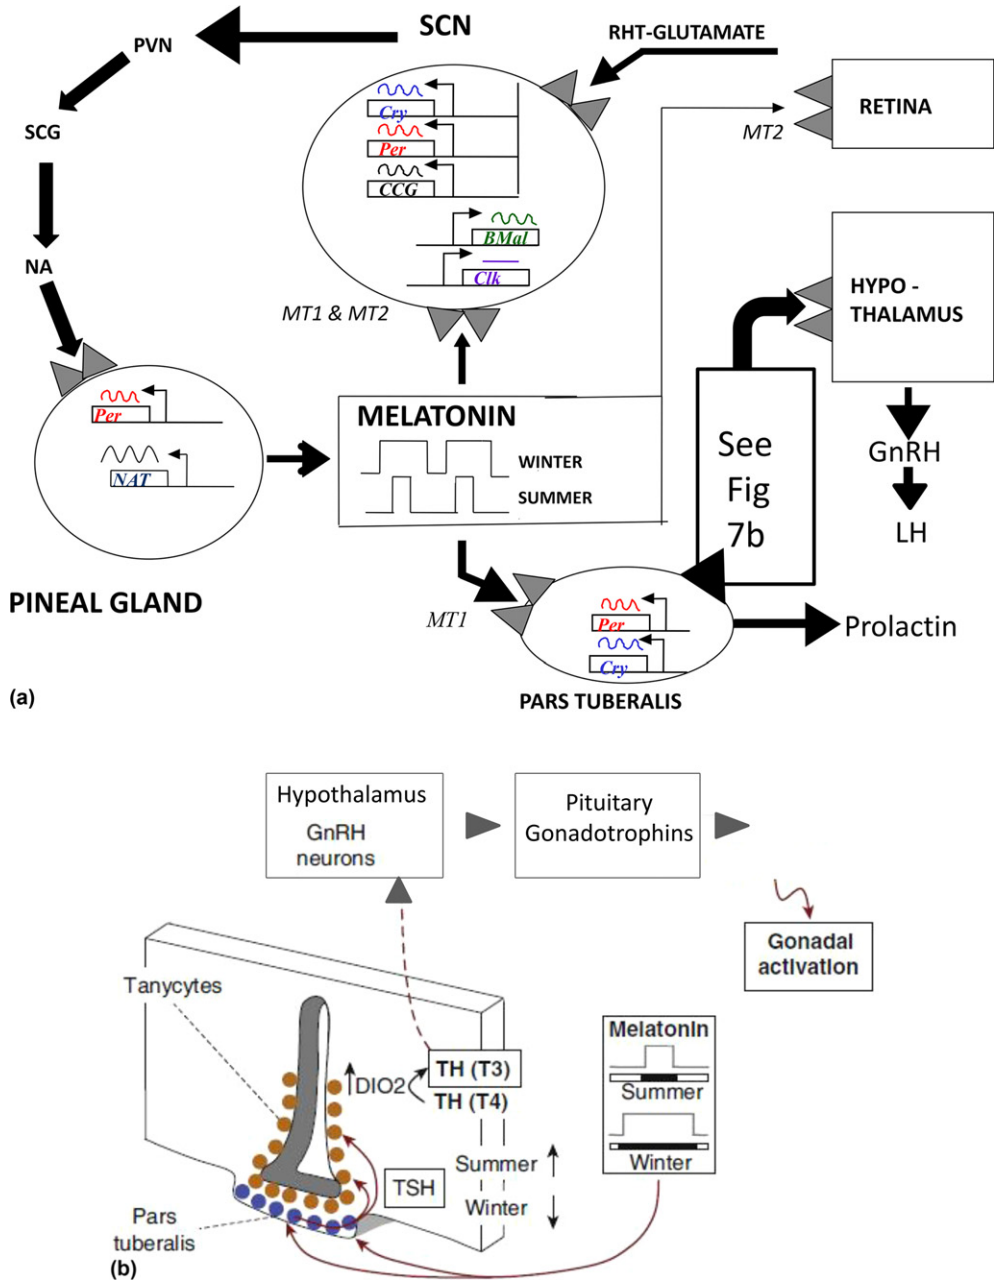

Fig. 7 (a) Diagrammatic representation of the control of production and the functions of melatonin with regard to seasonal and circadian timing mechanisms. RHT, retino-hypothalamic tract; NA, noradrenalin; SCN, suprachiasmatic nucleus; PVN, paraventricular nucleus; SCG, superior cervical ganglion; MT1 and MT2, melatonin receptor subtypes. The melatonin rhythm is generated by a closed-loop negative feedback of clock gene expression in the SCN. Clk and BMal, positive stimulatory elements; Per and Cry, negative elements; CCG, clock controlled genes. Per and NAT mRNA oscillate in the pineal, although posttranscription control is evident in some species. Melatonin influences SCN activity via two or more receptors. MT2 appears to be primarily the phase-shifting receptor in rodents, whereas MT1 is associated with suppression of SCN electrical activity. The MT2 receptor was first characterized in the retina and influences dopamine release. Melatonin conveys photoperiodic information influencing the patterns of clock gene expression in the pars tuberalis for the control of seasonal prolactin variations via an MT1 receptor. Mechanisms concerning the control of seasonal gonadotrophin changes are shown in Figure 11b. Based (with permission) on an original diagram by Elisabeth Maywood, MRC Laboratory of Molecular Biology, Neurobiology Division, Cambridge, United Kingdom. Modified from Encyclopedia of Endocrine diseases. (b) The mechanisms whereby melatonin influences gonadotrophin production according to season. Circulating melatonin binds to the MT1 receptors on the pars tuberalis. Here it induces TSH production under long photoperiods. The high levels of TSH cause the hypothalamic tanycytes in the third ventricle wall to produce thyroid hormone (T3) from the inactive form (T4) through increased expression of the enzyme DIO2 (type II thyroid hormone deiodinase). T3 then by a direct or indirect pathway drives the production of GnRH within the hypothalamus, to stimulate gonadotrophin production from the anterior pituitary once a critical length of photoperiod is present. Modified in part from Hut RA, Photoperiodism: Shall *EYA* Compare Thee to a Summer's Day? Current Biology 2011, 21:R22–R25, by permission.

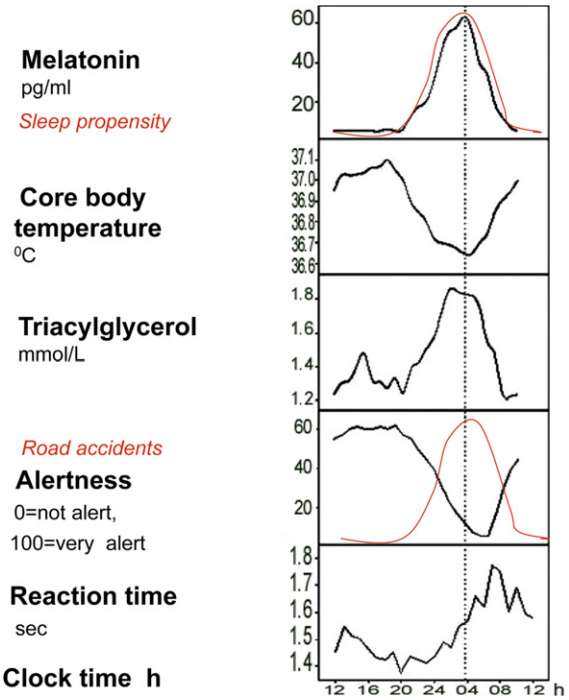

Fig. 8 Relationship of plasma melatonin to other major circadian rhythms. Note the close correspondence between the core temperature nadir and the melatonin peak. Reproduced from Rajaratnam SMW and Arendt J. Lancet 358:999–1005, 2001 by permission.

Melatonin and Human Reproduction

Melatonin declines during development, peaking at 3–4 years, with a plateau circa 18–35 years, followed by a decline into old age (although it should be noted that very healthy elderly subjects have not shown this decline). Early work suggested that it might have a role in the timing of human puberty, acting in an inhibitory capacity. Certainly exogenous melatonin is able to delay pubertal development in rats.

Pineal tumours are frequently associated with precocious/delayed puberty, but melatonin production has not been firmly implicated in normal or abnormal pubertal development in humans. Pineal tumors are heterogeneous and may arise from germ cells (teratomas, germinomas, choriocarcinomas, endodermal sinus tumors, mixed germ cell tumors), pineal parenchymal cells (pineoblastoma and pineocytoma), and the supporting stroma (gliomas). All are rare (less than 1% of intracranial space-occupying lesions) and tend to occur below 20 years of age with the exception of parenchymal cell tumors, which occur equally in adults and children. Most of the evidence now suggests that precocious puberty is due to the production of human chorionic gonadotrophin (hCG) by germ cell tumors of the pineal. Precocious puberty is associated with abnormally low melatonin levels whereas in delayed puberty, and in hypothalamic amenorrhoea melatonin levels are high in comparison to age matched normal subjects.

There is no doubt that suitable administration of melatonin can modify human reproductive function, generally speaking in an inhibitory capacity. It is able to suppress the ovulatory LH peak and to potentiate testosterone-induced LH suppression in very large doses. It can modulate the ultradian properties of LH and FSH secretion and acutely increases PRL (although chronic administration lowers prolactin in animals, corresponding to the effects of long nights). A series of studies in males with and without hypogonadism has reinforced the perception that melatonin is essentially inhibitory to human reproductive function. An (unsuccessful) attempt has been made to develop it as an oral contraceptive in combination with a progestin minipill, with very large daily doses (80 mg). These observations fuel worries concerning the possible reproductive side effects of over the counter availability of melatonin as a sleep aid in some countries.

General Human Pathology

Numerous reports exist of variations in melatonin secretion as a function of endocrine and other diseases. A problem with many publications is the possible influence of ambient light conditions and posture, together with sleep-wake characteristics of the subjects, especially if a hospitalised group is compared with a non-hospitalised control population. Liver disease such as cirrhosis, which impairs metabolic function, leads to higher than normal plasma concentrations and abnormal profiles of melatonin. Drugs that stimulate or suppress hydroxylation and conjugation mechanisms or that compete for metabolic pathways can be expected to

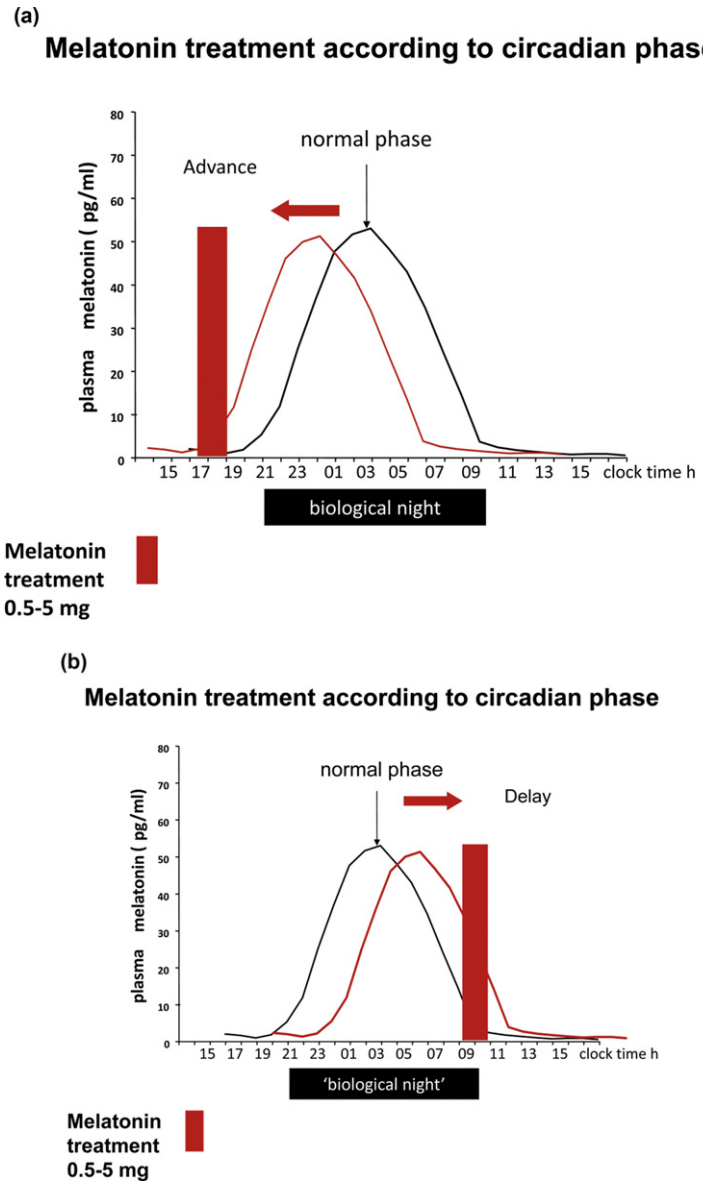

Fig. 9 (a and b) Diagrammatic representation of phase shifts induced by melatonin. Melatonin treatment, specifically timed according to internal circadian phase (shown here by the timing of the endogenous melatonin rhythm) can advance or delay the circadian clock as evidenced by shifts in its own endogenous rhythm, or that of core body temperature. The shift can be predicted by a 'Phase Response Curve' which describes the magnitude and direction of shift that can be obtained with specific circadian timing of treatment. Other rhythms that can be phase-shifted by melatonin include sleep, alertness, cortisol and TSH. The oral doses used are usually in the range of 0.5–5 mg fast release. The phase shift obtained is dose dependent, but individually variable.

affect circulating melatonin. There is little evidence for a disturbance of melatonin secretion in major sleep disorders such as narcolepsy and Klein–Levine syndrome (intermittent sleeping for days at a time). One very interesting genetic disorder, Smith–Magenis syndrome is caused by a deletion in chromosome 17p11.2. The syndrome is associated with various physical, developmental and behavioural disabilities, but it is not fully understood. It is associated with daytime melatonin production and poor nighttime sleep, but with normal cortisol rhythms. Pharmacological suppression of the daytime melatonin leads to improved daytime alertness and night time sleep. For some time sporadic publications have associated melatonin with aspects of diabetes and metabolism. For example light treatment to suppress melatonin and/or change its timing of secretion may reduce the need for insulin in diabetes mellitus. Recently a rare variant of the *MTNR1B* gene that encodes the receptor MT2 and impairs its function, has been reported and is associated with impaired glucose homeostasis, reduced insulin secretion, and an increased risk of developing type 2 diabetes. MT1 and MT2 knock-outs have provided some evidence that melatonin may synchronise the functions of the major organs involved in blood glucose regulation. Melatonin is also implicated in cardiovascular function with therapeutic

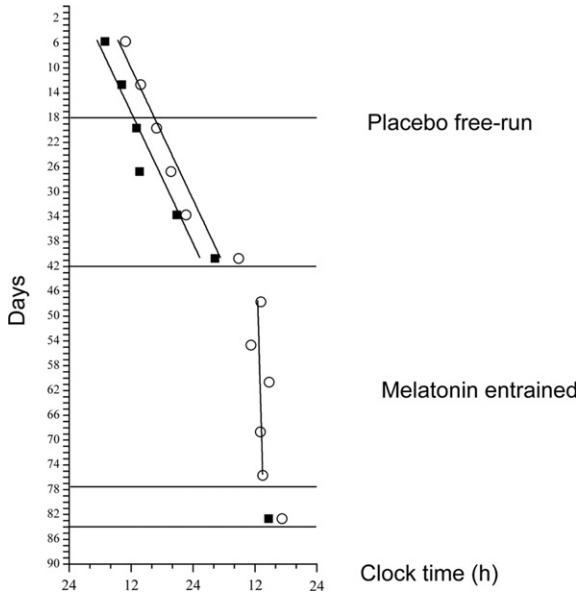

Fig. 10 Melatonin can phase shift and, in some cases, synchronise circadian rhythms in some sighted and blind subjects with suitable timing of treatment and dose. Shown are the times of the calculated peaks (acrophases) of urinary 6-sulphatoxymelatonin (squares) and cortisol (circles) of a free-running blind subject with a period of 24.57 h treated with placebo or 5 mg melatonin daily, timed to phase advance the internal clock. Note that with melatonin a 24 h period is maintained. Significant beneficial effects on sleep are found using melatonin treatment in non-24 h sleep disorder of the blind. Redrawn from Lockley SW, Skene DJ, James K, Thapan, K, Wright J and Arendt J. Melatonin administration can entrain the free running circadian system of blind subjects. J Endocrinol 164:R1–R6, 2000, reproduced by permission of the Society for Endocrinology.

possibilities in hypertension and other cardiovascular problems. Numerous attempts have been made to relate melatonin suppression to exposure to electromagnetic fields, with no consistent data in humans.

Melatonin has been extensively investigated in psychiatric disorder, particularly winter depression or seasonal affective disorder (SAD) where a causal role has been proposed. No firm conclusions can be drawn at present. Many antidepressant drugs acting on serotonergic or catecholaminergic systems will acutely increase or otherwise modify melatonin production. It is also invoked as a possible factor in autism and in Asperger syndrome.

There is some evidence for an involvement of melatonin and the pineal gland in vasopressin production.

Possible Role of Melatonin in Cancer

Melatonin suppression has been linked to infertility and increased incidence of certain cancers. There is evidence for low levels of melatonin in hormone dependent cancer (oestrogen receptor positive breast cancer, prostate cancer). Some cancers are photoperiod dependent in rodents and melatonin may have a role here. Pinealectomy in rats leads to a shortened survival time in dimethylbenzanthracene-induced mammary cancer: melatonin administration reverses this effect. There is good evidence for melatonin inhibition of growth of some hormone dependent cancer cell lines and also evidence for stimulation of immune function. Combined melatonin therapy with tamoxifen for breast cancer is being investigated in humans. It has been proposed that light at night during night shift work suppresses melatonin and that this loss of melatonin 'activity' is responsible for the increased cancer risk. However, to attribute any detrimental effects of shift work directly to loss of melatonin is overspeculative. The average drop in melatonin in rotating night shift workers at present appears to be around 20% and the meaning of such a (small) change is unknown). Moreover light at night has numerous other effects. The mere fact of frequent disruption of all circadian rhythms, not just melatonin, is effectively a physiological insult. In animals frequent forced change of phase (by manipulating the light–dark cycle) leads to increased vulnerability to development of cancer.

Melatonin as Anti-oxidant-Free Radical Scavenger

The melatonin molecule is easily oxidised, and therefore it is not particularly surprising that it demonstrates anti-oxidant/free radical scavenging effects. The concentrations required are, in general, orders of magnitude higher than physiological levels. However there is evidence that endogenous circulating melatonin may be responsible for some of the antioxidant status of blood. Many reports exist of its neuroprotective and cardioprotective ability which is attributed to free-radical scavenging activity. Some recent reports include its ability to improve in vitro sperm viability, oocyte competence and blastocyst development.

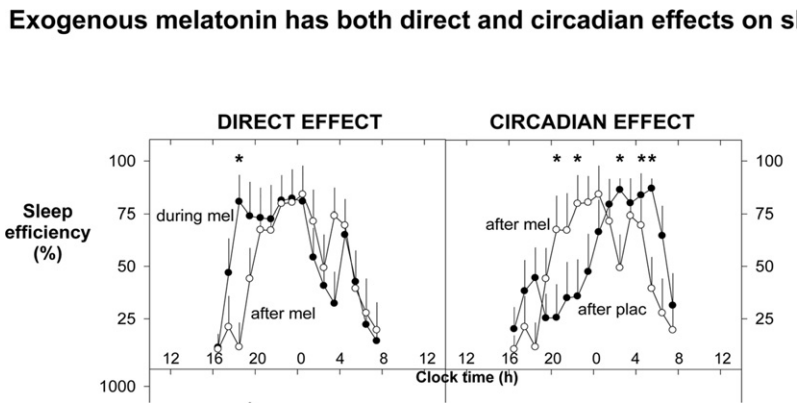

Fig. 11 Exogenous melatonin has both direct and circadian effects on sleep. Healthy young men (n = 8) received 1.5 mg surge sustained release melatonin or placebo in a double blind cross-over design at 1600 h daily for 8 days, recumbent, <5 lux, 1600–0800 h, sleep was evaluated by polysomnography on the night after the last dose of melatonin or placebo and on the subsequent night after melatonin washout. These data confirm the utility of melatonin for the treatment of delayed sleep. In a treatment situation the two effects can be maximised by suitable timing of the dose. Hormones (melatonin, cortisol, TSH) and heart rate variability showed similar substantial phase advances as seen for sleep. From Rajaratnam SMW, Middleton B, Stone BM, Arendt J, Dijk D-J. J Physiol 2004; 561:339–351, by permission.

Effects of Exogenous Melatonin in Humans

The sleepiness-inducing properties of melatonin have been known since its discoverer, the dermatologist Aaron Lerner, reported this effect after self administration. A substantial body of evidence indicates that taken during biological daytime (i.e. when endogenous melatonin is very low or absent), melatonin induces sleepiness/sleep and lowers alertness, cognitive performance and cBT. These effects are posture dependent: subjects must be recumbent and preferably in very dim light for maximum responses to be seen. Accompanying these direct effects is the important ability of melatonin to change the timing of the internal circadian clock as evidenced by shifts in the timing of endogenous melatonin itself, cortisol, cBT, TSH and sleep rhythms (Fig. 9–**11**). Administration during the (biological) afternoon/early evening (where biological night is the period of melatonin secretion) leads to phase advances, whereas taken in the early morning phase delays can be elicited. The existing data have been summarised as a 'phase response curve' from which specific timing of administration to induce a specific shift can be predicted.

Therapeutic Uses

In view of its ability to induce sleepiness, change the timing of sleep and shift the timing of the internal clock melatonin has been extensively investigated as a treatment for circadian rhythm related sleep disorders. It has proved successful, when correctly timed, for the alleviation of jet lag, improving daytime sleep in shift workers and normalising sleep time in delayed sleep phase syndrome. It is able to synchronise free-running sleep and other rhythms of some blind subjects with suitable dose and timing of treatment (**Fig. 10**). It is the latter indication which underlines the importance of such timed treatment. Circadian sleep disorders can normally be treated with appropriate exposure to bright light to shift the clock, inducing a resetting to a normal or near normal pattern of melatonin secretion. In the blind this is not possible and melatonin is the treatment of choice.

It is likely that SCN receptors mediate the circadian effects of melatonin, those in the pars tuberalis influence photoperiodic seasonal reproduction with regard to gonadotrophin secretion and prolactin, and those in the retina mediate the retinal processes influenced by melatonin (**Fig. 7(a)**). The physiological functions of the multiplicity of melatonin binding sites in other areas remain to be clarified.

Conclusions

Melatonin acts as both an internal clock and an internal calendar to influence the timing of circadian and seasonal rhythms. It is likely that any aspect of physiology which depends on perception of daylength change, and/or which is driven by the master circadian clock in the SCN, is susceptible to the effects of melatonin. These effects may be modulatory and complementary to the effects of light, in the case of the adult circadian system. In the perinatal period maternal melatonin may serve to set the timing of circadian rhythms in the offspring.

Suitable timing of melatonin administration is critical for therapeutic benefit in rhythm disorders. The acute effects of melatonin on sleep, in particular, reinforce its therapeutic effects. The possible clinical applications of anti-oxidant activity remain to be explored.

The effects of melatonin on photoperiod dependent functions are critically important and include, for example, the timing of pubertal development in photoperiodic species. It is used commercially in agriculture to modify the timing of breeding and seasonal changes in pelage.

Current research focuses on the mechanisms of action with particular emphasis on receptor mechanisms and modification of gene expression in target tissues. Melatonin is the marker rhythm of choice for the investigation of disturbed circadian rhythms in, for example, sleep disorder, shift work and jet lag. It is recommended by the American Academy of Sleep Medicine for the treatment of circadian rhythm sleep disorders, including jet lag, delayed sleep phse, free-running sleep-wake cycle and shift work.

Overview of Neurotransmitters☆

Floyd E Bloom, The Scripps Research Institute, La Jolla, CA, USA

Glossary

Acetylcholine The neurotransmitter for all autonomic ganglia and the terminal links of the parasympathetic nervous system, the neuromuscular junction, and large components of the central nervous system.

Anandamides A group of naturally occurring lipid amides whose receptors provide the molecular sites at which cannabinoid drugs (e.g., marijuana) produce their regulation of emotional responsiveness.

Catecholamines The chemical family of monoamine neurotransmitters, which are all produced from the amino acid tyrosine by the enzyme tyrosine, thus adding the second hydroxy to the phenyl ring characteristic of catechols.

Dopamine The main catecholamine neurotransmitter innervating the basal ganglia and some parts of the hypothalamic nuclei controlling pituitary secretion.

Endorphins One of the subfamilies of neuropeptide transmitters constituting the class whose receptors provide the molecular sites at which synthetic opiates provide pain relief and other effects.

GABA The major inhibitory neurotransmitter in the mammalian brain; the reaction product of glutamate decarboxylase.

Glutamate The major excitatory neurotransmitter in the mammalian brain; a dicarboxylic amino acid also used to synthesize proteins.

Histamine A significant neurotransmitter for neurons of the basal hypothalamus, with lengthy projections to the forebrain. Histamine is a diamine and chemically one of the aminergic neurotransmitters.

Neuropeptides A chemical class of neurotransmitters composed of three or more amino acids in peptide linkages, generally working in concert with amino acid or amine neurotransmitters. All hypothalamic hypophysiotrophic hormones are neuropeptides.

Norepinephrine The second major catecholamine neurotransmitter innervating most regions of the mammalian brain, including the magnocellular hypothalamic nuclei, hippocampus, cerebral cortex, olfactory bulb, and cerebellum.

Introduction

Neurotransmitters can be grouped within three main chemical categories: amino acids, amines, and neuropeptides. Other substances that may participate in central synaptic transmission include purines (e.g., adenosine and ATP), nitric oxide, and arachidonic acid derivatives.

Amino Acids

The central nervous system (CNS) contains uniquely high concentrations of two highly potent amino acids capable of affecting neuronal activity: glutamate and GABA. Neuroscientists were once quite reluctant to accept these or other amino acids as central neurotransmitters because of their broad distribution and their ability to produce powerful effects on virtually every neuron tested. Thus, glutamate and other dicarboxylic amino acids produce consistent excitation, whereas GABA, glycine, and other monocarboxylic amino acids produce consistent inhibition. There is general acceptance that the amino acids GABA, glycine, and glutamate are central transmitters.

GABA

GABA was recognized as a unique chemical component of brain in 1950, long before its functions were understood. Its neurotransmitter properties were first validated for the inhibitory nerves of crustacean (lobster) limb muscles, in which GABA content was shown to account for the inhibitory effects of extracts of these nerve fibers, and release of GABA with increased firing of the nerve fibers correlated with the inhibitory effects on the muscle.

In the mammalian CNS, GABA is considered the major mediator for local interneurons and for presynaptic inhibition within the spinal cord. Presumptive GABAergic inhibitory synapses have been demonstrated most clearly between cerebellar Purkinje neurons and their targets in Deiter's nucleus; between small interneurons and the major output cells of the cerebellar cortex, olfactory bulb, cuneate nucleus,

☆*Change History:* December 2014. FE Bloom updated the section on 'Comparison with Other Transmitters,' added new section on 'Modern Modes of Neuropeptide Discovery,' and updated references.

This article is an update of Floyd E. Bloom, Neurotransmitters, Overview, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 350-356.

hippocampus, and lateral septal nucleus; and between the vestibular nucleus and the trochlear motoneurons. GABA also mediates inhibition within the cerebral cortex and between the caudate nucleus and the substantia nigra. GABAergic neurons and nerve terminals have been localized with immunocytochemical methods that visualize glutamic acid decarboxylase, the enzyme that catalyzes the synthesis of GABA from glutamic acid. GABA-containing neurons have frequently been found to coexpress one or more neuropeptides. The most useful selective antagonists for demonstration of likely GABAergic synapses are bicuculline and picrotoxin.

GABA receptors exist in two main molecular forms, each with a functional representation. The more prominent GABA receptor subtype, the $GABA_A$ receptor, is a ligand-gated Cl^- ion channel that opens in the presence of GABA. As a typical ion channel receptor, akin to the classical cholinergic nicotinic receptor, the $GABA_A$ receptor is composed of four or five subunits, each of which is composed of proteins that exhibit four transmembrane domains and cluster to form the ion channel for Cl^-. Although there are four main classes of subunits, there are multiple variations, providing for an enormous number of possibly similar but distinct classes of GABA receptors. Many neuroactive drugs, such as benzodiazepines, ethanol, and barbiturates, act on $GABA_A$ receptors. The $GABA_B$ receptor is a G protein-coupled receptor able to activate second-messenger signal transduction pathways, and like other receptors of this class, it exhibits a structure composed of seven transmembrane domains. Many of the features described for the $GABA_A$ receptor family also apply to the glycine receptor, which appears to be the major inhibitory neurotransmitter in the brainstem and spinal cord.

Glutamate and Aspartate

Glutamate and aspartate are both abundant in brain, and both are powerful excitants for neurons in every brain region of the CNS, where they are considered the principal fast (classical) excitatory transmitters. Glutamate receptors, like GABA receptors, exist in two forms – as ligand-gated ion channel receptors with multiple possible combinations of a few isoforma of subunits or as G protein-coupled receptors. The ligand-gated glutamate ion channel receptors are further classified according to the agonists that selectively activate them, including α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), kainate, and *N*-methyl-D aspartate (NMDA) receptors, each of which has selective agonists and antagonists. The diversity of gene expression and, consequently, of the protein structure for glutamate receptors also arises by alternative splicing and RNA editing.

AMPA and kainate receptors mediate fast depolarization at most glutamatergic synapses in the brain and spinal cord. NMDA receptors are also involved in normal synaptic transmission, but activation of NMDA receptors is more closely associated with the induction of various forms of synaptic plasticity. AMPA or kainate receptors and NMDA receptors coexist at many glutamatergic synapses. Activation of NMDA receptors is obligatory for the induction of the form of plasticity known as long-term potentiation. Activation of NMDA receptors requires both the binding of glutamate and the simultaneous depolarization of the postsynaptic membrane to displace a Mg^{2+} normally bound within the channel. High concentrations of glutamate are lethal to neurons because of elevation of intracellular Ca^{2+} levels and induction of apoptosis. Studies suggest that local depletion of Na^+ and K^+, as well as small increases in extracellular Zn^{2+}, will activate both necrotic and proapoptotic cascades of neuronal death. Disordered glutamatergic transmission has been postulated as a mechanism of chronic neurodegenerative diseases and schizophrenia.

Amine Transmitters

In the following sections, all the neurotransmitters that are chemically amines are discussed, including the monoamines dopamine, norepinephrine, and epinephrine (which together comprise the catecholamines); 5-hydroxytryptamine (or serotonin); the diamine histamine; and the quaternary amine acetylcholine. However, all of these have been studied for far longer than their chemical similarities have been apparent.

Acetylcholine

Acetylcholine (ACh) became the first established chemical neurotransmitter when it was demonstrated to be the substance released by the vagus nerve to slow the heart rate as the terminal step in the parasympathetic control of heart rate. ACh was later identified as the transmitter at both neuromuscular and parasympathetic neuroeffector junctions, as well as at the major synapse within autonomic ganglia. Eventually, ACh received recognition as a central neurotransmitter, based on its irregular distribution within the CNS and the behavioral effects exerted by cholinergic drugs after central administration. The first established cholinergic central synapse was the recurrent excitatory synapse from Renshaw interneurons to spinal motoneurons.

As for the amino acid receptors, the classical pharmacological forms of the cholinergic receptors were also shown by molecular cloning and sequence determinations to be represented by ligand-gated ion channels (nicotinic receptors) and by G protein-coupled forms (muscarinic receptors). As is the case for the amino acids, nicotinic receptors have multiple combinations of four transmembrane domain subunits, whereas the muscarinic receptors, like all known G protein-coupled receptor forms, exist as a single seven-transmembrane domain. In most regions of the CNS, the effects of ACh, assessed either by iontophoresis or by radioligand receptor-displacement assays, appear to be generated by interaction with a mixture of nicotinic and muscarinic receptors. Several sets of presumptive cholinergic pathways have been described in addition to that of the nicotinic spinal Renshaw cell to motoneuron. Eight major clusters of ACh neurons and their pathways have been characterized, with four separate groups of

cell bodies located in the basal forebrain, two groups in the upper pons provide the major cholinergic innervation of thalamus and striatum, and there are two groups for the midbrain and brainstem. The intense cholinergic projections to neocortex and hippocampal formation are dependent on the trophic growth factors provided to them by retrograde axonal transport from their target neurons, and their loss has been the sole target of treatments for Alzheimer's disease through inhibition of the central catabolic enzyme, acetylcholinesterase.

Catecholamines

The brain contains separate neuronal systems that use three different catecholamines – dopamine, norepinephrine, and epinephrine. These monoamines are derived from the common precursors tyrosine and L-dihydroxyphenylalanine (L-DOPA), and they form a three-step synthetic metabolic pathway. Tyrosine is converted to L-DOPA by tyrosine hydroxylase, L-DOPA is converted to dopamine by DOPA decarboxylase, dopamine is converted to norepinephrine by dopamine β-hydroxylase, and norepinephrine is converted to epinephrine by the synthetic enzyme phenylethanolamine *N*-methyl transferase. When these enzymatic steps were determined, antibodies raised against these proteins were found to be useful cellular markers and defined three catecholamine-containing neuronal systems: Tyrosine hydroxylase defined dopamine- and norepinephrine-synthesizing neurons, antibodies to dopamine β-hydroxylase revealed exclusively the norepinephrine-synthesizing neurons, and antibodies to phenylethanolamine *N*-methyl transferase defined the epinephrine-synthesizing neurons. Each system is anatomically distinct and serves separate but similar functional roles within their fields of innervation.

Dopamine

Originally, dopamine was considered to be only a precursor for norepinephrine; however, assays of distinct regions of the CNS eventually revealed that the distributions of dopamine and norepinephrine are markedly different. In fact, more than half the CNS content of catecholamine is dopamine, and extremely large amounts are found in the basal ganglia (especially the caudate nucleus), the nucleus accumbens, the olfactory tubercle, the central nucleus of the amygdala, the median eminence, and restricted fields of the frontal cortex. The anatomical connections of the dopamine-containing neurons are categorized into three major morphological classes: (i) ultrashort neurons within the amacrine cells of the retina and periglomerular cells of the olfactory bulb; (ii) intermediate-length neurons within the tuberobasal ventral hypothalamus, critical for many endocrine regulatory processes within the median eminence and intermediate lobe of the pituitary, that connect the dorsal and posterior hypothalamus with the lateral septal nuclei and other hypothalamic nuclei; and (iii) long projections between the major dopamine-containing nuclei in the substantia nigra (named for the black pigment that these neurons exhibit in the postmortem human and monkey brain and that is lost when these neurons die in Parkinson's disease) and the ventral tegmentum. These dopamine neurons project to precise targets in the striatum, in the cerebral cortex, and in other major limbic structures except the hippocampus. All dopamine receptors are represented by two functional classes of G protein-coupled receptors – those that activate adenylate cyclase (D1 and D5) and those that inhibit the activation of adenylate cyclase (D2–D4). The D2 receptors couple to multiple effector systems, including the inhibition of adenylyl cyclase activity, suppression of Ca^{2+} currents, and activation of K^{+} currents. D2 dopamine receptors have been implicated in the pathophysiology of schizophrenia and Parkinson's disease.

Norepinephrine

The noradrenergic innervation of the forebrain, including the hypothalamus, cortex, hippocampus, and olfactory bulb, arises from the major cluster of noradrenergic neurons in the pontine nucleus called the locus ceruleus because of the blue pigment they contain in the brains of primates. There are relatively large amounts of norepinephrine within the hypothalamus and in certain zones of the limbic system, such as the central nucleus of the amygdala and the dentate gyrus of the hippocampus. However, norepinephrine is also present in significant but lesser amounts in most brain regions. Detailed mapping studies indicate that most noradrenergic neurons arise either in the locus ceruleus of the pons or in neurons of the lateral tegmental portion of the reticular formation. From these neurons, multiple branched axons innervate specific target cells in a large number of cortical, subcortical, and spinal fields. The pharmacological properties of such synapses are complex, with evidence of mediation by both α- and β-adrenergic receptors (both G protein-coupled receptors; the β-adrenergic receptors activate adenylate cyclase, whereas α-adrenergic receptors inhibit cyclic AMP synthesis, and each form has three or more subtypes). For example, stimulation of the locus ceruleus depresses the spontaneous activity of target neurons in the cerebellum mediated by a slowly developing hyperpolarization and a decrease in membrane conductance. However, activation of the locus ceruleus also enhances the higher firing rates produced by stimulation of excitatory inputs to these convergent target neurons to a lesser degree. The afferent circuits innervating the locus ceruleus neurons include medullary cholinergic neurons, opioid peptide neurons, raphe (5-HT) neurons, and corticotropin-releasing hormone neurons from the hypothalamus. Tricyclic antidepressant drugs act on noradrenergic neurons, augmenting levels in the extracellular space by inhibiting the norepinephrine transporter.

Epinephrine

Epinephrine-containing neurons are found in the medullary reticular formation and make restricted connections to a few pontine and diencephalic nuclei, such as the paraventricular nucleus of the dorsal midline thalamus. Their physiological properties have not been established.

5-Hydroxytryptamine

The early history of this neurotransmitter brought together two sets of previously unconnected work on factors extracted from serum (serotonin) and gut (enteramine) identified chemically as 5-hydroxy-tryptamine (5-HT), which is functionally detected in large amounts in brain. Through various cytochemical approaches, 5-HT-containing neurons have been characterized in nine pontine and medullary nuclei lying in or adjacent to the midline (raphe). The more rostral raphe nuclei innervate forebrain regions, whereas the caudal raphe nuclei project within the brainstem and spinal cord with some overlap. The median raphe nucleus makes a major contribution to the innervation of limbic cortical structures, and the dorsal raphe nucleus makes a similar contribution to the cerebral cortex and the neostriatum.

Molecular biological approaches have led to the identification of more than 12 distinct mammalian 5-HT receptor subtypes, all of which are G protein-coupled receptors linked to a variety of signal transduction cascades except for the 5-HT_3 receptor, which is a ligand-gated ion channel receptor. These subtypes exhibit characteristic ligand-binding profiles, couple to different intracellular signaling systems, exhibit subtype-specific distributions within the CNS, and mediate distinct behavioral effects of 5-HT. The 5-HT_{1A} receptors are abundantly expressed on 5-HT neurons of the dorsal raphe nucleus, where they are thought to be involved in temperature regulation. They are also found in regions of the CNS associated with mood and anxiety, such as the hippocampus and amygdala. 5-HT_{1D} receptors are potently activated by the drug sumatriptan, which is prescribed for acute management of migraine headaches.

The 5-HT_2 receptor class has three recognized subtypes: 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}. 5-HT_{2A} receptors are enriched in forebrain regions such as neocortex and olfactory tubercle as well as in several brainstem nuclei, including most cranial motoneurons. The 5-HT_{2C} receptor, which is very similar in sequence and pharmacology to the 5-HT_{2A} receptor, is expressed abundantly in the choroid plexus, where it regulates cerebrospinal fluid production. The hallucinogen LSD interacts through the 5-HT_2 receptors. Serotonin-containing pathways have been implicated in sleep disturbances, appetitive problems, pain, and depression. The class of drugs termed serotonin selective reuptake inhibitors is very effective in some patients with major depression.

Histamine

Although not recognized as a neurotransmitter for much of the recent history of such signaling molecules, histamine and antihistaminic drugs were long known to possess potent effects on animal behavior. The subsequent biochemical detection of histamine synthesis by neurons, as well as direct cytochemical localization of these neurons, established the existence of a histaminergic system in the CNS. Most histaminergic neurons are located in the ventral posterior hypothalamus and give rise to long ascending and descending tracts to the entire CNS. Histaminergic neurons function in the regulation of arousal, body temperature, and vascular dynamics.

Peptides

During the 1980s, numerous novel peptides were discovered in the CNS, each capable of regulating one or another aspect of neural function. Furthermore, certain peptides previously thought to exist only in gut or endocrine glands were also found in the CNS. Most CNS peptides are thought to act mainly in concert with coexisting transmitters, both amines and amino acids. Each neuropeptide system has significant implications for endocrinology and endocrine diseases. Three general approaches to the continuously growing families of neurons containing one or more neuropeptides are discussed here.

Organization by Peptide Families

Peptides can be grouped into families based on the possession of significant homology in amino acid sequences, with each having its own genetic representation through evolutionary gene duplication and subsequent divergence of functions. Such relationships are well illustrated by the tachykinin or the vasotocin (vasopressin/oxytocin) families, in which species differences can be correlated with modest variations in peptide structure. The multiple members of the tachykinin/substance P family coexist within mammalian neurons in the brain and in the intestines and may account for the apparent existence of subsets of receptors for each of these peptides. The mammalian representatives of the vasotocin family show two concurrent products, vasopressin and oxytocin, each having evolved to perform separate functions once executed in amphibia by a single vasotocin-related peptides and receptor. A different divergent evolutionary pathway is illustrated by the endorphin and by the glucagon–secretin peptide families. In the endorphin superfamily, three major genetically distinct systems of endorphin peptides (proopiomelanocortin, proenkephalin, and prodynorphin) exist in independent neuronal circuits. These natural opioid peptide families have emerged from independent but homologous genes. The peptides all share some actions at receptors once classed generally as ‘opioid’ but that are undergoing progressive refinement with molecular resolution of their structures, functions, and cellular expression patterns. In the glucagon–secretin family, multiple and somewhat homologous peptides are found simultaneously in different cells of the same organism but in separate organ systems: glucagon and vasoactive intestinal polypeptide (VIP) in pancreatic islets; secretin in duodenal mucosa; VIP and related peptides in enteric, autonomic, and central neurons; and growth hormone-releasing factor in central neurons only. The general metabolic effects produced by this family lead to increased blood glucose.

Organization by Anatomic Pattern

Some peptide systems follow consistent anatomical organizations. Thus, the hypothalamic peptides oxytocin, vasopressin, proopiomelanocortin, gonadotropin-releasing hormone, and growth hormone-releasing hormone all tend to be synthesized by single large clusters of neurons that give off multibranched axons to several distant targets. Others, such as systems that contain somatostatin, cholecystokinin, and enkephalin, can have many forms, with patterns varying from moderately long, hierarchical connections to short-axon, local-circuit neurons that are widely distributed throughout the brain.

Organization by Function

Since almost all peptides were initially identified on the basis of bioassays, their names reflect these biologically assayed functions (e.g., thyrotropin-releasing hormone and vasoactive intestinal polypeptide). These names will become trivial if more ubiquitous distributions and additional functions are discovered. Some general integrative role might be hypothesized for widely separated neurons (and other cells) that make the same peptide. However, a more parsimonious view is that each peptide has unique messenger roles at the cellular level and that these are used repeatedly in functionally similar pathways within large systems that differ in their overall functions. Cloning of the major members of the opioid–peptide receptors revealed unexpected and unexplained conservation of sequences with receptors for somatostatin, angiotensin, and other peptides.

Comparison with Other Transmitters

Peptides differ in several important respects from the monoamine and amino acid transmitters. Synthesis of a peptide is performed in the rough endoplasmic reticulum of the cell body, while monoamines and amino acids are synthesized in the nerve terminals, only with the rough endoplasmic reticulum of the neuronal cell body can the mRNA for the propeptide be translated into an amino acid sequence. The propeptide is cleaved (proteolytically processed) to the form that is secreted as the secretory vesicles are transported from the perinuclear cytoplasm to the nerve terminals. In addition, no active reuptake mechanisms for peptides have been described. Thus, peptidergic nerve terminals are dependent for their signaling on distant sites of synthesis. Much progress has been made in to the development of drugs that act as antagonists for neuropeptides and that are orally active and not peptides, thereby advancing roles for neuropeptides in human diseases such as stress and depression.

Modern Modes of Neuropeptide Discovery

While the vast majority of neuropeptides were discovered by exploiting brain abstracts for bioassay actions on presumptive end organs, that is, the hypophysiotrophic factors action on specific pituitary cell groups, new methods of discovery emerged in the 1990s. The initial drafts of the human genome revealed putative G-protein coupled receptors with no known ligands. Searching for factors in brain extracts that could bind to or activate these orphan receptors led to the discovery of at least 2 endocrinological important neuropeptides. Orphanin F/Q (also known as Nociceptin) is a 17 amino acid peptide, structurally related to Dynorphin A,but does not activate the classical opioid receptors, or do any of the endorphin or enkephalin peptides or their antagonists interact with the orphanin F/Q receptor termed the: NOP (Nociceptin Opioid Peptide) Receptor. Yet the Orphanin peptide is itself an anti-opioid peptide in terms of preventing opioid induced analgesia at supra-spinal levels. This peptide and synthetic antagonist analogs seem mainly to interact with actions of glutamate within reward circuits. Hypocretin, by amino acid sequence homology is a member of the secretin-VIP peptide family. It was discovered by searching for genes that were uniquely expressed in rat hypothalamus. Arising from neurons in the perifornical nucleus of the dorsal hippocampus, it projects heavily to midbrain structures regulating, sleep, blood pressure and appetite. Hypocretin receptors are mutated in narcolepsy, and hypocretin antagonists are under developments as sleep aids. The same peptide was discovered at the same time by another group panning for ligands for orphan receptors and named orexin for its ability to stimulate appetite in food satiated animals.

Other Regulatory Signals

In addition to the previously discussed major families of neurotransmitters, other endogenous substances have also gained attention as interneuronal signaling molecules that, if valid, will expand the definition of this process. For example, the purines adenosine monophosphate, adenosine triphosphate, and free adenosine have helped define a purinergic signaling system with two large families of purinergic receptors. ATP-regulated responses have been linked pharmacologically to a variety of supracellular functions, including anxiety, stroke, and epilepsy.

Although all the classical neurotransmitters described previously were detected on the basis of the ability to extract them as factors from their storage sites in brain, gut, or other organ systems, studies have revealed potent classes of signaling molecules that are apparently synthesized on demand and act at significant distances from their sites of synthesis and release through diffusion. Arachidonic acid, normally stored within the cell membrane as a glycerol ester, can be liberated when phospholipases are activated by a variety of neurotransmitter receptors and then converted to highly reactive signals by one of three enzymatic pathways:

cycloxygenases (leading to prostaglandins and thromboxanes), lipoxygenases (leading to the leukotrienes and other transient catabolites of eicosatetraenoic acid), and cytochrome P450 (which is inducible but expressed at low levels in brain). These arachidonic acid metabolites have been implicated as diffusible modulators in the CNS, particularly for long-term potentiation and other forms of plasticity, and include the anadamides, which are endogenous lipid signals identified on the basis of their interactions with the cannabinoid receptors.

Last, nitric oxide was initially recognized as an important regulator of vascular and inflammatory mechanisms and was later recognized to play analogous signaling roles in the brain after determination of the various forms of the enzyme nitric oxide synthase (NOS), through which NO is made and released. At least four isoforms of this biosynthetic enzyme have been identified in the brain: a constitutive form present in some neurons, capillary endothelial cells, and macrophages, as well as inducible forms of the enzyme. The availability of potent activators of NOS has led to reports of the presumptive involvement of NO in a host of phenomena in the brain, including long-term potentiation, guanylyl cyclase activation, neurotransmitter release and reuptake, and enhancement of glutamate (NMDA)-mediated neurotoxicity.

Anatomy of Hypothalamus

Béla Halász, Hungarian Academy of Sciences and Semmelweis University, Budapest, Hungary

This chapter is reproduced from Béla Halász, Anatomy of Hypothalamus, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 707–715.

Glossary

Anterior lobe of the pituitary gland (anterior pituitary) The major part of this organ; synthesizes hormones that control body growth, thyroid, adrenocortical, and gonadal functions, among others.

Brainstem The medulla oblongata, pons, and mesencephalon parts of the brain.

Hypophysiotropic neurohormones Well-characterized substances synthesized by neurons projecting to the median eminence and carried by the portal vascular system to the anterior pituitary.

Hypothalamic nuclei Areas of neurons of higher density than those in the neighborhood.

Neurohormones Bioactive substances synthesized by neurons and released into the blood.

Neurons The nerve cells.

Pathways (fiber tracts) Large number of nerve fibers running together, at least for some distance, and arising from and terminating in the same region, but with their origins and final destinations not necessarily always being identical.

Pituitary gland (hypophysis) An endocrine organ connected to the hypothalamus and being composed of an anterior lobe, an intermediate lobe, and a posterior lobe.

Posterior lobe (neural lobe or posterior pituitary) of the pituitary gland A small part of this organ that stores and releases hormones synthesized by neurons in the paraventricular and supraoptic nuclei.

The hypothalamus, a fairly small part of the brain being connected with the pituitary gland, is an extremely complex, highly integrated structure of the diencephalon that plays a key role in the control of homeostasis and reproduction.

Introduction

The hypothalamus, part of the diencephalon, is a rather small region of the brain. The human hypothalamus weighs about 4 g and, therefore, represents only 0.3% of the whole brain. In spite of its small size, the hypothalamus plays a fundamental role in the control of homeostasis as well as in reproduction. The structural organization of this diencephalic region is extremely complex, manifold interrelated, and integrated. The hypothalamus is closely and reciprocally linked to other parts of the brain (e.g., the autonomic nervous system), is connected to the pituitary gland, and produces neurohormones.

This article describes the basic structural organization of the hypothalamus, summarizing hypothalamic regions, cell groups within regions, and connections to the hypothalamus. Subsequently, it deals with the hypothalamo–anterior pituitary and hypothalamo– posterior pituitary systems. Finally, it describes the blood supply of the hypothalamus.

Basic Organization

Topography of the Hypothalamus: Hypothalamic Regions

From a morphological point of view, the hypothalamus can be subdivided into three longitudinal parts in the sagittal plane: periventricular (around the third ventricle), medial, and lateral. Both the periventricular hypothalamus and medial hypothalamus are cell rich, whereas the lateral hypothalamus is dominated by the longitudinal fiber system of the medial forebrain bundle. In the rostrocaudaldirection, the hypothalamus can be subdivided into five regions (**Fig. 1**): preoptic region, anterior hypothalamus, middle hypothalamus, premammillary region (also called the posterior hypothalamus), and mammillary region (topographically a part of the hypothalamus but functionally belonging to the limbic system that is not dealt with here). In the human hypothalamus, only three major parts can be distinguished: supraoptic region (corresponding to the preoptic and anterior hypothalamic regions of the rat), tuberal region (middle hypothalamic region), and mammillary region.

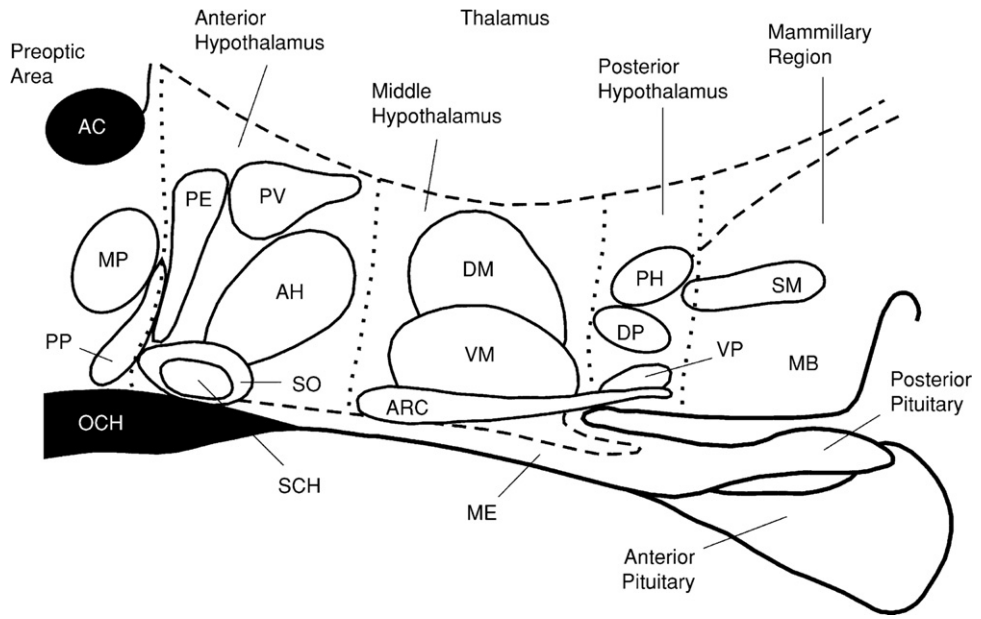

Fig. 1 Hypothalamic regions and cell groups within regions projected into the midsagittal section of the rat hypothalamus. AC, anterior commissure; AH, anterior hypothalamic nucleus; ARC, arcuate nucleus; DM, dorsomedial nucleus; DP, dorsal premammillary nucleus; MB, mammillary body; ME, median eminence; MP, medial preoptic nucleus; OCH, optic chiasm; PE, periventricular nucleus; PP, preoptic periventricular nucleus; PV, paraventricular nucleus; SCH, suprachiasmatic nucleus; SM, supramammillary nucleus; SO, supraoptic nucleus; PH, posterior hypothalamic nucleus; VM, ventromedial nucleus; VP, ventral premammillary nucleus.

Cell groups and areas

Preoptic region

The preoptic region extends from the basal forebrain and lamina terminalis to the level of the rostral half of the optic chiasm and continues into the anterior hypothalamus. Dorsally, it is bordered by the anterior commissure and the bed nucleus of the stria terminalis.

The cell-rich medial part of the preoptic region contains several cell groups, including the medial preoptic and preoptic periventricular nuclei, and contains gonadotropin-releasing hormone (GnRH) neurons. The lateral part is occupied by the medial forebrain bundle. In the midline, a circumventricular organ, the organum vasculosum laminae terminalis (also called the supraoptic crest) can be found around the tip of the third ventricle. The organ is outside of the blood–brain barrier.

Anterior hypothalamus

The anterior hypothalamus is a continuation of the preoptic region and extends caudally to the level of the arising of the median eminence. Its medial part comprises the anterior periventricular, suprachiasmatic, anterior hypothalamic, and paraventricular nuclei. The anterior periventricular nucleus contains somatostatin immunoreactive neurons projecting to the median eminence and dopaminergic neurons terminating in the posterior and intermediate lobe of the pituitary gland (periventriculo–hypophyseal dopaminergic system). The suprachiasmatic nucleus (a key structure in the control of biological rhythms) is situated just above the optic chiasm on the two sides of the third ventricle. It receives direct input from the retina and indirect neuronal input from the retina via the lateral geniculate body and from brainstem serotonergic neurons. The supraoptic nucleus is located along and around the lateral edge of the optic chiasm and is composed of magnocellular neurons. In humans, the supraoptic nucleus is situated above the rostral end of the optic tract. Neurons of this cell group synthesize oxytocin and vasopressin and project to the posterior pituitary. The paraventricular nucleus lies close to the two sides of the third ventricle, above the anterior hypothalamic nucleus. Magnocellular and parvocellular divisions can be distinguished. Magnocellular neurons synthesize oxytocin and vasopressin and project to the posterior pituitary. The cell group contains corticotropin-releasing hormone (CRH)- and thyrotropin-releasing hormone (TRH)producing neurons that terminate in the median eminence as well as medium-sized neurons that give rise to long descending projections to the brainstem and spinal cord. The lateral part of this hypothalamic region contains the supraoptic nucleus and fibers and cells of the medial forebrain bundle. Caudally, the so-called retrochiasmatic area containing loosely packed cells and fibers occupies the ventral part of the anterior hypothalamus. In both the medial and lateral parts of the anterior hypothalamus, magnocellular neurons form small groups (called accessory nuclei).

Middle hypothalamus (tuberal region)

The middle hypothalamus, starting behind the retrochiasmatic area, ends at the level of the separation of the pituitary stalk. The medial basal part of the region contains the arcuate and ventromedial nuclei and the median eminence, whereas the medial dorsal part contains the dorsomedial nucleus. The lateral part is called the lateral hypothalamic area and is largely occupied by the medial forebrain bundle.

The arcuate (also called the infundibular) nucleus, made up of five subdivisions, is an elongated cell group in the most ventromedial part of the middle hypothalamus and posterior hypothalamus, mostly on the two sides of the third ventricle (infundibular recess). The cell group contains, in addition to several other neuropeptides, pro-opiomelanocortinsynthesizing neurons and growth hormone-releasing hormone (GHRH) as well as dopaminergic neurons. These latter two project to the median eminence, forming the tubero–infundibular pathway. The ventromedial nucleus is a major cell group composed of five subdivisions that contain morphologically and functionally distinct neurons with neuronal connections to various components of the limbic system. The dorsomedial nucleus divided into three subdivisions is caudal to the paraventricular nucleus.

Posterior hypothalamus (premammillary region)

The main cell groups of the posterior hypothalamus, a relatively small part of the hypothalamus, are the ventral and dorsal premammillary, tuberomammillary, supramammillary, and posterior hypothalamic nuclei. The ventral premammillary nucleus is a small cell group in continuation with the ventromedial and partly the arcuate nuclei. The dorsal premammillary nucleus is located caudal to the ventromedial nucleus at the sides of the inframammillary recess of the third ventricle. The tuberomammillary nucleus is located in the most ventral and medial part of the posterior hypothalamus. Some neurons of the cell group synthesize histamine, providing the only source of neuronal histamine in the brain. The posterior hypothalamic nucleus is a fairly large group of cells occupying the dorsal part of the periaqueductal central gray. The unpaired supramammillary nucleus is dorsal to the mammillary body and projects to the hippocampus, dentate gyrus, and medial septum diagonal band nuclei.

Characteristics of hypothalamic cell groups

The hypothalamic cell groups are not at all homogenous, and in most cases subgroups can be distinguished. For example, in the arcuate nucleus, there are dopamine, GHRH, enkephalin, galanin, substance P, g-aminobutyric acid (GABA), atrial natriuretic peptide, neurotensin, gastrin-releasing peptide (GRP), and glutamate-containing neurons. The suprachiasmatic nucleus, representing a key structure of the biological clock, is composed of vasopressin, vasoactive intestinal peptide, somatotropin release-inhibiting hormone (SRIH), substance P, GABA, and GRP containing nerve cells. The situation is further complicated by the colocalization of various neuropeptides in the same neurons. The functional significance of colocalization of substances in the nerve cells needs to be clarified.

The paraventricular nucleus is unique among hypothalamic cell groups in housing substantial populations of cells that participate in the control of anterior and posterior pituitary secretions and also is associated with the autonomic nervous system. This nucleus is the predominant source of CRH and TRH. Neurons of the cell group synthesize oxytocin and vasopressin for release into the general circulation from terminals in the posterior pituitary. A third major cell type contains neurons that give rise to long descending projections to the brainstem and spinal cord that include sensory and motor structures associated with the autonomic nervous system. These three visceromotor populations are essentially separate and exhibit a high degree of topographic organization. On this high degree of anatomical organization is imposed a somewhat imprecise manner of chemical coding.

The neurons of a cell group display rich intrinsic connections. A local network of fibers seems to be a common feature of hypothalamic nuclei. Local circuit neurons may synchronize the activities of peptidergic neurons in a hypothalamic nucleus to integrate or coordinate them as a functional unit.

Hypothalamic Connections

Intrahypothalamic connections

A large number of intrahypothalamic connections exist between hypothalamic cell groups, and in most cases these connections are reciprocal. For example, arcuate neurons, in addition to projecting to the outer layer of the median eminence, project to several other regions such as the ventromedial nucleus, lateral hypothalamic area, anterior hypothalamic area, and preoptic area and also receive afferents from the preoptic area, the ventromedial nucleus, and several other hypothalamic regions.

The abundant intranuclear connections, as well as the rich connections among the various hypothalamic cell groups, support the general impression that the hypothalamus should be considered a neuronal network of quasirandom internal connections. In this network, where the impulses leave the hypothalamus through the main axons, excitation can spread from a given focus in any direction and can establish an infinite number of closed, self-reexciting chains.

Extrahypothalamic connections

Connections with telencephalic and diencephalic structures

A large number of regions project to the hypothalamus, including various parts of the limbic system (e.g., amygdaloid complex, hippocampus, septum), thalamus, basal ganglia, and cortex. Although the hypothalamus receives a large amount of sensory input through the regions mentioned, there are also some more or less direct pathways. There is a direct projection from the retina to the

hypothalamus, primarily to the suprachiasmatic nucleus. The effect of light on the hypothalamus, particularly on its control of the anterior pituitary, may be mediated by this pathway. Inputs from the olfactory bulb have relatively free access to the hypothalamus, although direct connections from the olfactory bulb to the hypothalamus are not known. The piriform cortex, which receives fibers from the olfactory bulbs, sends projections directly to the hypothalamus. Other olfactory pathways reach the hypothalamus mainly via the amygdala.

The efferent pathways of the hypothalamus appear to reciprocate several of the major afferent hypothalamic connections. Many such reciprocating connections are contained in the medial forebrain bundle, the dorsal longitudinal fasciculus, and the stria terminalis. These pathways appear to close neuronal circuits between the hypothalamus and several of the limbic forebrain structures. The major brain structures receiving hypothalamic efferents are the amygdala, hippocampus, and septum.

Hypothalamic connections with the brainstem

The hypothalamus has extremely rich connections with the brainstem. A significant part of the ascending fibers are aminergic, and they terminate in various hypothalamic cell groups. Noradrenalin-containing fibers arise from the medulla oblongata (from the so-called A1 and A2 catecholaminergic cell groups) and pons (from the locus coeruleus). Adrenalinsynthesizing neurons are in the medulla oblongata (C1 and C2 adrenergic cell groups). Ascending serotonergic fibers arise from the pons and midbrain raphe nuclei.

Descending fibers from the hypothalamus, primarily from the paraventricular, arcuate, and medial preoptic nuclei, terminate in the brainstem and spinal cord.

Recent findings indicate that there are polysynaptic neuronal connections between hypothalamic structures and endocrine glands such as the gonads, adrenal, and pancreas. The neural connections of the hypothalamus are summarized in **Fig. 2**.

The reciprocal connections of the hypothalamus with limbic forebrain structures and the brainstem are of such magnitude that it appears possible to interpret the hypothalamus, at least partly, as a way station in both the ascending and descending limbs of a polysynaptic neural circuit that extends between the limbic forebrain, on the one hand, and the primarily paramedian mesencephalic region, on the other. It may be assumed that the functional state of the hypothalamus is determined, to a significant

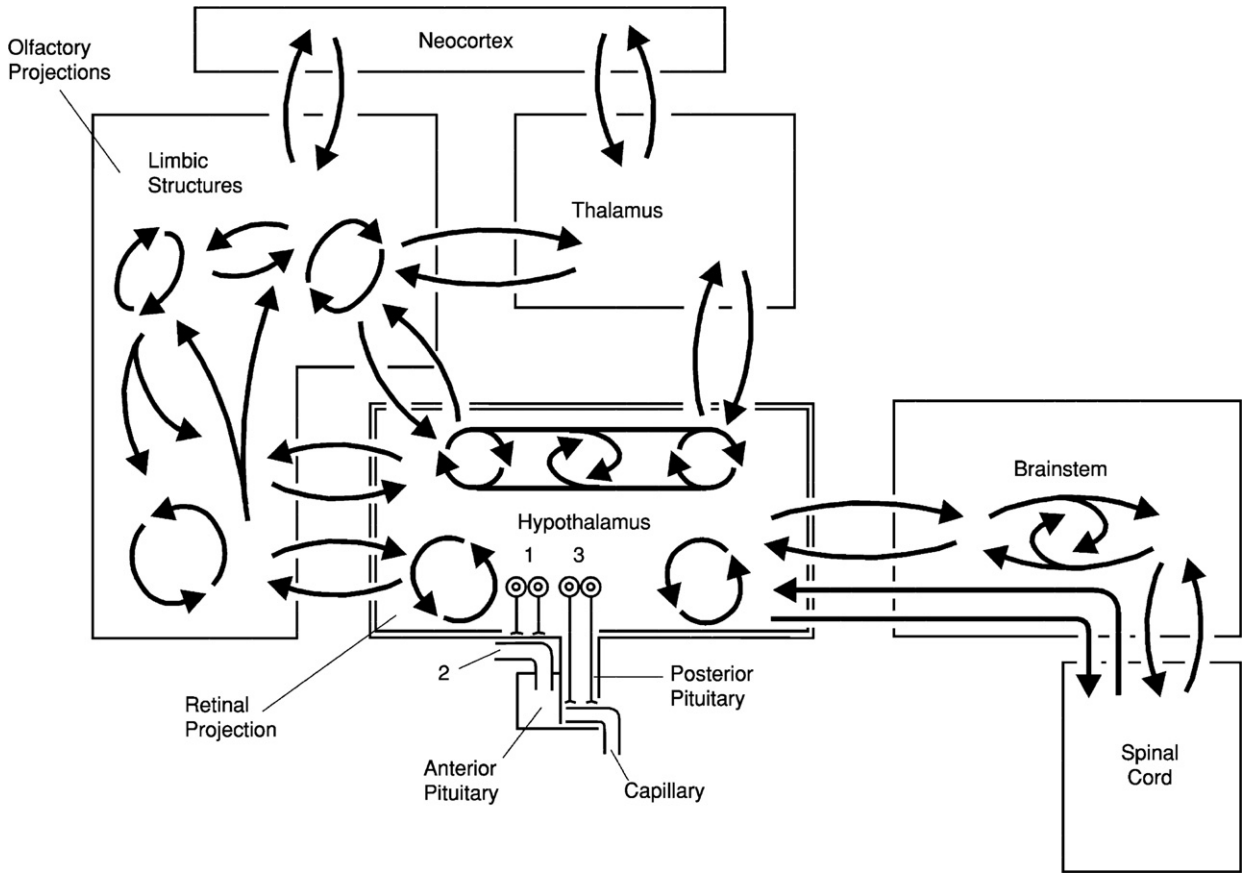

Fig. 2 A simplified drawing of the bidirectional neural connections within the hypothalamus (intranuclear and internuclear) and between hypothalamic and extrahypothalamic structures. The relations of the hypothalamus to the anterior and posterior pituitary are also indicated. (1) Neurons synthesizing hypophysiotropic neurohormones. (2) Portal capillary. (3) Neurons of the supraoptic and paraventricular nuclei terminating in the posterior pituitary.

extent, by the neural events that take place in the limbic structures and the lower brainstem, with both having a very integrated structural organization, including several reciprocal interconnections and neural circuits. In addition, they receive a vast amount of information from both the external and internal environments flowing in along neural and humoral pathways (there are hormone receptors in the hippocampus and amygdala). It should be mentioned that the hypothalamus itself also contains hormone receptors as well as several other types of receptors.

The extremely complex neuronal network of the hypothalamus and its reciprocal connections suggests that, apart from a few exceptions such as the supraoptico- and paraventriculohypophyseal system, there are not well-defined regions and pathways that are specifically and exclusively concerned with a discrete hypothalamic function. Of course, this does not exclude the predominance of one or the other hypothalamic area in the involvement of a particular hypothalamic function. Instead of a mosaic-type pattern, the hypothalamus can rather be envisaged as some kind of computer. This computer has a number of built-in programs, and its elements are involved in several processes. It elaborates the solution for each actual situation on the basis of a wealth of information that is partly stored and partly streaming in continuously. The results are then distributed over a number of neural and humoral output channels.

Major neuroanatomical pathways connecting the hypothalamus with extrahypothalamic structures

Medial forebrain bundle

The medial forebrain bundle running longitudinally andoccupyingthemajorityofthelateralhypothalamus contains a high number of fibers with different destinations from hypothalamic nuclei and from limbic, cortical, and brainstem structures directed to hypothalamic cell groups. It also contains many fibers that just pass through the hypothalamus.

Stria terminalis

The stria terminalis is a major pathway between the amygdala and the hypothalamus that provides reciprocal connections between the two structures.

Fornix

The fornix is a main link of the limbic system connecting the hippocampus, the septum, and the mammillary body. Some of its fibers deviate from the main bundle and terminate in the preoptic area as well as around the ventromedial nucleus of the hypothalamus.

Medial corticohypothalamic tract

The medial corticohypothalamic tract connects the hippocampus with the arcuate, ventromedial, and ventral premammillary nuclei.

Dorsal longitudinal fasciculus

The dorsal longitudinal fasciculus contains ascending and descending fibers connecting the dorsal hypothalamus and posterior hypothalamus with the periaqueductal central gray of the mesencephalon.

Hypothalamus–Anterior– Pituitary System

Neurovascular Contact Between the Hypothalamus and Anterior Pituitary

Theconnectionsbetweenthehypothalamusandanterior pituitary are neurovascular (Fig. 3). Hypophysiotropic substances, called trop hormone-releasing hormones (factors) or release-inhibiting hormones (factors), are produced by the hypothalamus. The

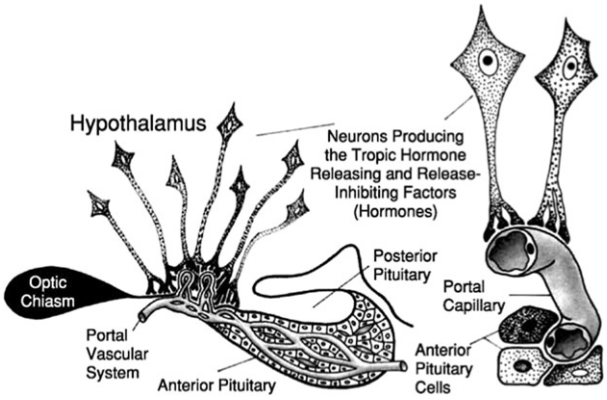

Fig. 3 Schematic illustration of the neurovascular contact between the hypothalamus and the anterior pituitary.

chemically identified hypophysiotropic substances are CRH or corticotropin-releasing factor (CRF); GnRH, also called luteinizing hormone-releasing hormone (LHRH) or gonadoliberin; GHRH; SRIH, somatostatin, or growth hormone-inhibiting factor (GIF); TRH; and prolactin-inhibiting factor (PIF), at least one of which is dopamine (DA). These substances are transported by the hypophyseal portal vascular system to the anterior pituitary cells. The median eminence and the proximal part of the pituitary stalk are the site where the axons of the neurons synthesizing the hypophysiotropic neurohormones are very close to the portal vessels.

Location of Neurons Synthesizing the Hypophysiotropic Neurohormones and Projecting to the Median Eminence

Corticotropin-releasing hormone

The most prominent CRH-containing cell group of the hypothalamus is the paraventricular nucleus, mainly its medial parvocellular part. The vast majority of the CRH terminals in the median eminence and pituitary stalk arise from here.

Gonadotropin-releasing hormone

In general, there are two areas that contain a significant amount of immunoreactive GnRH nerve cell bodies projecting to the median eminence: (1) The septal– preoptic–suprachiasmatic region and (2) the mediobasal area of the middle hypothalamus and posterior hypothalamus, especially the arcuate and premammillary nuclei. But therearegreatvariations inthe number of such cells in these two regions of various species. In humans and primates, they are concentrated mainly in the second region. In the rat, many GnRH cells are in the medial preoptic area, the diagonal band of Broca, and the septal nuclei, whereas some cells are in the anterior hypothalamic area.

GnRH neurons originate in the medial olfactory placodal epithelium of the developing nose, migrate across the nasal septum, and enter the forebrain with thenervusterminalis,acranialnervethatisapartofthe accessory olfactory system and projects directly from the nose to the septal–preoptic area and hypothalamus. This migratory route for GnRH-expressing neurons could explain the deficiency of gonadotropins seen in hypogonadotropic hypogonadism with anosmia.

Growth hormone-releasing hormone

The majority of the GHRH immunoreactive neurons projecting to the median eminence are in the arcuate nucleus.

Somatotropin release-inhibiting hormone

SRIH immunoreactive neurons terminating in the median eminence are located mainly in the medial preoptic and anterior periventricular areas.

Thyrotropin-releasing hormone

Although TRH immunoreactive neurons are widely distributed in the central and peripheral nervous systems, those projecting to the median eminence are gathered mostly in the medial parvocellular division of the paraventricular nucleus.

Prolactin-inhibiting factor

At least one PIF is dopamine and is produced by the tuberoinfundibular dopaminergic neurons. These neurons are situated in the arcuate nucleus and in the ventral part of the anterior periventricular nucleus.

The location of neurons synthesizing the hypophysiotropic neurohormones and projecting to the median eminence is summarized in **Fig. 4**.

The hypophysiotropic neurons receive very significant neural input mediated by several chemical messengers. Various peptidergic, monoaminergic, and GABAergic axons terminate on perikarya and dendrites of these nerve cells, providing the structural basis for the assumption that the actions of the neurotransmitters or neuromodulators are at least partly exerted directly on the structures producing the hypophysiotropic neurohormones. In addition, axons containing one or the other hypophysiotropic neurohormone form synaptic connections with neurons synthesizing the same peptide. This may be the morphological basis for an ultrashort feedback mechanism or may indicate an intrinsic circuit.

However, it should be kept in mind that neurons containing the troph hormone-releasing or releaseinhibiting neurohormones are widely distributed in the central nervous system; some of them are even present in other tissues. Not all of these neurons in the brain terminate in the hypothalamic median eminence and pituitary stalk; instead, some project to other brain structures.

Hypophysial Portal Vascular System

Besides the trop hormone-releasing and releaseinhibiting hormones, the portal vascular system represents the key structure required for the operation of the neurohumoral (neurovascular) mechanism controlling pituitary tropic functions. It transports the substances released from the nerve terminals in the median eminence to the pituitary.

The main features of the hypophyseal portal vascular system are the following (**Fig. 5**). The so-called superior hypophyseal arteries form a dense plexus, largely of precapillary character, within the so-called pars tuberalis, a small part of the pituitary gland. This plexus is especially dense on the contact surface between the median eminence and the pars tuberalis (mantleplexus). From this plexus arise the capillary loops that penetrate into the tissue of the median eminence and infundibular stem. The mantleplexus

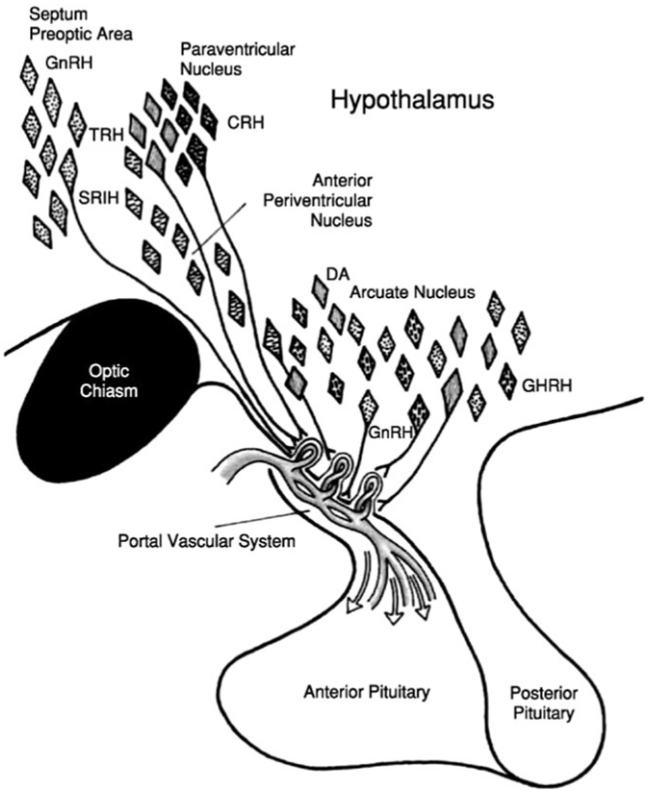

Fig. 4 Schematic drawing of midsagittal section of the hypothalamo–pituitary unit showing the location of neurons producing hypophysiotropic neurohormones and projecting to the outer layer of the median eminence. Fig. 5 Schematic illustration of the hypophyseal portal vascular system.

and capillary loops drain toward the portal vessels (some of the capillary loops drain toward the subependymal plexus of the third ventricle) that lie on the ventral surface of the pituitary stalk. These vessels are called the long portal vessels. Part of the blood from the posterior pituitary reaches the anterior pituitary by way of vessels known as short portal vessels. Each portal vessel supplies a certain part of the pituitary. Anastomoses between these vessels are rare. The majority of the portal blood is directed from the median eminence toward the pituitary, but some blood may flow in the reverse direction, toward the hypothalamus.

The presence of trop hormone-releasing and release-inhibiting substances in the portal blood is well documented, as is the fact that the concentration of these substances is much higher in the portal blood than in the peripheral plasma and that changes occur under certain experimental conditions.

Structure of the Median Eminence

The median eminence arising from the ventral surface of the tuberal region of the hypothalamus is a slight midline prominence. It continues into the pituitary stalk and represents the contact area between the nerve terminals of the neurons synthesizing the hypophysiotropic neurohormones and the precapillaries and capillaries of the portal vascular system. The inner surface of the median eminence is covered by ependymal cells. Two layers can be distinguished in the median eminence. The inner layer contains the fibers of the supraoptico – and paraventriculo–hypophysial system terminating in the posterior pituitary. The outer layer contains the trop hormone-releasing and release-inhibiting hormones and the vessels of the portal vascular system. It must be mentioned that in addition to the terminals of the neurons synthesizing the hypophysiotropic neurohormones, there are many other neurons containing chemical messengers different from these compounds (most of them are also peptides, but "classic" neurotransmitters are also present), which also terminate in the median eminence. The functional significance of these other chemical messengers is not known. The possibility of interactions of the various substances at the median eminence level exists.

Hypothalamus–Posterior Pituitary System

Magnocelluler neurons of the supraoptic and paraventricular nuclei and parvocellular neurons of the paraventricular nucleus project to the posterior pituitary, forming the so-called supraoptico- and paraventriculohypophyseal tract (Fig. 6). The neurons synthesize oxytocin and vasopressin. The hormones are synthesized in the cell bodies of the nerve cells and are transported down the axons of these neurons to their endings in the posterior pituitary. Some of the neurons make oxytocin and others synthesize vasopressin. Oxytocin- and vasopressin-containing cells are evident in both cell groups. Vasopressin- and oxytocin-producing neurons of the paraventricular nucleus project not only to the posterior pituitary but also to the brainstem and spinal cord and may be involved in cardiovascular control.

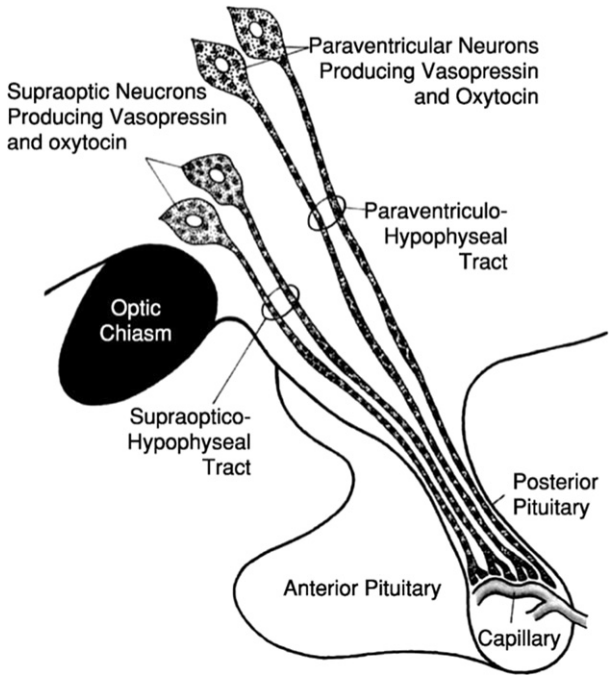

Fig. 6 The hypothalamus–posterior–pituitary system.

Neurosecretion

The term "neurosecretion" was originally coined to describe the secretion of hormones by neurons, but the term is now somewhat misleading because it became evident that nearly all neurons secrete chemical messengers.

Blood Supply

The hypothalamic arteries arise directly from the circle of Willis (circulus arteriosus Willisi). Six major groups of arteries supply the hypothalamus. The arteries cover each other like shells in a mediolateral direction. The vessels entering at the midline supply the medial and basal parts of the hypothalamus, whereas those entering laterally supply the lateral and dorsal parts of the hypothalamus. None of the hypothalamic nuclei is supplied by a single artery.

Most of the hypothalamic veins enter into the anterior cerebral, basilar, and interpeduncular veins. The anterior cerebral vein drains into the basilar vein. The venous blood is drained by the basal vein, which enters the great cerebral vein of Gallen.

Glossary

Adenohypophysis The glandular part of the hypophysis (pituitary) containing the hormone-producing cells and composed of the anterior lobe (pars distalis), the intermediate lobe, and the pars tuberalis.

Anterior lobe (pars distalis) of the pituitary A subdivision of the adenohypophysis; it constitutes approximately 80% of the gland and contains somatotroph, mammotroph, gonadotroph, corticotroph, thyrotroph, and folliculostellate cells.

Neurohypophysis The neural part of the pituitary composed of the posterior lobe (infundibular process), the neural stalk, and the median eminence.

Posterior lobe of the pituitary A subdivision of the neurohypophysis that develops as an evagination of the third ventricle of the brain: It stores and releases oxytocin and vasopressin.

Rathke's pouch The evagination of the roof of the primitive oral cavity (stomodeum), giving rise to the adenohypophysis.

The pituitary or hypophysis is an unpaired endocrine gland located in a midline depression (sella turcica) of the base of the skull under the hypothalamus and linked to it.

Introduction

The pituitary is an oval, symmetrical, unpaired organ. Its weight in adults ranges between 400 and 900 mg. On average, it measures 13 mm transversally, 6 mm vertically, and 9 mm anteroposteriorly. The gland is somewhat larger in women than in men and enlarges during pregnancy. It is usually heavier in multiparous women than in nulliparous women and decreases in size during advanced aging.

