On the other hand, some studies have associated the exposure to antibiotics with increases in body mass index in different circumstances, such as the first months of life, childhood, in malnourished subjects, or *Helicobacter pylori* infection in individuals with cystic fibrosis. It is difficult to discern whether this weight gain is due to the beneficial effects of antibiotic treatment in the prevention or treatment of bacterial infections, or through their effects on the microbiota. A possible explanation could be a mixture of these two mechanisms in many of the scenarios described (Million *et al.*, 2013; Trasande *et al.*, 2013; Garly *et al.*, 2006).

Epidemiological studies have supported the increased risk of overweight in late childhood after exposure to antibiotic therapy in early childhood (Murphy *et al.*, 2014). They have even linked the progressive increase of obesity in the population with higher use of antibiotics (Luoto *et al.*, 2010; Dao *et al.*, 2016). For decades, subtherapeutic doses of antibiotics have been used to promote growth in farm animals, with resulting increased fat mass. This relationship shows that increasing antibiotics use promotes obesity (Trehan *et al.*, 2013). In contrast, antibiotic exposure during the first years of life in children of overweight mothers has been associated with a lower risk of overweight in childhood (Ajslev *et al.*, 2011). Overall, these studies suggest that exposure to

antibiotics in the early stages of life may disrupt healthy gut microbiota, but conversely, it also has the potential to modify disturbed microbiota to a healthier state (Allin *et al.*, 2015).

Microbiota and Metabolic Diseases

Transcendent publications analyze trends in body mass index in 200 countries and estimate that the global prevalence of obesity has increased from 105 million people to 641 million in just four decades (NCD Risk Factor Collaboration (NCD-RisC), 2016). In Spain, over the last 20 years the rate of obese subjects has doubled from close to 12% in the 1990s to far exceed 20% at the present time. The determinants of this exponential growth of obesity prevalence cannot be just a consequence of increasing caloric intake and decreasing physical activity. Other environmental factors may explain this trend.

The origin of obesity is a complicated challenge due to the great genetic diversity and social differences between humans. Despite the tremendous efforts and the identification of some point mutations in the genome, an overall view of the exact molecular mechanisms involved in the development of diabetes and obesity has not been developed. Indeed, the discovery of candidate genes in genome-wide association studies (GWAS) has helped to identify novel genes for sensitivity/resistance to diabetes and extreme metabolic phenotypes (Jacquemont *et al.*, 2011). However, these steps forward cannot yet explain the overall diversity in the natural histories of metabolic diseases (Beck-Nielsen *et al.*, 2003). Epigenetic and environmental factors such as drastic change in dietary habits, less fiber and a high-fat diet contribute to the origin of metabolic diseases. Further investigations are trying to find a new paradigm that takes into account genetic diversity, the impact of environmental factors, the rapid development of metabolic diseases, and individual behavior in the development of diabetes and obesity.

Numerous published papers suggest that gut microbiota, and more specifically its variations in composition and diversity, play an important role in the development of metabolic disorders, such as diabetes and obesity. Perturbations of the gut microbiota, termed gut dysbiosis, affect the interplay between the gut microbiota and host cells, resulting in dysregulation of inflammation that contributes to the pathogenesis of chronic inflammatory diseases. Many studies demonstrate profound changes in the composition and metabolic function of the microbiota in obese subjects (Andersson *et al.*, 2008; Klindworth *et al.*, 2013). Gut microbiota is increasingly recognized as a fundamental element connecting genes, environment, and immune system, being involved in the regulation of metabolic function, development of low-grade inflammation and regulation of energy balance (Barengolts, 2016).

Pathophysiological Proposed Mechanisms Influencing Microbiota and Energy Homeostasis

Several mechanisms have been proposed as a link between gut microbiota and obesity. We summarize them in this list:

1. Generation of active metabolites such as short chain fatty acids (SCFA) or bile acids with well known antiinflammatory effects and regulatory properties on carbohydrates and lipid metabolism (Li *et al.*, 2017; Harakeh *et al.*, 2016; Moran and Shanahan, 2014; Tilg, 2010).

   Butyrate, propionate and acetate are SCFA produced by gut bacteria when digesting dietary fiber. These SCFA are absorbed in the intestine where butyrate, in particular, provides energy to the epithelial cells of the colon and contributes to decreasing intestinal permeability.

   Lipopolysaccharides (LPS) are a pro-inflammatory component of the cell wall of gram-negative bacteria. Metabolic endotoxemia and increased systemic LPS levels are related to an increase in gut permeability and the establishment of a chronic inflammatory state. Both animal and human studies have documented its importance in the development of obesity in (Moran and Shanahan, 2014).

   Obesity and diabetes have a low-grade inflammatory component accurately described in tissues directly involved in the regulation of metabolism, such as liver, adipose tissue and muscle. Animal experiments have shown how changes in microbiota are capable of altering the degree of inflammation in adipose tissue.

   Other studies have shown a relationship between dietary fiber intake or prebiotic substrate for the production of SCFA by microbiota and the release of gastrointestinal hormones such as GLP-1, YY intestinal peptide, ghrelin and other peptide hormones in both humans (Freeland *et al.*, 2010; Parnell and Reimer, 2009) and rodents (Zhou *et al.*, 2008). This phenomenon helps increasing satiety after a meal and decreases food intake. Also, SCFA have been linked to leptin expression through the GPR41 receptor in murine models (Xiong *et al.*, 2004). Likewise, adipocytes detect increased levels of SCFA produced by intestinal microbial fermentation and induce leptin production regulating host energy balance. Data obtained with experimental obesity models (Neyrinck and Delzenne, 2010; Dewulf *et al.*, 2011) on dietary supplementation with nondigestible carbohydrates demonstrate beneficial effects for the host. They reduced adiposity by counteracting G protein-coupled receptor 43 (GPR43) expression in adipose tissue inducing a decrease in the processes activated by the PPAR-gamma receptor (Li *et al.*, 2017). Similarly, ghrelin levels have shown negative correlations with *Bifidobacterium*, *Lactobacillus*, *Blautia coccoides*, and *Eubacterium rectale* and positive correlations with Bacteroides and Prevotella, suggesting the role of gut microbiota in the control of satiety and its association with the food-intake regulating hormones leptin and ghrelin.

   Interestingly, butyrate production is also linked to serotonin levels in animal models. Serotonin can regulate intestinal

permeability and is an important neurotransmitter in the gut and brain, involved in regulating body weight and satiety control (Simansky, 1996; Zhu *et al.*, 2009).

Another theory is related to primary bile acids. Five percent of these primary bile acids escape from enterohepatic circulation reaching the large intestine and transforming into the secondary bile acids through the action of gut microbiota. In overweight and diabetic subjects, fewer bile acids were observed in comparison to healthy subjects. Secondary bile acids appear to play an insulin-sensitizing role. They act as signaling-mediator molecules in brown adipose tissue and muscle and increase mitochondrial activity. They appear to improve carbohydrate metabolism stimulating the production of peptides such as GLP-1 by intestinal L cells (Allin *et al.*, 2015; Palau-Rodriguez *et al.*, 2015).

2. Increased endocannabinoid system tone (Moran and Shanahan, 2014; Cani *et al.*, 2016).

   The endocannabinoid system (ES) is a mediator involved in the communication between gut microbiota and adipose tissue, playing an important role in energy homeostasis through the regulation of appetite and metabolism. Moreover, the ES is involved in gut physiology through modulation of gastric emptying, gastrointestinal motility and inflammation. In animal models, the ES has been shown to control gut barrier function and adipogenesis by facilitating adipogenesis and expansion of adipose tissue, and regulating inflammation (Muccioli *et al.*, 2010). These effects of the ES and related bioactive lipids on gut physiology might be involved in the regulation of fat intake, satiety and postprandial glycaemia. The role of the ES in the regulation of brown adipose tissue metabolism and thermogenesis has been proposed to be dependent on cannabinoid receptor B1.

   These results provide strong support for crosstalk between adipose tissue and the gut microbiota, with the endocannabinoid system functioning as a potent mediator (Cani *et al.*, 2016). In humans, a direct relationship between changes in the gut microbiota and endocannabinoid system tone has yet to be conclusively demonstrated.

3. Decreased gut gene expression of fasting-induced adipocyte factor (FIAF) responsible for inhibiting lipoprotein lipase activity in relation to hepatic and fat adipose storage (Tilg, 2010; Burcelin *et al.*, 2012).

   Gut microbiota could decrease the production of FIAF carried out by the intestinal cells, which inhibit lipoprotein lipase activity. This enzyme promotes the release of non-esterified fatty acids into tissues such as liver and adipose cells (Bäckhed *et al.*, 2007).

4. Gut modulation derived from peptide secretion (GLP-1, GLP-2, YY peptide…) (Musso *et al.*, 2010).

   Yadav *et al.* (2013) demonstrated that the modulation of gut microbiota composition through the use of probiotics stimulates the production of butyrate. It favors the secretion of GLP-1 in L cells, improving the inflammatory state and resistance to insulin. Most of the pathways underlying the effects of SCFA remain unknown. Several studies have suggested that the effects of SCFA are mediated by members of the newly-identified G protein-coupled receptor family. These are G protein-coupled receptors 43 and 41 (GPR43 and GPR41, respectively). The binding of SCFA to GPR43 and GPR41 receptors increases plasma levels of GLP-1 and YY peptide, leading to improvements in glucose homeostasis and reduced appetite (Kuwahara, 2014; Everard and Cani, 2014; Li *et al.*, 2017).

   The GPR41 and GPR43 receptors are also found in the enteroendocrine L cells in the colon. The mode of action GLP-1 and YY peptide release in the colon is different from the mode of action in the small intestine. SCFA from the colonic lumen could be involved in regulating long-term energy homeostasis by inducing GLP-1 secretion through their action on GPR41 and GPR43 receptors. In the small intestine they would be involved in appetite control, ingestion, and short-term energy homeostasis (Kuwahara, 2014; Li *et al.*, 2017).

   Ingestion of fructoolisaccharides in the diet influences the density of L cells expressing GPR43 and GPR41 receptors (Ley *et al.*, 2005). Increases in the GLP-1 and YY intestinal peptide production have been related to the increase in *Bifidobacterium* generated by the use of some prebiotics. Higher *Bifidobacterium* modulates inflammation in obese mice by increasing incretin production and reducing intestinal permeability (Cani and Delzenne, 2009).

Evidence Link Between Gut Microbiota and Obesity

The first evidence of the relationship between gut microbiota in energy homeostasis regulation and adiposity comes from Ley *et al.* (2005) and Bäckhed *et al.* (2007). They observed how after microbial colonization of germ-free mice (axenic mice) there was an increase in weight and body fat. They found that axenic mice had 40% less total body fat than conventional mice, although the calorie consumption of the conventional animals was 29% higher. However, after microbial colonization, the total body fat of germ-free mice increased by 57% in 2 weeks (Bäckhed *et al.*, 2004).

There are many publications and discoveries that have emerged microbiota to be considered as an important factor in the genesis of metabolic diseases. In animal models, it has been shown that mice with a leptin gene mutation, and therefore genetically obese, had a different microbiota compared to mice without this mutation. In these obese animal models, the interaction between the dominant intestinal phyla, *Bacteroidetes* and *Firmicutes*, is modified with a significant reduction in the first and a corresponding increase in the second. The same trend was observed in humans. Ley *et al.* (2006) reported an altered composition in the microbiota of obese humans with a marked decrease in bacterial diversity, and similar characteristics to obese mice. Other authors (Turnbaugh *et al.*, 2009a,b; Schwiertz *et al.*, 2010; Kallus and Brandt, 2012; Ley, 2010) have confirmed this disturbance of the microbiota in relation to these two main phyla. In most of the published studies, an increase in the *Firmicutes* to *Bacteroidetes* ratio in the microbiome of obese subjects has been associated with an increased low-grade inflammatory state and a

higher capacity to capture the energy coming from food through the edge *Firmicutes* has over *Bacteroidetes*. Although within the edge held by Bacteroidetes, Bacteroides thetaiotaomicron (Hooper *et al.*, 2001) has shown to improve the absorption and processing of host nutrients. In addition, all these studies agree on the existence of gut microbiota variations with reduced microbial diversity. It is associated with greater adiposity, insulin resistance and a more pronounced inflammatory phenotype.

Specifically, the increase in *Firmicutes* observed in obese animals and subjects could be associated with an increase in the capacity to digest some indigestible polysaccharides and then produce monosaccharides and SCFA that are absorbed by the host and obtain energy from substances that would otherwise be eliminated by the feces. Therefore, there is a specific microbiota that is able to obtain more energy from the same daily caloric intake (Turnbaugh *et al.*, 2009a,b). Zhang *et al.* suggest that a higher energy harvest in obese individuals is related to the transfer of hydrogen between taxa. They observed a simultaneous increase in Prevotella that produces hydrogen and in methanogenic archaea that uses hydrogen (Zhang *et al.*, 2009). These findings agree with the observation that germ-free mice fed a high-fat diet gained less weight than their conventional counterparts (Bäckhed *et al.*, 2004).

However, not all studies found interaction between the dominant intestinal phyla *Bacteroidetes* and *Firmicutes* (Wu *et al.*, 2011; Jumpertz *et al.*, 2011; Duncan *et al.*, 2008; Hold *et al.*, 2014). A important study concludes that obesity is probably related to an increase in the phyla *Firmicutes* and *Actinobacteria*, with a reduction in *Bacteroidetes*, *Verrucomicrobia*, and *Faecalibacterium prausnitzii* species (Chakraborti, 2015). In this regard, authors such as Turnbaugh *et al.*, (2009a,b) and Furet *et al.*, (2010) propose a variable microbial pattern composition in obese individuals with a smaller representation of *Bacteroidetes* and greater representation of *Actinobacteria* (Monira *et al.*, 2011), with no apparent differences in *Firmicutes* compared to normal-weight subjects. This has also been associated with a decrease in the amounts of *Bifidobacterium* and Ruminococcus (Moran and Shanahan, 2014; Martín *et al.*, 2003).

A large study (Turnbaugh *et al.*, 2009a,b) describes how 75% of the microbial genes associated with obesity belonged to *Actinobacteria* and 25% to *Firmicutes*, while 42% of the genes associated with thinness belonged to *Bacteroidetes* (El Kaoutari *et al.*, 2013). The absorption of nutrients in relation to the different microbial patterns varies according to the study population, with the same microbial population responding differently to determined diets in normal weight versus obese individuals (Jumpertz *et al.*, 2011).

Significant studies have demonstrated modifications in the communities that are part of the gut microbiota of individuals who achieve weight loss with an increase in certain species of the genus *Bacteroides* (*Bacteroides fragilis*), Prevotella and *Lactobacillus* and a decrease in species of the genus *Clostridium* (*C. coccoides*, *C. histolyticum*), *Bifidobacterium* (*B. longum*), *Eubacterium* (*E. rectale*), and *Akkermansia* (Santacruz *et al.*, 2009; Nadal *et al.*, 2009). In addition, the relative proportion of *Bacteroidetes* and *Firmicutes* increased in obese subjects after weight loss indicates that modulation of microbiota can be an effective means for weight management. Caloric restriction in obese or overweight people has also shown changes in the fetal microbiome with increased microbial richness, correlating with improved metabolic parameters (Voreades *et al.*, 2014).

However, the experiment that has given the most solidity to the causality between microbiota and obesity was performed by Turnbaugh *et al.* in (2006). They demonstrated how microbiota transplantation from genetically obese mice to germ-free mice caused a significant increase in weight compared to germ-free mice transplanted with the microbes of thin mice, reinforcing the theory of the existence of a causal relationship between microbiota and obesity. Thus, surprisingly, the energy-harvesting phenotype is transmissible simply by the transfer of "obese microbiota" to healthy and lean individuals (Turnbaugh *et al.*, 2006, 2008). But not all genera and species play the same role within a given phylum. Different bacterial species present different characteristics, which may be related to beneficial or harmful traits. For example, *Lactobacillus* representation is greater in obese compared to thin individuals. However paradoxically, overweight adolescents who lose weight due to calorie restriction and increased physical activity have amplified *Lactobacillus* count. Thus, the probiotic approach with specific strains of *Lactobacillus* does not escalate, but even reduces the metabolic alterations that occur in obesity. A positive impact on insulin sensitivity has even been shown. The administration of specific probiotic strains such as *Lactobacillus rhamnosus* and *Lactobacillus gasseri* have shown beneficial effects on obesity with decreased body mass index and visceral and subcutaneous fat mass in overweight and obese subjects (Delzenne *et al.*, 2011). In addition, other species of *Lactobacillus* such as *Lactobacillus plantarum* and paracasei have been associated with thinness, compared to species such as Lactobacillus reuteri that have been associated with obesity. This suggests that the physiological effects of probiotics are highly dependent on the strain (Luoto *et al.*, 2010; Million *et al.*, 2012).

At the genus level, the presence of Acinetobacter, Aliivibrio, Marinomonas, Pseudoalteromonas, Shewanella, Lachnospira, Citrobacter and Shigella, as well as Parabacteroides distasonis and *Escherichia coli* have been positively associated with obesity. However, the presence of Bacteroides, Prevotella, Sutterella, and Methanobrevibacter has shown a negative association (Million *et al.*, 2013). Reduced levels of *A. muciniphila*, a mucin-degrading bacterium, have been associated with obesity and diabetes. Normalization of its levels using prebiotics and feeding type is associated with an improved metabolic profile in rodents (Walsh *et al.*, 2014; Everard *et al.*, 2013).

New findings indicate that an increased *A. muciniphila* abundance in obese or overweight subjects exposed to a calorie-restricted diet is associated with a healthier metabolic state, including improved lipid and carbohydrates metabolism and body fat distribution with decreased waist circumference (Dao *et al.*, 2016). Further investigation is needed building upon current data to determine the potential therapeutic applicability of *A. muciniphila*. This also indicates the importance of certain genera or species that exist in small proportions in the pathogenesis of obesity.