Anatomy

Divisions and Subdivisions

The pituitary has two main divisions: the adenohypophysis and the neurohypophysis (Fig. 1). Both the adenohypophysis and the neurohypophysis are composed of three subdivisions. The subdivisions of the adenohypophysis are the pars distalis or anterior lobe, the pars intermedia or intermediate lobe, and the pars tuberalis, which encircles the neural stalk. The anterior lobe constitutes approximately 80% of the pituitary. The subdivisions of the neurohypophysis are the posterior lobe, also called the neural lobe or infundibular process, the neural stalk, which connects the hypothalamus with the posterior lobe, and the median eminence, a midline eminence on the ventral surface of the hypothalamus, which is the portion of the neural stalk that ascends from the hypothalamus. The neural stalk and the pars tuberalis of the adenohypophysis form the pituitary stalk. The anterior lobe and posterior lobe are clearly separated and can easily be distinguished with the naked eye. The two main divisions of the pituitary have different origins.

Topography

The hypophysis is located under the brain in the sella turcica at the base of the skull (Fig. 2(A)). The sella turcica is the saddlelike part of the sphenoid bone. It is composed of three parts: an olive-shaped swelling, called the tuberculum sellae, which is located anteriorly; a seatlike depression, called the hypophysial fossa, for the pituitary gland; and the posterior part of the saddle, known as the dorsum sellae. The gland is surrounded laterally and inferiorly by the sphenoid bone and is covered from above by the diaphragma sellae, which is a dural sheath forming the roof of the sella (Fig. 2(B)). There is a central opening on the sellar diaphragm through which the hypophysial stalk passes through in connecting the hypothalamus to the pituitary. The optic chiasma lies directly above the sellar diaphragm ahead of the hypophysial stalk. Growth of a pituitary tumor may compress the chiasma and impair vision. The tuber cinereum of the hypothalamus also lies above the roof of the sella. Space-occupying lesions in the pituitary may compress and compromise the tuber cinereum and cause hypothalamo-hypophysial dysfunctions. The lateral walls of the sella are close to the cavernous sinuses containing the internal carotid arteries and several nerves including the oculomotor, trochlear, and abducens nerves and the first two branches of the trigeminal nerve. The sphenoid sinus, separated from the sella by a thin layer of bone, is inferior to the pituitary. In the case of a pituitary tumor, this bone may be resorbed and eroded, leading to tumor penetration into the sinus.

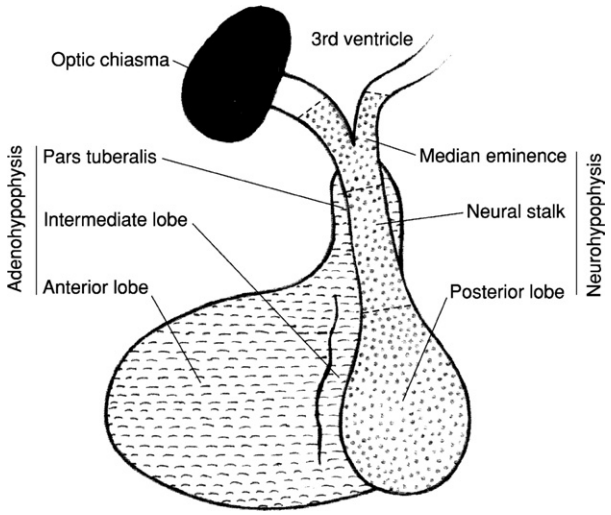

Fig. 1 Schematic of the divisions and subdivisions of the pituitary as seen in a midsagittal section of the gland.

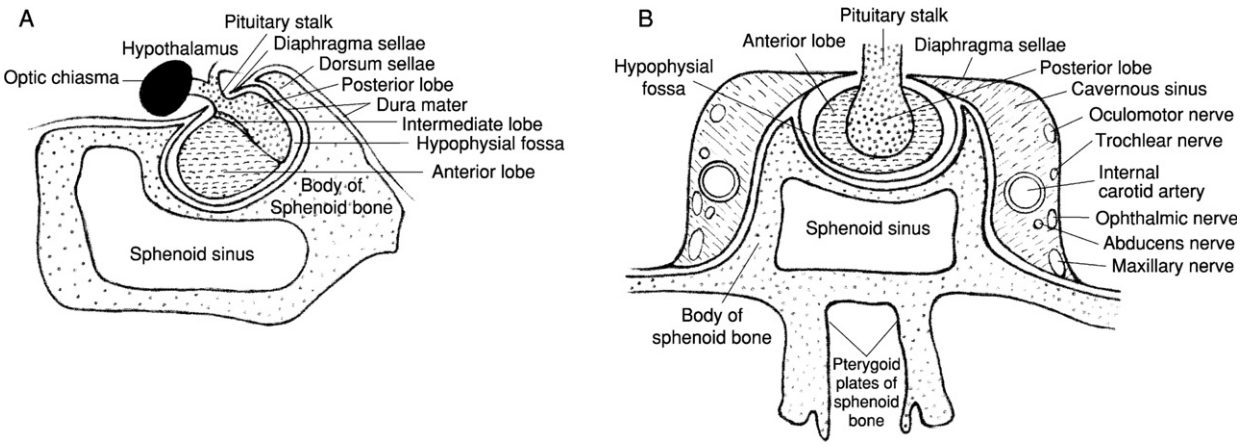

Fig. 2 Schematic of the location and topography of the pituitary in a midsagittal section (A) and a coronal section (B) of the sphenoid bone.

Blood Supply

The blood supply of the pituitary derives from two groups of arteries: from above, the right and left superior hypophysial arteries; from below, the right and left inferior hypophysial arteries. Both groups of arteries arise from the internal carotid arteries. The superior hypophysial arteries supply blood to the median eminence and proximal portion of the pituitary stalk. Here these arteries break up into a primary capillary plexus. The capillaries of this plexus rejoin to form the long portal vessels that traverse the pituitary stalk and break up into a secondary capillary plexus in the anterior lobe of the pituitary in close relationship to the cells of anterior pituitary. This hypophysial portal vascular system is of the utmost importance in regulating hormone secretion of the anterior pituitary. The posterior pituitary receives its blood supply from the inferior hypophysial arteries. Some vessels from the posterior lobe penetrate into the anterior pituitary (short portal vessels).

Venous blood leaves the pituitary through dural channels and enters the cavernous sinuses, which drain to the inferior petrosal sinus and the internal jugular vein. There may be anastomoses between the petrosal sinuses, which can lead to confusing observations with petrosal sinus sampling.

Although most blood flow is from the hypothalamus to the pituitary, there is evidence that some blood may flow in the opposite direction, from the anterior pituitary to the hypothalamus.

Innervation

The anterior lobe is poorly innervated. A few nerve fibers reach the anterior pituitary along the blood vessels. These nerve fibers are not believed to have major importance in the control of hormone secretion. The posterior pituitary contains the axon terminals of

the supraoptic and paraventricular neurons, synthesizing and releasing oxytocin and vasopressin. In addition, the intermediate pituitary and the posterior pituitary are innervated by hypothalamic dopaminergic neurons of the periventriculo-hypophysial and the tuberohypophysial dopaminergic system.

Embryology

The adenohypophysis originates from an evagination of the epithelium covering the vault of the stomodeum (primary oral cavity). The neurohypophysis develops as a process growing downward from the floor of the diencephalon, i.e., as an evagination of the third ventricle of the brain (Fig. 3). During embryonic development, the adenohypophysial primordium becomes located anterior to the neural primordium.

Development of the Adenohypophysis

The epithelium of the stomodeum (primitive oral cavity) becomes thicker just ahead of the pharyngeal membrane (Fig. 3(A)). This flat primordium invaginates and penetrates the connective tissue in the direction of the diencephalon, forming a diverticulum, Rathke's pouch (Fig. 3(B)). Initially, Rathke's pouch is composed of a small, thin-walled vesicle in the roof of the primitive oral cavity. It subsequently expands in the direction of the evagination of the third ventricle and will be situated just ahead of the evagination (Fig. 3(C)) and then it adheres to it. Rathke's pouch is attached to the stomodeal vault by a stalk (craniopharyngeal canal), which regresses, is obliterated, and usually disappears (Fig. 3(D)). Parts of it, however, may persist in a more or less differentiated and sometimes functional condition. Nests of adenohypophysial tissue may be deposited along the route of the craniopharyngeal canal. Remnants of the pharyngeal hypophysis may be capable of hormone synthesis and may give rise to ectopic adenomas. Occasionally, craniopharyngiomas (tumors) develop in the pharynx or in the sphenoid bone of the skull, but most often they form in or above the sella turcica of the sphenoid bone at the base of the skull.

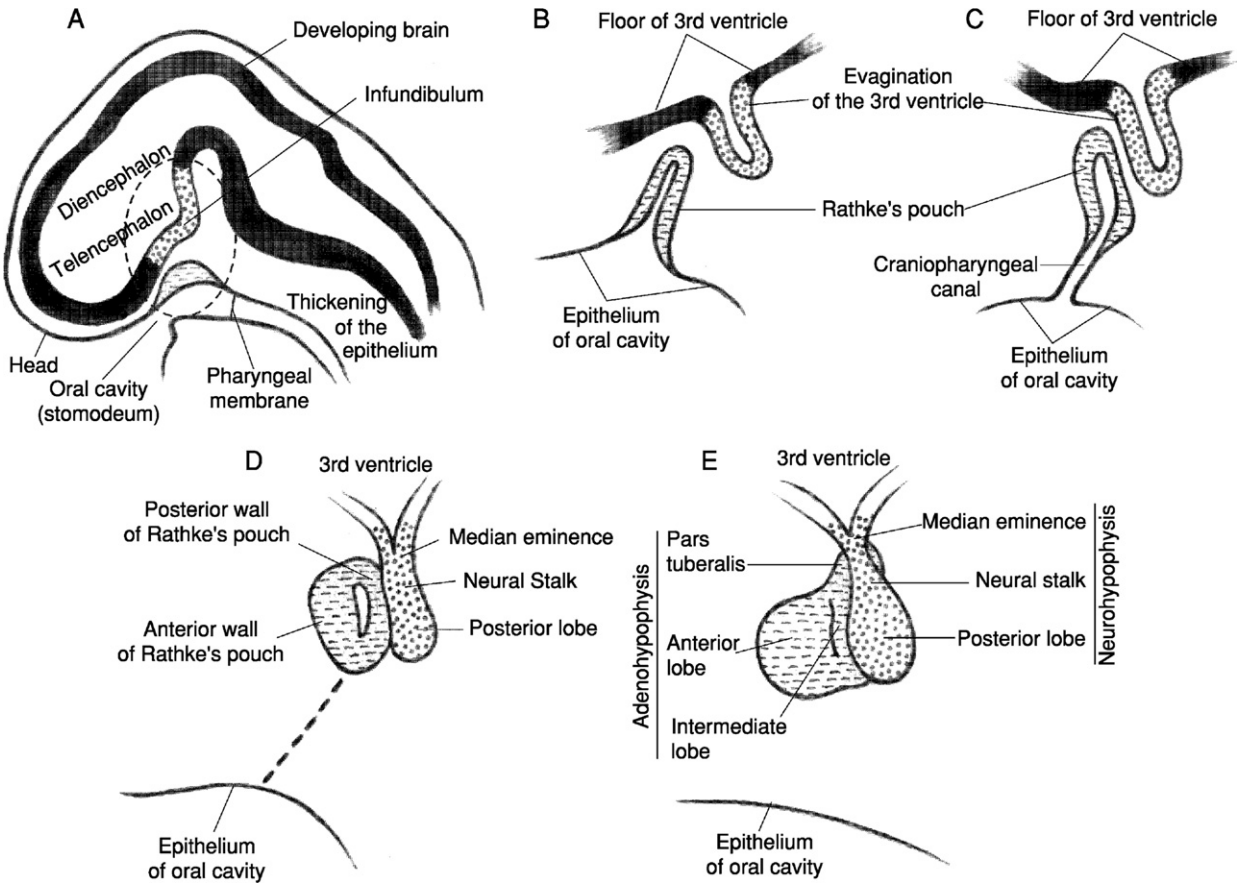

Fig. 3 Schematics of the development of the pituitary as seen in midsagittal sections. The drawings show the various stages of development: (A) very early stage; (B, C) intermediate stage; (D) nearly developed stage; and (E) completely developed stage.

Just behind the pharyngeal membrane, the entodermal epithelium also forms a pouch, the pouch of Sessel. This structure is involved in the formation of the adenohypophysis in lower vertebrates. However, this involvement decreases as the evolutionary scale increases and disappears completely in primates and human. In human, it sometimes persists and may cause certain tumors.

Development of the anterior lobe

The anterior lobe develops from the anterior wall of Rathke's pouch. Cells of this wall proliferate actively and give rise to the anterior lobe of the pituitary gland (Fig. 3(D)). Proliferation occurs in such a way that a small basin is formed, separated into two compartments by a median cellular septum. The compartments disappear progressively, due to the growth of the wall. The median septum forms the pars medialis and the lateral portions form the lateral part of the anterior lobe. The extensive proliferation of the anterior wall of Rathke's pouch reduces the lumen to a narrow residual cleft (Fig. 3(E)). It is usually not recognizable in the adult gland and is represented by a zone of cysts.

Acidophiliccellsaredetectableintheanteriorlobeof the human embryo at approximately the third month of gestation; basophilic cells can be detected somewhat later. Adrenocorticotropic hormone (ACTH)- and growth hormone (GH)-synthesizing cells are identifiable by the end of the second month of gestation. This is followed by the production of glycoprotein hormones. Blood vessels grow into the anterior lobe and establish a direct neurovascular link between the anterior lobe and the hypothalamus at approximately the eighth week of gestation. The mammotroph cell type (prolactin-producing) appears late, at approximately the fifth month of gestation. Hormone-producing cells differentiate in the absence of a hypothalamic influence. In anencephaly, all cell types of the anterior lobe except corticotrophs develop and are capable, to some extent, of hormone synthesis and release.

Development of the intermediate lobe

The posterior wall of Rathke's pouch gives rise to the intermediate lobe of the adenohypophysis (Fig. 3(D and E)). In humans, cells of the posterior wall of Rathke's pouch do not proliferate; instead, they form the poorly defined intermediate lobe, which becomes an inconspicuous, discontinuous layer.

Development of the pars tuberalis

The pars tuberalis of the adenohypophysis develops from the anterior wall of Rathke's pouch. The cells of the median septum of the anterior wall of Rathke's pouch proliferate upward along the pituitary stalk, which becomes gradually encircled by the cellular expansion of the developing pars tuberalis (Fig. 3(E)).

Development of the Neurohypophysis

The neurohypophysis develops from the evagination of the wall of the third ventricle (Fig. 3). The floor of the third ventricle becomes depressed and produces the infundibulum (Fig. 3(A)). This depression penetrates progressively toward the adenohypophysial primordium. Its ventral end forms a diverticulum (Fig. 3(B and C)). The wall of the diverticulum thickens and its lumen gradually fills, forming the neural or posterior lobe, which is attached to the posterior wall of Rathke's pouch (Fig. 3(D)). It remains to be connected to the diencephalon part of the brain by the thin neural stalk. The ascending part of the infundibulum is the median eminence. The median eminence, the neural stalk, and the posterior lobe (or neural lobe or infundibular process) form the neurohypophysis (Fig. 3(E)). The neural lobe differentiates and specific neuroglial cells, called pituicytes, appear in it. The neurohypophysis is then colonized by axons coming from the hypothalamic paraventricular and supraoptic nuclei. In the human, neurosecretory material, characteristic of the posterior pituitary, is demonstrable at approximately the fifth month of gestation.

Histology

Adenohypophysis

Anterior lobe (or anterior pituitary or pars distalis)

The anterior lobe accounts for approximately 75%–80% of the whole gland. It is highly vascular and contains various cell types. The lobe is largely enclosed by a dense collagenous capsule and is composed of glandular cells arranged in irregular cords or clumps, which are intimately related to an extensive system of dilated capillaries (sinusoids) of the blood vascular system. Reticular fibers surround the cords of parenchymal cells and are also present close to the wall of the sinusoids.

The glandular cells were originally classified as chromophilic and chromophobic on the basis of their avidity or lack of affinity for the dyes used in routine staining of histological sections. The chromophilic cells were subdivided into acidophilic and basophilic cells on the basis of staining with combinations of an acidic dye and a basic dye. In the human pituitary, acidophilic cells are most numerous in the posterolateral portions of the anterior lobe. They are rounded, small cells with a well-developed Golgi complex and rod-shaped mitochondria. The basophilic cells are larger and less numerous.

The most meaningful method applied at both the light and electron microscopic levels for identification of the cells producing various hormones involves the use of immunocytochemical procedures. Antibodies to a specific hormone induced in another species are conjugated with horseradish peroxidase or with fluorescence dyes. These labeled antibodies are reacted with sections of

the anterior lobe and the sites of the antigen in the tissue are localized by the histochemical method for peroxidase or by fluorescence microscopy.

The anterior pituitary produces six hormones: GH (or somatotropin), prolactin, thyrotropin (TSH), ACTH, and two gonadotropins – follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The acidophilic cells secrete simple proteins (somatotropin and prolactin) and the basophils secrete glycoprotein hormones (TSH, FSH, LH, and the precursor of ACTH). It has become a common practice to use the terms of the hormone secreted (ACTH cell, TSH cell, FSH/LH cell) or the name of the target organ stimulated (corticotroph, thyrotroph, gonadotroph) to denote the cell type. In addition to these cells, some other cell types, such as folliculostellate cells and null cells, are also found in the pituitary.

Somatotrophs

Somatotrophs represent approximately 50% of the anterior lobe cells. They are found in groups along the sinusoids and are located mainly in the two lateral wings of the anterior lobe. The cells are usually medium-sized and contain numerous spherical, evenly electron-dense granules, the majority being 350–500 nm in diameter. They have a well-developed endoplasmic reticulum and secrete GH. Immunocytochemical observations strongly suggest that the somatotrophs are not a uniform mass of cells. It appears that they consist of several subpopulations, all of which express somatotropin, but are also capable of producing other hormones, such as prolactin and TSH, in special circumstances. There is evidence that transdifferentiation of GH-/prolactin-synthesizing cells (somatomammotrophs) may contribute to the mass of prolactin-producing cells during development of prolactin cell hyperplasia in human pregnancy and further, that somatotrophs may transform into large thyrotroph cells in rats during experimental hypothyroidism.

Mammotrophs

Mammotrophs (or lactotrophs or prolactin cells) produce prolactin and constitute 10%– 25% of the anterior lobe cells. They are relatively small cells, are distributed individually in the interior of the cell cords, and are located throughout the entire anterior lobe. The cells are especially numerous at the posterolateral and posteromedial edges of the adenohypophysis. Two types of lactotrophs can be distinguished. The majority of the cells are small or medium in size and sparsely granulated. The secretory granules are spherical and evenly electron-dense, measuring 150–350 nm in diameter. The other, less frequently occurring type is densely granulated and the granules are larger (300–600 nm). The number of prolactin cells varies considerably. In pregnancy and lactation, lactotrophs are increased in number. During pregnancy, the cells undergo considerable hypertrophy: their Golgi complex enlarges and the endoplasmic reticulum becomes more extensive; multiple layers parallel to the cell membrane develop and the granules become larger (550–600 nm in diameter) and often irregular in outline. The mammotrophs are most active during lactation. After weaning has occurred, lysosomes play an important role in the elimination of excess secretory granules and the hypertrophied cellular organelles involved in the lactation period of active protein synthesis. Lysosomes fuse with the secretory granules to form autophagic vacuoles. The secretory granules are degraded by hydrolytic enzymes in these vacuoles. This procedure of disposal of secretory product that is no longer needed is called crinophagy. Excess cytomembranes and ribosomes are also enclosed in vacuoles and degraded by autophagy.

Thyrotrophs

Thyrotrophs, secreting TSH, are located mainly in the anteromedial part of the anterior lobe and constitute less than 10% of the lobe. The cells are medium or large in size and polygonal with long cytoplasmic processes. In electron micrographs, they are characterized by spherical secretory granules, are variably electron-dense, measure 100–200 nm in diameter, and often line up along the cell membrane, with short stacks of rough endoplasmic reticulum membranes and a Golgi complex with flattened sacculi and several vesicles. In hypothyroidism, thyrotrophs increase in size and number and transform into so-called thyroidectomy cells or thyroid-deficiency cells. These cells are large and contain widely dilated endoplasmic reticulum membranes, conspicuous Golgi complexes, and a varying number of secretory granules.

Gonadotrophs

Gonadotrophs synthesize both gonadotropic hormones, FSH and LH. These cells are larger than other cells of the anterior lobe, constitute approximately 15%–20% of the lobe, and are located throughout the anterior pituitary. They are near capillaries and often in close proximity to mammotrophs, suggesting the possibility of paracrine action between the two cell types. FSH and LH are located mostly in the cytoplasm of the same cells, but there are also gonadotrophs that show only FSH or LH positivity. In electron micrographs, the rough endoplasmic reticulum is prominent and forms slightly dilated stacks; the Golgi complexes are conspicuous. The secretory granules represent two populations: the diameter of one granule type is 150–250 nm and that of the other type is 350–450 nm. Following castration, the size and number of gonadotrophs increase and the cells show enlargement of the cytoplasm, proliferation, and dilation of the endoplasmic reticulum membranes.

Corticotrophs

Corticotrophs (or corticotropin- or ACTH-producing cells) are located mainly in the central part of the pituitary. Some cells are scattered in the lateral wings. They represent 10%–15% of the anterior lobe cells. Corticotrophs are medium-sized or large oval cells and show ACTH, β-lipotropin, and β-endorphin immunoreactivity (proopiomelanocortin-derived peptides). In electron micrographs, they have welldeveloped rough endoplasmic reticulum membranes and are usually numerous, spherical, irregular

secretory granules measuring 250–400 nm, showing varying electron density. The granules tend to be located adjacent to the cell membrane. In addition, the presence of type 1 filaments, which are bundles of filaments located mainly in the perinuclear area, are a characteristic feature of corticotrophs.

Folliculostellate cells

Folliculostellate cells, called also follicular cells, are mostly agranular cells with branching processes among the secretory cells. There are data indicating that they are derived from granulated cells after having been joined by junctional complexes around damaged and ruptured adenohypophysial cells and are capable of forming follicles. Folliculostellate cells produce several substances (interleukin G, follistatin, etc.). It is assumed that these cells play an important role in the paracrine mechanisms controlling pituitary functions.

Null cells

Null cells are relatively small, chromophobic cells that do not contain known anterior pituitary hormones in their cytoplasm. The cells have all the cytoplasmic organelles necessary for secretion. They contain secretory granules that may contain hormone fragments, precursors, or biologically inactive substances. They may represent resting cells, precursors of various cell types, or an unknown cell type.

It should be mentioned that the majority of what were originally called chromophobic cells contain specific granules with hormone content. The cells classified as chromophobes by light microscopy are not a homogenous population. Some are evidently chromophils agranulated to the point at which their specific nature is not detectable. There seems to be a considerable degree of cytological specialization among the cells normally classified as chromophobes. It is probable that many of the apparent chromophobes have already been determined and are capable of differentiating into only one of the chromophil types.

Intermediate lobe

There is considerable variation among species in the degree of development of the intermediate lobe. It is poorly developed in the human. It contains a few dilated cavities lined by a single layer of cuboidal or columnar epithelial cells and is filled with an amorphous proteinaceous material. Many cells lining the cystic cavities and cells between the cysts give a positive immunostaining for proopiomelanocortinderived peptides. These cells are smaller than the corticotrophs in the anterior lobe.

Pars tuberalis

The pars tuberalis is an upward extension of the anterior lobe and is attached to the neural stalk. It contains small groups of cells that produce mainly glycoprotein hormones, gonadotropins and thyrotropin. The functional significance of the pars tuberalis is not known.

Neurohypophysis

The human neurohypophysis consists of approximately 10,000 axons and terminals of neurosecretory cells located in the hypothalamic supraoptic and paraventricular nuclei. The unmyelinated fibers of the neurosecretory cells descend, converge, and form the supraoptico- and paraventriculohypophysial tract or pathway. These fibers descend through the median eminence and neural (or infundibular) stalk into the neural lobe of the hypophysis and make up the bulk of the substance of the lobe.

Median eminence and infundibular stalk

The median eminence is made up of two layers: the external layer and the internal layer. Not the capillary loops but the hypophysiotrophic neurons whose axon terminals are in the external layer are producing the neurohormones. This layer is a key structure of the neurovascular contact between the hypothalamus and the anterior pituitary.

The internal layer of the median eminence and the infundibular stalk contain the descending unmyelinated axons of the supraoptico- and paraventriculohypophysial tract, terminating in the posterior pituitary, transporting the neurosecretory material from the hypothalamic neurons to the posterior lobe at a rate of 1 to 4 mm/h. In histological preparations stained with chromalum hematoxylin, deeply stained neurosecretory material is seen in aggregations of varying sizes throughout the infundibular stalk and neural lobe. These aggregates are called Herring bodies. In electron micrographs, they are found to be large aggregations of the small secretory granules. The axons of these neurosecretory neurons vary greatly in caliber and have numerous dilations along their length. Approximately 60% of all neurosecretory material resides in these dilations and approximately 30% resides in axon endings in the posterior pituitary.

Posterior lobe (or neural lobe, or infundibular process)

The posterior pituitary is made up of axons and axon endings of the neurosecretory neurons of the hypothalamic supraoptic and paraventricular nuclei synthesizing oxytocin and vasopressin (called also antidiuretic hormone) and also contains an intrinsic population of cells called pituicytes, which resemble astrocytes and do not appear to be secretory. Axons of the neurosecretory neurons terminate blindly in close relation to the basal lamina of a rich capillary plexus.

The neurosecretory material is stored in granules at the dilated blind endings of the axons and are released as needed. The neurosecretory granules have a diameter of 100–200 nm, are surrounded by a membrane, and are more numerous apposed to fenestrated blood capillaries. The neurosecretory material consists of oxytocin or vasopressin and a binding protein (neurophysin) specific for each hormone. The hormone– neurophysin complex is synthesized as a single, long peptide on ribosomes attached to the membranes of the rough endoplasmic reticulum. The endoplasmic reticulum is a cell organelle from where the synthesized material is passed onto the Golgi complex. As the granules pass down axons of the supraoptico- and paraventriculo-hypophysial tract, proteolysis of the precursor occurs, yielding the hormone and its specific neurophysin. Vasopressin and oxytocin are stored in the posterior pituitary and are released into the blood by impulses in the nerve fibers from the hypothalamus.

In addition to the axons from hypothalamic nerve cells, approximately 25%–30% of the volume of the posterior pituitary consists of a distinctive type of glial cell, called a pituicyte. Pituicytes are highly branched cells with processes that form a three-dimensional network ensheathing the neurosecretory axons. Their cytoplasmic processes meander among groups of preterminal secretory axons and often intimately envelop their granule-filled terminal expansions. In the human, they are highly variable in size and shape. The cytoplasm of the pituicytes may contain lipid droplets and pigment. The processes of pituicytes are connected by gap junctions. Pituicytes are believed to have a trophic and supportive function and to maintain the appropriate ionic composition of the extracellular fluid compartment.

Hypothalamic Disease☆

Sylvia L Asa and Shereen Ezzat, University Health Network, Toronto, ON, Canada and University of Toronto, Toronto, ON, Canada

Glossary

Carcinoma A malignant growth of epithelial cells that exhibits the tendency to infiltrate surrounding tissues and gives rise to metastases.

Chordoma A malignant tumor arising from the embryonic remnants of the notochord.

Craniopharyngioma A tumor arising from the cell rests derived from embryonic Rathke's pouch that gives rise to the hypophysis (pituitary).

Cyst A closed cavity or sac that contains liquid or semisolid material (e.g., Rathke's cleft cyst, arachnoid cyst, and dermoid/epidermoid cysts in the hypothalamic region).

Diabetes insipidus A metabolic disorder due to deficient production or release of antidiuretic hormone, resulting in failure of tubular resorption of water by the kidney and thus causing excretion of abundant urine of low specific gravity and dehydration.

Gangliocytoma (ganglioneuroma) A benign neoplasm composed of nerve fibers and mature ganglion cells.

Germinoma (germ cell tumor) A tumor of germ tissue of the testis or ovary, arising in these sites or in ectopic sites along the midline.

Glioma A tumor composed of neurological tissue of any type, including astrocytes and ependymal cells.

Meningioma A hard, slowly growing tumor arising from the meninges.

Neurocytoma A tumor of small, poorly differentiated hypothalamic neurons.

Pituicytoma A tumor of the modified glia of the posterior lobe of the pituitary.

Pituitary tumor A tumor composed of adenohypophysial epithelial cells. Pituitary tumors may secrete hormones and may be infiltrative and locally aggressive but do not metastasize.

Sarcoidosis A chronic progressive systemic granulomatous inflammation of unknown etiology.

Sarcoma A malignant tumor composed of connective tissue elements (mesenchyme).

Schwannoma A neoplasm originating from Schwann cells of the myelin sheath of nerves.

Syndrome of inappropriate antidiuretic hormone (SIADH) Persistent hyponatremia, inappropriately elevated urine osmolality, and no discernible stimulus for ADH release.

Teratoma A neoplasm composed of a number of different types of tissue, none of which is native to the area in which it occurs. It is thought to derive from germ cells.

Introduction

The hypothalamus is a phylogenetically primitive structure that plays an important role in the regulation of autonomic or vegetative functions, behavior, and emotion. Its importance in physiology is highlighted by its key role in the regulation of most endocrine functions. The pituitary has been called "the conductor of the endocrine orchestra"; using the same analogy, the hypothalamus would have to be considered "the composer that writes the music."

Normal Hypothalamic Anatomy and Physiology

The hypothalamus is a poorly defined anatomical structure with arbitrary delineations: the anterior commissure, lamina terminalis, and optic chiasm define the anterior border, and the midbrain tegmentum and mamillary bodies identify the posterior boundary. Laterally, it is demarcated by the substantia innominata, internal capsule, subthalamic nucleus, and cerebral peduncle. The superior border is the hypothalamic sulcus and inferiorly it is defined by the optic chiasm and median eminence that gives rise to the pituitary stalk (Fig. 1A).

The hypothalamus is composed of nuclei, which are clusters of functionally distinct neuronal cell populations. These neurons are large and polyhedral cells known as ganglion cells (Fig. 1B). The nuclei of the hypothalamus are topographically distinct in lower-order animals and they are relatively well demarcated in the developing human fetus, but in the adult human they are ill defined. From animal studies, it is known that individual nuclei have important physiological functions; for example, there are specific nuclei implicated in hunger or satiety control, temperature regulation, olfaction, circadian rhythms, sexual drive, ovarian regulation, and parenting behaviors. However, functionally, a given hormone is often produced in more than one nucleus, and in

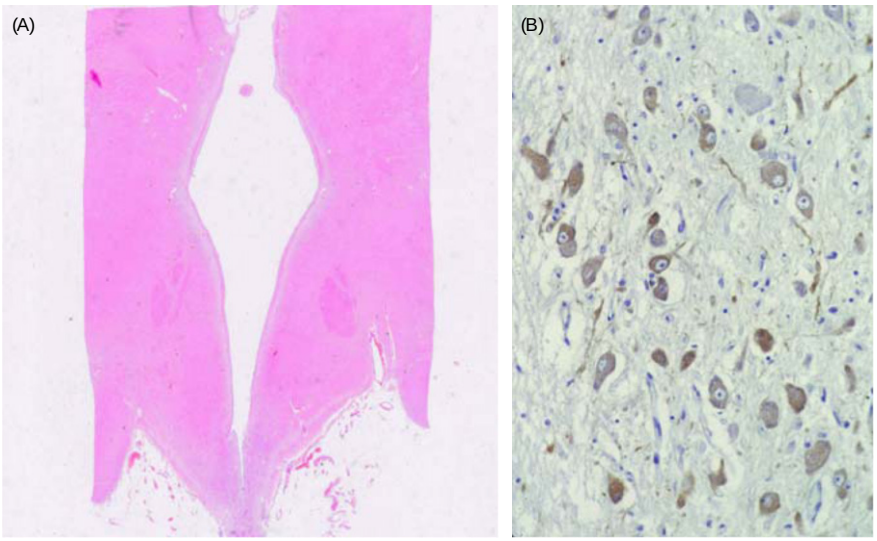

Fig. 1 Normal hypothalamus. (A) The third ventricle is lined by the lateral hypothalamus that harbors the paraventricular nuclei. Inferiorly, the infundibulum carries nerve fibers to the pituitary stalk. (B) The nuclei of the hypothalamus are collections of ganglion cells; in this supraoptic nucleus, the neurons contain vasopressin immunoreactivity.

many instances, a single nucleus produces more than one hormone. These data raise doubts about the concept of individual nuclei as designated with exclusive functional entities.

Clinical Manifestations of Hypothalamic Disease

Lesions of the hypothalamus cause headache, nausea, vomiting, somnolence, behavioral alterations, psychosis, and dementia. Hypothalamic destruction can result in bulimia or anorexia. Visual disturbance can result from oculomotor alterations or optic nerve damage. Hypopituitarism and diabetes insipidus are common manifestations. In severe cases, patients can develop hydrocephalus. Inflammation can result in meningitis.

Diabetes insipidus is the most common and often the initial manifestation. The presentation of hypopituitarism varies with age. In children, hypothalamic dysfunction may present with dwarfism. In adults, sexual dysfunction is the most common endocrine complaint, with impotence in males and primary or secondary amenorrhea in females. If the disease is predominantly hypothalamic or causes interruption of the pituitary stalk, pituitary hypofunction is associated with hyperprolactinemia due to interruption of the dopaminergic neurons that maintain tonic inhibition of that pituitary hormone, and stimulation confirms an intact pituitary response. If the lesion causes destruction of hypophysial tissue as well as hypothalamic disease, there is a reduction of all basal pituitary hormones or more subtle changes with reduced response to stimulation.

Some tumors are associated with pituitary hormone excess. Occasionally, this is due to the production of hormones stimulating pituitary function, such as in hypothalamic gangliocytomas that secrete adenohypophysiotrophic hormones. Alternatively, the clinical manifestations may be due to the production of substances that simulate or mimic pituitary hormones. For example, germ cell tumors associated with precocious puberty produce β-chorionic gonadotropin. Occasionally, patients manifest excessive secretion of vasopressin, resulting in the syndrome of inappropriate antidiuretic hormone.

Developmental Disorders

The failure of development of areas of the hypothalamus can lead to variable clinical manifestations. Major defects are incompatible with life.

Septo-optic dysplasia or de Morsier's syndrome is a complex developmental disorder with variable manifestations of aplasia of the septum pellucidum, hypoplasia of the optic nerves, and endocrine dysfunction as well as vegetative alterations. The disorder has been associated with mutations of a homeobox transcription factor, *Hesx1*, which is required for normal development of the affected regions of the central brain, and alterations in OTX2, SOX2, and PAX6 have also been implicated (Lopes, 2016).

Kallman syndrome is an X-linked developmental defect causing gonadal insufficiency in males due to hypothalamic GnRH deficiency associated with anosmia. It was initially attributed to mutation of the *KAL-1* or ANOS1 gene that encodes an extracellular glycoprotein, anosmin-1, that is expressed during the period of human organogenesis in the early olfactory system and is required for normal migration of gonadotropin-releasing hormone (GnRH)-containing neurons. Other genetic alterations associated with this syndrome involve CHD7, FGF8/FGFR1, PROK2/PROKR2, IL17RD, NELF, HS6ST1, FLRT3, SPRY4, DUSP6, SEMA3A, and WDR11 genes that play a role in neuronal migration (Valdes-Socin *et al.*, 2014).

Hypothalamic hypogonadotropic hypogonadism also occurs with normosmia and is classified separately. It is attributed to mutations in some of the same genes as Kallman syndrome (PROKR2, FGF8, FGFR1, CHD7, DUSP6, WDR11) as well as in mutations in KISS1/KISSR, GNRH1/GNRHR, TAC3/TACR3, LEP.LEPR, HESX1, and the gonadotropins (Valdes-Socin *et al.*, 2014).

Laurence–Moon–Biedl syndrome is a highly polymorphic disorder that includes pigmentary retinopathy, mental retardation, spinal paraplegia and hypogonadism associated with obesity, and digital anomalies. The genetic basis had remained unknown and the variable clinical manifestations suggest incomplete penetrance with differential expression of the anomaly. More recently, several mutations in families with Laurence–Moon syndrome were identified in the PNPLA6 gene, which encodes neuropathy target esterase (Hufnagel *et al.*, 2015).

Prader–Willi syndrome is characterized by obesity, short stature, delayed puberty, infertility, mental retardation, muscle hypotonia, hypopigmentation, and seizure disorder. It has been linked with deletions of chromosome 15q11–q13. This region contains an imprinting center that regulates paternally expressed genes whose expression is lost; some cases are attributed to maternal uniparental disomy. However, the precise causative gene(s) are unknown.

Wolfram syndrome (*WS*) is characterized by diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (hence the acronym DIDMOAD). This rare neurodegenerative disorder exhibits autosomal recessive inheritance usually due to compound heterozygous mutations of the *WFS1* gene, a member of a novel gene family that encodes wolframin, an endoglycosidase H-sensitive membrane glycoprotein that localizes in the endoplasmic reticulum. *WFS1* is expressed predominantly in selected neurons in the hippocampus, amygdala, olfactory tubercle, and superficial layer of the allocortex—components of the limbic system or structures closely associated with this system that account for the psychiatric, behavioral, and emotional abnormalities of this syndrome, as well as in the pancreas where it causes diabetes, and in the heart, bones, muscle, lung, liver, and kidneys. Heterozygous mutations are associated with nonsyndromic, low-frequency sensorineural hearing loss affecting only the 2000-Hz and lower range. This is an unusual disorder that worsens over time without progressing to profound deafness. Occasional cases have been associated with mutations of CISD2 that encodes a mitochondrial protein of unknown function.

Idiopathic growth hormone (*GH*) *insufficiency* is most often due to a defect in the synthesis or secretion of growth hormone-releasing hormone (GHRH) since patients usually have normal pituitary GH somatotroph structure and hormone content, and they respond to GHRH administration (Attie, 2000).

Hypothalamic Inflammation

Infectious Lesions

Acute and chronic infections of the hypothalamus are rare but they do occur, usually in association with sphenoid sinus infection, cavernous sinus thrombosis, otitis media mastoiditis, or peritonsillar abscess. Pituitary tumors have been associated with the development of pituitary abscess that can spread to the hypothalamus. It has been suggested that bony erosion by the tumor predisposes such patients to the spread of sinonasal infection. Rarely, infection results from vascular seeding of distant or systemic infection.

Noninfectious Inflammatory Lesions

Sarcoidosis is a multisystem granulomatous disease of unknown etiology. It has long been attributed to an infectious agent; however, none have been identified. Disease onset usually occurs in adults, and there is a predilection for blacks and females. There are usually systemic manifestations, and neural involvement is rare; however, it can occur in the hypothalamus, usually involving the meninges at the infundibulum and floor of the third ventricle. The granulomatous inflammation has a subacute or protracted course of tissue destruction that may respond to steroid suppression, and there rare reports of spontaneous resolution.

Neuroinfundibulohypophysitis is a rare inflammatory condition that affects the infundibulum, the pituitary stalk, and the neurohypophysis and may be part of a range of autoimmune disorders, including lymphocytic hypophysitis. Lymphocytic hypophysitis occurs mainly in women and most often presents in the later stages of pregnancy (Asa, 2011; Asa and Mete, 2016). Infundibulohypophysitis shows no sexual predilection and usually presents with diabetes insipidus. The cause is unclear but is thought to be autoimmune in nature (Asa, 2011; Asa and Mete, 2016).

Inflammatory pseudotumor, a lesion similar to orbital pseudotumor characterized by chronic inflammation and fibrosis, can involve the parasellar tissues and may be associated with other sclerosing lesions, such as Riedel's thyroiditis, retroperitoneal fibrosis, and sclerosing cholangitis that form the disorder known as IgG4 disease (Asa, 2011; Asa and Mete, 2016). The etiology and appropriate management of these disorders are uncertain.

Metabolic Lesions

Neurodegenerative Processes

Alzheimer's disease, Parkinson's disease, Huntington's chorea, and other neurodegenerative diseases can involve the hypothalamus, resulting in variable endocrine, behavioral, and vegetative abnormalities.

Systemic Processes

Wernicke's encephalopathy can alter hypothalamic function, but usually the manifestations are due to mamillary body degeneration. Hemochromatosis results in hypogonadotropic hypogonadism, but this is thought to be due to iron deposition in the pituitary gonadotrophs rather than a principally hypothalamic lesion.

Cystic Lesions

Rathke's Cleft Cysts

These cysts originate in the remnants of Rathke's pouch of the pituitary. Rathke's cleft arises from the oropharynx and migrates upward with an anterior and posterior limb that ultimately gives rise to the anterior and intermediate lobes of the adenohypophysis, respectively. In the human, the intermediate lobe is vestigial, and its remnants line small cystic cavities that are remnants of the cleft and usually <5 mm in diameter. When they enlarge and become detectable, they can cause symptoms. Initially the symptoms are hypopituitarism and diabetes insipidus, due to sellar compression (Shin *et al.*, 1999). When they develop suprasellar extension, symptoms of hypothalamic involvement ensue. There are rare cases of purely suprasellar Rathke's cleft cysts, and occasionally abscess formation develops within these lesions.

They usually present in adults but do occur in infants and young children. Computed tomography (CT) scans reveal low-density cystic areas with capsular enhancement in most cases; the magnetic resonance imaging (MRI) appearance is variable. Morphologic examination reveals a cyst lining characterized by ciliated cuboidal or columnar epithelium resembling respiratory epithelium, with occasional goblet cells and squamous elements. The degree of ciliation and the propensity for squamous metaplasia distinguish these cysts from the neuroepithelial-derived colloid cysts of the third ventricle.

The management of these lesions involves surgical drainage with or without partial excision. The recurrence rate is low. Most symptoms and signs are relieved postoperatively, but permanent hypopituitarism and diabetes insipidus require hormone replacement therapy.

In some patients, the cyst can rupture and the release of cyst contents induces a reaction that can vary from granulation tissue to xanthomatous inflammation, an accumulation of clear, lipid-laden macrophages with a characteristic appearance. Xanthomatous hypophysitis was initially described as an idiopathic phenomenon but has increasingly been recognized to be attributable to a ruptured Rathke's cleft cyst (Duan *et al.*, 2017).

Arachnoid Cysts

These lesions may be congenital anomalies or acquired cysts in the arachnoid of the sellar and suprasellar region. The cystic nature of these lesions evident on CT or MRI scans may make it difficult to distinguish them from other cysts that occur in this area (Shin *et al.*, 1999). These cysts are filled with clear, colorless fluid and are lined by arachnoid laminar connective tissue with a single layer of flattened epithelium. These lesions are also managed by drainage, with partial cyst wall excision.

Dermoid and Epidermoid Cysts

Dermoid and epidermoid cysts arise from epithelial cells that are misplaced during embryologic development or, rarely, traumatically. Epidermoid cysts are also known as cholesteatoma (Asa, 2011). These epithelial cysts can occur intracranially, most commonly at the cerebellopontine angle but often in the suprasellar area.

The cystic nature of these lesions evident on CT or MRI scans may make it difficult to distinguish them from other cystic lesions in this area. Epidermoid cysts are lined by keratinizing squamous epithelium; dermoid cysts are distinguished by the additional presence of skin appendages, including hair follicles and sweat glands.

Management usually involves surgical resection. Complications include rupture with chemical meningitis due to keratin debris or the development of squamous carcinoma.

Aneurysms

Aneurysms of the carotid arteries can expand to give rise to masses in the suprasellar region that compress hypothalamic structures and result in endocrine and other hypothalamic manifestations. It is important to distinguish these from other cystic lesions prior to surgery.

Meningoencephalocele

Encephaloceles involving the hypothalamus have been reported to cause symptoms of a mass lesion with variable endocrine manifestations.

Primary Hypothalamic Neoplasms

Craniopharyngioma

Craniopharyngiomas are thought to derive from the remnants of Rathke's pouch (Asa, 2011). They represent up to 13% of intracranial neoplasms and are the most common sellar tumor of childhood. They can occur at any age from infancy to old age, but the peak incidence is from 5 to 20 years. A second small peak occurs in the sixth decade. In some series, males are more often affected than females.

The majority of tumors occur in the suprasellar region; 15% have an intrasellar component. Craniopharyngiomas are usually cystic or may be cystic and solid, and approximately half have radiologically detectable calcification. Although they may be as small as 1 cm, the majority are much larger at the time of diagnosis. Grossly, they are well-circumscribed tumors, but there may be little or no capsule at the interface with brain parenchyma. The lesions usually contain a thick oil-like fluid that is described as "black sludge." Cholesterol crystals and calcification may be seen grossly. Rarely, these tumors may contain bone and/or teeth. Microscopically, they are composed of cords or islands of epithelial cells in a loose fibrous stroma and with intervening cysts (**Fig. 2**A). The epithelium usually has an outer palisaded layer, a midzone of stellate epithelial cells, and a superficial keratinizing layer. Masses of keratin often form the nidus for calcification. Occasionally, there is an inflammatory component. Microscopically, the borders are frequently irregular and may be associated with gliosis in the adjacent brain tissue.

Two subtypes of craniopharyngioma have been recognized. The adamantinomatous type has a predominance of stellate components, which yields a pattern resembling the dental ameloblastic organ and is similar to that seen in adamantinomas. The papillary variant is less common, rare in children, and believed to have a better prognosis. It is characterized by solid or cystic growth of pseudopapillary squamous epithelium and lacks the palisading, fibrosis, and cholesterol accumulation that characterizes the typical craniopharyngioma. These two variants have differing genetic alterations that have implications for management when complete surgical resection is not possible. Adamantinomatous craniopharyngiomas have mutations of beta-catenin that result in nuclear translocation of that protein that activates Wnt-signaling and can be detected by immunohistochemistry (**Fig. 2**B). In contrast, papillary craniopharyngiomas harbor BRAFV600E mutations (Brastianos *et al.*, 2014) that can be detected by mutant-specific immunohistochemistry using the VE1 antibody and that can be targeted by medical therapy using debrafinib and trametinib (Brastianos *et al.*, 2016).

Craniopharyngiomas can be extremely infiltrative lesions. They may cause extensive tissue damage, extending into the hypothalamus and as high as the third ventricle; obstruction of the ventricle may result in hydrocephalus. Rarely, craniopharyngiomas may spontaneously rupture or form abscesses; a rare form of hypophysitis has been described in this setting and is called sellar xanthogranuloma (Paulus *et al.*, 1999). Because of their highly infiltrative nature, they are often incompletely excised surgically. There is a 10%–40% recurrence rate, particularly in younger patients. Many surgeons advocate postoperative radiation. There is a single report of malignant transformation of a craniopharyngioma. This occurred on the fifth recurrence after a 35-year history of disease and 8 years following radiotherapy.

Neuronal Tumors

Hypothalamic neuronal tumors are very rare neoplasms that have been reported in the literature as "*gangliocytomas*" or "*ganglioneuromas*." These lesions are composed of mature neurons resembling hypothalamic ganglion cells and are capable of producing hypothalamic peptides (**Fig. 3**). Some researchers prefer to consider these hamartomas because they occur in children and it is thought that they represent developmental anomalies. They are commonly called ganglioneuromas or gangliocytomas because there is evidence that they represent neoplasms that have their onset in adulthood and are capable of continued growth. Such

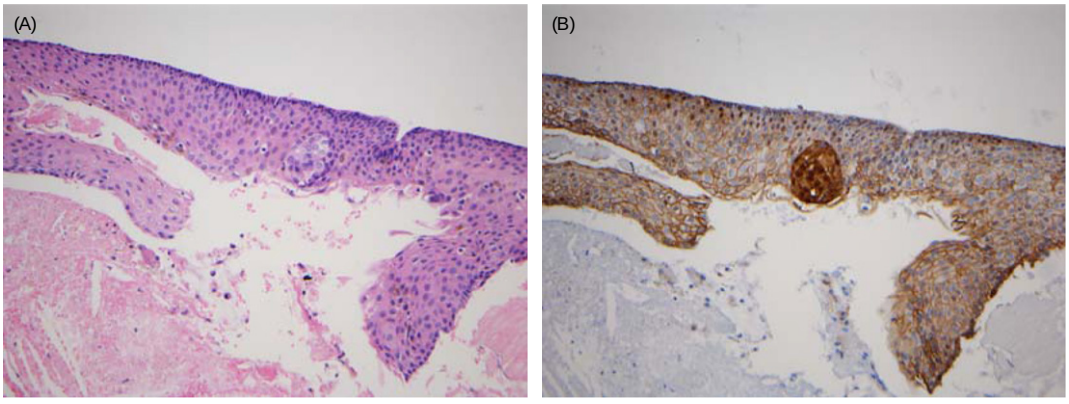

Fig. 2 Craniopharyngiomas. (A) These tumors are composed of squamoid epithelium that derives from remnants of Rathke's pouch. The infiltrative lesions destroy hypothalamic parenchyma. (B) This adamantinomatous craniopharyngioma has characteristic nuclear translocation of beta-catenin in morules, compared with the membranous pattern in the squamous component; this feature correlates with mutation.

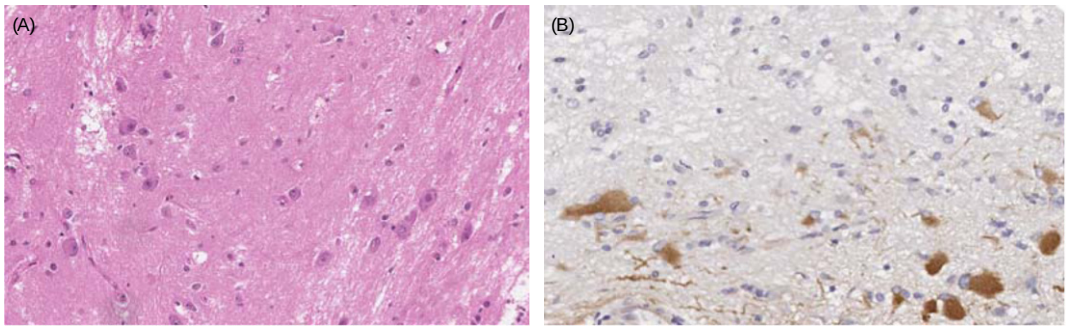

Fig. 3 Hypothalamic gangliocytoma. (A) The tumor is composed of ganglion cells resembling those of the normal nuclei of the hypothalamus but lacking organization and containing abnormal nuclei. (B) The tumor cells of this gangliocytoma associated with acromegaly contain GHRH immunoreactivity.

tumors have also been described in other parts of the brain as extrahypothalamic gangliocytomas. The term choristoma has been applied to describe collections of hypothalamic neurons within the adenohypophysis.

In addition to the usual symptoms of a hypothalamic mass lesion, some of these tumors are hormonally active and cause endocrinopathies that are usually mediated by the pituitary (Asa, 2011; Asa and Mete, 2016). They have been associated with acromegaly, precocious puberty, Cushing's disease, and amenorrhea–galactorrhea. The most common localization of these peculiar neoplasms is in the hypothalamus or tuber cinereum, with variable involvement of the third ventricle. They may be nodular, pedunculated, sessile, solid, or cystic. They may be within, attached to, or completely detached from the hypothalamus. These tumors may also be found within the parenchyma of the adenohypophysis. They vary from microscopic lesions composed of only a few cells and measuring a few millimeters to masses that measure >5 cm. In particular, hypothalamic hamartomas associated with acromegaly often present as a solitary intrasellar mass that mimics a simple pituitary GH-producing pituitary neuroendocrine tumor; microscopic examination reveals a gangliocytoma associated with a pituitary adenohypophysial tumor in such cases. They are composed of randomly oriented large mature ganglion cells with large nuclei and very prominent nucleoli; binucleated and even multinucleated cells are seen. Most of the ganglion cells contain abundant cytoplasm, and Nissl granules are conspicuous at the periphery of the cell body. Some tumors have a glial stroma.

In patients with acromegaly, the ganglion cells may contain GHRH (**Fig. 3**B), glucagon, somatostatin, vasoactive intestinal peptide (VIP), corticotropin-releasing hormone (CRH), GnRH, or gastrin; associated pituitary adenohypophysial neuroendocrine tumors generally contain GH, but some patients have somatotroph hyperplasia and, rarely, no pituitary abnormality is identified. In patients with amenorrhea–galactorrhea, prolactin and VIP have been localized in the cytoplasm of ganglion cells. One patient had an associated lactotroph tumor; another had a mixed GH- and prolactin-producing pituitary tumor. Tumors associated with Cushing's disease contain CRH and may also express ACTH, ß-lipotropin, and somatostatin; they have been associated with corticotroph hyperplasia or corticotroph neoplasia. Children with precocious puberty have neuronal tumors that contain GnRH but may also contain immunoreactivity for CRH, β-endorphin, and oxytocin. Some gangliocytomas not associated with clinical evidence of hormone excess show multiple immunoreactivities, including positivity for VIP, galanin, α-subunit of glycoprotein hormones, somatostatin, and serotonin. In a few cases, there is ultrastructural evidence of an intimate association between neurons and adenohypophysial cells, both neoplastic and nontumorous, supporting the theory of an endocrine relationship.

The pathogenesis of these lesions is not known. Their association with pituitary adenohypophysial tumors in some patients suggests that there may be a common causative mechanism. It has been suggested that sellar gangliocytomas may arise by abnormal differentiation during neoplastic proliferation of adenohypophysial cells. However, it is more likely that these tumors have a true hypothalamic origin. It may be that the same tumorigenic stimulus results in tumors of both hypothalamus and pituitary.

These tumors are diagnosed at the time of surgery, and cure has resulted from complete surgical resection in several published cases. However, despite the apparent cure of the endocrine disturbance, there may be radiographic evidence of residual tumor. When surgery cannot accomplish total resection of the lesion, the prognosis is varied. Most of these neuronal tumors have an extremely low proliferative potential, and the overall prognosis is good. A few have caused severe hypothalamic destruction and have resulted in the demise of the patient. Radiotherapy appears to ameliorate hormone excess in these patients, but it does not appear to be effective in preventing regrowth of the neuronal tumor.

Much more rare immature neuronal tumors known as "*neurocytomas*" occur in this region (Asa and Mete, 2016). They are composed of small round cells with variable but usually scant cytoplasm, and poorly developed neuropil. Morphologically they resemble small immature neuronal tumors in the regions of the cerebral ventricles that were called "central neurocytoma"; subsequent reports identified "extraventricular neurocytomas." The small primitive neurons express neuronal markers NeuN and scant neurofilaments, as well as synaptophysin and chromogranin. The hypothalamic ones also express TTF-1, a feature of hypothalamic cells that derived from the basal hypothalamus. Occasional tumors present with features of hormone excess due to dysregulated production of vasopressin.

Pituicytomas

Tumors of the posterior pituitary are composed of modified glial cells that form the sustentacular network surrounding the axons of hypothalamic neurons (Asa, 2011; Asa and Mete, 2016). These tumors clinically resemble pituitary adenohypohysial tumors but are distinguished from them morphologically and by their immunohistochemical profile. Pituicytes have five morphologic variants: dark, light, oncocytic, granular, and ependymal (Mete *et al.*, 2013). The tumors that derive from these cells also have a spectrum of morphology, including the usual spindle cell variant that is composed of dark and light cells, the oncocytic variant that was initially called "spindle cell oncocytoma" because of its large round cells with numerous mitochondria creating a granular basophilic cytoplasm, the granular cell variant that is also known as "granular cell tumor" with large granular complex lysosomes, and the rare "ependymal variant" that has elongated cells forming ependymal and perivascular pseudorosettes (Kamil *et al.*, 2013). These tumors are characterized by expression of TTF-1, GFAP, and occasionally epithelial membrane antigen (EMA), but they are completely negative for keratins, pituitary transcription factors, and hormones.

Gliomas

Gliomas are neoplasms derived from and composed of neuroglial cells. They include astrocytomas and glioblastoma multiforme, oligodendrogliomas, and ependymomas. These tumors show a wide range of biologic behaviors.

Aggressive, rapidly lethal malignant gliomas or glioblastoma multiforme in the hypothalamus occur following radiotherapy for pituitary neuroendocrine tumor, craniopharyngioma, or suprasellar germinoma. These tumors can occur 5–25 years after conventional radiation doses of 42.5–66 Gy. Glioma of the optic nerve is rare and usually occurs in children or adolescents who are predisposed due to neurofibromatosis or Beckwith–Wiedemann syndrome.

The radiologic features vary with the tumor type. On CT scan, low-grade astrocytomas are low-density lesions that do not enhance with contrast; enhancement suggests malignant transformation, particularly if it is peripheral to a central hypodense area of necrosis, as seen in glioblastoma multiforme. On MRI, astrocytomas usually have high T2-weighted signal intensity.

The most common glioma in the sellar region is the pilocytic astrocytoma (Asa, 2011; Asa and Mete, 2016). Most common in children, hence the term juvenile type, this is a relatively discrete, often cystic mass with prominent enhancement on CT scan. These tumors usually arise in the wall of the third ventricle, where they displace and compress the optic chiasm; they may also arise in the optic nerve, usually at the chiasm. The low-grade lesions in children have a relatively good prognosis because they grow slowly, but chiasmal lesions can be more aggressive. In contrast, optic gliomas that occur sporadically in adults are usually rapidly fatal tumors.

Meningiomas

Meningiomas are tumors derived from the meninges and their derivatives in the meningeal spaces. They may arise from dural fibroblasts or pial cells, but the most common are of arachnoid origin. Approximately 20% of tumors of arachnoid and meningothelial cells occur in the sellar and parasellar area (Asa, 2011; Asa and Mete, 2016); they are most common in the sphenoid ridge and tuberculum sellae but also occur in the clivus. Occasionally, meningiomas arise in the sellar region following irradiation of the area for pituitary neuroendocrine tumor or craniopharyngioma. These tumors are more common in women than in men, possibly due to their expression of progesterone receptors and estrogen receptors.

Meningiomas are histologically diverse tumors. The more familiar types and the most common in the suprasellar hypothalamic area are the meningothelial, fibrous or fibroblastic, and transitional variants. Papillary patterns and anaplastic changes portend a more aggressive behavior and the possibility of metastases.

The management of these lesions is generally surgical resection. These highly vascular lesions can create problems with intraoperative bleeding.

Schwannomas

Tumors composed of spindle-shaped Schwann cells derive from cranial nerves; they are also known as neurilemmoma or neurinoma. Hypothalamic and parasellar schwannomas occur rarely (Asa, 2011; Asa and Mete, 2016). On CT scan, these lesions are visualized as sellar or parasellar masses that enhance with contrast and can mimic pituitary neuroendocrine tumor. They are hypovascular on angiography.

The morphology of these lesions in the pituitary region is identical to that of schwannomas elsewhere. These tumors are usually encapsulated and sometimes cystic lesions composed of spindle-shaped cells arranged in compact Antoni type A and loose Antoni type B areas. The former may exhibit palisading that leads to the formation of Verocay bodies. Immunohistochemical staining for S100 protein is strong in these lesions. Using electron microscopy, these tumors are recognized by the prominent basal lamina surrounding individual cells and by the characteristic "long-spacing" collagen of the stroma.

Similar to Schwannomas elsewhere, these lesions are usually benign and are amenable to surgical resection unless they involve critical structures in the parasellar region, in which case conservative surgical resection is indicated.

Chordomas

Chordomas are rare lesions thought to derive from remnants of the notochord. They occur in the midline, most often in the sacral region, but also in the region of the clivus and occasionally in vertebrae and within the sella turcica (Asa, 2011; Asa and Mete, 2016). These slowly growing but locally aggressive neoplasms usually occur in patients older than 30 years of age, but patients with the unusual sphenoid lesions tend to be younger.

Chordomas are usually lobulated, calcified, and expansile osteolytic lesions that may cause characteristic elevation of the periosteum, in which case they may be suspected on the basis of the radiologic findings. They have a characteristic gelatinous gross appearance and may have areas of calcification. Histologically, they are composed of large polyhedral cells with a characteristic bubbly or "physaliphorous" vacuolation. The tumor cells have immunohistochemical markers of epithelial differentiation, keratins, and EMA, as well as S100 protein and vimentin. Some exhibit positivity for carcinoembryonic antigen. High-grade sarcomatous areas may herald dedifferentiation and are sometimes seen in metastatic deposits. These aggressive variants are rare in intracranial chordomas. In contrast, the spheno-occipital region is the preferred site of the "chondroid" variant, which exhibits areas of cartilaginous differentiation that may dominate the histologic picture. These chondroid chordomas lack keratin and EMA positivity and are considered by some to be chondrosarcomas. This variant has a better prognosis than the usual clival chordomas.

Surgery is the preferred initial therapeutic approach; however, the location and extent of tumor may make complete extirpation impossible. Radiotherapy is indicated for incompletely resected lesions. Mean survival is approximately 4 or 5 years, and metastases to the lung, liver, bone, and lymph nodes occur rarely.

Vascular and Mesenchymal Tumors

These tumors arise from vessel walls, fibrous connective tissue and fat, bone, and cartilage. They are rare in this area and can be benign or malignant.

The development of sarcoma in this region may be sporadic but more commonly is the result of previous ionizing irradiation. There are several reports in the literature of osteosarcoma and fibrosarcoma of the sella developing 4–21 years after irradiation for pituitary adenohypophysial tumor or craniopharyngioma (Asa, 2011; Asa and Mete, 2016). These aggressive neoplasms result in the rapid demise of the patient.

Germ Cell Tumors

These tumors are derived from germ cells that are residual along the midline; they are identical to germ cell tumors of the gonads and mediastinum. Intracranial germ cell tumors represent $<1\%$ of intracranial neoplasms, but in children they constitute up to 6.5% of such lesions. After the pineal, the suprasellar region is the second most common site of involvement. These tumors occur most often before the age of 20 years and occur more often in males than in females.

The most common type, the germinoma, is usually a well-demarcated tumor that has high density on CT scan and enhances with contrast. Teratomas may exhibit fat densities and calcifications that are recognized radiologically. Whereas the CT appearance of some of the other germ cell tumors may not be distinctive, MRI is more sensitive and can show features that are obscured on CT scan.

The classification of parasellar and intrasellar germ cell tumors (Asa, 2011; Asa and Mete, 2016) includes teratomas, germinomas, embryonal carcinomas, endodermal sinus tumors, and choriocarcinomas. Germinomas and teratomas predominate, and mixed germ cell tumors that show features of more than one tumor subtype are frequent, usually germinoma combined with one of the other tumor types or a combination of embryonal carcinoma and immature teratoma, known as teratocarcinoma. Recognition of even minor components that are characterized by more aggressive elements can predict a worse prognosis and may alter management.

If the diagnosis is suspected preoperatively, biopsy can be performed to type the lesion and determine whether surgery or other modalities, such as radiation or chemotherapy, are indicated. Germinomas are uniquely radiosensitive and long-term remission is achieved in approximately 70% of patients. The recognition of more aggressive elements in mixed tumors can predict failure of radiotherapy. Other tumors are more aggressive, and despite surgery, radiation, and chemotherapy, they may recur or metastasize both within and beyond the central nervous system. Seeding via ventriculoperitoneal shunt may also result in dissemination.

Secondary Neoplasms

Pituitary Neuroendocrine Tumors

Pituitary adenohypophysial cell tumors, recently classified as "pituitary neuroendocrine tumors (PitNETs) (Asa *et al.*, 2017), are common lesions, occurring in 20%–27% of the population, and at least one-third of these give rise to clinical manifestations. Many of these tumors exhibit suprasellar or parasellar invasion involving the hypothalamus.

Metastatic Carcinoma

Cranial metastasis is a manifestation of a systemic and usually terminal malignancy (Fig. 4A). The most common primary sites of these lesions are the lung, breast, and gastrointestinal tract. Most hypothalamic metastases are not associated with specific clinical symptomatology and are therefore found incidentally at autopsy. Patients may present with diabetes insipidus, and large tumors may cause headache, visual field defects, ophthalmoplegia, and ptosis. Rarely is there an endocrine manifestation, usually resulting in hypopituitarism. A few reported cases have identified hormone excess, and usually the culprit is ectopic ACTH production in a location that mimics primary pituitary Cushing's disease. A fascinating case of CRH production by a hypothalamic metastasis of prostate small cell carcinoma resulted in pituitary corticotroph hyperplasia.

Since these patients have disseminated malignancy, therapy is aimed at palliation. Surgical decompression with or without radiotherapy can relieve symptoms.

Hematologic Neoplasms

Tumors of leukocytic, lymphocytic, or plasmacytic differentiation are usually systemic disorders. Very rarely, lesions in the region of the hypothalamus appear to be solitary and primary at that site (Asa, 2011; Asa and Mete, 2016). As in the central nervous system in general, lymphoma or leukemia is most often meningeal and extradural.

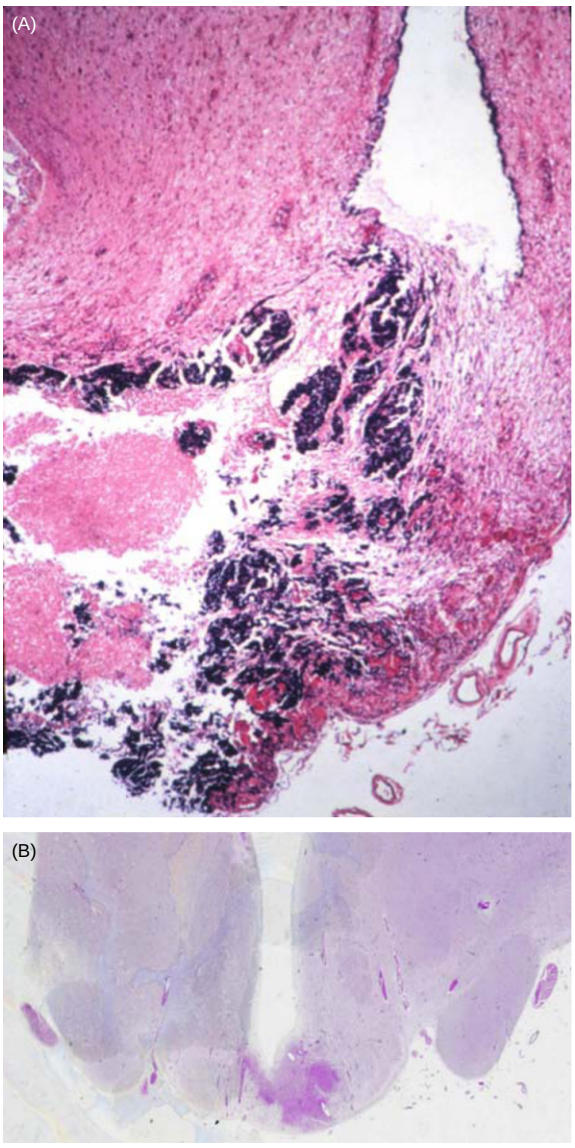

Fig. 4 Metastatic tumor. (A) This metastatic small cell lung carcinoma has replaced the arcuate nucleus and invades the infundibulum and superior pituitary stalk. (B) In this case of Langerhans cell histiocytosis, the lesion infiltrates and destroys normal hypothalamus.

Lymphomas are seen on MRI as masses with signals of similar intensity to those of their surroundings on T1-weighted images, but they are hyperintense on T2-weighted views. They enhance with contrast media and usually in a uniform pattern.

Histologically, the lymphomas of the central nervous system resemble systemic lymphomas. They are almost always non-Hodgkin lymphomas with a diffuse rather than follicular pattern; the majority are B cell tumors. Plasmacytomas are composed of well-differentiated plasma cells.

Langerhans cell histiocytosis includes the disorder formerly known as histiocytosis X, as well as eosinophilic granuloma, Hand–Schüller–Christian disease, Letterer–Siwe disease, Langerhans cell granuloma, and several other variants. This clonal proliferation of epithelioid histiocyte-like Langerhans cells may be localized, multifocal, or disseminated i. The classical presentation of Hand–Schüller–Christian disease involves the hypothalamus (**Fig. 4**B) and the disorder may involve the pituitary gland.

CT scans of Langerhans cell histiocytosis are characterized by ill-defined contrast-enhancing hypodense masses with areas of edema. MRI can detect the small multifocal lesions of this disorder more readily than CT scan; these lesions may be hypointense but can have slightly increased T1 contrast and intense T2-weighted images. Involvement of the pituitary stalk is characteristic of this disorder and may precede clinical manifestations of the disease.

Langerhans cells are characterized by an epithelioid, histiocyte-like appearance. They have kidney-shaped nuclei and abundant cytoplasm and stain for CD1 and S100 proteins. They are admixed with chronic inflammatory cells, foamy macrophages, and eosinophils. By electron microscopy, they contain pathognomonic Birbeck granules that allow a definitive diagnosis.

The prognosis of this disorder is variable. When systemic involvement is manifest, it is frequently lethal and apparently isolated lesions can progress rapidly to widely disseminated disease that is unresponsive to any form of therapeutic intervention. Surgery has been reported to be curative of localized lesions, and radiotherapy has been used postoperatively with success in cases of isolated involvement of this region.

Other rare hematologic neoplasms in this region include Rosai–Dorfman disease, Erdheim–Chester disease, hemophagocytic lymphohistiocytoses, and juvenile xanthogranuloma.

Glossary

Gene A segment of DNA within the chromosome that contains all of the information required for the synthesis of a product. It is the individual functional unit of heredity responsible for inherited characteristics that distinguish one individual from another. Genes may be passed from parent to progeny in one of several different methods, including autosomal and X-linked modes of transmission, in dominant or recessive fashion.

Hypertonicity An increase in the "effective" osmotic pressure of body fluids above the normal range, general considered to be a function of the plasma osmolarity or plasma concentration of sodium and its anions.

Magnetic resonance imaging An imaging technique used to image internal structures of the body. It employs the influence of a large magnet to polarize hydrogen atoms within tissues and then monitors the summation of these dipoles within cells. It is a particularly useful tool for imaging soft tissues, such as the brain, spinal cord, joints, and abdominal structures.

Osmolarity The concentration of osmotically active particles expressed in terms of osmoles of solute per liter of solution. One osmole represents the molecular weight of the solute, in grams, divided by the number of particles into which it dissociates in solution.

Pituitary gland A small, oval-shaped endocrine gland situated at the base of the brain, in the fossa of the sphenoid bone. Its role is to coordinate and regulate growth and metabolism. It is divided into anterior and posterior portions, each responsible for the production of its own set of unique hormones.

Polyuria The passage of an abnormally high volume of urine within a given period of time. Pathologic conditions are typically in excess of 45 mL of urine per kilogram of body weight over a 24-h period.

Water intoxication A state of dilutional hyponatremia induced by an inability to effectively excrete free water. The resultant reduction in sodium concentration may be marked by lethargy, nausea, and mild mental status alterations, with severe cases progressing to convulsions, coma, and even death.

Introduction

Diabetes insipidus (DI) is a clinical syndrome characterized by the production of abnormally large volumes of dilute urine (polyuria). It is usually associated with symptoms of urinary frequency, nocturia (awakening to urinate), and/or enuresis (bedwetting) and is almost always accompanied by a commensurate increase in fluid intake (polydipsia) which may or may not be attributed to thirst. DI is customarily divided into four types based on fundamental differences in the cause. The most common type is due to a primary deficiency in pituitary secretion of the antidiuretic hormone, arginine vasopressin (AVP). It is referred to here as pituitary DI but may also be called neurohypophyseal, neurogenic, hypothalamic, central, or cranial DI. Another type of DI is due to a deficiency of AVP caused by increased degradation of the hormone by an enzyme made in the placenta. It differs from pituitary DI not only in its cause but also in its clinical setting, history, and prognosis. It is referred to here as gestational DI. The third type of DI results from insensitivity of the kidneys to the antidiuretic effect of AVP and is called nephrogenic DI. The fourth type of DI is due to suppression of AVP secretion by excessive fluid intake. It is generally referred to as primary polydipsia and can be subdivided into three subtypes depending on whether the polydipsia is due to abnormal thirst (dipsogenic), a cognitive defect (psychogenic), or treatment of other real or imagined health problems (iatrogenic). All four types of DI and the methods used to differentiate and manage them will be described.

Normal Regulation of Water Balance

Arginine vasopressin (AVP) is the chemical name of the antidiuretic hormone (AVP). It is a nonapeptide containing a six member disulfide ring and a three membered tail in which the terminal glycine is amidated (**Fig. 1**). It is produced and secreted by the neurohypophysis, a collection of large neurons that originate in the supraoptic and paraventricular nucleus of the hypothalamus and project downward to form the posterior pituitary (Swaab, 1993). AVP is produced in these neurons through a series of steps directed by a gene located on chromosome 20 (Schmale *et al.*, 1987). Initially, it is synthesized as part of a large protein that is

folded and packaged in vesicles for transport down the axon. Within these vesicles, the precursor protein is cleaved to yield AVP and two other components, neurophysin-2 and co-peptin, all of which are stored together in bulbous nerve terminals until they are co-secreted into the circulatory system. Oxytocin is produced in other magnocellular neurons of the neurohypophysis, is secreted in response to different stimuli than AVP, and has little if any antidiuretic effect.

The measurement of AVP in plasma requires a radioimmunoassay of extraordinary sensitivity and specificity. Under physiologic conditions, it circulates at a concentration of only 1–3 pg/mL, is structurally similar to oxytocin and accompanied by large amounts of other, unidentified immuno-reactive material that does not come from the posterior pituitary and must be removed before assay. Until these problems were solved, physiologic and pathophysiologic data were limited and measurements for the purpose of differential diagnosis were impractical if not impossible. Therefore, indirect estimates using measurements of urine osmolarity in response to various procedures and treatments were widely employed. About 30 years ago, a relatively simple, sensitive, and specific radio-immunoassay was developed and used to better define the physiology and pathophysiology of AVP secretion and action (Robertson *et al.*, 1973). These findings have both confirmed and altered several widely held concepts and provided new insights and more accurate methods of differential diagnosis in several disorders of AVP function including DI.

In healthy adults, AVP secretion is regulated primarily by the effective osmotic pressure of extracellular fluid (**Fig. 2**, right panel) (Robertson, 1977; Robertson and Christensen, 2012). This variable, referred to as osmolarity, is determined by the concentration of solutes that do not readily cross cell membranes. In healthy humans, these solutes are principally sodium and its anions. The plasma and urine osmolarities usually measured by depression of the freezing point or vapor pressure. The measurements in plasma reflect the concentration not only of sodium and its anions but also those of other solutes such as glucose and urea. The latter normally do not contribute to effective osmotic pressure across cell membranes but their effect on the measurements of plasma osmolarity is customarily ignored because it is small and relatively constant from sample to sample. The effective osmotic pressure of plasma can also be estimated by doubling the molar concentration of sodium and the values so obtained correlate closely with measurements of plasma osmolarity unless other solutes such as glucose or urea are abnormally elevated.

The influence of plasma osmolarity/sodium on AVP secretion is mediated by specialized sensory cells known as osmoreceptors that are thought to be located in the hypothalamus near the supraoptic nucleus. They are capable of detecting minute changes in the plasma concentration of sodium, chloride and certain other exogenous solutes, such as mannitol, which do not readily cross cell membranes. The level of plasma osmolarity/sodium at which AVP secretion begins is known as the osmotic threshold or set point. It differs slightly among healthy adults, ranging from a plasma osmolarity of 270–290 mOsm/L and of sodium from 135 to 145 mEq/L (**Fig. 2**, right panel).

These small individual differences in set-point are reproducible and appear to be due to genetic influences. However, the set-points are also lowered by pregnancy, menstruation, and large decreases in blood volume or pressure. When plasma osmolarity rises above the threshold or set-point, AVP secretion also rises in direct proportion (**Fig. 2**, right panel). The magnitude of the rise in plasma AVP per unit increment in plasma osmolarity/sodium varies as much as fivefold between healthy individuals and these variations also appear to be genetically determined. However, like the set-point, the sensitivity can also be altered by large changes in blood volume or blood pressure.

The effect of blood volume and pressure on AVP secretion is mediated via specialized sensors known as baroreceptors located in the heart, aorta, and carotid arteries. These hemodynamic variables have little or no detectable effect on AVP secretion until blood volume and/or pressure fall by more than 10%–20% at which point plasma AVP begins to rise exponentially. However, hemodynamic stimuli do not abolish the osmoregulation of AVP. Rather, they appear to lower the threshold and/or increase the magnitude of the response to a given osmotic stimulus. Other nonosmotic stimuli, such as nausea, cortisol deficiency, and a rapid fall in blood sugar, may also increase AVP release. Nausea is one of the most powerful stimuli, resulting in 50- to 100-fold increases in plasma AVP. The potent effect of nausea requires special attention to symptoms in all studies of AVP function since even a mild, transient vasovagal reaction induced by the simple act of drawing blood from an anxious subject can result in massive release of the hormone that elevates plasma levels for hours.

The principal if not the only important action of AVP in humans is to reduce the rate of urinary water excretion by increasing its concentration (**Fig. 2**, left panel). The increase in urine osmolarity is achieved by selectively promoting the reabsorption of water from dilute filtrate as it passes through the collecting ducts of the kidney (**Fig. 3**) (Bichet, 2012).

When plasma AVP is very low, typically less than 0.5 pg /mL, the luminal membranes of the cells lining the collecting ducts are impermeable to water. Hence, the large volume of dilute filtrate that is not reabsorbed in the proximal nephron flows unmodified through the collecting ducts to be excreted as urine. In this condition, known as a water diuresis, the volume of urine output is very high (500–1000 mL/h depending on the solute load) and its concentration or osmolarity is very low (30–60 mOsm/L). At these rates of water excretion, it is nearly impossible to drink and retain enough water to reduce the osmolarity of body fluids below the normal range. Hence, the capacity to suppress AVP secretion and maximally dilute the urine provides a powerful barrier to over-hydration. When plasma AVP rises, it binds to receptors, designated AVPR-2, located on the serosal surface of cells lining the collecting ducts (**Fig. 3**). This binding increases the production of a substance known as cyclic AMP which then stimulates the

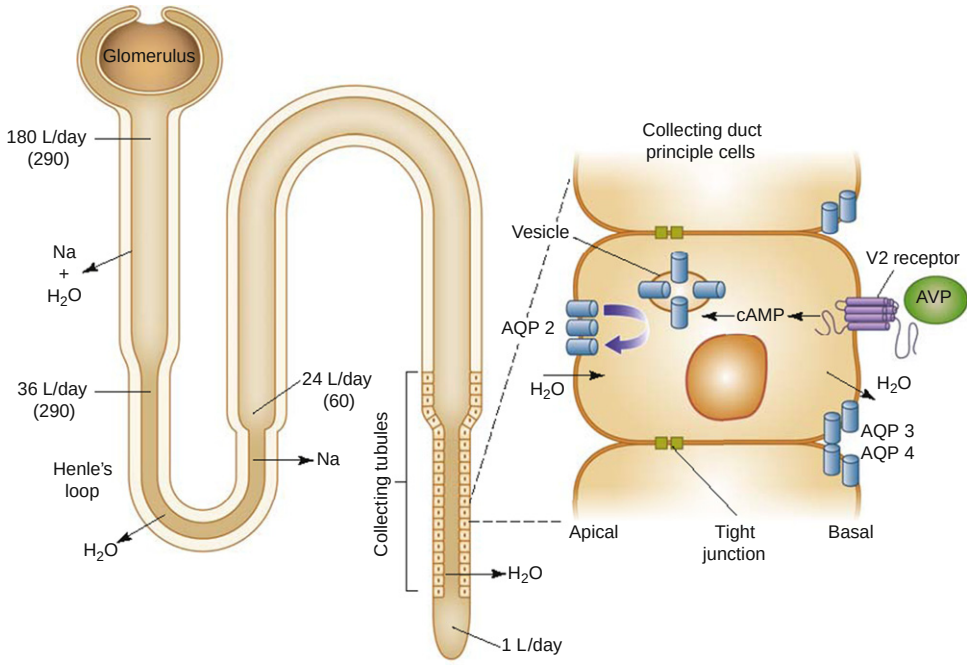

Fig. 3 Schematic diagram of a renal tubule showing the formation of urine by filtration of blood and reabsorption of water and solutes at different parts including the principle cells in the collecting tubules where AVP acts to regulate the rate of water reabsorption (Hay, 1996; Knepper, 1997; Bichet, 2012).

translocation and production of a protein, aquaporin-2 (AQP2), the production of which is directed by a gene on chromosome 12q13. The molecules of AQP2 associate into groups of four to form water channels that fuse with membranes on the side of the cell facing the lumen of the collecting duct. The insertion of these channels permits water to passively diffuse back from the lumen through the cell into the hypertonic environment of the renal medulla and thence back into the body. The fluid that remains in the collecting duct is excreted as urine that is more concentrated and smaller in volume than in the absence of AVP. AVP also acts via AVPR2 to stimulate readsorption of urea in the terminal inner medullary collecting ducts, thereby increasing the magnitude of urine concentration by enhancing the hypertonicity of the renal medulla. The magnitude of this antidiuretic effect varies as a function of plasma AVP (**Fig. 2**, left panel). In healthy adults, plasma AVP concentrations in the range of 2–4 pg/mL raise urine osmolarity to levels ranging from 900 to 1400 mOsm/L and reduce urine flow to less than 50 mL/h, the maximum levels of antidiuresis permitted by the hypertonicity of the renal medulla. This capability serves to minimize the amount of body water that must be excreted to eliminate solutes such as sodium, chloride, and urea. However, it does not completely prevent water loss from the kidneys and has no effect on evaporation from skin or lungs. Hence, some other mechanism to ensure replacement of these obligatory water losses is essential.

Thirst

In health humans, thirst is the principal mechanism for ensuring that water intake is always sufficient to replace obligatory losses from kidneys, skin, and lungs. It is regulated by hypothalamic osmoreceptors in much the same way as AVP. The only difference is that the osmotic threshold for thirst seems to be "set" slightly higher (5–15 mOsm/L) than that for AVP release. Thus, in a healthy adult, thirst is usually not stimulated until plasma osmolarity rises to a level at which AVP secretion is sufficient to produce a maximum antidiuresis. This arrangement ensures that the antidiuretic mechanism serves as the first line of defense against hypertonic dehydration and thirst provides essential backup protection that comes into play whenever the water ingested with food and provided by fat metabolism is insufficient to replace minimum obligatory losses. The thirst mechanism is normally so effective in this regard that, if an adequate supply of potable water is available, it increases intake sufficiently to keep plasma osmolarity and sodium within the normal range even when urinary output is abnormally high due to a defect in AVP secretion or action.