In addition, alterations in the microbiota seem to precede alterations in weight. The study by Kalliomäki *et al.* (2008) showed a greater proportion of *Bifidobacterium* and smaller number of *Staphylococcus aureus* in children with normal weight compared to those who were overweight over the years, proposing that *S. aureus* may act as a trigger for low-grade inflammation.

On the other hand, bariatric surgery is the most effective treatment nowadays for patients with morbid obesity. But the beneficial effects of bariatric surgery on carbohydrate homeostasis, energy expenditure and increased satiety are not completely explained by the ingestion restriction and malabsorption generated. Emerging data suggest changes in hormone levels and gut microbial profiles could be an added influence (Jain *et al.*, 2018). Certain surgical interventions such as Roux-en-Y gastric bypass have shown alterations in gut microbiota, which may contribute to some of the favorable effects of these surgeries. Zhang *et al.* (2009) published changes in the microbiota of subjects after Roux-en-Y gastric bypass with large increases in Gammaproteobacteria and proportional decreases in *Firmicutes*. A French study (Kong *et al.*, 2013) supports these findings and also describes an increase in the richness of the microbiome after surgery.

In animal models, (Liou *et al.*, 2013) germ-free mice received Roux-en-Y gastric bypass-microbiota, which induced a more significant weight loss and fat mass decrease compared to germ-free mice that received microbiota from mice undergoing other surgery.

Final Considerations

The obesity epidemic is increasing in recent decades so the traditional theories of weight gain as an imbalance between energy expenditure and consumption results too simplistic. Other elements such as gut microbiota must be involved as possible etiopathogenic factors.

Obesity is associated with profound changes in the composition and metabolic function of gut microbiota. The "obese microbiota" obtains energy from the diet more efficiently through greater absorption and deposition of nutrients. This is due to an improved capacity to decompose indigestible polysaccharides that cannot be digested by the host, which leads to increased monosaccharide and SCFA production. In addition, certain bacterial phyla are associated with greater energy utilization of food consumed. However, this increase in fat mass is not only related to a more efficient energy harvest, but also to the participation of microbiota in changes in the hormonal environment, the expression of genes regulating lipogenesis and insulin resistance.

Gut microbiota disturbances contribute to the development of metabolic disorders. In particular, these changes in the microbial community seem to precede the weight gain and metabolic consequences of obesity. The composition of the obese subjects microbiota is different from that of thin controls. The mechanisms by which the microbiota may influence the pathogenesis of obesity include modifications in FIAF expression, increases in the endocannabinoid system tone, changes in incretin secretion and active metabolites such as SCFA and secondary bile acids. Microbial transplants have been able to alter weight in animal models.

Overall, going deeper into strategies to integrate this emerging knowledge to understand the complex relationships between the host, gut microbiota and diet is necessary for the prevention and management of metabolic disease such us obesity.

Regulation of Food Intake

Albert Lecube and Carolina López-Cano, University Hospital Arnau de Vilanova, Lleida, Spain; Obesity, Diabetes and Metabolism Research Group (ODIM), Lleida Biomedical Research Institute (IRBLleida), Lleida, Spain; and University of Lleida, Lleida, Spain

Abbreviations

AgRP	Agouti-related peptide
Alpha-MSH	Alpha-melanocyte stimulating hormone
BBB	Blood–brain barrier
CART	Cocaine- and amphetamine-regulated transcript
CCK	Cholecystokinin
CNS	Central nervous system
GABA	Gamma amino butyric acid
GHS	Growth hormone secretagogue receptor
GLP1	Glucagon-like peptide 1
LHA	Lateral hypothalamic area
MC4R	Melanocortin 4 receptor
NPY	Neuropeptide Y
NTS	Nucleus tractus solitarious
PYY	Peptide YY

Introduction

In the healthy subject, many signals of internal and external signals of nutrient availability, such as behavior (i.e., food intake), the endocrine system, and the autonomic nervous system, translate information to the brain. All this information will be engaged in the central nervous system (CNS) to provide a synchronized response to fluctuations in energy balance and body weight that include the volitional control of intake and the energy expenditure (Broberger, 2005; Farr *et al.*, 2016). Under healthy conditions, there is a close correspondence between the intake and the expenditure of energy, and body weight is relatively constant: an excess of intake over expenditure of only 1% would lead to an increase in weight of more than 1 kg per year.

Traditional accounts of brain regulation of food intake describe two large systems that balance each other: the hypothalamus, receiving signals from the periphery that notify the decrease in energy stores, and the brainstem, receiving oral and gastrointestinal information as an online signal of the quantities and qualities of the food that has been ingested. This procedure would allow the hypothalamus to function as a long-term control orchestrating meal initiation and the brainstem would serve as a short-term control for meal termination (Broberger, 2005).

Peripheral signals from the gastrointestinal tract and from currently available metabolic fuels are both humoral and neural. Neural inputs are mainly transmitted via afferent (sensory) fibers on the vagus nerve (i.e., gastric distension is sensed and transmitted to the brain by vagal afferents in the stomach wall). Humoral factors comprise hormones (i.e., leptin and insulin), gut peptides (i.e., ghrelin), and circulating metabolites (i.e., fatty acids and glucose).

Although control of energy homeostasis includes a short-term (homeostatic) and a longer-term (hedonic) control of appetite and food intake, clearly the two pathways are interrelated and dependent (Saper *et al.*, 2002). Despite continuous improvement in both basic and clinical research, the control of normal eating remains only partly understood. In this article, part of this knowledge will be highlighted.

Peripheral Signals From the Gastrointestinal Tract

The gastrointestinal tract is one of several organs that contribute to the peripheral signaling of food intake and satiety. In fact, eating is affected by a wide variety of peptides emerging from the alimentary tract that communicate with the brain through both hormonal and neural signals, acting as a feedback controls (Badman and Flier, 2005) (**Fig. 1**).

Four are the main gastrointestinal peptides [cholecystokinin (CCK), peptide YY (PYY), ghrelin, and glucagon-like peptide 1 (GLP1)] that bind to their respective receptors located at the vagus nerve fiber terminals, distributed through the digestive mucosal layer. When gut peptide information is converted to electrical signals, it reaches the nucleous tractus solitarious (NTS) in the brainstem. Ghrelin is the only that enhances appetite. The other three peptides play a role in appetite suppression (Crawley and Corwin, 1994).

Cholecystokinin

CCK is secreted by the neuroendocrine I cell in the duodenal and jejunal mucosa in response to the presence of high intraluminal concentrations of proteins and long-chain fatty acids derived from the digestion of triglycerides. So that, CCK is involved in the short-term regulation of energy intake, with an important role as a satiety factor (Gibbs *et al.*, 1973). This satiating effect of CCK is enhanced by the administration of central leptin, suggesting the presence of physiologic interactions between short-term (CCK) and long-term (leptin) regulators of energy homeostasis (Emond *et al.*, 1999).

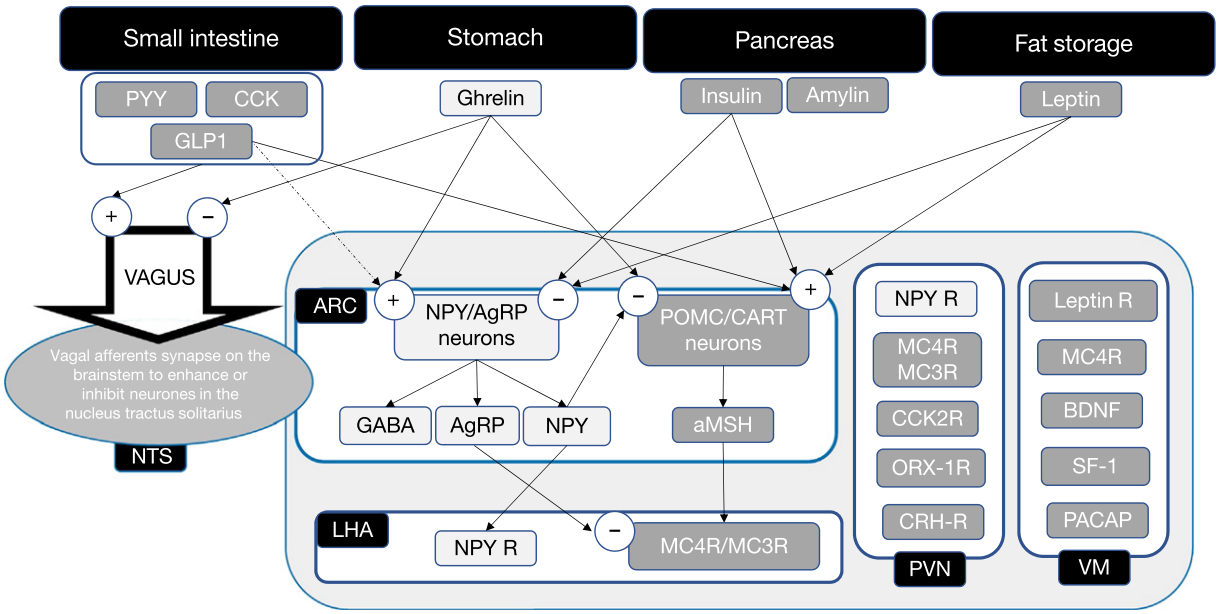

Fig. 1 Summary of the main functions of the key peptides and neurotransmitters that regulate food intake. *Black boxes* reflect anatomical places. *Dark gray* boxes indicate peptides that reduce food intake. *Light gray* boxes indicate appetite stimulators. AgRP, Agouti-related peptide; aMSH, alpha-melanocyte stimulating hormone; ARC, arcuatus nucleus; BDNF, brain-derived neurotropic factor; CART, cocaine- and amphetamine-regulated transcript; CCK, cholecystokinin; GABA, gamma amino butyric acid; GLP1, glucagon-like peptide 1; LHA, lateral hypothalamic area; MC4R, melanocortin 4 receptor; MC3R, melanocortin 3 receptor; NPY, neuropeptide Y; NTS, nucleous tractus solitarious; orexin A (ORX-1R); PYY, peptide YY; PVN, paraventricular nucleus; PACAP, Pituitary adenylate cyclase-activating polypeptide; SF-1, steroidogenic factor 1; VHA, ventromedial hypothalamic area.

CCK acts on the CCK-1 (originally named CCK-A) receptors on vagal sensory terminals in the upper gut, which project to the NTS in the brainstem (Kopin *et al.*, 1999). Mutations of this receptor produce severe hyperphagia and morbid obesity. In addition, CCK is not only a neurotransmitter; it also acts as an intestinal peptide hormone with actions that include contraction of the gallbladder.

Ghrelin

Ghrelin is a gut peptide described in 1999 as an endogenous ligand for the growth hormone secretagogue receptor (GHS-R), a G-coupled receptor broadly expressed in the CNS and in peripheral tissues (Kojima *et al.*, 1999; Mihalache *et al.*, 2016). Composed by 28-amino-acid, it is secreted mainly by X/A-like gastric cells in the oxyntic glands of the gastric fundus mucosa, and also in the brain, including the hypothalamic neurons (Stengel and Tache, 2012; Shuto *et al.*, 2001). And ghrelin is present in human plasma in two forms: an inactive form known as deacylated ghrelin, and an active form, the acylated ghrelin synthesized under the action of ghrelin *O*-acyltransferase enzyme (GOAT).

Ghrelin contributes to the control of energy homeostasis by acting as an orexigenic (appetite-stimulating) signal by a mixed mechanism. Ghrelin promotes the electrical activity of vagal afferent pathways, and this information is transmitted to noradrenaline neurons at NTS in the brainstem. In addition, ghrelin also acts through the GHS-R, which is widely expressed in hypothalamic appetite centers, enhancing NPY/AgRP neurons and suppressing POMC neurons (Nakazato *et al.*, 2001; Date *et al.*, 2006). So, ghrelin is the only peripheral orexigenic hormone that enhances appetite actions through its receptors localized in the hypothalamus.

Plasma ghrelin concentrations are closely related to hunger. Ghrelin secretion and serum levels exhibit a preprandial rise and a postprandially fall, which strongly suggest that the peptide plays a physiological role in meal initiation (Cummings *et al.*, 2001, 2005; Cummings and Overduin, 2007). In addition, besides the stimulation of food intake, ghrelin is also an adiposity signal that decreases its serum concentration with the increase of body fat (Tschöp *et al.*, 2001). Therefore, ghrelin also brings about a decrease in energy expenditure and promotes the storage of fatty acids in adipocytes. Ghrelin mutations have been associated with obesity (Ukkola *et al.*, 2001).

Glucagon Like Peptide 1

GLP1 is a hormone secreted predominantly by the L cells of the ileum in response to nutrient intake (Baggio and Drucker, 2007). Its main action is directed to stimulate the secretion of insulin by pancreatic beta cells and the suppression of glucagon secretion by pancreatic alpha cells.

The effect of GLP1 on food intake is exerted both indirectly and directly (Ban *et al.*, 2008; van Bloemendaal *et al.*, 2014). A portion of the GLP1 that reaches the portal circulation will contact the receptors present in the afferent roots of the vagus nerve, which will project its satiating effect on the NST in the brainstem. In turn, the NTS neurons are projected into several areas of regulation of intake, most of which also contain GLP1 receptors, including the ventral tegmental area and the nucleus accumbens.

Another part of the intestinal GLP1 will reach the HPT through the systemic circulation and permeable areas of the blood–brain barrier (BBB). In the arcuate nucleus, the neurons that produce POMC/CART have a higher density of GLP-1 receptors than the NPY/AgRP neurons, enhancing its satiating effect (Secher *et al.*, 2014).

Peptide YY

The peptide YY (PYY), also known as peptide tyrosine tyrosine is a peptide encoded by the gene PYY in humans. PYY is a short peptide of 36 amino-acid released from enteroendocrine cells in the ileum and colon in response to feeding (Adrian *et al.*, 1985). PYY, under the presence of lipids and carbohydrates, enhances a comparatively modest effect on satiety (Batterham *et al.*, 2002).

Peripheral Signals From Currently Available Metabolic Fuels

In human adults, changes in body weight are mainly attributable to fluctuations in adipose tissue. The regulation of this variability is partly explained by four hormones that circulate at levels proportional to fat mass, and participate in the control of food intake and energy expenditure. Leptin is the only one secreted by the adipocytes themselves; the other three are insulin, ghrelin and amylin.

Leptin

Leptin is a 16 kD hormone containing 146 amino acids that is encoded by the ob gene. Leptin is synthesized in the periphery mainly by white adipose tissue. In well-nourished humans, plasma leptin concentration is proportional to body fat mass (Ahima *et al.*, 2000). Therefore, its main role is to signal the amount of stored energy as adipose tissue, and consequently, to regulate energy intake and expenditure to maintain body weight (Stieg *et al.*, 2015; Farr *et al.*, 2015). At higher levels of body fat, increased circulating levels of leptin will limit food intake and increase energy outflow. This effect is facilitated by a saturable leptin transport system through the BBB. Once leptin has passed the BBB, it binds to its receptors (Ob-Rb) in several brain regions, mainly in the arcuate nucleus, where suppresses appetite by enhancing POMC/CART neurons and inhibiting NPY/AgRP neurons (Malik and Young, 1996; Zhang *et al.*, 1994; Pinto *et al.*, 2004). Similarly, in addition to its long-term lipostatic function, short-term famine results in severe decreases of leptin levels (Chan *et al.*, 2003). So, at lower levels of body fat, leptin circulates at lower levels increasing food intake and decreasing energy expenditure. Another known effect of leptin is also that enhances the satiating effect of CCK.

An inconsistent finding in the relationship between leptin and it strong regulatory effect in energy homeostasis occurs in obese patients, that show increased serum leptin concentrations. It has been suggested that, analogous to the reduced effects of insulin in people with insulin resistance and type 2 diabetes who overcome hyperinsulinemic, obese people develop a leptin resistance that impedes its homeostatic effects.

Mutations in the leptin gene cause an insatiable appetite, morbid obesity and numerous clinical abnormalities, all of which are corrected by leptin administration.

Insulin

The role of insulin is not limited to act as a key glucostatic regulator controlling peripheral glucose uptake. Insulin is also a circulating afferent signal, whose concentrations correlates with body fat mass, and shows many anabolic central effects, in synergism with leptin (Moehlecke *et al.*, 2016). Insulin enters by receptor-mediated processes in the BBB in the CNS, where its receptors are expressed in the hypothalamus and elsewhere (Banks and Kastin, 1998). When insulin activates its receptors in the arcuate nucleus stimulates the POMC/CART and inhibits the NPY/AgRP neurons to finally decrease food intake. In fact, mice without insulin receptors in the CNS develop hyperphagia and fat deposition (Obici *et al.*, 2002). However, obese individuals become resistant to insulin, similar to leptin, and remain hyperphagic despite high circulating levels of both hormones (Heymsfield *et al.*, 1999).

Amylin

Amylin is co-secreted with insulin from the pancreatic β-cells in response to nutrient stimuli during a meal, and suppresses postprandial blood glucose levels (Mietlicki-Baase, 2016; Scherbaum, 1998; Betsholtz *et al.*, 1989). However, amylin also has potent effects on energy balance, and acts within the brain to reduce food intake and body weight, promoting negative energy balance (Mietlicki-Baase and Hayes, 2014; Lutz, 2005). These effects are mediated via direct action in the central nervous system

(Lutz *et al.*, 1995) as amylin cross the blood–brain barrier to suppress food intake (Banks and Kastin, 1998) to activate its receptors. Amylin binding sites are distributed widely throughout the brain, mainly in the area postrema but also in hypothalamic nucleus and caudal brainstem (Lutz, 2012).

Integration of Peripheral Signals Through the Vagus Nerve

The vagus nerve is the 10th cranial nerve, is composed of both afferent (visceral sensory nerve) and efferent (motor nerve) fibers, and is an essential pathway in the regulation of food intake and energy metabolism (Berthoud and Neuhuber, 2000; Ueno and Nakazato, 2016). The vagus afferent nerve is a bipolar neuron with the cell body located in the nodose ganglion, exhibiting a projection to one to various peripheral organs and another to the NTS. That means that peripheral nerve terminals of the vagal afferent fibers distributed along the mucosal and submucosal layers of the digestive tract will exchange integrated nutritional information with the CNS. In addition, mucosal afferents terminals are most abundant in the upper small intestine, near to mucosal enteroendocrine cells (Powley *et al.*, 2011). Finally, it should be remembered that vagal afferent neurones signal in the NTS via glutamate and the neuropeptide cocaine- and amphetamine-regulated transcript (CART).

Multiple receptors are co-expressed on one cell body in the vagus nerve, and affect food intake in an additive, synergistic or antagonistic manner. Therefore, vagal afferents are broadly sensitive in a dose-dependent manner to gastrointestinal signals, including peptides produced by endocrine cells in the gut wall, the presence of chemically distinct nutrients within the gastrointestinal tract as well as gastroduodenal distension. Any abnormality in this essential pathway between the gastrointestinal tract and the CNS will lead to disrupted transmission of signals for appetite regulation.

Most GI peptides activate their receptors on vagal afferent nerve endings in a mostly paracrine manner increasing vagal afferent trigger. This vagal activation causes satiation and meal termination (Raybould, 2007). Ghrelin, in contrast, is released from the stomach and inhibits vagal afferent firing (Date, 2012). In addition, gastrointestinal peptides like CCK and GLP1 also enter the bloodstream and act as a neurotransmitter within the brainstem to affect vagal afferent and efferent responses. Although the contribution of paracrine versus non-paracrine modulation of vagal neurocircuits is not clear, gastrointestinal peptides seem to be able to exercise coordinated but temporally dissimilar actions to regulate vagally dependent functions.

The Neuroanatomy of Eating Regulation

Many brain areas are involved in a hierarchical mode in the neural regulation that regulates body weight, appetite, and energy homeostasis. In humans, the last integrator of metabolic information and hedonic drives that regulates food consumption is the hypothalamus, which contains many microscopically defined nuclei and interconnected areas, that are involved in the control of eating (Münzberg *et al.*, 2016; Berthoud *et al.*, 2017).

Brainstem and the Nucleus Tractus Solitarius

The brainstem is the second main port from vagal and other neural sensory signals that carry information pertaining to energy balance from the alimentary organs to the brain. Vagal afferents synapse on the brainstem to enhance or inhibit neurones in the NTS (Broberger, 2005). From the brainstem, projections fan further into the brain to involve other regions in the initiation and organization of food intake.

The Arcuate Nucleus

First, hormonal signals reflecting the availability and demand for metabolic fuel is relayed via neurones in the hypothalamus. The receptors for these signals are primarily expressed on two neurochemically distinct sets of neurones located in the arcuate nucleus (Arc) in the mediobasal hypothalamus, alongside the third ventricle [40]. One neurone group expresses neuropeptide Y (NPY); increasing NPY release or activation of these neurones by a variety of approaches results in increased food intake and decreased energy expenditure. The other group expresses the neuropeptide precursor pro-opiomelanocortin (POMC), which is processed to melanocortin peptides; activation of these neurons has the opposite effect of triggering the NPY cells, that is, decreased food intake and increased energy expenditure.

From the NTS signal reflecting the availability and demand for metabolic fuel will go to the arcuate nucleus, that lies around of the base of the third ventricle in the mediobasal hypothalamus. The ARC nucleus contains two distinct set of neurons that are crucial for controlling food intake and regulating body weight. The formers are the “hunger” neurons NPY/AgRP. They express two orexigenic peptides, mainly the neuropeptide Y (NPY) and also the Agouti-related protein (AgRP). Neuropeptide Y is one of the most potent feeding stimulators known, and translates the low nutrient availability into motivated behavioral action: increase appetite and decrease energy expenditure (Schwartz, 2005).

The second are the appetite-suppressing POMC/CART neurons that expresses the neuropeptides pro-opiomelanocortin (POMC) and CART. The triggering of these neurons transforms POMC, a large precursor protein, in several bioactive peptides,

mainly the alpha-melanocyte stimulating hormone (alpha-MSH). The alpha-MSH produced by POMC neurons suppresses appetite by acting as an agonist of the melanocortin 3 and 4 receptors (MC3R and MC4R) (Ollmann *et al.*, 1997). In fact, humans carrying the MCR4 mutation present with hyperphagia and obesity (Farooqi *et al.*, 2003).

In the arcuate nucleus, the AgRP/NPY neurons are able to control the activity of the POMC/CART cells via two mechanisms. First, the AgRP is an endogenous melanocortin antagonist in the MC4R. Thus, at the axon terminal, melanocortin action can be blocked by simultaneous release of AgRP. Secondly, at the cell body level, POMC neurones are innervated by NPY-ergic terminals and express the Y1 receptor, through which NPY causes a powerful inhibitory effect. Surprisingly, no reciprocal innervation has yet been described.

In addition, both groups of neurons are modulated by peripheral hormonal signals (insulin, leptin, ghrelin, and GLP1) that are transported by the specialized BBB of the arcuate nucleus to receptors on one or both populations: the AgRP/NPY population express receptors for the three peptides, whilst the POMC/CART neurons express receptors for leptin, insulin and GLP1. Insulin and leptin receptors serve to inhibit the transcription of NPY and increase POMC mRNA levels through differential second messenger systems. Furthermore, the NPY/AgRP neurons also release gamma amino butyric acid (GABA) and suppress POMC neurons through the GABA receptor (Wu *et al.*, 2009).

Finally, the axons of POMC/CART neurons and NPY/AgRP neurons have extensive projections to other nuclei of the hypothalamus, involved in eating as the lateral hypothalamic area (LHA) and the paraventricular nucleus, the ventromedial nucleus, the lateral nucleus and the dorsomedial nucleus. In additions, there are also projections to other non-hypothalamic brain regions like the corticolimbic system and the brainstem.

The Lateral Hypothalamic Area

The effects of POMC/CART and AgRP/NPY on food intake depend on subsequent excitatory effects in the lateral hypothalamic area (LHA) (Stratford and Kelley, 1999). This is an anatomically diffuse area that contains independent sets of neurons that express NPY and alpha-MSH receptors (MCR4). In response to these inputs, the LHA set of neurons secrete two eating-stimulating peptides: orexin A (also called hypocretin) and melanin-concentrating hormone (MCH) (Broberger *et al.*, 1998). In rodents, intracerebroventricular injection of MCH induces feeding. While fasting upregulates MCH mRNA expression (Qu *et al.*, 1996). MCH knockout mice are hypophagic and lean (Shimada *et al.*, 1998) whereas mice that overexpress MCH are obese and hyperleptinemic (Ludwig *et al.*, 2001). Moreover, the LHA also contains neurons that may sense serum long-chain fatty acids and glucose. On the other hand, the orexin neurons also project back to the ARC nucleus.

The Paraventricular Nucleus

The paraventricular nucleus (PVN) receives neuronal inputs from the arcuate nucleus and the HLA (Maejima *et al.*, 2009; Arletti *et al.*, 1989). Its neurons express receptors for NPY and alpha-MSH, as well as for other neurotransmitters that affect eating, mainly peptides suppressors of appetite such as CCK (CCK-R2), orexin A (ORX-1R), oxytocin, corticotrophin releasing hormone (CRH), nesfatin, thyrotropin releasing hormone (TRH), and serotonine. Neuronal projections to histamine neurons that suppress appetite are also observed in the PVN.

The Ventromedial Hypothalamic Area

The ventromedial nucleus (VMN) of the hypothalamus is considered a "satiety center." In concordance, the VMN expresses high levels of the leptin receptor and MC4R, together with the CCK-2 receptor. In addition, in the VMN there are also neurons containing other eating-inhibitory peptides, such as the brain-derived neurotrophic factors (BDNF), the steroidogenic factor 1 (that up-regulates leptin receptors expression), and the pituitary adenylate cyclase-activating peptide (that activates the POMC/CART neuron in the ARC nucleus (Mounien *et al.*, 2009; Kim *et al.*, 2011; Matsuda *et al.*, 2013; Choi *et al.*, 2013).

The Dorsomedial Hypothalamus Area (DMH)

The role of the dorsomedial hypothalamus (DMH) area is less known. Neurons producing NPY have been described in this hypothalamic area, with projections to the PVN. This PNY neurons contains CCK-1 receptors, and are tonically inhibited from the CCK released from neurons rather than the CCK derived from the periphery. Sustained exercise seems to be another cause of tonic inhibition of these neurons (Moran and Bi, 2006).

The Corticolimbic System

The corticolimbic system consist of large cortical areas, basal ganglia, hippocampus, and amygdala. This system is intimately connected to the hypothalamus and brainstem and provides the emotional, cognitive, and executive support for ingestion behavior (Kelley *et al.*, 2005; Murray and Rudebeck, 2013).

Food Reward

Feeding has an important motivational component. Food cues (visual and olfactory stimuli) and food consumption (gustatory stimuli, gastrointestinal signals) are naturally pleasant for humans, and typically acts on the reward pathways in the brain (Flier, 2004). These pathways are based in the dopaminergic neurons which originate in the ventral tegmental area (VTA) and substantia nigra in the midbrain (Burger and Stice, 2011). These neurons expand through the human brain to the main areas involved in the reception and integration of these dopaminergic inputs: the nucleus accumbens, striatum, and orbitofrontal cortex (Blum *et al.*, 2014). In fact, PET studies have consistently reported lower availability of dopamine receptors in the striatum of obese subjects as compared to normal weight individuals. These data suggest that lower dopaminergic signaling may lead to the search for highly rewarding foods (high calorie or high fat) and this in turn, leads to obesity.

A Last Remark

Few tasks hold greater survival value than keeping us fed and in adequate nutritional state. Most importantly, control of eating in human brain not only includes the homeostatic brain systems (hypothalamus), but also attention systems (including the parietal and visual cortices), emotion and memory systems (such as the amygdala and hippocampus), cognitive control (including the prefrontal cortex), and the reward network (including the VTA and striatum). It must be remembered that, much of neural processing within this core processor occurs outside awareness, rendering it relatively inaccessible to conscious manipulation.

Introduction

A leading reason for the success of the evolution of humans is our adaptability. Humans have favorably evolved to survive in almost all environments and circumstances. Even if in some occasions the lack of food has been substantial, the human body has always built-in different defences against starvation like our own storage of fat. Traditionally, the adipose tissue (AT) was simply defined as a mere storage organ for excess calories in the fed state from which free fatty acids (FFA) are released during fasting to fuel the energy demands of the organism (Scherer, 2006; Rosen and Spiegelman, 2014). Research over the past two decades has revealed AT as one of the largest endocrine organs in the body as well as an active tissue for cellular reactions with a key role in energy homeostasis secreting and expressing a wide range of biologically active molecules, which are known as adipokines (Fain *et al.*, 2004; Rodríguez *et al.*, 2007; Ibrahim, 2010). Evidence further shows that AT is also an important site expressing different receptors involved in adipokine-related metabolic processes exerting autocrine and paracrine actions. Adipokines may be also released into the systemic circulation showing further endocrine effects (Vona-Davis and Rose, 2007; Dunmore and Brown, 2013).

Obesity, defined as an excess of adiposity due to a prolonged status of positive energy balance, leads not only to changes in AT distribution but also to alterations in the metabolism as well as in the adipokines and lipid secretion profiles (Gesta *et al.*, 2007). The factors that determine AT mass and volume in adult humans are not totally understood, however, the increased lipid storage in the adipocytes due to an unhealthy lifestyle is thought to be an important reason (Björntorp, 1974; Hirsch and Batchelor, 1976; Frühbeck, 2012). The distribution of the different fat depots inside the human body is also an important factor influencing the development of obesity-associated comorbidities (Rodríguez *et al.*, 2007; Ibrahim, 2010). In this regard, a relationship between the distribution of central and upper body fat storages with metabolic diseases such as insulin resistance (IR), high blood pressure, dyslipidemia, fatty liver, cardiovascular diseases (CVD) or even cancer has been demonstrated in multiple studies, leading to a decreased life expectancy (Mokdad *et al.*, 2003; Angulo, 2006; Moore, 2010; Trayhurn, 2013; Van Gaal *et al.*, 2006; Landsberg *et al.*, 2013; Calle and Kaaks, 2004; Picon-Ruiz *et al.*, 2017).

Characteristics of Adipose Tissue

In mammals, three types of AT can be distinguished: white, brown and beige or "brite" (brown in white) that differ in their origin, morphology, location, and function (Frühbeck *et al.*, 2009a). White adipose tissue (WAT) is a heterogeneous tissue and its different anatomical locations determine its metabolic identity and core functions (Kusminski *et al.*, 2016; Frayn *et al.*, 2003; Lee *et al.*, 2013a). In humans, WAT mainly consists in a central intraabdominal component (visceral adipose tissue [VAT]), which is associated with metabolic disease risk and a peripheral subcutaneous AT depot (SAT), associated with protective effects on energy homeostasis (Rodríguez *et al.*, 2007; Fox *et al.*, 2007; Koster *et al.*, 2010; Björntorp, 1988). The major role of WAT is related to maintaining energy homeostasis by storing triglycerides and releasing fatty acids for energy synthesis. However, it is well-established that WAT also controls a wide variety of functions including immune and inflammatory regulation, glucose and lipid homeostasis, food intake control or metabolism by secreting a great number of adipokines (Catalán *et al.*, 2009a; Falcão-Pires *et al.*, 2012). Energy-storing white adipocytes exhibited a variable size (25–200 μm) and contain a single, large and unilocular lipid droplet surrounded by a layer of cytoplasm. Within the adipocyte, the nucleus is flattened and located on the periphery and few mitochondria with a low oxidative rate are found (Luo and Liu, 2016; Jeanson *et al.*, 2015; Frühbeck *et al.*, 2009b). Furthermore, these developed and spherical white adipocytes are well-vascularized by anatomically surrounding vessels. Cells are densely distributed and are subdivided into small lobules that are innervated by, both, the sympathetic and parasympathetic nervous systems.

Brown adipose tissue (BAT) is the main site of nonshivering thermogenesis and energy expenditure in mammals (Feng *et al.*, 2013; Cannon and Nedergaard, 2004; Villarroya *et al.*, 2017). BAT is a remarkably plastic tissue and its depots enlarge via hypertrophic and hyperplasic processes when thermogenesis is activated (Cannon and Nedergaard, 2004). Contrary to the initial concept that BAT is restricted in humans to neonates and young children, recent studies using positron emission tomography imaging techniques have documented the presence of functional BAT in adult humans, being mainly located in the ventral neck, the supraclavicular area as well as in mediastinum, paravertebral and suprarenal fat (Frühbeck *et al.*, 2009b; Virtanen *et al.*, 2009; Schulz *et al.*, 2011; Cypess *et al.*, 2009). Reportedly, BAT has been inversely correlated with BMI (Cypess *et al.*, 2009). The specific secretor profile of BAT is quite distinct from that of WAT, probably due to the different and largely opposite, physiological roles in

 doi:10.1016/B978-0-12-801238-3.65163-2

energy metabolism (Villarroya *et al.*, 2017). The brown adipocytes are characterized by expressing uncoupling protein 1 (UCP-1), which through the oxidative phosphorylation for ATP synthesis dissipates energy as heat, constituting a key regulator of thermogenesis (Wu *et al.*, 2012). Energy-expending brown adipocytes are cells with small lipid droplets in a multilocular pattern and contain many mitochondria with high oxidative capacity (Lynes and Tseng, 2017; Ricquier *et al.*, 1982). The higher amount of mitochondria compared to WAT favors its brownish color. BAT is highly vascularized and innervated by the sympathetic nervous system, promoting the dissipation of heat via blood vessels (Frühbeck *et al.*, 2009b; Park, 2014).

Recently, the existence of a third kind of AT has been proposed, the beige adipose tissue (Wu *et al.*, 2013). Sustained thermogenic activation induced by prolonged cold exposure leads to the "browning" of WAT, with the emergence of brown adipocyte-like cells in WAT depots (Wu *et al.*, 2012; Siersbæk *et al.*, 2012). The browning process is regulated by a complex hormonal interplay and many environmental factors such as chronic cold exposure, exercise, and environmental enrichment (Schulz *et al.*, 2013; Bartelt and Heeren, 2013; Jankovic *et al.*, 2015; Sidossis and Kajimura, 2015). Beige adipocytes are most abundant in the inguinal WAT, which is a major subcutaneous depot in rodents (Vitali *et al.*, 2012). The amount of beige adipocytes in different human WAT depots has not been carefully determined (Harms and Seale, 2013; Elabd *et al.*, 2009). These brite or beige cells exhibit different gene expression patterns compared to those of white or brown adipocytes (Svensson *et al.*, 2011; Shabalina *et al.*, 2013). Importantly, the thermogenic profile of beige adipocytes is reversible. On warm adaptation, former brite adipocytes change their morphology and their gene expression profile to that of a white adipocyte (Rosenwald *et al.*, 2013).

Cellular Heterogeneity of Adipose Tissue

Although adipocytes are the main cells of the AT as well as the responsible for energy homeostasis control and adipokine release, this connective tissue is formed by other different cellular types including preadipocytes, immune cells, nerve cells, and vascular cells that interplay among them contributing to the main functions of each AT depots (Lynes and Tseng, 2017).