Pathophysiology

Pituitary Diabetes Insipidus

When the capacity of the posterior pituitary to secrete AVP is reduced by 80% or more, urinary osmolarity falls below that of plasma and the rate of excretion rises. The polyuria, in turn, reduces body water and raises plasma osmolarity and sodium thereby stimulating thirst and an increase in fluid intake that compensates for the loss of body water and keeps plasma osmolarity/sodium within the normal range (Christensen and Robertson, 2012). However, if anything intervenes to prevent the increase in fluid intake for even a few hours, plasma osmolarity and sodium rise, delivering a stronger osmotic stimulus for both thirst and AVP release. If the loss of secretory capacity is severe (greater than 90%), the increase in osmotic stimulation has little or no effect on plasma AVP or urine osmolarity. Hence, the polyuria persists, the deficit in body water increases and plasma osmolarity and sodium rise to abnormally high levels. However, if the reduction in secretory capacity is less severe, the increase in osmotic stimulation caused by fluid deprivation produces a rise in plasma AVP that is subnormal but still sufficient to concentrate the urine, sometimes to near maximum levels. This condition, known as partial pituitary DI, is difficult to distinguish from primary polydipsia and partial nephrogenic DI by traditional fluid deprivation tests. Hence, some other approach to differential diagnosis is needed (see below).

The causes of pituitary DI are numerous, varied and often undetermined (**Table 1**). About half are attributable to acquired, congenital or genetic disorders. The acquired forms are usually due to trauma or diseases involving the brain and occur at any age. The congenital forms are due to various brain malformations that result in hypogenesis of the posterior pituitary and DI from birth. The genetic forms can be transmitted in an autosomal dominant, autosomal recessive or X-linked recessive manner. The autosomal dominant form is the most common. It is due to mutations of the AVP–neurophysin-2 gene that interfere with processing of the precursor causing it to accumulate and eventually destroy the neuron. The DI develops gradually, usually a few months or years after birth but sometimes later. The autosomal recessive forms appear to be rare. One is due to a mutation in AVP moiety of the precursor that results in production of a biologically inactive form of the hormone. In the homozygous state, it causes pituitary DI that manifests early in life. Two other forms are due to mutations in the AVP–neurophysin-2 precursor that interfere with its production and cause early onset DI in the homozygous state. Pituitary DI also develops at some stage in many patients with Wolfram syndrome, an inherited disorder commonly known as DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, deafness, and other degenerative neurological disorders). It is caused by recessive mutations in the WFS1 gene on chromosome 4. One family in which pituitary DI is inherited in an X-linked recessive manner has also been reported in preliminary form. It causes DI in males but not in obligate female carriers. The mutation responsible co-segregates with markers for Xq28 but has not yet been identified. In the remaining patients, almost half, the cause of the pituitary cannot be determined and they are classified as idiopathic.

Autosomal recessive
Inactivating mutation of AVP
Nonsynthesis of AVP-NP
WFS1 (DIDMOAD)
X-linked recessive
Mechanism unknown

Gestational Diabetes Insipidus

A decline in plasma AVP due to increased degradation of the hormone by an enzyme produced in the placenta results in a series of changes similar to those in pituitary DI (Durr, 1987; Barron, 1987). The laboratory findings differ only in that plasma osmolarity/sodium tends to be 1%–2% lower than in pituitary DI because the osmotic thresholds for thirst and AVP secretion are also reduced during pregnancy. The natural history differs from that in a pregnant patient with preexisting pituitary DI in that gestational DI begins during pregnancy, usually in the second trimester, and remits spontaneously 4–6 weeks after delivery of the placenta. There may also be a form of gestational DI that is caused by renal resistance to the antidiuretic effect of AVP during pregnancy. Differentiating between the two forms may be difficult. Assay of plasma AVP is problematic because pregnant plasma contains the enzyme that rapidly degrades the hormone in vitro, necessitating special precautions in sample collection. Evaluating the antidiuretic effect of a therapeutic trial of AVP is unreliable for the same reason. However, a therapeutic trial of standard doses of desmopressin, a synthetic analogue of vasopressin, may differentiate because it is more resistant than AVP itself to degradation by the enzyme. Thus, it is fully effective in controlling the DI if is due solely to increased degradation of the natural hormone but may be less effective if decreased renal sensitivity is the cause.

Although the primary cause of gestational DI is increased destruction of AVP by an enzyme made in the placenta, an underlying subclinical defect in secretory capacity appears to contribute in some patients. In at least one of these patients, the subclinical deficiency in AVP secretion was attributed to damage caused by prior treatment for a prolactinoma of the anterior pituitary.

Nephrogenic Diabetes Insipidus

Decreased renal sensitivity to the antidiuretic effect of AVP results in a series of changes similar to those in pituitary DI (Bockenhauer and Bichet, 2015). Urine osmolarity falls and the rate of excretion increases resulting in a decrease in body water and a slight rise in plasma osmolarity/sodium. The latter, in turn stimulates thirst which, if an unlimited supply of potable water is available, produces an increase in water intake that prevents overt dehydration. The main difference is that, in nephrogenic DI, plasma AVP is normal or elevated instead of low or undetectable relative to the concurrent level of plasma osmolarity/sodium. If fluid intake is restricted, body water decreases, and plasma osmolarity/sodium rise providing an even stronger stimulus to thirst and AVP secretion. The effect of the further rise in plasma AVP varies widely, depending on the

severity of the defect in renal sensitivity. If it is severe, the large increases in plasma AVP produced by fluid restriction have little or no effect on urine concentration. Hence, the deficit in body water increases and plasma osmolarity/sodium rise to abnormally high levels that vary depending on the duration of the restriction on intake. However, if the reduction in renal sensitivity to AVP is less severe, the rise in plasma AVP produced by fluid deprivation results in concentration of the urine, sometimes to near maximum levels. This condition, known as partial nephrogenic DI, is difficult if not impossible to distinguish from partial pituitary DI and primary polydipsia DI by traditional fluid deprivation tests. Hence, some other approach to differential diagnosis including assay of plasma AVP and magnetic resonance imaging (MRI) of brain is usually necessary (see below).

The causes of nephrogenic DI are also numerous but distinctly different from those of pituitary DI (**Table 2**).

The acquired forms of nephrogenic DI can occur at any age, are often caused by drugs or a metabolic disorder, vary in severity and may remit if the offending drug or condition is eliminated. The genetic forms manifest at birth, are caused by many different mutations of the genes that encode the AVP2 receptor or the AQP2 water channels and rarely if ever remit. However, the severity of the DI sometimes declines with aging. Over 200 different AVPR2 gene mutations have been identified. They usually occur in the trans-membranous portion of the receptor protein, impair receptor function by a number of different mechanisms and produce either a severe or partial defect in the antidiuretic response to AVP. The recessive AQP2 mutations also tend to occur in the trans-membranous portion of the protein. They impair the ability to join with other molecules to form water channels and move to the surface of the cell. They almost invariably result in a severe defect in antidiuresis. The dominant AQP2 mutations, on the other hand, alter the C-terminal portion of the protein causing most of the water channels to be misrouted to the wrong surface of the principal cell resulting in a less severe and partial defect in antidiuretic function.

Primary Polydipsia

Abnormal thirst or any other motivation for increased fluid intake produces a sequence of changes that are the reverse of those in pituitary or nephrogenic DI. The increase in fluid intake expands body water, slightly reduces plasma osmolarity/sodium, and suppresses AVP secretion to low levels (<0.1 pg/mL) indistinguishable from those in pituitary DI. The suppression of AVP, in turn, reduces urine concentration and increases urinary water excretion, thereby compensating for the increased water intake. The clinical picture differs from pituitary and nephrogenic DI only in that basal plasma osmolarity/sodium tends to be slightly lower in primary polydipsia but the overlap between the three disorders is considerable owing to individual differences in the set and

sensitivity of the osmoregulatory system. The only exception occurs in severe psychogenic polydipsia in which the rate of water intake is often so enormous that the kidneys cannot keep pace and frank hyponatremia develops. Administering desmopressin or AVP to a patient with primary polydipsia also produces hyponatremia making it very important to differentiate between the three disorders before embarking on treatment.

There are three causes or types of primary polydipsia. One is psychogenic (Barlow and De Wardener, 1959). It does not appear to be due to abnormal thirst but to a psychological or cognitive defect such as schizophrenia or obsessive compulsion. A second type, possibly related, may be termed iatrogenic since it seems to be motivated by a belief, wide spread on the internet, that a high fluid intake improves health. The third type of primary polydipsia appears to be motivated by abnormal thirst (Robertson, 1987). It is termed dipsogenic DI and has been observed in association with head trauma, lithium treatment, or certain acquired diseases of the brain including sarcoidosis, tuberculous meningitis, and multiple sclerosis. Like pituitary DI, dipsogenic DI is often idiopathic. Genetic forms have not been reported.

Diagnosis

When symptoms or signs such as urinary frequency, enuresis, nocturia, or thirst suggest the possibility of DI, the diagnosis should be confirmed before embarking on studies to determine the type. This cannot be done reliably from a single voided urine sample because false positive or negative results are common owing to large differences in the severity of the antidiuretic defects and other variables that impact urine production in the course of a normal day. Therefore, it is best to collect, pool, and test all the urine excreted over a 24 h period when the food and fluid intake are unrestricted. If the collection has a volume greater than 40 mL/kg body weight, an osmolarity of less than 300 mOsm/L and does not contain glucose, the diagnosis of DI is established and the evaluation should continue to determine the type. For this purpose, inquiries about the duration of symptoms as well as any injuries, disorders, or treatments prior to the onset of DI and a family history is often helpful. Plasma osmolarity and/or sodium should be measured to detect the rare patient with severe dehydration or over-hydration. In most cases, however, they are of little help in differential diagnosis because the values found in pituitary DI, nephrogenic DI, and primary polydipsia overlap extensively within the normal range.

Except in the rare patient who presents with hypernatremia under basal conditions, the traditional method of differential diagnosis is a fluid deprivation test. There are several versions of this procedure but the basic principle in all of them is to determine if with-holding fluids results in concentration of the urine *before* plasma osmolarity/sodium rise above the normal range. If it does not, primary polydipsia is excluded and AVP or its analogue desmopressin can be given to determine if it results in concentration of the urine. If it does, the DI is due to a severe deficiency in production of the hormone (pituitary DI). If it does not, the DI is due to severe defect in the antidiuretic effect of the hormone (nephrogenic DI). This test is simple in concept but has certain difficulties in practice that limit if not discourage its use. One is the need for constant close monitoring by well-trained medical, nursing, and laboratory staff for periods of 3–6 h or even longer. Another is the often intense discomfort of the patient due to thirst. But the most significant problem with the procedure is that the findings cannot be interpreted reliably if fluid deprivation alone results in concentration of the urine. That result, which is relatively common, is consistent with either primary polydipsia, partial pituitary DI, or partial nephrogenic DI. Some differentiation between them is possible if low doses of AVP or desmopressin are given and the percent increase in urine osmolarity is considered. Often, however, the results still not correlate well with other evidence or the response to therapy.

The development of a sensitive and specific assay for plasma vasopressin made it possible to differentiate more reliably between primary polydipsia, partial pituitary DI, and partial nephrogenic DI. When used in conjunction with the fluid deprivation/hypertonic saline infusion test, plotting the plasma AVP assay values in relation to the concurrent plasma and urine osmolarity permits a clear distinction between the three types of DI (**Fig. 4**).

For best results, the measurements of plasma AVP should be made when plasma osmolarity/sodium is raised above the normal range. Since this level of hypertonicity is often difficult to achieve by fluid deprivation alone when urinary concentration occurs, it is usually necessary to follow it with an infusion of 3% saline (0.1 mL/kg/min for 60–90 min) and repeat the AVP assay when plasma osmolarity/sodium reach the requisite levels at or above 295 mOsm/L and 145 mEq/L. While this method permits reliable differentiation between primary polydipsia, partial pituitary DII, and partial nephrogenic DI, it is even more involved and demanding of the time of trained staff, especially when the infusion of 3% saline is required. It also requires an AVP assay of extraordinary sensitivity and specificity. These requirements have severely limited the availability of an immunoassay suitable for diagnostic purposes. Therefore, a simpler much less demanding method of differential diagnosis is required if it is to be employed more widely in clinical medicine.

A new, much easier but equally reliable method of differential diagnosis has evolved in recent years (Robertson, 2016). It also entails the assay of plasma AVP but the requirements for sensitivity and specificity are slightly less stringent, the sample can be collected almost anytime under basal conditions of ad libitum fluid intake and the results can be interpreted with reference only to the concurrent urine osmolarity. If plasma AVP is clearly normal or elevated (≥ 1 pg/mL) when urine osmolarity is low (<300 mOsm/L), pituitary DI, and primary polydipsia are excluded and the cause of the DI is renal insensitivity to the antidiuretic action of the hormone (nephrogenic DI). No other diagnostic procedure is required other than a search for the cause. However, if plasma AVP is undetectable (<0.5–1 pg/mL), nephrogenic DI is very unlikely and an MRI of the brain without infusion can determine if the DI is due to a primary defect in the production of AVP (pituitary DI) or suppression of AVP secretion by excessive

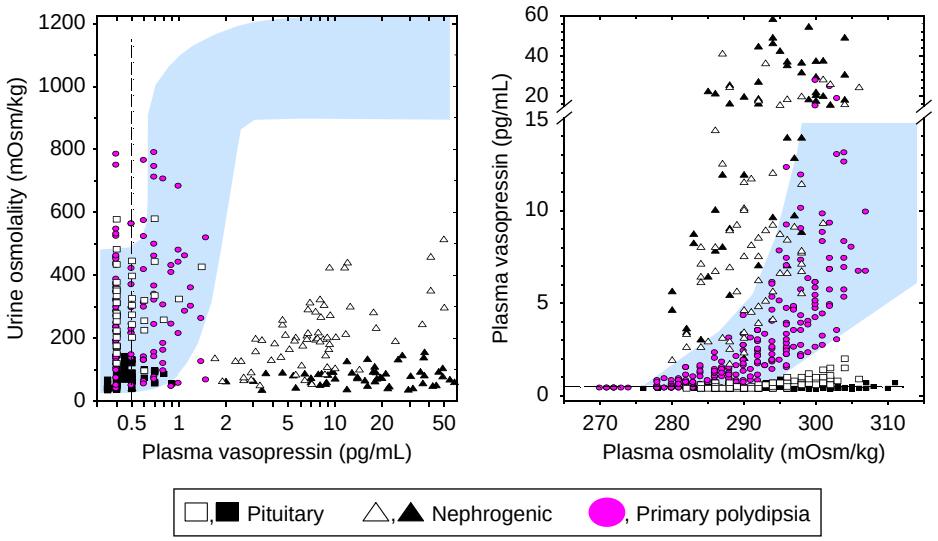

Fig. 4 Relationship of plasma vasopressin to the concurrent plasma osmolarity (right) and urine osmolarity (left) in healthy adults (*blue shaded* areas) and three types of DI. Plasma osmolarity was raised above 295 mOsm/L by fluid deprivation followed, when necessary, by infusion of hypertonic saline for 60–90 min. *Open* and *closed squares* indicate values in patients with severe and partial pituitary DI, respectively. *Open* and *closed triangles* indicate severe and partial nephrogenic DI. *Purple symbols* represent patients with primary polydipsia.

intake of fluids (primary polydipsia). Presence of the hyperintense signal (bright spot) normally emitted by the posterior pituitary on T1 weighted mid-saggital images indicates the gland is intact and the low plasma AVP levels are due to suppression by excessive fluid intake (primary polydipsia). On the other hand, absence or diminution of the bright spot indicates the low plasma AVP levels are due to impaired production of the hormone (pituitary DI). The posterior pituitary bright spot is also absent or feint in nephrogenic DI, probably as a result of hypersecretion and reduced stores of AVP. However, it is easily distinguished by elevated levels of plasma AVP under basal conditions. There are two potential sources of error in this method of differential diagnosis. One is confusion of the bright spot with the signal emitted by fat in the marrow of the dorsum sella. This problem can be reduced by use of fat suppression techniques with the MRI. The other potential problem is empty sella. It is usually associated with small or absent bright spot even if AVP secretion is normal. Therefore, if a patient with DI has empty sella, the functional state of the posterior pituitary cannot be reliably assessed by MRI and definitive diagnosis may require another approach such as repeat measurement of plasma AVP after a suitable stimulus such as hypertonic saline infusion.

As noted above, ordinary measurements of plasma AVP cannot be used to determine the mechanism of gestational DI owing to the presence of enzymes that rapidly destroy the hormone during sample collection. In this setting, assessing the antidiuretic effect of standard therapeutic doses of the AVP analogue, desmopressin, may suffice to differentiate renal insensitivity from a deficiency of the hormone.

Management

The first objective in the management of DI is to eliminate or at least reduce the symptoms of polyuria and polydipsia. In pituitary and gestational DI, this can be achieved by treatment with desmopressin acetate (dDAVP, Ferring), a synthetic analogue of AVP that is more resistant to degradation and has less vascular and other smooth muscle effects than the native hormone (Oisoi *et al.*, 2013). It is formulated for administration orally (po), intranasally (in), subcutaneously (sq), intramuscularly (im), or intravenously (iv). The optimum doses of desmopressin vary considerably due to individual differences in bioavailability and elimination. In an adult, they range from 50 to 200 mg po, 5–20 mg in, or 1–2 mg iv or sq. two to three times per day as needed to maintain the 24 h urine osmolarity and volume within the normal range–that is, from 400 to 800 mOsm/L and 15–30 mL/kg body weight. The resultant decrease in water excretion produces a small, 1%–2% increase in body water and a commensurate decrease in plasma osmolarity/sodium that reduces thirst and water intake, thereby maintaining water balance. Plasma osmolarity/sodium should be checked within a day or two of starting treatment and periodically thereafter to verify that they remain within the normal range. Desmopressin should not be given in a dose large enough to produce maximum antidiuresis "around the clock" because it may fix urine output below the level required to excrete all the water consumed in a normal diet even when thirst is completely suppressed. For the same reason, during desmopressin therapy, fluid intake should be limited to the amounts needed to satisfy thirst. Drinking for social or other reasons should be avoided because an increase in body water does not produce a compensatory increase in urine output when the level of antidiuresis is determined solely by the dose and frequency of desmopressin treatment. If following these guidelines does not prevent recurrent episodes of hypoosmolar hyponatremia,

consideration should be given to discontinuing therapy and undertaking more detailed diagnostic studies to rule out some form of primary polydipsia.

The treatment of nephrogenic DI differs from that of pituitary and gestational DI. In 5- to 10-fold higher doses, desmopressin may be effective if the insensitivity to AVP is partial as it is in many patients. However, the expense and inconvenience of this approach to therapy makes it impractical for long term use. When nephrogenic DI is caused by exposure to a drug such as lithium or demeclocycline or to a metabolic disorder such as hypercalcemia or hypokalemia, eliminating the drug or correcting the imbalance may also eliminate the defect at least if it has been present for no more than a year or two. If nephrogenic DI is of longer duration or is due to genetic mutation, other treatments may be used to reduce if not eliminate the polyuria, thirst, and polydipsia. In standard doses, thiazide diuretics have a paradoxical effect to increase urine osmolarity and reduce urine output and fluid intake in nephrogenic DI. This effect is the result of two related mechanisms; interference with the readsorption of sodium in the ascending limb of Henle's loop, which reduces urinary dilution followed by a compensatory increase in sodium reabsorption in the proximal tubule, which reduces urine volume by about 50%. The thiazides also produce potassium loss and hypokalemia which itself produces nephrogenic DI but this effect can be avoided by giving potassium supplements with the diuretics. Prostaglandin synthetase inhibitors such as indomethacin also reduce polyuria and polydipsia in nephrogenic DI. When given with a thiazide diuretic, the combination usually reduces urine output by about 75% and in some cases normalizes it completely. As in pituitary DI, reducing polyuria in nephrogenic DI also reduces the slight deficiency in body water, thereby decreasing the osmotic stimulus to thirst and polydipsia and keeping water balance within the normal range. Hyponatremia is rare.

The treatment of primary polydipsia differs completely from that of pituitary, gestational and nephrogenic DI. Desmopressin or any other medication that reduces urine output is contraindicated because these drugs have little or no effect on the excessive water intake that is the cause of the disorder. Consequently, reducing water excretion produces water intoxication, a syndrome that manifests as hyponatremia accompanied by symptoms and signs of confusion, headache, nausea, vomiting, coma, convulsions, and even death. If the polydipsia is motivated by a belief in the health giving value of drinking more water (iatrogenic), it can sometimes be cured by patient education. However, there is no documented way to reduce the polydipsia if it is motivated by abnormal thirst (dipsogenic) or a psychiatric disorder (psychogenic). In these conditions, the only help that can be provided is to try to minimize the risk of severe water intoxication by warning the patient and/or caregivers of the many drugs and diseases that can induce it and of the early signs and symptoms that should prompt them to seek immediate medical care.

The other objective in the management of DI is to try to determine the cause. In many cases it is obvious from the clinical setting but in others it can be ambiguous or misleading. For example, head trauma or certain infiltrative diseases of the brain can be associated with either pituitary DI or dipsogenic DI and lithium therapy can cause either nephrogenic DI or dipsogenic DI. Therefore, a careful search including a family history, physical examination, routine laboratory tests and, depending on the type of DI, an MRI of the brain should be undertaken. If these investigations are unrevealing, appropria1te genetic analyses should be undertaken, particularly if the DI dates from birth or the first few years of life, because absence of a family history does not rule out a recessive or de novo mutation.

John J Kopchick, Ohio University, Athens, OH, United States

Glossary

ADAM Acronym for "a disintegrin and metalloproteinase"; designates a family of zinc-dependent metalloproteinases involved in proteolytic modulation at the cell surface and in the extracellular matrix.
Growth hormone (GH) A pituitary hormone important for somatic growth, development, metabolism, and body composition.
Insulin-like growth factor 1 (IGF-1) Mediator of many actions of growth hormone.
Pituitary gland A master hormone gland located at the base of the brain and serving as the interface between the brain and peripheral hormone glands.
Somatotropin Synonym for growth hormone.
TACE A membrane-resident protease, also known as ADAM 17, cleaves ectodomains from several transmembrane proteins.

Introduction

Growth hormone (GH) is a pituitary hormone that serves as the master anabolic hormone during postnatal life. It is also known as somatotropin, perhaps a better name since GH has many actions beyond the promotion of body growth. GH is evolutionarily conserved from shark to humans. It is a polypeptide hormone whose primary structure varies among species while maintaining an overall physical similarity. A special feature is the so-called one-way species specificity, a term indicating that primate GH is biologically active in most if not all vertebrates, whereas nonprimate GH is biologically inert in primates, including humans. Minor differences in biopotency exist among the GHs of other species. Because description and discussion of all the chordate GHs are beyond the scope of this article, the principal focus is on human GH (hGH), one of the best studied GHs. A treatise on hGH is applicable to many other GHs because GH biology and action is similar among species despite structural differences in the hormone. Where applicable, important species differences are discussed.

The hGH Gene Cluster

In humans, there are two GH genes, *GH1* and *GH2*, located on the long arm of chromosome 17 (17q22–q24) (Baumann, 2009, 1991). They form part of a cluster of GH-like genes thought to arise by gene duplication that also includes two chorionic somatomammotropin (*CS* or *PL* [placental lactogen]) genes and a *CS* pseudogene. This 67-kb gene cluster consists of *GH1*, *CSHL1*, *CSH1*, *GH2*, and *CSH2* in a 5′ to 3′ orientation (*GH1* is also known as *GH-N*, and *GH2* is also known as *GH-V*). Each of these genes is composed of five exons and four intervening sequences. *GH1* is expressed in the pituitary (somatotrope cells), and the other members of the gene cluster are expressed in the placenta (syncytiotrophoblast). Thus, GH2 is also called placental GH. The intergenic DNA regions between the members of the cluster are highly homologous, rendering them vulnerable to gene deletions due to recombination.

GH Structure

Mature hGH, in its principal molecular form, is a 22-kDa, 191-amino acid, single-chain polypeptide with two intramolecular disulfide bridges. Its tertiary structure is that of a twisted bundle of four α-helices akin to the overall structure of many cytokines. GH contains two distinct receptor-binding epitopes (site 1 and site 2) allowing it to interact with the extracellular region of two GH receptors (GHR) in a dimerized complex (Gent *et al.*, 2003, 2002).

☆*Change History*: October 2017. Rikke Hjortebjerg, Gerhard Baumann, and John J Kopchick updated the section "Medical therapy in acromegaly" and "Further reading." Added "Figure 1" and "References" and minor grammatical errors have been corrected.

This chapter is an update of Gerhard Baumann, Growth Hormone (GH), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 383-389.

 doi:10.1016/B978-0-12-801238-3.98499-X

GH Isoforms

Several molecular forms of hGH exist (Baumann, 2009). The most abundant form (except during pregnancy) is pituitary GH1, also known as GH-N or 22-kDa GH. GH2 (also known as GH-V or placental GH) differs from pituitary GH1 at 13 of the 191 amino acid residues. In addition, GH2 contains an N-linked glycosylation site, and indeed, GH2 exists as both a glycosylated and a nonglycosylated form. During pregnancy, placental GH progressively supplants pituitary GH in the maternal circulation. The *GH-1* gene also generates an internally deleted GH (lacking 15 internal amino acids and named 20-kDa GH) through alternative mRNA splicing. A secondary or cryptic splice acceptor site within exon 3 is used for that purpose. This 20-kDa variant accounts for 5%–10% of GH production. A second postulated splice variant arises from complete exon 3 skipping, owing to the relatively weak splice donor site in intron 3. Although the mRNA for this so-called 17.5-kDa GH has been demonstrated, it is not entirely clear whether the corresponding protein is produced in significant amounts in normal individuals. Additional GH molecular variants arise from posttranslational processing. These include glycosylated (especially placental GH), acetylated, deamidated, and (in some animals) phosphorylated GHs. Further molecular heterogeneity results from oligomeric GH forms (up to at least pentameric GH), with both noncovalently associated oligomers and disulfide-linked oligomers. The biological roles of the GH variants are largely unknown. They vary in biological activity, with monomeric 22-kDa GH1 and GH2 being the most biologically active.

Regulation of GH Production and Secretion

Expression of the *GH1* gene in pituitary somatotropes is positively regulated by GH-releasing hormone (GHRH), glucocorticoids, and (in rodents) thyroid hormones (Gunawardane *et al.*, 2000). It is negatively regulated by insulin-like growth factor-1 (IGF-1) and somatostatin. GHRH is also very important for normal somatotrope cell proliferation during pituitary development. GH is stored in secretory granules and released in response to GHRH; its release is inhibited by somatostatin. Ghrelin or related GH secretagogues, in pharmacological amounts, are potent releasers of GH, but the physiological role of ghrelin in GH regulation appears to be minor at best. The various GH isoforms appear to be cosecreted, and no isoform-specific stimulus has been identified.

GH secretion is under complex hypothalamic control by at least two hypophysiotropic hormones: GHRH (stimulating) and somatostatin (inhibitory) (Gunawardane *et al.*, 2000; Giustina and Veldhuis, 1998). GH secretion is pulsatile, with a marked ultradian rhythm of pulses of widely varying amplitude occurring every 1–2 h. The highest secretory pulses are linked to slow wave sleep and typically occur during the first 2 h after sleep onset. However, major pulses can also occur at other times due to stimuli such as stress, exercise, pain, and other acute events. Feedback inhibition of GH secretion is provided by IGF-1 as well as by GH itself. Daily GH production is high and largely unregulated during fetal and neonatal life, falls after birth under the regulatory influence of IGF-1, is again high during puberty, and falls progressively thereafter by about 15% per decade. Physiological and metabolic regulators of GH secretion are nutrition, estrogen (stimulatory), glucocorticoids (the inhibitory effect at the hypothalamic level predominates over the stimulatory effect at the pituitary level), and thyroid hormone (stimulatory, especially in rodents) (Giustina and Veldhuis, 1998). In humans, undernutrition stimulates GH production, whereas overnutrition dampens GH production (the opposite is generally true in rodents). There is marked sexual dimorphism in the GH secretory rhythm, with women showing generally higher values, higher basal secretion, and more "noisy" circadian profiles. This difference can be largely attributed to an estrogen effect. In rats, the male secretion pattern is characterized by very high pulses interrupted by nearly complete quiescence, whereas the female secretion pattern is characterized by lower pulses but higher tonic secretion between pulses.

In contrast to this complex regulation of GH production in the pituitary gland, the expression and secretion of placental GH during pregnancy appear to be constitutive and largely unregulated.

The GHR- and GH-Induced Signal Transduction

The GHR is a 620-amino acid single-chain glycoprotein that belongs to the family of cytokine receptors. It has a large, 246-residue extracellular domain, a single-transmembrane domain, and a 350-amino acid cytoplasmic domain. The extracellular ectodomain is folded into two subdomains; the amino-terminal subdomain 1 contains the GH binding site, and the carboxy-terminal subdomain 2 is involved in receptor dimerization. A short ($\sim$10 residue) linear stem region between subdomain 2 and the transmembrane domain serves as the substrate for enzymatic cleavage that, in humans, yields the circulating GH binding protein (GHBP) (Baumann, 2001; Cunningham *et al.*, 1991; Kelly *et al.*, 1991; Wang *et al.*, 2002). The cytoplasmic domain contains several features involved in GH-induced signaling. Among those, a membrane-proximal proline-rich region (Box 1) is most important; it serves as a docking site for Janus kinase 2 (JAK2). Another important region in the cytoplasmic portion is the internalization domain.

The single *GHR* gene resides on the short arm of human chromosome 5 (5p13–p12), spans 298 kb, and consists of 10 exons, of which exons 2–10 encode the protein (Baumann, 2001). The 22-residue portion encoded by exon 3 is not necessary for function, and inclusion or exclusion of exon 3 occurs as a form of *GHR* polymorphism. Several alternative exons 1 can be used to express the GHR in a tissue- or metabolic state-specific manner. Two truncated splice variants of the GHR are known; they lack most of the cytoplasmic domain, represent a small part ($\sim$1%–5%) of the total GHR complement, and have an unknown function. The GHR is expressed ubiquitously, although the level of expression varies among tissues. The liver is the tissue with the highest GHR content.

Signal transfer along single-transmembrane cell-surface receptors is not well understood. It has long been thought that these receptors, such as the GHR, are activated by ligand binding through ligand-induced dimerization of the receptors (the "dimerization model") (Uchida *et al.*, 1999). Thus, GH would bind to a GHR monomer and prompt dimerization by recruiting a second GHR monomer. However, evidence now suggests that prior to ligand binding, the GHR exists predominantly as a constitutively dimerized, yet inactive, homodimer (Gent *et al.*, 2003, 2002). It is believed that GH interaction with the preformed GHR dimer induces a conformational repositioning, which allows for one receptor subunit to rotate relative to the other, the so-called rotation model (Brown *et al.*, 2005; Brooks and Waters, 2010; Waters *et al.*, 2006). The rearrangement of the intracellular domains unmasks the catalytic parts of adjacent JAK2 molecules, which are constitutively associated with the cytoplasmic GHR Box 1 motif. The JAK2 molecules are activated by transphosphorylation and subsequently phosphorylate distal cytoplasmic tyrosine residues on the GHR, which enables Src homology 2 (SH2) domain molecules, such as signal transducer and activator of transcription (STAT), to dock to these sites (Wang *et al.*, 1996). The STAT pathway has been regarded the most prominent, with STAT-5b in particular being an important mediator of the biological effects of GH. Following tyrosine phosphorylation by JAK-2, STAT-5b molecules dimerize and translocate to the nucleus where they bind DNA and regulate gene transcription. However, GHR activation also results in activation of Src family kinases (SFK) independent of JAK2. SFK activates the mitogen-activated protein kinase (MAPK) pathway through phospholipase Cγ/protein kinase C (PKC) and probably other signaling pathways (Herrington and Carter-Su, 2001; Lanning and Carter-Su, 2006).

The various pathways may subserve different components of the GH bioactivity spectrum. The growth-promoting/IGF-1-generating action is primarily mediated by signaling through the JAK2 pathway, whereas some metabolic activities are mediated by signaling through PI3K. A whole host of genes are activated or deactivated in response to GH-induced signaling. Among those best recognized are serine protease inhibitor 2.1 (Spi 2.1), c-Fos, and IGF-1. GH-induced signaling also has nongenomic effects in some cultured cells, such as enhanced glucose transport.

GH-induced signaling is negatively regulated by several mechanisms to prevent runaway cellular stimulation, with some acting in a classic feedback loop. Suppressors of cytokine signaling (SOCS) proteins and cytokine-inducible SH2 (CIS) proteins facilitate downregulation and termination of GHR activation by various unique mechanisms. Additionally, activation of phosphatases, GHR downregulation through GHR internalization, and perhaps GHR inactivation by proteolytic GHR decapitation are involved in termination of the GHR signal cascade.

Blood Transport of GH

GH circulates in blood partly bound to two different GHBPs. The principal carrier is the high-affinity GHBP that corresponds to the soluble ectodomain of the membrane-anchored GHR, and because of its origin, GHBP binds GH with similar affinity as the GHR (Baumann and Frank, 2002). In humans and many other species, the GHBP is produced by proteolytic cleavage of the GHR homodimer in its juxtamembranous stem region (between 8 and 9 residues outside the membrane), with shedding of the ectodomain from the cell as the GHBP (Baumann, 1995; Baumann and Frank, 2002). The cleavage is mediated by tumor necrosis factor-alpha converting enzyme (TACE), a transmembrane zinc metalloproteinase also known as ADAM-17. TACE is activated by MAPK- and PKC-dependent pathways, and is responsible for cleavage of various transmembrane proteins. The regulation of TACE activity and ectodomain shedding is poorly understood. Recent studies have suggested that intracellular domain modifications of the predimerized GHR may lead to positional rearrangements in the extracellular domains that enable ectodomain cleavage. Thus, GHR predimerization may be a requirement for ectodomain shedding. The GHR remnant protein, consisting of the transmembrane and intracellular domain, is subject to additional processing and may have biological functions of its own.

In rodents, the GHBP is generated from the *ghr* gene as an alternative mRNA spliced product. Exon 8 of the *ghr* gene encodes a 30-amino acid transmembrane domain sequence specific to the receptor, as well as exon 9–10, which encode the intracellular GHR domain. The soluble GHBP contains the extracellular domain of the GHR, but has a unique hydrophilic tail, which is encoded by a GHBP-specific exon in the *ghr* gene, designated exon 8A. Differential splicing of exon 7 to either exon 8 or the interposed exon 8A yields the GHR or the GHBP, respectively.

Under basal conditions, approximately half of circulating GH is bound to GHBP. A minority of GH ($\sim$5%) is bound to another low-affinity GHBP that appears to correspond to a modified form of α_2-macroglobulin. The GHBPs prolong the plasma half-life of GH and act to provide a circulating GH reservoir. The plasma half-life of free 22 kDa GH in humans is about 10 min; elimination occurs primarily through glomerular filtration and GHR-mediated clearance. However, due to the large size of the GH/GHBP complex, overall clearance is lower than that of free GH, with a half-life of about 18 min. In addition to its role in the circulation, the GHBP acts as a local modulator of GH action by competing with GHRs for GH binding. Thus, at the local tissue level, GHBP acts primarily as an inhibitor of GH action.

Biological Actions of GH

Many, but not all, of the activities of GH are mediated by its second messenger, IGF-1 (Leroith *et al.*, 2001). IGF-1 is generated in response to GH in liver and many other target tissues. It is primarily responsible for the growth-promoting action, serving as both a mitogen and a metabolically active hormone. For some GH actions, it is still not clear whether they are mediated by IGF-1, by GH

directly, or by both. In fact, mouse growth has been attributed to distinct and overlapping actions of GH, IGF-1, and IGF-2 (Lupu *et al.*, 2001). **Table 1** lists the principal bioactivities of GH. The diverse manifestations of GH action are evident from the table. All tissues and organs are targets for GH action; hence, the term "somatotropin" describes this hormone more aptly than does the term "growth hormone." The most prominent net effects of GH actions in vivo are somatic growth, loss or maintenance of fat mass, muscle anabolism, increase or maintenance of bone mineral density, fluid retention, and insulin antagonism.

IGF and IGF-Binding Proteins

GH is the most well characterized regulator of the IGF system. The primary components of the IGF system include IGF-1 and IGF-2 that are structurally related polypeptides of about 7.5 kDa, and the IGF-1 receptor (IGF-1R), which shares homology with the insulin receptor and is ubiquitously expressed on most cell types (Hjortebjerg *et al.*, 2014; Hjortebjerg and Frystyk, 2014). IGF-1 is more GH dependent than IGF-2, and in humans IGF-1 is the main IGF involved in mediating GH action. IGF activity is strictly regulated by six high-affinity IGFBPs (1 to 6), which bind most of the circulating IGFs, thereby prolonging their half-life and modulating their ability to activate the IGF-1R. Foremost among those is IGFBP-3, which complexes the great majority of IGFs in a 150-kDa ternary complex composed of IGF, IGFBP-3, and the acid-labile subunit (ALS). Besides the IGFs, GH is a potent regulator of circulating IGFBP-3 and ALS. Insulin may be the second most important regulator of the IGF system and although GH and insulin are able to modulate the hepatic IGF-1 production independently, GH significantly regulates and influences the biological actions of insulin and vice versa. Several other IGFBPs are likely to be GH dependent. IGFBP-1 is the most metabolically regulated IGFBP and is the primary acute regulator of IGF-1. IGFBP-2 is also metabolically regulated, albeit not as rapidly as IGFBP-1. Both IGFBP-1 and -2 are inhibited by insulin, and evidence suggests that GH regulates them both either directly or indirectly (Hjortebjerg *et al.*, 2014).

Abnormalities in the GH/IGF Axis

Disease States and Treatments in Humans

GH Deficiency

GH deficiency can result from a variety of causes such as genetic defects, birth trauma, and organic lesions affecting the pituitary or the hypothalamus (Baumann, 2002). The most common cause is a pituitary or hypothalamic tumor resulting in destruction of somatotropes or GHRH-producing neurons as well as interruption of hypothalamo–pituitary communication. In patients with pituitary tumors, GH deficiency usually develops before the other pituitary hormones are compromised. Genetic causes include inactivating mutations in the *GH-1* gene, the *GHRH receptor* gene, or genes involved in pituitary development such as *PROP1*,

Table 1 Biological activities of GH

A. *Direct GH effects*
Lipolysis
Inhibition of lipogenesis
Prechondrocyte differentiation
Preadipocyte differentiation
Amino acid transport in muscle
Glucose transport (acute hypoglycemic effect, so-called insulin-like effect)
IGF-1, IGFBP-3 and ALS generation
Hypothalamic somatostatin secretion (short-loop feedback)
Milk production (human GH only)
B. *IGF-1 mediated effects*
Sulfate and thymidine incorporation into growth cartilage
Clonal expansion of chondrocytes
Linear bone growth
DNA and RNA synthesis
Renal Na and phosphate retention
C. *Unknown or combined GH/IGF-1 effects*
Nitrogen retention
Somatic growth[a]
Insulin antagonism
Beta cell hyperplasia
Erythropoiesis
Immune system stimulation

[a]Somatic growth involves not only bone elongation but also concomitant muscle and organ growth. Somatic growth is possible with IGF-1 alone, but differs both quantitatively and qualitatively from that induced by GH.

POU1F1 (PIT1), *HESX1*, *PITX2*, *LHX3*, and *LHX4* (Baumann, 2002). Deficiency of the placental GH appears to have no adverse effects on either mother or fetus, as has been learned from naturally occurring cases with a deletion of the *GH2* gene.

One relatively common type of GH deficiency in childhood is called "idiopathic," meaning that no cause is evident (Bang, 2011). In general, this is a diagnosis of exclusion in a child with poor growth and subnormal serum GH levels. The delineation between this entity and normal variation of growth patterns is difficult.

The clinical manifestations of GH deficiency depend, in part, on whether it develops during childhood or during adult life. Childhood GH deficiency is characterized by growth retardation, a feature that does not apply to adults. Other clinical manifestations of GH deficiency include moderately delayed puberty, childhood hypoglycemia, increased adiposity, osteopenia, decreased lean body mass, low exercise tolerance and stamina, extracellular volume depletion, impaired psychosocial functioning, and decreased quality of life. In humans, immune function is not sufficiently affected to be clinically relevant. Except for growth retardation and hypoglycemia, the manifestations of GH deficiency are relatively subtle and not readily recognized unless sought out specifically. Diagnosis is suspected in the proper clinical setting and is confirmed by the failure of serum GH to rise in response to standard pharmacological stimuli. Typical biochemical features include low levels of serum IGF-1, IGFBP-3, and ALS as well as an elevated level of IGFBP-2.

Treatment of children and adults with GH deficiency consists of replacement therapy with recombinant hGH (Baumann, 2002; Carroll *et al.*, 1998). Starting in 1960 in the US, hGH was extracted from cadaveric human pituitaries because there was no other source of GH that was biologically active in humans. Only children were recipients of this GH because supplies were limited by necessity. In 1985, after the occurrence of cases of Creutzfeldt–Jacob disease attributed to GH contaminated with prions, the use of cadaveric hGH was discontinued. The simultaneous arrival of recombinant human GH (rhGH) in unlimited quantities resulted in a universal switch to rhGH, and today, numerous pharmaceutical companies manufacture 22-kDa rhGH, which is highly effective despite lacking all the other GH isoforms that are normally produced by the pituitary. Availability of GH has enabled large-scale use of GH therapy in all patients with GH deficiency as well as conditions not associated with GH deficiency (e.g., chronic renal failure, Turner syndrome, intrauterine growth retardation, Prader–Willi syndrome, and idiopathic short stature). Indications for GH continue to expand beyond classical GH deficiency, and much has been learned about GH biology from the availability of large quantities of chemically defined, highly pure GH preparations as well as from clinical trials and more intense scrutiny of the manifestations of GH deficiency and the effects of GH replacement therapy.

GH treatment improves height, body composition, bone density, and overall life quality. GH is administrated daily and injected subcutaneously. Especially in children, the daily administration may be inconvenient and discomforting and lead to low compliance and adherence. This problem has fueled the search for GH agents with longer absorption profiles, longer half-lives, and alternative routes of administration. Numerous long-acting GH preparations have been invented and are under development, all displaying different pharmacodynamics (Borras Perez *et al.*, 2017). The early published data are promising, but an improvement compared to currently available options remains to be demonstrated. Furthermore, in view of the nature of the pulsatile GH secretion, the long-acting GH preparations may result in altered levels of circulating GH and IGF-1 that may uniquely affect GH's biological actions. More research in this area of long-acting GHs is required.

With an increase in the use of GH over the past decades, a concomitant increase in the potential safety concerns has occurred. The mitogenic and antiapoptotic activity of GH and IGF has primarily raised concerns regarding the risk of malignancy. Notably, the GH-induced signaling pathways are among the most important in most types of cancers, and numerous studies have provided evidence that the GH/IGF-1 axis may be involved in cancer development (Boguszewski *et al.*, 2016; Brooks and Waters, 2010). The concerns are further supported by findings in various GH mouse strains with increased or decreased cancer occurrence. However, thus far, rhGH treatment of GHD patients has shown to be safe, and despite theoretical worries, various studies have failed to consistently demonstrate a causal relationship between GH therapy and cancer development in patients. However, further work will continue in this area as the age of rhGH-treated patients increase.

GH Insensitivity

GH insensitivity or resistance shows a clinical picture that is similar, although not identical, to GH deficiency. In a GH insensitive state, there is no shortage of GH; rather, there is an inability of GH to promote its various actions. In humans, GH insensitivity results in Laron syndrome (LS) (Laron *et al.*, 1968, 1966), a genetic disorder caused by inactivating mutations in the *GHR* gene (Rosenbloom, 2016; Brooks and Waters, 2010; Rosenfeld *et al.*, 1994). LS patients show all of the physical manifestations of GH deficiency, but serum GH levels are high, while IGF-1, IGFBP-3, and ALS levels are low. In most, but not all, cases, the serum GHBP level is low or undetectable (the type of mutation in the GHR determines the presence or absence of GHBP). The phenotype is one of complete absence of GH activity and resembles that of patients with the most severe degrees of GH deficiency. Diagnosis is suspected in the proper familial setting by measuring serum GH, IGF-1, and GHBP; it is usually confirmed by genetic analysis. Other, postreceptor forms of GH insensitivity are due to inactivating mutations in genes encoding downstream elements in the GH signaling cascade, such as Stat5b, IGF-1, ALS, and the IGF1R. Treatment in most cases consists of IGF-1 replacement therapy.

A mild to moderate form of acquired GH resistance is frequently seen in catabolic states. This appears to be an adaptive response, with low serum IGF-1 and elevated GH levels. The nutritional deprivation that frequently accompanies such conditions explains part, but not all, of this phenomenon. This is a reversible derangement in the GH–IGF axis that returns to normal when the underlying disease process is corrected. Treatment with GH is not recommended because GH therapy, in severe cases of illness, has been associated with increased mortality. However, one partially GH-resistant condition where GH treatment is beneficial is chronic renal failure.

GH Excess

Persistent GH hypersecretion in humans leads to a condition called acromegaly, where patients exhibit overgrowth of hands, feet, and facial structures, as well as internal organs (Dal *et al.*, 2016; Melmed *et al.*, 2009; Katznelson *et al.*, 2014). If the condition starts during childhood and is left untreated, it leads to gigantism, in which overall somatic growth is accelerated. In the vast majority of cases, the condition is caused by a GH-secreting pituitary adenoma. At least half of these adenomas have somatic mutations in the $G_s\alpha$-subunit of the signal-transducing G-protein, through which GHRH normally signals. The mutation renders the G-protein constitutively active and leads to tumor formation and unchecked GH production (Gadelha *et al.*, 2017a). A germ line variant of this type of G-protein activation is seen in McCune–Albright syndrome, which has as one of its manifestations the occurrence of acromegaly. In rare cases, acromegaly can be caused by overproduction of GHRH, either by a eutopic source (e.g., a hypothalamic lesion) or (more frequently) in an ectopic site by tumors of neuroendocrine lineage (e.g., carcinoids, islet cell tumors). The high levels of systemic unregulated GHRH lead to somatotrope hyperplasia and GH overproduction. Only one convincing case of ectopic production of GH itself—by an islet cell tumor—has been reported.

The diagnosis is typically delayed because of the insidious onset of clinical signs. Biochemical findings include increased serum GH and IGF-1 levels. The diagnosis is supported by demonstrating a pituitary tumor and confirmed by showing that serum GH is not normally suppressible by administration of glucose (an oral or intravenous glucose tolerance test). In cases of ectopic GHRH production, a high GHRH level in peripheral blood is diagnostic.

Besides the overgrowth of the extremities and organs, the clinical aspects of acromegaly include hypertension, nerve entrapment manifestations, insulin resistance or diabetes mellitus, and increased cardiovascular morbidity and mortality. Although GH/IGF-1 exhibits mitogenic and antiapoptotic effects in many tissues, it still remains to be clarified whether cancer incidence and prevalence are increased in acromegalic patients. Patients with acromegaly do have an increase in colon polyps, which is a risk factor for colon cancer.

First-line treatment of acromegaly consists of surgical removal of the pituitary adenoma (or, rarely, the ectopic tumor) (Buchfelder and Schlaffer, 2017). Surgical resection is frequently not curative, especially when the adenoma exceeds the confines of the sella turcica. In such cases, postsurgical radiation or medical therapy is used to acquire disease control. Radiotherapy has numerous adverse side effects and since more efficacious and safe medical treatments have emerged, it is only used in patients with persistent disease or where the medication is not tolerated.

Medical Therapy in Acromegaly

After noncurative surgery, medical therapy is often necessary to reduce GH and/or IGF-1into the normal range. Currently, medical treatment of acromegaly comprises three drug classes: somatostatin analogues, GHR antagonists, and dopamine agonists (**Fig. 1**).

Long-acting somatostatin analogues are recommended for first-line adjuvant use. These analogues act on the somatostatin receptors (SSTRs) in the pituitary gland and exhibit inhibition on the secretion of GH by the somatotrophs (Gadelha *et al.*, 2017b). The drugs also have antiproliferative effects on the pituitary adenomas. The first compounds approved for use in acromegaly were octreotide and lanreotide, both considered preferential ligands of the pituitary SSTR2 and, to a lesser extent, SSTR5. However, the different SSTR subtypes are heterogeneously expressed in pituitary adenomas, and SSTR distribution, tumor size, and tumor location all influence treatment outcome. At present, oral preparations of octreotide are also being tested and clinical trials are under way to evaluate the efficacy of oral octreotide in acromegaly (Tuvia *et al.*, 2012). With the aim to generate compounds with a broader binding profile, the next-generation multireceptor-targeting somatostatin compound, pasireotide, was developed and approved in 2014 (Mckeage, 2015). The formulation appears as a promising and more effective alternative to the first-generation therapies, and in a study of 358 medically naïve acromegaly patients, pasireotide demonstrated superior efficacy over octreotide (Colao *et al.*, 2014).

Somatostatin analogue treatment, however, exerts additional effects because SSTRs are ubiquitously expressed in many tissues. In particular, it has the disadvantage of inhibiting insulin secretion and inducing hyperglycemia, with resulting increased propensity to promote diabetes. Pasireotide is particularly prone to inducing hyperglycemia (Neggers *et al.*, 2011). These side effects of somatostatin analogues limit their clinical usefulness in certain patients, and if an inadequate response is achieved with one drug, combination therapy may improve efficacy and minimize the potential adverse effects associated with increased doses of somatostatin analogues.

The GHR antagonist, pegvisomant, which was licensed in the USA in 2003, represents another effective agent with which it is possible to achieve medical control of acromegaly (Kopchick *et al.*, 2002; Freda *et al.*, 2015; Berryman *et al.*, 2007), and it is the medical treatment that has the highest reported efficacy (Neggers *et al.*, 2014). Pegvisomant is a recombinant GH analogue that differs from wild-type GH by a single Gly120Lys substitution in GH binding site 2 and eight amino acid substitutions in GH binding site 1. The Gly120Lys change results in GHR site 2 being altered and likely prevents proper dimerization by sterically inhibiting the conformational rearrangement of the GHR dimers. Thus, whereas somatostatin analogues function in the pituitary to directly target pituitary tumor GH secretion and tumor growth, pegvisomant acts on the ubiquitous GHR to block GH-induced signaling. Furthermore, the eight amino acid substitutions in GH binding site 1 result in an enhanced affinity of it for the GHR. Additionally, pegvisomant is conjugated with 4–5 polyethylene glycol moieties, which reduces its immunogenicity and extends its

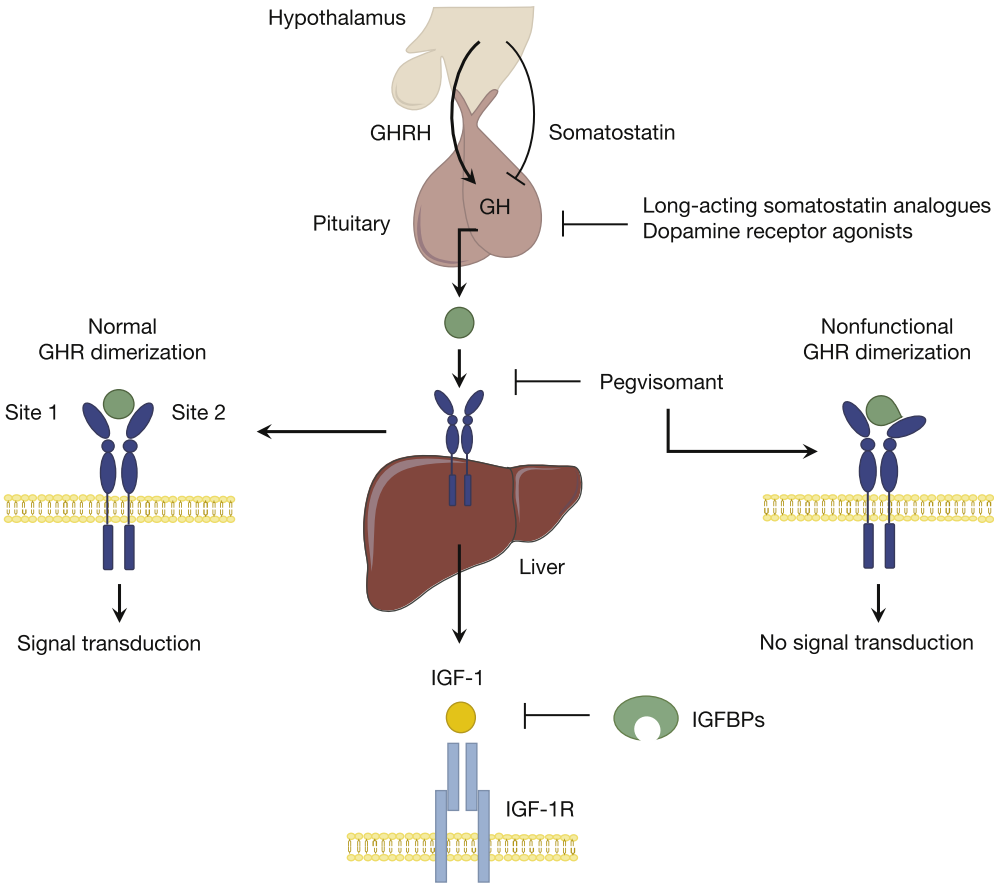

Fig. 1 The growth hormone (GH)-insulin-like growth factor (IGF) axis with therapeutic entry points for the treatment of acromegaly. Release of GH from the pituitary is regulated primarily by growth hormone releasing hormone (GHRH) and somatostatin. A single GH molecule binds to a constitutively dimerized, yet inactive, GH receptor (GHR) homodimer through sites 1 and 2. GH interaction with the GHR induces a conformational change and initiates downstream signal-transduction pathways, which promotes peripheral IGF-I secretion from the liver and other tissues. IGF-I binding to the IGF-I receptor (IGF-IR) mediates growth and metabolic functions. The IGF-IR binding is modulated by IGF-binding proteins (IGFBPs). Medical treatment of acromegaly comprises three drug classes: somatostatin analogues, dopamine agonists, and GHR antagonists. Long-acting somatostatin analogues act on the somatostatin receptors in the pituitary gland to inhibit GH secretion by the somatotrophs. Dopamine receptor agonists suppress GH hypersecretion through binding to D_2 receptors on adenomas. The GH analogue Pegvisomant contains amino-acid substitutions in the GHR binding sites, which blocks GH-induced signaling. Site 1 contains eight amino acid substitutions that improve receptor binding and site 2 contains a single amino acid substitution that blocks the conformational rearrangement of the GHR.

half-life from approximately 20 min to 2.5 days (Clark *et al.*, 1996). Overall, it prevents endogenous GH from binding to the receptor (Ross *et al.*, 2001).

The aim of pegvisomant therapy is to lower serum IGF-1 levels to the normal range. However, pegvisomant does not lower circulating GH levels; thus serum IGF-1 levels are used as a biomarker of drug efficacy. In most cases, it is possible to achieve IGF-1 normalization, and thus, pegvisomant represents a unique advance in treating the peripheral clinical sequelae of increased IGF-1 levels (Van Der Lely *et al.*, 2001). In contrast to somatostatin analogues, pegvisomant improves glucose tolerance and decreases fasting glucose levels, and thus, it is the safer choice in patients with diabetes mellitus. Effective treatment of acromegaly with pegvisomant is successful in reversing the soft tissue changes, improving cardiovascular risk parameters and insulin sensitivity, reducing the mortality rate, and improving quality of life. However, it is only partially effective in reversing the bony changes, and thus, early diagnosis and curative intervention are of paramount importance.

Pegvisomant can be used in the treatment of acromegaly both as a single agent and in combination with somatostatin analogues (Neggers and Van Der Lely, 2009; Muhammad *et al.*, 2016; Neggers *et al.*, 2014). Most studies on pegvisomant monotherapy efficacy have been based on clinical trials that evaluated the daily administration (Van Der Lely *et al.*, 2001; Trainer *et al.*, 2000), whereas few studies have assessed the weekly injection regimen (Higham *et al.*, 2009; Muhammad *et al.*, 2016). It has been suggested that conversion to weekly pegvisomant administration can be achieved with no loss of efficacy, and this may increase compliance and reduce the costs of medical treatment. Alternatively, pegvisomant and somatostatin analogue combination therapy shows promising results with regard to long-term efficacy and safety. The treatment appears highly effective at normalizing IGF-1 levels in most patients, and while pegvisomant monotherapy does not lead to a decrease in pituitary tumor

size, combination therapy with somatostatin analogues results in a decrease in tumor size in about 20% of patients (Neggers *et al.*, 2009). In 2005, the first study on the combined treatment of acromegaly with monthly high-dose long-acting somatostatin analogue therapy and weekly subcutaneous pegvisomant administration proved as effective as daily pegvisomant monotherapy (Feenstra *et al.*, 2005).

In patients with tumors cosecreting prolactin or only modestly increased IGF-1 levels and mild symptoms of GH excess, long-acting dopamine D_2 receptor agonists, usually cabergoline, may provide sufficient biochemical control (Sandret *et al.*, 2011). Physiologically, dopamine stimulates GH secretion, but dopamine receptor agonists paradoxically suppress GH hypersecretion in acromegalic patients through binding to D_2 receptors on adenomas (Chiodini *et al.*, 1974; Bernabeu *et al.*, 2013). However, clinical trials suggest that cabergoline monotherapy only normalizes IGF-1 levels in one-third of patients with acromegaly, and despite initial efficacy of cabergoline, the drug response appears to decrease with time.

Diagnostics

GH deficiency is diagnosed by pituitary stimulation test because a random serum GH level is largely uninformative due to the normally pulsatile nature of GH secretion. Various pharmacological tests are used for stimulation of GH secretion. The insulin tolerance test is often the first choice, as it measures the entire hypothalamo–pituitary axis. However, as it is attended by the risks of hypoglycemia, it must be administered under close supervision, and is contra-indicated in the elderly. The GHRH–arginine and pyridostigmine-GHRH tests are reliable and appear to have few drawbacks. Ghrelin is a strong GH secretagogue, and the GHRH–ghrelin and GHRH–hexarelin (a synthetic ghrelin analogue) tests are safe and convenient, but need further evaluation as to their diagnostic usefulness. Other less reliable tests include arginine alone, GHRH alone, L-dopa, glucagon, and clonidine. Clonidine appears to be a more potent secretagogue in children than in adults, where it is considered a weak stimulus. The absolute GH response to these provocative stimuli (in terms of serum GH levels achieved) varies depending on the GH assay used. Typically, monoclonal immunoassays yield lower GH values than do polyclonal assays. Diagnostic guidelines have been published by the GH Research Society (Ho and Participants, 2007) and by the American Association of Clinical Endocrinologists.

Acromegaly is readily diagnosed in the right clinical setting by an elevated serum IGF-1 level and a high GH level (the latter is not diagnostic by itself due to the normally pulsatile GH secretion) (Katznelson *et al.*, 2014). The confirmatory test, both in overt acromegaly and especially after surgical treatment, is the glucose tolerance test. Serum GH should fall below 1 ng/mL after glucose administration. In addition, IGF-1 should be within the normal age-adjusted range. Frequently, evidence for low-grade acromegaly persists after treatment even in cases where these criteria are met, as GH secretory dynamics remain disordered when examined carefully. For practical clinical purposes, an IGF-1 level in the mid-normal range is a reasonable criterion for a cure or biochemical control.

Studies in Mouse Strains With Altered GH-Induced Signaling

Most of our current understanding about the functions of GH has come from decades of studies in humans and animals. However, relatively recent reports dealing with mice with genetic mutations that alter GH action have increased our knowledge and appreciation of its multifunctional properties (Berryman *et al.*, 2008, 2016; Hjortebjerg *et al.*, 2017). Some of these mouse strains represent the murine counterparts of human diseases. A thorough description of all mouse lines that illustrate different aspects of GH actions is beyond the scope of this article, and thus, only three strains will be mentioned: the transgenic GH mouse with excess GH biological action; the GHR gene disrupted mouse (GHR $-/-$) with complete inability to mediate GH actions; and the transgenic GHR antagonist mouse (GHA) with reduced GH/GHR-induced action.

Genetically engineered mice with a GH transgene (human, bovine etc.) overexpress the GH gene and exhibit high GH and IGF-1 levels (Bartke *et al.*, 1994; Chen *et al.*, 1997). Depending on the origin of the transgene, there are modest variations in the phenotypes. However, all have organomegaly and display a giant phenotype that resembles the excessive somatic growth observed in acromegaly and gigantism. The mice are lean, but since GH is a diabetogenic hormone, they suffer from a number of pathological changes associated with glucose and lipid metabolism. Major metabolic characteristics of young GH transgenic mice are hyperinsulinemia, insulin resistance, hypercholesterolemia, and hypertension. These changes are the probable cause of the significantly reduced life span observed in these mice.

The GHR $-/-$ mouse displays a phenotype that is opposite to that of the GH transgenic mouse (Zhou *et al.*, 1997; List *et al.*, 2011). These mice lack both the GHR and the GHBP, and thus, they are GH insensitive, have low circulating IGF-1 levels, and suffer from severe growth retardation. Due to the absence of GH- and IGF- mediated feedback inhibition on GH secretion, circulating levels of GH are elevated, yet the mouse is GH insensitive. In many ways, this mouse strain mimics human LS. In this regard, most patients with LS harbor inactivating mutations in the GHR gene. The GHR $-/-$ mice are very insulin sensitive, and contrary to the transgenic GH mice, they are obese, mostly due to an increased subcutaneous adipose tissue accumulation. Interestingly, the subcutaneous adiposity has no negative influence on health and longevity, suggesting an importance of depot-specific lipid accumulation. Longevity is significantly increased in GHR $-/-$ mice when compared to wild-type littermates, and the increased life span is partly due to a reduction in malignant diseases, as well as a decrease in the occurrence of diabetes (Bartke *et al.*, 2016). A similar phenotype is found in LS patients, which are generally protected against cancer and diabetes.

A single codon change in the bovine *GH* transgene led to the generation of a transgenic mouse that expressed a GH analogue, namely, a molecule in which glycine in the 3rd alpha helix was replaced by arginine (Chen *et al.*, 1997; Kopchick *et al.*, 2014). Mice that expressed this mutated gene were dwarf with low levels of IGF-1. Subsequently, this GH analogue was found to act as a GHR antagonist. The dwarf GHA mouse phenotype is an intermediate between that of wild type and GHR −/− mice and illustrates the physiological impact of partial GH deficiency as opposed to the complete lack of GH actions (Chen *et al.*, 1991; Coschigano *et al.*, 2003). Again, the GHA mouse is small with low levels of IGF-1 compared to wild-type controls, but does not exhibit an extended life span like the GHR −/− mouse. Besides the usefulness of this novel mouse strain in assessing the impact of reduced GH action, the generation of the GHA mouse also resulted in the discovery of the drug pegvisomant used for the treatment of patients with acromegaly (Kopchick *et al.*, 2014).

Major results from studies of GH activity in mice over the last two decades are: the discovery of GHR antagonist (pegvisomant); the discovery of the influence of the GH/IGF-1 in aging and longevity, that is, low GH action can result in improved health and life span (at least in mice) (Junnila *et al.*, 2013); and the discovery of the effect of GH on "partitioning" of white adipose depots.

Natural and Synthetic Growth Hormone Secretagogues☆

Giovanna Motta, Stefano Allasia, Marco Zavattaro, Ezio Ghigo, and Fabio Lanfranco, University of Turin, Turin, Italy

From the First Growth Hormone Secretagogues to the Endogenous One, Ghrelin

Growth hormone secretagogues (GHSs) are a family of synthetic peptidyl and nonpeptidyl molecules that bind specific receptors (GHS-Rs) in the hypothalamus and pituitary with potent stimulatory effect on somatotrope secretion. Interestingly, the activity of GHSs is not fully specific for GH release; in fact, after acute administration they also possess a weak prolactin (PRL-), adrenocorticotropin hormone (ACTH-) and cortisol-releasing effect, but they have also been reported to be able to influence food intake and sleep patterns (Ghigo *et al.*, 1998). However, over the last 30 years, relevant scientific research has been focused on identifying synthetic GHSs in order to treat GH deficiency. The first GHSs were nonnatural synthetic peptides (also known as GH-releasing peptides, GHRP) endowed with a potent GH-releasing action. Invented in 1977 as met-enkephalin derivatives, they were devoid of any opioid activity and they did not affect the release of pituitary hormones (Bowers *et al.*, 1977; Ghigo *et al.*, 1998). The GHS family includes peptidyl analogues, such as GHRP-1, GHRP-2, GHRP-6, hexarelin (Bowers *et al.*, 1993), and nonpeptidyl molecules. A series of hexarelin analogues that contain one or several unnatural amino acids have been synthesized (Vodnik *et al.*, 2016). The peptidyl analogues possess strong GH-releasing activity, but they have the disadvantage of having an oral bioavailability of less than 1% with a short-lasting effect (Ghigo *et al.*, 1998). In the nineties, research at Merck & Co. led to the synthesis of an orally active nonpeptidyl molecule, MK-0677 also known as spiroindoline, one of the most potent peptidomimetic GHSs (Patchett *et al.*, 1995). MK-0677 shows an oral bioavailability of more than 60% and seems endowed with a long-lasting effect (Copinschi *et al.*, 1996). GHSs bind to specific sites in the rat forebrain and other brain regions, although the greatest density of binding sites is the hypothalamus and pituitary gland. GHS-R was in fact initially cloned in 1996 from pig pituitaries (Howard *et al.*, 1996). It is expressed in humans as two isoforms from the same gene on chromosome 3q26.2: GHS-R type 1a and GHS-R type 1b. GHS-R type 1a is a G protein-coupled receptor, composed of 366 amino acids with seven transmembrane regions and a molecular mass of approximately 41 kD, while GHS-R type 1b is a splice variant of type 1a made up of a truncated polypeptide of 289 amino acids with five transmembrane domains and a molecular mass of approximately 32 kDa (Laviano *et al.*, 2012). Whereas GHS-R type 1a binds both peptidyl and nonpeptidyl GHSs, GHS-R type 1b does not bind GHSs and its functional role is unknown. It has been hypothesized that the latter receptor would play a critical role in modulating the activity of GHS-R type 1a by forming hetero-dimeric complexes which attenuates trafficking of the active variant to cell surface (Laviano *et al.*, 2012; Chan and Cheng, 2004). The GHS-R1a is expressed predominantly in the anterior pituitary gland and in the hypothalamus, but also in extrahypothalamic areas of the central nervous system (ventral tegmental area, nucleus accumbens, hippocampus, and amygdala), in multiple peripheral endocrine (pancreatic islets, adrenal gland, thyroid) and nonendocrine organs and in different neoplastic tissues (Gnanapavan *et al.*, 2002).

Although GHS-R had been designated as an orphan receptor specific for the synthetic GHS molecules, in 1999 Kojima *et al.* isolated and characterized a natural bioactive ligand for this receptor, named ghrelin. The name ghrelin derives from the word "ghre," the Proto-Indo-European root of the word "grow" (Kojima *et al.*, 1999). It derives from the 117 amino acid precursor "preproghrelin" encoded by the gene GHRL located on chromosome 3p25–26, with five exons and four introns. Mature ghrelin consists of 28 amino acid residues, mainly produced from the enteroendocrine (X/A like) cells in the stomach wall (oxyntic mucosa), but lower levels of expression have been found in several other peripheral tissue, such as the gastrointestinal tract, adrenal gland, thyroid, breast, ovary, placenta, fallopian tube, testis, prostate, liver, gallbladder, fat tissue, human lymphocytes, spleen, kidney, lung, skeletal muscle, myocardium, vein, and skin (Date *et al.*, 2000; Kojima *et al.*, 2001; Gnanapavan *et al.*, 2002; Ghelardoni *et al.*, 2006). Ghrelin is also produced by neurons in several areas of the central nervous system, particularly in the nucleus arcuatus of the hypothalamus and in a group of neurons adjacent to the third ventricle between the dorsal, ventral, paraventricular, and arcuate hypothalamic nuclei (Kojima *et al.*, 1999; Korbonits *et al.*, 2001; Cowley *et al.*, 2003; Kojima and Kangawa, 2005). Ghrelin is the first peptide isolated from natural sources in which the hydroxyl group of its third serine residue (namely, serine 3) is acylated by *n*-octanoic acid, catalyzed by ghrelin-*O*-acyltransferase (GOAT). The acylation of the N-terminal tetra-peptide is critical for the peptide to be able to cross the blood–brain barrier and is essential for binding GHS-R type 1a and for endocrine actions (Banks *et al.*, 2002; Lorenzi *et al.*, 2009). This special feature is conserved across species (Muccioli *et al.*, 2007). Ghrelin circulates in two major forms, acylated ghrelin (AG) and nonacylated ghrelin (UAG), which is the most abundant and stable form. UAG does not bind GHS-R type 1a and is devoid of typical AG endocrine activities. Nevertheless, UAG is an active peptide sharing some of the activities of AG, either enhancing or opposing AG. In fact, UAG has been demonstrated to have opposite effects on glucose and insulin metabolism in healthy humans (Benso *et al.*, 2012). Moreover, several studies have shown that UAG exhibits biological activities on cell proliferation and binds to cell membranes of cardiomyocytes, adipocytes, prostatic,

☆*Change History*: February, 2018. G Motta, S Allasia, M Zavattaro, E Ghigo, and F Lanfranco, updated the text and references.

This article is an update of Romano Deghenghi, Ezio Ghigo, Fabio Broglio, Natural and Synthetic Growth Hormone Secretagogues, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 295–299.

and skeletal muscle cells (Cassoni *et al.*, 2001; Baldanzi *et al.*, 2002; Muccioli *et al.*, 2004; Filigheddu *et al.*, 2007). These effects are likely mediated through different GHS-R subtypes or completely different receptor families (Cassoni *et al.*, 2001; Baldanzi *et al.*, 2002; Ghigo *et al.*, 2005; Giovambattista *et al.*, 2008).

It is possible that ghrelin is not the sole natural GHS-R ligand and that GHS-R type 1a is one of a group of receptors for such ligands. Indeed, GHS-R is also bound by other molecules, such as Des-Gln14-ghrelin, which is a gastric homologue of ghrelin, with the exception that one glutamine is missing, and which has the same biological activities as ghrelin; adenosine, which binds but does not activate the receptor; and cortistatin, which is a neuropeptide that is homologous to somatostatin and is unable to recognize GHS-R type 1a. Moreover, there is strong evidence suggesting the existence of additional receptor subtypes. Specific binding sites for peptidyl GHS only, with very low binding affinity for ghrelin and nonpeptidyl GHS, have been shown in a wide range of nonendocrine peripheral human tissues.

The regulation of ghrelin secretion is still largely unknown, but it has already been shown that circulating ghrelin levels are increased in fasting states and declined 60–120 min after meals (Tschöp *et al.*, 2001; Cummings *et al.*, 2001), suggesting that ghrelin may act as an initiation signal for food intake (Ariyasu *et al.*, 2001; Tschöp *et al.*, 2001; Cummings *et al.*, 2001; Klok *et al.*, 2007; Lorenzi *et al.*, 2009). A diurnal and nocturnal rhythmicity of ghrelin levels in humans has also been observed by some (Cummings *et al.*, 2001; Koutkia *et al.*, 2004), but not by other authors (Barkan *et al.*, 2003). In addition, ghrelin levels seem to be influenced by age, gender, BMI, GH, glucose, and insulin (Ariyasu *et al.*, 2001; Tschöp *et al.*, 2001; Cummings *et al.*, 2001; Barkan *et al.*, 2003; Klok *et al.*, 2007). Notably, leptin has also been suggested to have influence on circulating ghrelin levels. In fact, it has been hypothesized that the satiety-inducing effects of leptin include the suppression of ghrelin secretion. In agreement with the critical influence of nutrition on ghrelin secretion, circulating ghrelin levels are increased in anorexia and cachexia but reduced in obesity (Yildiz *et al.*, 2004).

A comprehensive summary of ghrelin actions in vivo is provided in **Table 1**.

In the following paragraphs we will discuss the main endocrine and nonendocrine ghrelin activities.

Ghrelin and GHS Endocrine Activities

GH Releasing Action

Ghrelin GH-releasing property was its first recognized effect (Kojima *et al.*, 1999). Ghrelin, as well as synthetic GHS, possesses a strong and dose-related GH-releasing activity, both in vitro and in vivo, which is more marked in humans than in animals (Van der Lely *et al.*, 2004; Broglio *et al.*, 2006). Intravenous ghrelin administration stimulates GH release which peaks at 5–15 min and returns to basal levels after 1 h (Ghigo *et al.*, 2005).

AG GH-releasing effect is mediated by actions on two different sites: on the somatotrophs of the anterior pituitary gland and, within the hypothalamus, on GHRH secreting neurons (Benso *et al.*, 2013). The GHS-R is expressed in about one fourth of GHRH mRNA containing neurons in arcuate nucleus and ventromedial nucleus of the hypothalamus suggesting that ghrelin may influence GH secretion through interaction with the GHS-R and that the release of GHRH into the hypophyseal portal blood may also be influenced by ghrelin neurons (Khatib *et al.*, 2014). At the hypothalamic level, ghrelin and GHS act via mediation of GHRH-secreting neurons as indicated by evidence that passive immunization against GHRH, as well as pretreatment with GHRH antagonists, reduces their stimulatory effect on GH secretion (Osterstock *et al.*, 2010). Moreover, the GH-releasing effect of GHS is markedly reduced in animals with lesions of the pituitary stalk (Van der Lely *et al.*, 2004). The GH response to ghrelin bolus has been shown to be more robust than the response after GHRH bolus (Arvat *et al.*, 2000) or hexarelin (Arvat *et al.*, 2001) and is synergistic with the GHRH response (Arvat *et al.*, 2001; Veldhuis *et al.*, 2012), suggesting a potential therapeutic use of ghrelin as a GH secretagogue. Moreover, it was recently discovered that the somatotroph releasing effect of AG is refractory to the direct inhibitory effect of a short-term elevation of GH levels, while it is markedly inhibited in the presence of increased IGF-I levels induced by 4-day rhGH administration. This finding might suggest the possibility of a selective IGF-I-mediated feedback (Benso *et al.*, 2013).

The AG and GHS GH-releasing effect undergoes marked age-related variations, increasing at puberty, persisting similar in adulthood and decreasing with aging (Broglio *et al.*, 2003a); variations in estrogenic levels, the reduced expression of the hypothalamic GHS receptors in the aged human brain, GHRH hypoactivity and somatostatinergic hyperactivity would explain these age-related changes (Ghigo *et al.*, 2005). AG GH releasing effect is independent of gender, does not vary with the menstrual cycle (Messini *et al.*, 2013), and occurs in a dose-dependent manner (Takaya *et al.*, 2000).

Differently from GHRH, AG stimulatory effect on GH secretion is reduced both in obese and in anorectic patients (Tassone *et al.*, 2003; Broglio *et al.*, 2004), in polycystic ovary syndrome (Fusco *et al.*, 2007), hyperthyroidism (Molica *et al.*, 2010), Cushing's disease (Correa-Silva *et al.*, 2006), and primary hyperparathyroidism (Cecconi *et al.*, 2008). Moreover, the GH response to a ghrelin bolus is reduced by centrally acting cholinergic antagonism (Maier *et al.*, 2004), but is not affected by peripherally acting cholinergic blockade (Broglio *et al.*, 2003b), cholinergic agonist (Broglio *et al.*, 2003b; Maier *et al.*, 2004), oxytocin (Coiro *et al.*, 2011), dopamine receptor blockade or by the most important inhibitory inputs on GH secretion such as glucose, free fatty acids and b-adrenergic agonist, all acting to increase the hypothalamic somatostatin release. In healthy postmenopausal women, estradiol or combination estradiol–progestin replacement increases GH secretion in response to a ghrelin bolus (Veldhuis *et al.*,

Table 1 In vivo endocrine and nonendocrine ghrelin actions

Site of action	*Acylated ghrelin actions*	
	Hypothalamus ↑ GHRH secretion ↑ CRH secretion ↓ GnRH pulse generator ↑ Food intake (via NPY) and appetite	Pituitary ↑ GH secretion ↑ ACTH secretion ↑ PRL secretion ↓ LH in men/↓FSH and LH in women ↓↔ TSH
	Pancreas ↓ Insulin secretion (spontaneous and glucose stimulated) ↑ Glucose levels ↑ Glycogenolysis ↑ Glucagone secretion	
	Adipose tissue ↑ Lipogenesis	
	Cardiovascular system ↑ Cardiac output ↑ Cardiac contractility ↓ Systemic vascular resistances ↑ Vasodilation	
	Gastrointestinal system ↑ Gastric emptying ↑ Gastric acid secretion ↑ Gastric motility ↑ Intestinal motility	
	Liver ↑ IGF-I	

2006; Villa *et al.*, 2008), and estradiol replacement therapy increases basal, but not pulsatile, GH secretion in response to a ghrelin infusion (Kok *et al.*, 2008).

AG, as well as synthetic GHS, could have diagnostic and therapeutic implications based on GH-releasing effects. Since a damage to the pituitary stalk or to the pituitary reduces the GH response to a ghrelin bolus (Maghnie *et al.*, 2007; Popovic *et al.*, 2003), ghrelin and GHS, particularly when combined with GHRH, could be used as a potent and reliable provocative test to evaluate the capacity of the pituitary to release GH for the diagnosis of GH deficiency (Gasco *et al.*, 2012). Long-acting

and orally active ghrelin analogs might represent an anabolic treatment in frail elderly subjects or in catabolic patients. At present, however, there is no definite evidence showing the therapeutic efficacy of ghrelin analogs as GH/IGF-I axis-mediated anabolic agents in humans.

Potential use in cancer cachexia

Ghrelin and its agonists are the perfect candidate to treat cachexic and frail states because of the anabolic biology of the hormone (Vodnik *et al.*, 2016). Ghrelin has a very short half-life but the peptide can be engineered for a more sustained delivery and better pharmacokinetic properties (Müller *et al.*, 2015).

Few studies demonstrate that ghrelin or ghrelin mimetic administration in advanced incurable cancer and anorexia increases energy intake and appetite (Strasser *et al.*, 2008; Lundholm *et al.*, 2010). Anamorelin-ONO-7643 (ANAM) is a novel, orally active, ghrelin receptor agonist under clinical development for the treatment of cancer cachexia and has advanced to phase III studies (Garcia *et al.*, 2015; Vodnik *et al.*, 2016). It is found to be associated with significant appetite-enhancing activity and resultant improvements in body weight, lean body mass. However, further studies are needed to confirm the significant potential of ANAM in cancer anorexia-cachexia syndrome (Pietra *et al.*, 2014).

The composite preclinical literature indicates beneficial effects of ghrelin-based intervention in cancer-cachexia models and with an increase in lean body mass. Preliminary clinical data show that ghrelin maintains its GH releasing and orexigenic effect in the setting of cancer. However, further investigations should evaluate the effects of ghrelin administration on tumor growth (Guillory *et al.*, 2013).

Potential use in AIDS associated cachexia

Cachexia has also been found in AIDS and alterations in GHRH-GH-IGF-I axis are common in the complex of HIV and AIDS, particularly in case of lipodystrophy. The processes involved in lipodystrophy are related to the suppression of GH production. The mechanism of low GH levels is due to increased somatostatin tone and decreased ghrelin secretion. The GHRH analogue Tesamorelin is the only therapeutic option, which is FDA approved, to reduce abdominal fat excess in patients with HIV-associated lipodystrophy (Stanley *et al.*, 2014). On the other hand, elevated GH and low IGF-I levels are present in AIDS wasting syndrome, suggesting GH resistance (Jain *et al.*, 2013).

Lower ghrelin levels have been reported in HIV-infected lipodystrophic patients, but to date, no reports of ghrelin or GHS use in this clinical setting are available (Guillory *et al.*, 2013), even if ghrelin GH releasing effect could be used to improve lipodystrophy.

ACTH Releasing Action

The stimulatory effect of ghrelin and synthetic GHS on the hypothalamus–pituitary–adrenal (HPA) axis in humans is remarkable and similar to that of the administration of naloxone, vasopressin, and even corticotropin-releasing hormone (CRH) (Arvat *et al.*, 2001; Van der Lely *et al.*, 2004; Ghigo *et al.*, 2005). Interestingly, the effect of ghrelin on ACTH and cortisol secretion is even more pronounced than that elicited by synthetic GHS, such as hexarelin, as demonstrated by Arvat *et al.* (2001).

The ACTH-releasing effect of GHS is acute, being attenuated during prolonged treatment, is independent of gender, but shows peculiar age-related variations, increasing at puberty, then showing a reduction in adulthood and, again, a trend toward an increase in aging, when the GH-releasing activity of GHS is clearly reduced (Arvat *et al.*, 1997; Ghigo *et al.*, 1998, 2001; Broglio *et al.*, 2003a).

Under physiological conditions, ghrelin ACTH-releasing activity is entirely mediated via the central nervous system (CNS) (Ghigo *et al.*, 1998, 2001). In fact, transection of pituitary stalk decreased the stimulatory effect of ghrelin on HPA axis in animal models (Van der Lely *et al.*, 2004). These mechanisms via the CNS not only include CRH and/or vasopressin-mediated actions (Ghigo *et al.*, 1998, 2001; Ishizaki *et al.*, 2002) but also neuropeptide Y and/or γ-aminobutyric acid (GABA) (Arvat *et al.*, 1998; Korbonits *et al.*, 1999). More recently, Kageyama *et al.* found that ghrelin stimulates both CRH and AVP mRNA levels in incubated 4B rat hypothalamic cells, suggesting that ghrelin does not directly stimulate ACTH release from the pituitary cells (Kageyama *et al.*, 2011). Moreover, ghrelin does not have direct stimulatory effects on adrenal hormone secretion. While ghrelin stimulates the HPA axis, hypercortisolemia is associated with reduced ghrelin levels, as a consequence of a feedback mechanism (Otto *et al.*, 2004; Sherif *et al.*, 2011).