During normal AT turnover, mature adipocytes are replaced by newly differentiated and mature adipocyte progenitors or preadipocytes in a process called adipogenesis (Shan *et al.*, 2017). In adult humans, an adipocyte turnover of approximately 10% is observed (Spalding *et al.*, 2008). Preadipocyte functions in fat depots comprise the regulation of extracellular matrix (ECM) remodeling and the secretion of endocrine factors. Immune cells are also important cellular components present within the varied AT cellularity. Adipose tissue-resident macrophages (ATM) were the first immune cells described in AT showing a close association with obesity (Weisberg *et al.*, 2003). AT is innervated by a neuronal mesh that regulates processes such as lipolysis or thermogenesis. In cold environments, nerve cells comprising the neuronal mesh activate the sympathetic neural system in the parenchymal of WAT, leading to the release of FAA via lipolysis and also triggering BAT thermogenesis (Locke *et al.*, 2015; Garretson *et al.*, 2016). Equally, WAT is connected to other organs, including the brain, by sensory nerve afferent networks (Bamshad *et al.*, 1998; Bartness *et al.*, 2014). Vascularization of fat depots relies on endothelial and smooth muscle cells. Interestingly, high adipocyte precursor areas are highly vascularized compared to other sections of the AT, predicting the existence of a relationship between mature adipocyte turnover and vasculature. Adipocyte metabolic processes are also dependent on the adequate uptake or release of nutrients, with blood vessels being fundamental for this process (Sotornik *et al.*, 2012; Abreu-Vieira *et al.*, 2015).

Origin of Adipose Tissue

Each AT depot has a unique developmental origin with a different gene signature, lipid storage capacity and adipokine profile (Frühbeck *et al.*, 2009b; Tchkonia *et al.*, 2013). Although white and brown adipocytes derive from the same mesenchymal stem cells (Enerbäck, 2009), during gastrulation, the mesenchymal stem cells of the paraxial mesoderm express the myogenic transcription factor Myf5 and become brown adipocytes or myocytes. However, the mesenchymal stem cells of the lateral mesoderm do not express Myf5 and differentiate into white adipocytes or blood vessel-associated pericytes (Rodríguez *et al.*, 2015).

White adipogenesis is a tightly regulated two-step process involving multiple factors. Firstly, a pluripotent stem cell is differentiated into a unipotent adipocyte precursor or preadipocyte, which subsequently is differentiated into a phenotype of mature adipocytes achieving their corresponding functional properties. Peroxisome proliferator-activated receptor (PPAR)-γ, a member of the nuclear-receptor superfamily, has been identified as a master regulator of white adipogenesis (Rosen *et al.*, 2000). Whereas the deficiency of PPAR-γ, fails to promote adipogenesis, its overexpression is sufficient to induce adipocyte differentiation in fibroblasts (Tontonoz *et al.*, 1994; Koutnikova *et al.*, 2003). Other factors or pathways including pro-adipogenic factors such as C/EBPs and Krüppel-like factors (KLFs) regulate adipogenesis via PPARγ-dependent mechanisms (Luo and Liu, 2016). Bone morphogenetic proteins (BMPs), members of the transforming growth factor (TGF)-β superfamily, also play an important role in this transformation due to their regulatory function by boosting the differentiation of pluripotent stem cells to chondrocytes, osteoblasts or adipocytes (Bandyopadhyay *et al.*, 2013). BMP-2 and BMP-4 through their binding to two distinct serine/threonine kinase receptors induce the phosphorylation of SMAD-1, -5 and -8 that form complexes with SMAD-4 that move into the nucleus, regulating the transcription of target genes involved in white adipogenesis (Miyazono *et al.*, 2005). BMPs also mediate their signals through SMAD-independent pathways including the MKK3/p38 MAPK and TAK1 signaling pathways, regulating the expression of BMP target genes. Nonetheless, other transcription factors repress adipogenesis such as the antiadipogenic GATA transcription factor.

Adipogenesis of brown adipocytes is totally different from that of white adipocytes. The activation of both, BMP-7 and PR domain 16 (PRDM16), is necessary to promote BAT adipogenesis (Harms *et al.*, 2014). PRDM16 selectively initiates the switch of myoblasts to brown adipocytes by forming a transcriptional complex with C/EBPβ and by suppressing white adipocyte-specific genes forming complexes with C-terminal binding proteins CTBP1 and CTBP2 (Kajimura *et al.*, 2008) and also by the upregulation of brown fat-specific markers, such as PRDM16, PPAR coactivator 1 (PGC-1) α/β and UCP1 (Rodríguez *et al.*, 2015).

Dysfunctional White Adipose Tissue in Obesity

Obesity has reached epidemic proportions constituting one of the most important diseases of this century (Bray *et al.*, 2016; NCD Risk Factor Collaboration (NCD-RisC), 2017; GBD 2015 Obesity Collaborators, 2017; Anon, 2006). Despite body mass index (BMI) being the most widely used method to diagnose and define obesity, recent studies have proposed that BMI is only a surrogate for body fatness and does not provide an accurate measurement of body composition, misclassifying subjects with increased cardiovascular risk factors (Blundell *et al.*, 2014). In this regard, other indicators to determine the prevalence of obesity have been proposed with body fat percentage being one of the most useful due to its superior ability to stratify patients according to their metabolic and cardiovascular risks (Gómez-Ambrosi *et al.*, 2011, 2012). Thus, in adults, normal body fat levels are considered to be between 10%–20% and 20%–30% in males and females, respectively (Gómez-Ambrosi *et al.*, 2011).

During obesity, AT becomes severely dysfunctional and fails to appropriately expand to store the surplus energy being associated with disrupted metabolic homeostasis and promoting the obesity-associated metabolic alterations including type 2 diabetes mellitus (T2D) (Mokdad *et al.*, 2003), nonalcoholic fatty liver disease (NAFLD) and other chronic liver diseases such as cirrhosis (Angulo, 2006; Moore, 2010), obstructive sleep apnoea (OSA) (Trayhurn, 2013) as well as cardiovascular diseases (CVD) including cerebrovascular disorders and hypertension (Van Gaal *et al.*, 2006; Landsberg *et al.*, 2013). Furthermore, emerging evidence relates obesity with several types of cancer (Calle and Kaaks, 2004; Picon-Ruiz *et al.*, 2017).

Adipose Tissue Expansion: Hyperplasia and Hypertrophy

Adipocyte hyperplasia (increase in cell number) and hypertrophy (increase in cell size) can both contribute to AT expansion (Sun *et al.*, 2011). Small variations in the adipocyte cell number during adulthood has been postulated, suggesting that the number of adipocytes for lean and obese individuals is set during childhood and adolescence and that any alterations in fat mass during adulthood are due to alterations in adipocyte hypertrophy (Spalding *et al.*, 2008; Arner *et al.*, 2011). The total number of adipocytes in AT appears to be tightly controlled with the rate of newly emerging adipocytes being regulated by adipocyte death. Alterations in two forms of programmed cell death, apoptosis and autophagy, are closely related to AT dysfunction. Autophagy is a complex evolutionarily conserved cellular process that targets intracellular components of lysosomal degradation involving many autophagy-related genes (ATGs) (Maixner *et al.*, 2016; Ezquerro *et al.*, 2017). Autophagy is thought to be upregulated in human AT in obesity particularly in patients with insulin resistance and/or T2D, being also higher in the visceral depot (Maixner *et al.*, 2012; Kosacka *et al.*, 2015). However, controversial results about the topic with other studies showing obesity-related attenuated autophagy in adipocytes have been reported (Soussi *et al.*, 2015; Yoshizaki *et al.*, 2012).

Adipose Tissue Inflammation

Obesity is characterized by a chronic state of low-grade inflammation (Wellen and Hotamisligil, 2003). The interaction between immune cells and adipocytes leads to inflammation and subsequent AT dysfunction accompanied by changes in adipokine production profile (Nishimura *et al.*, 2009).

Immunometabolism and adipocyte-derived cytokines

AT contains different types of immune cells including macrophages, lymphocytes, mast cells, eosinophils, neutrophils, and foam cells (Rodríguez *et al.*, 2015; Olefsky and Glass, 2010; Shapiro *et al.*, 2013) that establish complex interactions with adipocytes leading to the development of inflammation and subsequent AT dysfunction. Immune activated cells infiltrate the AT in a chronological sequence regulated by both, the innate and the adaptive immune systems (Catalán *et al.*, 2013a).

– *The innate immune system* provides plenty of different pro-inflammatory cells with macrophages and monocytes being the most representative immune cells (McFarlin *et al.*, 2012; Dey *et al.*, 2015; Dalmas *et al.*, 2011). Growing evidence reveals that AT from obese subjects is markedly infiltrated by macrophages that participate in inflammatory pathways with important roles in obesity-associated comorbidities (Weisberg *et al.*, 2003). Reportedly, infiltrated macrophages in AT depots from obese patients account for almost 50% of the fat depot, as opposed to the 5% observed in lean individuals (Weisberg *et al.*, 2003; Xu *et al.*, 2003; Kanneganti and Dixit, 2012). Depending on the secretion profile of cytokines and markers present on their surface, two phenotypes of macrophages can be differentiated: M1 and M2 macrophages (Bai and Sun, 2015). The proliferation of M1 cells might be stimulated in an intrinsic manner by the secretion of internal proteins such as interferon (IFN)-γ or tumor necrosis factor (TNF)-α and in an extrinsic manner, by lipopolysaccharides (LPS) from bacterial walls, constituting one of the most potent inducers of M1 differentiation (Rodríguez *et al.*, 2015; Festuccia *et al.*, 2014). Oppositely, the switching to the

antiinflammatory phenotype M2 is influenced by the production of specific immunosuppresive agents including arginase or different interleukins (IL) [IL-10, IL-4, IL-13, IL-33, and IL-1Ra] (Bai and Sun, 2015). A phenotype switch from M2 to M1 macrophages in the AT of obese subjects has been described, leading to increased levels of inflammatory markers (Lumeng *et al.*, 2007). Mast cells, eosinophils and neutrophils are other cells from the innate immune system (Ferrante, 2013; Hotamisligil, 2006). The role of these types of cells during inflammation in dysfunctional AT has not been totally determined. Mast cells, predominantly localized in fibrotic fat depots, have been proposed to secrete IL-6 and IFN-γ favoring inflammation and strengthening their link with the pathophysiology of obese AT (Ferrante, 2013; Divoux *et al.*, 2012). Eosinophils could exert an important protection against metabolic disorders via the secretion of the antiinflammatory cytokines IL-4 and IL-13 (Nakamura *et al.*, 2014). Finally, neutrophils act as precursors of inflammatory processes by secreting chemokines and cytokines that help the infiltration of macrophages in the AT.

- *The adaptive immune system*. On the other hand, B- and T-lymphocytes constitute the most important immune cells of the adaptive immune system. The vast majority of T lymphocytes can be classified in CD4+ and CD8+ cells with important functions in the regulation of inflammation of AT by regulating not only effective immune responses to pathogens but also macrophage differentiation, activation and migration. Important subgroups of obesity-related CD4+ T-lymphocytes have been recently identified in AT (Couturier *et al.*, 2015; Bornstein *et al.*, 2000). T-helper 1 cells (Th1), with a pro-inflammatory profile, are responsible for the secretion of IFN-γ, stimulating macrophage differentiation and increasing their infiltration into the AT in the obese state. Oppositely, T-helper 2 cells (Th2) are activated to exert an antiinflammatory role by the expression of IL-4 and IL-13. T regulatory cells (Treg) have been recently described in AT regulating the activity of macrophages and adipocytes by secreting IL-10. In the case of obesity, a decrease in the number of Treg cells has been described, promoting the infiltration of macrophages into the AT and increasing the production of pro-inflammatory cytokines (McLaughlin *et al.*, 2014; Lee and Lee, 2014; Rocha *et al.*, 2008; Hansson and Libby, 2006). The presence of CD8+ cells in hypoxic areas of the AT reinforces the hypothesis about their involvement in the recruitment and activation of macrophages. In this line, the removal of CD8+ cells in genetic knock-out animal models was associated with an improvement of the inflammatory state and the insulin sensitivity of the AT (Nishimura *et al.*, 2009; Khan *et al.*, 2014). B lymphocytes have been characterized as the precursors of metabolic abnormalities due to their accumulation into inflamed areas of AT before the arrival of T lymphocytes. B cells promote T cell activation and the production of pro-inflammatory cytokines, that also favors the polarization of M1 macrophages (DeFuria *et al.*, 2013; Winer *et al.*, 2014). Natural killer T (NKT) cells have been also related to the development of obesity-associated diseases. NKT cells are mainly located in AT and liver being of special interest to disentangle their activation sequence in order to get insight into the mechanisms involved in the crosstalk between the AT and the liver (Catalán *et al.*, 2013a; Ferrante, 2013; Satoh *et al.*, 2012).

Dysregulated adipokine profile in obesity

Adipose tissue acts as an important endocrine organ via the synthesis of several adipokines, which regulate insulin sensitivity, control of energy intake or inflammatory processes (**Fig. 1**) (Frühbeck and Gómez-Ambrosi, 2001; Frühbeck, 2006a). Obesity affects the secretion profile of adipokines leading to alteration in multiple physiological processes (Jung and Choi, 2014; Ahima and Osei, 2008). The identification of leptin and adiponectin were the first indications that AT is an endocrine organ with control over systemic energy homeostasis (Stern *et al.*, 2016). In addition to the well-known role of these classic adipokines, new adipokines involved in the regulation of multiple physiological processes have emerged in recent years (**Table 1**).

- *Adiponectin*, also known as Acrp30, Adipoq, apM1 or GBP28, is a 30-kDa protein mainly expressed in AT, with considerably high circulating concentrations, accounting for approximately 0.01% of total serum protein (Scherer *et al.*, 1995; Kadowaki and Yamauchi, 2005). It was originally identified independently by four groups using different approaches (Scherer *et al.*, 1995; Hu *et al.*, 1996; Maeda *et al.*, 2012; Nakano *et al.*, 1996) while its insulin-sensitizing effect was first identified by three independent groups in 2001 (Yamauchi *et al.*, 2001; Berg *et al.*, 2001; Fruebis *et al.*, 2001). Adiponectin exerts a wide variety of biological effects mediated by its binding of at least three different transmembrane receptors, AdipoR1, AdipoR2, and T-cadherin, which are expressed in many tissues and activate the downstream targets AMP-activated protein kinase (AMPK), peroxisome proliferator-activated receptor (PPAR)-α and p38 MAPK (Kadowaki and Yamauchi, 2005). Plasma adiponectin levels have been reported to be reduced in humans with obesity, particularly those with visceral obesity (Arita *et al.*, 2012; Weyer *et al.*, 2001). Hypoadiponectinaemia has been also associated with insulin resistance and patients with T2D are also reported to have decreased concentrations of adiponectin (Weyer *et al.*, 2001; Hotta *et al.*, 2000; Spranger *et al.*, 2003). On the contrary, adiponectin levels increase with weight loss (Yang *et al.*, 2001). Recently, circulating concentrations of adiponectin have been shown to be positively regulated by leptin ameliorating obesity-associated oxidative stress and inflammation in mice (Frühbeck *et al.*, 2017).
- *Leptin*, the *OB* gene product, is a16 kDa-secreted protein mainly produced by adipocytes (Zhang *et al.*, 1994) and directly correlated with adipose tissue mass (Beltowski, 2006). In AT, the secretion levels of leptin are strictly controlled to ensure an adequate regulation of food intake, energy expenditure, and, hence, body weight by its binding to specific hypothalamic receptors (Zhang *et al.*, 1994; Friedman and Halaas, 1998; Halaas *et al.*, 1995). Since its receptor is expressed in almost all tissues (Tartaglia *et al.*, 1995; Lee *et al.*, 1996; Frühbeck *et al.*, 1999), leptin shows a high functional pleiotropism involving glucose metabolism, energy homeostasis, angiogenesis, wound healing, immunity, reproduction, gastrointestinal function, bone remodeling, and cardiovascular function (Frühbeck *et al.*, 1998; Frühbeck and Salvador, 2000; Muruzábal *et al.*, 2002;

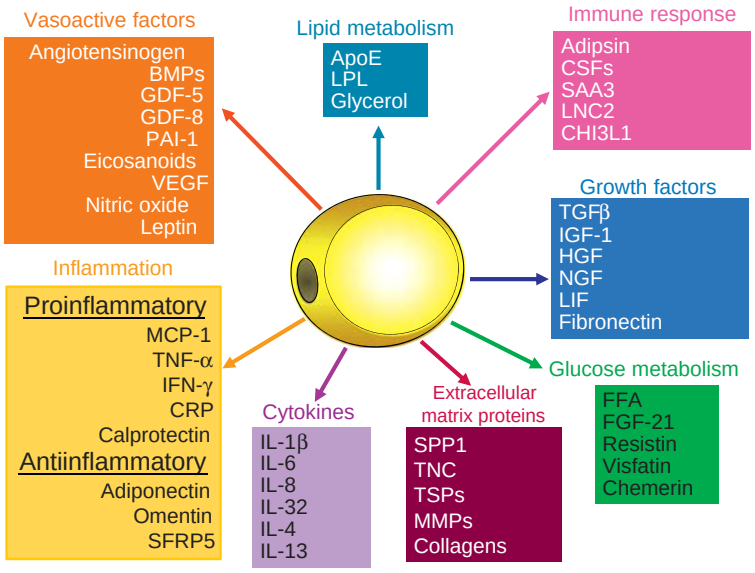

Fig. 1 Adipose tissue (AT) plays a crucial role in the regulation of whole-body homeostasis via the synthesis and release of adipocyte-specific factors known as adipokines. Much of the research in this area has focused on the study of classical cytokines and chemokines, vasoactive and coagulation factors, regulators of lipid and glucose metabolism and proteins specifically secreted by the adipocytes, such as leptin or adiponectin. However, the number of adipokines has notably increased in the last years with new molecules including visfatin, tenascin C, osteopontin, omentin or IL-32, demonstrating the complexity of the human adipokinome. *ApoE*, apolipoprotein E; *BMPs*, bone morphogenic proteins; *CHI3L1*, chitinase 3 like 1; *CRP*, C-Reactive protein; *CSFs*, colony stimulating factors; *FGF-21*, fibroblast growth factor 21; *FFA*, free fatty acid; *GDF-5*, growth/differentiation factor 5; *GDF8*, growth/differentiation factor 8; *HGF*, hepatocyte growth factor; *IGF-1*, insulin growth factor; *IFN-γ*, interferon γ; *IL-1β*, interleukin 1β; *IL-6*, interleukin 6; *IL-8*, interleukin 8; *IL-32*, interleukin 32; *IL-4*, interleukin 4; *IL-13*, interleukin 13; *LIF*, leukemia inhibitory factor; *LNC2*, lipocalin 2; *LPL*, lipoprotein lipase; *MCP-1*, monocyte chemoattractant protein 1; *MMPs*, metalloproteinases; *NGF*, nerve growth factor; *PAI-1*, plasminogen activator inhibitor 1; *SFRP5*, secreted frizzled-related protein 5; *SAA3*, serum amyloid A3; *SPP1*, osteopontin; *TNC*, tenascin C; *TGF-β*, tumor growth factor β; *TNF-α*, tumor necrosis factor α; *TSPs*, thrombospondins; *VEGF*, vascular endothelial growth factor.