Since GHS and ghrelin ACTH releasing activity is sensitive to the negative glucocorticoid feedback in healthy individuals and in patients with ACTH independent Cushing syndrome (Ghigo *et al.*, 1997, 1998, 2001; Arvat *et al.*, 1998), it is remarkable and intriguing that in patients with pituitary ACTH-dependent Cushing's disease (Arvat *et al.*, 1998; Leal-Cerro *et al.*, 2002; Martinez-Fuentes *et al.*, 2006) and in patients with ectopic ACTH-dependent Cushing syndrome (Korbonits *et al.*, 1998; Ghigo *et al.*, 1998), despite chronic hypercortisolism, the responsiveness to ghrelin and GHSs is remarkably enhanced. An over-expression of ghrelin receptors on corticotroph adenoma cells may at least in part account for this finding (Rotondo *et al.*, 2011). Only two studies have investigated the ACTH and cortisol responses after the combined administration of GHS hexarelin + CRH in healthy subjects (Korbonits *et al.*, 1999) and in patients with Cushing disease (Arvat *et al.*, 1999). Korbonits *et al.* have shown that hexarelin stimulates HPA axis independently of CRH in healthy subjects, while Arvat *et al.* reported additive mean ACTH responses after combined CRH + hexarelin administration in eight female patients with Cushing's disease. In the following in vitro study by

Pecori-Giraldi *et al.* the ghrelin-stimulated ACTH response in cell cultures of human pituitary corticotroph cells collected from ACTH secreting adenomas was significantly lower than the one induced by CRH, suggesting that ghrelin acts on both hypothalamic and pituitary sites to stimulate ACTH secretion in Cushing's disease (Pecori-Giraldi *et al.*, 2007). In line with this, evidences from in vitro animal studies suggest potent AVP, CRH, and NPY releasing effects of ghrelin from rat hypothalamic explants (Mozid *et al.*, 2003). These complex interactions may account for CRH and ghrelin synergistic effects on ACTH release at the hypothalamic and pituitary level. Miljic and colleagues have recently demonstrated that ghrelin in combination with CRH additionally enhances ACTH secretion without further additive effects on cortisol output (Miljic *et al.*, 2017). These data suggest uncoupling of ACTH and cortisol after achieving maximal cortisol values similar to that observed in states of psychological or physical stress (Veldhuis *et al.*, 2005) or during pharmacological stimulation (Keenan *et al.*, 2003). The expression of ghrelin receptors in some neuroendocrine tumors with ectopic ACTH secretion may reduce its potential for use in the differential diagnosis of ACTH dependent Cushing syndrome (Miljic *et al.*, 2017).

PRL Releasing Action

According to the previous in vitro and in vivo studies on synthetic GHS (Ghigo *et al.*, 1999), ghrelin significantly stimulates PRL secretion in humans in a gender- and age-dependent manner (Takaya *et al.*, 2000). The ghrelin effect on PRL secretion is higher than that of hexarelin (Arvat *et al.*, 2001).

On the contrary, an inhibitory effect on PRL secretion acting primarily at the hypothalamus has been shown in prepubertal male and female rats (Tena-Sempere *et al.*, 2004), even if the reason for this discrepancy is unclear. The species specificity could be explained by higher levels of mammosomatotroph cells in humans than in animals. Data in mice have shown that different parts of the brain, including the hypothalamus, contain neurons that coexpress the dopamine receptor subtype 1 and GHS-R (Jiang *et al.*, 2006). In such neurons, ghrelin had the capacity to amplify dopamine-induced cyclic adenosine monophosphate accumulation, thus providing temporal control over the magnitude of dopamine signaling (Jiang *et al.*, 2006). Additional data have shown that ghrelin can activate the mesoaccumbal dopamine system in the ventral tegmental area of mice and rats (Abizaid *et al.*, 2006; Jerlhag *et al.*, 2006) and protect nigral dopaminergic neurons by reducing apoptosis (Jiang *et al.*, 2008).

Concerning the effects in humans, Messini *et al.* (2010) have showed that bromocriptine, which is a dopamine agonist, blocked the ghrelin stimulating effect on PRL release and attenuated the GH response to the same stimulus in women. The same authors also evaluated the effect of exogenous thyrotropin-releasing hormone (TRH) on ghrelin-induced PRL release in women. They showed that ghrelin induced a smaller PRL increase than TRH did and that the ghrelin stimulating effect on PRL secretion was not additive with that of TRH (Messini *et al.*, 2009). More recently, the same research group demonstrated that physiological secretion of ovarian steroids does not affect the GH and PRL response to ghrelin in a group of 10 women during menstrual cycle (Angelidis *et al.*, 2012). Fasting serum ghrelin levels had no relationship with PRL in patients diagnosed with prolactinoma, suggesting that ghrelin levels have no significant effect on weight gain and could not explain increased obesity prevalence in prolactinoma (Delibaşı *et al.*, 2015).

Influence on Gonadal Function

Ghrelin regulates the hypothalamus–pituitary–gonadal (HPG) axis acting both at the central and at the peripheral level (Tena-Sempere *et al.*, 2002; Caminos *et al.*, 2003) and several in vitro or in vivo studies indicate that ghrelin negatively influences the gonadal axis (Rak-Mardyla, 2013), as summarized in **Table 2**.

AG suppresses LH pulsatility in rodent, ovine and primate models (Furuta *et al.*, 2001; Kawamura *et al.*, 2003; Barreiro and Tena-Sempere, 2004; Vulliémoz *et al.*, 2004; Fernández-Fernández *et al.*, 2005; Iqbal *et al.*, 2006). However, ghrelin infusion decreased LH pulse frequency but not pulse amplitude in adult ovariectomized rhesus monkeys, suggesting that ghrelin could inhibit the GnRH pulse activity (Vulliémoz *et al.*, 2004). Ghrelin can suppress not only LH, but also FSH secretion in male and female rats and this effect may depend on the manner of ghrelin administration (Fernández-Fernández *et al.*, 2006; Martini *et al.*, 2006).

Table 2 Ghrelin effects on HPG axis

	Effect	*References*
Animal studies		
Ovariectomized rat	↓ GnRH ↓ LH	Furuta *et al.* (2001)
Female and male rat	↓ LH ↓ FSH	Fernández-Fernández *et al.* (2006) and Martini *et al.* (2006)
Sheep	↓ LH	Iqbal *et al.* (2006)
Rhesus monkey	↓ LH	Vulliemoz *et al.* (2004)
Human studies		
Men and women	↓ GnRH ↓ LH ↔ GnRH-stimulated LH	Kluge *et al.* (2007), Messini *et al.* (2014), and Lanfranco *et al.* (2008a,b)

Ghrelin regulation of gonadotropin secretion in humans has been investigated mainly in male subjects. While in the first published study (Takaya *et al.*, 2000) different dosages of ghrelin increased GH but did not affect LH concentrations in normal males, two studies in men showed a delay and a suppression in LH pulse amplitude following acute i.v. ghrelin administration (Kluge *et al.*, 2007) and an inhibitory effect of ghrelin infusion on LH pulsatility (Lanfranco *et al.*, 2008a). More in details, Lanfranco *et al.* showed that a prolonged AG infusion quantitatively and qualitatively inhibits LH but not FSH secretion in healthy young males (Lanfranco *et al.*, 2008a). Morerover, in contrast with in vitro data showing that ghrelin reduces the LH response to GnRH in rodents (Fernández-Fernández *et al.*, 2005), the LH response to GnRH in humans is not modified by the exposure to AG (Lanfranco *et al.*, 2008a). These findings are therefore against the hypothesis that ghrelin plays a direct inhibitory role on pituitary gonadotropic cells. As AG inhibits the LH response to naloxone in humans, this clearly points toward a CNS-mediated inhibitory action on the HPG axis (Lanfranco *et al.*, 2008a). In addition, ghrelin decreases GnRH release by hypothalamic explants/fragments ex vivo (Fernández-Fernández *et al.*, 2005), reinforcing the contention of a complex mode of action of ghrelin with inhibitory effects at the central level and a direct stimulatory action on basal gonadotropin secretion. Whether ghrelin action on the GnRH pulse generator takes place directly on GnRH neurons or through indirect regulatory pathways is yet to be determined (Muccioli *et al.*, 2011). Some evidences suggest that ghrelin indirectly decreases gonadotropin secretion acting on central NPY, AgRP, or orexin expression (Tena-Sempere *et al.*, 2002; Rak-Mardyla, 2013), which exhibit inhibitory effect on LH secretion (Muccioli *et al.*, 2011). On the other side, Forbes *et al.* (2009) demonstrated that ghrelin administration significantly reduces LH pulsatility and suppresses kisspeptin mRNA expression in ovariectomized rats and suggested that downregulation of kisspeptin expression may play a critical role in the transduction of ghrelin-induced suppression of the reproductive function often observed during caloric restriction.

In women experimental studies, Messini *et al.* (2009) demonstrated for the first time the inability of a ghrelin bolus to affect basal and GnRH-induced LH and FSH, suggesting that ghrelin does not play a major physiological role in gonadotropin secretion in female subjects (Messini *et al.*, 2009). However, more recent studies have shown opposite results: a pharmacological dose of ghrelin, divided in four boluses, suppressed LH and FSH secretion in young women (Kluge *et al.*, 2012). Ghrelin decreased the frequency of LH pulses in all women and of FSH pulses in the one woman who exhibited clear FSH pulses resulting in a diminished secretion. This pattern further corroborates the widely accepted concept that ghrelin inhibits the hypothalamic GnRH pulse generator (Kluge *et al.*, 2012). The inhibitory effect of ghrelin has been recently demonstrated to be more evident in the late follicular phase of the cycle (Messini *et al.*, 2014).

It is well known that ghrelin is an important signal of energy insufficiency. In fact anorexia, malnutrition and cachexia are generally associated to hypogonadism that reflects a functional impairment of neuroendocrine mechanisms (Vanhorebeek *et al.*, 2006). The pathophysiological conditions mentioned above are associated with ghrelin hypersecretion (Shimizu *et al.*, 2003; Broglio *et al.*, 2004) and this could have a role in the functional hypogonadism connoting anorexia, malnutrition, and cachexia.

Influence on Thyroid Function

In humans plasma ghrelin levels have been reported to be reduced or unaffected in hyperthyroidism and unaffected or increased in hypothyroidism (Kosowicz *et al.*, 2011). A few contrasting published data on the relationship between thyroid status and circulating ghrelin are available in patients affected by Hashimoto's thyroiditis (HT). Recently it was demonstrated that euthyroid HT is associated with a decrease in plasma ghrelin levels and altered body fat distribution and increased anti-TPO levels do not seem to be directly involved in lower ghrelin levels in euthyroid HT patients (Biyikli *et al.*, 2014).

Concerning ghrelin administration, Molica *et al.* demonstrated that GH values after ghrelin boluses results lower in hyperthyroidism, suggesting that thyroid hormones are likely to affect ghrelin neuroendocrine action (Molica *et al.*, 2010). Ghrelin decreases energy expenditure and suppresses TSH secretion, but published literature shows contrasting results. Although Takaya *et al.* had shown no significant variation of TSH levels in humans after intravenous ghrelin administration (Takaya *et al.*, 2000), a more recent study by Kluge *et al.* has demonstrated that consecutive boluses of AG decrease the activity of hypothalamus–pituitary–thyroid axis in 20 healthy adults (Kluge *et al.*, 2010). Ghrelin may exert a stimulating effect at the thyroid level, as suggested by an increase of thyroxine (Kluge *et al.*, 2010; Morillo-Bernal *et al.*, 2011), but a suppressing effect at the hypothalamus level, as indicated by a TSH and TRH decrease (Kluge *et al.*, 2010).

Ghrelin and GHS Activities on the Endocrine Pancreas

Extensive research established a role for ghrelin and GHS in the regulation of insulin release and glycaemia (Yada *et al.*, 2014). GHS-R mRNA and protein are expressed in pancreatic islets of rats and humans (Volante *et al.*, 2002) and in beta cell lines (Wierup *et al.*, 2004).

Ghrelin modulates glucose metabolism in humans and in animal models and glucose homeostasis in a GH-independent manner, suggesting a link between ghrelin and the endocrine pancreas. In particular, both a ghrelin bolus and a ghrelin infusion have been shown to increase glucose levels in healthy young men and women (Broglio *et al.*, 2001, 2003c, 2008; Gauna *et al.*, 2005), and in obese subjects (Tassone *et al.*, 2003). This effect is blunted in patients affected by anorexia nervosa (Broglio *et al.*, 2004; Miljic *et al.*, 2007) and malnourished dialysis patients (Ashby *et al.*, 2009; Garin *et al.*, 2013). A clear relationship between

ghrelin and insulin secretion has been found in humans: AG pharmacological doses inhibit spontaneous, glucose- and arginine-stimulated insulin secretion (Broglio *et al.*, 2001, 2003c), despite increasing or unchanged glucose levels (Mori *et al.*, 2006). Insulin resistance was found in healthy subjects (Vestergaard *et al.*, 2008) and gastrectomized patients (Damjanovic *et al.*, 2006) in hyperinsulinemic euglycemic clamp studies after ghrelin infusion (Garin *et al.*, 2013).The hyperglycemic response to ghrelin is independent of GH (Vestergaard *et al.*, 2008) and the vagus nerve (Huda *et al.*, 2010): ghrelin may likely block insulin inhibitory effects on gluconeogenesis and have a direct, non-GHS-R type 1a-mediated, stimulatory effect on glycogenolysis, since this activity is not shared by synthetic GHS; instead, a direct effect on both insulin resistance and insulin secretion occurs. AG diminishes insulin secretion from beta cells lines or the isolated pancreas in vitro (Granata *et al.*, 2010), whereas it exerts a positive effect on glucagon release, acting on alpha cells (Qader *et al.*, 2008).

In contrast to AG, UAG infusion decreased fasting glucose and increased postprandial insulin in healthy humans (Benso *et al.*, 2012). Administration of AG and UAG in GH deficient men increased fasting and postprandial glucose levels, whereas coadministration of AG and UAG increased insulin sensitivity (Gauna *et al.*, 2004).

Concerning fat metabolism, acute ghrelin administration increased lipolysis in healthy subjects (Vestergaard *et al.*, 2008, 2011) and potentiated a beta-agonist-induced increase in free fatty acids (FFAs) (St-Pierre *et al.*, 2010). AG infusion was associated with a rise in FFA before each meal in healthy, obese and gastrectomized patients (Huda *et al.*, 2011). On the contrary, long term exogenous administration of AG has adipogenic properties (Tschöp *et al.*, 2000; Wells, 2009), inhibiting the sympathetic nervous system through stimulation of orexigenic NPY neurons in order to promote fat deposition (Wells, 2009).

Lipolysis is ghrelin dose-dependent and independent of circulating insulin and GH levels (Vestergaard *et al.*, 2011). On the contrary, UAG infusion decreased circulating FFA levels in healthy volunteers (Benso *et al.*, 2012) and the coadministration with AG decreased postprandial FFA in GH deficient men (Gauna *et al.*, 2004).

Potential Use of Ghrelin Blockade in Glucose Intolerance/Diabetes

The ghrelin blockade counteracts the obesity-associated glucose intolerance in two different models: in ob/ob mice, a genetic model of obesity due to leptin deficiency, ablation of ghrelin augmented insulin release and reduced hyperglycaemia (Sun *et al.*, 2006); in ghrelin Knock Out mice, fed high fat diet for 4 weeks, plasma insulin increased and blood glucose levels did not increase, in comparison with wild-type mice (Dezaki *et al.*, 2006). Thus, under conditions of insulin resistance, the lack of ghrelin may increase the maximal capacity of glucose-induced insulin release in beta cells, enabling them to secrete more insulin in order to prevent glucose intolerance (Yada *et al.*, 2014). Suppression of ghrelin actions could have a potential to counteract diabetes, hyperphagia, and obesity simultaneously, with a specific therapeutic role against the metabolic syndrome (Yada *et al.*, 2014). However, a direct antagonism of the receptor does not always have an antidiabetogenic effect, since it can cause body weight gain (Delhanty and van der Lely, 2011). Pharmacological suppression of the AG/UAG ratio by treatment with UAG may also be a viable alternative approach which appears to improve insulin sensitivity (Van der Lely, 2009; Benso *et al.*, 2012). A promising approach appears to be the GOAT activity blockade using a specific inhibitor, although the longer term effects of this treatment remain to be investigated (Barnett *et al.*, 2010).

Ghrelin and GHS Nonendocrine Actions

Effects on Energy Balance

Ghrelin is the first known peripheral hormone to display orexigenic effects through its action on the hypothalamic appetite-regulating pathways (Nakazato *et al.*, 2001).

The clear preprandial rise and post prandial fall in plasma ghrelin levels support the hypothesis that ghrelin acts as a hunger signal triggering meal initiation in humans (Cummings *et al.*, 2001). This action would be mediated by GHS-R nontype 1a subtypes, as suggested by evidence that GHS analogues devoid of any GH-releasing effect stimulate food intake. Because the rate at which peripheral ghrelin passes the blood–brain barrier has shown to be very low, peripheral ghrelin must activate the appropriate hypothalamic regions via an indirect pathway. The GHS-R localizes on vagal afferent neurons in the rat nodose ganglion. Then, ghrelin signals from the stomach are transmitted to the brain via vagus nerve (Date *et al.*, 2002). This peripheral signaling through vagus nerve, reaches arcuate nucleus of the hypothalamus (Date *et al.*, 2006). In the arcuate nucleus the ghrelin—containing neurons send efferent fibers onto NPY- and AgRP expressing neurons in order to stimulate the release of orexigenic peptides and onto proopiomelanocortin (POMC) neurons in order to suppress the release of anorexigenic peptides (Cowley *et al.*, 2003; Sato *et al.*, 2014). Thus, ghrelin is produced primarily in the stomach in response to hunger and starvation, circulates in the blood and serves as a peripheral signal, informing the arcuate nucleus of CNS to stimulate feeding.

Published literature has demonstrated that exogenous ghrelin and GHS central or peripheral administration has an orexigenic effect in humans as well as in animal models. AG infusion and/or bolus increases appetite and/or food intake in healthy volunteers, obese patients (Druce *et al.*, 2005), cancer patients (Lundholm *et al.*, 2010), and patients with some form of cachexia (Nagaya *et al.*, 2005). The only patient populations in which a single infusion of AG does not exert appetite stimulation are postvagotomy or gastrectomy patients (Huda *et al.*, 2009; le Roux *et al.*, 2005).

Potential ghrelin use in obesity

Plasma ghrelin levels inversely correlate with body mass index (BMI). Thus, ghrelin is reduced in obesity compared to normal weight as an adaptation to a long-term positive energy balance (Williams *et al.*, 2006; Sherif *et al.*, 2011). Recent evidence suggests that one of the mechanisms of diet-induced obesity is that ghrelin resistance arises by reducing NPY/AgRP responsiveness to plasma ghrelin and suppressing the neuroendocrine ghrelin axis in order to limit further food intake (Sato *et al.*, 2014). It has been shown that selective ghrelin blockade in diet-induced obese mice results in reduction of food intake, body weight, and body fat mass (Shearman *et al.*, 2006; Sherif *et al.*, 2011).

Both ghrelin and its related substances have been investigated as targets against obesity (Sato *et al.*, 2014). Neutralization of ghrelin by the specific antibody reduced body weight gain with the reduction of fat mass in rats (Zorrilla *et al.*, 2006).

Spiegelmers, antisense polyethylene glycolmodified L-oligonucleotides, have the ability of specifically binding a target molecule. Inhibitory effects of ghrelin-induced GH release in rats were exerted by NOX-B11-3 (Helmling *et al.*, 2004; Becskei *et al.*, 2008). Thus, vaccination against ghrelin and the use of ghrelin spiegelmers may be useful in the treatment of obesity.

GHS-R is also an useful target for obesity drugs. For many years, several classes of GHS-R1a antagonists have been developed (Sato *et al.*, 2014). A representative GHS-R1a antagonist is [D-Lys3-]GHRP-6. By treatment of [D-Lys3-]GHRP-6, food intake is decreased and weight gain is reduced in lean and obese mice (Asakawa *et al.*, 2003; Beck *et al.*, 2004). Piperidine-substituted quinazolinone derivatives were identified as a novel class of small GHS-R1a antagonist molecules (Rudolph *et al.*, 2007). A piperidine substituted quinazolinone derivative, YIL-781, improved glucose-stimulated insulin secretion and reduced food intake in diet-induced obese mice (Esler *et al.*, 2007). Thus, a certain result on obesity is expected from GHS-R1a antagonists.

Inverse GHS-R1a agonist may also be one of the candidates. In fact, an inverse agonist, such as [D-Arg1, D-Phe5, D-Trp7,9, Leu11] substance P, may be a candidate to regulate ghrelin action (Holst and Schwartz, 2004). Reduction of the GHS-R1a constitutive activity by an inverse agonist could increase the sensitivity to anorexigenic hormones like leptin, and then, inhibit food intake.

GOAT has been implicated as another attractive and potential target for the development of antiobesity treatment. Barnett *et al.* described the design, synthesis, and characterization of GO-CoA-Tat, a peptide-based bisubstrate analog that antagonizes GOAT (Barnett *et al.*, 2010). Intraperitoneal administration of GO-CoA-Tat improves glucose tolerance and reduces weight gain in wild-type but not ghrelin-deficient mice (Barnett *et al.*, 2010); thus, its beneficial metabolic effects are due specifically to GOAT inhibition. Moreover, quantitative magnetic resonance measurements showed that, relative to controls, GO-CoA-Tat treated animals displayed significantly lower fat mass, but not lean mass (Barnett *et al.*, 2010). GOAT is therefore a potentially useful target for future development of therapeutic compounds.

Bariatric surgery, weight loss and improvement in glucose tolerance and role of ghrelin

Currently used bariatric procedures are classified as restrictive, malabsorptive, or combined, according to the mechanism of weight loss. Restrictive procedures, such as laparoscopic adjustable gastric banding (LAGB), vertical banded gastroplasty (VBG), and sleeve gastrectomy (SG) greatly reduce the volume of the stomach in order to decrease food intake and induce early satiety. In particular, SG totally removes the gastric fundus. Malabsorptive techniques, such as biliopancreatic diversion with duodenal switch (BPD/DS), shorten the small intestine to decrease nutrient absorption while combined procedures, such as the Roux-en-Y gastric bypass (RYGB, considered as gold standard procedure for bariatric surgery), incorporate both restrictive and malabsorptive elements. RYGB additionally creates malabsorption by the rapid shunt of undigested food to the distal small intestine (Vetter *et al.*, 2009).

Both short and long-term effects of bariatric surgery upon ghrelin concentration are still unclear. Different bariatric procedures seem to have different effects on ghrelin secretion, possibly due to anatomical variations influencing the stomach volume and the degree of contact between ingested nutrients and gastric mucosa where ghrelin producing cells are located (Meek *et al.*, 2016).

Although an empty stomach is associated with an increased ghrelin level in the short term, it is possible that the permanent absence of food in the stomach and duodenum causes a continuous stimulatory signal that ultimately suppresses ghrelin production through a process of "override inhibition" (Cummings *et al.*, 2002). Moreover, ghrelin levels are affected by the vagus nerve and tend to be higher after procedures that preserve the vagal fibers, such as LAGB, in comparison with RYGB (Vetter *et al.*, 2009).

The effects of RYGB on ghrelin levels are contradictory (Frühbeck *et al.*, 2004): although many studies report decreased ghrelin levels after surgery (Cummings *et al.*, 2002), others report no changes (Faraj *et al.*, 2003; Yousseif *et al.*, 2014) or increased concentrations (Holdstock *et al.*, 2003; Kalinowski *et al.*, 2017). Moreover, Nergård and colleagues demonstrated that the density of ghrelin cells and ghrelin mRNA levels did not differ 12 months after RYGB (Nergård *et al.*, 2015). These disparate effects could be due to variations in surgical technique resulting in different dimensions and consequent different amount of intact ghrelin-producing tissue (Vetter *et al.*, 2009). In fact, when present, the reduction in fasting ghrelin after RYGB occurs as early as after surgery (2–6 weeks), suggesting that its reduction is mostly a consequence of altered anatomy (Jeon *et al.*, 2004).

Sleeve gastrectomy may decrease circulating AG concentrations, possibly due to the removal of ghrelin-producing cells in the stomach (Anderson *et al.*, 2013; Yousseif *et al.*, 2014; Kalinowski *et al.*, 2017). Hypothetically, the additional mechanism of reduced appetite post SG, due to the significant lowering of ghrelin levels, could compensate the lack of the malabsorption effect which does not occur with a restrictive surgery as SG (Makris *et al.*, 2017).

However, weight loss itself may play a central role in regulating plasma ghrelin levels. The increase in fasting ghrelin after LAGB seems to occur over time, suggesting a predominant role of weight loss instead of restriction of nutrient flow (Korner *et al.*, 2009). Ghrelin levels after RYGB remain unchanged in weight-stable patients but increase by approximately 60% in

weight-reducing subjects, suggesting that weight loss and negative energy balance may be an important determinant of postsurgical ghrelin levels (Faraj *et al.*, 2003). No correlations between decrease in ghrelin concentrations and change in appetite were found (Bužga *et al.*, 2014).

These data suggest that the role of ghrelin in the induction and maintenance of weight loss after bariatric surgery might be marginal although procedures in which ghrelin is decreased could benefit from the additional inhibition of feeding resulting from a reduced ghrelin action (Ionut *et al.*, 2013).

A summary of the described effects of bariatric surgery on ghrelin levels is provided in **Table 3**.

Changes in ghrelin concentrations induced by bariatric surgery may contribute to improvement of glycaemic metabolism and remission of diabetes (Ramón *et al.*, 2012).

Beneficial effects on glucose metabolism, including remission of type 2 diabetes mellitus (T2DM), occurs in 48% and 84% of patients who underwent LAGB and RYGB respectively (Korner *et al.*, 2009), but those percentages can vary depending on the different thresholds used to define the improvement of glycaemic control.

The rate of remission also depends on the phenotype of the patients: short diabetes duration, reliable β-cell function (assessed by C-peptide measurements), and absence of insulin requirement are predictors of type 2 diabetes remission after bariatric surgery (Madsbad *et al.*, 2014). In fact, in earlier studies of RYGB, longer duration of diabetes (>10 years), poor preoperative glycaemic control and preoperative insulin use reduced the probability of diabetes resolution (Schauer *et al.*, 2003). Similarly, Dixon and colleagues reported that a short duration of disease (<3 years) could predict T2DM remission after LAGB (Dixon *et al.*, 2003).

Another important factor involved in improvement of glycaemic control is the percentage in excess weight loss (%EWL) after surgery (Hady *et al.*, 2012); a remission of symptoms of T2DM after LAGB was observed in patients with higher %EWL (Polat *et al.*, 2010). In comparative studies for LAGB, RYGB, and BPD/DS the percentage of patients with T2DM symptoms remission in a 5 year follow-up was similar for all procedures, excluding differences in %EWL (Hady *et al.*, 2012).

Changes in plasmatic concentration of gut hormones (GLP-1 and GIP) might also play a central role in T2DM remission. Korner *et al*. reported that postprandial GLP-1 levels after RYGB were significantly greater than presurgical values and higher when compared with LAGB (Korner *et al.*, 2009). Furthermore, GLP-1 cell density was 4.9-fold higher 12 months after RYGB; a larger increase in GLP-1 cell density was evident in patients with longer biliopancreatic limb (200 cm) (Nergård *et al.*, 2015). Finally, low deterioration in beta cell function may maximize the effect of surgery in increasing plasmatic levels of gut peptides (mainly GLP-1) that enhance insulin secretion (Vetter *et al.*, 2009).

In conclusion, improvements in glycaemic control in diabetic patients undergoing bariatric surgery are probably mediated by several mechanisms, including caloric restriction, increased satiety and change in plasmatic concentration of hormones such as ghrelin, GLP-1, GIP, and PYY. Collectively, caloric restriction and alterations in the enteroinsular axis probably affect both insulin secretion and sensitivity, resulting in improvement or remission of T2DM (Vetter *et al.*, 2009).

Effects on the Cardiovascular System

Ghrelin has been proposed to act on the cardiovascular system in a direct and an indirect way. Ghrelin could have beneficial effects on the cardiovascular system in a direct way, through an increase in GH activity, similar to what is seen during GH replacement therapy in GH-deficient patients (Amato *et al.*, 1993). Ghrelin could act directly on the cardiovascular system, binding GHS receptors in the myocardium and blood vessels (Katugampola *et al.*, 2001). In fact, ghrelin is demonstrated to dilate human arteries (Okumura *et al.*, 2002) in an endothelium-independent mode. In addition, ghrelin inhibits apoptosis of cultured cardiomyocytes and endothelial cells possibly through activation of extracellular signal-regulated kinase-1/2 and Akt serine kinases (Baldanzi *et al.*, 2002).

In humans, Nagaya *et al*. studied the cardiovascular effects of 10 mg/kg ghrelin in healthy volunteers (Nagaya *et al.*, 2001). In this study, plasma GH levels increased 15-fold 20 min after i.v. ghrelin administration and there was also an increase in epinephrine concentrations, while norepinephrine levels did not change. It was noted that ghrelin treatment produced a decrease of

Table 3 Effects of bariatric surgery on ghrelin levels compared with the condition of obesity

	Ghrelin	*References*
Obesity (without surgery)	↓ Fasting and postprandial	Sherif *et al.* (2011)
Laparoscopic adjustable gastric banding (LAGB)	↑	Korner *et al.* (2009)
Sleeve gastrectomy (SG)	↓ Fasting and postprandial	Anderson *et al.* (2013), Yousseif *et al.* (2014), and Kalinowski *et al.* (2017)
Roux-en-Y gastric bypass (RYGB)	↓	Frühbeck *et al.* (2004)
	↓	Cummings *et al.* (2002)

systemic vascular resistance and mean arterial pressure and increased cardiac index and stroke volume index in normal subjects and in patients with chronic heart failure (Nagaya *et al.*, 2001). Thus, since the administration of ghrelin has been demonstrated to decrease blood pressure, reduce cardiac afterload and increase cardiac output without affecting heart rate in humans and in animals (Matsumura *et al.*, 2002; Nagaya *et al.*, 2001), the therapeutic potentials of ghrelin in different cardiac diseases have been speculated. In patients with congestive heart failure, for instance, ghrelin intravenous administration for 3 weeks significantly improved left ventricular ejection fraction (from 27% to 31%; $P < .05$) and increased peak workload and peak oxygen consumption during exercise, which was accompanied by a dramatic decrease in plasma norepinephrine (from 1132 to 655 pg/mL; $P < .001$) (Nagaya *et al.*, 2004; Kishimoto *et al.*, 2012).

Antiproliferative Effects

Ghrelin and its receptor are now known to be expressed not only in normal, but also in malignant tissues. GHS-R have been also found in neoplastic endocrine and nonendocrine tissues even from organs that do not express these receptors under physiological conditions, such as the breast. The first suggestion that the ghrelin/GHSR1a axis could be involved in cancer progression, before the discovery of ghrelin itself, was the finding that the GHSR1a is expressed not only in normal pituitary, but also in pituitary and neuroendocrine tumors (Korbonits *et al.*, 1998). Then, soon after its discovery, it was speculated that ghrelin and GHSR1a could play a role in pituitary tumor pathogenesis through an autocrine or paracrine pathway (Kim *et al.*, 2001) by modulating pituitary hormone release (Korbonits *et al.*, 2001). Ghrelin was later demonstrated to increase cell proliferation in the rat pituitary somatotroph GH3 cell line through the ERK1/2 pathway (Nanzer *et al.*, 2004).

Ghrelin and its receptor may be an autocrine/paracrine growth factor in a number of cancer tissues (Chopin *et al.*, 2012). The first functional study indicating that ghrelin treatment stimulated cell proliferation was about the HepG2 hepatoma cell line (Murata *et al.*, 2002). Then other studies followed: human leukaemic cell lines, in adrenocortical carcinoma, in pancreatic adenocarcinoma, in colorectal cancer, in prostate, breast and endometrial cell lines (Chopin *et al.*, 2011). However, some reports indicate that ghrelin may inhibit cell proliferation: in thyroid, prostate, breast, and small cell lung carcinoma cell lines (Chopin *et al.*, 2011). These discrepancies could be explained by the different ghrelin concentration used: for example the application of supraphysiological doses of ghrelin in prostate cancer cell lines could have an inhibitory effect, while physiological levels could stimulate cell proliferation (Lanfranco *et al.*, 2008b). As there have been a number of conflicting results, it is now unclear whether ghrelin promotes cancer or inhibits its development and further studies are required.

Conclusions

Ghrelin, a 28-residue acylated peptide predominantly produced by the stomach, displays a strong GH-releasing action but also shows other central and peripheral endocrine and nonendocrine actions via the activation of the GHS-R. Indeed, ghrelin isolation helped elucidate GH–IGF-I physiology and the hypothalamic appetite-regulating pathways but also opened new promising perspectives in other medical fields, such as internal medicine, oncology, and cardiology. Nowadays ghrelin and/or GHS analogues have certainly a diagnostic application and researchers are working on the possibility that ghrelin has a potential therapeutic role, mostly in glico-metabolic fields.

Luteinizing Hormone (LH)☆

Livio Casarini and Daniele Santi, University of Modena and Reggio Emilia, Modena, Italy
Gary R Marshall, University of Pittsburgh School of Medicine, Pittsburgh, PA, United States
Manuela Simoni, University of Modena and Reggio Emilia, Modena, Italy

Introduction

Luteinizing hormone (LH) is a glycoprotein secreted by the pituitary gland in a pulsatile fashion and, in concert with follicle-stimulating hormone (FSH), plays a central role in reproduction. LH acts directly on the gonads, binding to its receptor on the surface of the target cells and initiating a cascade of molecular events beginning with the activation of specific signaling pathways and ending with the expression of gene products. In the ovary, LH stimulates (1) the outer layer of the primary follicle, the theca cells, to produce androgens to be converted to estrogens during folliculogenesis; (2) ovulation; and (3) the formation of the corpus luteum, which secretes progesterone. These structures and their products prepare the female reproductive tract for fertilization, implantation, and pregnancy. In the testis, this gonadotropin stimulates the synthesis of androgens by the Leydig cells. Androgens are required for fetal development of the male phenotype, for sexual maturation of male mammals, and for spermatogenesis in the adult testis. In both sexes, the gonadal products of LH stimulation that enter the circulation regulate the secretion of this gonadotropin by modifying the release of the hypothalamic peptides, kisspeptin and gonadotropin-releasing hormone (GnRH), or acting directly on the pituitary gland.

Molecular Structure

LH is a protein composed of two glycosylated polypeptide subunits, designated α and β, and has a molecular weight of approximately 28 kDa, varying with the species and the length of the added oligosaccharides. The α-subunit (14 kDa) is common to two other glycoprotein hormones, namely, FSH, chorionic gonadotropin (CG) and thyroid-stimulating hormone (TSH) (Ascoli *et al.*, 2002). Especially, in primates, the placenta secretes CG during pregnancy, that has more oligosaccharide moieties and a longer carboxyl-terminal peptide in its β-subunit. These modifications confer a longer half-life on CG in the circulation, leading to a more sustained action (Fournier *et al.*, 2015). Acting on the LH receptor (LHCGR), human CG (hCG) may replace LH during treatments of infertility. The β-subunit is unique to each glycosylated hormone and is specific for receptor binding, thus conferring biologic activity to the hormone. Although the α-subunit alone may be secreted and may achieve relatively high concentrations in the blood, no function for the free α-subunit per se has been demonstrated. However, α-subunit interacts with LHCGR during binding (Kreuchwig *et al.*, 2013).

Carbohydrate groups are present at specific locations on each subunit and are important determinants of the biological activity and metabolic clearance of LH. The oligosaccharide moieties are coupled through *N*-acetylglucosamine at a specific amino acid, asparagine. The α-subunit of human LH has two sites, while one site is in the β-subunit. The oligosaccharides, containing the monosaccharides mannose, galactose, glucosamine, *N*-acetylgalactosamine, and sialic acid, are branched, heterogeneously, and terminate mainly in sulphate and fucose. These differences are largely responsible for the variation in isoelectric point (6–10) of this gonadotropin. The alkaline forms are biologically more active in bioassays, but are also more rapidly cleared from the circulation. Removal of terminal sialic acid residues from the oligosaccharides reduces the half-life of LH in circulation, but has little effect on the binding of LH to its receptor (Arey and López, 2011).

Synthesis and Secretion

Human LH β-subunit is encoded by the *LHB* gene located on chromosome 19q13.3. It falls within a genetic cluster spanning about 40 Kbase-pairs and comprising eight genes, encoding hCG β-subunits (*CGBs*), likely originated by repeated duplications of an ancestral *LHB* gene. It was theorized that, during ancient evolution of primates, *CGB* genes were subjected to frame-shift mutations and nucleotide insertions producing 24 additional codons and a variety of CG molecules (Hallast *et al.*, 2005).

The pituitary cells that synthesize LH are called gonadotropes and they can be placed in one of three categories based on the results of immunocytochemical staining. The majority of the gonadotropes synthesize both LH and FSH, whereas the two other categories are composed of cells that exclusively synthesize either FSH or LH. The gonadotropes are stimulated by the

 doi:10.1016/B978-0-12-801238-3.64299-X

hypothalamic polypeptide, GnRH, which secretion is pulsatile. GnRH is released by neurons that terminate on the blood vessels running along the pituitary stalk. GnRH release occurs under the stimulation of a peptide product named kisspeptin, which was described in several mammalian species as a stimulator of the gonadotrophic axis and an activator of GnRH neurons at puberty (Tena-Sempere, 2006). Kisspeptin is produced mainly in the hypothalamus and regulated upon a feedback mechanism played by steroid hormones and acts through a G protein-coupled receptor (GPCR) (**Fig. 1**). It supports the pulses of GnRH to the gonadotropes in the pituitary gland and stimulate the synthesis and release of LH. Accordingly, LH is also released from the pituitary gland in pulses. The frequency of the GnRH pulses results in concurrent, selective pulsatile secretion of LH or FSH (Thompson and Kaiser, 2014). GnRH binds to a GPCR on the surface of the gonadotrope cells, activating the Gq/11 proteins, which, in turn, stimulate phospholipase C. This enzyme generates inositol 1,4,5-triphosphate and diacylglycerol. The increased levels of these intracellular messengers activate protein kinase C (PKC) and increase intracellular calcium also. PKC and calcium regulate the expression of the *LHB* gene, whereas the secretion of LH is regulated by the increase in intracellular calcium (Millar, 2005; Caunt *et al.*, 2006).

Differently to LH, hCG is released by trophoblast cells during pregnancy in a constant, increasing manner, achieving the peak at about 3 months of gestation. Several hCG isoforms and glycosylation variants are produced, resulting in a number of molecules featuring different half-life and functions not completely characterized (Evans *et al.*, 2015). This hormone mediates trophoblast invasion of maternal tissues, angiogenesis and progesterone production acting through LHCGR. Moreover, it mediates thyroid hormones production, at least in part, cross-reacting with the TSH receptor. A relatively low amount of pituitary hCG was also described, but its function is still to be elucidated.

Receptor and Receptor Defects

LHCGR is predominantly in the gonads of each sex, although extragonadal receptors with not fully clear functions have been found in tumors as well as other tissues. LHCGR (85–95 kDa) is a member of the family of GPCRs; therefore, it is composed of three domains: a transmembrane domain, an extracellular domain, and an intracellular domain (Troppmann *et al.*, 2013). The transmembrane domain is composed of seven hydrophobic stretches of 20–25 amino acids that form α-helices traversing the cellular membrane alternating between intracellular and extracellular loops. The extracellular domain of the receptor binds LH, which, in turn, causes the conformational change transmitted through a hinge region to the intracellular domain, activating the Gαs protein. This is the first step in an intracellular cascade that continues with the activation of the enzyme adenylyl cyclase and the conversion of adenosine tri-phosphate (ATP) to 3′,5′-cyclic adenosine mono-phosphate (cAMP). In turn, protein kinase A (PKA) is activated and phosphorylation of the transcription factor CREB (cAMP regulatory element-binding protein) leads to the expression of genes coding for several factors regulating steroid synthesis, cell proliferation and differentiation. The activation of this intracellular signaling cascade, known as cAMP/PKA-pathway, may be linked to pro-apoptotic signals via a complex intracellular cross-talk, resulting in TP53 gene expression, p53 activation, procaspase 3 cleavage and apoptosis (Amsterdam *et al.*, 1999;

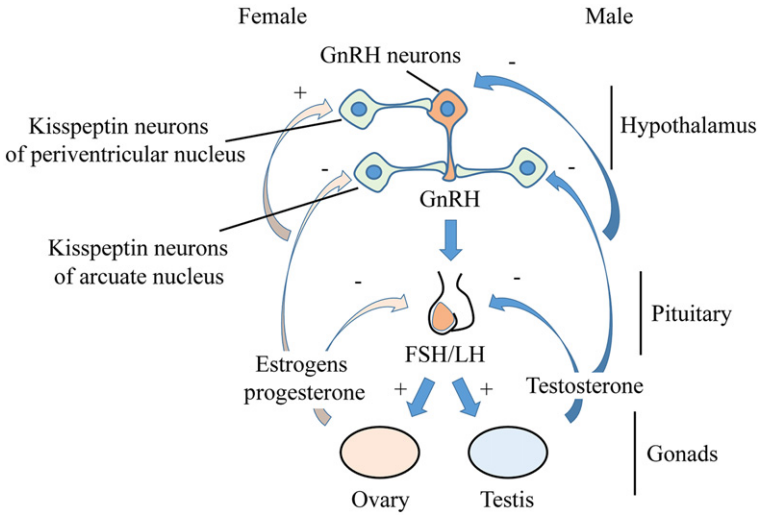

Fig. 1 Feedback controls of gonadotropins' production. In the hypothalamus, kisspeptin neurons stimulate GnRH secretion under the control of steroid feedback. GnRH release is pulsatile and induces the release of LH and FSH by the anterior pituitary. In the gonads, gonadotropins promote gamete formation and the production of steroid hormones, which, in turn, regulate GnRH release by a feedback mechanism. In females, steroid hormones estrogens and progesterone exert a positive feedback on kisspeptin neurons of the periventricular nucleus, inducing the preovulatory surge of GnRH and LH. On the contrary, estrogens and progesterone inhibit kisspeptin production in the arcuate nucleus. In the male, testosterone exerts a negative feedback on kisspeptin neurons of the arcuate nucleus, as well as on GnRH neurons and pituitary, inhibiting GnRH and gonadotropins release.

Casarini *et al.*, 2016a,b). This pathway has been expanded to include various isoforms of adenylyl cyclase, phosphodiesterase, and anchoring proteins of PKA. Other transcription factors, for example, stimulatory protein 1, upstream stimulatory factor, and estrogen receptor α and β, have been shown to be activated by high intracellular concentrations of cAMP. In addition, CREB can be phosphorylated by kinases other than PKA, such as extracellular-regulated kinase 1/2 (ERK1/2) (Menon and Menon, 2012). ERK1/2 is rapidly recruited by PKA (1–5 min after ligand-receptor binding) and has the dual role to amplify the steroidogenic signal mediated through CREB, and, in parallel, trigger the recruitment of GPCR kinases, which catalyze the phosphorylation of LHCGR at the intracellular level. The phosphorylated receptor is a target of other intracellular interactors, such as β-arrestins, which bind LHCGR before internalization as a system for cell desensitization (Musnier *et al.*, 2010). Moreover, β-arrestins mediate a late ERK1/2 phosphorylation (5–15 min), important for the maintenance of steroidogenic and proliferative signals. Since LHCGR may be coupled to different types of G proteins, several signaling pathways may be simultaneously activated upon hormone binding, such as the antiapoptotic phosphatidylinositol 3-kinase (PI3K)/protein kinase B (AKT) pathway, thus resulting in a complex balance between life and death signals and determining the cell fate (Amsterdam *et al.*, 2003).

The gene encoding LHCGR contains 11 exons, and several splice variants have been identified. Exons 1–10 encode the N-terminal and extracellular domain, as well as part of the hinge region, while exon 11 encodes the remaining part of the hinge region, the transmembrane and intracellular G protein-activating domains. Several LHCGR mutations have been identified, resulting either in constitutive activation or in inactivation (Latronico and Arnhold, 2012; Ulloa-Aguirre *et al.*, 2014). Activating mutations of LHCGR in boy results in precocious puberty observed at 1–4 years of age. Activating mutations in girls do not lead to precocious puberty because the gonadotropin FSH is necessary to stimulate folliculogenesis. However, polymorphic LHCGR or LHβ variants may impact on LH signaling resulting in hyperandrogenic females affected by pathological conditions linked to androgen excess, such as polycystic ovary syndrome (Rosenfield and Ehrmann, 2016). Mutations that completely inactivate LHCGR in boys result in genetically male infants displaying female external genitalia but having abdominal testes and lacking Müllerian structures. Interestingly, inactivation of LH-mediated signaling may occur due to mutations within untranslated *LHCGR* short variants, causing male pseudohermaphroditism (Kossack *et al.*, 2008). These variants are produced at the mRNA level as truncated forms at the level of exon 6 and display an additional, primate-specific exon (exon 6A) featuring stop codons. They are highly expressed in Leydig and granulosa cells where trigger nonsense-mediated mRNA decay (NMD). Mutations leading to aberrant amount of exon 6A transcripts result in *LHCGR* destruction by NMD and are linked to the pathological phenotype. Mutations that do not completely inactivate the LH receptor in boys, however, result in male infants with micropenis sometimes associated with hypospadia, but the intra-abdominal testes have few, if any, androgen-secreting Leydig cells. Deletions of *LHCGR* exon 10 are associated to hypogonadism due to impaired LH signaling (Müller *et al.*, 2003). In patients carrying homozygous mutant LHCGR, testosterone synthesis may be restored upon treatment by hCG, revealing that exon 10 encodes part of the receptor fundamental for differentiating LH- and hCG-specific signaling (Grzesik *et al.*, 2015). Interestingly, in the New World monkey *Callithrix jacchus*, pituitary messenger RNAs corresponding to choriogonadotropin transcripts were found. This may be an endocrine adaptation of the pituitary-gonadal axis, which molecules able to bind Lhcgr naturally lacking the amino acid sequence from exon 10 were encoded (Gromoll *et al.*, 2003). In girls, inactivating mutations of the LH receptor, either complete or incomplete, result in normal primary and secondary female characteristics, but also result in amenorrhea because LH is required for folliculogenesis.

Action in the Ovary

During fetal development of the female mammal, the primitive germ cells in the putative ovary enter meiosis and arrest in the prophase of meiosis I. Each oocyte is surrounded by a single layer of granulosa cells, and soon after formation, these primordial follicles enter a resting phase. The mechanisms that stimulate the primordial follicles to initiate folliculogenesis are unknown, but the process begins at once and continues until all follicles are depleted from the ovary. During fetal life, at least in primates and ruminants and within the first 2 weeks after birth in rodents, some of the primordial follicles are activated and become primary follicles. Two layers of cells develop around the oocyte: the outermost are the theca cells that are separated from the innermost layers of granulosa cells by a basement membrane.

The rupture of the follicle, along with the release of the oocyte and some of the granulosa cells surrounding it, is called ovulation. During the periovulatory period, antiinflammatory factors are produced and appear to aid in rapid healing and vascularization of the ruptured follicle. The theca and granulosa cells remaining in the ruptured follicle differentiate into luteal cells, forming the corpus luteum, which characterizes the luteal phase of the ovarian cycle. If no pregnancy occurs, after a finite time specific to each species, the corpus luteum dies, marking the end of the luteal phase. The rapid involution of the corpus luteum is called luteolysis and is regulated by specific factors. Luteolysis is necessary before a subsequent ovarian cycle can begin. The follicular phase, ovulation, the luteal phase, and luteolysis constitute the ovarian cycle and LH plays some role in all phases of the cycle (Atwood and Vadakkadath Meethal, 2016).

LH has three functions in the ovary: (1) stimulation of androgen synthesis during the follicular phase; (2) stimulation of ovulation; and (3) following ovulation, differentiation of the thecal and granulosa cell remnants of the ruptured follicle into luteinized cells. The luteal cells constitute the steroidogenic cells of the corpus luteum, shifting from predominantly estrogen-producing cells to progesterone-producing cells.

LH binds to its receptor on the theca cells of the follicle and stimulates the synthesis of androgens. Steroidogenesis begins with the movement of cholesterol from its storage site on the outer mitochondrial membrane to the inner mitochondrial membrane, where the cytochrome P450-associated enzyme removes the side chain of cholesterol, producing pregnenolone. This mobilization of cholesterol is the rate-limiting step in steroidogenesis and LH, as well as FSH, regulates the production of a protein called steroidogenic acute regulatory (StAR) protein (Miller and Auchus, 2011). The tertiary structure of this 30 kDa protein has a domain containing a cholesterol-binding hydrophobic tunnel that may permit StAR to shuttle cholesterol across the mitochondrial membranes. The steroids are lipid-soluble, unlike cholesterol, and the steroidogenic enzymes are readily accessible for production of the androgen, androstenedione. This androgen diffuses out of the thecal cells and into the granulosa cells, where the enzyme aromatase, stimulated by FSH action, converts androstenedione into estradiol. As the theca and granulosa cells of the maturing follicles proliferate, a greater amount of estradiol is produced, which triggers proliferative signaling in the follicles. Moreover, the number of LH receptors on each granulosa cell is increased under FSH stimulation, leading to increased sensitivity to the hormone mediating both proliferative and antiapoptotic signals via ERK1/2, AKT-, and other pathways (Kayampilly and Menon, 2009). With the increased number of LH receptors on the theca and granulosa cells, only those follicles with sufficient LH stimulation will continue folliculogenesis. Once the circulating estradiol produced by the antral follicle is elevated, this steroid causes an abrupt release, or surge, of LH from the pituitary. The surge of LH causes ovulation by increasing the expression of PKA and increasing the inositol lipid hydrolysis that activates PKC, shifting the pattern of gene expression in the granulosa cells. The shift results in the suppression of cell division and change of the intracellular enzymatic milieu of the granulosa cells, signaling of the oocyte to reenter meiosis, and rupture of the follicle wall.

After ovulation, the luteinized granulosa and theca cells remaining in the ruptured follicle begin to synthesize progesterone. Although the luteal cells of some species, for example, human, are able to produce small amounts of estrogen, the cellular differentiation leads to primarily, or, in some species, only progesterone production by luteal cells. This hormone prepares the endometrium of the uterus to be receptive for the blastocyst, if fertilization of the oocyte occurs, and exerts a negative feedback on GnRH and gonadotropin production by pituitary. The corpus luteum under LH regulation continues to survive for a specific period of time, depending on the species. If, on one hand, no blastocyst is formed, then the corpus luteum involutes through programmed cell death, as a consequence of declined LH levels. If, on the other hand, implantation of a blastocyst occurs, hCG secreted by the blastocyst and later by the placenta binds to LHCGR on the corpus luteum, at least in human, rescuing it from luteolysis and maintaining the production of progesterone. hCG has a greater potency in activating cAMP-mediated signals (**Fig. 2**), such as steroidogenesis, and a longer half-life in the circulation than LH itself, which, instead, retains higher proliferative and antiapoptotic potential, at least in granulosa cells (Casarini *et al.*, 2012; Riccetti *et al.*, 2017; Casarini *et al.*, 2017). These gonadotropin-specific features reflect the different physiological role of the two hormones, providing LH as a mediator of proliferative stimuli occurring in folliculogenesis, while hCG is suitable for massive progesterone synthesis supporting pregnancy (Casarini *et al.*, 2016a,b).

Action in the Testis

In the testis, LH acts through binding to its receptor expressed in the Leydig cells, stimulating the production of the androgenic steroid, testosterone. The adult mammalian testis is an ovoid structure covered by a capsule called the tunica albuginea. The parenchyma of the organ is composed of two compartments, the seminiferous tubules and the interstitium between the tubules. The seminiferous tubules contain the epithelium where spermatogenesis takes place. The interstitium contains the Leydig cells, fibroblasts, macrophages, nerves, blood, and lymphatic vessels.

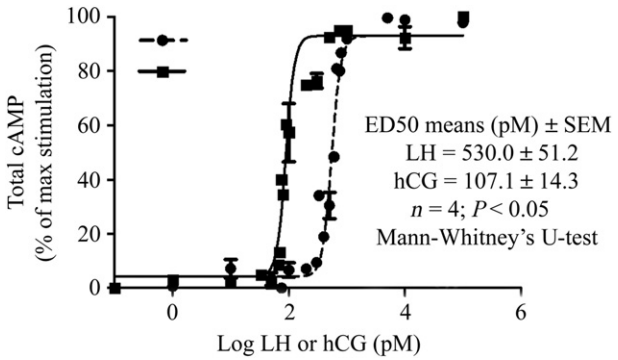

Fig. 2 Different potency of LH and hCG in activating cAMP. In LHCGR-transfected COS-7 cells, total cAMP production was evaluated upon 3-h treatment by recombinant LH and hCG. Statistical analysis revealed different effective dose 50% (ED50) between LH and hCG, demonstrating that hCG is about fivefold more potent than LH in inducing cAMP production (Mean ± SEM; Mann-Whitney's U-test; $P < .05$; $n = 4$). Image extracted and modified from the original article under Creative Commons Attribution license (Casarini, L., Lispi, M., Longobardi, S., *et al.* (2012). LH and hCG action on the same receptor results in quantitatively and qualitatively different intracellular signalling. *PloS One*, **7**, e46682).

Steroidogenesis begins in the Leydig cell, as it does in the theca cell of the ovary as a counterpart of female, with the movement of cholesterol from its storage site on the outer mitochondrial membrane to the inner mitochondrial membrane, where the cytochrome P450-associated enzyme removes the side chain of cholesterol, producing pregnenolone. This mobilization of cholesterol is the rate-limiting step in steroidogenesis and LH regulates the production of StAR protein. The steroids are lipid-soluble, unlike cholesterol, and the steroidogenic enzymes are readily accessible for production of the androgen, testosterone (**Fig. 3**). This androgen is a major stimulator of spermatogenesis in the adult male mammal. Since hCG binds LHCGR and stimulates StAR production, exogenous administration of the pregnancy hormone results in testosterone synthesis by male Leydig cells, providing a strategy to treats the hypogonadotropic hypogonadism in males (Pitteloud and Dwyer, 2014).

Testosterone is an important regulator of the spermatogenesis. This process starts from diploid, spermatogenetic stem cells called spermatogonia which, in human, exist as type Ad and the more differentiated Ap spermatogonia. The latter undergo mitosis forming type B spermatogonia. This final generation of differentiated spermatogonia undergoes mitosis and produce the primary spermatocytes. Spermatocytes are the germ cells that undergo meiosis and the products of this cell division are the haploid spermatids. The spermatids enter spermiogenesis, during which the nuclear contents condense, the specialized lysosome, the acrosome, is formed, a tail is produced, and the amount of cytoplasm is reduced. The duration of the whole spermatogenesis is of about 74 days in human and is structurally and metabolically supported by Sertoli cells.

Sertoli cells mediate hormonal effects on the seminiferous epithelium and on spermatogenesis, and their activities are regulated mainly by FSH. These cells are the only somatic component of the epithelium and provide the cytoarchitecture of the seminiferous epithelium, nourish the germ cells, and secrete the hormone inhibin B for pituitary control of the spermatogenesis. Moreover, Sertoli cells produce the androgen-binding protein (ABP), which binds testosterone resulting in the accumulation of the hormone in proximity of gametes. Testosterone plays a central role in the regulation of spermatogenesis, especially for the progress of meiotic phases. The hormone acts through the nuclear, androgen receptor (AR) expressed in Sertoli cells, sperms and other peripheral tissues. The functional significance of testosterone on spermatogenesis was provided by studies in complete AR knockout (ARKO) and Sertoli cell-selective AR knockout (SCARKO) mice (Tan *et al.*, 2005). All these knockout models displayed impairment of normal spermatogenesis, but ARKO revealed a more severe phenotype than SCARKO mice. Especially, Sertoli and Leydig cell number was extremely decreased in ARKO mice compared to controls, while it was slightly reduced in SCARKO mice, which even maintained the capacity to support spermatogonia by Sertoli cells. These data support the concepts that AR is not expressed exclusively in Sertoli cells and androgens may acts on other gonadal cells.

Most importantly, endocrine disrupting chemicals have recently attracted the attention of several researches, since they may impact on fertility affecting steroid hormones signaling and, therefore, resulting in low sperm quality and decreased sexual functions. For instance, the organic synthetic compound bisphenol A mimics the effects of estrogens and acts as an androgen antagonist injuring Sertoli cells (Rochester, 2013).

Pituitary plays a central role in stimulating spermatogenesis (Steinberger, 1971). Surgical removal of the pituitary gland of adult rats led to a decrease in testicular weight and the seminiferous epithelium comprised Sertoli cells and germ cells as mature as spermatids. Hypophysectomy of adult rhesus monkeys resulted in a precipitous decline in testicular size associated with the complete regression of the seminiferous epithelium to the extent that the tissue comprised only Sertoli cells and type A spermatogonia, that is, only stem cells. Further experiments on adult rodents and monkeys have confirmed these earlier observations. GnRH receptor antagonist, which suppresses all gonadotropin secretion, chemical hypophysectomy achieved the same results as observed using a surgical hypophysectomy (Matthiesson and McLachlan, 2006). Namely, the rodent seminiferous epithelium

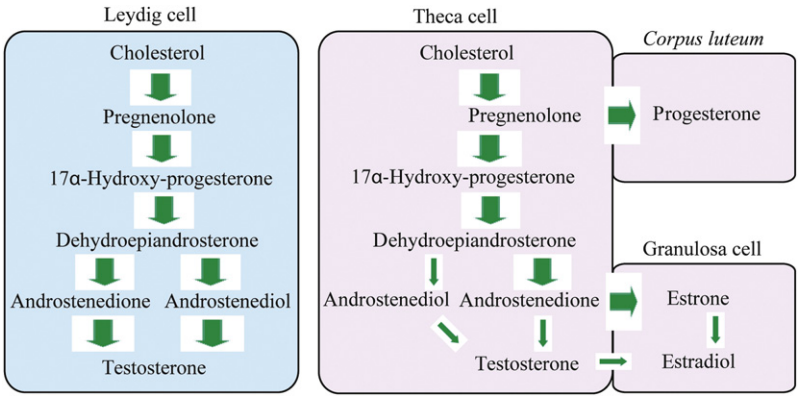

Fig. 3 Comparison between Leydig and theca cells steroidogenesis. In Leydig cells, cholesterol is efficiently converted to testosterone, as a major product obtained *via* both androstenedione and androstenediol under stimulation by LH. In the ovary, granulosa cells convert cholesterol to progesterone and its precursor pregnenolone. The latter is the substrate for progesterone production in the *corpus luteum*, during the luteal phase, as well as to androgens in theca cells stimulated by LH. Androstenedione is the primary product of theca cells, serving as a substrate for the aromatase enzyme and estradiol production by FSH-stimulated granulosa cells. *Large arrows* indicate major steroidogenic pathways, minor pathways are shown by *thin arrows*.

comprised Sertoli cells and germ cells as mature as spermatids, whereas the primate seminiferous epithelium comprised only Sertoli cells and stem spermatogonia.

Physiological replacement of testosterone in rats that had been previously rendered hypogonadotropic results in full restoration of the seminiferous epithelium containing the normal number of spermatogenic cells. Testosterone alone is sufficient to stimulate spermatogenesis in this and related species (Huhtaniemi, 2015). Replacement of testosterone in hypogonadotropic, hypogonadal rhesus monkeys, however, results in stimulation of testicular growth but to less than normal size. The gonadal growth is due primarily to the stimulation of spermatogenesis by androgen, but morphometric analysis of the seminiferous epithelium of the monkeys revealed that the smaller testicular size was accounted for by a deficit in the number of all differentiated, or type B, spermatogonia. Replacement of FSH in testosterone-treated hypophysectomized adults results in a greater number of all four generations of type B spermatogonia. These observations led to the conclusion that testosterone alone stimulates spermatogenesis, but FSH is necessary to restore spermatogenesis completely in primates (Ramaswamy and Weinbauer, 2014). This action of FSH in primates is posited to be the rescue of the differentiated spermatogonia from programmed cell death.

Testosterone is also secreted into the circulatory system and transported to the male reproductive tract, stimulating growth and differentiation. The androgen also causes the increased body size, muscle mass, and behavior characteristic of male mammals. In the case of humans, beard growth and male pattern baldness are also manifestations of testosterone action. Testosterone acts to reduce the secretion of LH exerting a negative feedback at different levels. It induces the inhibition of LH secretion by direct action on the anterior pituitary, as well as on the GnRH- and kisspeptin-secreting neurons in the hypothalamus.

Fetal Development of the Male Reproductive System

Fetal development of the male reproductive system requires the presence of a testis capable of secreting two hormones, testosterone and Müllerian inhibiting hormone. The formation of a testis requires the action of the testis-determining factor (SDF) protein, encoded by the sex-determining region Y gene (*SRY*) (Windley and Wilhelm, 2016). This factor causes the undifferentiated gonad to develop into a testis. If this factor is absent or defective, a testis will not form and a female phenotype will be produced. The fetal testis produces testosterone, which stimulates the Wolffian ducts to differentiate into the male reproductive tract consisting of the epididymis, vas deferens, seminal vesicle, and prostate. Testosterone also causes the formation of the penis and scrotum into which the testes descend. Testosterone is produced in the fetal testis by Leydig cells and Müllerian inhibiting hormone is produced by the fetal Sertoli cells.

The stimulus for the fetal Leydig cells to produce testosterone cannot be the fetal pituitary since the secretion of testosterone precedes the effective secretion of LH by the fetal pituitary. In the case of higher primates, hCG may cause the fetal testis to form Leydig cells as well as stimulate those cells to secrete testosterone (O'Shaughnessy *et al.*, 2006). Interestingly, placental LH is produced in equids during pregnancy and is also called equine CG (eCG) (Hoppen, 2009). This molecule is differently glycosylated from pituitary LH and has longer half-life, although the β-subunit is encoded by the same *LHB* gene of pituitary LH. The situation in the other mammalian genera, however, must be different because these species do not produce a placental gonadotropin. In fact, human qualitative LH- and hCG-specific signaling and steroid synthesis is lost in primary Leydig cells expressing the rodent LH receptor, although it retains binding capability for both the hormones (Peltoketo *et al.*, 2011). Anyway, in rodents, the fetal Leydig cells seem to be autonomous; that is, they synthesize testosterone without the stimulus of a gonadotropin. In all mammalian species, the fetal Leydig cells cease producing androgens soon after birth and seem to disappear in the interstitium of the testes of newborns.

During sexual maturation at the time of puberty, the adult Leydig cells form from undifferentiated cells, called mesenchymal-like cells, in the interstitial spaces between the seminiferous tubules. In rats, these cells actively proliferate from 2 to 4 weeks after birth, but their numbers diminish, suggesting differentiation into a new type of cell. The interstitial cells that give rise to the adult Leydig cell population have been posited to be part of the population of mesenchymal-like cells that during uterine life produced the fetal Leydig cells. Nonetheless, these mesenchymal cells have a very high mitotic index of rapid and multiple cell divisions. The next generation of differentiated cells express the proteins of the adult Leydig cell, 3β-hydroxyl dehydrogenase and LH receptors. These latter cells have been called immature Leydig cells and divide once and produce the adult Leydig cell (Benton *et al.*, 1995).

Feedback controls of gonadotropins' production. In the hypothalamus, kisspeptin neurons stimulate GnRH secretion under the control of steroid feedback. GnRH release is pulsatile and induces the release of LH and FSH by the anterior pituitary. In the gonads, gonadotropins promote gamete formation and the production of steroid hormones, which, in turn, regulate GnRH release by a feedback mechanism. In females, steroid hormones estrogens and progesterone exert a positive feedback on kisspeptin neurons of the periventricular nucleus, inducing the preovulatory surge of GnRH and LH. On the contrary, estrogens and progesterone inhibit kisspeptin production in the arcuate nucleus. In the male, testosterone exerts a negative feedback on kisspeptin neurons of the arcuate nucleus, as well as on GnRH neurons and pituitary, inhibiting GnRH and gonadotropins release.

Different potency of LH and hCG in activating cAMP. In LHCGR-transfected COS-7 cells, total cAMP production was evaluated upon 3-h treatment by recombinant LH and hCG. Statistical analysis revealed different effective dose 50% (ED50) between LH and hCG, demonstrating that hCG is about fivefold more potent than LH in inducing cAMP production (Mean $\pm$ SEM; Mann-Whitney's U-test; $P < .05$; $n = 4$). Image extracted and modified from the original article under Creative Commons Attribution license (Casarini *et al.*, 2012).

Comparison between Leydig and theca cells steroidogenesis. In Leydig cells, cholesterol is efficiently converted to testosterone, as a major product obtained via both androstenedione and androstenediol under stimulation by LH. In the ovary, granulosa cells

convert cholesterol to progesterone and its precursor pregnenolone. The latter is the substrate for progesterone production in the *corpus luteum*, during the luteal phase, as well as to androgens in theca cells stimulated by LH. Androstenedione is the primary product of theca cells, serving as a substrate for the aromatase enzyme and estradiol production by FSH-stimulated granulosa cells. Large arrows indicate major steroidogenic pathways, minor pathways are shown by thin arrows.

Glossary

Azoospermia The complete lack of spermatozoa in an ejaculate.

Gonadotropin receptor A G-protein coupled receptor, belonging to a wide family characterized by seven transmembrane domains.

Oligospermia Less than 39 millions of sperms in an ejaculate, or a less than 15 millions/mL of sperm concentration.

Receptor A protein that resides either on the surface or in the cytoplasm of a cell. The protein configuration allows interaction with a particular hormone. The binding of the hormone elicits a cascade of reactions in the cell that result in the expression of genes that affect the cell's function.

Single nucleotide polymorphism (SNP) A nucleotide point change with a frequency more than 1% within a population.

Introduction

Follicle-stimulating hormone (FSH) is a glycoprotein secreted by the pituitary gland and, in concert with luteinizing hormone (LH), plays a central role in mammalian reproduction (Simoni and Casarini, 2014). FSH acts directly on the gonads in both sexes, binding to its receptor on the surface of target cells, initiating a cascade of molecular events beginning with the activation of specific signaling pathways and ending with the expression of gene products (Hansson *et al.*, 2000). The gene products, in turn, set in motion processes specific to each gonad. In the ovary, FSH stimulates folliculogenesis and steroidogenesis, which, in turn, prepare the female reproductive tract for fertilization, implantation, and pregnancy (Messinis *et al.*, 2014). In the testis, this gonadotropin plays a central role in testicular development and spermatogenesis (Huhtaniemi, 2015). In both sexes, the products of FSH stimulation regulate the secretion of FSH either by modifying the release of the hypothalamic secretagogue, gonadotropin-releasing hormone (GnRH), or by acting directly at the pituitary gland.

Molecular Structure

FSH is a protein composed of two glycosylated polypeptide subunits, designated α and β, and has a molecular weight of approximately 33 kDa, varying with the species and the length of the added oligosaccharides. The α-subunit (14 kDa) is common to other glycoprotein hormones produced by the pituitary gland, LH and thyroid-stimulating hormone (TSH), as well as chorionic gonadotropin (CG), the latter produced mainly by trophoblast cells during pregnancy. The α-subunit may be secreted and in certain circumstances may achieve high concentrations in the blood, but no function for the free subunit has been demonstrated. The β-subunit is unique to each glycosylated hormone and, when associated with the α-subunit, confers biologic activity on the hormone (Berger and Lapthorn, 2016).

Carbohydrate groups are present at specific locations on each subunit with two oligosaccharide moieties on each subunit (Bousfield and Dias, 2011). These carbohydrate groups are important determinants of the biologic activity and metabolic clearance of FSH. The oligosaccharide moieties are coupled through *N*-acetylglucosamine to specific asparagine groups in the α- and β-subunits. The oligosaccharides contain the monosaccharides mannose, galactose, glucosamine, *N*-acetylgalactosamine, and sialic acid. In addition, the oligosaccharides are branched and heterogeneously terminate mainly in sialic acid and fucose. These differences are largely responsible for the variation in the isoelectric point (4.5–5) of this gonadotropin. The alkaline forms are biologically more active in bioassays, but are also more rapidly cleared from the circulation. Moreover, acidic FSH isoforms consisting in hyperglycosylated hormones display higher activity in the human granulosa KGN cell line in vitro than those fully glycosylated. These results were confirmed using *Fshb* knock-out male mice, where hyperglycosylated human recombinant FSH induced marked transcription of target genes and proliferation of Sertoli cell compared to the less acidic isoforms. Removal of terminal sialic acid residues from the oligosaccharides reduces the half-life of FSH in circulation and decreases its ability to activate target cells in both the ovary and testis (Bousfield *et al.*, 2014).

☆*Change History*: May 2017. Manuela Simoni, Livio Casarini, and Daniele Santi introduced the abstract, updated all sections and references.

This article is an update of Gary R. Marshall, FSH (Follicle-Stimulating Hormone), In Encyclopedia of Endocrine Diseases, edited by L Martini, Elsevier, New York, 2004, Pages 75–80.

Synthesis and Secretion

Gonadotropes are the pituitary cells synthesizing FSH, and they could be classified in three categories, based on the results of immunocytochemical staining (Simoni *et al.*, 1997). The majority of the gonadotropes belong to the category of cells synthesizing both FSH and LH, while other categories are composed of cells that exclusively synthesize FSH or LH. The secretion of gonadotropins is constitutive and it is mainly stimulated by the hypothalamic polypeptide GnRH. GnRH is released in a pulsatile fashion by neurons that terminate on the blood vessels running along the pituitary stalk. These vessels constitute a specialized form of the circulatory system, called "portal system." Portal systems are characterized by special veins, arising in one organ system and terminate in another before returning to the heart. They carry the pulses of GnRH to the gonadotropes in the pituitary gland and stimulate the synthesis and pulsatile release of both FSH and LH, according to the GnRH pulses. Changing the pattern of the GnRH pulses results in coincidental changes in the pattern of pulsatile secretion of FSH. GnRH binds to a G protein-coupled membrane receptor on the surface of the gonadotrope, activating the $G_{q/11}$ proteins that, in turn, stimulate phospholipase C. This enzyme generates inositol-1,4,5-triphosphate and diacylglycerol. The increased levels of these intracellular messengers activate protein kinase C (PKC) and increase intracellular calcium. PKC and calcium regulate the expression of the β-subunit gene, whereas secretion of FSH is regulated by the increase in intracellular calcium.

Recently, together with the known GnRH function, the role of kisspeptin in regulation of gonadotropin release was demonstrated. Kisspeptin is a 54-amino acid peptide, which is encoded by the *KISS-1* gene (Ratnasabapathy and Dhillo, 2013). Kisspeptin activates the G protein-coupled receptor (GPCR)54, regulating the mammalian and human reproduction. GPCR54-deficient mice showed abnormal sexual development, whereas inactivating GPR54 mutations in humans are responsible for normosmic hypogonadotrophic hypogonadism (Ratnasabapathy and Dhillo, 2013; Lanfranco *et al.*, 2005). On the other hand, the GPR54 signaling activation is associated with premature puberty (Ratnasabapathy and Dhillo, 2013). Moreover, several studies demonstrated that the acute intravenous administration of kisspeptin in healthy humans potently increases both LH and FSH serum levels (Ratnasabapathy and Dhillo, 2013). These results suggest the important role of the kisspeptin/GPR54 system in the regulation of gonadotropin secretion.

FSH Receptor Structure and Signaling

The first FSH receptor (*FSHR*) gene cloned and functionally expressed in mammalian cells was of rat Sertoli origin and obtained from a cDNA library (Sprengel *et al.*, 1990). Its predicted structure displayed high similarity with other GPCRs and was characterized by a relatively large extracellular domain and seven transmembrane segments. The human *FSHR* gene is located on chromosome 2p21 (Rousseau-Merck *et al.*, 1993). It spans 10 exons encoding for a mature protein, which consists of 678 amino acids (75–80 KDa). Mature FSHR is located in the gonads and belongs to the superfamily of rhodopsin-like GPCRs. Like all members of this family it is characterized by seven transmembrane domains, totally of 264 amino acids. These hydrophobic stretches are of 21–24 amino acids connected by intracellular and extracellular loops (Simoni *et al.*, 1997). The extracellular domain consists of 349 amino acids and serves for FSH binding, while the intracellular domain spans 65 amino acids and interacts with G proteins and other cytoplasmic molecules (Simoni *et al.*, 1997). Upon hormone binding, the receptor undergoes a conformational change leading to dissociation of G protein heterotrimer at the intracellular level, thus inducing signal transduction. Especially, the activation of Gαs protein subunit induces the conversion of ATP to cAMP by adenylyl cyclase. This is the first step in the intracellular signaling cascade leading to protein kinase A (PKA) activation which, in turn, induces the phosphorylation of the mediator of proliferative signals extracellular-regulated kinase (ERK1/2) (Gloaguen *et al.*, 2011). Downstream to PKA and ERK1/2 activation, the phosphorylation of the transcription factor cAMP-responsive element binding protein (CREB) (Hunzicker-Dunn *et al.*, 2012) induces the expression of steroidogenesis-related target genes, such a *STARD1* and *CYP19A1* (Freimann *et al.*, 2004). *STARD1* encodes for steroidogenic acute regulatory protein (StAR) (Amsterdam *et al.*, 2003), a mediator of cholesterol transport within the mitochondria, as a rate-limiting step of the steroidogenesis (Miller and Auchus, 2011). FSHR binding to the ligand is linked to simultaneous activation of different G protein subunits (Gloaguen *et al.*, 2011), such as the Gαi protein, which induces the phosphorylation of ERK1/2 and inhibits cAMP synthesis (Saltarelli, 1999). Moreover, Gαi protein mediates receptor desensitization via activation of GPCR-specific kinases (Pitcher *et al.*, 1999). Other FSHR cytoplasmic interactors were found. β-arrestins are involved in phosphorylated GPCR internalization (Benovic *et al.*, 1987; Ferguson *et al.*, 1996), and mediates both proliferative and antiapoptotic signals via ERK1/2 signaling (Casarini *et al.*, 2016; Kara *et al.*, 2006; Cassier *et al.*, 2017). The result of these intracellular pathways, simultaneously activated by FSH, range from steroidogenesis, to cell differentiation, proliferation, and apoptosis (Dias *et al.*, 2010).

In 2005, the structure of FSH combined with its receptor was studied with a 2.9-A-resolution structure (**Fig. 1**) (Fan and Hendrickson, 2005). FSH binds the FSHR into the concave face of the curved extracellular receptor domain, similar to a hand clasp (**Fig. 1**) (Fan and Hendrickson, 2005).

FSHR and FSHβ Polymorphisms and Mutations

More than 2000 *FSHR* and *FSHB* single nucleotide polymorphisms (SNP) were described. SNP is characterized by a nucleotide point change with frequency $>1\%$ within a population. Most of these SNPs fall within introns or are synonymous, while a

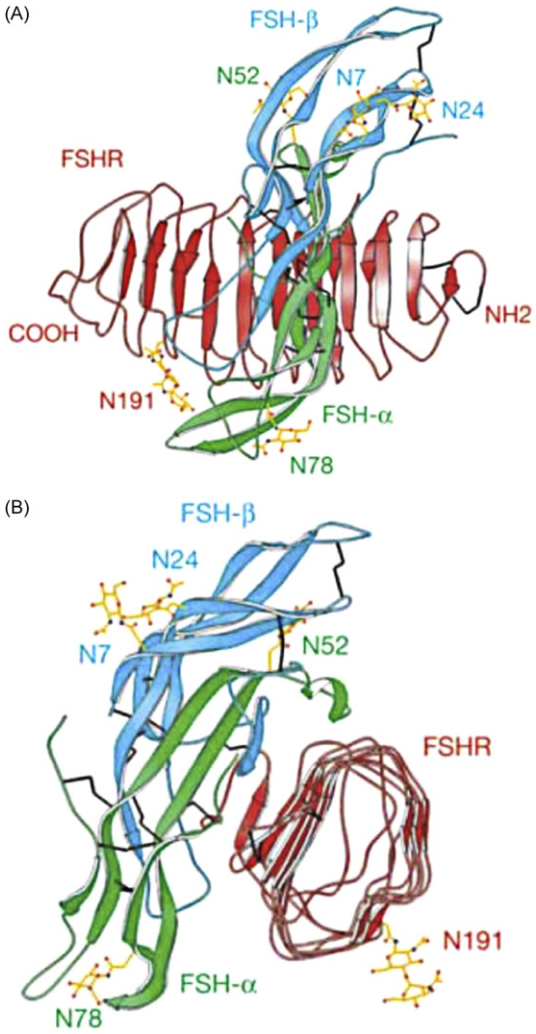

Fig. 1 Crystal structure of human FSH bound to FSHR. Ribbon diagram of the complex structure shown in two views related by a 90 degree rotation about the vertical axis (panel A and B). FSH a-chains and b-chains are in *green* and *cyan*, respectively. FSHR is in *red*. Modified from Fan, Q. R. and Hendrickson, W. A. (2005). Structure of human follicle-stimulating hormone in complex with its receptor. *Nature* **433**, 269–277.

number of them lead to amino acid change. Among the SNPs located within the exons of the *FSHR* gene, only two were associated with the gonadal response to FSH. These SNPs are the threonine to alanine change at position 307 of the amino acid sequence (p.T307A; rs6165, in the National Center for Biotechnology Information SNP database) and the asparagine to serine at position 680 (p.N680S; rs6166). They are associated with different kinetics of cAMP/PKA- and ERK1/2-pathway activation, as well as progesterone synthesis in vitro (Casarini *et al.*, 2014), suggesting that the FSHR p.N680S "S" is a variant less sensible to FSH stimulation. Indeed, p.N680S S homozygous women display higher FSH serum levels and require higher hormone doses than N homozygous for ovarian stimulation (Grigorova *et al.*, 2013; Perez Mayorga *et al.*, 2000). In fact, the FSHR gene is located in a genomic region which is a "hot spot" of the gonadal physiopathology (Chen *et al.*, 2011). Interestingly, the SNP p.N680S seems to be linked to sperm DNA fragmentation index (Simoni *et al.*, 2016) and testes volume (Grigorova *et al.*, 2013) in males, confirming the relevance of the genetic *locus* for the gonadal physiology.

Another common SNP falling within the *FSHR* gene is the amino acid change G to A, located 29 base pairs upstream the transcription start codon ($-29G>A$; rs1394205). It is located in the promoter region of the receptor gene modulating the transcription levels of the gene (Desai *et al.*, 2011), resulting in relatively low FSHR protein and, therefore, affecting the gonadal response to FSH (Desai *et al.*, 2013). Since the distribution of the FSHR genotypes is variable worldwide, the cumulative effects of FSHR $-29G>A$ in association with p.T307A and p.N680S was discussed, as well as their role in the evolution of different endocrine phenotypes among humans was suggested (Simoni and Casarini, 2014).

Among the more than 20 *FSHB* gene SNPs described, the c.$-211G>T$ (rs10835638), located within the promoter region and influencing FSH production, is one of the most commonly studied (Benson *et al.*, 2013). Due to the low gene transcription of the promoter featuring the "T" genotype, the SNP modulates the FSH circulating levels and is linked to age of menopause and follicle growth in women (Busch *et al.*, 2016; Ruth *et al.*, 2016). In men, c.$-211G>T$ SNP is linked to FSH serum levels as well

(Grigorova *et al.*, 2010) and age at testicular growth (Busch *et al.*, 2017). The potential, combined effect of the *FSHB* c. − 211G > T and the *FSHR* SNPs on human fertility were investigated, suggesting the existence of haplotypes associated with "less sensitive" FSH trait (Grigorova *et al.*, 2014; Tuttelmann *et al.*, 2012).

Several inactivating and activating *FSHR* gene mutations have been identified, providing a wide spectrum of effects depending on the nature of amino acid change and location. Mutations differ from SNPs due to their frequency (< 1%) in the population. An example of inactivating mutation is given by the C to T nucleotide point mutation found in Finnish families (Aittomaki *et al.*, 1995). This mutation results in the alanine to valine substitution, falling within the FSHR extracellular domain, and in reduced binding capacity and signal transduction. The women of these families have hereditary hypergonadotropic ovarian failure, with amenorrhea and atrophic ovaries with follicles that do not develop beyond primary follicles. Men homozygous for this mutation are normally virilized and have sufficient testosterone to initiate and maintain spermatogenesis, although displaying variable degrees of spermatogenic failure (Tapanainen *et al.*, 1997).

Only few *FSHR* gene activating mutations were described so far, most of them located at the transmembrane domain of the receptor. For example, the first case was reported in 1996 in a hypophysectomyzed hypogonadotropic man with normal fertility in spite of undetectable gonadotropin serum levels, due to an activating mutation on the *FSHR* gene (Gromoll *et al.*, 1996). It was an aspartic acid to glycine substitution at position 566 displaying constitutive activity in vitro. This mutation falls within the third intracellular loop of FSHR, which is a crucial region for glycoprotein hormone receptor functioning. In a woman, the same mutation induced ovarian hyperstimulation syndrome during pregnancy, moreover revealing that the mutant receptor mediated hCG- and TSH-induced signaling (Smits *et al.*, 2003). *FSHB* gene mutations were reported as well. Especially, five inactivating mutations leading to the insertion of a stop codon or to a loss of residual cysteine were described so far (La Marca *et al.*, 2013). All these mutations compromise the subunit folding and lead to abnormal puberty or primary amenorrhea in women, and altered pubertal development and azoospermia in men.

Action in the Ovary

FSH acts on the ovary by stimulating folliculogenesis (Rimon-Dahari *et al.*, 2016) (**Fig. 2**). During fetal development of the female mammal, the primitive germ cells in the ovary enter meiosis and arrest in the prophase of meiosis I. Each oocyte is surrounded by

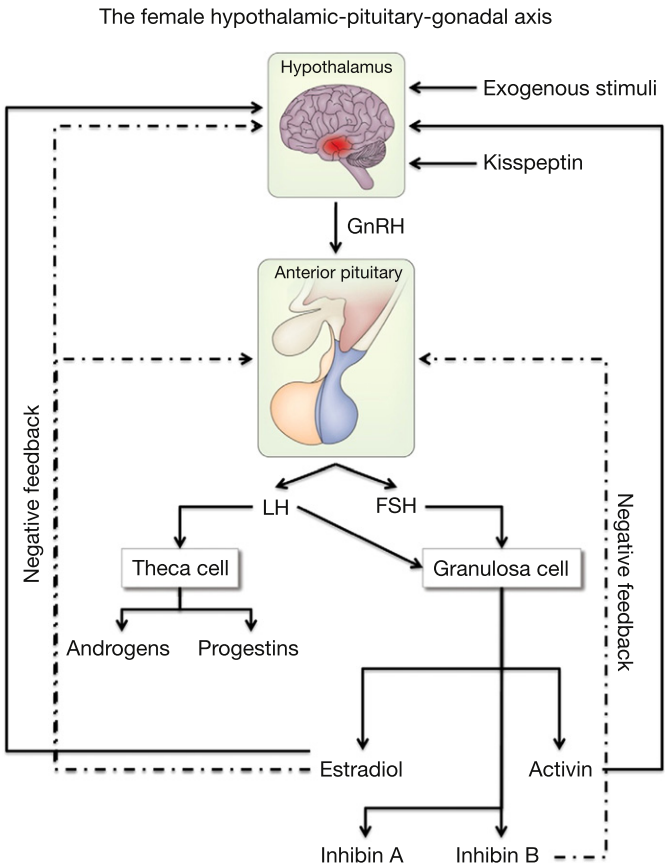

Fig. 2 The female hypothalamic-pituitary-gonadal axis. Abbreviations: *GnRH*, gonadotropin-releasing hormone; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

a single layer of cells, and enters in the resting phase. During fetal life in primates and ruminants and within the first 2 weeks after birth in rodents, some of the primordial follicles are activated and become primary follicles. The mechanisms stimulating the primordial follicles to initiate folliculogenesis are unknown, but are clearly independent of gonadotropin action. Two layers of somatic cells develop around the oocyte. The outermost layer is composed of theca cells that are separated from the innermost layer, comprising granulosa cells, by a basement membrane. Both types of cells proliferate, increasing the size of the follicle until a fluid-filled cavity, or antrum, forms in the layers of the granulosa cells. The mature, or antral, follicle ruptures, marking the end of folliculogenesis and representing the ovulation phase, results in releases of the oocyte and some of the granulosa cells surrounding it. During the periovulatory period, antiinflammatory factors are produced and appear to aid in rapid healing and vascularization of the ruptured follicle. The theca and granulosa cells remaining in the ruptured follicle differentiate into luteal cells, forming the corpus luteum that characterizes the luteal phase of the ovarian cycle. If no pregnancy occurs, after a finite time specific to each species, the corpus luteum dies, marking the end of the luteal phase. The rapid involution of the corpus luteum is called luteolysis and is regulated by specific factors. Luteolysis is necessary before a subsequent ovarian cycle can begin. The follicular phase, ovulation, luteal phase, and luteolysis constitute the ovarian cycle and FSH plays an important role only during the first phase of the ovarian cycle.

The theca cells of the developing ovary produce androgens in response to LH. FSH stimulates the granulosa cells to produce the enzyme aromatase, which converts the androgens produced by the theca cells into estradiol, thus exerting a negative feedback on gonadotropins production by pituitary. The number of granulosa cells increases by mitosis occurring under FSH-induced proliferative stimuli, which are preferentially mediated by FSHR at low density on the cell surface (Tranchant *et al.*, 2011; Casarini *et al.*, 2016). In growing follicles, FSH also increases estradiol production and the number of LH receptors (LHCGR) on theca and granulosa cells. With the increase in LH receptors on the granulosa cells of one or more follicles in the presence of decreased FSH, only those follicles with sufficient gonadotropin and estrogen stimulation will continue folliculogenesis. As the follicle enlarges, a cavity forms around the oocyte so that layers of granulosa cells and fluid surround it, but a peduncle of granulosa cells remains attached to the rest of the follicle. Once the level of circulating estradiol produced by the Graafian follicles is elevated, estradiol cause an abrupt release of LH and FSH, which results in ovulation, that is, the extrusion of the oocyte and the granulosa cells immediately surrounding it, which is subsequently referred to as the oophorus cumulus. Once ovulation has occurred, the role of FSH is greatly diminished and the formation of the corpus luteum and maintenance of the endometrium of the uterus are under the influence of LH.

Action in the Testis

The role of FSH in regulating spermatogenesis in adult mammals has been controversial for several decades (Huhtaniemi, 2015) (**Fig. 3**). Although the direct role of FSH in adult male rodents on spermatogenesis is limited, it remains the primary determinant of the spermatogenic capacity. This capacity is defined as the number of sperm potentially produced by the male gonad and intuitively this must directly relate to the number of spermatogenetic stem cells and the capacity of the structure of the gonad to nourish and support the progeny of these stem cells.

The Sertoli cells of the mammalian testis are the only somatic cells in the seminiferous epithelium and are known to proliferate only during fetal and peripubertal development in rodents. A third period of Sertoli cell proliferation occurs during infancy in higher primates. After these, somatic cells have attained a population size associated with adulthood, proliferation ceases, and the cells terminally differentiate. The mature Sertoli cells serve to organize and nourish the germ cells that make up the remainder of the cell types in this epithelium. Moreover, they are the mediators of FSH action because they are the only cells in the male that have FSHR. FSH stimulates Sertoli cell proliferation in the rodent testis, but, in primates, both FSH and LH are equally effective in stimulating the proliferation of these cells. Because the Sertoli cells provide the nutrients and structural support to spermatogenesis, it was immediately recognized that FSH regulates the spermatogenic capacity of the testis. In contrast to the situation in rodents, FSH plays a more direct role in regulating spermatogenesis in primates.

Spermatogenesis is a complex process occurring in the seminiferous tubules, with the final outcome of the mature male gamete production. This network comprises several phases, such as spermatogonia proliferation, spermatogonial differentiation into spermatocytes, spermatocytes meiotic division producing spermatids, maturation of round spermatids; and the release of highly specialized mature spermatozoa into the testicular tubule lumen (Neto *et al.*, 2016). This process is allowed by the stem cell continuous renewal, which ensures a large and undiminishing number of undifferentiated germ cells available for the subsequent waves of spermatogenesis (Heller and Clermont, 1963; Misell *et al.*, 2006). The spermatogenetic stem cells are called type A spermatogonia, which are continuously renewed and differentiate forming type B spermatogonia. The entire spermatogenic process requires approximately 74 days, varying between 42 and 76 days, with an overall daily production from 150 to 275 millions of sperms (Misell *et al.*, 2006). In this process, several testicular structures are involved, from which Sertoli cells are indispensable for spermatogenesis (Neto *et al.*, 2016). Their function is regulated by hormonal, nonhormonal, and paracrine factors. In this context, FSH represents the most important regulator of Sertoli cells action.

The importance of pituitary in stimulating spermatogenesis was demonstrated by hypophysectomy of adult rats, which led to a decrease in testicular weight and impairment of germ cells maturation to spermatids. Hypophysectomy of adult rhesus monkeys resulted in a precipitous decline in testicular size associated with the complete regression of the seminiferous epithelium to the extent that the tissue comprised only Sertoli cells and type A spermatogonia. In hypogonadotropic hypogonadal rhesus monkeys,

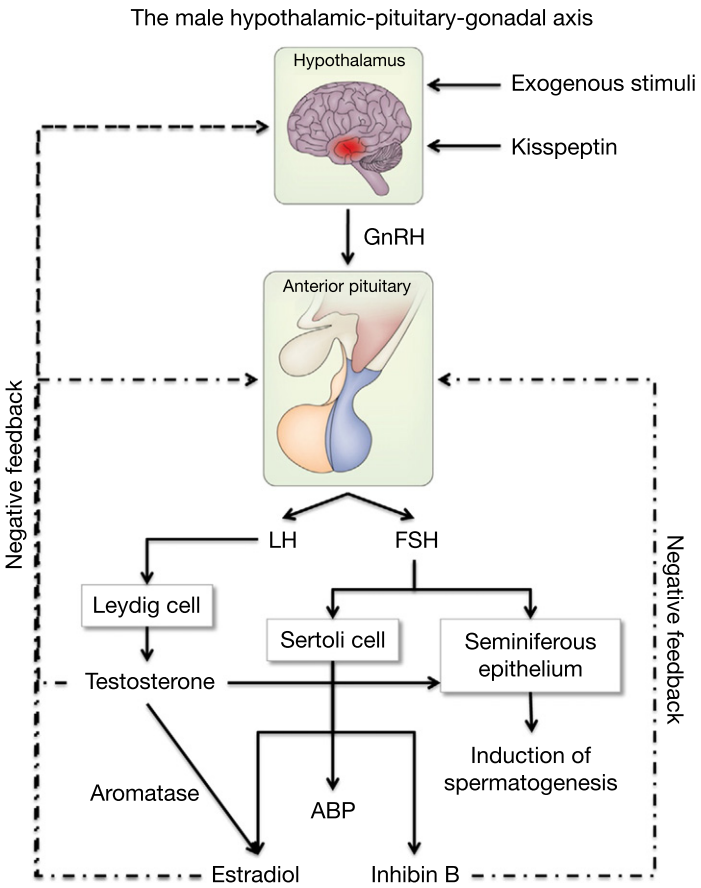

Fig. 3 The male hypothalamic-pituitary-gonadal axis. Abbreviations: *ABP*, androgen bindingprotein; *GnRH*, gonadotropin-releasing hormone; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

testicular growth is partially recovered by testosterone replacement. Therefore, gonadal growth was due primarily to the stimulation of spermatogenesis by androgen, but morphometric analysis of the seminiferous epithelium of the monkeys revealed that the smaller testicular size was accounted for by a deficit in the numbers of all type B spermatogonia. Replacement of FSH in testosterone-treated hypophysectomized adults resulted in a greater number of all four generations of type B spermatogonia. These results led to the conclusion that testosterone alone stimulates spermatogenesis, but FSH is necessary to restore spermatogenesis completely. This action of FSH is posited to be the rescue of type B spermatogonia from programmed cell death.

Unilateral orchidectomy in adult macaques results in a compensatory growth of the remaining testis. The number of Sertoli cells per testis was identical in the gonad removed at the time of unilateral orchidectomy and the gonad that remained in the animal for 45 days. The number of all germ cells more mature than type A (subtype "p"; Ap) spermatogonia was greater in the remaining testis than in the removed testis. Moreover, the removal of one testis was occasioned by a transient decline in testosterone that in turn led to a transient increase in LH. By 4 days after surgery, the testosterone and LH concentrations were restored to those measured prior to surgery. The removal of one gonad in these primates was marked also by a decline in inhibin B, which is secreted by Sertoli cells into the circulatory system. The concentrations of FSH in the circulation increased, confirming the role of inhibin B in the negative feedback on FSH secretion by the pituitary gland of the primate (**Fig. 3**). The role of inhibin B is less clear in rodents and the steroid testosterone may play a greater role in the regulation of FSH secretion in those species. On the contrary, other investigators have presented results indicating that FSH increases the number of germ cells in the primate testis indirectly, and FSH administration to adult macaques resulted in an increase in spermatogonia in the seminiferous epithelium.

Glossary

Cathepsin Cathepsins are proteases (enzymes that degrade proteins) found in all animals as well as other organisms.

ERK Protein kinase whose action can mediate numerous cellular responses.

GABA gamma-Aminobutyric acid (γ-aminobutyric acid). It is a neurotransmitter in the central nervous system of mammals.

JAK proteins Janus kinase (JAK) is a family of intracellular, nonreceptor tyrosine kinases that transduce cytokine-mediated signals via the JAK-STAT pathway.

Kallikrein Kallikreins are a subgroup of serine proteases, enzymes capable of cleaving peptide bonds in proteins.

MAPK A mitogen-activated protein kinase (MAPK or MAP kinase) is a type of protein kinase that is specific to the amino acids serine, threonine, and tyrosine (i.e., a serine/threonine-specific protein kinase). MAPKs are involved in directing cellular responses to a diverse array of stimuli, such as mitogens, osmotic stress, heat shock and proinflammatory cytokines.

PACAP Pituitary adenylate cyclase-activating peptide. 38-amino acid C-terminally alpha-amidated peptide known to act throughout the body and brain, modulating the activity of the central nervous system, metabolism, blood pressure, pain sensitivity and immune function.

Pit-1 PIT1 is a pituitary-specific transcription factor responsible for pituitary development and hormone expression.

RAS Ras family of proteins belong to a class of proteins involved in signal transmission within cells.

STAT proteins Members of the signal transducer and activator of transcription (STAT) protein family are intracellular transcription factors that mediate many aspects of cellular immunity, proliferation, apoptosis and differentiation.

Tubero-infundibular dopaminergic system (TIDA) The tuberoinfundibular pathway refers to a population of dopamine neurons that project from the arcuate nucleus in the tuberal region of the hypothalamus to the median eminence.

Definition

Prolactin (PRL) is a hormone primarily secreted by the anterior pituitary gland involved in regulation of reproductive and nonreproductive processes.

Structure

The PRL gene, consisting of five exons and four introns, was cloned in 1981 and it is located on chromosome 6 in humans. Human PRL cyclic DNA is 914 nucleotides long and contains a 681-nucleotide frame encoding for PRL pro-hormone (227 amino acids) (Freeman *et al.*, 2000). PRL is a single chain polypeptide of 199 amino acids (molecular weight 23 kD, half-life 50 min) with three intramolecular disulfide bonds between six cysteine residues (Cys4-Cys11, Cys58-Cys174, and Cys191-Cys199 in humans), primarily synthesized and secreted by lactotrope cells in the anterior pituitary gland (Freeman *et al.*, 2000). Lactotropes represent 40%–50% of the total pituitary cell population and are mostly aggregated in the postero-lateral areas of the gland. The PRL pituitary content is relatively low (approximately 135 micrograms per gland). The disparity between the content of PRL and the amount of lactotrope cells is probably due to the fact that the PRL has a turnover considerably high with consequent limited storage in pituitary gland.

PRL structure has a remarkable degree of homology in amino acids sequence with human growth hormone (hGH) and placental lactogen (hPL). Specifically, human mRNAs of PRL and GH have 42% of homology, consisting with the hypothesis that they arose by consecutive duplications of a common ancestral gene (Ben-Jonathan *et al.*, 2008).

PRL is secreted in different forms depending on post-translational glycosylation, proteolysis and phosphorylation processes (Sinha, 1995). Phosphorylated PRL form represents about 5%–30% of the PRL released by the anterior pituitary gland with

☆*Change History*: March 2018. F Maffezzoni, G Mazziotti, and Andrea Giustina was updated in the text and references concerning the neuroregulation of PRL secretion (pages 7–11) and extra-gonadal effects of PRL (14–16). Moreover, new 2 Figures (#2,4) and one Table (#1) were included.

This article is an update of Nira Ben-Jonathan, Robert Hnasko, Prolactin (PRL), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 99–103.

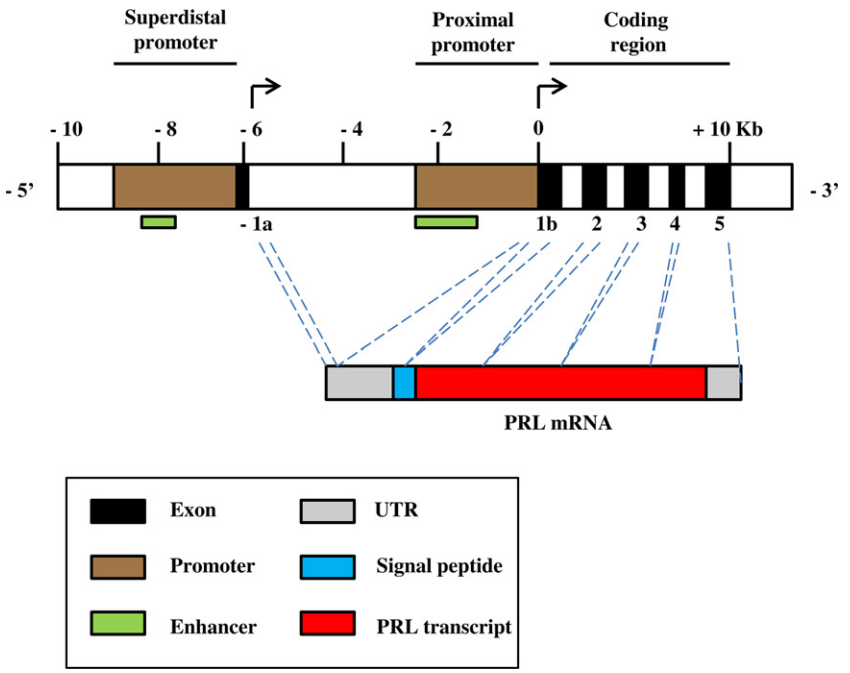

Fig. 1 Diagram of the human PRL gene, mRNA transcript, and mature PRL. The *left* and *right arrows* in the upper panel designate extrapituitary and pituitary transcription start sites, respectively, and the numbers designate the exons. The locations of the enhancers in both promoters is also shown. The extrapituitary PRL mRNA is longer in the 50 untranslated region (UTR). The structure of the PRL protein is composed of four up-up-down-down alpha helices.

both agonistic and antagonistic properties. Moreover, PRL fragments may derive from post-secretion proteolytic cleavage of full hormone. For instance, kallikrein and cathepsin D were shown to produce the 22 and 16 kD fragments, respectively, which may be important in regulating non reproductive functions (see, section on physiological actions). Finally, large forms of PRL hormone may result from dimerization and multimerization processes. In blood stream several forms of circulating PRL may be found:

- Small PRL (molecular weight 23 kD), which corresponds to the monomeric nonglycosylated hormone with high receptor affinity, biological and immunological complete activities.
- Two glycosylated forms (G^1 and G^2) of PRL (~ 25 kD), different in carbohydrate units chain and both with reduced immunoreactivity (G^1-PRL has only a quarter of the bioactivity of the G^2-PRL).
- Big PRL (molecular weight ~50 kD), which consists of a mixture of forms dimeric and trimeric glycosylated PRL (G-PRL).
- Big–Big PRL (~100 kD), probably represented by G-PRL, combined with immunoglobulins by covalent bond.

Regulation of Secretion

Two independent promoters have been identified in PRL gene with tissue- and cell-specific response to regulatory mediators (Marano and Ben-Jonathan, 2014). Specifically, the proximal promoter is the 5000-bp region involved in regulation of PRL secretion by pituitary gland whereas the downstream promoter region is responsible for regulation of extrapituitary expression of the hormone (**Fig. 1**). Interestingly, the two promoters regulate expression of the same PRL isoforms. The pituitary-specific expression of PRL is regulated by the Pit-1 (pituitary transcriptional factor-1), which is a member of the POU domain family (a family of proteins that have well-conserved homeodomains). Pit-1 exerts similar effects on PRL, GH, and thyroid stimulating hormone (TSH) expression. Indeed, point mutations in the human gene encoding for Pit-1 is responsible for a congenital disease characterized by combined deficiencies of GH, PRL, and TSH. In extra-pituitary sites, such as decidua and lymphocytes, expression of PRL occurs independently of Pit-1.

PRL is secreted by pituitary gland in a pulsatile manner, but it also has a circadian fluctuation (Mancini *et al.*, 2008). PRL secretion is high during the nighttime sleep (non rapid eye movement—REM phase). Specifically, PRL release begins to increase rapidly (10–60 min) after the onset of sleep with several secretory peaks (i.e., from three to eight) determining high PRL levels persistently during sleep. In the first hour after waking up, plasma PRL concentration falls rapidly reaching the lowest levels in late morning (i.e., between 9 and 11 a.m.). Interestingly, the biologically active form of PRL (23 kD) is produced during the day, whereas the glycosylated form of the hormone is released predominantly during sleep.

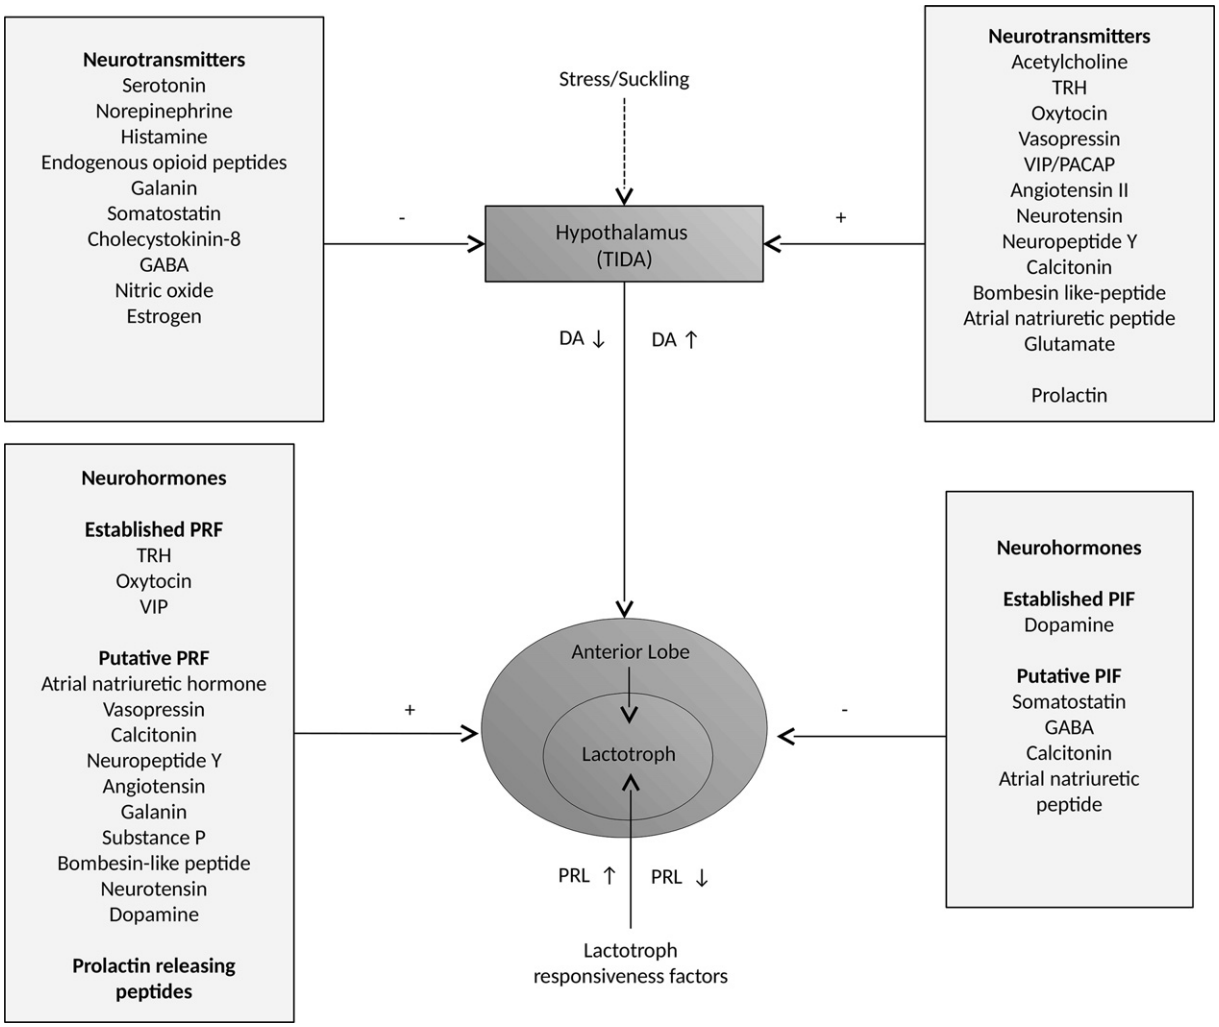

Fig. 2 Regulation of PRL secretion. Permission is required from Mancini, T., Casanueva, F.F., Giustina, A. (2008). Hyperprolactinemia and prolactinomas. *Endocrinology & Metabolism Clinics of North America*. **37**, 67–99.

Secretion of PRL from pituitary gland is regulated by endocrine, paracrine and autocrine factors. Endocrine regulators originate from the hypothalamus and the peripheral glands and reach the lactotrophs via the blood. Paracrine factors reach the lactotropes by diffusion from neighboring pituitary cells. Autocrine agents are synthesized by the lactotropes themselves. The regulation is complex involving neurotransmitters, neurohormones, neuropeptides, metabolic substrates and systemic hormonal signals divided in PRL-inhibiting factors (PIFs) and PRL-releasing factors (PRFs) (**Fig. 2**) (Mancini *et al.*, 2008). Consequently, the overall secretory activity of the lactotropes reflects a balance between local and distant PIFs and PRFs which can be influenced by physiological and pathological conditions (**Table 1**). Pregnancy and lactation are two physiological conditions associated with increase in PRL secretion. In fertile women, a progressive and significant increase in serum PRL is observed during the late follicular phase, with a maximal value concomitant to the LH peak. Serum PRL levels is also higher during the luteal phase than during early follicular phase. The overall pattern of serum PRL during the menstrual cycle resembles that reported for circulating 17beta-estradiol. This is relevant to the timing of blood sample collection which should be done in the early follicular phase when PRL is at nadir. Moreover, PRL levels increase after exercise, meals, psychological stress and stimulation of the chest wall. As predicted from the physiologic dopaminergic inhibition of PRL secretion (see below), treatment with dopamine receptor antagonist drugs commonly induce hyperprolactinemia (**Table 1**). Twelve to thirty percentage of women taking higher estrogen containing oral contraceptives may have a small increase in serum PRL. This effect was shown to be often transient resolving spontaneously in about 50% of women (Luciano *et al.*, 1985). Similarly, occupational exposure to heavy metals and some over-the-counter herbal or alternative remedies may cause an increase in PRL (Mancini *et al.*, 2008).

Unlike GH, lactotropes have spontaneously high secretory activity and the hypothalamic control of PRL secretion is predominantly inhibitory mediated by dopamine (DA). DA is secreted by neurons in the arcuate nucleus and released in the portal vessels from the tubero-infundibular dopaminergic system (TIDA). DA exert its action by binding to dopamine receptors (DRs) on lactotrope cells (Ben-Jonathan and Hnasko, 2001). Five receptor subtypes of DRs (DR1, DR2, DR3, DR4, DR5) have been characterized. DRs receptors are also

Table 1 Physiological and pathological conditions influencing prolactin (PRL) secretion

Factors increasing PRL secretion	*Factors inhibiting PRL secretion*
Neurohormones	
• TRH	• Dopamine (DA)
• VIP	• Somatostatin
• Oxytocin	• GABA
• ADH	• Atrial natriuretic peptide (ANP)
Hormones	
• Estradiol	• Glucocorticoids (endogenous—exogenous)
	• Calcitonin
	• Prolactin
Neurotransmitters	
• Serotonin, norepinephrine, histamine, galanin, GABA, nitric oxide, endogenous opioid peptides	• Acetylcholine
Drugs	
• Antipsychotics (haloperidol, phenothiazines, risperidone, amisulpride, chlorpromazine)	• Dopamine agonists (cabergoline, bromocriptine, quinagolide, pergolide)
• Antihypertensive (α metil dopa, reserpine, verapamil)	• Indirect D2 receptor activators (amphetamines)
• Prokinetics (metoclopramide, domperidone)	• Antipsychotics (aripiprazole)
• H2-receptor antagonists (cimetidine, ranitidine)	
• Antidepressants (amitriptyline, sertraline, fluoxetine, paroxetine)	
• Opiates (morphine)	
Psychological conditions	
• Acute psychological and physical stress	
• Pregnancy/Breastfeeding	
• Sleep	
• Physical/sexual activity	
• Hypoglycemia	
Pathological conditions	
• Hypothalamic/pituitary diseases (primitive tumors, metastases, lymphocytic hypophysitis, infiltrative diseases, cranial irradiation, aneurisms)	• Hypothalamic/pituitary diseases (primitive tumors, metastases, lymphocytic hypophysitis, infiltrative diseases, postpartum pituitary necrosis)
• Genetic syndromes (multiple endocrine neoplasia, Carney complex, McCune–Albright syndrome)	• Congenital (familial puerperal alactogenesis, traumatic brain injury)
• Primary hypothyroidism	• Autoantibodies against PRL (lymphocytic hypophysitis, Hashimoto's thyroiditis)
• Kidney failure	
• Hepatic cirrhosis	
• Polycystic ovary syndrome	

classified into two subclasses (DR1-like) and (DR2-like), based on the phylogenetic classification and the type of pathway used for the post-receptor transduction signals. DR1 class (DR1 and DR5 subtypes) has a stimulatory effect on intracellular signaling pathways, while DR2 class (DR2, DR3, and DR4 subtypes) has mainly inhibitory activity on cAMP production. Type DR2 is the predominant dopamine receptor in pituitary lactotrope cells with essential role in maintaining physiological PRL levels. Indeed, pituitary hyperplasia with persistent hyperprolactinemia was reported in receptor knock-out (KO) mice for DR2. Two alternatively spliced isoforms of DR2 exist, termed DR2-short (DR2-S) and DR2-long (DR2-L) receptors, differing for the insertion of 29 amino acids of the third cytoplasmic loop. The two isoforms of DR2 dopamine receptor are both present on lactotrope cells. After interaction of DA to DR2, inhibition of cAMP production occurs along with activation of voltage-gated calcium channels and inhibition of potassium channels, finally resulting in membrane either depolarization or hyperpolarization changes.

A short positive feed-back between PRL and DA exists, consisting in increase of DA release in TIDA in response to increase in PRL secretion by pituitary gland. Other neuromediators and neuropeptides may influence the cross-talking between DA and PRL (Mancini *et al.*, 2008). For instance, melanocyte-stimulating hormone (MSH), a product of pro-opiomelanocortin (POMC) gene was shown to activate TIDA neurons and then favoring the release of DA and inhibition of PRL secretion by lactotropic cells. Similarly, acetylcholine causes a decrease in serum PRL levels through the TIDA stimulation. By contrast, β-receptors activation by norepinephrine and epinephrine inhibits DA release in TIDA with consequent increase in PRL secretion (**Fig. 2**).

Glucocorticoids were shown to exert inhibitory effects on PRL secretion (Giustina and Wehrenberg, 1992). In experimental models, glucocorticoids suppress the differentiation of lactotropes whereas hypocortisolism post-adrenalectomy significantly increased plasma levels of PRL (Brann *et al.*, 1990). Interestingly, the effect of adrenalectomy were reversed by the administration of exogenous corticosteroids.

Although the hypothalamic control of PRL secretion is mediated by a tonic inhibitory mechanism, a PRF is necessary for the acute secretory activity (Mancini *et al.*, 2008) (**Fig. 2**). TRH is a powerful stimulator of pituitary PRL release both in vivo and in vitro conditions. The concentration of TRH request to cause a PRL release in vitro is within the range found in the portal blood

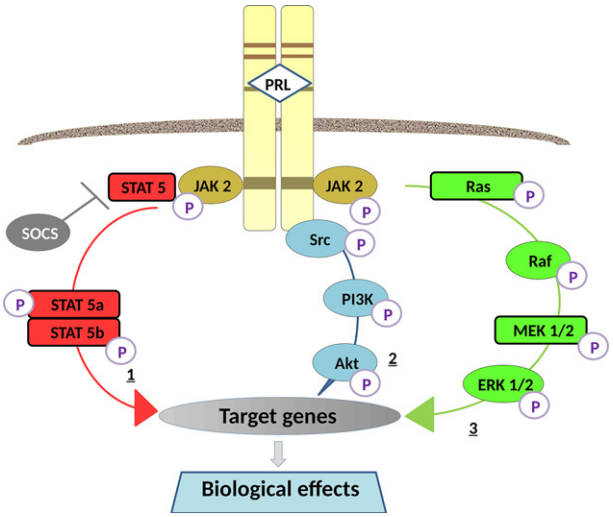

Fig. 3 The PRL receptor (PRLR) and its signaling cascade. PRL binds to the extracellular domain of the receptor and rapidly phosphorylates both Jak2 and the intracellular domain of the PRLR. PRL activates three major signaling pathways: Jak2/Stat (1), PI3K/Akt (2), and Ras/MAPK (3). P designates activation by phosphorylation.

(from 200 to 500 pg/mL). Specific receptors for TRH are present on lactotrope cells and stimulate the transcription of PRL gene in a few minutes. Consisting with these effects, hyperprolactinemia is commonly observed in patients with primary hypothyroidism due to the lack of negative feed-back of thyroid hormones on TRH. Similarly, estradiol increases PRL secretion, modulating PRL gene expression, modifying its sensitivity to physiologic stimuli but also inhibiting the activity of hypothalamic neuroendocrine dopaminergic neurons (Mancini *et al.*, 2008) (**Fig. 2**). The presence of VIP and oxytocin in high concentrations in pituitary portal blood and the presence of specific anterior pituitary receptors suggests that these neuropeptides may be involved in the regulation of anterior pituitary function. In fact, VIP stimulates PRL secretion in the rat, acting at both the hypothalamus and pituitary gland. The effects of VIP seem to be mediated by oxytocin. At pituitary level, VIP was shown to interfere with the inhibitory action of DA on the adenylate cyclase-cAMP system in an autocrine and paracrine manner. Angiotensin II (AII) is a potent secretagogue of PRL both in vivo and in vitro. It acts on specific receptors of lactotrope cells and PRL release may be blocked by an antagonist of the IIA. The stimulation of PRL release by the IIA is more intense, faster and transient as compared to the effects of TRH.

PRL secretion can also be affected by many different molecules that act indirectly on response of lactotropes to PIFs and PRFs (**Fig. 2**). For example, galanin increases PRL secretion (De Marinis *et al.*, 2000; Giustina *et al.*, 1994), and somatostatin inhibits baseline and induced PRL secretion in vitro. Somatostatin neurons receive abundant efferent connections from galanin, neurotensin, neuropeptide Y, g-aminobutyric acid (GABA), serotonin, enkephalin, substance P, TRH, and the catecholaminergic system (Giustina and Veldhuis, 1998). Moreover, γ-aminobutyric acid (GABA) is in part responsible for the nondopaminergic PIF activity. Finally, hypoglycemia and arginine stimulate PRL secretion.

PRL acts also as a leukocyte-derived cytokine in the immune system and is regulated by cytokines in an autocrine and paracrine way. In T-lymphocytes, interleukin (IL)-2, IL-1β, and IL-4 reduces PRL mRNA (Gerlo *et al.*, 2006). On the other hand, in myeloid leukemic cells, the PRL alternative promoter is activated by the proinflammatory cytokine tumor necrosis factor alpha (TNFα). A TNFα responsive region was located between -1842 and -1662 of the extrapituitary PRL promoter. Interestingly, the stimulatory effect of TNFα upon PRL is blocked by a protein kinase C (PKC) inhibitor. Since TNFα is a proinflammatory cytokine, its involvement in PRL stimulation might have clinical relevance in view of several studies indicating that leukocyte-derived PRL may be involved in autoimmune and hematological disorders.

Prolactin Receptors

PRL receptor (PRL-R) is a trans-membrane protein belonging to the superfamily of cytokine receptors of type 1, which also includes the receptors of GH and IL-1 (Bole-Feysot *et al.*, 1998). PRL-R is encoded by a gene located on chromosome 5 near the gene associated with the GH receptor. The size of human PRL-R gene exceeds 200 kb and contains 11 exons, the 3–10 exons being those encoding the full length of receptor (599 aminoacids). Several isoforms of human PRL-R have been identified including the full length receptor and at least eight other variants depending on the different splicing in the gene transcription. The long PRL-R is the major form that transmits PRL signaling, while the short isoforms, when co-expressed with the long isoform, can act as dominant negatives.

As a member of the cytokine receptor family, PRL-R consists of an extracellular binding domain, a single transmembrane domain and an intracellular domain required for signal transduction that lacks intrinsic kinase activity (**Fig. 3**). The extracellular

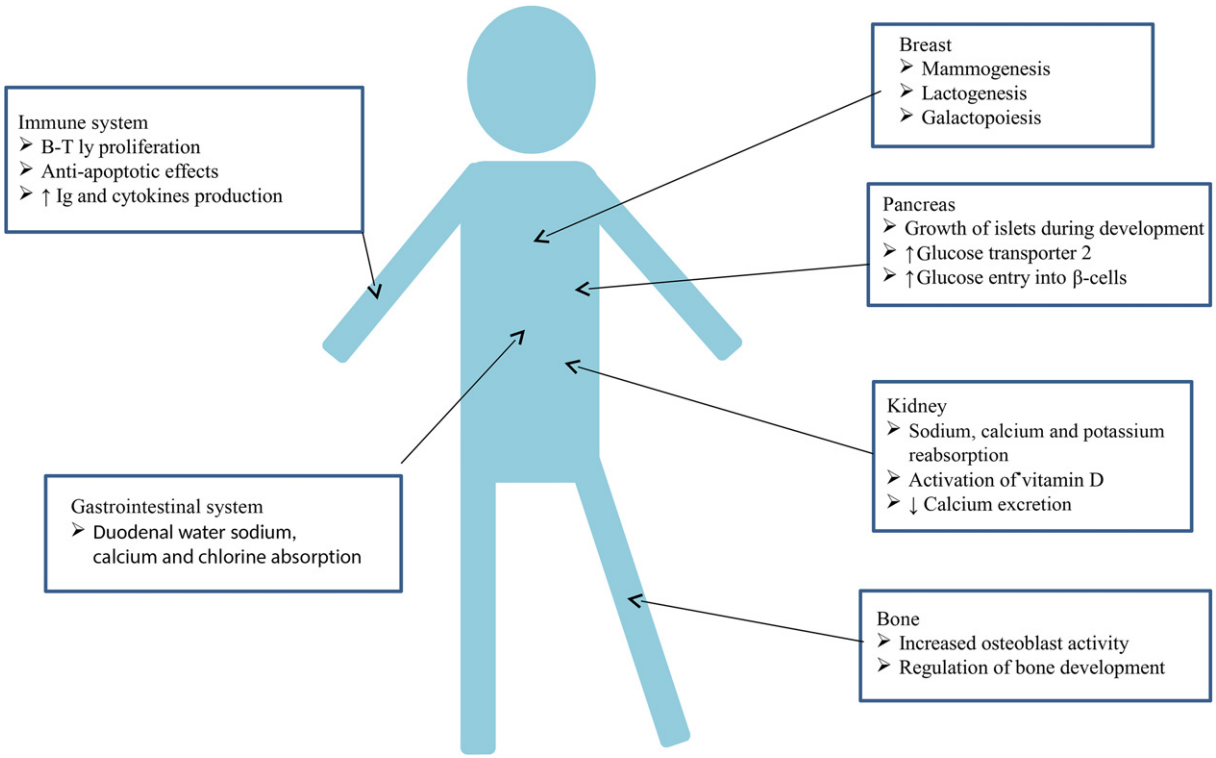

Fig. 4 Extragonadal effects of PRL. Ly, lymphocytes, Ig, Immunoglobulin.

segment of PRL-R is homologous to that of GH, whereas the intracytoplasmic segments of PRL-R are different and shorter than those of GH.

After binding, PRL induces receptor dimerization which is needed for intracellular signal transmission, being the Jak2 (Janus kinase 2)-STAT (Signal transducers and activators of transcription) pathway the main signaling cascade. Jak2 is rapidly phosphorylated upon PRL binding and induces the phosphorylation of the receptor itself, other associated kinases and STAT proteins. The phosphorylation of STAT proteins promotes their dimerization that is required for the final signal transduction in the nucleus, where they regulate gene expression. Other signals used by PRL-R include the pathways of the MAP kinases (MAPK), second messengers phosphatidylinositol and calcium channels.

Physiological and Pathophysiological Actions of Prolactin

PRL-Rs are present in the mammary gland, ovaries, pituitary gland, heart, lung, thymus, spleen, liver, pancreas, kidney, adrenal gland, uterus, skeletal muscle, skin and areas of the central nervous system supporting the concept that PRL may exert physiological effects on several tissues and organs (Bole-Feysot *et al.*, 1998) (**Fig. 4**).

Effects on Mammary Gland

PRL exerts different effects on the mammary gland stimulating the growth and development (mammogenesis), the synthesis of human milk (lactogenesis) and maintenance of milk secretion (galactopoiesis). During pregnancy, circulating levels of PRL increase in a progressive manner but lactation occurs only after the completion of delivery. This phenomenon is due to high levels of estrogens during pregnancy, which exert a dual effects on PRL secretion (i.e., stimulation) and activity (i.e., blocking). After delivery, the postpartum drop of estrogen secretion removes the blocking effects on PRL activity.

Gonadal Effects

While hyperprolactinemia effects on gonadal function are well known in males and females (Mancini *et al.*, 2008), less is known about PRL physiological effects. The physiological effect of PRL on the female gonad is represented by an increase in progesterone secretion favoring the LH stimulation of granulosa cells and inhibiting the 20-α-hydroxysteroid dehydrogenase activity (i.e., the enzyme which inactivates progesterone) (Zhong *et al.*, 1997). Interestingly, effects of PRL on progesterone production depend on hormone concentration since hyperprolactinemia was shown to be associated with inhibitory effects on progesterone secretion. In

males, PRL could act modulating the binding of gonadotropins to Leydig cell receptors and interfering with the enzymatic cascade of steroidogenesis. Moreover, in experimental conditions, normal levels of PRL were needed for spermatogenesis (Hair *et al.*, 2002). These physiological effects of PRL on progesterone synthesis in females and steroidogenesis and spermatogenesis in males may be clinically relevant in the specific setting of patients with prolactinomas (over)-treated with DA agonists.

Effects on Immune System

The relationship between PRL and the immune system has been studied and characterized over the last 20 years, opening important horizons in the field of immunoendocrinology. PRL-R is expressed in splenocytes, thymocytes, bone marrow cells, peripheral blood mononuclear cells, lymphocytes and monocytes. Interestingly, PRL was shown to stimulate B and mainly T lymphocyte proliferation. Moreover, PRL induces an anti-apoptotic effect, enhances the proliferative response to antigens and mitogens, and increases the production of immunoglobulin, cytokines and autoantibodies (**Fig. 4**). These effects may at least in part explain the association already reported in literature between PRL excess and several autoimmune diseases, such as systemic lupus erythematosus, rheumatoid arthritis, Sjogren syndrome, Hashimoto's thyroiditis, and multiple sclerosis (Savino, 2017; Wang *et al.*, 2017).

Metabolic Actions

PRL exerts a well-defined role on osmotic adjustment in numerous animal species. This is particularly evident in fish and in many invertebrates in which there is a direct relationship between PRL, sodium levels and volume of body fluids. Its action as osmotic-controller would involve renal and extra-renal targets through the stimulation of the transport of solutes across the cell membranes such as duodenal absorption of water, sodium, calcium and chlorine and resorption of sodium, potassium and water in the kidney (**Fig. 4**). This mechanism is more easily detectable during the late stage of pregnancy, facilitating the subsequent lactation.

PRL also appears to play a role in pancreatic and adipose development. In adipose tissue, PRL is essential in adipogenesis, adipocyte differentiation and lipid metabolism through the stimulation of leptin and inhibition of adiponectin production (Ben-Jonathan *et al.*, 2006; Carre and Binart, 2014). At pancreatic level, PRL promotes growth of islets during development, and glucose-stimulated insulin secretion. It also increases expression of glucose transporter 2 and promotes glucose entry into β-cells (**Fig. 4**). These actions are important during pregnancy and lactation with adaptive changes in lipid metabolism and glucose homeostasis (Ladyman *et al.*, 2012). Failure of this adaptive response may result in gestational diabetes.

PRL-Rs have been found in the arcuate, ventromedial and paraventricular hypothalamic nuclei involved in regulation of food intake. An excess in PRL secretion, as physiologically occurs during pregnancy, may contribute to the rapid increase in food intake commonly observed during this period and during lactation.

PRL favors renal activation of vitamin D, stimulates intestinal calcium absorption and inhibits the fractional excretion of calcium by the kidney (Rojas-Vega and Gamba, 2016) (**Fig. 4**). All these effects are important for guaranteeing adequate calcium levels for fetal development during pregnancy and breastfeeding during lactation. Over the recent years, there has been convincing evidence that PRL may have also direct effects on osteoblasts which results seem to be variable in relationship to the duration of exposure and likely to the hormone concentrations. Physiological PRL levels are likely required for normal bone development, as suggested by the experimental evidence that knock-out mice for PRL-R have decreased bone mass and deformed skeletal development. However, a prolonged exposure of osteoblasts to PRL excess can have an inhibitory effect on osteoblast number, mineralization and differentiation (Seriwatanachai *et al.*, 2009). This direct effect of PRL on osteoblasts may explain the clinical observation that skeletal fragility may occur in males and females with prolactinomas regardless of coexistent hypogonadism (Mazziotti *et al.*, 2011a,b, 2015).

PRL and Cancer

PRL promotes the proliferation of breast epithelial cells and the differentiation of alveoli in physiological conditions. Moreover, PRL may modulate angiogenesis with variable effects depending on the PRL isoform. Whereas native PRL has angiogenic properties, the 16 K-PRL fragment is a potent antiangiogenic factor inhibiting the effects of vascular endothelial growth factor and fibroblast growth factor (Clapp and De La Escalera, 1997).

An association between circulating PRL levels and risk in breast cancer has been reported in both pre- and post-menopausal women. Interestingly, expression of PRL and PRL-R has been found in breast cancer cells suggesting that a paracrine–autocrine action of PRL may occur in this setting (Shemanko, 2016). Moreover, PRL-PRL-R pathway was involved in determining resistance of breast cancer cells to anti-neoplastic drugs (Idelman *et al.*, 2011). PRL has been studied in other type of cancers with rather discordant results. For instance, in hepatocellular carcinoma, PRL was shown to either impeding liver carcinogenesis by promoting the innate immune response or to promote tumor progression leading to a worse survival of patients (Kong *et al.*, 2016).

However, the emerging evidence that PRL-PRL-R pathway may be involved in some forms of carcinogenesis has highlighted its potential role as target for anti-neoplastic drugs (Wen *et al.*, 2014; Kelly *et al.*, 2017).

Molecular Pathogenesis of Pituitary Tumors☆

Shereen Ezzat and Sylvia L Asa, University Health Network, Toronto, ON, Canada; University of Toronto, Toronto, ON, Canada; and Princess Margaret Cancer Centre, Toronto, ON, Canada

Glossary

Adenohypophysial Pertaining to the adenohypophysis or anterior pituitary.
Epigenetic Functionally relevant changes to the genome that do not involve changes to the nucleotide sequence.
Heterozygous Pertaining to heterozygosity.
microRNA Small non-coding RNAs.
Monoclonal Derived from a single cell.
Nonsense Pertaining to altered recognition or identification.
Somatic mutations Genetic changes pertaining to a specific cell lineage.
Transgenic Pertaining to the experimental splicing of a segment of DNA from one genome onto DNA of a different genome.

Introduction

This article is an update of Shereen Ezzat, Pituitary Tumors, Molecular Pathogenesis, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 681-686.Pituitary tumors are common neoplasms that exhibit a wide range of biological courses as evidenced by hormonal and proliferative activities (Asa *et al.*, 2017a). Traditionally, there was an on-going controversy regarding the basis of pituitary tumorigenesis. Two prevailing theories confronted hormonal stimulation as an extrinsic stimulus against a somatic mutation as an intrinsic pituitary defect. While a minority of these tumors harbors genetic mutations, several animal models and unique clinical cases have provided support for hormonal stimulation in the development of these tumors. These findings along with evolving experimental evidence favor a theory that accounts for epigenetic dysregulation of the balance between stimulatory and inhibitory influences, irrespective of their origin (Asa, 2011; Asa and Ezzat, 2009). In this review, we highlight recent insights into mechanisms implicated in the dysregulated balance of signals that control pituitary adenohypophysial cell growth and function.

Pituitary Tumor Classification by Cytogenesis

Pituitary tumors have been recognized to produce hormones and immunohistochemistry has complemented the clinical measurement of circulating hormone excess to classify pituitary tumors that cause hormone excess. The clinical features of these functioning tumors are discussed elsewhere. Morphologically, classification of such tumors entails the identification of subcellular features that identify the cell lineage, transcription factors, hormones, and other structural parameters (Asa, 2011) that indicate altered signaling pathways. Acromegaly due to pituitary growth hormone (GH) excess is indeed not one disease, but rather comprises several distinct disorders that have different clinical manifestations, radiologic characteristics, and responses to therapeutic agents (Asa *et al.*, 2017b); the importance of recognizing sparsely granulated somatotroph tumors and distinguishing them from densely granulated somatotroph or mammosomatotroph neoplasms has implications for the postoperative management of residual or recurrent disease. Similarly, although most tumors that are called "prolactinoma" represent sparsely granulated lactotroph tumors, those with unusual clinical manifestations and that fail to respond to dopaminergic agents are frequently discovered to be rare variants such as acidophil stem cell or poorly differentiated Pit-1 lineage tumors (Gomez-Hernandez *et al.*, 2015). In patients with Cushing disease, there are several morphologic variants; the classical microadenoma that causes florid Cushingoid features is usually a densely granulated tumor, whereas the sparsely granulated tumors are usually large when discovered and may not be associated with obvious hypercortisolemia, a phenomenon that has been called a "whispering" rather than "silent" tumor. Rarely, corticotroph tumors may present when large and invasive and with an unusual history that sometimes is considered to be "cyclical" Cushing syndrome, and these tumors are found to be composed of corticotrophs with Crooke's hyaline change.

Clinically nonfunctioning tumors are equally if not more complex. The vast majority of these is now known to be of gonadotroph differentiation; although functioning gonadotroph tumors are rare, the silent tumors usually have focal gonadotropin reactivity and with the use of immunohistochemistry for steroidogenic factor-1, are proven to be of gonadotroph lineage (Asa, 2011). However, those that are not, whether they are silent corticotroph tumors, silent tumors of Pit-1 lineage, or true "null cell" adenomas that have no evidence of any lineage differentiation, are more aggressive (Nishioka *et al.*, 2015).

Armed with the knowledge that pituitary tumors are a complex family of different neoplastic cell types (**Fig. 1**), it is not surprising to find that their pathogenesis is equally complex, often with distinct alterations in different tumor types.

☆*Change History:* September 2017. S Ezzat and SL Asa updated references in all sections. A new list of Further Reading was also updated.

This article is an update of Shereen Ezzat, Pituitary Tumors, Molecular Pathogenesis, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 681–686.

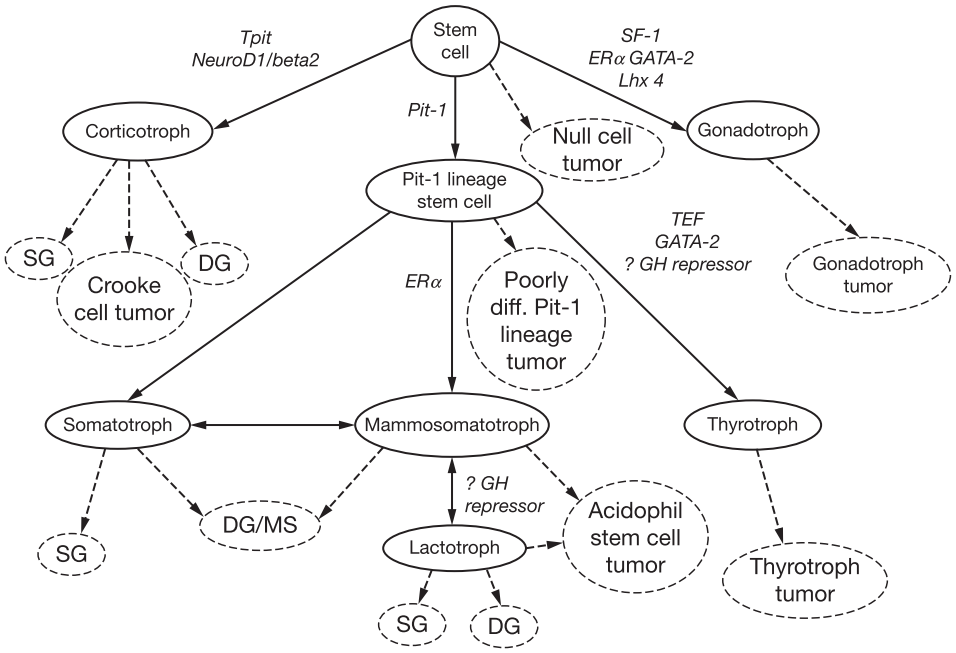

Fig. 1 Pituitary cytodifferentiation. Pituitary stem cells differentiate along three major pathways of pituitary differentiation that are determined by expression of transcription factors (italics); the Pit-1 lineage is more complex, giving rise to four cell types again determined by expression of additional transcription factors. Each cell type can give rise to specific tumor types. *SG*, sparsely granulated; *DG*, densely granulated; *MS*, mammosomatotroph.

Molecular Events

Evidence in favor of an intrinsic pituitary defect accounting for the development of pituitary tumors has been based primarily on the monoclonal composition of these tumors. Although pituitary tumors are monoclonal, somatic mutations in genes that have been identified in other malignancies are usually absent. For example, mutations in codon 12 of *H-RAS* have been reported in an aggressive prolactinoma (Cai *et al.*, 1994; Karga *et al.*, 1991) and in rare metastasizing pituitary carcinomas, but are exceptionally uncommon in the usual pituitary tumors, even when locally invasive. The mutations leading to pituitary tumorigenesis primarily involve components of the hormone regulatory signaling pathways.

Molecular alterations have been identified in the setting of familial pituitary neoplasia (Lyssikatos *et al.*, 2016). Several of the important clinical entities, including multiple endocrine neoplasia type 1 (MEN1) and type 4 as well as most patients with Carney complex, are due to mutations in known genes, specifically MEN1 (Chandrasekharappa *et al.*, 1997; Zhuang *et al.*, 1997), p27 (Georgitsi *et al.*, 2007; Pellegata *et al.*, 2006) or p18 (Georgitsi, 2010), and PRKAR1A (Sandrini *et al.*, 2002), respectively. Familial somatotropinoma and familial isolated pituitary adenoma (FIPA) syndromes are associated with aryl hydrocarbon receptor-interacting protein (AIP) mutations (Beckers *et al.*, 2013; Beckers and Daly, 2007). More recently, the 3PA syndrome (pituitary adenoma with paraganglioma/pheochromocytoma) has been attributed to SDH complex mutations (Xekouki and Stratakis, 2012). Mosaic germline GNAS mutations have been known to be associated with McCune–Albright syndrome (Weinstein *et al.*, 1991) and recent identification of Xq26 microduplications and GPR101 mutation associated with early childhood gigantism is now classified as X-linked acrogigantism (X-LAG) (Trivellin *et al.*, 2014). Dicer mutations have been implicated in the extremely unusual pituitary blastoma (de Kock *et al.*, 2014).

These mutations and their impact will be discussed later. Many of them are implicated in altered signaling pathways that are important in adenohypophysial cells. However, with a few exceptions, these mutations are not found as somatic events that can explain the much more common sporadic pituitary tumors.

Hormone Regulatory Pathways

Activation of Stimulatory Hormone Receptor Pathways

Growth hormone-releasing hormone and its receptor

GH-releasing hormone (GHRH) can cause somatotroph proliferation as evidenced by somatotroph hyperplasia in patients with endocrine carcinomas ectopically secreting GHRH (Asa, 2011). Intrapituitary GHRH expression is well documented and GHRH may be overexpressed in some aggressive tumors. Human somatotroph tumors respond to GHRH stimulation in vitro, consistent

with functional GHRH receptors (GHRHR) on these tumors. In some instances, however, they may lose the downregulation characteristic of normal somatotrophs. Thus, GHRH stimulation can contribute to the development of some pituitary neoplasms. Moreover, older transgenic mice overexpressing GHRH develop pituitary neoplasia. However, in situations of GHRH excess, GH-producing tumors are usually accompanied by somatotroph hyperplasia, which is distinctly unusual in human pituitary GH tumors. Moreover, prolonged exposure to GHRH does not always lead to true neoplastic transformation in humans.

Cloning of the GHRHR has permitted examination of the role of GHRH in somatotroph function. Indeed, loss of GHRHR signaling is recognized as the genetic basis for the little (lit/lit) dwarf mouse. A truncated alternatively spliced form of the GHRHR with limited signaling properties has been identified in GH-producing pituitary tumors. Unlike the case with other examples of endocrine hyperfunction where constitutive activation of the relevant receptor has been described, no intrinsic constitutively active forms of the GHRHR have thus far been identified in pituitary tumors. A truncated GHRHR identified in GH-producing pituitary tumors reduces signaling; there are no reports of activating mutations of *GHRHR* in pituitary tumors (Asa, 2011; Asa and Ezzat, 2009, 2014).

Estrogen

Estrogen excess is implicated in the physiological lactotroph proliferation of pregnancy. In rat models, estrogen-induced lactotroph hyperplasia is associated with enhanced expression of other growth factors such as vascular endothelial growth factor (VEGF) and galanin (Lloyd, 1983). In contrast, a dominant-negative ER induces apoptosis. Although estrogen may be implicated in the development of lactotroph neoplasms in rare situations, such as in a male-to-female transsexual, the administration of estrogen in contraceptive agents or in postmenopausal hormone replacement is not associated with any increased risk of the development of pituitary lactotroph tumors.

Thyrotropin-releasing hormone and the thyroid axis

Primary hypothyroidism is a well-recognized cause of pituitary thyrotroph and lactotroph hyperplasia. Patients with untreated primary hypothyroidism exhibit the spectrum of hyperplasia to neoplasia, suggesting that continuous stimulation by thyrotropin-releasing hormone (TRH) may lead to thyrotroph tumor (Asa, 2011; Asa and Ezzat, 2009). TRH has also been shown to be expressed in the pituitary and by the different types of pituitary tumors.

TRH signaling appears to be intact in pituitary tumors as evidenced by intact binding and normal release of thyroid stimulating hormone (TSH) and prolactin (PRL) in response to TRH exposure. TRH receptor expression and structure are grossly unaltered even in thyrotroph tumors. TRH mRNA is alternatively spliced in some pituitary tumors with deletion of exon 3, resulting in a truncated product that does not bind TRH. The relatively higher levels of the truncated forms compared to the full-length form of the TRH receptor in lactotroph tumors may explain some of the paradoxical in vivo responses to TRH administration.

Thyroid hormones mediate feedback suppression through dedicated nuclear DNA-binding thyroid hormone receptors (TRs), α and β, each of which undergoes alternative splicing. TRβ2 is predominantly expressed in hypothalamus and pituitary; the other isoforms are ubiquitously expressed. Mice with disrupted *TRβ* exhibit elevated thyroid hormone levels but do not develop pituitary tumors. Rare *TRα* missense mutations have been reported, one that was specific to the TRα2 and two that would affect both TRαs isoforms. Thus far, no somatic TRβ alterations have been reported in pituitary tumors (Asa, 2011; Asa and Ezzat, 2009).

Corticotropin-releasing hormone and the glucocorticoid axis

Tumor-associated overproduction of corticotropin-releasing hormone (CRH) causes pituitary corticotroph hyperplasia and Cushing syndrome; however, most CRH-producing tumors also express ACTH, resulting in pituitary suppression. A mouse model of systemic CRH excess similarly caused a Cushing syndrome phenotype but there was no evidence of pituitary corticotroph hyperplasia, because multiple other sources of ACTH respond to CRH. Activating mutations of the CRH receptor have not been reported in corticotroph tumors (Asa, 2011; Asa and Ezzat, 2009).

Conversely, loss of glucocorticoid inhibition in primary adrenal cortical deficiency can result in corticotroph hyperplasia. Corticotroph adenomas have been associated with germline *GCR* mutations and a somatic inactivating *GCR* mutation (Karl *et al.*, 1996a,b).

G proteins

The family of seven transmembrane domain G-protein coupled receptors signal through a family of G proteins to transduce signaling to downstream effectors. Stimulatory G proteins (Gs) have three subunits; on ligand binding, the α-subunit dissociates from the β- and γ-subunits, thereby stimulating adenylyl cyclase to convert ATP to cyclic AMP (cAMP). Activating mutations in the *GNAS* gene alter two domains of Gsα to interfere with GTP hydrolysis, constitutively increasing cAMP. These G-protein oncogenes (*gsp*s) were the first somatic mutations described in endocrine tumors, including some pituitary densely granulated somatotroph neoplasms, as well as hormone-secreting tumors of other endocrine glands including thyroid and adrenal cortex (Landis *et al.*, 1989; Lyons *et al.*, 1990). The resulting elevation of cAMP is thought to be the reason for the clinical responsiveness of densely granulated somatotroph tumors to somatostatin (SS) analog therapy (Bhayana *et al.*, 2005).

Germline mosaicism of these *GNAS* mutations causes McCune–Albright syndrome, which features somatotroph hyperplasia or neoplasia (as well as thyroid and adrenal cortical autonomously functioning adenomas) (Salpea and Stratakis, 2014; Weinstein *et al.*, 1991). This gene exhibits monoallelic imprinting and the mutations usually involve the maternal allele.

More recently, germline and somatic changes in the orphan G-protein receptor GPR101 have been implicated in childhood gigantism and adult acromegaly respectively. Indeed, germline duplication of Xq26.3 with overexpression of GPR101 has been implicated in a rare form of pediatric GH excess termed X-LAG (Trivellin *et al.*, 2014). Somatic mutations of GPR101, however, do not appear to play a role in sporadic somatotroph tumors that develop in adolescence and adulthood.

Protein kinase-A

The role of cAMP signaling in somatotroph proliferation and transformation is evident from Carney's complex, an autosomal dominant disorder in which affected patients develop spotty pigmentation of mucosal surfaces, cardiac myxomas, and hypersecreting endocrine tumors of the pituitary (somatotroph and mammosomatotroph), adrenal cortex, and gonads. Most Carney complex patients have germline inactivating mutations in the PRKAR1Aα gene that encodes the protein kinase-A (PKA) regulatory subunit 1Aα, one of four components of the tetrameric holoenzyme that is critical for intracellular protection from unrestrained catalytic activity and elevation of cAMP (Kirschner *et al.*, 2000). However, this gene is not implicated in the pathogenesis of sporadic pituitary tumors (Salpea and Stratakis, 2014). A second locus at 2p16 has been implicated but the responsible gene remains unknown. Patients with this disorder develop pituitary somatotroph or mammosomatotroph tumors (Asa, 2011). Animal models proved that loss of PRKAR1A activity can lead to pituitary tumor development (Yin *et al.*, 2008).

The aryl hydrocarbon receptor-interacting protein

AIP is a chaperone protein with multifunction properties, including modulation of the transcriptional activity of the aryl hydrocarbon receptor, which mediates toxicological and carcinogenic dioxin effects. Recent studies have shown that AIP regulates cAMP concentrations through Gαi-2 and Gαi-3 proteins that inhibit cAMP synthesis (Beckers *et al.*, 2013). Germline mutations in AIP have been identified in some families with the isolated familial somatotropinoma syndrome where acromegaly and gigantism predominate, and in those with FIPA syndrome, with various types of pituitary tumors but usually including some GH- and PRL-secreting tumors (Beckers *et al.*, 2013). Loss of heterozygosity (LOH) of the *AIP* gene in the tumors suggests that it acts as a tumor suppressor, consistent with its role in cAMP modulation. Nevertheless, numerous studies have shown that AIP mutations are not found in sporadic pituitary tumors (Asa and Ezzat, 2014).

Inactivation of Inhibitory Hormone Receptor Pathways

Dopamine

The role of diminished hypothalamic inhibition was first suggested based on the observation of neovascularization in lactotroph tumors (Bergland and Page, 1979). It was speculated that neovascularization would allow lactotrophs to escape from tonic dopaminergic inhibition. Dopamine signal transduction is mediated through D1 receptors that stimulate adenylyl cyclase activity and D2 receptors (D2R) that inhibit this enzyme. The family of dopamine receptors is complex in biochemical, physiological, and pharmacological diversity. Nevertheless, it appears that the predominant anterior pituitary dopamine receptor is the D2R. Targeted disruption of D2R activity in D2R knockout mice results in lactotroph hyperplasia and, subsequently, lactotroph neoplasia in female D2R-deficient mice (Schuff *et al.*, 2002). Interestingly, these lesions are monohormonal PRL-immunoreactive neoplasms that display a characteristic juxtanuclear Golgi pattern of PRL staining and loss of the reticulin fiber network. Several of these tumors have been noted to be much larger than normal glands, with marked suprasellar extension and invasion of brain but no gross evidence of distant metastases.

Although some pituitary tumors have been shown to be responsive to dopamine suppression, the dopaminergic resistance that is found in some tumors implicates diminished D2R activity as a putative factor in pituitary tumorigenesis. Thus far, however, investigation of the D2R gene has revealed it to be structurally intact in human lactotroph tumors (Asa and Ezzat, 2009).

Prolactin

The autoregulation of PRL secretion in the rat has been demonstrated at the levels of both the hypothalamus and the pituitary. In transfected somatolactotrophs, PRL exerts a strong and specific inhibition of PRL gene transcription. These effects appear to be mediated by intermediate and long forms of the PRL receptor (PRL-R). Deletions of the PRL promoter indicated that the autoregulatory effect of PRL requires the same regulatory domains that have been described for the other PRL gene regulators. These studies support an extra-short loop of PRL transcriptional autoregulation. In the normal human pituitary, PRL and lutei-nizing hormone-expressing cells exhibit the highest levels of PRL-R mRNA expression, whereas PRL-producing pituitary tumors have significantly higher levels of PRL-R mRNA than other types of pituitary neuroendocrine tumors. Dopamine agonist treatment decreases the levels of PRL-R mRNA in PRL tumors. Although *PRL-R* mutations are not found in human prolactinomas (Asa, 2011; Asa and Ezzat, 2009), an inactivating germline mutation has been reported in familial hyperprolactinemia (Newey *et al.*, 2013).

Somatostatin

GH secretion is under contrasting influence from hypothalamic stimuli including GHRH, which stimulates GH secretion, and SS, which inhibits GH secretion. Specific receptors for SS (SSTRs) are expressed by somatotroph tumors. Earlier studies suggested a relationship between the density of SS receptors on GH tumors and the secretory response to this analog both in vitro and in vivo. Binding sites for SS, however, have been identified by autoradiography in tumors resistant to the GH-lowering effects of octreotide.

These findings are consistent with differential adenylyl cyclase coupling by the five known subtypes of SSTRs and their heterogeneous expression in pituitary neoplasia. A germline SSTR5 inactivating mutation has been associated with acromegaly in one patient but no other mutations have been described to account for loss of SS inhibition. Expression of SS itself in large invasive GH tumors appears to be diminished compared to that in the normal pituitary (Lania *et al.*, 2008). These findings suggest multiple paracrine, autocrine, and endocrine mechanisms for SS-mediated control of somatotroph function and proliferation.

Growth hormone

GH feedback on somatotrophs has been shown in mice, where interruption causes mild somatotroph enlargement and hyperplasia. Pharmacologic inhibition of GH receptor signaling with the GH antagonist pegvisomant induces the development of keratin aggresomes known as "fibrous bodies" that are the hallmark of sparsely granulated somatotroph adenomas, and a rare somatic histidine-to-leucine mutation that destabilizes the GH receptor have been reported in tumors of that morphology, suggesting that altered STAT signaling is implicated in their development (Asa *et al.*, 2007; Asa and Ezzat, 2009).

Thyroid hormones

The development of pituitary thyrotroph adenomas in patients with prolonged primary hypothyroidism has provided further evidence supporting the hypothalamic role in pituitary tumorigenesis. Thyroid hormones mediate their actions via nuclear TRs that bind to specific regulatory hormone-response elements. There are two major classes of TRs, designated α and β, each of which undergoes alternative splicing to generate $\alpha 1$ and $\alpha 2$ and $\beta 1$ and $\beta 2$ isoforms. With the exception of the $\beta 2$ form, which is predominantly expressed in the hypothalamic–pituitary system, these receptor isoforms are ubiquitously expressed. Of interest, in the pituitary, the $\beta 1$ and $\beta 2$ isoforms appear to be expressed to a lesser extent in tumors than in the normal gland. Screening TR-α mRNA identified three novel missense mutations, two in the common TR-α region and another that was $\alpha 2$ specific. TR-β-response elements failed to show any differences from published sequences.

Mice with targeted disruption of the entire TR-β locus exhibit elevated thyroid hormone levels as a result of abnormal central regulation of thyrotropin but do not develop pituitary tumors (Abel *et al.*, 1999). Thus, the putative differential hormone regulatory and mitogenic effects of the different THR isoforms in the pituitary remain unclear.

The TGF-β family, activins, inhibins, and follistatins

TGF-β has been implicated in the regulation of normal and neoplastic cell function. TGF-β regulates the expression of various proteins, including the cell-cycle inhibitory protein p27Kip1 (p27). TGF-β 1/2/3 isoforms and the TGF-β receptor are expressed in normal and neoplastic pituitaries. Dispersed pituitary tumor cells show a biphasic response to TGF-β with changes in follicle-stimulating hormone (FSH) secretion. The TGF-β family, however, is represented in at least three different forms in the pituitary. Inhibins and activins consist of two homo- or heterodimeric polypeptide subunits derived from a common precursor; inhibin A (α-βA) and inhibin B (α-βB) selectively inhibit the release of FSH from pituitary gonadotroph cells, whereas activin (βA-βB), activin A (βA-βA), and activin B (βB-βB) stimulate its release. Inhibin subunits are expressed by pituitary gonadotroph tumors and activin is known to stimulate hormone secretion by these tumors. Activin, however, inhibits cell proliferation in a variety of cell types including pituitary tumors. These actions are mediated through type I and type II serine/threonine kinase receptors. The predominant form is type I (ActRIB or Alk4). Truncated forms of the type I receptors expressed by gonadotroph tumors interfere with wild-type receptor function and block the antiproliferative effects of activing (Zhou *et al.*, 2000). In addition, follistatin expression is diminished in these tumors (Penabad *et al.*, 1996), which represent the vast majority of clinically nonfunctioning pituitary neoplasms and almost 40% of pituitary tumors (Asa, 2011). These findings suggest an important role for the activin/follistatin/activin receptor balance in modulating pituitary tumor cell replication.

Gonadal steroids

The development of pituitary gonadotroph neoplasia in patients with prolonged primary hypogonadism (Asa, 2011) suggests that the lack of hormone negative feedback may facilitate pituitary tumor development. The role of GnRH stimulation cannot be easily distinguished from that of gonadal hormone inhibition in the development of these tumors.

Glucocorticoid hormones

Loss of glucocorticoid inhibition has been reported to cause corticotroph hyperplasia and neoplasia in rare patients with prolonged primary adrenal insufficiency. Germline inactivating mutations in the human glucocorticoid receptor (GCR) cause familial glucocorticoid resistance. A small number of pituitary corticotroph tumors causing Cushing's disease may be attributed to novel germline GCR mutations or rare somatic GCR mutation that can interrupt glucocorticoid inhibition (Karl *et al.*, 1996b).

Growth Factor Regulatory Pathways

Growth Factors and Their Receptors

Transforming growth factor-α

Transforming growth factor-α (TGF-α) is expressed as a membrane-anchored protein by human adenohypophysial cells and tumors (Ezzat *et al.*, 1995). TGF-α may alter pituitary production of GH, PRL, and TSH as well as cell proliferation. Estrogen stimulation has been implicated in pituitary tumorigenesis and TGF-α appears to mediate some estrogenic effects (Liu *et al.*, 1987). Targeted overexpression of TGF-α to the pituitary results in lactotroph tumor (McAndrew *et al.*, 1995), providing compelling evidence for the significance of this growth factor in pituitary tumorigenesis.

Epidermal growth factor and its receptor

Epidermal growth factor (EGF) is detectable by immunohistochemistry in most adenohypophysial cells and its mRNA is expressed with marked variation in all types of functional and nonfunctional adenohypophysial tumors. EGF potently stimulates PRL and adrenocorticotropic hormone secretion with variable effects on rat pituitary cell proliferation. The selective expression and specific effects of EGF suggest that the pituitary is an important target site for this growth factor's action.

The common receptor of EGF and TGF-α, EGF receptor (EGF-R), is a 170 kDa plasma membrane tyrosine kinase product of the proto-oncogene v-*erb*B. EGF-R is overexpressed in several types of human cancers and in most instances this overexpression is accompanied by TGF-α expression; expression of this receptor appears to correlate with tumor aggressiveness. EGF-R is expressed by human pituitary tumors with the highest levels in recurrent somatotroph tumors and suggesting a selective mechanism for the EGF/EGF-R family in the growth of aggressive somatotroph tumors (LeRiche *et al.*, 1996). The importance of the EGF-R in the somatotroph is further supported by the selective loss of somatotrophs in transgenic mice overexpressing a dominant-negative EGF-R mutant lacking the intracellular protein kinase domain (EGFR-tr) (Roh *et al.*, 2001). These findings point to EGF-R as an integral component in the differentiation and proliferation of somatotrophs. However, unlike other cancers, no mutations of the EGF-R have been identified in pituitary neuroendocrine neoplasms.

The human EGF-R family includes four members, the prototypic EGF-R (ErbB1, HER1), as well as p185Her2/neu (ErbB2 and HER2), ErbB3 (HER3), and ErbB4 (HER4). Recently, mutations in the deubiquitinase USP8, a component of the proteasomal degradation pathway, were shown to impair EGF-R degradation thereby augmenting signaling in some corticotroph tumors (Hayashi *et al.*, 2016; Ma *et al.*, 2015; Reincke *et al.*, 2015). Like EGF-R, the ErbB2 receptor is expressed by all tumor subtypes and is upregulated in invasive tumors but there is no evidence of mutation or gene amplification as in other cancers. ErbB3 is expressed in lactotroph tumors and upregulated in aggressive forms, and Heregulin (HRG), the ligand for ErbB3 and ErbB4, is involved in PRL regulation. ErbB4 is expressed in the normal adenohypophysis but its expression and possible function in pituitary tumors is not known (Cooper *et al.*, 2011). Recent studies involving pharmacologic approaches that interrupt Erbb2 signaling have highlighted the potential role of exploiting this pathway in pituitary tumors (Liu *et al.*, 2015).

Fibroblast growth factors and their receptors

Basic fibroblast growth factor (also known as FGF-2) is one of an expanding family of at least 23 members of ligands with variable mitogenic, angiogenic, and hormone regulatory effects. FGF-2 immunoreactivity was described originally in nonhormone-producing bovine pituitary folliculo-stellate cells and has since been shown to regulate GH, PRL, and TSH secretion by the rodent pituitary. FGF-2 is produced by adenohypophysial cells in human pituitary tumors. Pituitary-derived FGF-2 has been shown not only to stimulate replication of PRL-secreting cells but also to inhibit DNA synthesis in pituitary tumor cells, suggesting that some forms of the growth factor or its receptor may act as growth inhibitors. Elevated concentrations of FGF-2-like immunoreactivity have been documented in patients with MEN1 and in patients with sporadic pituitary tumors. The FGF-related *hst* has been found in transforming DNA of human PRL-secreting tumors and facilitates lactotroph proliferation. Transgenic mice expressing FGF-2 under the control of the GH and the α-subunit promoters develop hyperplasia of several adenohypophysial cell types but not frank neoplastic transformation. FGFs or homologous family members may, therefore, play an important role in pituitary tumorigenesis.

FGF signaling is mediated through FGF receptors (FGFRs). Four FGFR genes encode a complex family of transmembrane receptor tyrosine kinases. Multiple forms of cell-bound or secreted receptors are produced by the same gene. Tissue-specific alternative splicing, variable polyadenylation sites, and alternative initiation of translation result in truncated receptor forms. Structural alterations of FGFRs may play a role in human tumorigenesis; for example, antisense targeted interruption of FGFR1 reduces malignant melanoma cell proliferation and differentiation. The normal pituitary expresses mRNAs for FGFR1, 2, and 3 (Abbass *et al.*, 1997). FGFR2-IIIb is expressed in normal adenohypophysial cells; it acts as a tumor suppressor and is downregulated in pituitary tumors, associated with increased proliferation and release of expression of the cancer/testis-melanoma associated antigen MAGE-A3 (Zhu *et al.*, 2008).

Altered FGFR4 expression in pituitary tumors (Qian *et al.*, 2004) results in distinctive cytoplasmic localization that is implicated in dysadhesion of pituitary tumor cells (Ezzat *et al.*, 2006). Similarly PSA-NCAM, which is associated with tumor growth and invasiveness, likely alters the FGFR4 complex that maintains adhesion and normal acinar architecture of adenohypophysial cells (Ezzat *et al.*, 2006). A common germline polymorphism in the transmembrane domain of the FGFR4 gene has also been implicated in modulating growth and function of pituitary tumor cells; the FGFR4-R388 variant yields an isoform whose signaling

relies heavily on Src and STAT3 activation to enhance pituitary cellular growth and impair normal hormone regulation (Nakano-Tateno *et al.*, 2014; Tateno *et al.*, 2011) and may play a role in determining response to SS analog action (Ezzat *et al.*, 2017b).

Angiogenesis and hypoxia

VEGF plays a role in angiogenesis and is thought to be important in tumorigenesis. It is expressed in some pituitary tumors (Takano *et al.*, 2014); however, it does not correlate with microvascular density that varies between tumor types but is generally much lower in tumors than in the normal adenohypophysis (Jugenburg *et al.*, 1995). This interesting observation is consistent with the reduced gadolinium enhancement seen in pituitary tumors during magnetic resonance imaging and indicates a hypoxic environment.

Hypoxia-driven gene and protein changes are implicated in epithelial-to-mesenchymal transition, drug resistance, cancer stem cell formation, and evasion from immune surveillance. These were not traditionally considered to be features of pituitary tumors; however, the evidence for reduced blood flow led to studies of hypoxic responses in pituitary tumors. C-terminal binding protein, a transcriptional corepressor that mediates development and tumorigenesis, interacts with Ikaros isoforms in pituitary cells and both are induced by hypoxia (Dorman *et al.*, 2012) and target the metalloproteinase ADAMTS10 (Shen *et al.*, 2017). Mammalian sterile-20-like kinase (MST4) is also overexpressed in tumors compared with normal pituitaries and is thought to mediate proliferation and survival in a hypoxic environment (Xiong *et al.*, 2015).

Cell-Cycle Regulatory Pathways

Loss of Tumor Suppressors

Multiple endocrine neoplasia type 1

According to the two-hit model of tumorigenesis, both copies of a gene situated on opposite alleles must be inactivated, such as by deletion, rearrangement, or silencing through methylation, to confer a selective growth advantage to a precursor cell, which may subsequently proliferate in a clonal neoplastic fashion. Such genes that require homozygous inactivation of both copies are termed tumor suppressor genes (TSGs), anti-oncogenes, or recessive oncogenes. Examples of TSGs include retinoblastoma (Rb) and p53. In the affected tumors, allelic loss of the gene in question is invariably noted.

After a decade of search, the MEN1 gene was identified by positional cloning with germ-line mutations characterized in kindreds with familial MEN1. The gene product was coined menin to describe the 610-amino-acid protein product. Targeted gene inactivation of menin results in prolactinomas characterized by somatic loss of the wild-type allele with remarkable similarity to humans with MEN1. As predicted, mutations in sporadic pituitary tumors have been described. One copy of the MEN1 gene was found to be deleted in 10% of sporadic tumors examined. Missense mutations have been described throughout the gene of the remaining allele. Thus, as predicted by Knudson's two-hit TSG hypothesis, mutational inactivation of one copy of MEN1 coupled with deletion of the second allele strongly indicates that this gene is involved in the pathogenesis of hereditary (familial) pituitary tumors and in a subset of sporadic pituitary tumors. Up to 20% of sporadic pituitary tumors exhibit LOH at the 11q13 locus even in the absence of menin mutations, suggesting additional TSG at this locus. The characterization of normal menin function will likely prove to be of evolving significance in pituitary tumorigenesis. Thus far, menin has been shown to modulate a number of growth-regulatory pathways including that of the inhibitory transforming growth factor-β (TGF-β) as a result of interaction with the Smad3 transcription factor.

The Rb gene

The Rb gene is another member of the family of TSGs that has been implicated in several neoplasms including Rb and osteosarcoma. Mice heterozygous for an Rb mutation develop pituitary tumors of intermediate lobe corticotroph differentiation. In contrast, proteoglycan NG2-mediated Rb inactivation leads to anterior pituitary tumors highlighting the cell-type selective actions of this TSG (Tateno *et al.*, 2016). Nevertheless, no such mutations have been identified in human pituitary adenohypophysial tumors. Instead, there is LOH at sites telomeric and centromeric to the Rb locus in some aggressive pituitary neoplasms. These data argue for an independent TSG on 13q, which is closely linked with but distinct from Rb. In addition, methylation of the Rb promoter region has been described in association with diminished detectable Rb protein expression.

Cyclins, cyclin-dependent kinases, and cyclin-dependent kinase inhibitors

A series of cyclins and cyclin-dependent kinases (cdks) plays a central role in the regulation of cell cycle progression. The cyclin D (cdk4) and E (cdk2) complexes are catalytically active during the late G_1 phase and are implicated in the regulation of G_1/S progression. The Rb protein is one of the putative substrates of the cdks. Rb phosphorylation abrogates the ability of these proteins to inhibit transactivation of transcription factors important in cell cycle control. In turn, cdk activity is modulated by cdk inhibitors. These include $p27^{kip1}$, $p57^{kip2}$, $p16^{ink4A}$, $p15^{ink4B}$, $p18^{ink4c}$, and $p19^{ink4D}$.