Myers *et al.*, 2008; Gautron and Elmquist, 2011). Contrary to adiponectin, leptin levels are increased in obese individuals (Ryan *et al.*, 2003), being strongly correlated with BMI and the percentage of body fat, as well as with leptin mRNA expression in AT (Frühbeck *et al.*, 2001; Frühbeck, 2006b). Mice knockout for leptin and its receptor exhibit an early-onset obesity, diabetes and reduced energy expenditure (Lindström, 2007). Leptin replacement induces a dramatic loss of adipose mass in rodents (Halaas *et al.*, 1995; Pelleymounter *et al.*, 1995) and a reduction in body weight mainly at the expense of the fat compartment in humans (Farooqi et al., 1999, 2002; Paz-Filho *et al.*, 2011). Furthermore, a low adiponectin/leptin ratio, hallmark of a dysfunctional AT, has been suggested to contribute to an increased oxidative stress and inflammation in humans (Frühbeck *et al.*, 2017).

- *Tumor necrosis factor (TNF)-α* is a recognized multifunctional regulatory cytokine that can regulate many cellular and biological processes such as inflammation, cell apoptosis, survival, and proliferation as well as the induction of insulin resistance and energy metabolism (Cawthorn and Sethi, 2008; Ruan and Lodish, 2003). TNF-α represents the first evidence that inflammatory proteins can mediate insulin resistance. Hotamisligil et al. reported that TNF-α was highly induced in the AT of obese animals (Hotamisligil *et al.*, 1993) and human subjects (Hotamisligil *et al.*, 1995) with adipocytes being the predominant source of TNF-α and also expressing both types of TNF-α receptors (Hotamisligil *et al.*, 1993; Montague *et al.*, 1998; Kern *et al.*, 1995). Further investigations have revealed that long-term exposure of cultured cells to TNF-α induces insulin resistance (Hotamisligil *et al.*, 1994a), whereas the blockade of TNF-α action in *fa/fa* Zucker rats can restore insulin sensitivity (Hotamisligil *et al.*, 1994b). Interestingly, TNF-α action on AT can modify the expression of different adipokines with relevant systemic effects of TNF-α on insulin sensitivity and whole body energy homeostasis. In this sense, TNF-α can regulate the production of other pro-inflammatory cytokines (IL-6 and IL-1) (Cawthorn and Sethi, 2008) as well as suppress the production of adiponectin (Ruan *et al.*, 2002); indeed, plasma levels of adiponectin are negatively associated with circulating levels of TNF-α (Bruun *et al.*, 2003). A main role of TNF-α on lipid metabolism in adipocytes by inhibiting the uptake of FFA and lipogenesis as well as by stimulating FAA release has been also described (Cawthorn and Sethi, 2008).
- *Interleukin-6* has been strongly associated with chronic inflammatory states, including the low-grade inflammation associated with obesity and T2D (Pradhan *et al.*, 2001; Bastard *et al.*, 2000, 2002; Wellen and Hotamisligil, 2005). However, increasing evidence points to a beneficial role of IL-6 in a variety of pathophysiological conditions, including functions related to obesity and insulin resistance (Mauer *et al.*, 2015). In support of this, *Il6* knockout mice develop systemic insulin resistance and late-onset obesity (Matthews *et al.*, 2010). Furthermore, an acute IL-6 treatment results in an increase in insulin-stimulated whole-body glucose disposal in humans (Carey and Febbraio, 2004; Carey *et al.*, 2006). Reportedly, IL-6 is also produced by

Table 1 Adipokines secreted by white adipose tissue (WAT)

Symbol	*Name*	*Metabolic function*
ADIPOQ	Adiponectin	Hormone with antidiabetic, antiatherogenic, and antiinflammatory properties
AGT	Angiotensinogen	Precursor molecule of angiotensin II, that causes vasoconstriction, increased BP and release of aldosterone from the adrenal cortex
APL	Apelin	Peptide implicated in the control of BP and one of the most potent stimulators of cardiac contractility; inhibits insulin secretion; involved in lipolysis
CCL2	C–C Motif chemokine ligand 2	Chemokines that promotes inflammation and monocyte chemotaxis
CFD	Adipsin	Protein involved in the activation of the alternative complement pathway
CHI3L1	YKL-40 (Chitinase 3 like 1)	Proinflammatory factor that stimulates innate immune system, extracellular matrix remodeling, and angiogenesis
CLU	Clusterin	Lipoprotein that promotes tumor progression, angiogenesis, and is involved in metabolic and cardiovascular diseases
CRP	C-reactive protein	Acute-phase reactant involved in inflammatory processes
CTF-1	Cardiotrophin-1	Cytokine involved in the hypertrophy of cardiomyocytes
CTS	Cathepsins	Cystein proteases that promote adipogenesis and extracellular matrix remodeling
CXCL8	Interleukin 8	Chemokine involved in the pathogenesis of atherosclerosis and cardiovascular diseases
CXCL10	C–X–C motif chemokine 10	Chemokine produced by T cells
FGF-21	Fibroblast growth factor 21	Hormone that stimulates glucose uptake into adipocytes, increases thermogenesis, energy expenditure and fat utilization
FIAF/ ANGPTL4	Angiopoietin like 4	Protein induced by fasting and hypoxia
FNDC5	Irisin	Myokine/adipokine involved in the promotion of myogenenesis and fat browning
GHRL	Ghrelin	Orexigenic and adipogenic hormone that exerts a depressor effect on BP control and acts as a cardioprotective agent
GRN	Progranulin	Chemoattractant protein involved in adipose tissue inflammation and neurodegenerative diseases
HAMP	Hepcidin	Pro-inflammatory cytokine that activates MMP-9
HGF	Hepatocyte growth factor	Factor that stimulates proliferation and development in adipocytes and antiinflamatory effects
HMGB1	High mobility group box 1	Alarmin involved in DNA repair and the secretion of insulin in pancreatic β cells
HP	Haptoglobin	Acute-phase reactant with angiogenic and chemotactic properties
HSPA1A	Heat shock protein 1A1	Damage-activated protein that induces neutrophil and natural killer cell recruitment
IGF-1	Insulin growth factor	Factor that stimulates proliferation and differentiation in adipocytes
IL-1 β	Interleukin 1 β	Proinflammatory cytokine involved in a paracrine inflammatory pathway in adipose tissue
IL-6	Interleukin 6	Proinflammatory cytokine implicated in acute-phase responses
IL-32	Interleukin 32	Proinflammatory cytokine involved in adipose tissue inflammation and remodeling
ITLN1	Omentin	Novel adipokine that modulates insulin sensitivity and exerts antiinflammatory properties
LEP	Leptin	Anorexigenic hormone with lipolytic and vasoactive effects in addition to other pleiotropic activities
MIF	Macrophage migration inhibitory factor	Factor involved in proinflammatory processes and immunoregulation
MMPs	Metalloproteinases	Proteins implicated in adipogenesis
NAMPT	Visfatin	NAD+ biosynthetic enzyme involved in the regulation of β pancreatic cells
NGAL/LNC2	Lipocalin-2	Adipokine showing antiinflammatory properties
NGF	Nerve growth factor	Neurotropin involved in the development and survival of sympathetic neurons
NUCB2	Nesfatin-1	Anorexigenic peptide also involved in the inflammatory response
PAI-1	Plasminogen activator inhibitor 1	Potent inhibitor of fibrinolysis that is implicated in the development of atherosclerotic plaques
PEDF	Pigment epithelium derived factor	Secreted glycoprotein that belongs to the noninhibitory serpin group with antiangiogenic, antioxidant, antiinflammatory, and lipolytic effects
RARRES2	Chemerin	Chemoattractant protein involved in adaptive and innate immunity as well as in adipogenesis
RBP4	Retinol binding protein 4	Factor involved in the development of insulin resistance, visceral fat distribution, and dyslipidemia
RETN	Resistin	Hormone involved in the development of insulin resistance, which participates in the proinflammatory response
S100A8, S100A9	Calprotectin	Proinflammatory factor involved in cell adhesion, chemotaxis, and antimicrobial activity
SAA	Serum amyloid A	Acute-phase reactant produced in response to injury, infection or inflammation
SERPINA12	Vaspin	Adipokine of the serine protease inhibitor family showing insulin-sensitizing effects
SPP1	Osteopontin	Proinflammatory factor involved in vascular and myocardial remodeling; cytokine implicated in insulin resistance, and cancer
SRFP5	Secreted frizzled related protein 5	Inhibitor of WNT5A signaling with antiinflammatory properties
STEAP4	Six transmembrane protate protein 2	Metalloreductase that plays a role in cellular import of copper and iron as well as in the reduction of macrophage recruitment and polarization towards the M1 phenotype

Table 1 Continued

Symbol	*Name*	*Metabolic function*
TIMP1	Tissue inhibitor of metalloproteinase 1	Inhibitor that decreases adipogenesis and impairs glucose tolerance
TNC	Tenascin C	Damage-activated protein that induces immune responses and extracellular matrix remodeling
TGF-β	Tumor growth factor β	Regulatory factor of preadipocyte proliferation, differentiation and apoptosis
TNF-α	Tumor necrosis factor α	Proinflammatory cytokine involved in systemic inflammation and the development of insulin resistance in obesity
VEGF	Vascular endothelial growth factor	Factor involved in angiogenesis stimulation in adipose tissue
WNT5A	WNT family member 5A	Secreted glycoprotein of the WNT family with antiadipogenic and proinflammatory actions

ADIPOQ, adiponectin; *AGT*, angiotensinogen; *APL*, apelin; *CCL2*, C–C motif chemokine ligand 2; *CFD*, adipsin; *CHI3L1*, chitinase 3 like 1; *CLU*, clusterin; *CRP*, C-reactive protein; *CTF-1*, cardiotrophin-1; *CTS*, cathepsins; *CXCL8*, interleukin 8; *CXCL10*, C–X–C motif chemokine 10; *FDF-21*, fibroblast growth factor 21; *ANGPTL4*, angiopoietin like 4; *FNDC5*, irisin; *GHRL*, ghrelin; *GRN*, progranulin; *HAMP*, hepcidin; *HGF*, hepatocyte growth factor; *HMGB1*, high mobility group box 1; *HP*, haptoglobin; *HSPA1A*, heat shock protein 1A1; *IGF-1*, insulin growth factor; *IL-1β*, inteleukin 1 β; *IL-6*, interleukin 6; *IL-32*, interleukin 32; *ITLN1*, omentin; *LEP*, leptin; *MIF*, macrophage migration inhibitory factor; *MMPs*, metalloproteinases; *NAMPT*, visfatin; *NGAL*, lipocalin-2; *NGF*, nerve growth factor; *NUCB2*, nesfatin-1; *PAI-1*, plasminogen activator inhibitor 1; *PEDF*, pigment epithelium derived factor; *RARRES2*, chemerin; *RBP4*, retinol binding protein 4; *RETN*, resistin; *S100A8-S100A9*, calprotectin; *SAA*, serum amyloid A; *SERPINA12*, vaspin; *SPP1*, osteopontin; *SRFP5*, secreted frizzled related protein 5; *STEAP4*, six transmembrane prostate protein 2; *TIMP1*, tissue inhibitor of metalloproteinase 1; *TNC*, tenascin C; *TGF-β*, tumor growth factor β; *TNF-α*, tumor necrosis factor α; *VEGF*, vascular endothelial growth factor; *WNT5A*, WNT family member 5A.

M2-polarized ATMs in obesity, promoting M2 polarization, probably by the upregulation of IL-4Rα expression (Braune *et al.*, 2017). These beneficial metabolic effects seem to be mediated by an IL-6 alternative signaling pathway known as *trans*-signaling, in which IL-6 binds to a soluble form of the IL-6R (Timper *et al.*, 2017). Therefore, the role of IL-6 as a pro-inflammatory cytokine and its prognostic value in obesity need to be reconsidered.

- *Resistin* is a member of the resistin-like molecule (RELM) hormone family. It is a 12-kDa cysteine-rich protein initially proposed as a link between increased adiposity and the development of insulin resistance and obesity in rodents (Steppan *et al.*, 2001). The expression patterns of resistin in rodents and humans differ considerably and while AT constitutes the main source of resistin in mice, this molecule is mainly secreted by monocytes and macrophages in humans (Dupont *et al.*, 2012). The precise role of resistin in human physiology and whether or not it is involved in the development of insulin resistance is not completely elucidated (McTernan *et al.*, 2006; Kusminski *et al.*, 2005; Schwartz and Lazar, 2011). Human resistin plays a major regulatory role in the inflammatory response (Filková *et al.*, 2009) upregulating the expression of proinflammatory cytokines such as TNF-α, IL-6, IL-12, and monocyte chemoattractant protein 1 (MCP-1) (Bokarewa *et al.*, 2005). Resistin expression has also been identified in the stromal vascular fraction of WAT, fibrotic livers, and atherosclerotic lesions. Indeed, resistin has been closely implicated in the pathogenesis of atherosclerosis by promoting smooth muscle cell proliferation and migration, ICAM-1, and VCAM-1 expression, as well as by regulating patterns of adhesion and inflammation in atherosclerotic plaques (Filková *et al.*, 2009).
- *Monocyte chemoattractant protein-1 (MCP-1)* is a proinflammatory cytokine involved in the infiltration of macrophages into the AT (Kanda *et al.*, 2006; Linton and Fazio, 2003) as well as in their in situ proliferation (Amano *et al.*, 2014). The gene expression levels of MCP-1 are significantly upregulated in adipocytes (Amano *et al.*, 2014) whereas its receptor, chemokine (C-C motif) receptor 2 (CCR2), has been shown to be mostly expressed in ATM (Lumeng *et al.*, 2008). Indeed, the gene expression levels of MCP-1 correlate with measures of adiposity in human AT (Christiansen *et al.*, 2005) and higher levels of MCP-1 can be found in obese subjects compared with lean subjects (Catalán *et al.*, 2007). Similar results have been reported in animal models with the expression of MCP-1 being increased in obese mice as compared with wild type ones (Takahashi *et al.*, 2003). MCP-1 is also involved in the regulation of insulin sensitivity in 3T3-L1 adipocytes via downregulation of genes such as *SLC2A4* (the gene encoding GLUT-4), lipoprotein lipase, and peroxisome proliferator-activated receptor-γ (Sartipy and Loskutoff, 2003). In this regard, MCP-1 is elevated in patients with T2D (Nomura *et al.*, 2000).
- *Visfatin* also known as pre-B cell colony enhancing factor (PBEF) or nicotinamide phosphoribosyltransferase (NAMPT), is a 52-kDa protein originally identified as a modulator of B cell differentiation expressed in lymphocytes, bone marrow, skeletal muscle, and liver (Ouchi *et al.*, 2011). The name of visfatin is because it is highly secreted by visceral fat of both mice and humans and its expression levels in serum increase with obesity and T2D (Ouchi *et al.*, 2011; Fukuhara *et al.*, 2005). Visfatin was reported to have insulin-mimetic actions (Fukuhara *et al.*, 2005). However, these findings are currently controversial with Fukuhara and colleagues being forced to retract some of their original findings (Fukuhara *et al.*, 2007). However, visfatin has been shown to stimulate glucose-induced insulin secretion in pancreatic β-cells (Revollo *et al.*, 2007) and appears to have an important role in different inflammatory conditions (Moschen *et al.*, 2007).
- *Lipocalin 2 (LNC2)* is a 25 kDa glycoprotein member of the highly heterogeneous family of lipocalins. LCN2 is a component of the innate immune system with a significant role in the induction of apoptosis as well as in the acute-phase response to infection (Flo *et al.*, 2004; Devireddy *et al.*, 2005). LCN2 is expressed in many tissues including AT and liver (Liu and Nilsen-Hamilton, 1995). LCN2 has been also identified as an adipokine associated to obesity and insulin resistance with increased

expression levels in *db/db* obese diabetic mice (Yan *et al.*, 2007). Furthermore, higher circulating levels of LCN2 have been described in obese humans being associated with anthropometric variables, measures of insulin resistance and inflammatory markers (Wang *et al.*, 2007; Catalán et al., 2009b).

- *Osteopontin (OPN)*, also known as secreted phosphoprotein-1 (SPP1), early T lymphocyte activation (Eta-1) and bone sialoprotein-1, is a matrix phosphoprotein expressed by a wide variety of cell types including osteoclasts, macrophages hepatocytes, and adipocytes (Gómez-Ambrosi *et al.*, 2008). As reported, OPN gene expression is extensively upregulated upon obesity in human and murine AT with OPN plasma concentrations being elevated in morbidly obese patients (Kiefer *et al.*, 2008; Nomiyama *et al.*, 2007). Moreover, OPN has been suggested to play a pivotal role linking obesity to insulin resistance development by promoting inflammation and the infiltration of macrophages into the AT (Nomiyama *et al.*, 2007). In murine models and cell cultures, OPN expression was required for the development of insulin resistance, being prevented by the deletion of OPN (Chapman *et al.*, 2010; Zeyda *et al.*, 2011; Kiefer *et al.*, 2010). Higher levels of expression of osteopontin have been shown to be associated with liver steatosis in morbidly obese subjects (Bertola *et al.*, 2009) and in diet-induced obese mice (Lancha *et al.*, 2014), by the promotion of inflammation, fibrosis, and oxidative stress (Lancha *et al.*, 2014; Syn *et al.*, 2011).
- *Chitinase-3-like protein 1 (CHI3L1)* also known as YKL-40 or human cartilage glucoprotein-39, is a member of mammalian chitinase-like proteins involved in the activation of the innate immune system and in the extracellular matrix remodeling. Increased circulating and AT gene expression levels of YKL-40 in obesity and T2D have been reported (Catalán *et al.*, 2011; El-Mesallamy *et al.*, 2011), with YKL-40 being proposed as a new inflammatory marker related to insulin resistance (Rathcke and Vestergaard, 2006).
- *Tenascin C* is an extracellular matrix glycoprotein that belongs to the damage-associated molecular patterns (DAMPs) family (Midwood *et al.*, 2011). The expression of TNC is specifically induced and tightly controlled during acute inflammation and persistently expressed in chronic inflammation (Chiquet-Ehrismann and Chiquet, 2003; Goh *et al.*, 2010). In this line, TNC has been identified as the endogenous activator of TLR4, whose activation promotes innate and adaptive immune responses as well as the expression of procollagen type 1 and integrin-1β (Midwood *et al.*, 2009; Lu *et al.*, 2008). Interestingly, increased levels of *TNC* in the VAT of obese subjects with or without T2D as well as in obese volunteers with NAFLD have been reported (Catalán *et al.*, 2011). Consistently, the AT gene expression levels of *Tnc* are also increased in murine models of obesity (Catalán *et al.*, 2011).
- *Chemerin* or retinoic acid receptor responder 2 (RARRES2) is an adipokine with important roles in the regulation of adipogenesis and glucose metabolism (Bozaoglu *et al.*, 2007; Goralski *et al.*, 2007; Roman *et al.*, 2012). Chemerin and its receptor, the chemokine-like receptor 1 (CMKLR1) are highly expressed in AT (Catalán *et al.*, 2013b.) and different studies have demonstrated an association of chemerin with markers of the metabolic syndrome and inflammation including TNF-α, IL-6 and C-reactive protein (Bozaoglu *et al.*, 2009; Weigert *et al.*, 2010; Lehrke *et al.*, 2009). In particular, chemerin has been considered as a possible link between obesity and the development of T2D (Ernst and Sinal, 2010). Weight loss induced by both, caloric restriction or bariatric surgery, is accompanied by reduced serum chemerin levels, supporting the relationship between adiposity and chemerin (Chakaroun *et al.*, 2012; Sell *et al.*, 2010).
- *Interleukin-32* is a recently described cytokine produced by epithelial cells, blood monocytes, T lymphocytes and natural killer cells that acts as an important regulator of inflammation (Dahl *et al.*, 1992; Dinarello and Kim, 2006; Joosten *et al.*, 2006). Increased IL-32 expression has been found in VAT from patients with obesity promoting inflammation and ECM remodeling. Reportedly, the increased circulating levels of IL-32 in human obesity and obesity-associated T2D decrease after weight loss (Catalán *et al.*, 2016).

The adipocyte as a key regulator of the extracellular matrix components

Adipocytes and the stromovascular fraction cells are surrounded by a specific extracellular matrix (ECM). The ECM is a complex nest of collagens, fibrillins, proteoglycans and nonproteoglycan polysaccharides (Lin *et al.*, 2016; Mariman and Wang, 2010) characterized by a constant remodeling that not only serve as a mechanical support but also regulate adipocyte functions including nutritional demand adaptation, responses to different signaling factors and secretion of adipokines (Yoshizaki *et al.*, 2012; Sun *et al.*, 2013). The ECM is maintained through secretion of ECM components by both resident adipocytes and stromal cells, particularly fibroblasts (Crewe *et al.*, 2017). Maintaining a high degree of flexibility of the ECM allows AT to expand in a healthy manner, without adverse metabolic consequences (Virtue and Vidal-Puig, 2010).

- *Collagen* accumulation in WAT is considered an important pathological alteration related to obesity-associated comorbidities (Sun *et al.*, 2013; Divoux *et al.*, 2010). Compared to other ECM components, collagen I, V, and VI are the major ECM components to support adipocyte structure and functions, including cell adhesion, migration, and differentiation (Sun *et al.*, 2013). Among them, collagen VI is highly enriched in adipocytes and evidences of its contribution to the pathology of obesity-related diseases exist (Pasarica *et al.*, 2009; Spencer *et al.*, 2010). For a stable collagen VI formation, functionality of the three subunits is needed: α1, α2, and α3. A high upregulation of collagen VI in AT from obese and diabetic *db/db* mice has been reported (Khan *et al.*, 2009). In this line, its expression increases with BMI independently of the presence of diabetes and is also accompanied by AT inflammation in humans (Pasarica *et al.*, 2009). Collagen V expression is also upregulated in obesity being localized close to fibrotic areas (Henegar *et al.*, 2008; Spencer *et al.*, 2011). Reportedly, SAT displayed increased collagen V degradation after bariatric surgery-induced weight loss and related metabolic improvements (Liu *et al.*, 2016). Studies

performed in obese animal models by genetic engineering or induced by a high-fat diet have reported an increase in myocardial collagen types I and III (Toblli *et al.*, 2005; Carroll *et al.*, 2006). In contrast, no effect was found on myocardial collagen type III expression in diet-induced obese rats after 30 weeks (da Silva *et al.*, 2013).

- *Fibronectin* is an adhesion protein with chemotactic activity for inflammatory cell recruitment, including macrophages and monocytes (Adair-Kirk and Senior, 2008). An important decrease in fibronectin synthesis during adipose conversion of 3T3-F442A cells has been reported (Antras *et al.*, 1989; Spiegelman and Ginty, 1983). Additionally, depot-specific fibronectin expression in AT as well as significant associations of fibronectin expressions in both VAT and SAT with obesity parameters and serum leptin concentrations have been shown, suggesting an important function of fibronectin in the pathophysiology of obesity-related diseases (Lee et al., 2013b).
- *Hyaluronan acid (HA)* is increasingly recognized as an active player in AT fibrosis and metabolic dysfunction (Zhu *et al.*, 2016). It is a linear nonsulfated glycosaminoglycan with repeated units of D-glucuronic acid and *N*-acetyl-D-glucosamine (Dicker *et al.*, 2014; Fraser *et al.*, 1997). Despite its simple structure, hyaluronan has diverse biological activities depending on its molecular size and its cellular localization (Cyphert *et al.*, 2015). Hyaluronan synthesis is stimulated by the induction of the differentiation of the preadipocytes 3T3-L1 (Allingham *et al.*, 2006; Calvo *et al.*, 1991) and its downregulation in the ECM has been reported to inhibit in vitro and in vivo adipogenesis (Park *et al.*, 2015; Ji *et al.*, 2014). Furthermore, hyaluronan fragments can stimulate inflammation or induce the loss of the ECM components (Park *et al.*, 2015). The blocking of hyaluronan has been proposed as a possible therapeutic option in obesity and its related metabolic diseases (Ji *et al.*, 2014).
- *Thrombospondins (TSPs)* constitute a family of five extracellular matrix secreted proteins with different expression profiles, structures and, therefore, functions (Calabro *et al.*, 2014). Whereas TSP-1 and TSP-2 are of particular interest due to their antiangiogenic activity and therefore, their roles in wound repair and tissue remodeling, the function of TSP-3, TSP-4, and TSP-5 remains unclear. Pro-fibrotic properties have been also associated to TSP-1 by the activation of the tumor growth factor (TGF)-β (Calabro *et al.*, 2014; Stenina-Adognravi, 2013; Belmadani *et al.*, 2007). Recently, the usefulness of the determination of circulating levels of TSP-1 as a mediator of insulin resistance and AT inflammation has been demonstrated (Matsuo *et al.*, 2015).
- *Matrix metalloproteinases (MMPs)* are also important enzymes secreted by the adipocytes that affect directly or indirectly the regulation of the ECM. MMPs constitute a family of zinc-dependent endopeptidases involved in degrading the ECM components (Lin *et al.*, 2016; Kawatani *et al.*, 2015). At least 25 types of MMPs have been discovered in humans and classified depending on their function and substrate specificity in collagenases, gelatinases, stromelysin, matrilysin, membrane-type MMPs, and elastases (Lin *et al.*, 2016). Since their initial identification, the functions and activation pathways of these types of molecules in relation to metabolic diseases has been characterized in more depth. In this line, MMP-2 and MMP-9 are of great interest due to their role in AT remodeling that occurs during the development of obesity with their mRNA expression levels being upregulated in metabolic disorders (Catalán *et al.*, 2009b; Stamenkovic, 2003).

Brown Adipose Tissue As a Secretory Organ

Our understanding about the potential roles of BAT has been transformed with the recognition that it is also present in adulthood in humans (Nedergaard *et al.*, 2007; Cypess *et al.*, 2013). The traditional concept of BAT just as a site of metabolic energy consumption is changing. Although the exact endocrine roles of BAT remain to be fully understood, accumulating evidence indicates that BAT releases multiple bioactive molecules that act in a paracrine or autocrine manner, strengthening the concept of BAT as a secretory organ (Villarroya et al., 2013, 2017) (**Table 2**). Members of the bone morphogenetic proteins (BMPs) have a significant impact on the differentiation of brown and beige adipocytes (Tseng *et al.*, 2008). In this sense, an early expression in brown adipogenesis of BMP-7 is necessary for the formation of classic BAT depots (Villarroya *et al.*, 2017). Moreover, mice lacking Bmp7 showed a reduction in the total mass of BAT (Tseng *et al.*, 2008). Another member of the family, BMP-8b, is induced in response to nutritional and thermogenic factors in mature BAT (Whittle *et al.*, 2012). Recent evidences suggest that BMPs not only has autocrine effects in BAT but also acts in differentiated mature adipocytes and neurons (Whittle *et al.*, 2012). Another interesting batokine is the fibroblast growth factor 21 (FGF21), mainly synthesized in the liver but also secreted by BAT when it is thermogenically activated (Chartoumpekis *et al.*, 2011; Hondares *et al.*, 2011; Izaguirre *et al.*, 2017). FGF21 was identified by Kharitonenkov et al. as a potent enhancer of glucose uptake through the upregulation of glucose transporter 1 (GLUT-1) expression levels (Kharitonenkov *et al.*, 2005). Furthermore, FGF21 enhances thermogenic pathways in BAT and also induces the browning of WAT (Hondares *et al.*, 2011). Nevertheless, recent findings have shown that FGF21 also induces the expression and secretion of adiponectin, an insulin-sensitizing adipokine (Holland *et al.*, 2013). Wang et al. demonstrated that BAT protects against diet-induced insulin resistance and hepatic steatosis through attenuating de novo liver lipid synthesis via neuregulin 4 (Nrg4), suggesting a potential therapeutic role for the treatment of obesity-associated disorders for this brown fat-enriched endocrine factor (Wang *et al.*, 2014; Pfeifer, 2015). Recent studies have shown a positive correlation between BAT and bone mineral density (Bredella *et al.*, 2014) with several factors secreted in vivo by beige fat tissue such as the insulin-like growth factor binding protein 2 (IGFBP-2) exhibiting an important role in this process (Rahman *et al.*, 2013). The expression of betatrophin or angiopoietin-like 8 is induced in BAT in response to cold (Fu *et al.*, 2013) but its biological significance remains unclear. Brown adipocytes have been also shown to express the vascular endothelial growth factor A (VEGFA) (Asano *et al.*, 2001). VEGFA not only targets endothelial cells to induce vascularization of BAT (Fredriksson *et al.*, 2005) but also promotes direct beneficial

Table 2 Batokines secreted by brown adipose tissue (BAT)

Symbol	*Name*	*Function*
ADIPOQ	Adiponectin	Induces M2 macrophages proliferation
BMP8b	Bone morphogenic protein 8b	Enhances local response of BAT to β3-adrenergic stimulation Increases activation of BAT thermogenesis by inducing the activity of the hypothalamus
ET-1	Endothelin-1	Inhibit thermogenic processes
FGF-21	Fibroblast growth factor 21	Enhances glucose waste in AT, promoting glycaemia and lipidaemia
FGF-2	Fibroblast growth factor	Controls sympathetic innervation and number of preadipocytes in BAT
FST	Follistatin	Antagonizes GDF-8 effects
GDF5	Growth/differentiation factor 5	Controls brown and beige adipogenesis and boost energy expenditure
GDF8	Growth/differentiation factor 8	Inhibits BAT thermogenesis, WAT browning and metabolic behavior
IL-1α	Interleukin 1α	Enhances BAT thermogenesis
IL-6	Interleukin 6	Enhances BAT thermogenesis
METRNL	Meteorin-like protein	Induces the release of IL-4 release by activating eosinophils
NGF	Nerve growth factor	Controls sympathetic innervation and the number of preadipocytes in BAT
NO	Nitric oxygen	Increases blood flow Regulates trophic adaptation of BAT after thermogenesis
RARRES2	Chemerin	Promotes lipid deposition Recruits immune cells into BAT
sLR11	Soluble form of low-density lipoprotein receptor relative 11	Suppresses thermogenesis Prevents excessive energy waste
T_3	Triiodothyronine	Induces the expression UCP-1
VEGFA	Vascular endothelial growth factor A	Promotes BAT vascularization leading to higher perfusion Increases thermogenesis by upregulating UCP-1 expression
	Adenosine	Enhances thermogenic activation.
	Endocannabinoids	Control of β3-adrenoreceptor-induced BAT

ADIPOQ, adiponectin; *BMP8b*, bone morphogenic protein 8b; *ET-1*, endothelin-1; *FGF-2*, fibroblast growth factor; *FGF-21*; fibroblast growth factor 21; *FST*, follistatin; *GDF5*, growth/differentiation factor 5; *GDF8*, growth/differentiation factor 8; *IL-1α*, interleukin 1α; *IL-6*, interleukin 6; *METRNL*, meteorin-like protein; *NGF*, nerve growth factor; *NO*, nitric oxygen; *RARRES2*, chemerin; *sLR11*, soluble form of low-density lipoprotein receptor relative 11; *T3*, triiodothyronine; *VEGFA*, vascular endothelial growth factor A.

effects including their survival, proliferation, and maintenance of mitochondria (Bagchi *et al.*, 2013; Mahdaviani *et al.*, 2016). We are currently in a new era of BAT research aimed to exploit its thermogenic capacity for the management of obesity and metabolic diseases.

Comorbidities of Obesity

Vettor Roberto and Di Vincenzo Angelo, Center for the Study and the Integrated Treatment of Obesity - Bariatric Unit, University of Padua, Padua, Italy

Introduction

Obesity meets all accepted criteria of a medical disease, including a known etiology, recognized signs and symptoms, and a range of structural and functional changes that culminate in pathologic consequences. It represents major public health concern in many countries from the dual aspects of prevalence and consequences. Obesity is associated with a number of important chronic diseases such as type 2 diabetes (T2D), hypertension (HTN), dyslipidemia, coronary heart disease, stroke, several cancers, disability, and increased mortality (**Fig. 1**). Subjects suffering from obesity have also a higher risk of liver disorders, such as nonalcoholic fatty liver (NAFLD) and nonalcoholic steatohepatitis (NASH). Moreover obstructive sleep apnea (OSA) and osteoarthritis further affect the quality of life of these patients. Therefore additional goal of obesity treatment is the prevention of these complications.

Type 2 Diabetes

Obesity is a major risk factor for T2D, and trends in prevalence and incidence of T2D have closely mirrored those of obesity. When trends were examined by body mass index (BMI), diabetes mellitus only increased among those who were obese, suggesting that much of the increase in the prevalence of diabetes mellitus is because of the increasing prevalence of obesity. In fact, more than 80% of people with T2D are overweight or obese (Guh *et al.*, 2009). As obesity is a primary risk factor for T2D and because both diseases share common causes, the term "diabesity" is currently used when the two abnormalities are present simultaneously (Eckel *et al.*, 2011). However, not all patients with obesity develop T2D, and not all the patients with T2D are overweight or obese. Furthermore, genetic studies have failed to demonstrate a shared heritability between the two diseases. Therefore, the

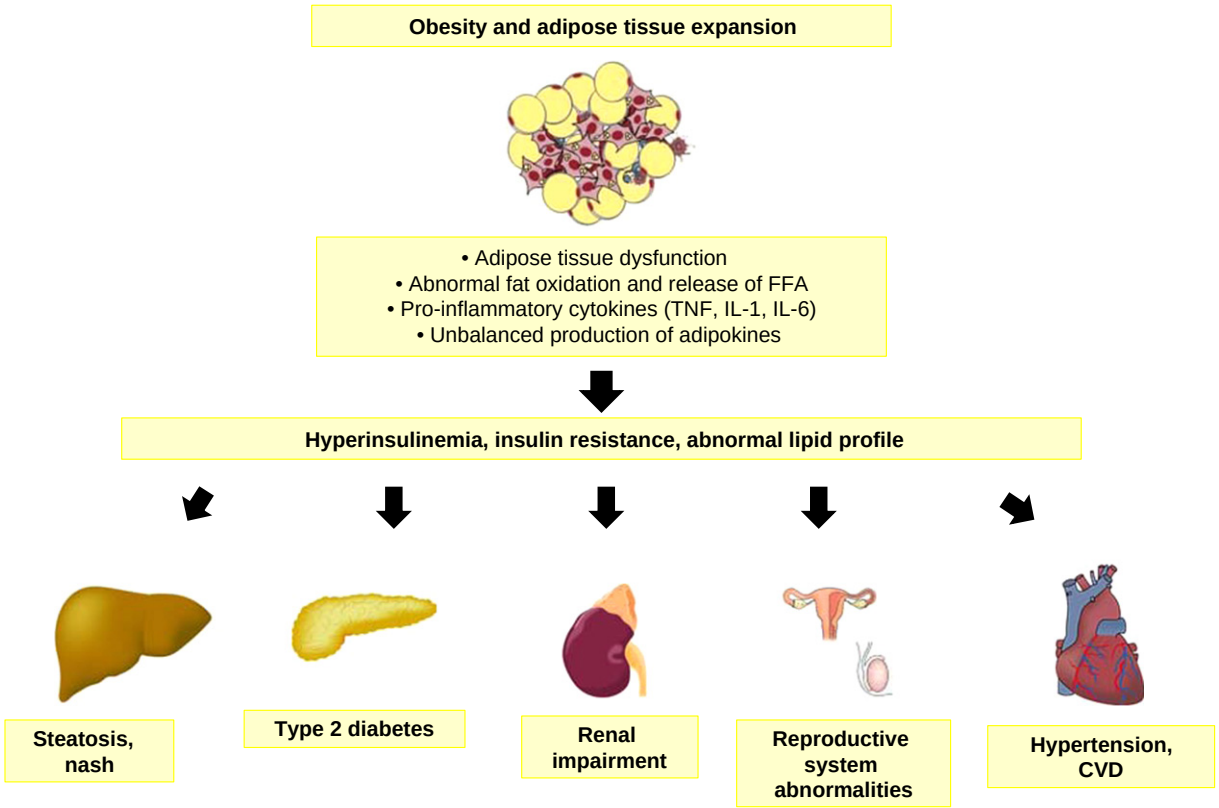

Fig. 1 Comorbidities of obesity. Dysfunction of adipose tissue is involved in several tissue abnormalities.

pathophysiological mechanisms underlying this association are probably more complex and far to be clearly identified, resulting from an interconnection between genetics, environmental factors and the presence of concomitant diseases.