Prompted by the potentially pivotal role of the Rb protein in regulating pituitary cells (Tateno *et al.*, 2016) and the negative findings involving the *Rb* gene itself, factors governing Rb phosphorylation became obvious candidates. Specifically, cdk inhibitors have received extensive attention. As with Rb itself, p16 has not been found to be mutated in pituitary tumors, but is frequently

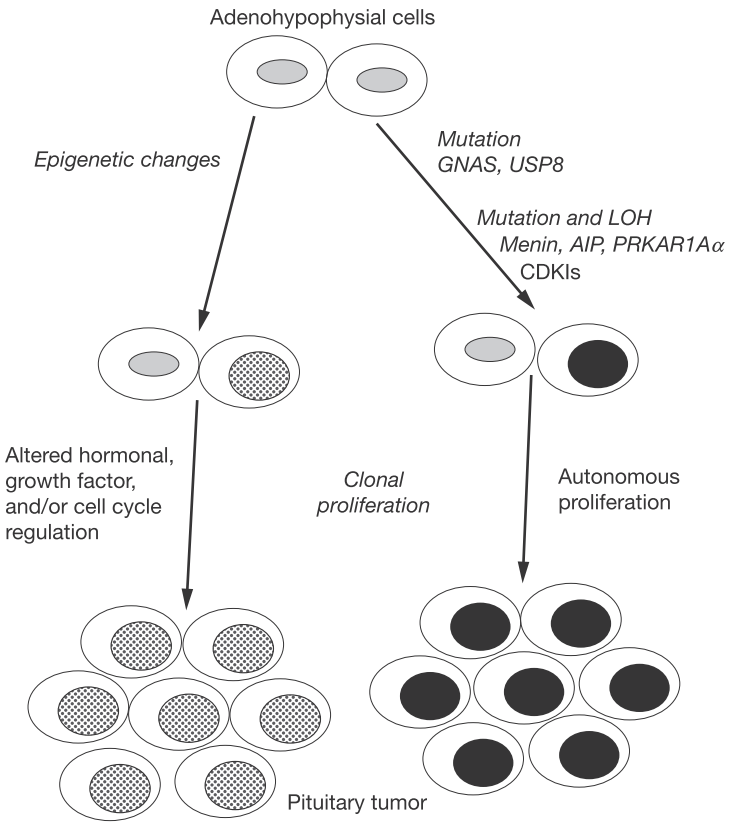

Fig. 2 Proposed model of pathogenesis of pituitary tumorigenesis. While some tumors undergo the classical mutation of oncogenes or mutation and loss of heterozygosity leading to clonal proliferation (right), the majority of pituitary tumors have no known mutations. Instead, epigenetic changes are implicated in cell transformation and subsequent clonal proliferation (left).

silenced by means of extensive methylation in human pituitary neoplasms. These findings suggest an alternative mechanism in modulating Rb-related protein control of the pituitary tumor cell cycle.

Mice lacking $p27^{kip1}$ have an increased propensity for the development of multiorgan neoplasia including pituitary tumors. Mutations in the CDKNIB/p27Kip1 gene were found in a kindred with Cushing disease and hyperparathyroidism and mutations in the CDKN2C/p18INK4c gene have been associated with an MEN-1-like syndrome classified as MEN-X or MEN-4. As with the *Rb* gene, however, intragenic mutations of these genes do not appear to play a role in sporadic human pituitary tumorigenesis. There is a single report of a pituitary tumor with reduced p27 translation due to a mutation of *DKC1* that encodes dyskerin, a pseudouridine synthase implicated in translation of p27 (Bellodi *et al.*, 2010).

p53

This nuclear protein is critical in the control of G_1/S phase progression by regulating the gene expression of p21, the first of the group of cdk inhibitors to be identified. Following DNA damage, p53 can induce growth arrest during the G_1 or G_2 phase of the cell cycle or by stimulating apoptosis, thereby protecting the normal cell from replicating damaged DNA. Conversely, p53 mutations render the cell genome more vulnerable to mutations that represent the rate-limiting steps in tumor progression. Indeed, inactivating mutations of p53 have proven to be among the most commonly encountered gene alterations in human malignancies. However, studies have failed to identify p53 mutations in human pituitary tumors.

Epigenetic Events

The vast majority of sporadic pituitary adenohypophysial tumors lack mutations of candidate genes; however there is common pattern of altered expression levels. The various changes in signaling pathways of key hormonal and growth factors and the silencing of cell cycle regulators discussed earlier are likely attributable to epigenetic factors (Ezzat *et al.*, 2017a).

A number of mechanisms have been implicated in the epigenetic dysregulation that underlies pituitary tumors. DNA methylation has been identified as a mechanism of silencing several TSGs including Rb, p27, p16, and p18 (Yacqub-Usman *et al.*, 2012), and the mediators of this, the DNMT enzymes, are also altered in these tumors. Histone modifications are mediated by

changes in multiple chromatin remodelers, including Ikaros (Ezzat and Asa, 2008) and HMGA proteins (De Martino *et al.*, 2009). Alterations in miRNA expression are also becoming discovered as putative mechanism of epigenetic dysregulation (Li *et al.*, 2014).

In contrast to mutational events, epigenetic alterations are potentially reversible, offering novel therapeutic approaches for the management of pituitary tumors.

Conclusions

Accumulating evidence suggests that the control of pituitary cell multiplication rests on a precarious balance between growth factor stimulation and inhibition with dominant contributions from the FGF/FGFR and TGF-β systems. Mutations in oncogenes and TSGs have been identified as causative of neoplastic transformation in several familial syndromes and in a small subset of sporadic tumors, but the events leading to pituitary tumorigenesis in the vast majority of tumors remain to be validated. Epigenetic changes that alter cell cycle regulators and the signaling pathways induced by hormones and growth factors are frequent but their cause is unknown (**Fig. 2**). Differences between pituitary and other endocrine and nonendocrine neoplasms will likely emerge to explain the remarkably varied spectrum of biologic behavior in terms of invasiveness and metastatic potential, which is unique to human pituitary adenohypophysial neoplasms.

Classification of Pituitary Neuroendocrine Tumors (PitNets)

Jacqueline Trouillas, Groupement Hospitalier Est, Bron, France and Claude Bernard University, Lyon, France
Alexandre Vasiljevic, Emmanuel Jouanneau, and Gérald Raverot, Groupement Hospitalier Est, Bron, France

Introduction

Since the first description of acromegaly by Pierre Marie (1902) and Cushing's disease by Cushing (1932), these endocrine pituitary diseases are now considered oncologic pathologies. Recently, use of the term pituitary neuroendocrine tumors (PitNETs) rather than pituitary adenomas has been proposed (Asa *et al.*, 2017). These pituitary tumors, arising from the adenohypophyseal cells, are common intracranial neoplasms, affecting 1/1000 of the population (Daly, *et al.*, 2006; Fernandez *et al.*, 2010).

Over the years, the increase in technology and knowledge has meant pathological classification has evolved from a tinctorial classification (three types: acidophilic, basophilic, and chromophobic) to a morphofunctional classification (five main types: somatotroph, lactotroph, corticotroph, gonadotroph, and thyrotroph). The great majority of these tumors are benign. However, 30–45% of them invade the cavernous or the sphenoid sinus, and a substantial proportion (10%) are considered aggressive, based on recurrence during follow-up. The absence of histological signs of malignancy means that only the tumors that develop metastasis during follow-up (0.2%) are considered to be malignant and termed carcinomas. Recent evidence suggests that the benign status of the pituitary tumors must be reconsidered. A prognostic clinicopathological five-tiered classification has been proposed, as well as the term "atypical adenoma" to describe tumors suspected of malignancy. These classifications, and several pathological, molecular, and genetic markers associated with tumor behavior, are presented in this chapter.

Nomenclature and Definitions

From Adenoma to PitNET

The current classifications do not accurately reflect the clinical spectrum of pituitary tumor behavior, because the simplistic distinction between adenoma and carcinoma is based solely on metastatic spread. Recently, members of the International Pituitary Pathology Club present at the 14th meeting in Annecy (France) in November 2016 proposed new terminology: the pituitary neuroendocrine tumor (Asa *et al.*, 2017). This revision of nomenclature is not intended to negate the well-established morphofunctional classification that encompasses five main subtypes (somatotroph, lactotroph, corticotroph, gonadotroph, and thyrotroph). Instead, it is intended to modify the term from "adenoma" to "tumor". The new nomenclature is consistent with that used for other neuroendocrine neoplasms and should favor the establishment of tumor registries to capture data on these tumors. Indeed, PitNETs are not simply endocrine diseases, but should be considered tumors with endocrine manifestations within the context of oncology. This is not only a semantic interest. In most jurisdictions, these tumors are not currently reported in cancer registries. Patients and healthcare providers have long expressed frustration that these lesions are considered rare, benign, and inconsequential, and they are often denied access to health insurance.

We will use this new terminology in this chapter.

Pituitary Tumors

According to the WHO 2017 classification (Osamura *et al.* 2017), "a pituitary tumor is a neoplastic proliferation of the anterior pituitary hormone-producing cells. The tumors are typically benign, but can be aggressive and invasive into adjacent structures" (ICD-O-Code 8272/0).

Ectopic Tumors and Invasive Tumors

Most pituitary tumors are found in the sella turcica, but may sometimes occur in the sphenoid sinus, separated from the normal pituitary. These tumors are named "ectopic" pituitary tumors (Thompson *et al.*, 2012) and are sometimes difficult to differentiate from the invasive tumors that originate from the pituitary.

A total of 30–45% of tumors invade adjacent structures, particularly the sphenoid and the cavernous sinuses (Meij *et al.*, 2002; Zada *et al.*, 2011). From anatomical studies (Francois *et al.*, 2010), suprasellar extension is differentiated from "true" invasion into the cavernous or the sphenoid sinus. Based on endoscopic verification, only grade 3b and 4 tumors as defined by the Knosp's classification are now considered to be invasive into the cavernous sinus (Micko *et al.*, 2015).

 doi:10.1016/B978-0-12-801238-3.64275-7

Aggressive Tumors and Carcinoma

The definition of aggressiveness is clinically defined, based on the clinical characteristics of the tumor during the follow-up period (review by Raverot *et al.* 2012). Aggressive Pit-NETs are typically large with radiological signs of invasion and, despite optimal standard therapies (surgery, radiation therapy, and conventional medical treatments), exhibit an unusually rapid growth rate, and/or clinically relevant tumor growth or recurrence. The frequency of aggressive tumors is not well established; recent studies suggest it is around 10% (Raverot *et al.*, 2017). Although aggressive PitNETs are usually large and invasive, invasion alone does not automatically indicate aggressiveness, and in fact recurrence does not occur in all invasive PitNETs (Chatzellis *et al.*, 2015). Moreover, some giant lactotroph tumors, which regress under dopamine agonist treatment, are not considered to be aggressive tumors.

According to the WHO 2017 classification (Osamura *et al.*, 2017), "Pituitary carcinoma is strictly defined as a tumor of adenohypophyseal cells that metastasizes craniospinally or is associated with systemic metastasis" (ICD-O code 8272/33). This subtype is detailed in a specific chapter. We will discuss this definition in a following section on the prognostic classifications.

Functioning, Nonfunctioning, and "Silent" Tumors

Pituitary endocrine tumors are clinically classified as functioning tumors, when the tumor induces symptoms caused by hormonal hypersecretion (acromegaly with elevated plasma growth hormone (GH) levels, amenorrhea-galactorrhea or hypogonadism with hyperprolactinemia, or Cushing's disease with hypercortisolism), or nonfunctioning tumors, where there are no signs of hypersecretion; these are mainly gonadotroph tumors. These nonfunctioning tumors should be differentiated from silent tumors, where the patient shows no clinical sign or hormonal elevation in the plasma, but immunohistochemistry (IHC) detects tumor hormone production. Somatotroph and corticotroph silent tumors are the most common and may be aggressive.

Classifications of PitNETs

Morphofunctional Classifications

Previous classifications

Until the 1980s, based on their tinctorial properties with hematoxylin eosin/phloxine saffron and their correlation with clinical disease, pituitary tumors were classified as eosinophilic or acidophilic tumors with acromegaly, basophilic tumors with Cushing's disease, or chromophobic tumors without signs of hypersecretion. Later, the development of electron microscopy (EM) and IHC resulted in tumor classification based on the appearance of their organelles (such as granulations, mitochondria) and their hormonal secretion (Asa and Kovacs, 1983; Trouillas *et al.*, 1974; Trouillas and Girod, 1996). Taking into account the clinical signs, and the ultrastructural and IHC data, subtypes were described: lactotroph (prolactin (PRL) adenoma or prolactinoma (review by Nosé *et al.*, 2017), somatotroph (GH) adenoma with both the sparsely and densely ultrastructural subtypes (review by Mete *et al.*, 2017), gonadotroph (FSH/LH) adenoma, with hypersecretion (review by Snyder, 1985) or with normal plasma values (Trouillas *et al.*, 1981; Trouillas *et al.*, 1986), null cell adenoma (Kovacs *et al.*, 1980; Yamada *et al.*, 2017), also termed immunonegative adenoma (Trouillas and Girod, 1996), and thyrotroph (TSH) adenoma (review by Beck-Peccoz *et al.*, 1996; Bertholon-Grégoire *et al.*, 1999).

The pathological characteristics of these types are not described here. Illustrated descriptions can be found in the chapters of the WHO 2017 classification (Lloyd *et al.*, 2017), and a detailed history of these different classifications are available in a recent review (Trouillas 2015).

The WHO 2004 and 2017 classifications

The WHO 2004 (Lloyd *et al.*, 2004) and 2017 (Osamura *et al.*, 2017) classifications remain morphofunctional, and keep the term "adenoma". The pituitary "adenomas" are classified into five main types using immunocytochemistry: GH-, PRL-, FSH/LH-, ACTH-, and TSH-producing adenomas in the WHO 2004 classification, and somatotroph, lactotroph, corticotroph, gonadotroph, and thyrotroph adenomas in the WHO 2017 classification. Many of the 12 ultrastructural subtypes in the WHO 2004 classification are abandoned in the WHO 2017 classification, because the EM technique is expensive, time-consuming, and not in routine use. Recognizing the role of transcription factors in the differentiation of the anterior pituitary cells and regulation of specific pituitary hormones (Pit-1, SF-1, Tpit), the 2017 classification concentrates on pituitary-cell lineage for designation of adenomas. For example, the term somatotroph adenoma defines this as a group of tumors that secrete GH and are derived from a Pit-1 lineage, rather than being a GH-producing adenoma.

The differentiation of normal pituitary cells during embryonic development depends on transcription factors. Pit-1 is the transcription factor responsible for somatotroph differentiation, Pit-1 and the estrogen receptor alpha are associated with lactotroph differentiation, and Pit-1 and GATA-2 control thyrotroph differentiation. Corticotroph differentiation depends on Tpit and NeuroD1, and gonadotroph differentiation depends on SF-1 and GATA-2 (Asa *et al.*, 1996; Sanno *et al.*, 1998; Nishioka *et al.*, 2015; Umeoka *et al.*, 2002). IHC detection of these transcription factors remains difficult because of technical problems related to antibody specificity. In our opinion, IHC detection increases the costs of pathological analysis without giving any more useful

Table 1 Morphofunctional classification of PitNETs (adapted from the WHO 2017 classification)

Tumor types	*Cytological aspects*	*Immunophenotypes*	*Transcription factors and receptors*
Somatotroph	Densely granulated[a]	GH ± PRL ± α-subunit LMW CK: perinuclear or diffuse pattern	Pit-1, SSTR
	Sparsely granulated	GH ± PRL LMW CK: fibrous bodies	Pit-1, ±SSTR
	Mammosomatotroph	GH + PRL (in same cell) ± α-subunit	Pit-1, ERα, ±SSTR
	Mixed somatotroph-lactotroph	GH + PRL (in different cells) ± α-subunit	Pit-1, ERα, ±SSTR
Lactotroph	Sparsely granulated[a]	PRL	Pit-1, ERα
	Densely granulated	PRL	Pit-1, ERα
Thyrotroph	Sparsely granulated	βTSH, α-subunit	Pit-1, GATA2, SSTR
Corticotroph	Densely granulated[a]	ACTH, βend LMW CK: diffuse pattern	Tpit, ±SSTR
	Sparsely granulated	ACTH, βend LMW CK: diffuse pattern	Tpit
	Crooke's cell	ACTH, βend LMW CK: ring-like pattern	Tpit
Gonadotroph	Sparsely granulated	βFSH, βLH, α-subunit (various combinations)	SF-1, GATA2, ERα, SSTR (variable)
Immunonegative[b]	Sparsely granulated	None	None
Plurihormonal[c]		GH, PRL, βTSH ± α-subunit	Pit-1
Double tumors	Distinct tumors	Usually PRL and ACTH	Pit-1 and Tpit,

[a]Most common subtype.
[b]Also termed null cell adenoma.
[c]Previously termed silent subtype 3 adenoma.
LMW CK, low-molecular weight cytokeratin; *PitNETs*, pituitary neuroendocrine tumors.

information on the functional type. However, it is useful in the case of immunonegative or plurihormonal tumors, such as plurihormonal Pit-1-positive tumors.

We adapted the WHO 2017 classification in **Table 1**, using the term tumor instead of adenoma, and immunonegative tumor instead of null cell adenoma. This tumor type is now found very rarely (down from 10% in 1992 to 1% in 2012 in Lyon's pathological series). Many studies find a high percentage of these tumors, at around 30%. However, these tumors correspond to gonadotroph tumors with a low intracellular hormonal content that is undetected by some antibodies, but that can be identified in culture or with more sensitive IHC techniques. We have not mentioned oncocytoma (Kovacs and Horvath, 1973; Trouillas *et al.*, 1975); it is not an entity, but ultrastructural aspect of gonadotroph tumor with numerous mitochondria. This is also the case for acidophilic stem cell adenoma (Horvath *et al.*, 1981), which are likely to be lactotroph tumor with giant and dilated mitochondria.

Prognostic Classifications

Typical and atypical adenomas

In the decade after the millennium, it appeared that some tumors without metastasis behaved differently from benign tumors. MRI indicated that some of these tumors invaded the skull base or both cavernous sinuses; however, pathologists could not histologically detect the invasion and metastasis to ascertain the malignancy.

The WHO 2004 classification (Lloyd *et al.*, 2004) classified all benign tumors as typical adenomas (ICD-0 8272/0) and identified "atypical" adenomas showing "borderline or uncertain behavior" (ICD-0 8272/1). Such tumors were described to have "atypical morphologic features suggestive of aggressive behavior such as invasive growth. Other features include an elevated mitotic index and a Ki-67 labeling index greater than 3%, as well as extensive nuclear staining for p53 immunoreactivity". Likely due to these vaguely defined criteria, the reported incidence of atypical adenoma varies widely ranging from 2.9% (Miermeister *et al.*, 2015) to 18.7% (Chiloiro *et al.*, 2015). In addition, the few small studies that examined the prognostic usefulness of this classification delivered controversial results (Zada *et al.*, 2011; Saeger *et al.*, 2007; Yildirim *et al.*, 2013; Del Basso De Caro *et al.*, 2017).

As stated in the WHO 2017 edition (Osamura *et al.*, 2017), "the use of the term atypical adenoma is therefore no longer recommended". Moreover, some special subtypes that commonly show aggressive behavior must also be taken into account. These include sparsely granulated somatotroph tumor, lactotroph tumor in men (Delgrange *et al.*, 1997; Delgrange *et al.*, 2015), Crooke's cell tumor (Kovács *et al.*, 2013), silent corticotroph tumor (review in Raverot *et al.*, 2010a), and silent plurihormonal Pit-1-positive tumor (Chinezu *et al.*, 2017; Mete *et al.*, 2016).

A clinicopathological five-tiered classification

In 2013, we proposed a new clinicopathological, five-tiered classification of PitNETs (Trouillas *et al.*, 2013), that considers invasion assessed by pituitary imaging, the immunohistological subtype, and proliferative markers (Ki-67, mitosis, p53), as shown in **Fig. 1** (review in Raverot *et al.* 2014; Raverot *et al.* 2015; Vasiljevic *et al.* 2016). The tumors were classified according to size (micro, macro, and giant tumors), type (somatotroph, lactotroph, corticotroph, gonadotroph, and thyrotroph), and grade (grade 1a: non-

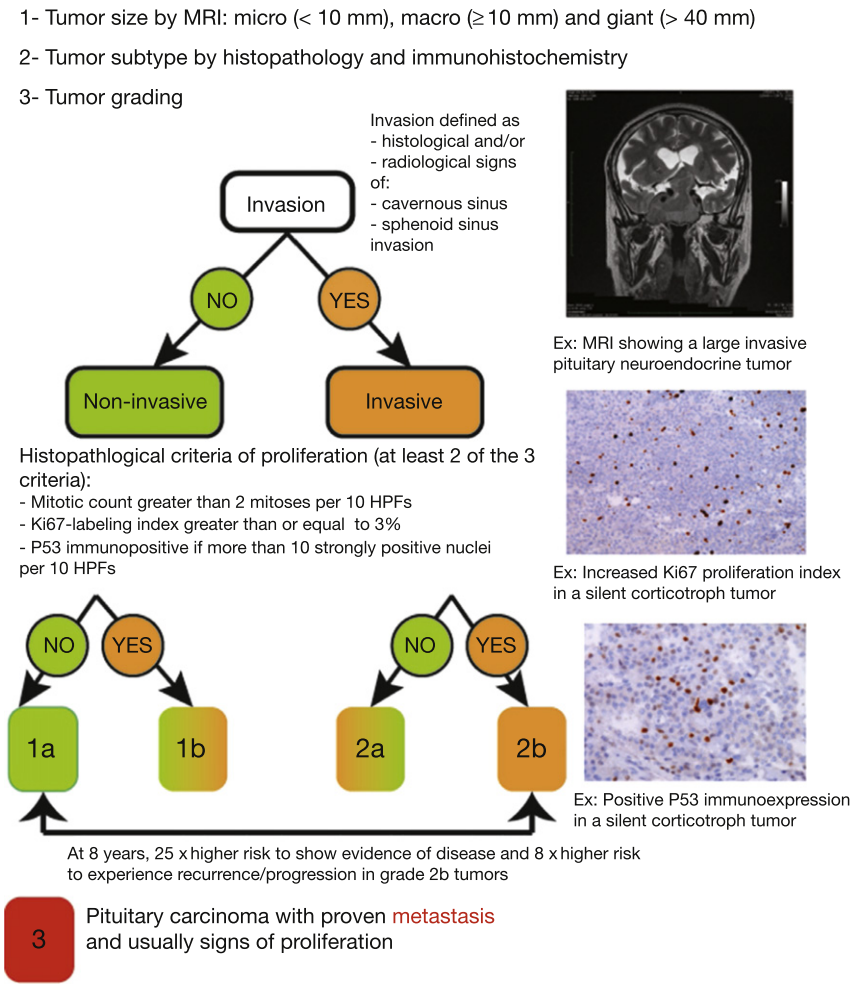

Fig 1 Clinocopathological five-tiered classification of Pit Nets. Adapted from Vasiljevic A., Jouanneau E., Trouillas J., Raverot G. (2016). Clinicopathological prognostic and theranostic markers in pituitary tumors. *Minerva Endocrinologica* **41**, 377–389.

invasive tumor; 1b: non-invasive and proliferative; 2a: invasive; 2b: invasive and proliferative; 3: metastatic tumor). A retrospective case-control study of 410 patients at 8 years after surgery (Trouillas *et al.*, 2013) and a prospective study of 365 patients at 3.5 years after surgery (Raverot *et al.*, 2017) validated the prognostic value of this classification. These two studies showed that grade 1a tumors were the most common (51.2%), followed by grade 2a (32.3%), 2b (8.8%), and 1b (7.7%). The frequency of invasive tumors (grades 2a and 2b: 41%) is similar to other large surgical series. At 3.5 or 8 years after surgery, 30–40% of tumors had recurred or progressed. Multivariate analyses of disease-free status and recurrence/progression status revealed the significant prognostic value ($p < 0.001$) of age, tumor type, and grade across all tumors and for each tumor type. The risk of recurrence was respectively 12- and 3.5-fold higher for a grade 2b tumor (invasive and proliferative) compared to grade 1a (non-invasive and non-proliferative) tumor. The lower risk found in the prospective study is related to the shorter duration of follow-up and the exclusion of patients treated by initial postoperative radiotherapy and second surgery for recurrence. Indeed, many patients had grade 2b tumors. In these two studies, thyrotroph tumors and silent GH and ACTH tumors were not classified separately because the number of cases was too small. There were no cases of grade 3 tumors or carcinoma in these two cohorts.

Discussion of the criteria

Invasion

Some pathologists did not agree with including invasion in a pathological classification of pituitary tumors because, as previously stated, histological proof of invasion is very rare (9%), requiring the pathologist to consider MRI data. While it is true that the pathologist cannot directly interpret the MRI, the diagnosis of the neuroradiologist and the preoperative data should be considered (Vasiljevic *et al.*, 2016). This requires the data to be available before the pathologist's diagnosis; this is in fact the case in the majority of the expert centers where patients typically receive surgery. As for all malignant tumors, invasion is an important criterion. In our most recent study (Raverot *et al.* 2017), differences in the Kaplan-Meier progression-free survival curves obtained

for different grades for invasion and for the immunocytochemical profile for the grade were mainly due to the effect of invasion; the effect of proliferation was lower than the effect of invasion.

Proliferative markers

The Ki-67 index, a proliferative marker, has been used in pituitary tumor analysis since 1996 (Thapar *et al.*, 1996). It is now routinely evaluated, but its value in determining PitNET prognosis remains controversial. This could be because various cut-offs for the Ki-67 index, ranging from 1.3% (Gejman *et al.*, 2008) to 10% (Kovacs, 2006) have been applied to identify tumors with a high risk of recurrence and have sometimes been adapted to tumor subtype (Righi *et al.*, 2012). Furthermore, most studies were based on a limited number of cases, an expert opinion, or a retrospective analysis. The Ki-67 index alone is regarded as insufficient to predict tumor behavior. The prognostic value of immunopositivity for p53, a criterion of the WHO classification, has also been debated, as a reliable method of quantification had not been established (Di Ieva *et al.*, 2014). Recent studies, however, defined p53 staining as positive if >10 nuclei per 10 high-power fields were strongly labeled (Miermeister *et al.*, 2015, Trouillas *et al.*, 2013, Gejman *et al.*, 2008). A prospective study (Raverot *et al.*, 2017) validated the choice of criteria. Indeed, 80% of proliferative tumors (grade 1b and 2b) displayed two proliferative markers and 20% had three proliferative markers. The Ki-67 index above 3% has major prognostic value. First, a Ki-67 value $\geq$3% was found in the majority of proliferative grade 1b and 2b tumors and only rarely (10%) in non-proliferative grade 1a and 2a tumors. Second, p53 positivity was much more common in tumors with Ki-67 $\geq$ 3% (83.3%) than in those with a Ki-67 index below 3% (11.7%). For grade 1a and 2a tumors, the great majority did not present any proliferative markers. In 21.6% of tumors, only one marker was present (Ki-67 $\geq$ 3%: 9.5%; mitotic count >2: 3.0%; p53: 9.2%).

This classification is easy to use, but some parameters, such as cellular differentiation, silent subtype, and sex of the patient for lactotroph tumor, are not considered. A scoring system such as that used for other neuroendocrine tumors, especially pancreatic tumors (Rindi *et al.*, 2006), could be proposed. However, early identification of those pituitary tumors with a high risk of recurrence associated with a malignant potential is now possible. In such cases (grade 2b), an optimized therapeutic strategy should be proposed, taking into account new therapeutic options in addition to conventional therapies associating including surgery and radiotherapy (Zemmoura *et al.* 2013).

Grade 3 tumors or pituitary carcinomas

Pituitary tumors with metastases, otherwise known as pituitary carcinomas, are rare and account for about 0.2% of pituitary tumors (reviews by Kaltsas *et al.*, 2005 and Heaney, 2011). In 40 years, we have only observed eight carcinomas with metastasis out of around 4000 pituitary tumors studied (0.2%), and 132 cases were reported in the literature between 1961 and 2009 (Dudziak *et al.* 2011). Most pituitary carcinomas are functioning and in the majority of cases secrete PRL (36% of cases) or ACTH (30% of cases). Nonfunctioning carcinomas are less common (23% of cases). Histological signs of malignancy were once thought to be absent, but the frequency of certain signs reported in previous pathological studies of pituitary carcinomas (Pernicone *et al.*, 1997; Scheithauer *et al.*, 2005) means we can make reasonable assumptions with regards to potential malignancy. These assumptions would be based on the following pathological signs which, when combined, might be considered criteria of malignancy: invasion, neoangiogenesis, vascular invasion, abnormal mitoses, very high indices for Ki-67 (i.e. >10%) and p53 (i.e. >5%), and genomic alteration (chromosome 11 deletion in lactotroph tumors). However, these cut-off values have not been validated, and this, together with the absence of some of the above signs in particular metastatic pituitary carcinomas, is a concern (Lubke and Saeger, 1995; Scheithauer *et al.*, 2005). Based on analyses comparing human lactotroph tumors to our animal model (Trouillas *et al.*, 1994), and on the observations that in our cohort (Trouillas *et al.*, 2013) none of the eight carcinomas were grade 1a at the time of the first surgery, and six of them were grade 2b, we suggested that grade 1a tumors are benign and do not transform into carcinoma, and grade 2b tumors are malignant tumors without metastases (Wierinckx *et al.*, 2007; Wierinckx *et al.*, 2010; Wierinckx *et al.*, 2011).

Molecular and Genetic Biomarkers

Biological Markers Detected by IHC

Expression of several biological markers, analyzed using IHC, correlates with invasiveness and/or aggressive behavior, but no single marker has been found that can predict tumor behavior, and until now their detection remains in the research setting. As three recent and exhaustive reviews expand this subject (Gurlek *et al.*, 2007; Mete *et al.*, 2012, Raverot *et al.*, 2014), we focus here on biomarkers that seem to correlate with invasive and aggressive behavior.

Fibroblast growth factors (FGFs) and their receptors (FGFRs) regulate growth, differentiation, migration, and angiogenesis. The expression of a truncated isoform of FGFR4, known as pituitary tumor-derived FGFR4 (ptd-FGFR4) induces invasive growth of pituitary tumor cells in vivo with loss of membranous N-cadherin expression (Ezzat *et al.*, 2004). Moreover, ptd-FGFR4 cross-talks with a PolySiAlilated form of Neuro Cell Adhesion Molecule (PSA-NCAM), which correlates with invasiveness (Trouillas *et al.*, 2003). Loss of E-cadherin correlates with larger size, invasiveness, and progression of pituitary tumors (Fougner *et al.*, 2010; Evang *et al.*, 2011). Expression of endocan, a proteoglycan secreted by endothelial cells, is associated with size and progression of pituitary tumors (Cornelius *et al.*, 2012). Matrix metalloproteinases (MMPs) are a family of proteolytic enzymes that cleave extracellular matrix molecules and play a role in the invasiveness of many neoplasms. MMP9 expression is significantly higher in invasive pituitary

tumors (Kawamoto *et al.*, 1996) and there may be a correlation with protein kinase C activation, which is involved in pituitary tumor invasion. The pituitary tumor transforming gene (PTTG) is part of the securin family that regulates sister chromatid separation during mitosis, and its expression is higher in invasive pituitary tumors than their non-invasive counterparts (Zhang *et al.*, 1999). In the lactotroph subtype, low ERα expression characterized dopamine agonist-resistant tumors. The expression of ERα is lower in men than in women and is inversely correlated with tumor size and grade (Delgrange *et al.*, 2015).

Gene Expression by Transcriptomic Analyses

Initial transcriptomic studies compared normal pituitary with pituitary tumors as a whole or according to tumor subtype. A meta-analysis on these published results (Wierinckx *et al.*, 2010) identified only six genes (GADD45B, SAT1, ID1, VIM, IGFBP5, and ZFP36L1) with proven roles in cell proliferation or tumorigenesis. The functional involvement in the pituitary tumor has been determined for only two genes: GADD45γ, and a novel noncoding RNA gene, termed the maternally expressed gene 3 (MEG3) identified by Zhang *et al.* (Zhang *et al.*, 2002; Zhang *et al.*, 2003). Indeed, downregulation of these two genes occurs more frequently in non-functioning adenomas than in functioning tumors, and MEG3, as a tumor suppressor gene, interacts with both p53 and Rb to control cell proliferation (Zhou *et al.*, 2007). However, none gene has been associated with prognosis (Farrell, 2006).

Only a small number of studies analyzed the differential gene expression according to tumor characteristics. Galland *et al.* (Galland *et al.*, 2010) identified a stronger overexpression of MYO5A in invasive than in non-invasive nonfunctioning tumors. In lactotroph tumors, a set of nine genes (PTTG, ASK, CCNB1, AURKB, CENPE, PITX1, ADAMTS6, CRMP1, and DCAMKL3) was associated with pathological tumor classification (Wierinckx *et al.*, 2007) and seven (ADAMTS6, CRMP1, PTTG, ASK, CCNB1, AURKB, and CENPE) correlated with a higher risk of recurrence or progression during a long-term follow-up of over 10 years (Raverot *et al.*, 2010b).

MicroRNAs (miRNAs) are a class of small noncoding RNAs deregulated in many types of cancer. They act as tumor suppressors or oncogenes depending on the function of the targeted genes, and appear to be involved in the regulation of many steps of pituitary tumor progression (review by Wierinckx *et al.*, 2017). At this time, transcriptomic analysis is a very difficult and expensive technique that remains in the research setting, and cannot be carried out extensively in pituitary tumors. However, the technique could help to find new markers.

Chromosomal Alteration and Genetic Mutations

In contrast, genetic analysis seems very promising. Use of whole genome sequencing or comparative genomic hybridization methods has identified a high frequency of chromosomal alterations in somatotroph tumors (Välimäki *et al.*, 2015). In tumors exhibiting aggressive behavior, an allelic deletion is clustered at four loci: 11q13 (multiple endocrine neoplasm type 1 (MEN1) and aryl-hydrocarbon receptor-interacting protein (AIP) gene), 13q12–14, 10q26, and 1p (Bates *et al.*, 1997). T53 mutations have occasionally been reported in pituitary tumors (Levy *et al.*, 1994). Trisomy of chromosome 12 has been also found in lactotroph tumors (Finelli *et al.*, 2000). Wierinckx *et al.* showed that a deletion of the 11p region occurred more commonly in lactotroph aggressive tumors than in non-aggressive ones, and the three aggressive tumors that developed metastasis during follow-up showed a loss of the whole chromosome 11 and a gain of the 1q arm (Wierinckx *et al.*, 2011). It therefore appears that the accumulation of genomic alterations may transform an aggressive pituitary tumor into a pituitary carcinoma.

Pituitary tumors are mostly sporadic. However, somatic activating mutations of G-protein alpha sub-unit (GNAS) have been identified in 40% of sporadic somatotroph tumors, resulting in upregulation of the cAMP pathway (Landis *et al.*, 1989), and in the *USP8* gene in 36–62% of corticotroph tumors, leading to an upregulated EGFR pathway (Perez-Rivas *et al.*, 2015; Reincke *et al.*, 2015). Moreover, some familial cases have been identified, leading to the characterization of a genetic form of pituitary tumors. Germline AIP gene mutations are observed in 20% of familial isolated pituitary adenoma (FIPA), and various other mutations in genes encoding MEN1, MEN4, and Carney complex and in those linked to syndromic diseases such as succinyl dehydrogenase (SDH) in paraganglioma, and phaeochromocytoma. Genetic testing for MEN1 or AIP mutations is recommended where there is a familial history of pituitary tumors (Beckers *et al.*, 2013; Verges *et al.*, 2002; Vierimaa *et al.*, 2006), or in cases of large macro-adenomas in young patients (Cazabat *et al.*, 2007) or of unusual plurihormonality and double adenomas (Trouillas *et al.*, 2008).

Theranostic Factors

Theranostics is defined as a diagnostic process to stratify patients who will respond to a specific treatment. Predicting sensitivity to a specific treatment is important for the choice of postoperative therapeutic strategy. However, this analysis is highly dependent on the definition of the therapeutic response and on the techniques and methods used to analyze them. Somatostatin receptors, especially subtypes 2 and 5, are expressed in almost all the somatotroph tumors, all thyrotroph tumors, and around 20% of gonadotroph tumors (Chinezu *et al.*, 2014). In somatotroph tumors, the effects of somatostatin analogs seem positively correlated with somatostatin receptor expression (Casar-Borota *et al.*, 2013; Gatto *et al.*, 2013).

O^6-methylguanine DNA methyltransferase (MGMT), a DNA repair enzyme that counteracts the effects of temozolomide by removing alkylating adducts from DNA, is the most frequently studied to attempt to predict the tumor response to temozolomide treatment. Results of the studies are still debated (Bush *et al.*, 2010; Bengtsson *et al.*, 2015, McCormack *et al.*, 2011), but a high MGMT expression level is generally associated with a poor tumor response.

Perspective and Conclusions

Taken separately, clinical symptoms, biochemical hormone levels, radiological features, and histopathology have failed to effectively predict the behavior of pituitary tumors. It is a combination of all these data that allow the optimal management of patients affected by pituitary tumors. The development of a "mixed" classification (invasion assessed via MRI/endoscopy and histopathological characteristics) is a way to improve the prognostic assessment of aggressive pituitary tumors. It requires multidisciplinary collaboration between pathologist, endocrinologist, and neurosurgeon. The role of the pathologist may be more active in the clinicopathological assessment of patients with pituitary tumors than previously appreciated. By identifying potentially aggressive pituitary tumors, and by analyzing theranostic factors, the pathologist can directly guide the clinical choice of the optimal postoperative management of these patients.

Genetic Causes of Familial Pituitary Tumors

Maria Manuel Costa, Centro Hospitalar São João, Porto, Portugal and Queen Mary University of London, London, United Kingdom
Márta Korbonits, Queen Mary University of London, London, United Kingdom

Introduction

Pituitary adenomas (PA) are frequent benign monoclonal tumors representing approximately 15% of all primary intracranial tumors, being the third most frequent tumor type after meningioma and glioma (Scheithauer *et al.*, 2006). The majority of the lesions identified incidentally remain clinically silent; however, clinically relevant adenomas are found in approximately 1:1100 patients in the general population (Daly *et al.*, 2006; Fontana and Gaillard, 2009; Fernandez *et al.*, 2010; Raappana *et al.*, 2010; Gruppetta *et al.*, 2013; Agustsson *et al.*, 2015).

PA can be divided by size into microadenoma (<1 cm) and macroadenoma (>1 cm), the latter being responsible for 40% of the cases (Aflorei and Korbonits, 2014). They can also be classified as hormone secreting or clinically nonfunctioning adenomas (NFPA) according to whether or not they secrete hormones. Approximately 66.2% of PA are prolactinomas, 14.7% are NFPA, 13.2% are somatotropinomas, and 5.9% are corticotropinomas, with the other subtypes being rarer (Daly *et al.*, 2006).

Although only 0.2% of pituitary tumors are classified as malignant, defined by distant metastasis, they cause significant morbidity. PA are associated with hormonal disturbances and compression symptoms like headaches, visual disturbances, and hypopituitarism due to mass effect. Due to pituitary gland localization, they can put pressure on the optic chiasm and the pituitary stalk, as well as invading areas like the cavernous sinus and suprasellar area.

Most of PA appear to occur sporadically, but about 5% occur due to an inherited condition, either isolated or as a part of an endocrine tumor syndrome.

Several conditions are associated with a known genetic defect causing a predisposition to familial PA. Familial PA can be considered when at least two family members have a PA, but in cases of low penetrance seemingly simplex cases may have an inherited germline mutation, or "de novo" mutations can establish the potential for familial disease in further generations. The two most frequent forms are familial isolated pituitary adenomas (FIPA) and multiple endocrine neoplasia type 1 syndrome (MEN1), which are responsible for 2%–3% and 3%, respectively, of PA (Daly *et al.*, 2006). X-linked acrogigantism (XLAG) syndrome, Carney Complex (CNC), multiple endocrine neoplasia type 4 (MEN4), pheochromocytomas/paragangliomas and pituitary adenomas, and pituitary blastoma (PitB) are other rare causes of familial PA (**Fig.1**). McCune–Albright syndrome is

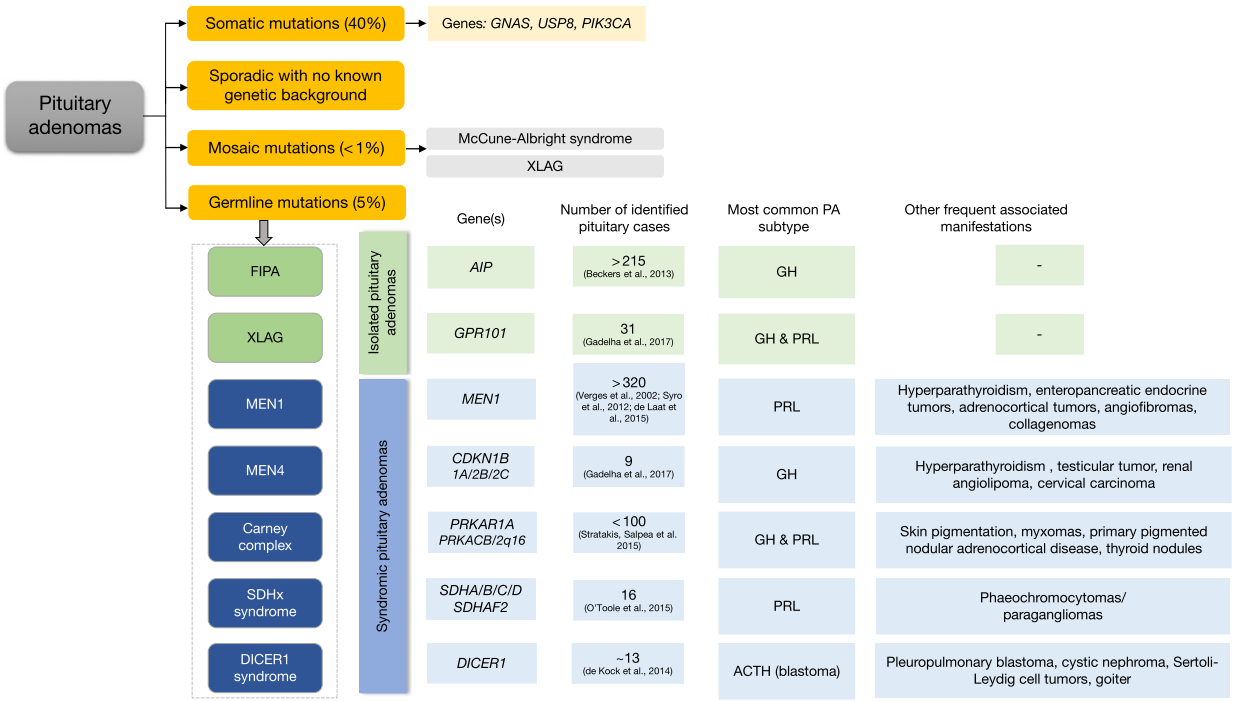

Fig. 1 Pituitary adenomas due to somatic, mosaic, and germline mutations. In the group of germline mutations, the estimated number of described cases of pituitary adenomas for each condition is presented.

caused by postzygotic activating mutations in the guanine nucleotide-activating alpha-subunit gene (*GNAS*), which could lead to PA, but no familial has been reported to date.

Familial Isolated Pituitary Adenomas

Overview

FIPA syndrome is defined as the occurrence of at least two cases of PA in a family that does not exhibit any other abnormality (Chahal *et al.*, 2010; Beckers *et al.*, 2013). However, there are many simplex cases with germline mutations, either due to low penetrance or due to "de novo" mutations, where the possibility of familial disease is present.

Based on data of over 400 families, FIPA appears to be more common than initially thought, but the exact prevalence is unknown (Beckers and Daly, 2007; Stiles and Korbonits, 2011). It is the most common familial cause of acromegaly/gigantism (Gadelha *et al.*, 2017).

FIPA can be divided into three subgroups of patients with significant phenotypic differences among them: patients with mutations in the *AIP* gene, patients with XLAG due to duplication of *GPR101*, and patients with a family history of PA with no known genetic cause, which represent the largest subgroup of FIPA (Caimari and Korbonits, 2016). Not all cases have a known family history, either due to low penetrance (*AIP* mutation-positive subgroup) or due to "de novo" mutation (XLAG subgroup) (Caimari and Korbonits, 2016).

The same type of PA can be present in all affected family members (homogeneous family, 60%) or affected members can have different types of tumors (heterogeneous family, 40%). These families show an autosomal dominant inheritance with incomplete penetrance (Daly *et al.*, 2006; Vierimaa *et al.*, 2006; Georgitsi *et al.*, 2008; Leontiou *et al.*, 2008; Daly and Beckers, 2015).

Germline *AIP* mutations are identified in 20% of patients with FIPA or 40% when only somatotropinoma families are considered (Chahal *et al.*, 2010; Daly *et al.*, 2010; Beckers *et al.*, 2013; Hernandez-Ramirez *et al.*, 2015).

The *AIP* gene is located at the 11q13 chromosome region and consists of 6 exons, encoding a 330 amino acid cytoplasmic cochaperone protein (Dull *et al.*, 2002). *AIP* is composed of an N-terminal domain similar to the immunophilin proteins, three tetratricopeptide repeats (TPR) of 34 amino acids comprising two antiparallel helices, and an α-helix in the C-terminal. These helices are essential for interaction with AIP partners (Trivellin and Korbonits, 2011).

AIP was identified in 1996, but heterozygous germline mutations were found in PA only in 2006, in a large Finnish family with acromegaly and prolactinoma.

AIP is widely expressed in the human body (Petrulis and Perdew, 2002). In the normal pituitary gland, *AIP* is expressed only in somatrotroph and lactotroph cells, associated with secretory vesicles (Leontiou *et al.*, 2008). In sporadic PA, *AIP* is expressed in all cell types. Higher *AIP* expression levels are observed in NFPA, and low expression was described in invasive somatotropinomas (Leontiou *et al.*, 2008; Jaffrain-Rea *et al.*, 2009).

More than 90 *AIP* mutations have been reported in the literature, with some of the variants with uncertain clinical significance (Korbonits *et al.*, 2012; Beckers *et al.*, 2013) (**Fig. 2**; **Tables 1–3**). Missense, nonsense, splice-site, promoter mutations, segmental duplication, small deletions and insertions, and large genomic deletions have been described (**Tables 1–2**). 10% of *AIP* mutations are large genomic deletions and can only be detected with specific techniques such as multiplex ligation-dependent probe amplification (MLPA) (Georgitsi *et al.*, 2008; Gadelha *et al.*, 2013). About two-thirds of *AIP* mutations occur at the C-terminal end, resulting in a truncated protein, while missense variants and in-frame segmental changes mostly affect the TPR domain or the C-terminal α-helix (Chahal *et al.*, 2010, Alband and Korbonits, 2014). There are hotspot mutations mostly affecting CpG sites such as codons 81, 271, 304 (Daly *et al.*, 2006; Tichomirowa *et al.*, 2009; Chahal *et al.*, 2010).

All known mutations are predicted to lead to loss of function of the protein (Gadelha *et al.*, 2013). The loss of function together with the loss of heterozygosity in pituitary tumors of FIPA patients supports its role as a tumor suppressor gene in the pituitary gland (Vierimaa *et al.*, 2006; Leontiou *et al.*, 2008; Heliovaara *et al.*, 2009; Igreja *et al.*, 2010). According to the Knudson two-hit hypothesis, the first hit is due to a germline mutation of an allele and the second hit is a somatic deletion of the other allele (Knudson, 1971).

Numerous proteins have been identified to interact with *AIP* directly, which suggests that *AIP* is involved in various cellular pathways (Gadelha *et al.*, 2013). *AIP* has numerous binding proteins, such as viral proteins (HBVX and EBNA-3) AhR, Hsp90, Hsc70, phosphodiesterases (PDE4A5 and PDE2A3), nuclear (AhR, PPARa, TRb1), and transmembrane (RET) receptors, G proteins, mitochondrial import receptor (TOMM20), survivin, cardiac-specific kinase (TNNI3K), ubiquitin ligase FBXO3, cytoskeletal proteins (actin), and growth factor receptor (EGFR) (Trivellin and Korbonits, 2011). However, the way in which *AIP* exerts its tumor-suppressive action in the pituitary is not fully clear. The most studied association is with AhR, which is a transcription factor whose best-known function is as a mediator in the toxic effects of the environmental toxin 2,3,7,8-tetrachloro-*p*-dioxin although it is unclear whether this is involved in pituitary tumorigenesis. AhR binds environmental toxins and translocates to the nucleus to induce the transcription of xenobiotic enzymes. AhR has many roles, including regulation of the activity of nuclear receptors, transcription factors, and protein kinases and modulation of the cell cycle, cell adhesion, and migration, as well as alteration of multiple intracellular signaling pathways (Denison *et al.*, 2011). *AIP* forms a complex with AhR/Hsp90/p23 and appears to act in part by stabilizing AhR in cytoplasm. Low levels or loss of AIP correlate with low expression of AhR (Lees *et al.*, 2003; Jaffrain-Rea *et al.*, 2009). Cyclic adenosine 3′, 5′-monophosphate (cAMP) functions as an intracellular second messenger in several signaling pathways, including stimulation of cell proliferation in somatotroph cells via GHRH receptors (Formosa and Vassallo, 2017). The association between cAMP levels and PA has been made in CNC and McCune–Albright syndrome. PDEs degrade the phosphodiesters bond, inactivating cAMP. *AIP* interacts with different PDEs, but the role of this interaction is still uncertain (Stork and Schmitt, 2002; Horvath and Stratakis, 2008). Another study showed that the lack of *AIP*

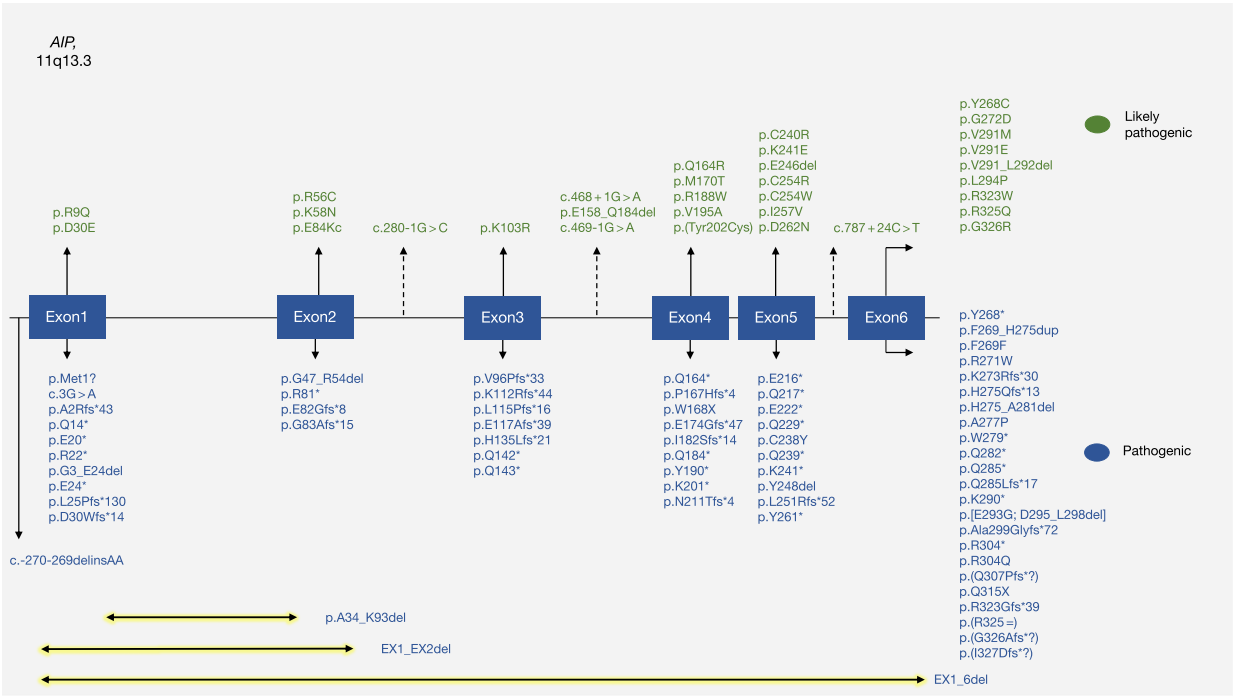

Fig. 2 AIP gene and likely pathogenic and pathogenic variants. *Blue boxes* represent exon (6) and introns are represented by *black line*. Mutations are distributed according to the localization.

leads to reduced inhibitory G protein Gα1–2 expression with the result of increased levels of cAMP, suggesting that this could be a major contributor to the development of somatotropinomas in *AIP* mutation carriers (Tuominen *et al.*, 2015). *AIP* also interacts with survivin, an inhibitor of apoptosis, and forms a complex with it in addition to Hsp90. The result is the prevention of ubiquitinations, thus stabilizing it. This interaction can be altered by another partner, RET, which will prevent the formation of the AIP/survivin complex (Kang and Altieri, 2006).

No other tumor types have been consistently associated with *AIP* mutation. Somatic mutations have not been found in PA either (Barlier *et al.*, 2007; Leontiou *et al.*, 2008).

Pituitary Adenomas

In families with multiple affected generations, the children/grandchildren present earlier than their ancestors, maybe due to patient education regarding the symptoms and surveillance among later generations (Daly *et al.*, 2006; Tichomirowa *et al.*, 2009).

Macroadenomas are seen in 63% of cases, which is a higher percentage compared with sporadic PA. PRL in FIPA are mainly microadenomas in women and macroadenomas in males (Tichomirowa *et al.*, 2009). Most *AIP* mutation-positive PA are somatotropinomas and prolactinomas (Daly *et al.*, 2010; Hernandez-Ramirez *et al.*, 2015). In a cohort of FIPA with *AIP* mutation, 80% were somatotropinomas and somatolactotropinomas, 14% were prolactinomas, and 6% were NFPA and gonadotropinomas (Korbonits *et al.*, 2012). Overall management of PA in FIPA families does not differ from the management of sporadic cases.

There are phenotypic differences in *AIP* mutation-positive families when compared with *AIP* mutation-negative families (Tichomirowa *et al.*, 2009; Gadelha *et al.*, 2013):

- The penetrance in *AIP* mutation-positive families is calculated 22.7% (range 15%–45%), being higher than in *AIP* mutation-negative families (Igreja *et al.*, 2010; Occhi *et al.*, 2010; Chahal *et al.*, 2011; Hernandez-Ramirez *et al.*, 2015);
- The mean age of diagnosis in *AIP* mutation-positive families is 20–24 years, 12–13 years lower than in *AIP* mutation-negative families and sporadic adenomas. The majority of PA from *AIP* mutation-positive families are diagnosed before the age of 30 (Chahal *et al.*, 2010; Daly *et al.*, 2010; Igreja *et al.*, 2010; Williams *et al.*, 2014; Hernandez-Ramirez *et al.*, 2015) (**Fig. 3**). Childhood-onset disease is present in 11% of *AIP* mutation-negative families, while it is demonstrated in 80% of *AIP* mutation-positive families (Cain *et al.*, 2010; Daly *et al.*, 2010; Hernandez-Ramirez *et al.*, 2015);
- The majority of studies reported a predominance of male patients in *AIP* mutation-positive families, but this was not reaching significance when extended fully studied families were considered (Hernandez-Ramirez *et al.*, 2015);
- Patients in *AIP* mutation-positive families are harbor either pure somatotropinoma or mixed somatotroph and lactotroph adenomas, while in *AIP* negative families there is more variability, although prolactinoma and somatotropinoma are also the most common tumor type seen (Chahal *et al.*, 2010; Daly *et al.*, 2010; Igreja *et al.*, 2010; Chahal *et al.*, 2011; Korbonits *et al.*, 2012);

– *AIP* mutation-positive patients with acromegaly often exhibit sparsely granulated somatotropinomas, a subtype that has been previously suggested to respond less to somatostatin analogues and to be more aggressive (Leontiou *et al.*, 2008; Daly *et al.*, 2010; Chahal *et al.*, 2012). They also have an aggressive clinical behavior, being large (88% macroadenomas), 80% of them being extrasellar, with frequent invasion (56% of cases) and submitted to more surgery and radiotherapy (Daly *et al.*, 2010; Martucci *et al.*, 2012); *AIP* mutation-positive tumors responded more poorly to somatostatin analogues (Leontiou *et al.*, 2008; Daly *et al.*, 2010; Kasuki Jomori de Pinho *et al.*, 2011; Chahal *et al.*, 2012; Gadelha *et al.*, 2013). The first generation of somatostatin analogues increases *AIP* expression, and this upregulates the expression of *ZAC1*, a tumor suppressor gene known to be upregulated by somatostatin-analogues and linked to their antiproliferative effects. This fact can explain the poor response to SRLs in *AIP* mutation-positive patients (Gadelha *et al.*, 2017). They also possibly have a lower IGF-1 control on pegvisomant therapy (Daly *et al.*, 2010). *AIP* mutation-negative patient response to treatment is poor although not as bad as in *AIP* positive (Beckers and Daly, 2007).

Regarding *AIP* mutation-positive PA, there is only one genotype–phenotype correlation for age: patients with truncating mutations are significantly younger at disease onset and diagnosis in comparison with patients with nontruncating *AIP* mutation (Cazabat *et al.*, 2009; Gadelha *et al.*, 2013; Xekouki *et al.*, 2013; Hernandez-Ramirez *et al.*, 2015).

Low *AIP* expression has been shown to be a better predictor of tumor invasion in somatotropinomas than Ki-67 or p53 (Korbonits and Kumar, 1993; Kasuki Jomori de Pinho *et al.*, 2011). They also have an increased risk for pituitary apoplexy (Daly *et al.*, 2010; Xekouki *et al.*, 2013).

In sporadic pituitary tumor, *AIP* mutations have been found in 2%–3.6% of patients (Tichomirowa *et al.*, 2009; Chahal *et al.*, 2010; Cazabat *et al.*, 2012; Preda *et al.*, 2014). PA in these patients present at a younger age and mainly with somatotropinoma (Georgitsi *et al.*, 2007a). In apparently sporadic PA patients, 20% of childhood-onset and 11.7% of macroadenoma in patients with <30 years harbor an *AIP* mutation (Tichomirowa *et al.*, 2011; Cazabat *et al.*, 2012). The lack of family history is probably due to incomplete penetrance, absence of information about family, or lack of diagnosis in family members in previous generations (Alband and Korbonits, 2014).

Who Should Be Tested?

Most reviews agree that there are three groups of patients that should do molecular genetic testing for an *AIP* mutation: (1) patients fulfilling the criteria for FIPA, (2) patients with PA diagnosed before the age of 18, and (3) patients with macroadenoma before the age of 30 (Korbonits *et al.*, 2012; Beckers *et al.*, 2013).

Mutation testing includes sequencing and testing for large deletions/duplications using MLPA if the first study is negative (Korbonits *et al.*, 2012).

Patients should be advised about the low penetrance of the disease, and the fact that only 20% of FIPA families harbor an *AIP* mutation.

Management

Treatment of pituitary adenomas is not significantly different between AIP positive patients, AIP-negative FIPA patients, or sporadic patients although we need to keep in mind that AIP-positive cases are more aggressive and respond poorly to SSA therapy, so other treatment modalities need to be considered early (e.g., pegvisomant, radiotherapy).

(A) *AIP* mutation-positive carriers:

Family member screening of *AIP* mutation carriers was shown to identify 24% of previously "unaffected" carriers with biochemical or radiological abnormalities (Korbonits *et al.*, 2012).

– Children: Based on the youngest known affected AIP positive case (3 years symptoms and 4 years diagnosis with a large invasive adenoma), the screening should start at the age of 4 years (Korbonits *et al.*, 2016). Yearly measurements of height and weight with calculation of height velocity and documentation of development of puberty together with pituitary function are recommended. MRI scanning is suggested around the age of 10 and then every 5 years if pituitary tests remain normal (Korbonits *et al.*, 2012; Williams *et al.*, 2014).
– Adult: Baseline clinical assessment with pituitary function tests and MRI followed by yearly pituitary function test, and consider repeat MRI every 5 years until the age of 30 if clinical and biochemical tests are normal. Due to the fact that the vast majority of patients are diagnosed before the age of 30 and due to the likelihood of the development of PA after the age of 50 years being low, the screening can be reduced by the age of 30 years and potentially stopped above the age of 50 (Chahal *et al.*, 2010; Korbonits *et al.*, 2012; Williams *et al.*, 2014).

(B) *AIP* mutation-negative:

The screening and follow-up of *AIP* mutation-negative families is more difficult due to a low penetrance and the fact that asymptomatic carriers cannot be identified by genetic screening. Some authors suggest education regarding symptoms, and clinical, laboratory, and MRI screening could be performed upon patients' request and/or under a research protocol (Korbonits *et al.*, 2012; Gadelha *et al.*, 2013).

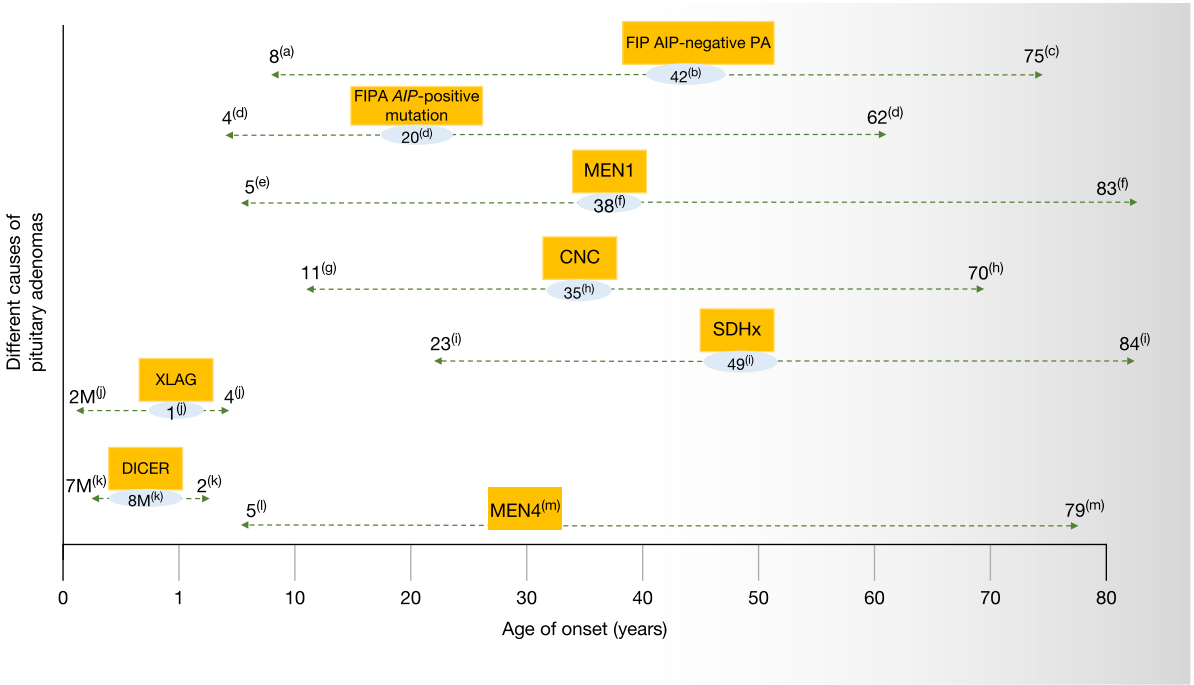

Fig. 3 Schematic representation of age of onset for familial pituitary adenoma. Mean age of onset is shown (in *light blue oval*), except for DICER1, where median is shown. Very few patients were reported with MEN4 with age of onset ranging between 5 and 79 years (median of 9 cases). The arrows represent the range of age of onset. X-Linked Acrogigantism (XLAG) Syndrome

Overview

XLAG syndrome presents an early-onset of pituitary gigantism, caused by duplications of the *GPR101* gene located at chromosome Xq26.3 (Trivellin *et al.*, 2014). Current data suggest that there are no other conditions associated up till the age of 50 years (Iacovazzo *et al.*, 2016).

This group represents the smallest group of FIPA and is responsible for 8%–10% of the cases of the patients with no syndromic pituitary gigantism, representing the second largest group of patients with childhood-onset acromegaly, after *AIP* positive-mutation patients (Rostomyan *et al.*, 2015; Iacovazzo *et al.*, 2016; Iacovazzo and Korbonits, 2016). Altogether 31 patients have been reported to date (Gadelha *et al.*, 2017).

The usually duplicated Xq26.3 region codes four genes, but only one of them, *GPR101*, was overexpressed in the patients with a microduplication of this region. There is also a patient described with duplication affecting only the *GPR101* (Iacovazzo *et al.*, 2016). The *GPR101* gene encodes an orphan G protein-coupled receptor that is significantly expressed in the hypothalamus and in pituitary samples of XLAG patients whose physiological function and endogenous ligand are unknown. This receptor, when activated, causes increase in cAMP levels, which represents a key factor involved in the regulation of GH secretion and cell proliferation in response to GHRH (Bates *et al.*, 2006; Trivellin *et al.*, 2014; Iacovazzo *et al.*, 2016). However, the exact mechanism how this duplication leads to tumorigenesis is unclear.

XLAG occurs as a simplex condition due to a "de novo" mutation in the majority of cases, but it can also be associated with FIPA: there are two familial cases described with transmission from affected mother to son (Beckers *et al.*, 2015). In addition, mosaic somatic mutation cases have also been described in males where the mutation was identified in the pituitary tissue and/or at low-level germline. The phenotype of somatic and germline *GPR101* duplication patients is the same (Daly *et al.*, 2016; Iacovazzo *et al.*, 2016; Rodd *et al.*, 2016).

Genetic testing could include CGH array or GPR101-specific droplet PCR. Negative genetic tests on peripheral blood DNA do not exclude the diagnosis of XLAG as the disease can result from mosaic somatic mutation. If the phenotype is characteristic of XLAG, testing of DNA samples from pituitary or other tissues should be considered (Iacovazzo *et al.*, 2016).

Pituitary Abnormalities Related to XLAG

Patients usually present with increased growth velocity before the end of the first year (range 0.5–2 years) and with a median age at diagnosis of 3 years old (range 1–22). Their growth curves significantly exceed the 97th percentile and acral enlargement and

coarsened facial features can be noticed (Trivellin *et al.*, 2014; Beckers *et al.*, 2015; Iacovazzo *et al.*, 2016; Rodd *et al.*, 2016). The majority of the cases are females (Trivellin *et al.*, 2014; Beckers *et al.*, 2015; Iacovazzo *et al.*, 2016).

Pituitary macroadenoma has been identified in most cases, but a significant minority of the patients have pituitary hyperplasia. All patients have elevated growth hormone levels with accompanying hyperprolactinaemia in most cases. The pituitary tissue shows a characteristic sinusoidal and lobular architecture and contains densely and sparsely granulated somatotrophs and microcalcifications, and follicle-like structures are also commonly observed with usually a low Ki-67 staining, but higher Ki-67 has also been described (Iacovazzo *et al.*, 2016; Naves *et al.*, 2016).

Hyperprolactinemia accompanies the GH excess in about 80% of the cases, and about 50% present with clinic of hyperprolactinemia. GHRH levels can be normal or slightly elevated, and in some patients a paradoxical response is seen in the TRH test (Iacovazzo and Korbonits, 2016).

XLAG typically occurs earlier than *AIP* mutation-positive PA, presenting with larger height *Z*-scores at diagnosis and lower rate of pituitary adenoma invasion (Iacovazzo and Korbonits, 2016).

Treatment of XLAG is challenging (Naves *et al.*, 2016). Treatment includes surgery, medical therapy, and, in some cases, radiotherapy as responses to somatostatin analogues are poor. Dopamine agonists effectively control prolactin excess although they seem to have no significant effect on GH/IGF-1 levels (Beckers *et al.*, 2015, Iacovazzo *et al.*, 2016).

GH receptor antagonists have been used successfully even in patients who were not controlled by surgery or somatostatin analogues. Patients with pituitary hyperplasia, where extensive pituitary surgery was not considered due to the risk of hypopituitarism, can be treated with a combination of SSA, dopamine agonist, and pegvisomant (Beckers *et al.*, 2015; Rodd *et al.*, 2016). Permanent hypopituitarism is common due to a need for aggressive treatments (Iacovazzo and Korbonits, 2016).

Who Should Be Tested?

The frequency of XLAG in nonsyndromic pituitary gigantism supports the need for testing for *GPR101* duplication in patients with early-onset (<5 years) pituitary gigantism (Beckers *et al.*, 2015; Iacovazzo *et al.*, 2016).

Management

XLAG patients represent a significant management problem. In cases of hyperplasia, although the rest of the pituitary function is normal, only hypophysectomy was shown to be effective surgical option for the GH excess (Moran *et al.*, 1990). More recently combined SSA, carbergoline, and pegvisomant achieved normal biochemistry and growth velocity (Rodd *et al.*, 2016).

For patients with pituitary tumors, surgery and, if necessary, combined medical therapy (as above) or radiotherapy need to be employed (Beckers *et al.*, 2015; Iacovazzo and Korbonits, 2016).

Multiple Endocrine Neoplasia Type 1 Syndrome

Overview

MEN1 is characterized by development of tumors mainly in endocrine but also in nonendocrine organs in a single patient. It is an autosomal dominant condition with high penetrance but may also occur sporadically (Wermer, 1954). The penetrance is different by the various components of the disease, overall it is >50% by age of 20 years (Brandi *et al.*, 2001; Machens *et al.*, 2007; Thakker, 2010).

The incidence of MEN1 is around 0.25% from postmortem studies and affects about 1/30.000 individuals, usually in a familial context (Alband and Korbonits, 2014).

The *MEN1* gene is located on chromosome 11q13 and has 10 exons, of which exons 2–10 encode a 610 amino acid nuclear protein called menin (Chandrasekharappa *et al.*, 1997; Marx, 2005). MENIN directly regulates the expression of the cyclin-dependent kinase-inhibiting (CDKI) genes, *CDKN1b* (encoding p27) and *CDKN2C* (encoding p18), and thereby negatively regulates the proliferation of the cells (Giusti *et al.*, 1993). The correlation of menin with p27 is particularly interesting because mutations in the *CDKN1B* are associated with a MEN4 syndrome (Caimari and Korbonits, 2016). Decreased p27 expression, whose main function is to control the progression from G1 to S phase, is enough for tumor development in p27Kip1 $\pm$ mice (Fero *et al.*, 1998; Lee and Pellegata, 2013a). A reduction in *CDKN1B* expression has been described in some endocrine malignant and benign tumors (Pellegata *et al.*, 2007; Marinoni and Pellegata, 2011). Inheritance of germline *MEN1* mutation predisposes carriers to the development of a tumor that arises after somatic mutation, leading to loss of heterozygosity in 11q13 in the tumor DNA, consistent with the Knudson two-hit hypothesis and a tumor suppressor role for menin (Lemos and Thakker, 2008; Thakker, 2010). LOH in 11q13 occurs in around 90% of MEN1 tumors, with deletions and point mutations representing other mechanisms by which the second hit may occur (Thakker *et al.*, 2012).

MENIN is located in the nucleus and interacts with the promoter regions of thousands of genes, which indicate that it may be implicated in the regulation of gene transcription, DNA repair, and cell division and proliferation (Lemos and Thakker, 2008; Tichomirowa *et al.*, 2009; Syro *et al.*, 2016).

Mutations in the *MEN1* gene were first described in 1997, and more than 1500 mutations identified (Chandrasekharappa *et al.*, 1997; Lemos and Thakker, 2008). These mutations include frameshift mutations, nonsense mutations, missense mutations, splice site mutations, and large deletions. There are mutational hotspots in exons 2, 3, 9, 10, and intron 4 (Lemos and Thakker, 2008). Seventy percent of *MEN1* mutations cause truncated forms of menin (Lemos and Thakker, 2008).

MEN1 mutations can be identified in 75%–95% of all cases, and about 10% of the mutations are "de novo" mutations (Lips *et al.*, 1984; Thakker, 2010). The absence of an identified mutation may be due either to other currently unknown disease-causing genes, phenocopies or to lack of full assessment of the known disease causing-gene. Phenocopies have been reported in around 5% of MEN1 patients (Turner *et al.*, 2010).

In addition, there are 24 *MEN1* polymorphisms identified that may not be easily distinguished from pathological variants (Brandi *et al.*, 2001; Lemos and Thakker, 2008).

MENIN has many known partners that include JunD, NF-kB, Pem, SIN3A, HDAC, elements of the Smad family, Runx2, MLL, estrogen receptor-α hostel cell factor 2, and RBBP5 (Thakker, 2014). Menin activates the transcription of *CDKN1B* and *CDKN2C* by recruiting the histone methyltransferase MLL protein to the promoters and coding regions of these genes. The *CDKN1B* and *CDKN2C* are predominantly expressed in endocrine organs, which may explain the preference for endocrine tumors in patients with MEN1 (Taguchi *et al.*, 2011). Menin also regulates transcription of homeobox (HOX) genes (Wu and Hua, 2011). In the pituitary menin negatively regulates the cell proliferation and secretion of PRL, GH, and ACTH. The expression of IGFBP-2, IGF-2, and PTHrp is negatively modulated by menin (La *et al.*, 2004; Fontaniere *et al.*, 2006).

The three main components of the syndrome are hyperparathyroidism (in almost all patients by the age of 50), enteropancreatic endocrine tumors (in about 60% of cases), and PA (in about 30%–40% of cases) (Wermer, 1954). Other endocrine manifestations include foregut carcinoids, adrenal cortex tumors, and rarely pheochromocytoma. Lipomas, facial angiofibromas, collagenomas, and ependymomas are nonendocrine tumors also associated with MEN1 (Brandi *et al.*, 2001; Caimari and Korbonits, 2016).

A diagnosis of MEN1 may be established in an individual by one of the three criteria: (1) occurrence of two or more primary MEN1-associated endocrine tumors; (2) the occurrence of one of the MEN1 associated tumors in a first degree relative of a patient with a clinical diagnosis of MEN1; (3) an identification of a germline *MEN1* mutation even in the absence of a clinical or biochemical manifestation of MEN1 (Turner *et al.*, 2010).

Pituitary Adenomas

Overall about 2.7%–3% of all pituitary adenomas are due to MEN1 (Chandrasekharappa *et al.*, 1997; Thakker, 2010; Alband and Korbonits, 2014). Approximately 30%–40% of *MEN1* gene mutation carriers develop PA, with a slight female preponderance. This is the presenting problem in 15% (ranging from 10% to 25%) of MEN1 cases although underdiagnosed hyperparathyroidism is often already present (Skogseid *et al.*, 1991; Burgess *et al.*, 1996; Marx *et al.*, 1998; Verges *et al.*, 2002; Lecoq *et al.*, 2015).

The most common clinically manifest form are prolactinomas (Verges *et al.*, 2002; Benito *et al.*, 2005), but small NFPA have also been seen in prospective screening studies (de Laat *et al.*, 2015). On the other hand, the proportion of plurihormonal adenomas and multiple adenomas is significantly higher in MEN1 patients (Trouillas *et al.*, 2008). In patients with *MEN1* mutation and clinical signs of acromegaly, the possibility of GHRH-secreting NET should be considered and GHRH level should be assessed (Garby *et al.*, 2012; Saleem *et al.*, 2012).

PA in MEN1 patients appear to occur at younger ages when compared to sporadic PA: the earliest age reported is 5 years and the mean age of onset has been reported to be 38 ± 15.3 years (Farrell *et al.*, 2011). They are also larger and more aggressive than sporadic tumors, with 85% of macroadenoma cases, lower rate of hormonal normalization and higher recurrence rates (Verges *et al.*, 2002; Trouillas *et al.*, 2008; Tichomirowa *et al.*, 2009; Thakker, 2010; Syro *et al.*, 2012; Toledo *et al.*, 2013). However, one study concluded that PA in MEN1 seems to be much less aggressive than previously suggested by their demonstrations of a good response to the prolactinoma treatment and a limited growth of NFPA (de Laat *et al.*, 2015).

The clinical management of PA is not different from sporadic cases although it is likely that surgery will be required more frequently (Thakker *et al.*, 2012). Untreated patients with MEN1 have a decreased life expectancy, but even with treatment 70% of MEN1 patients die due to MEN1 complications (Dean *et al.*, 2000; Geerdink *et al.*, 2003; Goudet *et al.*, 2010).

Who Should Be Tested?

The *MEN1* germline mutation screening is recommended for index cases and their relatives, either asymptomatic or with clinical manifestations of MEN1. *MEN1* germline mutation testing of asymptomatic relatives should be offered at the earliest opportunity because manifestation may occur by the age of 5 (Brandi *et al.*, 2001; Thakker *et al.*, 2012).

MEN1 mutation testing can be considered in patients with PA and no other MEN1 manifestation in childhood or young-onset cases (de Laat *et al.*, 2015), and may be recommended in individuals with atypical MEN1 phenotypes like multigland hyperparathyroidism or multiple pancreatic NET at any age (Thakker *et al.*, 2012; Alband and Korbonits, 2014).

Management

MEN1-related pituitary adneomas could be challenging, where multimodal therapy is needed especially in aggressive pediatric cases (Gan *et al.*, 2015; Syro *et al.*, 2016). Regarding pituitary screening in *MEN1* mutation-positive carriers, yearly clinical assessment and plasma prolactin and IGF-1 measurements starting at the age of 5 years and pituitary MRI every 3 years are recommended (Brandi *et al.*, 2001, Thakker *et al.*, 2012).

Multiple Endocrine Neoplasia Type 4 Syndrome

Overview

There are patients with MEN1-like phenotype and no identifiable *MEN1* mutations. A small minority of these patients have been identified with loss-of-function mutations in the *CDKN1B* gene, establishing a distinct entity called MEN4. The *CDKN1B* gene is a tumor suppressor gene localized on chromosome 12q13 (Pellegata *et al.*, 2006; Agarwal *et al.*, 2009; Igreja *et al.*, 2009). There are only a handful of different discovered heterozygous frameshift, nonsense, or missense mutations (Thakker, 2014) and two cases of alterations in the 5′ open reading frame (Occhi *et al.*, 2013; Sambugaro *et al.*, 2015). Loss of p27 is frequently observed in PA especially in corticotropinomas and pituitary carcinomas (Lidhar *et al.*, 1999) although somatic *CDKN1B* mutations have not been found in PA (Dahia *et al.*, 1998; Pellegata *et al.*, 2006; Marinoni and Pellegata, 2011). Mutations in other cyclin-dependent kinases inhibitors, encoding p15 (*CDKN2B*), p18 (*CDKN2C*), and p21 (*CDKN1A*), were also implicated in rare cases of MEN1-like phenotype (Agarwal *et al.*, 2009).

Human cyclin-dependent kinases inhibitor-related MEN1-like cases are very rare. They are inherited in a dominant manner and due to their rarity, and it is not possible to determine the penetrance of the syndrome, frequency of familial and sporadic cases, and phenotype–genotype correlation.

Hyperparathyroidism is present in almost all the cases, but PA are only reported in about a third of these cases (Gadelha *et al.*, 2017). Other tumors described include renal angiomyolipoma, adrenal nonfunctional tumor, uterine fibroma, gastrinoma, neuroendocrine cervical carcinoma, bronchial carcinoid, papillary thyroid carcinoma, and gastric carcinoma (Georgitsi *et al.*, 2007b; Molatore *et al.*, 2010; Malanga *et al.*, 2012).

Pituitary Adenomas

The most common tumor type is somatotropinoma, but corticotropinoma, NFPA, and a possible prolactinoma have also been described (Lee and Pellegata, 2013b; Gadelha *et al.*, 2017). A childhood-onset somatotropinoma case has been described (Sambugaro *et al.*, 2015).

Who Should Be Tested?

In cases that are negative for *MEN1* mutation but display a MEN1 phenotype, screening for *CDKN1B* gene mutation could be considered (Tichomirowa *et al.*, 2009; Georgitsi, 2010). *CDKN1B* mutation is rare but can be found in 1.5%–2.8% of patients with MEN1 features and negative *MEN1* testing and represents 0.1%–0.2% of all MEN1 cases (Ozawa *et al.*, 2007; Agarwal *et al.*, 2009; Owens *et al.*, 2009; Georgitsi, 2010).

Carney Complex

Overview

Carney Complex (CNC) is a rare condition characterized by endocrine, including pituitary hyperplasia or adenoma, and other tumor types (Stratakis *et al.*, 2001). Nowadays there are approximately 700 people described (Stratakis *et al.*, 2015). It is an autosomal dominant disease with unknown prevalence and high penetrance for some of the manifestations (>95% by age 50 years) (Horvath *et al.*, 2010). It is familial in 70% of cases and the diagnosis is made at a median age of 20 years (Stratakis *et al.*, 2001; Boikos and Stratakis, 2007).

Originally two distinct loci for CNC have been identified: one on chromosome 17q22-24 and the other on chromosome 2p16 (Stratakis *et al.*, 1996; Kirschner *et al.*, 2000). The gene located on 2p16 has not been identified, while the chromosome 17 locus is associated with the gene encoding the protein kinase A regulatory subunit Iα (*PRKAR1A*) and is the cause of the vast majority (>70%) of CNC cases (Stratakis *et al.*, 1996; Veugelers *et al.*, 2004; Horvath *et al.*, 2010). There is now a third locus also identified on chromosome 1p31.1, coding for the enzymatic subunit of PKA (Forlino *et al.*, 2014).

PKA is implicated in a wide range of cellular processes including hormone release, transcriptional regulation, cell cycle progression, and apoptosis. Loss of regulatory activity of PKA results in enhanced activity of PKA and therefore enhances the response to cAMP signaling in affected tissues. PKA is a tetramer composed of 2 homodimers of regulatory and 2 catalytic subunits (Horvath and Stratakis, 2008; Stratakis *et al.*, 2010).

PRKAR1A comprises 11 exons and over 125 pathogenic variants have been identified (Kirschner *et al.*, 2000; Correa *et al.*, 2015). Most *PRKAR1A* mutations lead to mRNA instability, decreased or absent protein expression, and *PRKAR1A* haploinsufficiency in CNC tumors (Kirschner *et al.*, 2000). Large *PKRAR1A* deletions, 21.6% of patients with CNC, seem to have a more severe phenotype (Salpea *et al.*, 2014) and specific testing with MLPA or long-PCRs need to be performed to identify these mutations. LOH at 17q22-24 and allelic loss have been shown in CNC tumors, supporting a tumor suppression function, and the loss of PRKAR1A function enhances intracellular response to cAMP in CNC tumors (Bossis and Stratakis, 2004).

Recent studies have shown gene duplication affecting the catalytic B subunit of PKA in association with elements of the CNC phenotypes (Forlino *et al.*, 2014; Syro *et al.*, 2016).

Variants of the phosphodiesterase type 11A (*PDE11A*) showed association with a higher incidence of hyperplasia and large-cell calcifying Sertoli tumors, suggesting that PDE11A can modify the phenotype (Libe *et al.*, 2011).

The diagnosis of CNC is established in a proband with two or more major clinical manifestations and/or when a pathogenic variant is identified in *PKRAR1A*. Major criteria include: spotty skin pigmentation with typical distribution (lips, conjunctiva and inner or outer canthi, vaginal and penile mucosal); cutaneous and mucosal myxoma or cardiac myxoma; sporadic isolated primary pigmented nodular adrenocortical disease or paradoxical positive response of urinary glucocorticoid excretion to dexamethasone administration during Liddle's test; acromegaly as a result of GH-producing adenoma; large-cell calcifying Sertoli cell tumor or characteristic calcification on testicular ultrasound, thyroid carcinomas (at any age) or multiple hypoechoic nodules on thyroid ultrasound in prepubertal child; psammomatous melanotic schwannomas; blue nevus; breast ductal adenoma and osteochondromyxoma. The supplemental criteria include affected first-degree relative and inactivating mutation of the *PRKAR1A* gene (Correa *et al.*, 2015; Stratakis *et al.*, 2015).

Pituitary Adenomas

PA in CNC are somatotropinoma and prolactinoma and rarely stain positively for TSH, LH, and alpha-subunit (Pack *et al.*, 2000). Acromegaly is rare and occurs in 10%–12% of cases, but 75% of patients have biochemical abnormalities like elevation in GH, IGF-1, or PRL levels or abnormal responses to dynamic pituitary testing due to pituitary hyperplasia (Pack *et al.*, 2000; Raff *et al.*, 2000; Correa *et al.*, 2015). Histology more commonly shows multifocal hyperplasia of somatomammotrophic cells which may lead to formation of GH/PRL adenoma. Most of the patients do not have an aggressive PA and acromegaly usually develops insidiously. The mean age of onset of acromegaly in CNC patients is 35.8 years; however, a few cases of gigantism have been described. Microadenomas are more common than macroadenomas, and they are frequently multiple and surrounded by hyperplastic tissue (Stratakis *et al.*, 2001; Pack *et al.*, 2005; Boikos and Stratakis, 2007; Caimari and Korbonits, 2016).

Who Should Be Tested?

Genetic testing should be offered to patients with two or more CNC major manifestations or relatives of CNC patients (Stratakis *et al.*, 2015).

Management of CNC-Related Pituitary Adenoma

The treatment of PA in CNC does not differ from sporadic cases. Selective adenomectomy is the preferred treatment for PA, but in CNC cases where multiple adenomas can occur, partial or complete hypophysectomy may be necessary to achieve biochemical remission (Lonser *et al.*, 2016).

Regular screening for the manifestations of the disease is recommended for patients with CNC and known carriers of *PRKAR1A* mutations. Regarding pituitary abnormalities, for postpubertal patients, annual serum IGF-1, GH, and PRL should be performed (Stratakis *et al.*, 2001; Correa *et al.*, 2015) with pituitary MRI and 3-h oral glucose tolerance test for GH alterations in suspected GH excess (Stratakis *et al.*, 2015).

Pheochromocytoma/Paraganglioma and Pituitary Adenoma

Overview

The coexistence of pheochromocytoma/paraganglioma is rare. In the recent years a common genetic basis has been described in a number of cases now termed 3PA syndrome or the "three P association" of pituitary adenoma with pheochromocytoma/paraganglioma (Denes *et al.*, 2015; Xekouki *et al.*, 2015).

Of the 74 cases reviewed (O'Toole *et al.*, 2015), 30% have mutations in predisposing pheochromocytoma/paraganglioma or PA genes, *SDHA*, *SDHB*, *SHDC*, *SDHD*, *SDHAF2*, and *MEN1*, with the most common mutation (15 patients) being in the *SDHx* gene (especially the *SDHB* mutation), and 31% are patients with a personal or family history that is suggestive of a hereditary case, but without confirmed pathogenic genetic mutation (O'Toole *et al.*, 2015).

The presence of *SDHx* mutations in PA is rare but is more likely if pheochromocytoma/paraganglioma are also present or if there is a positive family history of pheochromocytoma/paraganglioma (Papathomas *et al.*, 2014; Xekouki *et al.*, 2015).

Succinate dehydrogenase (SDH) is a multimeric enzyme bound to the inner mitochondrial membrane. SDH consists of two hydrophilic subunits, a flavoprotein (SDHA) and an iron–sulfur protein (SDHB), which form the catalytic core of the enzyme with its associated assembly factor (SDHAF2), and two hydrophobic subunits, SDHC and SDHD, which anchor the homotetramer to the membrane and serve as the ubiquinone-binding site (Oyedotun and Lemire, 2004). It plays a critical role by transferring electrons directly to the ubiquinone pool in the Kreb's cycle and the respiratory chain. Mutations in the genes encoding subunits A, B, C, and D are associated with the development of pheochromocytoma, paraganglioma, gastrointestinal stromal tumors, renal cancer, papillary thyroid cancer, neuroblastoma, adrenal medullary hyperplasia, testicular seminoma, and PA (Papathomas *et al.*, 2014; Xekouki *et al.*, 2015).

The loss of heterozygosity demonstrated at the *SDH* locus in PA and a reduction of the respective SDH protein expression in PA tissue support the causality between these genes and PA tumorigeneses (Xekouki and Stratakis, 2012; Papathomas *et al.*, 2014; Denes *et al.*, 2015; Xekouki *et al.*, 2015). Inactivation of SDH can lead to activation of the hypoxia-inducible factor (HIF-1α) pathway and a pseudohypoxic state. It was shown that an increased HIF-1α level in a *SDHD* mutation case was linked to PA (Xekouki and Stratakis, 2012).

In the differential there are also cases described of this association in *MEN1* positive-mutation patients, with the demonstration of LOH at the MEN1 locus together with absent menin staining in the pheochromocytoma samples (Denes *et al.*, 2015). There are a few cases of MEN2 and VHL syndrome and concomitant PA; however, there is insufficient evidence available at present to conclude whether they play a role in pituitary tumorigenesis (O'Toole *et al.*, 2015).

Pituitary Adenomas

Prolactinoma are the most common followed by somatotropinoma and NFPA. They usually present as macroadenomas with aggressive behavior and resistant to medical therapy and most often require surgery (O'Toole *et al.*, 2015; Syro *et al.*, 2016). A pituitary carcinoma has also been described in a patient with paraganglioma and *SDHB* mutation (Tufton *et al.*, 2017).

PA of these patients have an unusual appearance of extensive vacuolization of cytoplasm (Denes *et al.*, 2015). The age of onset of PA is comparable with that of sporadic tumors. The penetrance of PA in patients with *SDHx* mutation is low.

Who Should Be Tested?

SDHx mutations are very rare in unselected sporadic PA, and therefore genetic screening is not justified routinely in patients with PA, unless there is coexistence of and/or family history of pheochromocytoma/paraganglioma (Xekouki *et al.*, 2015).

Management of Pituitary Adenoma in *SDHx* Positive Mutation Carriers

In patients with *SDHx* positive mutation under MRI surveillance for pheochromocytoma/paraganglioma, pituitary MRI should be added to at least the first MRI screening of the neck and skull base (Caimari and Korbonits, 2016).

DICER1

Overview

DICER1 syndrome is a rare condition of multiple tumors arising from infancy with unknown prevalence caused by a heterozygous germline mutation in the *DICER1* gene, which is located on chromosome 14q32.13 and is comprised of 1922 amino acids and 27 exons (Foulkes *et al.*, 2011). DICER1 is an RNA processing endoribonuclease that cleaves precursor microRNAs (miRNA) into active miRNA, which in turn posttranscriptionally regulate cellular protein production (Foulkes *et al.*, 2011).

DICER1 germline mutations usually lead to truncated proteins, whereas the "second hit" somatic mutations are typically in the metal-binding sites of the catalytic RNAase IIIa and b domains, which are hotspot mutations (Rio Frio *et al.*, 2011). It is currently unclear how *DICER1* mutation leads to tumorigenesis in general or specifically to pituitary blastomas (Sahakitrungruang *et al.*, 2014; Caimari and Korbonits, 2016).

DICER1 syndrome is characterized by autosomal-dominant inheritance with variable clinical presentation and with a low penetrance (Foulkes *et al.*, 2011; de Kock *et al.*, 2014).

The main manifestations of the DICER1 syndrome include pleuropulmonary blastoma, rhabdomyosarcoma, nasal hamartoma, cystic nephroma, multinodular goiter, and Sertoli–Leydig cell tumors. Pituitary blastoma is a rare manifestation but a pathognomonic one (Foulkes *et al.*, 2011; Slade *et al.*, 2011; Sabbaghian *et al.*, 2012; de Kock *et al.*, 2014).

Pituitary Blastoma

The first description of pituitary blastomas was in 2008 in a 13-month-old child with Cushing's disease and diabetes insipidus (Scheithauer *et al.*, 2008; Scheithauer *et al.*, 2012).

In the histological composition it is possible to find Rathke epithelium cells, folliculostellate cells, and differentiated pituitary hormone secretory cells (Scheithauer *et al.*, 2008). Pituitary blastomas always express ACTH in at least a subset of cells and sometimes also express GH (de Kock *et al.*, 2014). Its ultrastructure resembles that of 10- to 12-week embryonic pituitary (Scheithauer *et al.*, 2008).

There are only a few cases described in the literature, but all confirmed cases are due to the DICER1 syndrome (Scheithauer *et al.*, 2012; de Kock *et al.*, 2014; Sahakitrungruang *et al.*, 2014). The penetrance appears to be below 1% (de Kock *et al.*, 2014).

Pituitary blastoma development occurs early in life, usually before the age of 2 years, and is associated with ACTH secretion and severe Cushing's diseases in the majority of the cases. They frequently extend to the suprasellar and parasellar regions, and ophthalmoplegia and strabismus are present in about 50% of cases (de Kock *et al.*, 2014). In an overview of all known cases, 61.5% were female, the age of pathological diagnosis ranged from 7 $\pm$ 24 months, and in 61.5% patients pituitary blastoma was the only manifestation at the time of the study (de Kock *et al.*, 2014). Mortality rate of pituitary blastomas is around 40%, and it could be due to mass effect or due to a severe Cushing syndrome (de Kock *et al.*, 2014).

Who Should Be Tested?

ACTH-dependent Cushing syndrome during infancy (under the age of 2 years) is very rare, so in its presence the clinician should consider pituitary blastomas and look for other *DICER1* mutation-related disease in the patient or relatives.

Management

Due to its rarity and its recent discovery, clinical experience is very limited. The prognosis is unfavorable, but recent studies showed better outcomes with the association of surgery, polychemotherapy, and adjuvant radiotherapy (de Kock *et al.*, 2014; Sahakitrungruang *et al.*, 2014).

Conclusion

Several advances have been made in the genetic aspects of PA in the last few years. The knowledge of particular aspects of each disease may facilitate the diagnosis, allowing for genetic screening. Genetic screening and clinical follow-up of patients with PA of genetic origin allow early identification, diagnosis, and treatment of its manifestations and consequently decrease its significant complications both in patients and in family members.

Glossary

Arthropathy Abnormality in the condition of a joint of the body; enlargement, swelling, degeneration, or other such disturbance in a joint.

Growth hormone (GH) A polypeptide hormone that is secreted mainly by the pituitary gland, although it is also produced by other cell types, such as lymphoid cells. Its actions are related mainly to growth (soft tissues, long bones, etc.) and to metabolism. It belongs to a family of hormones that includes prolactin and placental lactogens as well as other placental factors. Acromegaly results from GH hypersecretion.

Insulin-like growth factor type 1 (IGF-1) A hormone structurally related to insulin, exhibiting strong proliferative effects and facilitating differentiation of tissues., IGF-1 overproduction is associated with acromegaly.

Multiple endocrine neoplasia syndrome type 1 (MEN-1) A group of genetically distinct familial diseases in which two or more endocrine glands develop excess normal tissue (hyperplasia) and/or adenoma (tumor).

Sleep apnea A sleep disorder in which the subject has intermittent periods of a failure to automatically control respiration; these involuntary pauses in breathing may occur repeatedly during a given period of sleep.

Introduction

Clinical Characteristics of Acromegaly

Acromegaly is due to the hypersecretion of growth hormone (GH) and the resultant secondary overproduction of insulin-like growth factor-1 (IGF-1). In the vast majority of the cases (>99%), the source of excessive GH is a benign pituitary tumor of purely somatotroph or mixed somatotroph or lactotroph origin. Rarely, somatotroph tumors arise in an ectopic pituitary, a remnant of the primitive Rathke's pouch, and are found in the posterior pharynx, sphenoid bone, or sphenoid sinus or even within the sella, separate from the normal pituitary gland. Ectopic production of GH-releasing hormone (GHRH) leads to pituitary somatotroph hyperplasia. Carcinoids and islet cell tumors are the most frequent sources of ectopic GHRH. Hypothalamic/pituitary gangliocytomas or choristomas, or in one case the pituitary adenoma itself, were shown to be a source of excessive GHRH production. Ectopic GH secretion was documented in only very few cases: one by a malignant islet cell tumor and another by a non-Hodgkin's lymphoma. Acromegaly may be part of endocrine tumor syndromes, such as MEN-1 and MEN-4 (parathyroid, pituitary, pancreas), McCune–Albright syndrome and Carney complex. In some instances, the clinical syndrome of acromegaly may be overshadowed by other manifestations of a malignant or polyglandular diseases.

Clinical manifestations of acromegaly correlate better with the prevailing levels of IGF-1 than with GH, and the duration of GH/IGF-1 excess may play a major role. A clinical and biochemical syndrome of acromegaly may be transiently expressed during normal puberty or pregnancy. This is due to physiological overproduction of GH by the normal pituitary gland during sexual maturation or by the placental synthesis of placental GH, a variant of pituitary GH.

In most cases, acromegaly is an insidious disease, and its early clinical manifestations usually go unnoticed by the patient, the patient's family, and/or the patient's physician. Retrospective questionnaires and the inspection of old photographs usually set the clinical onset of disease at 5-10 years prior to the diagnosis.

Clinical presentation of acromegaly consists of the mass effects of the tumor itself, the manifestations of the abnormal growth affecting virtually all organs and tissues, and the metabolic derangements effected by GH itself.

Mass Effects of the Tumor

The majority of GH-secreting adenomas (60–80%) are ≥10 mm at the time of diagnosis (macroadenoma) and are often invasive towards the sphenoid sinus, cavernous sinus or 3rd ventricle (Potorac *et al.*, 2015). Headache is present in over half of the patients and can be severe enogh to significantly interfere with everyday activities. Headache may be present even in patients with relatively small tumors, where mass effect is unlikely to provide an explanation. It has been suggested that headache is typical in patients with previous predisposition or family history of headaches. The headache can be the result of a combination of factors, including the hormonal activity of the tumour, relationship to the cavernous sinus and patient predisposition to headache (Levy *et al.*, 2005). Hypopituitarism

(ACTH, TSH and LH/FSH deficiency leading to hypogonadism) can also occur due to the mechanical effects of the pituitary adenoma. Symptomatic pituitary apoplexy occurs in less than 5% of patients, often presenting as sudden onset of severe headache with or without ophthalmoplegia (III, IV, VI, and V_1, V_2 nerves), but it is significantly more common in *AIP*-mutation positive cases, especially in children (Hernández-Ramírez *et al.*, 2015). Asymptomatic pituitary hemorrhage may occur in 30-40% of the cases. Photophobia occurs in about half of cases and is most troublesome in bright sunlight and during night driving.

Abnormal Growth

If abnormal GH hypersecretion occurs before puberty, rapid linear growth may lead to gigantism. Combination of high GH levels with hypogonadism due to mass effect of the tumor damaging LH/FSH levels or due to prolactin secretion inhibiting LH/FSH via inhibition of kisspeptin and GnRH, delays epiphyseal closure and continued growth. Gigantism is a defined as pituitary adenoma with (i) abnormally high growth velocity in children or teenagers with abnormal IGF-1 and OGTT, (ii) height >3SD above the mean height for age, (iii) >2SD over the calculated midparental height, using country-specific growth charts. Height increase is often seen if disease starts later in puberty, and height increase might not reach the threshold of gigantism. Pre-pubertal onset of disease with delayed puberty leads to disproportionate growth (arm span/body height is $>1+5$ cm, sometimes referred as eunuchoidal-infantile gigantism or daddy-longlegs syndrome. The typical dysmorphic features of acromegaly usually occurs in postpubertal disease, or can develop later in patients with prepubertal disease, although the very high GH levels recorded in XLAG syndrome can produce these features in young children as well (Beckers *et al.*, 2015).

Face

The combination of bone and soft tissue overgrowth leads to a typical acromegalic face: widened and thickened nose, thick lips, macroglossia, coarsening of the features and facial and infraorbital puffiness, thickened oily skin sometimes with acne, exaggerated nasolabial and forehead skin furrows, maxillary widening, mandibular overgrowth and prognathism. The face and skull changes also include thickening of the calvarium, increased size of the frontal sinuses, which leads to prominence of the supraorbital ridges and frontal bossing. Patients may seek care for dental problems (teeth separation, malocclusion), and the diagnosis is often raised by a doctor, such as a locum doctor, who has never seen the patient before.

Patients may have asymmetrical faces, especially in cases due to McCune–Albright syndrome. Exophthalmos may be noted; however, it might be masked by frontal bossing. Hypertrophic tissue surrounding the canal of Schlemm may impede aqueous filtration, leading to open-angle glaucoma (Melmed *et al.*, 2011). Photographs show a slow, insidious transformation of the facial features over several years. These features are seen in 98-100% of patients (see Fig. 2).

Although the clinical diagnosis of acromegaly can be easy, in case the physician is considering this disease, the typical features are often under-recognized leading to long delay in diagnosis (4–10 years). An attempt has been made to recognize acromegalic face by a computer program using a model that establishes a three-dimensional model from a regular 2D photograph (Fig. 1). Despite having several limitations, the study of Schneider *et al.* suggest that acromegaly can be detected by computer software using photographs of the face. The accuracy of acromegaly diagnosis by software was higher than by medical experts or general internists, particularly in patients with mild features of acromegaly, making this software a promising tool to help detecting acromegaly (Schneider *et al.*, 2011).

Fig. 1 Computer software recognizing acromegaly based on detecting of texture of the skin under the marked nodes and on the geometry of the face by analyzing edge length and distances between the nodes depicted on this example (courtesy of Dr Schneider following from Schneider *et al.* JCEM 2011)

Extremities

Hands and feet become very "fleshy" (Fig. 2). An increase in finger circumference and a widening of the hands and feet develop in 98-100% of patients (Fig. 3). Patients routinely recall repeated resizing of rings and changes in shoe size (mostly widening). Patients with acromegaly often have a characteristic handshake: a large, soft, slight sweaty doughy hand often makes the diagnosis relatively easy. Diagnosis of acromegaly is often made by orthopedic, rheumatologic or neurologist colleagues (Table 1) due to joint abnormalities and pain.

Skin and appendages

Skin is characteristically thickened because of excessive deposition of the glycosoaminglycans, hyaluronic acid, chondroitin sulfate, and dermatan sulfate in the papillary and upper reticular dermis. These compounds are very hydrophilic, causing the development of a non-pitting edema and consequently leading to the appearance of facial wrinkles and prominent nasolabial folds. The heel pads are thickened, this sign was used in the past form diagnosing the condition. Body hair may become coarsened (Ben-Shlomo and Melmed, 2006). Skin thickening at the vertex causes a peculiar appearance of cutis verticis gyrata (skin folds at the top of the head). Similar skinfolds can be seen in patients pachydermaperiostosis or elevated IGF-II levels. Hair growth is increased, and women complain of hirsutism or hypertrichosis. As opposed to the androgen-related hirsutism, this is pronounced even on the forearms and forelegs. Many women with acromegaly have exceedingly thick scalp hair growth. Hair loss after successful therapy is often a cause of concern but is essentially a physiological return to normal hair growth (Barkan, 2004).

The functional capacity of sweat and sebaceous glands is increased, resulting in excessive perspiration, often with offensive odor, in acne and sebaceous cysts, hyperhidrosis and malodorous oily skin occurring in up to 70% of patients. Skin tags are frequently present, particularly on the neck and may be markers for the adenomatous colonic polyps (Leavitt *et al.*, 1983). Acanthosis nigricans of the axillae and neck is common as well. Raynaud's phenomenon is reported in up to one third of patients.

Fig. 3 Hand of a patent with acromegaly showing thickened sausage like fingers (representing a pathognomonic feature of acromegaly with a diagnostic odds ratio of 131, according to a recent study (Prencipe *et al.*, 2016)) and atrophy of the thenar muscles due to carpal tunnel syndrome (Photo from Comprehensive Clinical Endocrinology, Besser and Thorner, Elsevier).

Neuromuscular

The muscle mass is increased, but this is primarily due to increased intracellular water, so that muscle strength is either normal or low. In fact, many patients have clinically obvious proximal myopathy. Muscle biopsy often shows hypertrophy of type I and/or atrophy of type II fibers. Proximal myopathy may also be accompanied by myalgias, cramps, and nonspecific myopathic changes on electromyography.

Neural enlargement and wrist tissue swelling may lead to carpal tunnel syndrome in up to half of all patients, causing acroparesthesias. Patients may have thenar atrophy (Fig. 3) due the median nerve paresis. Compression neuropathies are common (30–50%), the median nerve being most often affected. Median and ulnar nerve cross-sectional areas increase, and nerve conduction is abnormal (Tagliafico *et al.*, 2008). Occasionally, distal symmetric polyneuropathy may be present. Peripheral acroparesthesias and symmetric peripheral neuropathy should be distinguished from diabetic neuropathy, which may occur secondarily to acromegaly (Jenkins *et al.*, 2000).

Oral cavity and larynx

Prognathism and widening of the interdental spaces are typical signs of acromegaly. The size of the tongue is usually enlarged and contributes to the obstruction of the pharynx, with the resultant sleep apnea and impaired mastication. The abnormal oral anatomy often results in speech disturbances. The diameter of the trachea is increased, and the vocal cords are thickened. Together with grossly enlarged sinus cavities, this results in a low and hollow voice. Salivary glands are typically enlarged.

Joints and spine

Acromegalic arthropathy can affect up to 84% of the cases (depending on the affected joint), especially older patients or females. Both axial and appendicular skeleton may be affected. Carpal tunnel syndrome occurs often bilaterally. Musculoskeletal pain is extremely common in patients with acromegaly and adversely impacts the quality of life (Miller *et al.*, 2008).

GH receptors are present on all major cell types comprising the skeletal system: fibroblasts, chondrocytes, and osteoblasts. These cells readily produce IGF-1 and are targets for both endocrine and autocrine IGF-1 effects (Barkan, 2004). Knees, hips, shoulders, lumbosacral joints, elbows, and ankles are affected as monoarticular or polyarticular arthritis, but joint effusions rarely develop. The degree and severity of arthropathy best correlate with the duration of disease. However, it is unclear whether higher GH levels correlate with increased articular disease activity. Joint pain and low back pain may be experienced soon after the clinical onset of acromegaly but are often reversible with successful therapy. However, clinical duration of acromegaly in excess of 10 years is often associated with clinical and radiological joint deformities that are only minimally affected by GH-lowering therapy. There is a high prevalence of self-reported joint complaints which persist despite successful long-term treatment of acromegaly (Biermasz *et al.*, 2005). These joint problems significantly contribute to the impaired quality of life of patients with acromegaly (Biermasz *et al.*, 2004). Therapeutic responses usually depend on the degree of irreversible bony changes already in place.

The most frequently affected appendicular joint is the knee, followed by the shoulder, hip, ankle, elbow, and small hand joints. Radiological changes are usually seen even in clinically unaffected joints. Initially, GH and IGF-1 excesses are responsible for replication of articular chondrocytes and increased matrix synthesis, growth of periarticular structures and synovial hypertrophy.

Table 1 Reasons for visits to physicians before diagnosis of acromegaly (Ilonka Kreitschmann-Andermahr *et al.*, 2014)

General practitioner (67.5%)
Headache (10.9%)
Changes of hands and feet (7.3%)
Lack of energy (6.7%)
Hypertension (5.5%)
General unwellness (5.5%)
Orthopedist (35.6%)
Troubles with hands and feet (8.5%)
Back pain (7.3%)
Joint pain (7.3%)
Carpal tunnel syndrome (6.7%)
Headache (3%)
Neurologist (27.0%)
Headache (7.9%)
Carpal tunnel syndrome (7.9%)
Depression (1.8%)
Numbness/Tingling (1.8%)
Depression (1.2%)
Endocrinologist (26.4%)
Suspected acromegaly (5.5%)
Hormone investigation (2.4%)
Diabetes (2.4%)
Thyroid disease (2.4%)
Other diagnostics (1.8%)
Internist (23.3%)
Heart disease (4.8%)
Hypertension (3%)
Sleep apnea (2.4%)
Thyroid disease (1.8%)
Lack of energy (1.8%)
Ophtalmologist (22.7%)
Disturbance of vision (10.9%)
Defective vision (10.9%)
Check-up (1.8%)
Headache (1.8%)
Photosensitivity (1.8%)
Dentist (20.9%)
Jaw pain (3%)
Change of bite occlusion (3%)
Enlargement of interdental spaces (3%)
Damaged teeth (3%)
Malposition of teeth (1.8%)
Gynecologist (20.2%)
Menstrual disturbances (10.3%)
Abnormal hair growth (3%)
Menopause (2.4%)
Lactation (1.8%)
Weight gain (1.2%)
Cardiologist (14.7%)
Heart disease (8.5%)
Hypertension (4.8%)
Dermatologist (8.0%)
Abnormal hair growth (2.4%)
Skin changes (2.4%)
Acne (1.2%)
Warts (1.2%)
Neurosurgeon (6.1%)
Carpal tunnel syndrome (2.4%)
Brain tumor (1.8%)
Psychiatrist (4.3%)
Depression (3%)
Anxiety (1.2%)

As a result, there is thickening of the cartilage, widening of the joint space, alteration of normal joint geometry and hypermobility, leading to abnormal mechanical loading of the joint. At this earlier phase of arthropathy the process could be reversible by controlling GH and IGF-1 hypersecretion. With disease progression, cartilage surface fissures develop and progressively enlarge with regenerative fibrous cartilage proliferating disproportionately, more than in osteoarthritis not associated with GH excess, presumably as a result of GH stimulation. The regenerative fibrocartilage frequently becomes calcified, resulting in osteophyte formation. In advanced cases, fissures extend to the subchondral bone, widen, and produce ulceration of the joint cartilage. The underlying bone shows an accelerated turnover, eburnation, and subchondral cyst formation. Finally, the articular cartilage becomes thinned with narrowing of the joint space, a process that shares many features with osteoarthritis. At this phase, arthropathy becomes irreversible and biochemical control of acromegaly, as documented by a normal IGF-1, will have a little effect improving the clinical status (Barkan, 2004; Killinger *et al.*, 2012).

The deformations can also affect the spine resulting in dorsal kyphosis with deformation of rib cage, leading to the classical "punchinello" aspect, especially when GH hypersecretion begins prior to closure of the epiphyses. Lumbar involvement is the most common spine abnormality, followed by thoracic and cervical arthropathy. Overall, approximately 50% of patients complain of back pain and limitation of movements. In early phase of the disease widened intervertebral spaces and vertebral enlargement may be present on spine X-ray (Killinger *et al.*, 2012). Thickened intervertebral discs and lax paraspinal ligaments contribute to abnormal joint mobility. End-stage arthropathy is characterized by the narrowing of the intervertebral space. Ossification of the anterior aspect of the vertebral bodies with exuberant osteophyte formation often bridges the disc space, mimicking diffuse idiopathic skeletal hyperostosis (DISH) (Barkan, 2004).

Bone metabolism

GH has anabolic bone effects so bone mass is usually increased compared to normal subjects (Kaji *et al.*, 2001), unless untreated hypogonadism is also present (Capatina and Wass, 2015). Biochemical markers of bone remodeling are increased in patients with acromegaly. However, histomorphometric data are conflicting; cortical bone shows predominance of bone formation over resorption, whereas trabecular bone has the opposite pattern. As many patients with acromegaly have concomitant hypogonadism, a combination of acromegaly and hypogonadism induced bone changes may be identified.

Bone density studies are equally controversial, but overall it appears that cortical bone mineral density may be normal or even increased, whereas trabecular bone mineral density (BMD) is normal or decreased. Bone density measurements could be influenced by interference of osteophytes. However, a recent meta-analysis of the literature revealed a high risk of vertebral fractures in active acromegaly even in patients with normal BMD regardless of gender suggesting a possible low quality of the bone despite a high bone mass (Mazziotti *et al.*, 2015).

Cardiovascular

Symptomatic cardiac disease is present in about 20% of patients with acromegaly and is a major cause of morbidity and mortality (Colao *et al.*, 1999a). Moreover, increased mortality of untreated or poorly treated acromegaly is almost completely attributable to cardiovascular disease. Early stages of acromegaly, typical of young patients with short disease duration, are characterized by tachycardia and increased systolic output (hyperkinetic syndrome). Arterial hypertension is among the most frequent complications in subjects with acromegaly, present in 36–40% of patients (Mestron *et al.*, 2004; Reid *et al.*, 2010). Left ventricular hypertrophy is observed in half of patients with hypertension and also in about half of normotensive patients with acromegaly. Therefore, the suspicion of acromegaly is sometimes raised by cardiologists.

Valvulopathies and arrhythmias are also more prevalent in these populations (Colao *et al.*, 2004; Pereira *et al.*, 2004) and in approximately 20% of patients the development of hemodynamic abnormalities is augmented by valvular involvement. Rhythm abnormalities, occurring in 40% of patients, are more ominous. Ectopic beats, paroxysmal atrial fibrillation, paroxysmal supraventricular tachycardia, sick sinus syndrome, ventricular tachycardia, and bundle branch blocks all are seen with increased frequencies in patients with acromegaly and are exacerbated by physical exercise. In one study, almost a half of a small cohort of acromegaly patients presented complex ventricular arrhythmias (Lown III–IV), especially those with a long disease duration (Kahaly *et al.*, 1992). A multicentric study performed in Italy using 24-h ECG-Holter monitoring reported a lower but still very significant rate of ventricular extrasystoles (in 33% of the cases with acromegaly evaluated) (Lombardi *et al.*, 2002). 24-h ECG-Holter monitoring might be useful in the preoperative evaluation of the patients, especially those with clinically detected abnormalities (Fedrizzi and Czepielewski, 2008).

If untreated, the presence of these significant morphological and functional changes leads to a complex cardiomyopathy characterized by concentric hypertrophy (predominantly affecting the left ventricle, found hypertrophic in 60% of cases) (Colao *et al.*, 2004), diastolic dysfunction and progressive systolic impairment eventually leading to heart failure (Mosca *et al.*, 2013). Cardiac enlargement may be secondary to hypertension, atherosclerotic disease, or, rarely, to acromegalic cardiomyopathy. Other cardiovascular risk factors such as elevated triglycerides, lipoprotein(a), fibrinogen, plasminogen activator inhibitor, and small dense LDL particles are also often present in acromegaly (Colao *et al.*, 2004). Although the prevalence of coronary artery disease is not clearly increased in these patients and most subjects belong to the low-risk category if assessed with the Framingham score (Bogazzi *et al.*, 2007), aggressive management of all cardiovascular risk factors is indicated. The aim is to reduce the cardiovascular morbidity and mortality (Katznelson *et al.*, 2014). Normalization of GH and IGF-1 can reduce the degree of left ventricular hypertrophy within 2-4 weeks. Disturbingly, biochemical control of acromegaly might not improve conduction abnormalities.

Late ventricular potentials (low-amplitude, high-frequency waves in the terminal phase of QRS complexes) are strong predictors of future arrhythmic events and are seen in 50% of patients with active acromegaly.

Plasma renin levels are suppressed and endogenous plasma digitalis-like activity with chronic volume expansion has been identified in acromegaly (Deray *et al.*, 1987). Renal sodium channel activity is induced by GH at the aldosterone-sensitive distal nephron (Kamenicky *et al.*, 2008).

The presence of cardiovascular disease at the time of diagnosis portends a high risk of mortality despite improved cardiac function after effective GH and IGF-1 control.

Sleep apnea

Sleep apnea has been reported at varying frequencies from 13% to over 50-75% of cases (Capatina and Wass, 2015; van Haute *et al.*, 2008), more frequently in diabetic or hypertensive patients. Most patients have obstructive sleep apnea (mediated by the GH-related soft tissue growth around the upper airways), and a minority of cases have either pure central apnea or mixed apnea (Roemmler *et al.*, 2012). More specifically, in approximately one-third of patients, there is a central component of sleep apnea associated with higher GH and IGF-1 levels.

Prognathism, thick lips, macroglossia, and hypertrophied nasal structures may obstruct airways. Irregular laryngeal mucosa, cartilage hypertrophy, tracheal calcification, and cricoarytenoid joint arthropathy lead to unilateral or bilateral vocal cord fixation or laryngeal stenosis with voice changes. Tracheal intubation may be particularly difficult in patients undergoing anesthesia, and tracheostomy may be required. A suggested predictor of difficult direct laryngoscopy and endotracheal intubation is Mallampati score (Table 2), a high Mallampati score (class 3 or 4) being associated with more difficult intubation as well as a higher incidence of obstructive sleep apnea. Obstructive sleep apnea, characterized by excessive daytime sleepiness, fatigue, habitual excessive snoring and headache with at least five episodes of apnea per hour of sleep, causes daytime somnolence, especially in men with acromegaly who also have a ventilation-perfusion defect with hypoxemia (Melmed *et al.*, 2011). There are several methods for measuring sleepiness, among which the Epworth sleepiness scale is used widely to assess the risk of sleep apnea. The higher the score, the higher the person's level of daytime sleepiness. Sleep apnea is a strong predictor of future cardiovascular events, hypertension, or stroke. Many patients are unaware of their snoring; family members provide markedly more reliable information. However, both subtypes of apnea may be ameliorated by GH-lowering therapy.

Renal

Kidney size and glomerular filtration rate are characteristically increased in acromegaly. GH enhances glomerular filtration through an IGF-1-mediated decrease in renal vascular resistance, leading in turn to increased glomerular perfusion. GH, in concert with IGF-1, stimulates epithelial sodium channel (ENaC)-mediated sodium transport in the late distal nephron, accounting for the pathogenesis of sodium retention when GH/IGF-1 is secreted in excess. Patients with acromegaly frequently have phosphate and calcium abnormalities. Mild hyperphosphatemia due to both increased calcitriol-stimulated dietary phosphate absorption and to a direct anti-phosphaturic action of IGF-1 in the proximal tubule is often seen. There is also a tendency toward increased plasma calcium levels, and hypercalciuria. In these cases PTH should be measured and the diagnosis of MEN1 should be ruled out.

Hypercalciuria may lead to kidney stone formation in approximately 10% of patients.

The hypercalciuria observed in patients with acromegaly is classically related to increased calcitriol-driven intestinal calcium absorption via the intestinal epithelial calcium channel TRPV6. In addition to this absorptive mechanism, increased bone turnover may also participate in hypercalcemia. IGF-1 induced activation of renal epithelial calcium channel TRPV5 results in increased distal calcium reabsorption. Disturbances in calcium and phosphate handling in acromegaly may well contribute to the increased spinal skeletal fragility in acromegaly (Kamenicky *et al.*, 2014). In patients with kidney stones and hyperparathyroidism Multiple Endocrine Neoplasia syndrome type 1 should be considered.

Gastrointestinal

Liver and spleen sizes are normal. Hepatomegaly in patients with acromegaly always should be assumed to result from another disease process and should be investigated. Similarly, the incidence of cholelithiasis is not increased relative to that in the general population. Patients with acromegaly often suffer from constipation due to long and tortuous colon and many years of strain could lead to rectal prolapse. The incidence of colonic polyps appears to be increased (see below).

Metabolic

Acromegaly is frequently associated with impaired glucose tolerance (IGT) and type 2 diabetes mellitus because the GH excess is associated with insulin resistance (in the liver and in periphery), hyperinsulinemia, increased gluconeogenesis, and decreased

Table 2 Mallampati score

Class 0: Ability to see any part of the epiglottis upon mouth opening and tongue protrusion
Class I: full visibility of tonsils, uvula and soft palate
Class II: Soft palate, upper portion of tonsils and uvula visible
Class III: Soft palate and hard palate, base of uvula visible
Class IV: Soft palate not visible at all

peripheral glucose uptake. Diabetes prevalence has been variably reported (reflecting the significant heterogeneity with respect to ethnicity, disease status, age, etc.), but the highest prevalence rates were 40–52% (Biering *et al.*, 2000; Kasayama *et al.*, 2000; Fieffe *et al.*, 2011); similarly, IGT can be found in up to 28–46% of cases The GH-lowering effect of some of the treatment methods used in acromegaly (surgery, pegvisomant) improves the glucose tolerance, while somatostatin analogs may have milder (SSTR2 agonists) or stronger (pasireotide) deleterious effect (Mazziotti *et al.*, 2009). Hyperglycemia was noted in 33 or 31% of patients treated with 40 or 60 mg pasireotide and 14% subjects with SSTR2 agonist, while diabetes was found in 21, 26 and 8%, respectively (Gadelha *et al.*, 2014).

Moderate weight gain may be noted in patients with acromegaly. Other metabolic abnormalities in acromegaly include hypertriglyceridemia, hypercalciuria, and hyperphosphatemia. Hypercalcemia is not a feature of acromegaly per se, and its presence should suggest another pathological process, such as MEN1 syndrome.

Neuropsychiatric

The patients often complain of lethargy and fatigue. Additionally, similar to any chronic disease associated with physical discomfort and lifelong therapy, acromegaly is associated with decreased quality of life. Progressive facial and bodily disfigurement often leads to lowered self-esteem. Depression, apathy and mood swings may occur secondarily to physical deformity (Furman and Ezzat, 1998) or chronic pain from headache or joints.

Neoplasia

Acromegaly has been associated with an increased risk of certain tumors, presumably due to the stimulatory effect of the IGF-1 on tumorigenesis. However, it is challenging to study the incidence of cancer in a population of people with a rare disease.

The best-documented data are those regarding colorectal neoplasia. However, the precise mechanism for the increased risk of colon tumors is not known. Potential mechanisms include direct GH or IGF1 actions on the colonic epithelial cells, altered bile acid secretion pattern, impaired immune response mechanisms in the colon mucosa, and increased colonic length (Renehan *et al.*, 2003). The pooled odds ratio (OR) is increased for both benign tumors (2.48 for adenomas and 3.557 for hyperplastic polyps) and colon cancer (2.04–4.351) (Renehan *et al.*, 2003; Rokkas *et al.*, 2008). The mortality rate for colon cancer is also higher in active acromegaly compared to the general population. The timing of the baseline colonoscopy is still debated. Some only consider it at 50–55 years (Renehan *et al.*, 2001), but even younger patients harbor colonic tumors, so initial colonoscopy at acromegaly diagnosis has been suggested (Terzolo *et al.*, 2005). Repeated colonoscopy every 10 years in controlled acromegaly with a normal initial result and every 5 years in those with benign tumors or uncontrolled disease appears reasonable (Dworakowska *et al.*, 2010).

The risk of thyroid nodular disease and thyroid cancer is also raised in acromegaly, with an OR of 6.9 and 7.5, respectively, and a prevalence of 59 and 4.3% respectively (Wolinski *et al.*, 2014). Whether this reflects a specific effect of the GH/IGF-1 excess or the increased worldwide availability and use of precise diagnostic techniques is controversial. Only a circumstantial relationship between acromegaly and prostate or breast cancer has been described to date. Until large epidemiological studies to clarify this relationship become available, it seems prudent to offer prostate cancer surveillance to older uncontrolled male patients and routine breast cancer prevention in females (Webb *et al.*, 2002).

The analysis of the German Acromegaly Registry did not find higher cancer incidence compared to the general population overall, nor did it suggest higher incidence specifically for colorectal, breast, thyroid, or prostate cancer. There was no correlation between GH levels and cancer (Petroff *et al.*, 2015).

Endocrine complications

About 30% of patients with acromegaly present elevated serum PRL levels (up to 100 $\mu g\,L^{-1}$ or more), with or without galactorrhea (Barkan *et al.*, 1989). Functional pituitary stalk compression by a pituitary mass prevents access of hypothalamic dopamine to the lactotroph, releasing the cell from tonic hypothalamic inhibition. Moreover, a mixed GH-cell and PRL-cell adenomas secrete both GH and PRL. Additionally, the tumor may cause galactorrhea in the face of normal PRL levels because of the agonist effect of

T®	TUMOR	Describe the tumor *(tick the worst choice by default)*	Corresponding score	Score T *from 0 to 5*
		No visible tumor ○ Micro tumor intrasellar < 10 mm ○ Macro tumor intrasellar ≥ 10 mm ○ Extrasellar tumor < 40 mm ○ Invasive tumor ○ Giant tumor ≥ 40 mm ○	T = 0 T = 1 T = 2 T = 3 T = 4 T = 5	T = ____

Fig. 4 SAGIT scoring system to assess disease activity in patients with acromegaly (Giustina *et al.*, 2016).

GH for breast PRL-binding sites. Tumor mass compressing surrounding normal pituitary tissue may also cause hypopituitarism. More than half of all patients have menstrual abnormality or amenorrhea, decreased libido or impotence and secondary thyroid or adrenal failure is present in about 20% of patients (Melmed *et al.*, 2011). Hypogonadism occurs in 60% of female and 46% of male patients and is of multifactorial origin; tumor growth and compression may impair pituitary gonadotropin secretion, and associated hyperprolactinemia or the PRL-like effect of excessive GH secretion may impair gonadotropin and gonadal function. Gynecomastia occurs in about 10% of men. Thyroid dysfunction in acromegaly may be caused by diffuse or nodular, toxic or nontoxic goiter or by Graves' disease, especially because IGF-1 is a major determinant of thyroid cell growth (Kasagi *et al.*, 1999). Associated MEN1 features may be present in affected individuals, including hypercalcemia with hyperparathyroidism or pancreatic tumors. Benign prostatic hypertrophy has been documented in acromegaly with no apparent increase in prostate cancer rates (Melmed *et al.*, 2011; Colao *et al.*, 1999b).

Visceromegaly

Enlarged tongue, bones, salivary glands, thyroid, bowels, heart are the effects of generalized visceromegaly.

Facilitating optimal acromegaly diagnosis and management

The delay in acromegaly diagnosis is a fundamental issue: the longer the delay, the higher the risk of progression, tumor invading the cavernous sinus and therefore being inoperable, the risk of comorbidities and the mortality rate. Great efforts have been made to reduce the time between first symptoms and diagnosis. Currently, it is a commonly accepted opinion that the best strategy to shorten the time to acromegaly diagnosis is to build awareness amongst general practitioners and the specialists who generally take care of the comorbidities associated with the disease (cardiologists, orthopedic physicians, dental practitioners and ophthalmologists, etc., Table 1) so they consider acromegaly as a diagnosis. As part of this strategy, a scoring system (ACROSCORE), focused on the cardinal symptoms and signs of acromegaly (Table 3), has been developed for physicians (Prencipe *et al.*, 2016). Each symptom/sign, if present, is given a rating, and the sum of these ratings determines the final score. ACROSCORE classifies the patient as having a low, medium or high risk of disease suspicion and might become a new tool for GPs and non-endocrinology specialists in the clinical screening for acromegaly, if further validation in a general population suggests its usefulness.

Furthermore, aiming to provide a reference instrument for acromegaly staging in clinical practice, a score system has been developed, SAGIT (Giustina *et al.*, 2016) (Fig. 4). This acronym represents signs and symptoms (S), associated comorbidities (A), GH levels (G), IGF-1 levels (I), and the Tumor profile (T). The higher the number, the more severe the disease. The SAGIT instrument is intended to be used as an instrument offering a standardized classification, with potential for distinguishing clinical stages of acromegaly, assessing treatment response and aid therapeutic decision-making. Future studies are needed to assess its usefulness.

Diagnosis of Acromegaly

I Ilie, Iuliu Hatieganu' University of Medicine and Pharmacy, Cluj Napoca, Romania
M Korbonits, Queen Mary University of London, London, United Kingdom

Clinical Diagnosis

The major challenge in acromegaly is early diagnosis of a disease that develops insidiously. Once the suspicion of acromegaly has been arisen, further assessments can rapidly decide on the diagnosis. What takes a long time is to have the suspicion in the back of the mind of clinicians seeing the patient for various complains related to acromegaly. Clinical assessment and diagnosis of patients with suspected acromegaly should focus particularly on the characteristic symptoms and signs as well as on common complications of acromegaly, as mentioned in the "Clinical features of acromegaly" chapter. A thorough physical examination including detailed observation of the skin, cardiovascular and neurological testing with confrontal visual field assessment is important in the diagnosis of the main symptoms and complications. Description of the past medical history and assessment of previous photographs of the patient can rapidly turn the clinical suspicion to firm clinical diagnosis. Biochemical tests and imaging studies are needed to establish the diagnosis of acromegaly. In addition, syndromic presentation, positive family history and young-onset disease should prompt appropriate genetic testing to identify a possible genetic background of the disease.

Biochemical Diagnosis

GH secretion is pulsatile, with six to ten GH pulses over 24 h separated by long periods of low or virtually undetectable GH levels. While this secretory pattern would suggest that measurement of a random serum GH concentration has little value, in clinical practice morning GH correlates well with overall GH status in the majority of the cases, although this is not used in the diagnosis of acromegaly. Insulin-like growth factor 1 (IGF-1), mediates many of the actions of GH and is considered a marker of integrated GH secretion. Age-related normal range needs to be established for the particular GH assay used, and various factors influencing circulating IGF-1 levels need to be taken into account (Table 1). The biochemical diagnosis of acromegaly requires the confirmation of persistently elevated serum levels of IGF-1. Lack of suppression of GH in response to oral glucose tolerance test (OGTT) (GH $< 1\ \mu g\ L^{-1}$) is diagnostic. Therefore, the biochemical diagnosis is usually straightforward. However, the assessment can be challenging in some cases, such as with mild disease, in teenagers and in pregnancy.

Measurement of IGF-1 Levels

Measuring an IGF-1 level is recommended as the initial screen for patients with clinical suspicion of acromegaly, in cases with pituitary masses and in selected patients where suspicion of acromegaly is instigated by combination of several comorbidities commonly present in acromegaly (Katznelson *et al.*, 2014a).

Serum IGF-1 levels are invariably elevated in active acromegaly, are stable during the day (its half-life is approximately 15 hours), independent of food intake, and correlate well with the GH levels.

IGF-1 levels peak at adolescence and are lower before and after puberty. Therefore, all levels must be assessed in relationship to age-matched normal values (adults) or age- and sex-matched levels (children and adolescents) for the specific assay being used. There is significant inter-assay variability for measurement of IGF-1 that needs to be taken into account if values are assessed by different laboratories (Bidlingmaier *et al.*, 2014; Frystyk *et al.*, 2010). In fact, the diagnosis of acromegaly was inaccurately excluded in 30% of single samples assayed for IGF-1 in 23 different laboratories (Pokrajac *et al.*, 2007). Active acromegaly is associated with elevated IGF-1 levels compared to normal subjects, so an age-matched normal IGF-1 excludes the diagnosis in most patients (Katznelson *et al.*, 2014a). However, certain pathological conditions (Table 1), apart from assay variability or inaccurate reference ranges (Pokrajac *et al.*, 2007), can lead to false negative results, especially in mild cases. Systemic illnesses, severe infection, hepatic or renal failure, malnutrition, diabetes mellitus and oral estrogens (which may render the liver less responsive to GH) may decrease IGF-1 levels which might result in false-negative interpretations (Katznelson *et al.*, 2011; Isotton *et al.*, 2012). Elevated IGF-1 levels during pregnancy and the wide normal range in adolescence may render the diagnosis of acromegaly difficult.

Moreover, in patients with acromegaly and poorly controlled diabetes mellitus, the OGTT is also not reliable and serum IGF-I levels should be re-assessed when glycemic control has been established (Muhammad *et al.*, 2015).

This chapter is based on the chapter by Prof Klaus von Weder (von Werder K. diagnosis of Acromegaly. In Encyclopedia of Endocrine Diseases. Elsevier Inc 2004;1).

Table 1 Factors affecting IGF-1 and GH

Factors interfering with IGF-1 concentration
Low IGF-1
● Poorly controlled diabetes mellitus
● Liver or renal failure
● Exogenous estrogen
● Malnourishment
● Systemic illness
High IGF-1
● Adolescence/puberty
● Pregnancy
● Hyperthyroidism (note: acromegaly can be associated with hyperthyroidism due to goiter or due to TSH co-secretion)
High GH and low IGF-1
● Kidney failure: GH ↑ or ↔, IGF-1 ↓
● Liver failure - GH↑, IGF-1↓
● Anorexia nervosa GH ↑, IGF-1↓
● GH insensitivity - GH↑, IGF-1↓
False-positive oral glucose challenge
● Diabetes mellitus
● Liver disease
● Renal insufficiency
● Malnutrition
● Adolescence
● Women receiving estrogen or pregnant

Measurement of Growth Hormone Levels

Although an elevated random GH level in a patient with suspicious clinical features is suggestive of acromegaly, random serum GH is more used for follow-up of patients after treatment rather than for diagnosis. Random serum GH level $<0.4\ \mu g\ L^{-1}$, on the other hand, is very suggestive of lack of acromegaly, especially with corresponding normal IGF-1 (Giustina *et al.*, 2000; Giustina *et al.*, 2010).

The serum GH concentration measured during an OGTT (with 75 g of oral glucose) is the gold-standard diagnostic test and should be used to confirm the diagnosis. In acromegaly, GH levels may decrease, increase, or show no change in response to glucose load; however, they do not decrease to less than $1\ \mu g\ L^{-1}$ and this lack of suppression establishes the diagnosis (Dimaraki *et al.*, 2002).

The cutoff for nadir GH during OGTT is highly dependent on the assay used.

A nadir serum GH $<0.4\ \mu g\ L^{-1}$ after an oral glucose load has been considered for establishing the diagnosis (Freda *et al.*, 2003). However, although current GH assays have improved sensitivity, many assays do not have sufficient accuracy at GH levels $<1\ \mu g\ L^{-1}$, and it has been suggested that a cutoff GH $<1\ \mu g\ L^{-1}$ after the glucose load is sufficient for excluding the diagnosis (Katznelson *et al.*, 2014b). On the other hand, it should always be remembered that using this cutoff could lead to the inaccurate exclusion of the diagnosis in a significant percentage of cases (25%) (Giustina *et al.*, 2010) with mild active disease, since significant GH suppression during OGTT, as low as $0.33\ \mu g\ L^{-1}$ was noted in some cases of active mild acromegaly (Dimaraki *et al.*, 2002; Freda *et al.*, 2003; Freda *et al.*, 1998), these cases sometimes mentioned as "micromegaly".

Increasing age, female gender, obesity, and elevated body mass index may be associated with abnormal post-glucose GH suppression, and there is a need to define normal ranges for these variables (Arafat *et al.*, 2008; Carmichael *et al.*, 2009).

Accurate measurement of GH and IGF-I is important for the diagnosis and monitoring of acromegaly. Despite the use of international reference preparations of GH, the commercially available immunoassays produce heterogeneous values. We face a lack of uniform assay standardization, poor reproducibility between laboratories and assays, imprecise standards, and there is also a lack of robust normal control values using sensitive immunometric assays (Clemmons, 2011). In an illustrative paper, the same GH sample was measured in 104 centers across the UK using different assays (Pokrajac *et al.*, 2007). The results varied more than threefold for GH. Even when using the same automated immunoassay, significant intra-individual variability still existed.

Another test to assess GH burden is a GH day curve (GHDC), which significantly correlates with the GH nadir during OGTT and with the IGF-1 level (Dobrashian *et al.*, 1993; Minuto *et al.*, 2012). In normal subjects, at least one GH value is usually undetectable over repeated sampling during the day. In active acromegaly, nadir GH levels during a GHDC do not suppress below $1\ \mu g\ L^{-1}$(Ho and Weissberger, 1994). As a research tool mean integrated 24-h levels can also be used being significantly elevated in active acromegaly. Barkan *et al.* evaluated the correlation between plasma IGF-1 and the degree of GH hypersecretion assessed by multiple GH determinations throughout a 24-h period before and during therapy with a long acting somatostatin analog. They noted that when mean plasma GH was higher than $12.0 \pm 0.6\ \mu g\ L^{-1}$, plasma IGF-1 concentrations plateaued, whereas below this

GH value it was accompanied by a linear decrease in IGF-1 levels (Barkan *et al.*, 1988). In addition, there was also a lack of correlation between GH and IGF-1 in patients with high IGF-1 and clinical acromegaly but low (<1 μg L^{-1}) nadir GH on OGTT. These data suggest that while GH and IGF-1 change in a linear fashion in the mid-range of GH values, at high GH (>12 on integrated GH values (Barkan *et al.*, 1988)) and low GH (<1 μg L^{-1} on OGTT) GH and IGF-1 do not change in a linear fashion (Dimaraki *et al.*, 2002; Ribeiro-Oliveira *et al.*, 2011).

Further complicating the diagnosis in cases with mildly active disease (who could derive a great benefit from an early diagnosis and treatment) are the frequent (around 30% of cases) discrepancies between the GH and IGF-1 hypersecretion (Capatina & Wass, 2015). A finding of an elevated IGF-1 with normal GH values needs to be interpreted based on the clinical findings because this may reflect earlier disease (Dimaraki *et al.*, 2002) and usually should prompt a thorough investigation (including imaging) to clarify the diagnosis. (Fig. 1)

IGFBP3

The major binding protein of IGF-1, IGFBP3 is not useful for diagnosis or treatment follow-up of patients with acromegaly as significant overlap occurs between normal controls and patients (Wass, 1997).

Measurement of other anterior pituitary hormones in patients with acromegaly

Patients with suspected acromegaly should have a full pituitary workup. Hyperprolactinemia is common either due to prolactin co-secretion (up to 1/3 of patients) or due to the stalk effect. PRL levels higher than 200 μg L^{-1} are usually indicative of a co-secreting adenoma. GH can also be co-secreted with TSH, with symptomatic secondary hyperthyroidism. Large tumor mass or prolactin hypersecretion can lead to the hypofunction of the adrenal, thyroid or gonadal axes.

Assessment of complications and related issues

Electrocardiogram and echocardiography could inform of the degree of the cardiac involvement (Katznelson *et al.*, 2011). X-ray of the spine and bone density measurement, especially with history of hypogonadism, informs of spine abnormalities (Wassenaar

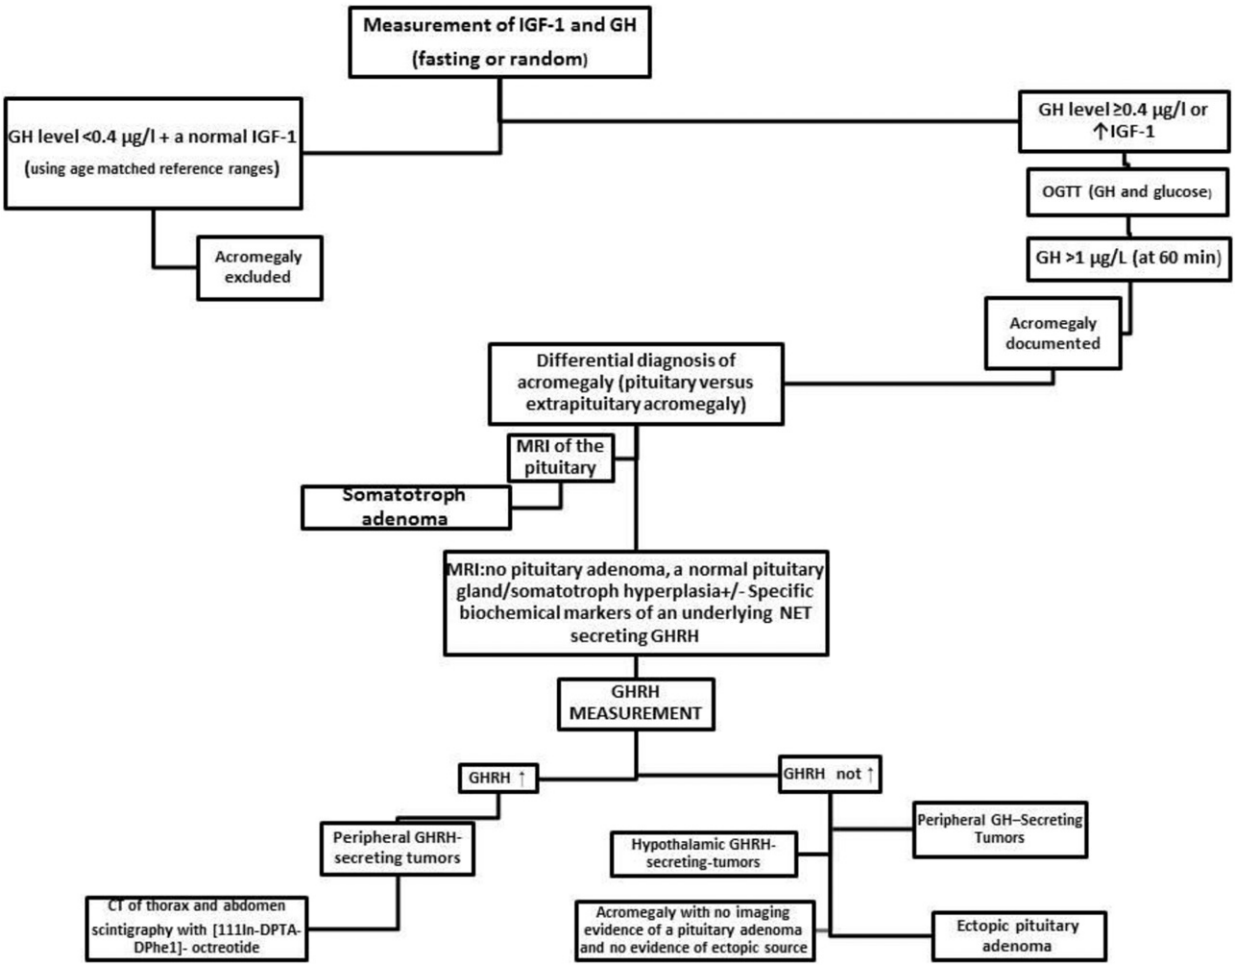

Fig. 1 Algorithm for the diagnostic workup in acromegaly

et al., 2011; Claessen *et al.*, 2013) and abnormal bone density. In young patients bone age assessment and follow-up of height velocity is necessary, and some of these patients need rapid intervention. Assessment of painful joints could be necessary. Presence of sleep apnea should be investigated and finding of hypercalcemia should prompt for search for MEN1 syndrome. Syndromic presentation, childhood-onset disease and positive family history for pituitary adenomas should prompt genetic assessment.

Neuroradiological and Neuro-Ophtalmological Investigations

Following biochemical diagnosis of acromegaly, a contrast-enhanced T1 and T2 pituitary MRI is recommended with thin slices as the imaging modality of choice to identify a pituitary adenoma. This will assist to establish tumor size and appearance, as well as parasellar extension. High-resolution T1-weighted sections in the coronal and sagittal planes, obtained both before and after gadolinium pentetic acid contrast administration, are the mainstay of pituitary imaging and will identify most pituitary masses causing acromegaly. After administration of gadolinium, microadenomas usually appear hypodense compared with the normal gland, especially when multiple thin-section echo sequences are examined during the first few minutes after contrast injection. In contrast, macroadenomas, which are significantly more vascular than microadenomas, have a higher affinity for gadolinium. They often enlarge the sella turcica by remodeling the bony fossa; they can grow upward toward the optic apparatus and cause draping of the nerves over the tumor, but especially somatotroph adenomas often go downwards and can extend into the sphenoid sinus. Invasion of the cavernous sinuses are significant as can hinder total tumor removal (Nishioka *et al.*, 2014).

Coronal T2 weighted sequences can also provide added information. It has been suggested that the signal characteristics of GH-secreting adenomas on T2 weighted sequences, whether they are of lower or higher signal than the adjacent grey matter (Heck *et al.*, 2012) or the adjacent normal pituitary (Potorac *et al.*, 2015), can be an indicator of their histological composition: densely granulated GH-secreting adenomas are typically hypointense, whilst sparsely granulated GH-secreting adenomas are hyperintense. Furthermore, it has been described that the low T2 signal (densely granulated) adenomas are seemingly responding better to somatostatin analogues (Fougner *et al.*, 2012).CT does not provide such excellent soft tissue resolution as MR but can be a very useful investigation if MR is contraindicated.

More than 99% of patients with acromegaly harbor a GH secreting pituitary adenoma. However, in rare circumstances, patients with acromegaly may not have imaging evidence of a pituitary adenoma and an ectopic source should be ruled out. Management of these patients poses special challenge, and once ectopic source of GH/GHRH is ruled out, surgical exploration of pituitary might be useful (Khandelwal *et al.*, 2011; Daud *et al.*, 2011; Lonser *et al.*, 2010).

While confrontal visual field testing is part of the physical examination, formal visual field testing should be performed when the tumor is found to abut the optic chiasm on an imaging study.

Special considerations

Diagnosis of Gigantism

Pituitary gigantism is usually a spectacular disorder, although delayed diagnosis is still well-described in this patient group. Pituitary gigantism should be considered in children who are more than 3 standard deviations above normal mean height for age or more than 2 standard deviations over their adjusted mean parental height. The biochemical diagnosis is similar to that for acromegaly: GH levels are in excess of 1 $\mu g\ L^{-1}$ after a glucose load, and age-adjusted IGF-1 concentrations are elevated. However, in healthy children undergoing pubertal growth spurts, GH suppression to glucose could be lacking in upto 1/3 of tall pubertal children (Holl *et al.*, 1999) and GH can even paradoxically rise after glucose (Hindmarsh *et al.*, 1986). Serum IGF-1 concentrations are often physiologically elevated and they must be interpreted with an age- and sex-specific reference range (Holl *et al.*, 1999; Davies & Cheetham, 2014). Therefore, the diagnosis requires clear-cut MRI evidence for a pituitary lesion.

Acromegaly in pregnancy

An initial diagnosis of acromegaly during pregnancy could be problematic due to placental secretion of GH that binds to GH receptors increasing IGF-1 secretion by $>30\%$ over pre-pregnancy levels as well as to marked alteration of GH response to suppressive testing. Pregnancy is associated with a pseudo-acromegaloid state, because of production of placental GH (GH-2 or GH-V) from syncytiotrophoblast. Placental GH binds to hepatic GH receptor stimulating IGF-1 production, which on its turn decreases pituitary GH production. If GH-like activity is measured during pregnancy, only 3% of the activity is explained by maternal GH and 12% by placental lactogen. There is a decrease in the number of somatotroph cells during pregnancy, resulting in decreased circulating pituitary GH levels. Maternal levels of IGF-1 are slightly elevated. A lack of GH suppression to oral glucose challenge would be expected during pregnancy, since estrogen facilitates GH secretion (Cheng *et al.*, 2012). However, high levels of estrogen block the normal stimulation of IGF-1 production by GH (Laway & Mir, 2013).

GHRH-induced or ectopic GH excess

In more than 99% of cases, acromegaly is due to a GH-secreting pituitary adenoma (Fig. 2).

GHRH Hypersecretion

Neuroendocrine tumors, usually located in the lungs, endocrine pancreas (often associated with MEN1 syndrome) or thymus can secrete GH-releasing hormone (GHRH), but rarely phaeochromocytoma (Vieira Neto *et al.*, 2007) or paraganglioma (Ghazi *et al.*, 2013) could also be the source (Fig. 2).

GHRH secretion is responsible for 0.5% of all cases of acromegaly (Losa & von Werder, 1997). In the rare situation where a non-pituitary etiology is suspected, the serum GHRH level should be measured. Plasma GHRH levels are usually elevated in patients with peripheral GHRH-secreting tumors, and are normal or low in patients with pituitary acromegaly (Gola *et al.*, 2006). Measuring GHRH plasma levels therefore provides a precise and cost effective test for the diagnosis of ectopic acromegaly. In case of GHRH-related acromegaly, the pituitary gland may appear normal or slightly bulky on MRI. Elevated levels of other hormones usually secreted from neuroendocrine tumors of the pancreas, such as insulin, calcitonin, gastrin, chromogranin could draw attention to ectopic GHRH-secreting tumors. Somatostatin receptor scintigraphy and PET scanning could be helpful to identify the source of the ectopic hormone secretion. The diagnosis of MEN1 should be considered. CT scan of the thorax and abdomen could be used to identify a neuroendocrine tumor (Gola *et al.*, 2006).

Rarely, hypothalamic tumors, including hamartomas, choristomas, gliomas, and gangliocytomas, may produce GHRH with subsequent somatotroph hyperplasia or even a pituitary GH-cell adenoma and resultant acromegaly (Sano *et al.*, 1988) (Fig. 2). Peripheral GHRH levels are not elevated in patients with hypothalamic GHRH-secreting-tumors, supporting the notion that excess eutopic hypothalamic GHRH secretion into the hypophyseal portal system does not appreciably enter the systemic circulation.

GH excess originating from outside the pituitary fossa

Ectopic acromegaly due to a GH-secreting adenoma arising from abnormally located pituitary tissue is a rare entity. The most frequent localization for these ectopic tumors has been the sphenoid sinus, followed by the clivus and isolated cases of tumors in the cavernous sinus or the suprasellar region (Ramirez *et al.*, 2013; Appel *et al.*, 2012; Gondim *et al.*, 2004; Warner *et al.*, 1982; Guerrero *et al.*, 2007).

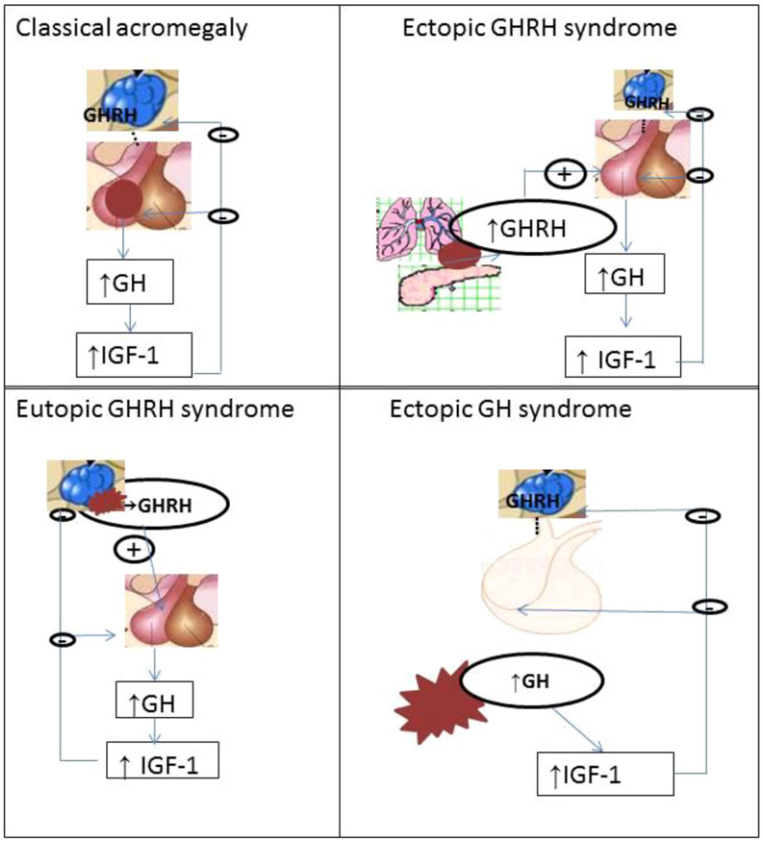

Fig. 2 Pituitary acromegaly (over 99% of cases) versus extrapituitary acromegaly: peripheral GHRH-secreting tumors (ectopic GHRH syndrome), hypothalamic GHRH-secreting-tumors (eutopic GHRH syndrome) and ectopic GH syndrome, respectively.

Table 2 Genetic alterations leading to GH excess

Syndromic disease	*Isolated GH-secreting pituitary adenoma*
MEN1 syndrome (*MEN1*)	FIPA (*AIP*)
MEN4 syndrome (*CDKN1B*)	FIPA – X-linked acrogigantism (XLAG) (*GPR101*)
SDHx (*SDHA*, *SDHB*, *SDHC*, *SDHD*)	Unknown gene(s)
Carney complex (*PRKAR1A*, *PRKACB*)	
McCune–Albright syndrome (mosaic *GNAS*)	
Neurofibromatosis (very rare (Crawford & Buckler, 1983; Drimmie *et al.*, 2000)) (*NF1*)	
Von Hippel–Lindau syndrome (single case report (Tudorancea *et al.*, 2012)) (*VHL*)	

Cases of GH secretion from non-pituitary tissue are exceptionally rare (Fig. 2). Two cases have been described: one with GH secretion from a pancreatic cancer and the other in a patient with non-Hodgkin lymphoma (Werder., 2004). Elevated GH and IGF-1 levels with no evidence of a pituitary lesion (either adenoma or somatotroph hyperplasia), and normal GHRH levels could suggest the diagnosis, but XLAG needs to be considered in very young patients.

Acromegaly due to genetic predisposition

Acromegaly is the most common type of pituitary adenoma associated with a genetic abnormality. Predisposing factors include mutations causing syndromic diseases (Table 2) or isolated pituitary adenomas. Family history may not be positive due to low penetrance, such as in AIP mutation kindreds, or due to *de novo* mutations (often in XLAG).

Abbreviations

ACTH	Adrenocorticotropin
CSF	Cerebrospinal fluid
DA	Dopamine agonist
FSH	Follicle-stimulating hormone
GH	Growth hormone
IGF-I	Insulin-like growth factor-I
LH	Luteinizing hormone
MRI	Magnetic resonance imaging
PRL	Prolactin
SA	Somatostatin analogs
SMR	Standardized mortality ratio
Sst	Receptors subtypes
TSH	Thyroid-stimulating hormone

Acromegaly is a rare disease characterized by progressive somatic modifications, mainly involving the face and extremities, together with systemic manifestations related to organ overgrowth and fluid retention. Acromegaly is associated with severe comorbidity and premature death if not adequately treated. It is due to excessive secretion of growth hormone (GH), originating from a pituitary adenoma in the vast majority of cases and stimulating production of insulin-like growth factor-I (IGF-I). Management of acromegaly is now rather consensual (Ribeiro-Oliveira and Barkan, 2012; Chanson and Kamenicky, 2012; Sherlock *et al.*, 2011; Giustina *et al.*, 2010, 2014; Melmed, 2009; Katznelson *et al.*, 2014). If surgical removal of the pituitary GH-secreting adenoma is usually the first line therapy, it is able to cure the disease only in microadenomas or small non invasive macroadenomas. In the other cases persistent postoperative GH/IGF-I hypersecretion needs to be treated with medical therapy, which is now generally preferred to radiation therapy for second line treatment. The various therapeutic options are presented on **Fig. 1**.

Objectives of Treatment

Clinical Aims

The clinical aims are to relieve symptoms, to reduce the volume of the pituitary tumor, to avoid tumor relapse, and to improve long-term morbidity and mortality (Melmed *et al.*, 2002).

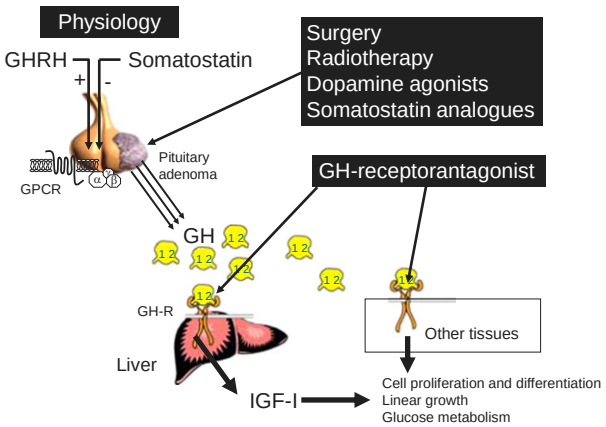

Fig. 1 Therapeutic options in acromegaly. Site of action of the different therapeutic tools in acromegaly. Surgery, radiotherapy, somatostatin analogs and dopamine agonists act at the level of the pituitary adenoma, while GH-receptor antagonists act in the periphery by blocking the GH receptor and thus impairing the effects of GH on the different tissues. Biochemical Criteria of Successful Treatment

The 2000 consensus on the definition of acromegaly cure

More than 15 years ago, an expert consensus group considered that control of acromegaly was achieved when, biochemically, circulating IGF-I levels are reduced to the age-adjusted normal range and when the nadir GH level after an oral glucose load is less than 1 $\mu g\ L^{-1}$ (Giustina *et al.*, 2000). However, many endocrinologists preferred to assess "random" GH levels, particularly in therapeutic trials using somatostatin analogs (SA), as criterion of disease control. Level of 2 or 2.5 $\mu g\ L^{-1}$ to define disease control were chosen with regard to earlier epidemiological studies linking mortality to GH serum levels, and because the majority of patients reaching these levels also have normal IGF-I levels (Freda *et al.*, 2005; Chanson *et al.*, 2009b; Sherlock *et al.*, 2011). A meta-analysis of all published studies providing estimates of mortality, published in 2008 (Holdaway *et al.*, 2008), confirmed the prognostic relevance of this cutoff (GH $<2.5\ \mu g\ L^{-1}$), as mortality among patients with a final GH level below 2.5 $\mu g\ L^{-1}$ was very close to that expected in the general population, while a final GH level above 2.5 $\mu g\ L^{-1}$ was associated with a 1.7-fold excess risk of death. The same was true for IGF-I, final normal IGF-I being associated with absence of excess mortality while a 2.5-fold mortality risk was found for patients with final IGF-1 levels above the age-adjusted normal range (**Fig. 2**).

However, one of the main drawbacks of former epidemiological studies is that they were based on old radio-immunoassays for serum GH measurement. Modern assays (two-site antibody "sandwich" methods), have better sensitivity (Cazabat *et al.*, 2008). European experts, followed by a larger international consensus group, recommended the use of the World Health Organization (WHO) international standard (WHO IS 98/574 for GH and WHO IS 02/254 for IGF-I) (Trainer *et al.*, 2006; Clemmons, 2011).

The 2010 and 2014 consensus on the definition of acromegaly cure

A subsequent expert consensus meeting (Giustina *et al.*, 2010) defined optimal disease control (i.e., posttreatment remission of acromegaly) as follows: "an IGF-I level (determined by a reliable standardized assay) in the age-adjusted normal range and a GH level less than 1.0 $\mu g\ L^{-1}$ from a random GH measurement (using an ultrasensitive assay). Normalization of IGF-I is the only reliable marker of disease control under pegvisomant. In patients with acromegaly undergoing surgical management of GH-secreting tumors, OGTT can be used to assess the outcome. There is substantial evidence to suggest that nadir GH levels less than 0.4 $\mu g\ L^{-1}$ (with ultrasensitive assays) may define control in these circumstances. In the case of discrepant biochemical results, multiple GH sampling may be useful."

The Endocrine Society Clinical Practice Guideline proposed by a Task Force sponsored by the Endocrine Society and the European Society of Endocrinology (Katznelson *et al.*, 2014) also suggests "a biochemical target goal of an age-normalized serum IGF-1 value, which signifies control of acromegaly" and "using a random GH $<1.0\ \mu g\ L^{-1}$ as a therapeutic goal, as this correlates with control of acromegaly."

Surgical Treatment

Surgery Aims to Reduce Mass Effects

Surgery is generally the first-line treatment, as tumor excision, usually by the trans-sphenoidal route, is the most rapid way of reducing tumor symptoms, particularly visual defects. However, it must be acknowledged that it may be possible to reduce the

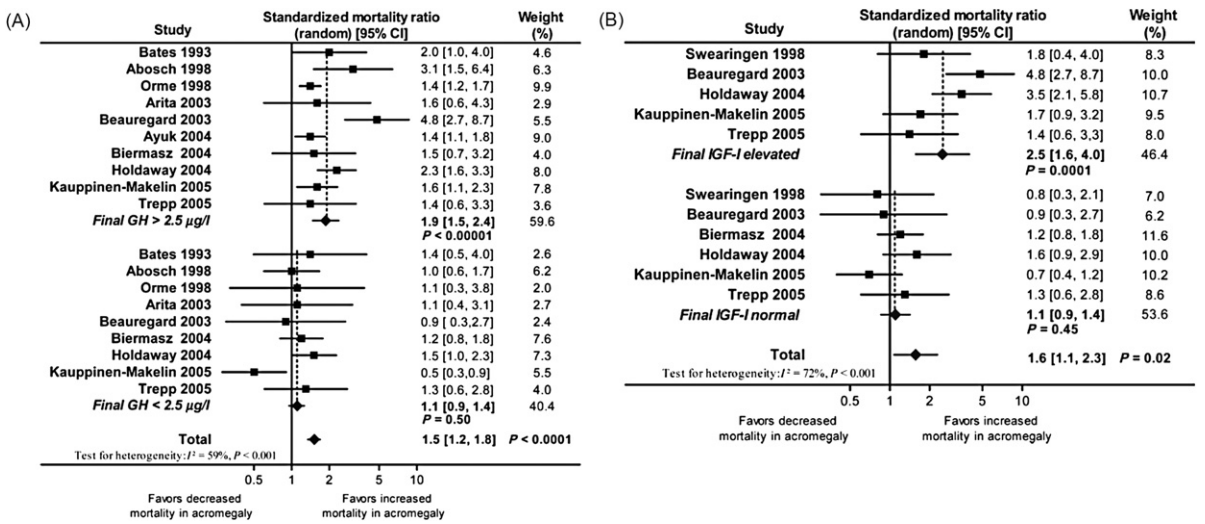

Fig. 2 Pooled standardized mortality ratios (SMRs) in studies of acromegaly grouped according to GH (A) or to IGF-I (B) level at final follow-up. Data are SMR (95% confidence interval). Reproduced with permission from Holdaway, I. M., Bolland, M. J. and Gamble, G. D. (2008). A meta-analysis of the effect of lowering serum levels of GH and IGF-I on mortality in acromegaly. *European Journal of Endocrinology* **159**, 89–95.

tumor volume by medical treatment with SA, particularly when the tumor is distant from the optic chiasm (see the paragraph "SA as first-line treatment").

Before initiating treatment, patients with acromegaly must undergo a workup focusing on tumor mass effects (headaches, visual field and acuity, magnetic resonance imaging, MRI). This will guide therapeutic decisions, particularly the use of surgery. The mass effect of the tumor can also affect other pituitary functions, and other pituitary hormones should thus be measured to determine if they are deficient or, on the contrary, secreted in excess. Another aim of surgical treatment, besides the control of GH/IGF-I levels, is to improve hormone deficiencies or PRL hypersecretion related to mass effects on the normal pituitary or the pituitary stalk. Indeed, hyperprolactinemia is present in 10%–30% of patients, and may be either functional (secondary to impaired hypothalamic dopamine production or tumor compression of the pituitary stalk, hindering dopamine delivery to the pituitary) or due to a mixed adenoma (Grynberg *et al.*, 2010; Petrossians *et al.*, 2017).

Surgery Aims to Reduce/Normalize Serum GH/IGF-I Levels

Tumor resection, usually by the trans-sphenoidal route, is also the most rapid way of reducing GH and IGF-I concentrations in patients with acromegaly. Percent reduction of GH levels (but not of IGF-I levels) correlates closely with percent resected tumor volume (Schwyzer *et al.*, 2015). Nevertheless, GH and IGF-I levels normalize in only 40%–70% of cases (Fahlbusch *et al.*, 1992; Swearingen *et al.*, 1998; Biermasz *et al.*, 2000; Nomikos *et al.*, 2005, Jane *et al.*, 2011; Roelfsema *et al.*, 2012; Abu Dabrh *et al.*, 2014), depending on the size of the tumor (microadenomas are more amenable to cure), the preoperative GH concentration (the success rate is higher when GH concentrations are low, i.e., $<10\ \mu g\ L^{-1}$), the length of follow up and the surgeon's experience. After true surgical cure, true recurrence of acromegaly is very rare, $<5\%$ (Roelfsema *et al.*, 2012). When surgery fails to achieve good disease control, or when surgery is impossible or contraindicated, patients are now generally offered medical treatments (Katznelson *et al.*, 2014; Giustina *et al.*, 2014).

Adverse Effects of Surgery

Surgical removal of pituitary adenomas can occasionally have severe adverse effects such as cerebrospinal fluid (CSF) leak with a risk of meningitis or epistaxis in fewer than 5% of patients. In a meta-analysis of 92 studies enrolling 6988 patients, Carvalho *et al.* found weighted incidence rates of 13% for hypopituitarism, 2.5% for panhypopituitarism, 6.5% for ACTH deficiency, 4.4% for TSH deficiency, 6.7% for FSH/LH deficiency, 10% for transient and 2.4% for permanent diabetes insipidus (Carvalho *et al.*, 2015). Endoscopic surgery does not markedly improve these rates compared with microscopic series (Jane *et al.*, 2011). If pituitary functions are deficient, the aim of replacement therapy, is to achieve euthyroidism, eucortisolism, and eugonadism (Fleseriu *et al.*, 2016; Higham *et al.*, 2016). A major determinant of the rate of surgical complications is the neurosurgeon's experience (Ahmed *et al.*, 1999; Bates *et al.*, 2008). Thus, when surgery is indicated, one precondition is to find a good surgeon!