As already mentioned above, obesity is a condition tightly associated with insulin resistance (IR) and hyperinsulinemia, and the development of diabetes is correlated with chronic impaired insulin signaling cascade and a progressive reduction of pancreatic β-cells function (Grundy, 2004). Several hypothesis have been proposed to explain the connection between obesity and T2DM and, at present, the relationship between body fat accumulation and the development of the related metabolic diseases has been clearly recognized as a cause-effect phenomenon. Obesity-related IR due to insulin-signaling cascade defects in the target organs, such as liver, adipose tissue and skeletal muscle is probably the major determinant in the progression from obesity to T2D in particular when it combines with insufficient insulin secretion from the pancreatic β-cells.

Severity of obesity is defined according to BMI-based categories. However, more than excessive fat deposition, adipose tissue architectural and functional changes have a prominent role in the genesis of IR and diabetes. The positive energetic balance induced by excessive calorie intake in genetically predisposed subjects promotes a pathological enlargement of adipocytes, with a concomitant reduction of capillary density and expansion of stromal extracellular matrix. These anatomic abnormalities result in functional alterations of fat depots, in particular visceral adipose tissue (VAT), which is assessed by abdominal circumference or waist-hip ratio. Respect to subcutaneous adipose tissue (SAT), VAT present a higher metabolic activity, with a strong production of adipokines, pro-inflammatory citokines as tumor necrosis factor alpha (TNF-α) and interleukin-6 (IL-6) which contribute to the metabolic and vascular diseases (Bays, 2011).

When the adipose storage capacity of intra-abdominal adipose tissue is exceeded, an increased splanchnic FFAs overflow is observed. Acute and chronic exposure to high levels of FFAs beside to reduce insulin sensitivity of visceral organs is involved in the altered production of insulin by the Langherans islets. NAFLD typically correlates with a reduced insulin response, leading to an increase in hepatic gluconeogenesis. On the other hand, the insulin resistant status of adipose cell fails to inhibit properly the lipolysis process thereby enhancing the adipose FFAs leakage. Lipotoxicity due to their deposition in different tissue contributes to a further impairement of muscle glucose uptake and to pancreatic β-cell exhaustion. The low-grade inflammation of adipose tissue and the production of cytokines induce an impaired expression of genes encoding for transcription factors involved in insulin signaling and adipocyte differentiation.

Above the abnormal fat metabolism and the releasing of pro-inflammatory cytokines, also intracellular modification can be responsible for the risk of T2DM in obese subjects. Mitocondrial dysfunction and endoplasmic reticulum stress are issues of adipocyte dysfunction and these abnormalities are commonly observed also in the β-cells.

There is consistent evidence that obesity treatment can delay progression from prediabetes to T2D and may be beneficial in the treatment of T2D. In obese patients with T2D, even a modest but sustained weight loss has been shown to improve glycemic control and to reduce the need for glucose-lowering medications. Weight loss–induced improvements in glycemia are most likely to occur early in the natural history of T2D when obesity-associated IR has caused reversible β-cell dysfunction but insulin secretory capacity remains relatively preserved. The significant weight loss induced by GLP-1 receptor agonist treatment, and in particular liraglutide, has extended its indication to weight loss in obese subjects (BMI >30 or >27 with comorbidities) independently of the presence of diabetes, and it has also shown a clearly positive effect in the prevention of T2D development (Pi-Sunyer *et al.*, 2015). The amelioration, and sometimes, the remission of diabetes after bariatric surgery have been extensively demonstrated, with a greater effect in comparison to other glucose-lowering medications in morbidly obese patients with T2D (Schauer *et al.*, 2017). Obesity and T2D are two quantitatively defined diseases sharing a common epidemiology, pathophysiology, natural history, and complications. They clearly represent a continuum of the same disease with a progressive clinical worsening giving rise to deadly complications. The dysfunctional adipose organ probably accounts for the large proportion of all the detrimental phenomena which induce and accelerate the progression of obesity toward T2D and its complications.

Hypertension

Obesity-associated hypertension is characterized by activation of the sympathetic nervous system (SNS), activation of the renin-angiotensin system (RAS), and sodium retention, among other abnormalities; however, mechanisms linking obesity and arterial hypertension are much more complex and not yet fully clarified.

Blood pressure levels are tightly linked with BMI. Obesity represent a major cause of HTN, and subjects with a BMI greater than 26 kg/m^2 have a two- to threefold increased risk of HTN compared with those with normal weight, and the risk increases further with the severity of obesity (Huang *et al.*, 1998). The Framingham Heart Study has shown that 78% essential hypertension in men is related to excess weight gain, and weight reduction is in fact considered as one of the most relevant strategy for the prevention of hypertension in normotensive subjects or blood pressure reduction in hypertensive patients.

IR has been demonstrated to be associated with hypertension because of a complex action at the level of the kidney. Chronic hyperinsulinemia, as could be seen in obesity, seems to induce the production of angiotensinogen and aldosterone, unbalancing the RAS. Furthermore, hyperinsulinemia and hyperglycemia increase renal sodium reabsorption directly. The increased tubular sodium retention results in an increased cardiac output and vascular stress, with arterial remodeling and vasoconstriction leading to HTN. Renal anatomical and structural changes have also a great impact on the development of HTN in obese subjects. An increased blood pressure can partially results from external renal compression by increased retroperitoneal fat surrounding the kidneys, together with increased abdominal pressure secondary to central obesity (Hall *et al.*, 2015). This mechanical stress is

responsible for increased intraparenchymal pressure, glomerular hyperfiltration, and reduced natriuresis, which further contributed to increase blood pressure levels.

Obesity causes renal vasodilatation and glomerular hyperfiltration as compensatory mechanisms to maintain sodium balance despite the increased tubular reabsorption that, along with increased arterial blood pressure and metabolic abnormalities as well as other factors such as inflammation, oxidative stress and lipotoxicity, may contribute to the exacerbation of renal injury or dysfunction through a vicious cycle.

However, obesity per se can induce hypertension, independently from hormone and metabolic changes.

Obesity is in fact associated with elevated cardiac output due to the increased adipose accumulation and to an even greater extent fat-free mass, resulting in an increased total and central blood volume, which in turn leads to hemodynamic modifications such as augmentation in left ventricular (LV) stroke volume, LV hypertrophy and imbalanced production of cardiac natriuretic peptides.

These modifications, in absence of a reduction of systemic resistance, are responsible for the increased blood pressure levels; this condition is defined as obesity-associated hypertension (Hall, 2000). The dysfunctional adipose tissue induces deep changes in the pattern of secretion of several adipokines among them leptin, which is involved not only in the control of energy balance by regulating satiety and energy intake, but also in the activation of SNS with consequences for both central and peripheral regulation of blood pressure.

Dyslipidemia

Metabolic syndrome is characterized by the presence of atherogenic dyslipidemia, characterized by elevated levels of triglycerides (>150 mg/dL) with increased VLDL particle, increased small LDL, and/or low HDL-C (<40 mg/dL in men and <50 mg/dL in women). These abnormalities are common in obese subjects (60%–70% of obese subjects suffer for dyslipidemia), and they are vary associated with insulin resistance and adipose tissue expansion (Bays *et al.*, 2013). Insulin acts on adipose tissue (1) by stimulating glucose uptake and triglyceride synthesis and (2) by suppressing triglyceride hydrolysis and release of FFA and glycerol into the circulation. Adipose tissue insulin resistance, that is, the impaired suppression of lipolysis, has been associated with elevated plasma FFA levels with consequent peripheral deposition in nonadipose tissue organs. In particular, increased FFA afflux in the liver circulation promotes hepatic synthesis of TGs and, consequently, of VLDL particles. The increased levels of TGs influence the synthesis of the other lipoproteins. In particular, TGs accumulation modulate cholesterol ester transfer protein (CETP) activity: this enzymes increases the triglyceride content of LDL particles, which are subsequently hydrolyzed in the liver, with the production of small dense LDL.

Remnants of chylomicrons and VLDL are involved in the development of atherosclerosis and postprandial hyperlipidemia, and accumulation of atherogenic remnants is especially linked to visceral obesity. It has been shown that diurnal triglyceridemia in obese subjects correlates better to waist circumference than to BMI, which is in agreement with the hypothesis that the distribution of adipose tissue modulates postprandial lipemia.

Inflammation and adipokines have a further role for predisposition to dyslipidemia in obese subjects. TNF and IL-1 seems further promote the triglyceride production through an inhibition of lipoprotein lipase via expression of angiopoietin-like protein 4 (ANGPTL-4) (Khovidhunkit *et al.*, 2004). In addition, they also reduce the synthesis of HDL lipoproteins. Leptin and adiponectin seem involved in these abnormalities: leptin increase enzymatic lipolytic activity of adipose tissue resulting in higher production of FFA, whether on the contrary adiponectin, which levels are low in obese subjects, reduce TGs levels and increase the activity of lipoprotein lipase.

Adipose tissue in man is a major site for cholesterol storage. In obesity over half of total body cholesterol may reside within this tissue; however the uptake, synthesis, and mobilization of adipose tissue cholesterol appears to be mediated and/or regulated, as in other tissues, by the plasma lipoproteins. Recent studies suggest that dietary cholesterol contributes to increased adipocyte cholesterol. However, there is an emerging role of dietary cholesterol in AT cholesterol balance, inflammation, and systemic energy metabolism. It is now becoming obvious that cholesterol can no longer be considered only as a structural component of plasma membranes, but it also actively participates in the regulation of cell physiology. Reducing excessive dietary cholesterol intake is suggested as a simple, but novel, way to attenuate obesity-associated metabolic diseases (Chung and Parks, 2016).

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is a spectrum of liver abnormalities that ranges from simple liver steatosis to steatohepatitis and cirrhosis, which actually represents the most common chronic liver disorder worldwide and is predicted to became the main indication for liver transplantation in the future (Charlton *et al.*, 2011).

NAFLD present a strong epidemiological and physiopathological correlation with obesity, T2DM, and dyslipidemia, and it is in fact considered as an additional feature of metabolic syndrome. Obesity is the major phenotype and risk condition for NAFLD.

BMI and waist circumference are positively related to the presence of NAFLD and predict the progression of the disease. The association is supported by high rates of NASH, advanced fibrosis and cirrhosis in morbidly obese patients undergoing bariatric surgery. Hepatic steatosis on ultrasound ("bright liver") is common in obesity, and the prevalence of NAFLD varies, according to the different studies, up to 80% in diabetic subjects (Ortiz-Lopez *et al.*, 2012), and from 80% to 90% in severe obese subjects (Bellentani *et al.*, 2010). According with international guidelines, in presence of NAFLD a comprehensive evaluation of associated

metabolic conditions is suggested in patients at risk (Marchesini *et al.*, 2016). Overweight patients with visceral fat accumulation or a dysfunctional adipose tissue can exhibit NAFLD with/without abnormal liver tests. Therefore the currently used concept of "metabolically healthy obese" individuals should be considered with caution, given that these individuals may have altered liver tests and adverse health outcomes when longitudinally examined.

A "multiple-hit process" model has been put forth to understand the molecular events about NAFLD induced liver injury. It is believed that the initial "hit" is an ectopic accumulation in liver fat, resulting in hepatic lipotoxicity, which eventually triggers the inflammatory response in the microenvironment of liver and causes other "hits." Obesity is characterized by overeating and excessive calorie intake, exceeding the storage capacity of adipose tissue and leading to ectopic deposition of fat. This condition leads to dysfunctional adipocytes an increased plasma levels of FFAs because of increased triglycerides hydrolysis and consequent increased uptake of circulating FFAs by the liver. In addition with abnormal glucose homeostasis, these metabolic disarrangements promote the accumulation of intra-hepatic triglycerides (IHTG).

In NAFLD patients, excess of FFA, IHTG, and consequent lipotoxicity have crucial role for the progression of metabolic alteration and the fibrosis, increasing the production of diacylglicerol, activating protein kinase C-delta (PKC-δ), nuclear factor kinase-B (NF-κB), and leading IR and inflammation (Fabbrini *et al.*, 2010).

The liver-adipocyte axis well represent the multisystem consequences of obesity: adipose tissue dysfunction (with increased lipolysis), adipose-derived cytokines and hormones, along with the low-grade inflammation promote insulin resistance and increase circulating levels of FFA in the portal vein; insulin resistance favor increased hepatic lipogenesis and concomitant reduced fatty acid oxidation, then lipid accumulation induced liver steatosis and IHTGs induce hepatic inflammation and reduce hepatic insulin sensibility (Lomonaco *et al.*, 2012). Inflammation and hepatocyte injury and death are the hallmarks of non-alcoholic steatohepatitis (NASH), the progressive form of NAFLD. Recent observations have also shown that in subjects with NAFLD, more than liver damage, cardiovascular complications represent the leading cause of mortality (Targher *et al.*, 2010). So, NAFLD represents a new challenge for treatment of patient with obesity and/or metabolic syndrome.

Cardiovascular Complications

The most important consequences of obesity are the long term effects of obesity-related metabolic disease on cardiovascular risk associated with greater rates of atherosclerosis, HTN, vascular disease and cardiovascular mortality. The complications associated with obesity, and in particular when T2D develops, include peripheral vascular disease, coronary artery disease, heart failure (HF), and atrial fibrillation (AF).

Vascular markers of inflammation such as plasminogen activation inhibitor (PAI-1), fibrinogen and C-reactive protein (CRP) are also positively correlated with obesity thus explaining the higher prevalence of deep venous thrombosis and pulmonary embolism in obesity (Head, 2015; Campello *et al.*, 2015).

As already mentioned, obesity leads to cardiac ventricular abnormalities, both of right and left ventricle: increased LV stroke volume, LV hypertrophy, and LV diastolic dysfunction are in fact commonly observed in patients with obesity. These morphological and functional changes explains why obesity represents an important risk of heart failure (Kenchaiah *et al.*, 2002; Horwich and Fonarow, 2010). However, patients with HF and higher BMI either with reduced ejection fraction or with preserved ejection fraction had a lower mortality rate than those with a lower BMI suggesting a protective effect of obesity status called "obesity paradox." It has been described that mortality was highest in the low body fat (BF)/low lean mass index (LMI) group (15%), followed by the high BF/low LMI group (5.7%), low BF/high LMI group (4.5%), and high BF/high LMI group (2.2%) (Lavie *et al.*, 2012).

Moreover, left atrial enlargement is a common feature in patients who are obese, particularly those with class III obesity and comorbid hypertension; abnormal left atrial strain has been reported in such individuals predisposing to AF (Lavie *et al.*, 2018).

Alterations in microvascular function could contribute to the increased cardiovascular morbidity and mortality in obesity and the influence of obesity on coronary microvessels has been investigated only recently by assessing the relationship between coronary microvascular dysfunction, inflammation, and obesity. Coronary flow reserve (CFR) by transthoracic Doppler echocardiography is reduced in obese subjects without clinical evidence of heart disease, suggesting a coronary microvascular impairment. This microvascular dysfunction seems to be related to a chronic inflammation mediated by adipocytokines rather than to the increased adiposity (Tona *et al.*, 2014).

Obstructive Sleep Apnea

In obese subjects the most serious impact upon respiration comes during recumbent sleep when increased fat and soft tissue in the throat obstruct the airway which is known as obstructive sleep apnoea (OSA) strongly linked to an increased risk of developing hypertension because of an increased sympathetic activity.

OSA is a condition characterized by repeated episodes of upper airway collapse which happen during sleep. These phenomena usually occur during the REM phase, and patients go awakening to interrupt apnea episodes. This condition presents a relevant social burden because of its association with clinical entities affecting different organs.

OSA is in fact associated with several diseases, such as arterial hypertension, pulmonary hypertension, atrial fibrillation, but also T2DM, cardiovascular diseases, and all causes mortality.

Obesity may promote or aggravate OSA, and in obese patients prevalence of OSA is about 45% (Young *et al.*, 1993), with higher percentages with a more severe grade of obesity. Weight gain in patients with OSA is associated with a worsening of the disease; on the contrary, weight loss can achieve an improvement of OSA.