Medical Treatment

Dopamine Agonists (DAs)

Dopamine receptors

Physiologically, dopamine stimulates GH secretion (Giustina and Veldhuis, 1998), but DAs paradoxically suppress GH hypersecretion in patients with acromegaly (Chiodini *et al.*, 1974). Dopamine binding sites were found on the surface of GH-secreting adenomas (Bression *et al.*, 1982), and expression of dopamine type 2 (D2) receptor (D2R), the predominant DR subtype in somatotropinomas, has later been confirmed (Stefaneanu *et al.*, 2001; Missale *et al.*, 1998; Neto *et al.*, 2009). D2 receptors and type 5 somatostatin receptors (SSTR5) can heterodimerize, thus enhancing the functional activity of both agonists (Rocheville *et al.*, 2000).

Cabergoline is now the most used DA

DAs were the first drugs to be used in acromegaly. Bromocriptine moderately attenuates the symptoms of acromegaly and reduces the GH concentration, but it normalizes the IGF-I level in only some 10% of patients (Jaffe and Barkan, 1992). Cabergoline is an ergot derivative which is more selective for D2R and with a long duration of action allowing once- or twice-weekly administration. Cabergoline has been used for more than three decades in the treatment of hyperprolactinemia (Gillam *et al.*, 2006). It was also tested in acromegaly (Kuhn and Chanson, 2017) but its potential value was overshadowed by the advent of SAs such as octreotide and lanreotide. Marketing authorization has never been sought for cabergoline in this indication, meaning that the drug is used off-label in acromegaly.

A systematic review, in 2011, of clinical trials using cabergoline in acromegaly showed that available studies were generally small, non randomized or placebo-controlled and their results variable (Abs *et al.*, 1998; Colao *et al.*, 1997b; Cozzi *et al.*, 1998; Ferrari *et al.*, 1988; Freda *et al.*, 2004; Jackson *et al.*, 1997; Moyes *et al.*, 2008; Muratori *et al.*, 1997; Sherlock *et al.*, 2009; Vilar *et al.*, 2002). The meta-analysis (Sandret *et al.*, 2011) of cabergoline monotherapy in a total of 149 patients showed that 48% and 34% of patients achieved a GH level below $2.5\ \mu g\ L^{-1}$ and a normal serum IGF-I level, respectively (**Fig. 3**). In multivariate analysis, the

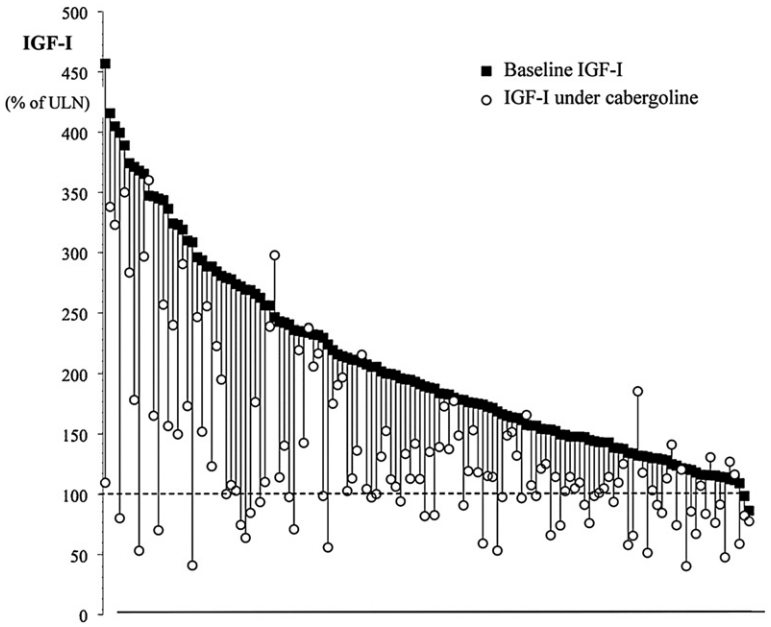

Fig. 3 Individual IGF-I levels, expressed as a percentage of the upper limit of the age-adjusted normal range (ULN) before (*black squares*) and after treatment with cabergoline (*open circles*) in patients with acromegaly. Data from a meta-analysis. Reproduced with permission from Sandret, L., Maison, P. and Chanson, P. (2011). Place of cabergoline in acromegaly: A meta-analysis. *Journal of Clinical Endocrinology and Metabolism*, **96**, 1327–1335.

decline in IGF-I was related to the baseline IGF-I concentration and to the baseline PRL concentration and a trend towards a relationship with the cabergoline dose was also found (Sandret *et al.*, 2011). A retrospective study of patients enrolled in the UK Acromegaly Register published after the meta-analysis confirmed these results (Howlett *et al.*, 2013).

The effect of cabergoline on tumor volume was examined prospectively in only five studies (Ferrari *et al.*, 1988; Jackson *et al.*, 1997; Colao *et al.*, 1997b; Muratori *et al.*, 1997; Abs *et al.*, 1998. On monotherapy, tumor shrinkage was observed in about one third of patients (Sandret, 2011). Tumor shrinkage was linked to a higher baseline PRL concentration, a higher baseline IGF-I concentration, and prior treatment status. The study population was too small for multivariate analysis.

Thus, cabergoline is mainly recommended for patients with borderline or moderately increased plasma IGF-I levels (< 150% X the upper limit of normal) (Giustina *et al.*, 2014; Katznelson *et al.*, 2014), even though it is sometimes effective (leading to normal IGF-I levels) in patients with high baseline IGF-1 levels (**Fig. 3**) and also in patients with normal PRL levels (Sandret *et al.*, 2011).

Adverse effects

The adverse effects of carbergoline are rare, usually mild, and include nausea, headache, constipation, postural hypotension, dizziness, nasal stuffiness, and Raynaud's phenomenon. They tend to occur after the initial dose and at each dose increment, but can be minimized by initiating the drug at a low dose at bedtime, and then escalating dosage very progressively. Symptoms of psychosis (or exacerbation of pre-existing psychosis) (Boyd, 1995) and impulse control disorders (such as pathological gambling, hypersexuality, compulsive shopping or eating) have been observed under bromocriptine and cabergoline in patients with prolactinomas (Bancos *et al.*, 2014; Noronha *et al.*, 2016; Barake *et al.*, 2014; Moore *et al.*, 2014). These reactions usually resolve within 72 h of drug interruption.

Mixed GH-PRL secreting adenomas or mammosomatotroph adenomas treated with cabergoline may shrink and, rarely be complicated by CSF leak (Lam *et al.*, 2012; Thakur *et al.*, 2011).

The use of very high doses of DAs, and particularly cabergoline, in patients with Parkinson's disease has been linked to an increased risk of cardiac valve disease (Schade *et al.*, 2007; Zanettini *et al.*, 2007). Since these publications, several retrospective cross-sectional studies have focused on cardiac complications in patients treated with cabergoline for prolactinoma: in fact, this occurrence seems extremely rare as a maximal prevalence of 0.17% patients with typical cabergoline-associated valvulopathy was found on more than 1800 patients reviewed (Caputo *et al.*, 2015). The same concern has been raised regarding the use of cabergoline in acromegaly, particularly as acromegaly itself is associated with an increased prevalence of cardiac valve disease (Colao *et al.*, 2003, 2008; Pereira *et al.*, 2004; van der Klaauw *et al.*, 2006). Data on cardiac valve status in acromegalic patients treated with cabergoline are scarce (Lafeber *et al.*, 2010; Izgi *et al.*, 2010). Cardiac valve status was studied in a large population of cabergoline-treated patients with acromegaly (Maione *et al.*, 2012). The cross-sectional study (42 patients who had received cabergoline at a median cumulative dose of 203 mg for a median of 35 months, compared to 46 acromegalic patients who had never received cabergoline and who were matched for age, sex and disease duration) and the longitudinal study (26 patients studied before and during cabergoline treatment, compared with a group of acromegalic patients who were not receiving

cabergoline and who were managed during the same period) did not find a higher prevalence or incidence of valve abnormalities (Maione *et al.*, 2012). Thus, at the doses used, cabergoline was not associated with an increased risk of cardiac valve regurgitation or remodeling.

Medical Treatment With Somatostatin Analogs (SAs)

Somatostatin receptors subtypes

SAs suppress GH secretion by binding to somatostatin receptors (Patel and Srikant, 1998; Hofland and Lamberts, 2003; Jaquet *et al.*, 2000; Kubota *et al.*, 1994; Reisine and Bell, 1995). There are five somatostatin receptors subtypes (sst), on somatotroph adenoma cells. First generation somatostatin analogs such as octreotide or lanreotide, exert their antisecretory and antitumoral effects by acting on sst2 and 5 on which they bind with high affinity (**Table 1**).

Antisecretory effects of first generation SAs

SAs analogs have been widely used in the treatment of acromegaly (Chanson, 2016). Octreotide (Sandostatin®) can be injected subcutaneously (SC) at a dose of 100–500 μg two or three times a day. This was the first such analog to be marketed, in the 1980s (Lamberts *et al.*, 1985), and represented a major therapeutic advance (Lamberts *et al.*, 1996). Sustained-release lanreotide (Somatuline® LP 30 mg) was the first slow-release preparation to be marketed. It was injected intramuscularly every 10–14 days (the frequency of injections being adjusted to GH/IGF-I concentration). Lanreotide is now available for deep SC injection every 28 days, at doses of 60, 90, and 120 mg (Somatuline® Autogel®). Octreotide LAR (Sandostatin® LAR 10–20 or 30 mg), the sustained-release version of octreotide, is administered intramuscularly, once a month. SAs are usually initiated at the median dose and are then titrated (decreased or increased) according to the GH/IGF-I concentration.

The two SAs have largely similar efficacy (Murray and Melmed, 2008; Carmichael *et al.*, 2014). They allow to achieve GH concentrations below 2 $\mu g\,L^{-1}$ in 60%–70% of patients and normalize IGF-I levels in 50%–80% of patients (Freda *et al.*, 2005; Bevan, 2005; Chanson, 2008). The wide range of SAs efficacy from one study to the other was recently analyzed (Carmichael *et al.*, 2014). This meta-analysis showed that overall achieved control rates were 56% for mean GH and 55% for IGF-1 normalization (**Fig. 4**). If treatment duration, prior SA therapy and year of study publication were related to biochemical control, no significant differences in GH or IGF-I response rates were observed for multicenter versus single center, retrospective versus prospective, study drug, preselection for SA responsiveness, dosing scheme, GH response criterion, or switch study design (Carmichael *et al.*, 2014). However, when studies reported a composite end point (GH + IGF-I), this lowered the remission rate: the mean difference between the composite and individual GH and IGF-1 efficacy rates were 13 ± 14.5% and 8 ± 9.3%, respectively (thus, around 43%–47%) (Carmichael *et al.*, 2014). This lower efficacy rate (compared to what was claimed previously) was confirmed by another recent meta-analysis of the effects of SAs in an unbiased group, that of treatment-naïve patients: using strict combined cutoff criteria (normal serum IGF-I levels *and* serum GH less than 1 $\mu g\,L^{-1}$), remission was observed in only 45% of these patients (Abu Dabrh *et al.*, 2014). It must be noted that 25%–40% of treated patients exhibit discordant GH and IGF-I concentrations (Alexopoulou *et al.*, 2008; Ayuk *et al.*, 2004; Carmichael and Bonert, 2008; Kanakis *et al.*, 2016), with a higher proportion of patients considered as in remission who have normal IGF-I and who keep increased GH levels (Kanakis *et al.*, 2016). This may be related to the GH assays which are now more sensitive or to the effect of sex (female patients have increased GH levels compared with males) or younger age (Alexopoulou *et al.*, 2008).

Several long-term studies have shown that the cure rate tends to improve over time (Ayuk *et al.*, 2002; Cozzi *et al.*, 2003; Maiza *et al.*, 2007). SA therapy must be continued indefinitely because, theoretically, it only suspends GH hypersecretion. In fact, it seems possible, in a handful of very good responders, to lengthen the interval between injections, or even to stop the treatment permanently with no subsequent increase in GH/IGF-I concentrations (Ronchi *et al.*, 2008; Ramirez *et al.*, 2012).

An oral formulation of octreotide is currently in development. Absorption to the circulation is apparent within 1 h after dose administration and escalating doses resulted in dose-dependent increased plasma octreotide concentrations, with an observed rate of plasma decay similar to parenteral administration; both 20 mg oral octreotide and injection of 0.1 mg sc octreotide resulted in equivalent pharmacokinetic parameters supporting an oral octreotide alternative to parenteral octreotide treatment for patients with acromegaly (Tuvia *et al.*, 2012).

Table 1 Binding affinities of SRIF-14, first generation somatostatin analogues (lanreotide and octreotide), and second-generation somatostatin analogue (pasireotide) for the receptor subtypes, hsst1–5

Compound	*hsst1*	*hsst2*	*hsst3*	*hsst4*	*hsst5*

S., Nuno, M., Ly, D. and Melmed, S. (2014). Acromegaly clinical trial methodology impact on reported biochemical efficacy rates of somatostatin receptor ligand treatments: A meta-analysis. *Journal of Clinical Endocrinology and Metabolism*, **99**, 1825–1833.

Anti tumoral effects of first generation SAs

SAs also have effects on tumor volume (**Fig. 5**), which decreases in 20%–70% of patients (Melmed *et al.*, 2005; Bevan, 2005). A meta-analysis showed that, on average, this was achieved in 53% of patients treated with octreotide (Giustina *et al.*, 2012), and in 66% of patients treated with octreotide LAR. The overall weighted mean percentage reduction in tumor size was 37.4%, rising to 50.6% with octreotide LAR (Giustina *et al.*, 2012). The reduction in tumor volume is larger when a SA is the first-line treatment (Colao *et al.*, 2001). Even when SA therapy does not lead to a reduction in tumor volume, it does at least control tumor volume in the vast majority of cases (Bevan, 2005). The antitumoral effects of SAs vary from one study to the other, probably for methodological reasons. In a recent multicenter study, where the primary endpoint was the proportion of patients with clinically significant ($\geq$20%) tumor volume reduction under lanreotide administered at a dose of 120 mg every 4 weeks, in treatment naive patients, it was shown that 62% of patients reached this criterion after one year of treatment (Caron *et al.*, 2014). The main anti-tumoral effect is generally achieved within the first three months and slowly progresses thereafter (Bevan *et al.*, 2002; Caron *et al.*, 2014).

First generation SAs as first-line therapy

SA therapy is indicated after surgical failure, but it can sometimes be used for first-line treatment, especially when severe comorbidities (heart failure or respiratory problems) provide a risk of perioperative complications (Colao *et al.*, 2004; Attal and Chanson, 2010). This has been introduced in the new recommendations for the treatment of acromegaly (Giustina *et al.*, 2014; Katznelson *et al.*, 2014). In some cases, when the tumor is very large and invasive, and is not completely resectable by surgery (which would justify postoperative SA therapy), a SA can be administered first in the hope of controlling GH hypersecretion and

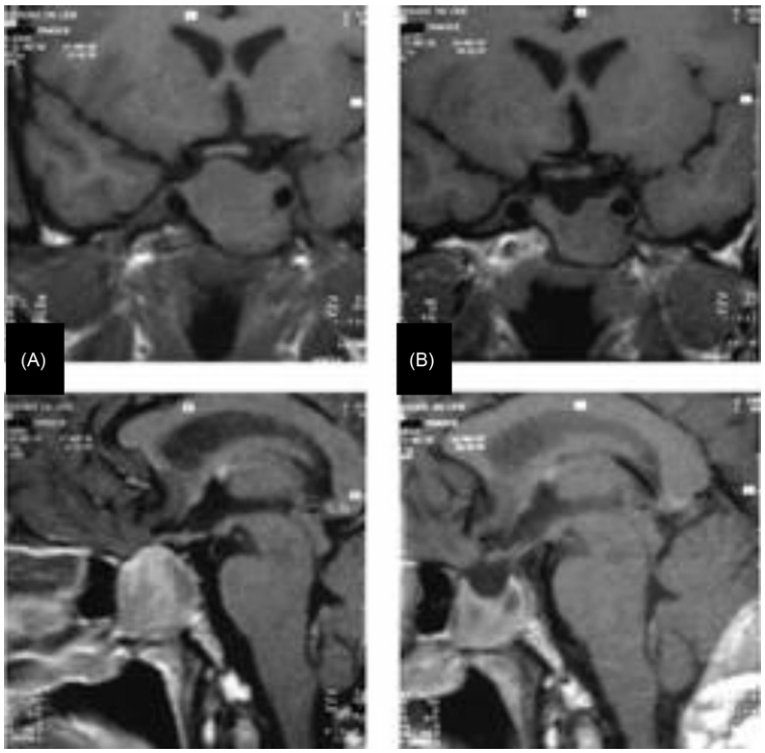

Fig. 5 Effect of treatment with first generation somatostatin analogue on tumor volume as assessed by MRI. (A) Before treatment; (B) after 3 months of treatment with somatostatin analogues. Upper panels, coronal view; lower panels, sagittal views.

tumor growth, thus avoiding the need for surgery (Giustina *et al.*, 2014; Katznelson *et al.*, 2014). Indeed, it has long been considered that the effectiveness of first-line medical therapy (in treatment-naive patients) is equivalent to that of second-line treatment after surgery or radiotherapy (Newman *et al.*, 1998; Sheppard, 2003; Colao *et al.*, 2001; Bevan *et al.*, 2002; Attanasio *et al.*, 2003). In fact, according to the meta-analysis published by Freda *et al.*, IGF-I is more likely to normalize after second-line treatment than after first-line drug therapy (Freda *et al.*, 2005). In this setting, it is interesting to know how primary medical or surgical therapy compare in terms of efficacy, both in secretory (GH/IGF-I) and tumoral terms. Retrospective data from the German Registry indicate that SA treatment is less effective than surgical treatment (Petersenn *et al.*, 2008). This has not been confirmed by the only prospective study which did not find significant differences in terms of efficacy and adverse events (Colao *et al.*, 2009). In a systematic review and meta-analysis to synthesize the existing evidence comparing these two approaches in treatment-naive patients, surgery was associated with a higher remission rate (67% vs. 45%), particularly when follow-up periods were long ($\geq$24 months) and when performed by a single operator (Abu Dabrh *et al.*, 2014).

Strategy in case of first generation SAs partial resistance

When first generation SA therapy fails to achieve remission, some authors report that an increase in the SA dose or a shorter interval between injections, whether by octreotide or by lanreotide, can rescue some patients (Giustina *et al.*, 2009, 2017).

When first generation SA therapy is inadequate, another possibility is debulking surgery for lowering hormone levels, in which case retreatment with an SA often provides disease control (Petrossians *et al.*, 2005; Karavitaki *et al.*, 2008).

It is also possible to combine first generation SAs with other drugs (see below "Combination therapy") or to shift to a GH receptor antagonist such as pegvisomant (see below).

The availability of second generation SAs such as pasireotide may also be helpful for controlling some patients resistant to first generation SAs (see below).

Effects of preoperative first generation SA treatment on surgical outcome

There is some controversy about the ability of preoperative SA therapy to improve surgical outcome (Jacob and Bevan, 2014): some studies (Stevenaert *et al.*, 1992; Colao *et al.*, 1997a; Barkan *et al.*, 1988; Abe and Ludecke, 2001; Lucas *et al.*, 2003; Carlsen *et al.*, 2008; Mao *et al.*, 2010; Shen *et al.*, 2010) indicate that, in some patients with somatotroph macroadenomas, surgery provides better control of acromegaly when patients have been pretreated with an SA, compared with those operated immediately, without SA preparation, while other studies showed no difference (Biermasz *et al.*, 1999; Kristof *et al.*, 1999; Losa *et al.*, 2006). A recent meta-analysis of all controlled trials showed a borderline effect, on short term with a pooled odds ratio (OR) of 1.62 (95% CI, 0.93–2.82) for biochemical cure with SA treatment; analysis of the three prospective controlled trials showed a statistically

significant effect (OR 3.62, 95% CI, 1.88–6.96) (Pita-Gutierrez *et al.*, 2013). However, after a longer follow up, even the studies which were initially in favor of preoperative SA treatment did not confirm any differences in terms of acromegaly control after surgery between patients treated preoperatively or not with SAs (Shen *et al.*, 2010; Fougner *et al.*, 2014). In any case, patients with minimally invasive macroadenomas (e.g., minor cavernous sinus invasion) represent the subgroup most likely to benefit from improved remission rates after preoperative SA therapy, particularly in centers with low surgical results (Jacob and Bevan, 2014).

Second-generation SAs: pasireotide

First generation SAs bind with high affinity to somatostatin receptor subtypes sst2 and 5. A significant proportion of somatotroph adenomas appear partially or totally resistant to octreotide or lanreotide, possibly owing to variable expression or a reduced density of receptor subtypes (Hofland and Lamberts, 2003). Pasireotide (Signifor®) is a new SA that binds with high affinity to sst 1, 2, 3, and 5 (**Table 1**) (Bruns *et al.*, 2002) and seems more effective than octreotide in terms of the GH/IGF-I levels achieved in patients with acromegaly (Petersenn *et al.*, 2010). Pasireotide LAR is administered every 28 days at a dose of 40–60 mg. In a head-to head prospective, randomized, double-blind trial led in treatment naive patients, biochemical control was achieved by significantly more pasireotide LAR patients than octreotide LAR patients (31.3% vs. 19.2% and 35.8% vs. 20.9% when including patients with IGF-I below the lower normal limit) (Colao *et al.*, 2014). This drug may be particularly interesting in patients with partial resistance to first-generation SAs such as octreotide or lanreotide. This has been recently studied in a large multicenter randomized trial performed in patients inadequately controlled with maximal doses of octreotide LAR or lanreotide LAR: 15% of patients in the pasireotide 40 mg group and 20% of patients in the pasireotide 60 mg group achieved biochemical control, compared with no patients in the active control group (who pursued their previous SA treatment) (**Fig. 6**) (Gadelha *et al.*, 2014).

Side-effects of SAs

First generation SAs have mild adverse effects, consisting mainly of transient gastrointestinal disorders (abdominal bloating, nausea, diarrhea), and also gallstones in 10%–20% of cases (ursodeoxycholic acid has no proven effectiveness in this setting) (Attanasio *et al.*, 2008). Gallstone complications are rare, and guidelines for their monitoring have been much relaxed in recent years (Chanson *et al.*, 2009a). Changes in glucose metabolism are sometimes observed, including impaired glucose tolerance or even diabetes in patients who are overweight. In other cases, however, glucose tolerance improves following the reduction in insulin resistance due to lowering of GH concentrations. Overall, according to a recent meta-analysis, the consequences are very minor in terms of fasting glucose and HbA1c levels (Mazziotti *et al.*, 2009). Regular metabolic monitoring is nevertheless justified.

On pasireotide, gastrointestinal adverse events occurred at a similar frequency compared to first generation SAs but glucose metabolism was more strongly altered (57.3% vs. 21.7% in the head-to-head comparison study) (Colao *et al.*, 2014). This was confirmed in the study conducted in patients resistant to first generation SAs (Gadelha *et al.*, 2014) where the most common adverse events were hyperglycemia (33% under 40 mg pasireotide and 31% under 60 mg pasireotide, vs. 14% with active control), and diabetes (21% under 60 mg and 26% under 40 mg pasireotide vs. 8% in active controls). Diarrhea was also more frequent during pasireotide in this trial (Gadelha *et al.*, 2014).

Medical Treatment With GH-Receptor Antagonists

Pegvisomant (Somavert®) has a different mechanism of action. It acts in the periphery, blocking the effects of GH on its target organs by binding to GH receptors and preventing their dimerization (**Fig. 7**); this blocks GH signal transduction and inhibits GH activity, including IGF-I production (Kopchick *et al.*, 2002). As pegvisomant inhibits the action of GH but not its secretion, GH concentrations cannot be used to evaluate treatment efficacy. IGF-I is used as a surrogate marker, together with clinical parameters. Pegvisomant is administered subcutaneously at a daily dose of 10, 15 or 20 mg (or even more), the dose being titrated according to hormone response (IGF-I normalization). Pegvisomant is highly effective, as IGF-I levels normalize in more than 90% of patients (Trainer *et al.*, 2000; van der Lely *et al.*, 2001a). In fact, efficacy may be slightly lower in routine practice, as shown by observational studies (Moore *et al.*, 2009), where normalization of IGF-I was achieved in around 70% of cases (Schreiber *et al.*, 2007; Colao *et al.*, 2006; Marazuela *et al.*, 2009; van der Lely *et al.*, 2012; Chanson *et al.*, 2015). For the moment this treatment is reserved for patients in whom SAs fail. In a series of 304 patients in whom tumor volume was monitored for at least 3 years, an increase in tumor volume occurred in 9 cases, within 8 months after commencing pegvisomant. This is likely related to rebound expansion after discontinuation of SAs and/or to the natural history of aggressively growing pituitary tumors (Jimenez *et al.*, 2008); this latter situation may justify combination with a SA to reduce tumor volume (van der Lely *et al.*, 2001b). Tumor volume must therefore be monitored (by MRI) during this treatment. Available clinical data on pegvisomant concern a relatively small number of patients and relatively short treatment periods. Adverse effects are limited to rare liver enzymes elevations: in 2.5% of patients according a large surveillance study (van der Lely *et al.*, 2012), that generally normalize either spontaneously or after treatment interruption. Exceptional cases of true hepatitis have been reported (Schreiber *et al.*, 2007; van der Lely *et al.*, 2012). Gilbert disease has been suggested as a risk factor for severe hepatitis (Bernabeu *et al.*, 2009, 2010) but this was not confirmed by an Italian study (Filopanti *et al.*, 2014). Lipohypertrophy has also been observed, likely related to repeat injections in the same site without rotating the sites of injections (Maffei *et al.*, 2006).

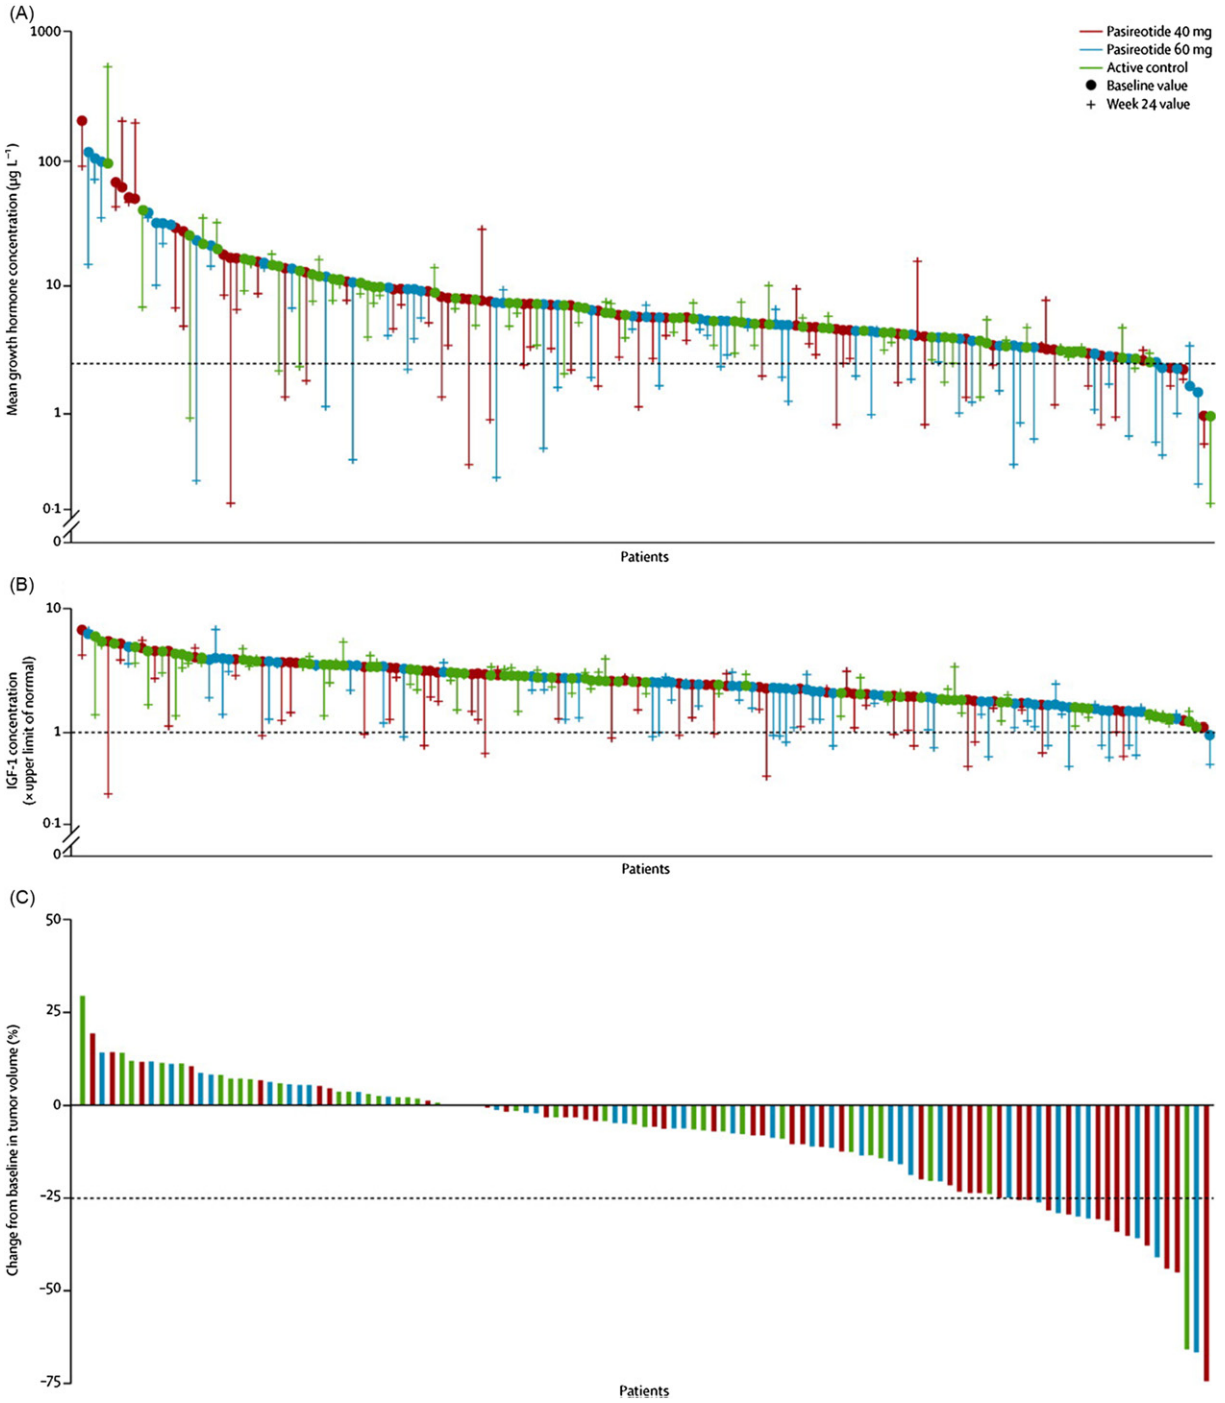

Fig. 6 Effect of treatment with pasireotide. Change in GH (A), IGF-1 concentration (B), and tumor volume (C) from baseline to week 24 of treatment with pasireotide 40 mg (in *red*), 60 mg (in *blue*) or active controls (in *green*) administered monthly in patients not controlled by their first generation somatostatin analog (octreotide or lanreotide). Data are individually shown for patients with available data at baseline and week 24. The dashed line represents $2 \times 5\ \mu g\ L^{-1}$ for GH concentration, the upper limit of normal for IGF-I concentration, and 25% reduction for tumor volume. K., Fleck, J., Aout, M., Pedroncelli, A.M., and Colao, A. (2014). Pasireotide versus continued treatment with octreotide or lanreotide in patients with inadequately controlled acromegaly (PAOLA): A randomised, phase 3 trial. *Lancet Diabetes Endocrinol* **2**, 875–884.

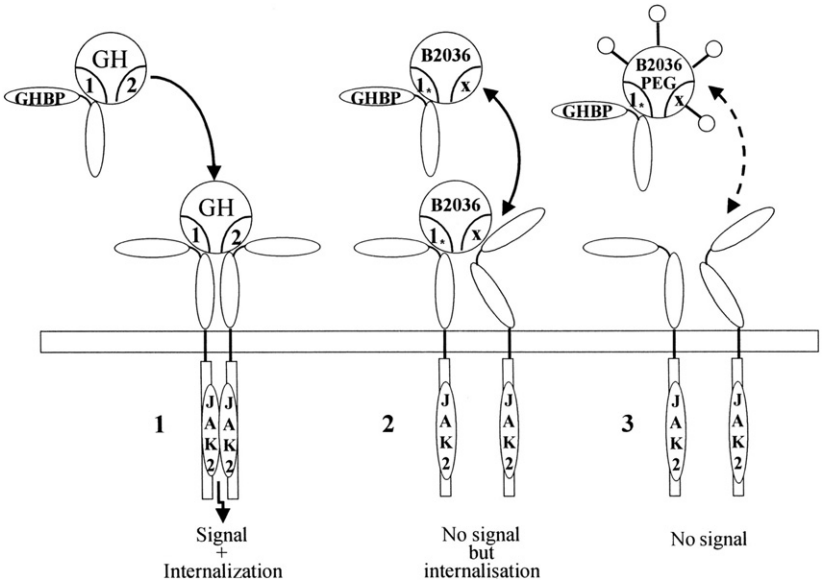

Fig. 7 Mode of action of pegvisomant. Hypothesis for interaction of GH, B2036, and B2036-PEG (pegvisomant) with the GH receptor (GHR). (1) GH binds, through site 1, to GH binding protein (GHBP); and binding to the GHR, through sites 1 and 2, triggers a conformational change, signaling, and internalization. (2) B2036 binds preferentially to GHBP, because of the site 1 mutations (1*), but this advantage is lost in the GHR dimer, where other interactions are revealed within the trimeric complex. The site 2 mutation (x) blocks the conformational change required for signaling, but internalization still occurs. (3) B2036-PEG (pegvisomant) binds to GHBP through site 1, which is protected from pegylation by the mutation of the site 1 lysines, but the PEG moieties do conjugate in site 2 to the G120K mutation. Pegylation sterically reduces binding to the GHR dimer at the cell surface, although binding is sufficient, at high concentration of B2036-PEG, to block GHR signaling. Reproduced with permission from Ross, R.J., Leung, K.C., Maamra, M., Bennett, W., Doyle, N., Waters, M.J., Ho, K.K. (2001). Binding and functional studies with the growth hormone receptor antagonist, B2036-PEG (pegvisomant), reveal effects of pegylation and evidence that it binds to a receptor dimer. *Journal of Clinical Endocrinology and Metabolism* **86**, 1716–1723.

Combined Medical Therapy

Cabergoline and SAs combinations

In a systematic review published in 2011, out of 77 patients who failed to normalize IGF-I under SA treatment alone (in three prospective studies and two retrospective studies), 40 (52%) achieved normal IGF-I levels on combined treatment with cabergoline (**Fig. 8**); mean IGF-I and GH serum concentrations fell by respectively 30% and 19%. Multivariate analysis confirmed the predictive value of the baseline IGF-I level but not that of the baseline GH level. Four more recent studies also reported the effects of adding cabergoline to SAs, with very similar results (Mattar *et al.*, 2010; Vilar *et al.*, 2011; Suda *et al.*, 2013; Puig-Domingo *et al.*, 2016). Cabergoline adjunction to ongoing SA therapy seems particularly beneficial for patients with borderline or moderately elevated serum IGF-I levels (<150% the upper limit of normal). A Japanese retrospective study reported a significant decrease in tumor volume after combination therapy (Suda *et al.*, 2013). Finally, a Spanish retrospective study showed that IGF-I levels normalized after cabergoline adjunction to lanreotide in 48% of patients (Puig-Domingo *et al.*, 2016).

The synergistic effect of DA and SA has led to develop chimeric agonists binding both DA and SRIF receptors (particularly sst2 and sst5) (Saveanu *et al.*, 2002). One of this compound BIM 23A760 (Jaquet *et al.*, 2005), with an in vitro, synergistic effect on GH secretion, showed promising results in studies led in the monkey or in man after unique dose. Unfortunately, in patients with acromegaly, the multicenter trial which was initiated in 2008 was prematurely interrupted due to insufficient efficacy.

Somatostatin analogues and pegvisomant combination therapy

SA-pegvisomant combination therapy has also been developed (Feenstra *et al.*, 2005), a long acting SA being given once a month at the highest marketed dose (30 mg octreotide LAR or 120 mg lanreotide Autogel) and pegvisomant being injected once a week at escalating doses until the IGF-I level normalizes. IGF-I normalization was obtained in all the patients with a median weekly pegvisomant dose of 60 mg (Neggers *et al.*, 2007). This decrease in dose requirement during combined therapy might be partially explained by an increase of about 20% in serum levels of pegvisomant (Jorgensen *et al.*, 2005). Biochemical hepatic anomalies were frequent (although always transient) (Neggers *et al.*, 2009). By comparison with octreotide monotherapy, this combination appears to have a greater positive impact on quality of life for a given degree of IGF-I normalisation (Neggers *et al.*, 2008), an effect that might be due to an extrahepatic action of pegvisomant (Neggers and van der Lely, 2009).

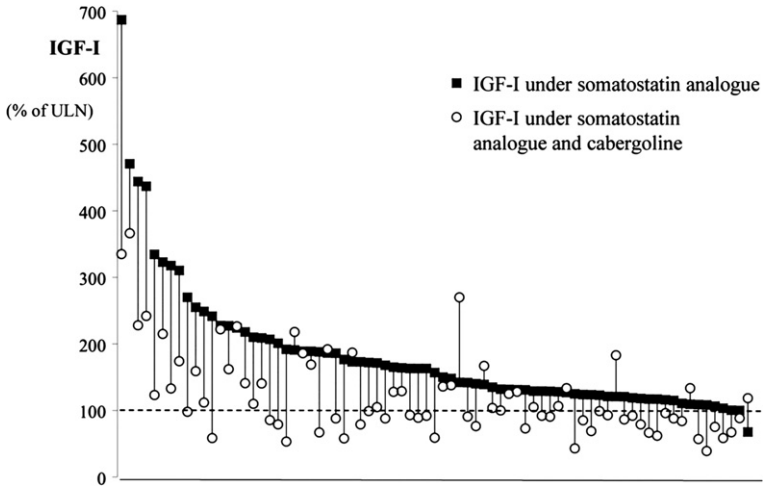

Fig. 8 Individual IGF-I levels, expressed as a percentage of the age-adjusted ULN range during treatment with somatostatin analogs alone (*black squares*) and after cabergoline adjunction (*open circles*) in patients with acromegaly. Place of cabergoline in acromegaly: A meta-analysis. *Journal of Clinical Endocrinology and Metabolism* **96**, 1327–1335.

Cabergoline and pegvisomant combination therapy

Cabergoline–pegvisomant combination therapy has been used to treat patients in whom cabergoline monotherapy failed to achieve adequate serum GH/IGF-I levels, but few data are available. In an observational retrospective cross-sectional study of 14 patients with acromegaly who were on pegvisomant monotherapy for partial resistance to SA, the IGF-I level was normal in four patients (28%) 18 months after cabergoline adjunction (Bernabeu *et al.*, 2013), but all the patients whose serum IGF-I level normalized by the end of the study had received radiotherapy. A better response to the combined therapy was associated with a lower baseline IGF-I level, a higher PRL level, female gender, and lower body weight (Bernabeu *et al.*, 2013). In a prospective study of 24 acromegalic patients, Higham *et al.* found that the cabergoline–pegvisomant combination was more effective than either drug used alone (Higham *et al.*, 2012). Thus, cabergoline adjunction may be of interest when pegvisomant alone does not achieve a normal IGF-I level in a patient with moderately elevated serum IGF-I.

Radiotherapy

Techniques

Radiotherapy techniques have evolved. Radiation can be delivered in a single session by stereotactic radiosurgery or in fractionated form. Radiosurgery is a term used to define radiation delivered at a high dose to a typically small target in a single or few sittings. Fractionated radiotherapy refers to radiation therapy delivered at smaller doses delivered over typically 5–6 weeks in 25–30 sessions. In order to minimize the dose to surrounding tissue, techniques for stereotactic localization are now used. Different forms of stereotactic radiosurgery (SRS) are available, with radiation delivered as photons (Gamma Knife, Linac, CyberKnife) or charged particles (protons). Stereotactic fractionated radiotherapy (SFR) is a hybrid form that has been developed which employs stereotactic localization techniques with fractionated therapy, administered by 3D-conformal radiation therapy, intensity modulated radiation therapy or proton radiation therapy (Colin *et al.*, 2005; Shih and Loeffler, 2008; Kuhn and Chanson, 2015).

For acromegaly, SFR delivers an average total dose of 50 Gy in about 25 daily sessions. SRS delivers 20–25 Gy in one (or few) session(s). The choice between the two methods, SFR and SRS, depends on the size of the tumor and its vicinity with the optic apparatus (Loeffler and Shih, 2011). If the lesion measures less than 3 cm and is situated more than 3–5 mm from the optic chiasm, SFR is indicated, while SRS can be proposed in other cases.

Results of Radiotherapy

Fractionated irradiation

Fractioned irradiation resulted in GH concentrations below 2 $\mu g\ L^{-1}$ and normal IGF-I levels in 22% of patients at 2 years, 60% at 10 years, and 77% at 20 years in a British study (Jenkins *et al.*, 2006), and respectively 23% of patients at 5 years, 42% at 10 years and 61% at 15 years in an Italian study (Minniti *et al.*, 2005). Results of a French study using SFR showed similar results: remission (defined as normal IGF-I without medical treatment) was 25% at 5 years, 43% at 10 years, and 50% at 15 years (Diallo *et al.*, 2015). Here again, the baseline GH concentration seemed to be predictive of treatment outcome (Barrande *et al.*, 2000; Jenkins *et al.*, 2006; Diallo *et al.*, 2015). Control of tumor growth is excellent (>90% of cases) with SFR (Minniti *et al.*, 2016).

Stereotactic radiosurgery

SRS provides more focused irradiation. In a French series of over 80 patients, the efficacy of gamma-knife irradiation was close to that of fractionated radiotherapy (Castinetti *et al.*, 2005). In a recent meta-analysis, good control of acromegaly (without complementary treatment) was achieved in 48%–53% of cases after a mean follow-up of 4 years. This apparently better efficacy of SRS is probably explained by the fact that tumors treated with this approach are relatively small ($2.11 \pm 1.16\ cm^3$)(Yang *et al.*, 2010). However, in another meta-analysis (Abu Dabrh *et al.*, 2015), the difference in the percentage of patients in remission at last follow up between fractionated radiotherapy and SRS appeared to be not significant (52% vs. 36%; $P = .14$).

Whether or not SRS achieved a faster remission rate than SFR, remains a matter of discussion (Minniti *et al.*, 2016). The efficacy of the different SRS techniques seems to be similar in terms of tumor control which is excellent in >95% of cases (Yang *et al.*, 2010; Loeffler and Shih, 2011; Castinetti *et al.*, 2005, 2009; Minniti *et al.*, 2016).

Side-Effects of Radiotherapy

Whatever the technique, radiotherapy leads to variable degrees of anterior pituitary insufficiency in 50%–80% to 100% of patients after 10–15 years. SRS may have a lower incidence of hypopituitarism than fractionated radiotherapy; however, the difference was not statistically significant (32% vs. 51%, respectively; $P = .05$) in a recent meta-analysis (Abu Dabrh *et al.*, 2015).

Complications such as radionecrosis and optic neuropathy are now very rare. In contrast, the risk of stroke may be increased, sometimes many years after irradiation (Brada *et al.*, 1999): stroke may be 1.7–2.8 times more frequent (Loeffler and Shih, 2011; Minniti *et al.*, 2011) and is considered to be an important factor of excess mortality in these patients (Sherlock *et al.*, 2010), together with cortisol deficiency and inadequate hormonal substitution. If this increased cerebrovascular risk is related to older techniques of radiotherapy and will not be associated with modern procedures used nowadays is presently unknown.

Trends in the Therapeutic Strategy in the Previous Years

As exemplified by national registries, the treatment strategy is multimodal in the majority of cases: most patients undergo surgery and receive adjuvant medical treatment. As in other registries, almost 80% of patients in the French Acromegaly Registry (Maione *et al.*, 2017) underwent at least one neurosurgery. This proportion did not change over time, indicating that surgery remains the preferred strategy for cure, or at least for removing as much tumor as possible in order to enhance the efficacy of adjuvant therapy. In contrast, the proportion of patients who received radiation therapy fell gradually with time (**Fig. 9**), as in other national registries and series (Abosch *et al.*, 1998; Bex *et al.*, 2007; Kauppinen-Makelin *et al.*, 2005). The majority of patients received medical treatment. A variety of drugs were being used at the last visit, as in other registries, most patients still being treated with SAs. The percentage of patients on SA declined, while the percentage of patients on pegvisomant increased; this latter drug being more recently available.

Current Therapeutic Strategy

The advantages, disadvantages and costs of the different treatment options must be taken into account.

A therapeutic strategy is proposed in **Fig. 10**. Currently, if surgical treatment fails to cure acromegaly, medical treatment with SAs is preferred to radiotherapy. In some selected patients (those with moderately increased IGF-I), cabergoline may be tried first. If SA therapy fails, it may be interesting to propose repeat surgery in order to remove a large tumor remnant, before trying a SA

again. Combination with cabergoline may also be interesting if a SA is only partially effective. If this does not allow good control of GH/IGF-I levels, pegvisomant is generally proposed, either in combination with SAs if they are partially effective, in particular in tumoral terms or in replacement of SAs. The recent introduction of second-generation SAs such as pasireotide might change these strategies in the future if their superiority to first-generation SAs is confirmed. However, side-effects, particularly on glucose metabolism of these new SAs will need to be taken into account for the choice of the SAs to be used. Finally, the cost of these medical treatments, which may be required indefinitely (except if a radiotherapy susceptible to progressively decrease the GH production is proposed and presumably lead to decrease the requirement for medical treatment) needs also to be considered in the therapeutic decision.

If surgery is contraindicated, first-line SA therapy may be proposed.

All these treatments must be re-assessed on a yearly basis if the treatment is effective but as requested if the treatment is ineffective or in case of titration. After radiotherapy, if a medical treatment is necessary in waiting for the effects of irradiation, its regular withdrawal is necessary for assessing the persistence of active disease. Moreover regular evaluation of other pituitary functions (when normal at time of radiotherapy) is also mandatory during the years following radiotherapy for diagnosis of hypopituitarism to be replaced.

ACTH-Secreting Pituitary Tumors☆

Rosario Pivonello, Maria Cristina De Martino, Davide Iacuaniello, Chiara Simeoli, and Annamaria Colao, University of Naples Federico II, Naples, Italy

Abbreviations

11β-HSD2	11β hydroxysteroid dehydrogenase type 2
ACTH	Adrenocorticotropic hormone
AMP	Adenosine monophosphate
AVP	Arginine vasopressin
AVPR1B	AVP receptor
brg1	ATPase subunit of the Swi/Snf complex
BIPSS	Bilateral inferior petrosal sinus sampling
BmAH	Bilateral micronodular adrenal hyperplasia
BMAH	Bilateral macronodular adrenal hyperplasia
CBG	Cortisol binding globulins
CD	Cushing disease
CRH	Corticotrophin releasing hormone
CRH-R1	CRH receptor
CRT	Conventional radiotherapy
CS	Cushing syndrome
DDAVP	Desmopressin
DMX	Dexamethasone
DST	Dexamethasone suppression test
ECS	Ectopic Cushing syndrome
EGFR	Epidermal growth factor receptor
ELISA	Enzyme-linked immunosorbent assay
FIPA	Familial isolated pituitary adenomas
GC	Glucocorticoid
GR	Glucocorticoid receptor
HPA	Hypothalamus–pituitary–adrenal
HPLC	High performance liquid chromatography
IA	Immunoassay
LCMS/MS	Liquid chromatography tandem mass spectrometry
LINAC	Linear accelerator system
LNSC	Late-night salivary cortisol
m	Mean
MC2-R	ACTH receptor
MEN1	Multiple endocrine neoplasia type 1
MEN4	Multiple endocrine neoplasia type 4
MR	Mineralocorticoid receptor
MRI	Magnetic resonance imaging
POMC	Pro-opiomelanocortin
SRT	Stereotactic radiotherapy
UFC	Urinary free cortisol

Introduction

The chronic exposure to excessive concentrations of circulating glucocorticoids (GCs), mainly cortisol, also named hypercortisolism, determines a chronic and severe disease named Cushing syndrome (CS). Adrenocorticotropic hormone (ACTH)-secreting pituitary tumors (or corticotroph pituitary tumors) induce adrenal cortisol hypersecretion and represent the most frequent form (around 70%) of endogenous CS (**Table 1**). This serious endocrine disorder is known as Cushing's disease (CD) (Pivonello *et al.*, 2008; Lacroix *et al.*, 2015; Pivonello *et al.*, 2016b).

Since 1932, when Harvey Cushing firstly described the clinical picture of glucocorticoid excess in a young woman, CS has continued to attract great interest among endocrinologists from both a clinical and an experimental point of view. Although, the low prevalence of the syndrome and its variable clinical and laboratory features have slowed down the progress in understanding pathophysiology and in developing treatments for this rare endocrine disorder, in recent times progresses have been made in this field (Pivonello *et al.*, 2008; Lacroix *et al.*, 2015; Pivonello *et al.*, 2016b, 2017).

This article reviews the clinical features of CD and the diagnostic procedures required to establish the diagnosis of CS, and, subsequently, to differentiate between pituitary (CD) and non-pituitary (ectopic and adrenal) causes of CS. Finally, currently available therapeutic approaches, including surgery, radiotherapy and medical therapy, are illustrated.

Clinical Picture

The typical clinical picture of CD usually presents with the classical stigmata of CS which includes central obesity, with round face ("moon face"); cervical ("buffalo hump") and supraclavicular fat pad; weakening of the upper and lower limbs associated with proximal muscle atrophy and asthenia; thinning of the skin with purplish striae and easy bruising. CD is associated with several complications including hypertension, glucose intolerance or diabetes mellitus and dyslipidemia which can constitute a specific form of metabolic syndrome; osteoporosis; myopathy; coagulopathy (hypercoagulopathy/hemostatic abnormalities);

Table 1 Causes of Cushing syndrome (CS)

Type	*Form*	*Etiology*	*Estimated percentage (%)*
ACTH-dependent CS			
	Cushing disease	● ACTH-secreting pituitary adenomas (in most cases) ● Corticotroph hyperplasia (not associated to a CRH producing tumor) ● Corticotroph pituitary carcinomas	70
	Ectopic CS	● ACTH-secreting extra-pituitary tumors (in most cases) ● CRH-secreting extra-pituitary tumors	10
ACTH-independent CS			
	Adrenal CS	● Cortisol secreting adrenocortical tumors (adrenocortical adenomas and less frequently adrenocortical carcinomas) ● BMAH ● BmAH	20

ACTH, adrenocorticotropic hormone; *BMAH*, macronodular adrenal hyperplasia; *BmAH*, bilateral micronodular adrenal hyperplasia; *CRH*, corticotrophin releasing hormone; *CS*, Cushing syndrome.

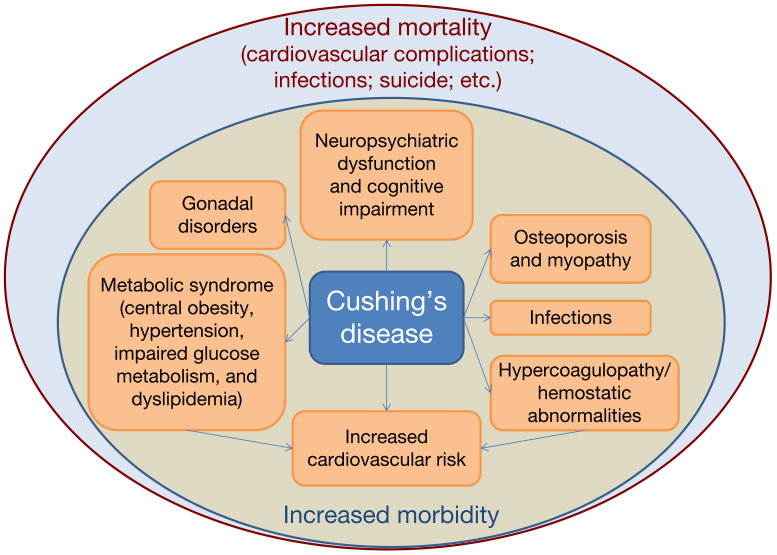

Fig. 1 Consequences of untreated or uncontrolled Cushing disease.

neuropsychiatric dysfunction; cognitive impairment and susceptibility to infections which are responsible for an impairment of quality of life and an increased morbidity and mortality (**Fig. 1**; Pivonello *et al.*, 2008; Lacroix *et al.*, 2015; Pivonello *et al.*, 2016a, 2016b, 2017; Newell-Price *et al.*, 2006; Isidori *et al.*, 2015a; Faggiano *et al.*, 2003; Pivonello *et al.*, 2005; Colao *et al.*, 1999; Scillitani *et al.*, 2014). In addition, gonadal disorders, mainly characterized by hypogonadism and increased androgen levels in women, manifesting with menstrual disturbances associated with hirsutism, acne, and alopecia, and hypogonadism with decrease of testosterone levels in men, manifesting with loss of libido and erectile dysfunction, can be also observed (**Fig. 1**; Pivonello *et al.*, 2016b, 2017).

CD has to be differentiated from diseases such as metabolic syndrome, visceral obesity, polycystic ovary syndrome, major depression, and chronic alcoholism which can present clinical and laboratory findings resembling those of Cushing syndrome and represent the so-called "pseudoCushing's states"(Newell-Price *et al.*, 1998; Findling *et al.*, 2017).

Epidemiology, Etiology and Physiopathology of Cushing Disease

Overall CS has an estimated prevalence of around 40 cases per million and an estimated incidence of 0.7–2.4 cases per million per year. The incidence of CD has been estimated to range from 1.2 to 2.4 per million. However, the worldwide epidemiology of both, CS and CD, has not been fully determined. CD is at least three times more prevalent in women than in men, and mainly occurs during the fourth to sixth decades of life (Pivonello *et al.*, 2015, 2016b).

In approximately 80% of cases, endogenous CS is a consequence of an ACTH hypersecretion (ACTH-dependent CS), generally due to a corticotroph pituitary tumor (pituitary-dependent CS, or CD, 70%), and, rarely, to an ACTH-secreting or corticotrophin releasing hormone (CRH)-secreting extra-pituitary tumor (ectopic CS, ECS, 10%) (Pivonello *et al.*, 2008; Newell-Price *et al.*, 2006; Pivonello *et al.*, 2016b). In the remaining 20% of cases, CS is independent from ACTH hypersecretion (ACTH-independent CS), and cortisol excess is a direct consequence of autonomous overproduction by the adrenal glands, because of unilateral benign or malignant adrenocortical tumors or bilateral macronodular adrenal hyperplasia (BMAH), or bilateral micronodular adrenal hyperplasia (BmAH) (**Table 1**; Pivonello *et al.*, 2008; Newell-Price *et al.*, 2006; Pivonello *et al.*, 2016b).

Cortisol, the main GC in humans, is produced from the adrenal glands under the control of the hypothalamus–pituitary–adrenal (HPA) axis. In physiological conditions, in response to several changes in the external and internal environment, including the stimulation from light or stress exposure, biological clocks regulation and nutrients balance, the hypothalamus produces CRH and arginine vasopressin (AVP), which, after the binding to their specific receptors (CRH-R1 and AVPR1B receptor, respectively), stimulate the corticotroph cells of the anterior pituitary to produce ACTH through the cleavage of the pro-opiomelanocortin (POMC). In turn, the ACTH, binding its specific receptor (MC2-R) on cells of the adrenal cortex and increasing the intracellular levels of cyclic AMP, stimulates the production of cortisol. The 24-hour profiles of ACTH and cortisol show a circadian rhythm with an early morning maximum, declining levels throughout daytime, a quiescent period of minimal secretory activity usually centered around midnight, and a sharp elevation during late sleep culminating in an early morning maximum (Oster *et al.*, 2017). The main regulation mechanisms of HPA axis includes: the circadian rhythm of ACTH and cortisol secretion; the negative feedback of cortisol on CRH and ACTH production and the response to stress (Papadimitriou and Priftis, 2009; Jacobson, 2005). These regulation mechanisms are generally compromised in CS (Raff *et al.*, 2014; Newell-Price *et al.*, 2006).

In *ACTH-dependent CS*, the hypercortisolism is consequence of an increased ACTH stimulation of adrenal gland. This ACTH stimulation involving both the fasciculate and reticularis adrenal layers can also promote the production of adrenal androgens and can determine bilateral adrenal hypertrophy and hyperplasia with possible micro/macronodular modifications (Raff *et al.*, 2014; Newell-Price *et al.*, 2006). As above mentioned, in the majority of cases the reason of the abnormal ACTH secretion is CD, generally caused by corticotroph pituitary adenomas, although corticotroph hyperplasia (not associated to a CRH producing tumor) or rarely corticotroph pituitary carcinomas are also possible (Newell-Price *et al.*, 2006; Biller *et al.*, 1992; Mampalam *et al.*, 1988; Young *et al.*, 1988; Holthouse *et al.*, 2001; Colao *et al.*, 2010). The majority of corticotroph pituitary tumors are microadenomas (maximal diameter <10 mm), whereas macroadenomas (maximal diameter >10 mm) are less frequent (about 10%) (Pivonello *et al.*, 2015; Newell-Price *et al.*, 2006; Raff *et al.*, 2014; Hofmann *et al.*, 2008). These tumors secrete an increased amount of ACTH, although macroadenomas can also secrete unprocessed POMC. Rarely, corticotroph pituitary tumors can be silent corticotroph tumors being unable to secrete large amounts of ACTH, but capable to secrete unprocessed POMC, and potentially causing tumor mass effects (Newell-Price *et al.*, 2006). CRH-R1 and AVPR1B receptors are expressed on the majority of corticotroph pituitary tumors that can therefore secrete ACTH in response to CRH and vasopressin, whereas these tumors have an impaired sensitivity to the negative feedback of cortisol on CRH and ACTH production (Newell-Price *et al.*, 2006; Raff *et al.*, 2014). These features give the rationale to the tests currently used in the diagnostic algorithm of CD.

Recently, progress has been made in understanding the genetic background of corticotroph pituitary tumors although the pathogenesis of these tumors still need to be better addressed (Lacroix *et al.*, 2015; Newell-Price *et al.*, 2006; Raff *et al.*, 2014; Perez-Rivas and Reincke, 2016). Pituitary corticotroph tumors derive from the clonal expansion of a single cell manifesting adaptive advantages acquired through one or few mutations and are generally sporadic; rarely pituitary corticotroph tumors are caused by germline gene alterations and arise in the context of familial syndromes (Lacroix *et al.*, 2015; Perez-Rivas and Reincke, 2016). Indeed, CD has been described in the context of multiple endocrine neoplasia type 1 (MEN1), an autosomal dominant disease caused by germline mutations in the *MEN1* gene (encoding menin); multiple endocrine neoplasia type 4 (MEN4), a very rare condition caused by germline mutations in *CDKN1B* gene (encoding p27/KIP1), and familial isolated pituitary adenomas (FIPA), a syndrome, characterized by the familial occurrence of isolated pituitary tumors and caused, in about 20% of cases, by germline mutation in *AIP* gene (encoding aryl hydrocarbon receptor interacting protein) (Lacroix *et al.*, 2015; Perez-Rivas and Reincke, 2016). Recently, in pituitary corticotroph tumors, frequent (35%–62%) somatic mutations in the *USP8* gene have been found (Reincke *et al.*, 2015). The product of *USP8* gene is a deubiquitinase, which enhances the epidermal growth factor receptor (EGFR) signaling, by protecting activated EGFR from lysosomal degradation. This discovery has suggested a role of EGFR signaling in the pathogenesis of corticotroph pituitary tumors (Lacroix *et al.*, 2015; Perez-Rivas and Reincke, 2016; Reincke *et al.*, 2015). A potential role in the pathogenesis of corticotroph pituitary tumors has also been attributed to factors causing a reduced sensitivity to the cortisol feedback, such as an increased inactivation of cortisol by 11β hydroxysteroid dehydrogenase type 2 (11β-HSD2); an altered expression of brg1 (ATPase subunit of the Swi/Snf complex) or histone deacetylase-2 proteins, which are involved in glucocorticoid receptor (GR) signaling or rarely to mutations in *GR* gene (encoding glucocorticoid receptor) (Lacroix *et al.*, 2015; Perez-Rivas and Reincke, 2016; Dworakowska and Grossman, 2012). Other rare mutations have been described in *TP53* gene, which encodes for the tumor suppressor protein p53 (Lacroix *et al.*, 2015; Perez-Rivas and Reincke, 2016). Considering the increased incidence of CD in women, a role of estrogens in the pathogenesis of corticotroph pituitary tumors might also be hypothesized (Newell-Price *et al.*, 2006).

ACTH-dependent CS can also be caused by a large spectrum of non-pituitary ACTH-secreting or CRH-secreting tumors, mostly represented by small cell lung carcinomas and neuroendocrine tumors of the lung, thymus and pancreas, and less frequently medullary thyroid carcinomas, pheochromocytoma or other tumors. This type of CS is known as ECS (Lacroix *et al.*, 2015; Newell-Price *et al.*, 2006; Raff *et al.*, 2014; Alexandraki and Grossman, 2010).

In *ACTH-independent CS,* the hypercortisolism is consequence of an autonomous adrenal cortisol production, independent from the ACTH stimulation and caused by a heterogeneous group of diseases. In these conditions the GC negative feedback on hypothalamus and pituitary is preserved determining a reduction in circulating ACTH levels. Particularly, in adrenal tumors, hypercortisolism can be associated with hyperandrogenism because of a possible autonomous androgen production by the tumor (Lacroix *et al.*, 2015; Newell-Price *et al.*, 2006; Raff *et al.*, 2014). The most common causes of endogenous ACTH-independent CS are the cortisol secreting adrenocortical tumors (adrenocortical adenomas and less frequently adrenocortical carcinomas). Additional rare causes include BMAH and BmAH (Lacroix *et al.*, 2015; Newell-Price *et al.*, 2006).

In physiological conditions most of the effects of cortisol on peripheral tissues are mediated by its specific receptor GR, whereas the binding of cortisol to the mineralocorticoid receptor (MR) is prevented by 11β-HSD2 enzyme that converts cortisol to cortisone, which is unable to activate the MR. In CS the increased cortisol levels can overcome the capacity of 11β-HSD2 to inactivate cortisol, leading to potential MR activation with possible induction of systemic blood hypertension and hypokalemia (Newell-Price *et al.*, 2006). Cortisol regulates several physiological functions including glucose, lipid and protein metabolism, blood pressure, calcium and electrolyte balance, coagulation, immune, endocrine and reproductive functions, mood and cognition. These pleiotropic actions of GCs explain the metabolic, cardiovascular, musculoskeletal and neuropsychiatric diseases and the immune, endocrine, reproductive and sexual disorders observed in CS, and are responsible for the increased morbidity and mortality observed in CS syndrome (Pivonello *et al.*, 2016b; Newell-Price *et al.*, 2006).

Diagnosis of Cushing Syndrome

Although patients with CS usually present with the classical stigmata of hypercortisolism, the diagnosis of these patients can be challenging, because the clinical features of CS can largely overlap with the above mentioned "pseudoCushing's states" (Newell-Price *et al.*, 1998; Findling *et al.*, 2017). Despite several tests have been extensively used, none of them has been proven to be fully able to distinguish the affected patients from the non-affected subjects (Nieman *et al.*, 2008; Arnaldi *et al.*, 2003).

Therefore, the first step in the diagnostic algorithm of CD is the confirmation of CS (endogenous chronic hypercortisolism), trying to exclude "pseudoCushing's states." This step is based on a set of tests defined *screening tests*, characterized by an high sensitivity and including (1) urinary free cortisol (UFC); (2) late-night salivary cortisol (LNSC); (3) 1 mg-overnight dexamethasone (DMX) suppression test (DST); (4) low-dose DST (**Table 2**; Nieman *et al.*, 2008; Arnaldi *et al.*, 2003).

Urinary free cortisol (UFC) consists in the measurement of cortisol concentration in the urine of patients collected over a 24-h period. Due to the high intra-individual and inter-individual variability, at least two UFC measurements are required and their mean value is generally considered (Nieman *et al.*, 2008; Arnaldi *et al.*, 2003). Depending on the assay methods used, UFC sensitivity and specificity range from 38% to 100% and from 44% to 100%, respectively, with higher sensitivity and specificity reported with the use of new methodologies, such as the high performance liquid chromatography (HPLC) or liquid chromatography tandem mass spectrometry (LCMS/MS), and with lower sensitivity and specificity reported with the use of classical immunoassay (IA) methodologies (El-Farhan *et al.*, 2017; Elamin *et al.*, 2008; Nieman *et al.*, 2008).

An high fluid intake (more than 5 L/day), the use of substances as liquorice or carbenoxolone that inhibit the 11β-HSD2, hampering the conversion of cortisol in cortisone, the use of specific drugs such as carbamazepine and fenofibrate (if HPLC is

Table 2 Diagnosis of Cushing disease

Aim	*Phase of diagnosis*	*Type of test*
Confirmation of hypercortisolism/diagnosis of CS	Screening tests	• Urinary free cortisol • Late-night salivary cortisol • 1 mg-overnight DST • Low-dose DST
Confirmation of hypercortisolism/diagnosis of CS	Additional screening tests	• Midnight serum cortisol • DMX-CRH test • DDAVP test
Differential diagnosis	Noninvasive tests and procedures for differential diagnosis	• Plasma ACTH levels • High dose DST • CRH stimulation test • DDAVP stimulation test • Pituitary MRI • Other imaging techniques such as TC and/or MRI of the chest and/or abdomen (in case of CS different from CD)
	Invasive procedure for differential diagnosis	• BIPSS

ACTH, adrenocorticotropic hormone; *BIPSS*, bilateral inferior petrosal sinus sampling; *CD*, Cushing disease; *CRH*, corticotrophin releasing hormone; *CS*, Cushing syndrome; *DDAVP*, desmopressin; *DMX-CRH*, dexamethasone-CRH; *DST*, dexamethasone suppression test; *MRI*, magnetic resonance imaging; *TC*, computerized tomography.

used), or the use of some synthetic GCs such as prednisolone and methylprednisolone (if IA is used) might cause false positive results in UFC measurement, whereas moderate to severe renal failure (creatinine clearance <60 mL/min) might cause false negative results (Nieman *et al.*, 2008).

Late-night salivary cortisol (LNSC) is a simple test to measure cortisol through saliva collections. Because the physiological reduction of cortisol secretion at evening is generally compromised in CS patients, salivary cortisol is evaluated at late-night and at least two separate samples are collected between 23.00 and 24.00 h. The sensitivity and specificity of this test range from 92% to 100% and from 93% to 100%, respectively, with a variability attributed to the different assays used (Nieman *et al.*, 2008). Normal validated ranges are assay-dependent, requiring local laboratory validations (Nieman *et al.*, 2008; Arnaldi *et al.*, 2003; El-Farhan *et al.*, 2017). Although further validation are required, according to Endocrine Society Clinical Practice Guidelines, the best validated assays are enzyme-linked immunosorbent assay (ELISA) and LCMS/MS; considering these two techniques, salivary cortisol levels at bedtime, or between 23.00 and 24.00 h, higher than 145 ng/dL (4 nmol/L) suggest CS (Nieman *et al.*, 2008).

The chew of liquorice or tobacco, which contain the 11β-HSD2 inhibitor glycyrrhizic acid, smoke of cigarettes, variability in bedtime, night work, depression, critical illness, eating, stress, salivette contamination with steroid contained in lotions or oral gels, sample contamination with blood (including blood leakage, periodontal diseases and vigorous tooth brushing) might cause false positive results in LNSC (Nieman *et al.*, 2008). Lastly, although the influence of gender, age, and coexisting medical conditions has not been fully characterized, men aged 60 years or older, diabetic and hypertensive subjects seem to have a high percentage of false positive results (Nieman *et al.*, 2008).

Overnight dexamethasone (DMX) suppression test (DST) test, also known as 1 mg DST or *Nugent test* is performed administrating to the patient 1 mg of DMX between 23.00 and 24.00 h, and measuring serum cortisol between 8.00 and 9.00 h on the following morning. Patients with CS are less sensitive to the negative feedback exerted by GC, therefore in these patients the administration of 1 mg of DMX is not followed by an inhibition of endogenous cortisol production. The test is considered positive and suggestive of CS when serum cortisol levels are equal or above the cut-off of 1.8 μg/dL (50 nmol/L) with a sensitivity of 98%–100%, and a specificity of 58%–80% (Nieman *et al.*, 2008; Arnaldi *et al.*, 2003; Wood *et al.*, 1997; Pecori Giraldi *et al.*, 2007).

Variable absorption and metabolism of DMX might influence the DST results. Particularly, drugs such as phenobarbital, phenytoin, carbamazepine, rifampicin and alcohol, accelerate DMX metabolism, reducing the plasma DMX concentrations, and causing false positive results. All conditions that can increase the cortisol binding globulins (CBG) such as the use of oral contraceptive pill or mitotane might also cause false positive results (Nieman *et al.*, 2008). Conversely, drugs such as itraconazole, ritonavir, fluoxetine, diltiazem and cimetidine, decrease DMX metabolism causing false negative results. False negative results might also occur in case of liver and/or renal failure, due to decreased DMX metabolism (Nieman *et al.*, 2008).

Low-dose dexamethasone suppression test, also known as 48 h 2 mg DST or *low-dose Liddle test* consists in the administration of 0.5 mg of DMX every 6 h, for 48 h, starting at 9.00 h or at 12.00 h of the first day. Serum cortisol should be assessed at 9.00 h or at 8.00 h, 6 or 2 h after the last DMX dose, accordingly to different protocols (Nieman *et al.*, 2008). As the above reported Nugent test, also the low-dose Liddle test is considered positive and suggestive of CS when serum cortisol levels are equal or above the cut-off of 1.8 μg/dL (50 nmol/L) with a sensitivity of 98%–100% and specificity of 70%–88% (Nieman *et al.*, 2008; Wood *et al.*, 1997; Martin *et al.*, 2006). False positive and negative results might occur in the conditions reported above for Nugent test.

In case the performed screening test results abnormal, or in case of normal test results associated with the persistence of a high clinical suspicion of CS, the diagnostic algorithm should continue performing additional screening tests among the above-mentioned tests, or one of the following tests: (1) midnight serum cortisol; (2) dexamethasone-CRH test; (3) desmopressin (DDAVP) test (**Table 2**; Nieman *et al.*, 2008; Arnaldi *et al.*, 2003). These procedures require an appropriate expertise in the execution and interpretation, therefore they should be performed in specialized endocrine centers.

Midnight serum cortisol can be performed in a sleeping or awake state. The physiological reduction of cortisol secretion at evening is generally compromised in CS patients. In case of sleeping procedure, blood must be drown through an in-welling line or within 5–10 min of waking patients. Values higher than 1.8 μg/dL (50 nmol/L) are suggestive of CS, with a high sensitivity (98%–100%) but poor specificity (18%–26%) (Nieman *et al.*, 2008; Pecori Giraldi *et al.*, 2007; Vilar *et al.*, 2007).

In case of awake procedure, values higher than 7.5 μg/dL (207 nmol/L) are suggestive of CS, with a high sensitivity (56%–100%) (Nieman *et al.*, 2008; Papanicolaou *et al.*, 1998; Friedman *et al.*, 2007) and specificity (83%–100%) (Nieman *et al.*, 2008; Vilar *et al.*, 2007; Friedman *et al.*, 2007). Hospitalization stress and all conditions that can increase CBG levels might cause false positive results in the measurement of midnight serum cortisol (Nieman *et al.*, 2008).

Dexamethasone-CRH test (DMX-CRH test) is performed administering 48 h 2 mg-DMX followed by 1 μg/kg/i.v. CRH 2 h after the last DMX dose, with measurement of serum cortisol 15 min after CRH injection. This combined test has been developed with the scope to improve the diagnostic accuracy of DST particularly in the discrimination between patients with CS as compared with pseudo-Cushing's states. Patients with CS as compared with pseudo-Cushing's states are expected to have an altered sensitivity to both DMX and CRH, therefore a response to DMX-CRH test is expected in individuals with CS but not in those with pseudo-Cushing's states and a mild degree of hypercortisolism (Yanovski *et al.*, 1993; Newell-Price *et al.*, 1998). CRH after DMX elevates plasma ACTH and cortisol levels in the majority of patients with CD but not in normal individuals or patients with pseudo-Cushing's states. Serum cortisol levels higher than 1.4 μg/dL (38 nmol/L) have been proposed to be suggestive of CS, with sensitivity rates of 94%–100% and specificity rates of 60%–100% (Nieman *et al.*, 2008; Martin *et al.*, 2006; Pecori Giraldi *et al.*, 2007; Yanovski *et al.*, 1993; Reimondo *et al.*, 2008). However, the diagnostic accuracy and the advantages of DMX-CRH test over the other screening tests remain to be validated. False positive or false negative results might occur in the same conditions above mentioned for other DMX tests (Newell-Price *et al.*, 1998; Nieman *et al.*, 2008).

Desmopressin (DDAVP) test is performed administrating 10 μg i.v. DDAVP, a vasopressin analogue with measurement of plasma ACTH levels 30 or 15 min before, and at time 0, 15, 30, 45, 60, 90 and 120 min after the injection of DDAVP. DDAVP elevates plasma ACTH and cortisol levels in the majority of patients with Cushing's disease but not in normal individuals or patients with pseudoCushing's states. Using as criteria to suggest CD diagnosis a Δ-ACTH increase ≥6 pmol/L (>27 pg/mL) versus the baseline, this test has shown a sensitivity of 75%–87%, and a specificity of 90%–91% (Findling and Raff, 2017), however it remains still poorly validated and therefore is not recommended as a routinely screening diagnostic test (Nieman *et al.*, 2008).

Diagnosis of Cushing Disease

Once the diagnosis of CS has been established the following step in the diagnostic algorithm is to distinguish CD from different possible causes of endogenous CS (differential diagnosis) and possibly to visualize the anatomical cause by imaging techniques. To this purpose several methodologies are required, including: (1) the measurement of plasma ACTH levels; (2) the high dose DST; (3) the CRH stimulation test; (4) the DDAVP stimulation test; (5) pituitary magnetic resonance imaging (MRI) and (6) the bilateral inferior petrosal sinus sampling (BIPSS) (**Table 2**; (Arnaldi *et al.*, 2003; Newell-Price *et al.*, 1998).

Plasma ACTH is measured at morning using non-haemolysed EDTA-coated plastic tubes mostly by fully automated IA. Samples have to be preserved at cool temperature prior to be rapidly processed (Arnaldi *et al.*, 2003; Newell-Price *et al.*, 1998). ACTH measurement represents the first step in differential diagnosis of CS. Suppressed ACTH levels (<2 pmol/L or 10 pg/mL) suggests an adrenal ACTH-independent CS form, whereas non-suppressed ACTH levels (>4 pmol/L or 20 pg/mL) suggests an ACTH-dependent CS form (Arnaldi *et al.*, 2003).

In case of intermediate ACTH levels (2–4 pmol/L or 10–20 pg/mL), the differential diagnosis between ACTH-dependent versus ACTH-independent CS forms requires a CRH stimulation test, which shows an emphatic ACTH response in ACTH-dependent forms and a blunted ACTH response in ACTH-independent forms (Arnaldi *et al.*, 2003).

Baseline ACTH levels may also suggest the origin of ACTH secretion given that ACTH levels tend to be higher in ECS than in CD, but this distinction requires further investigation with high dose DST or CRH test as reported below. These tests rely on the fact that the tumoral corticotroph cells of pituitary tumors, although partly autonomous, retain some features of normal corticotroph cells (i.e., sensitivity to glucocorticoid feedback and CRH stimulation). In contrast, tumors causing ECS are generally different from corticotroph cells and are not likely to respond to glucocorticoid or CRH administration.

High-dose DST or 8 mg DST or high-dose Liddle test is performed administrating DMX according with one of the following protocols: (1) oral administration of 2 mg of DMX every 6 h, for 48 h, starting at 9.00 h or at 12.00 h of the first day and assessment of serum cortisol at 9.00 h or at 8.00 h or alternatively, 6 or 2 h after the last dose of DMX; (2) oral administration of 8 mg DMX in one single dose at 23.00 h and assessment of serum cortisol between 8.00 and 9.00 h on the following morning; (3) intravenous DMX infusion at a rate of 1 mg/h for 5–7 h (5–7 mg) and assessment of serum cortisol before and at the end of infusion (Newell-Price *et al.*, 1998). A suppression of serum cortisol (>50% vs. basal values after oral 8 mg DST and after 5 mg intravenous test; or >190 nmol/L vs. basal values after 7 mg intravenous test) suggests CD with a sensitivity and specificity within the ranges of 65%–100% and 60%–100%, respectively (Newell-Price *et al.*, 1998). False positive or false negative results might occur in the same conditions above mentioned for other DMX tests. Additionally, a false-positive response might be observed in some cases of ECS, especially some benign differentiated carcinoid tumors, which can be sensitive to GC feedback inhibition.

CRH stimulation test is performed administrating 1 μg/kg or 100 μg of CRH i.v. with measurement of ACTH and serum cortisol 15 min before at time 0, 15, 30, 45, 60, 90 and 120 min after the CRH injection (Arnaldi *et al.*, 2003; Newell-Price *et al.*, 1998). In the majority of patients with CD a marked rise in plasma ACTH and cortisol is observed, whereas the hormonal response is modest or absent in patients with ECS. A rise over the baseline in plasma ACTH> of 50% or > of 35% at time 15′–30′ or a rise in cortisol>20% over the baseline can identify patients with CD with a sensitivity and a specificity of 86%–93% and 95%–100% respectively (Arnaldi *et al.*, 2003; Newell-Price *et al.*, 1998). False positive response to CRH test might be rarely observed in ECS particularly in some bronchial carcinoid tumor (Newell-Price *et al.*, 1998).

DDAVP stimulation test is performed as above mentioned. As for the CRH test, in the majority of patients with CD a rise in plasma ACTH and cortisol is expected. A rise from baseline in plasma cortisol of 20% or more than four times the intra-assay coefficient of variation suggests CD with a reported sensitivity of 84% and specificity of 83%. A rise in plasma ACTH of 35% suggests CD with a reported sensitivity of 77% and specificity of 73% (Newell-Price *et al.*, 1998). A false positive DDAVP response might be observed also in 20%–50% of ECS. Because the limited experience with this test, CRH test should be preferred (Arnaldi *et al.*, 2003; Newell-Price *et al.*, 1998).

Pituitary MRI should be performed in case of biochemical suspect of CD. Pituitary corticotroph tumors are visualized by MRI with gadolinium enhancement in up to 70% of cases due to their extremely small size (mostly 3–5 mm). In patients with classic clinical presentation and dynamic biochemical studies compatible with CD, the presence of a focal lesion (>6 mm) on pituitary MRI may provide a definitive diagnosis (Arnaldi *et al.*, 2003; Vitale *et al.*, 2017). However, in about 10%–20% of the general population pituitary imaging might also visualize small lesions (e.g., incidentalomas, which are incidentally discovered pituitary tumors), that might be erroneously interpreted as ACTH-secreting pituitary tumors (Arnaldi *et al.*, 2003; Scangas and Laws, 2014). For this reason, in patients showing discordant biochemical tests and/or a pituitary MRI negative or showing a pituitary tumor <6 mm, an additional evaluation, by using BIPSS, should be performed (Arnaldi *et al.*, 2003). In case of CS different from CD,

other imaging techniques such as computerized tomography and/or MRI of the chest and/or abdomen are required (Arnaldi *et al.*, 2003; Isidori *et al.*, 2015b).

BIPSS. When the diagnosis of CD cannot be firmly established by previously reported noninvasive procedures, BIPSS needs to be performed, preferably in a highly specialized center. This technique requires the catheterization of both the right and left inferior petrosal sinuses, which drain the respective hemipituitaries, and the collection of ACTH samples simultaneously from both petrosal sinuses and a peripheral vein. The ratio between petrosal and peripheral plasma ACTH concentrations, obtained before and after stimulation with CRH, permits to distinguish CD from ECS. If the gland harbors a corticotroph tumor, higher ACTH levels in the veins draining the pituitary are observed, whereas if the source of ACTH is outside from pituitary, petrosal ACTH levels does not differ from peripheral concentrations. A baseline center/periphery ratio greater than 2 and/or greater than 3 after CRH stimulation supports a pituitary source of ACTH hypersecretion with high sensitivity and specificity (95%–99%), representing the "gold standard criteria" in the diagnosis of CD (Arnaldi *et al.*, 2003). However, false negative results might occur in CD patients with anomalous venous drainage. IPSS might also provide useful information for identification of the site of the tumor within the pituitary, but its predictive value remains controversial. Despite the fact that BIPSS is an invasive procedure, the occurrence of adverse events is extremely rare (severe adverse events have a prevalence lower than 1%), particularly if it is performed by experienced operators in referral centres. They mainly include: deep vein thrombosis, pulmonary emboli and brain stem vascular damages (Arnaldi *et al.*, 2003; Pecori Giraldi *et al.*, 2015; Zampetti *et al.*, 2016).

Therapy

The aims of treatment OF CD are: (1) the normalization of cortisol secretion; (2) the reversal of clinical picture in terms of clinical signs and symptoms; (3) the prevention or improvement of concomitant comorbidities; and (4) the long-term disease control without recurrence (Nieman *et al.*, 2015; Pivonello *et al.*, 2015). The main treatment approaches include pituitary surgery, which usually represents the first-line treatment, and repeat pituitary surgery, pituitary radiotherapy, adrenal surgery and medical treatment, which usually represent second-line approaches (Nieman *et al.*, 2015; Pivonello *et al.*, 2015).