The connection between obesity and OSA lies in the anatomical and metabolic basis of the disease. In fact, sleep fragmentation has been demonstrated to affect several metabolic pathways and, in this sense, a bidirectional interconnection more than a putative mechanism can explain the association between these two conditions. Subjects with obesity have a larger neck circumference because of excessive fat deposition on upper airways, but they suffer also for restrictive pattern because of truncal and abdominal obesity. These abnormalities present adverse mechanical effects on lung function responsible for a condition of chronic hypoxia.

OSA is independently associated with insulin resistance, inflammatory cytokines, higher levels of C-reactive protein (CRP) and systemic inflammatory state. On the other hand, sleep deprivation (and night shift) is a recognized risk factor for weight gain. Sleep disorders are associated with activation of neuronal centers responsible for energy intake, and seems influence leptin production with consequent loss of satiety, overeating and hypercaloric diet preference (Romero-Corral *et al.*, 2010).

However, whether CPAP treatment seems to have positive effects on some metabolic complications of OSA, there is no data about the effects of this therapy on weight reduction. On the contrary, surgical weight loss has shown an amelioration also on apnea-hypopnea index (AHI) in patients with OSA (Greenburg *et al.*, 2009).

Reproductive Function Abnormalities

Sexual dysfunctions and reproductive system abnormalities are common in subjects suffering for obesity. Obese women suffer for menstrual irregularity, reduced fertility and also polycystic ovary syndrome (PCOS), whether obese men show signs of testosterone deficiency. Obesity represent also a risk factor for gestational diabetes, gravidic hypertension and risk of obesity for children.

Prevalence of PCOS in reproductive women is 4%–7%, but this increase in obese subjects, ranging from 6% to 100% (Lim *et al.*, 2012). Despite the common association, the role of obesity in the development of PCOS is not entirely known. Hyperinsulinemia seems affect the peripheral synthesis of sexual hormones, and in women it may stimulate ovarian androgen production inducing phenotype modifications typical of hyperandrogenemia, such as hirsutism and infertility. Treatment with metformin reduces circulating androgen levels increasing insulin sensitivity.

Male-obesity secondary hypogonadism (MOSH) represents a relevant endocrine dysfunction related to obesity, with a reported prevalence about 40%–50%, but it is often unrecognized in clinical practice. MOSH is characterized by decreased lean body mass, sexual dysfunction, and depression. VAT alter sex hormones levels by aromatization of circulating testosterone to estradiol, whether low testosterone levels promote abdominal fat deposition. Furthermore, obesity may affect gonadal function and testosterone levels through its related metabolic comorbidities, in particular T2D and metabolic syndrome. Several studies have demonstrated an inverse relationship between BMI, waist circumference and testosterone levels. In addition, low testosterone levels was been associated with the development of T2D (Stellato *et al.*, 2000), and low circulating levels of total and free testosterone are frequently observed in subjects with metabolic syndrome, whether testosterone therapy seems have positive effect on manifestations of metabolic syndrome.

Body weight loss appears to revert hypogonadism in patients suffering for obesity, and extensive literature has shown that weight loss after bariatric surgery is correlated with increase in testosterone levels greater than those obtained with lifestyle interventions. However, the effects of bariatric surgery on gonadal function in obese male remain not entirely known.

Osteoarthritis

Osteoarthritis (OA) represents one of the most relevant cause of disability for obese subjects. Mechanical stress associated with higher BMI is responsible of a chronic damage of weight-bearing joints, increasing the risk of knee or hip replacement (Liu *et al.*, 2007). The excessive body weight and the consequent articular overload give reason for a predilection of the lower extremities (knee and hip), but osteoarthropathy is associated with high disability also when are involved different joints, such as the carpometacarpal of the hand.

Pathophysiology of OA in obesity in fact seems go beyond the simple weight-induced mechanical damage. In fact, metabolic abnormalities seems to affects articular function, with a possible tissutal effects of adipose-derived cytokines and adipokines. This mechanisms can explain the OA of nonweight bearing joints which are usually found in obese subjects. In this sense, OA represents another systemic manifestation of obesity-related inflammatory state (Yusuf *et al.*, 2010).

In addition, also an in situ production of cytokines and adipokines has been demonstrated by synovial components, chondrocytes and adipose tissue near joints as infrapatellar fat pad, with release of matrix metalloproteinases, nitric-oxide (NO), and further pro-inflammatory mediators.

Weight loss seems associated to a modification in proteoglycan component and reduction of pro-inflammatory cytokines (Messier *et al.*, 2000), and bariatric surgery can promote articular remodeling not only reducing joint overload, but also decreasing systemic and local inflammation.

Gout

Gout represents an important disorder affecting obese patients, and the impact of gout in this population is likely to increase.

The prevalence of metabolic syndrome in patient with gout is in fact about 62% (Roddy and Choi, 2014), and the risk of gout is higher in presence of hypertension, abdominal obesity, dyslipidemia or diabetes.

However, the pathophysiological mechanisms explaining this association still remain unclear. Diet represent most relevant modifiable risk factors, but the other metabolic diseases seems further influence this risk. Dysfunctional adipose tissue and adipocytokines can influence the metabolism of uric acid (UA): IR and hyperinsulinemia affect the renal metabolism of UA because insulin enhances urate tubular reabsorption, resulting in increased serum levels of UA responsible for the higher risk of gout.

Weight loss and dietary changes represent the first line treatment for patients with gout (Khanna *et al.*, 2012), but there is limited evidence about the effects of surgical weight loss: bariatric surgery is associated with reduction of hyperuricemia in the long-term, despite a higher frequency of acute gouty attacks is observed in the early postoperative period.

Rheumatologic and Immune-Mediated Diseases

Secretory activity of adipose tissue, with production of inflammatory cytokines seems influence also the immune system, and this mechanism is considered responsible for emerging association between obesity and several autoimmune disorders.

Obesity is in fact is vary associated with psoriasis and psoriatic arthritis, asthma, rheumatoid arthritis, and systemic lupus erythematosus (Versini *et al.*, 2014). Hashimoto thyroiditis is often observed in overweight and obese subjects, but adipose tissue expansion seems to play a role also in development of type 1 diabetes, Crohn's disease, inflammatory bowel disease, and also multiple sclerosis.

The dysfunction of adipose tissue is responsible for the development of a chronic low-grade inflammation, which is partially the results of a in situ modulation of regulating T-cells present in the extracellular matrix. It is possible that adipose tissue can modulate the immune response of the whole body, and in this sense the disregulation of immune systems observed in obesity can lead to autoimmune disorders.

However, at this moment, epidemiological studies have described only a mild association between obesity and immune-mediated diseases.

Cancer

Increasing evidence has shown the link between body mass and cancer, with excessive BMI which seems associated with an increased risk for cancer mortality whereas weight loss is linked with a reduction of this risk (**Fig. 2**).

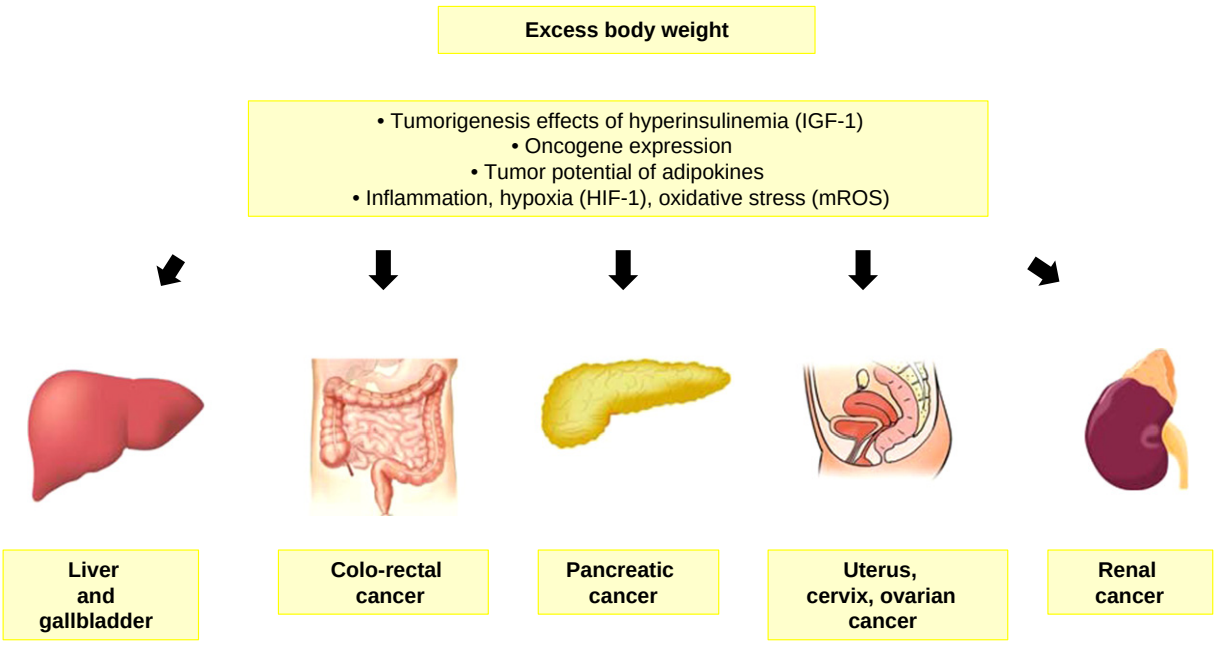

Fig. 2 Association between obesity and some forms of cancer.

In a prospectively studied population of more than 900,000 US adults who were free of cancer at enrollment in 1982, there were 57,145 deaths from cancer during 16 years of follow-up. The heaviest members of this cohort had death rates from all cancers combined that were 52% higher (for men) and 62% higher (for women) than the rates in men and women of normal weight. For men, the relative risk of death was 1.52; for women, the relative risk was 1.62. In both men and women, BMI was also significantly associated with higher rates of death due to cancer of the esophagus, colon and rectum, liver, gallbladder, pancreas, and kidney; the same was true for death due to non-Hodgkin's lymphoma and multiple myeloma. Significant trends of increasing risk with higher BMI values were observed for death from cancers of the stomach and prostate in men and for death from cancers of the breast, uterus, cervix, and ovary in women. On the basis of associations observed in this study, we estimate that current patterns of overweight and obesity in the United States could account for 14% of all deaths from cancer in men and 20% of those in women (Calle *et al.*, 2003).

In a recent UK absolute estimates of population effect emphasized the importance of BMI in driving the incidence of several cancers (Bhaskaran *et al.*, 2014).

The swedish obese subjects (SOS) study was the first intervention trial in the obese population to provide prospective, controlled cancer-incidence data and the effect of intentional weight loss. Weight loss induced by bariatric surgery was associated with reduced cancer incidence in obese women but not in obese men (Sjöström *et al.*, 2009).

There is paucity of studies evaluating hypothetical mechanisms to explain this associations. One of the most considered theory is the tumorigenesis effects of hyperinsulinemia, which promotes the activation of insulin-like growth factor 1 (IGF-1) pathway. In vitro studies have shown the effects of this metabolic via on promotion of apoptosis and cell proliferation. Several lines of evidence suggest that obesity-associated adipose tissue and neoplastic cells share key pathophysiological features in terms of diabetogenic, atherogenic, prothrombotic, and proinflammatory abnormalities. For example, low-grade chronic inflammation is both a hallmark of adiposopathy and a trigger for oncogene expression. Also adipokines are been evaluated for the development of cancer, and elevated levels of leptin has been found in some forms of cancer, such as colon and breast cancer, but its tumoral potential is unknown. Other mechanisms are inflammation, oxidative stress, and obesity-related hypoxia (Calle and Kaaks, 2004). Oxidative stress can promote cancer development because of excess of free radicals and reactive'oxygen species (ROS), whether inflammation and activation of NF-κB system are associated with induction of apoptosis. An important player is therefore represented by mitochondrial reactive oxygen species (mROS), which on one side are induced by altered lipid metabolism, and on the other promote neoplastic transformation and cancer progression. In addition hypoxia-inducible factor 1-α (HIF1-α), a master regulator of cancer progression and metastasis formation, contributes to obesity-induced inflammation and insulin resistance. Thus, a yet unexplored two- way direct communication may exist between these two tissues, which influence *the fate of both*.

Conclusions

There is convincing evidence in order to consider obesity a "disease" which increases the risk of developing a number of serious health conditions that, as for the other diseases, we can call complications. The severity of obesity, together with the presence and severity of complications and age, are important to grade interventions. The so-called EOSS (Edmonton Obesity Staging System), which takes into consideration all these variables, is able to identify patients at increased mortality risk who therefore deserve more clinical and therapeutic attention (Sharma and Kushner, 2009).

Introduction

Increasing prevalence of obesity constitutes now a prime importance problem for public health (Farooqi and O'Rahilly, 2005; Flier, 2004; Friedman, 2003; Medina-Gomez and Vidal-Puig, 2005). The reasons for the rising prevalence of obesity are complex, but social and environmental factors in combination with genetic predisposition are first to overall positive energy balance. Nowadays, obesity has become a pandemic disease around the world (Tobias *et al.*, 2014). In addition, increased prevalence was found either in developed countries as in developing countries (Hossain *et al.*, 2007; Zheng *et al.*, 2011).

Obesity is a consequence of an imbalance between energy intake and energy expenditure which leads to an increase in body weight gain and adiposity (Popkin and Gordon-Larsen, 2004; Simopoulos, 1999). In addition, the altered energy homeostasis in obesity is related with the metabolic syndrome characterized by insulin resistance and type 2 diabetes, fatty liver (Cota *et al.*, 2007; Farooqi and O'Rahilly, 2005; Flier, 2004; Medina-Gomez and Vidal-Puig, 2005; Plum *et al.*, 2006; Sarafidis and Nilsson, 2006), and other pathologies such as different types of cancer (Calle and Kaaks, 2004).

In the last years several metabolic pathways have been revealed as crucial actors in the regulation of energy balance. In fact, lipid metabolism is directly involved in metabolic homeostasis, since an excess of lipids may result in an ectopic storage of lipids in organs such as liver or skeletal muscle, causing lipotoxicity (Astrup *et al.*, 2008; Astrup and Raben, 1992; Kahn *et al.*, 2006).

The interaction between central nervous system (CNS) and peripheral organs can regulate energy balance (Carling *et al.*, 2008; Kahn *et al.*, 2005; Lage *et al.*, 2008; Ruderman *et al.*, 2003). This was revealed almost 80 years ago when a study focus in obesity and homeostasis control showed that animals with hypothalamic lesions present an increase in adiposity, diabetes, and obesity. Under this context several central mechanisms, specially located at hypothalamic level, constitute the main regulators of energy homeostasis and have been shown involved in the physiological process regulating food intake, body weight but also lipid metabolism and glucose homeostasis.

Hypothalamic Control of Food Intake

In the past, it was described that specific hypothalamic nuclei modulate food intake (Anand and Brobeck, 1951; Hervey, 1959; Teitelbaum and Stellar, 1954). This relation was supported by the finding showing that lesions in the hypothalamic nuclei modulate orexigenic or anorexigenic responses. Accordingly, it was described that lesions in ventromedial nucleus of hypothalamus (VMH) leads to hyperphagia, while lesions located in the lateral hypothalamic area (LHA) induce anorexia and loss of weight (Miller, 1957).

Energy balance is coordinated into the CNS, and the most studied area in this regard is the hypothalamus, which regulates food intake and energy expenditure in response to neural, hormonal, and nutrient-related signals. The hypothalamus is situated under the thalamus, including the major portion of the ventral diencephalon. This brain region is involved in a wide range of homeostatic functions such as the regulation of endocrine axes and energy balance. The hypothalamus is organized in neuronal clusters, known as nuclei, which constituted interconnected neuronal circuits via axonal projections (Elmquist *et al.*, 2005; Gao and Horvath, 2007; Lopez *et al.*, 2007a,b; Morton *et al.*, 2006). The different hypothalamic nuclei including arcuate nucleus (ARC), the paraventricular nucleus (PVH), the LHA, the dorsomedial nucleus (DMH), and the VMH (Adam and Mercer, 2004; Kalra *et al.*, 1999; Morton *et al.*, 2006; Schneeberger *et al.*, 2014; Schwartz *et al.*, 2000).

In response to changes in energy status, hypothalamic nuclei modulate the expression of neurotransmitters/neuromodulators that lead adaptations in energy intake and expenditure (Elmquist *et al.*, 2005; Gao and Horvath, 2007; Lopez *et al.*, 2007a,b; Morton *et al.*, 2006). In response to peripheral metabolic signals such as glucose, amino acids, and lipids and also to hormones, such as leptin, ghrelin, adiponectin (ADPN), resistin (RSTN), glucagon-like peptide-1 and insulin the hypothalamic neurons regulate the expression and synthesis of neuropeptides (Elmquist *et al.*, 2005; Gao and Horvath, 2007; Lopez *et al.*, 2007a,b; Morton *et al.*, 2006).

The arcuate nucleus (ARC) is a hypothalamic area known as the *"master hypothalamic center"* because it is mainly involved in the control of feeding by different neural populations. Different nutritional/feeding factors from the periphery are integrated in different neuronal populations in the ARC. A group of neurons in the ARC expresses the orexigenic (increasing appetite) neuropeptides agouti-related protein (AgRP) and neuropeptide Y (NPY) which promote feeding and project to other hypothalamic nuclei. On the other way, in the ARC a population of neurons expresses the anorexigenic (inhibiting food intake) products of proopiomelanocortin (POMC), the precursor of alpha-melanocyte stimulating hormone (α-MSH) and the cocaine and amphetamine regulated transcript (CART), the two of them inhibitors of feeding. Neurons expressing AgRP and NPY project to other

second order neurons located in different hypothalamic nuclei, mainly to PVH; differently neurons expressing anorexigenic neuropeptides (POMC, α-MSH, and CART), affects to secondary hypothalamic nuclei such as the DMH, LHA, PVH, and the perifornical area (PFA). The VMH receives projections from AgRP/NPY and CART/POMC neurons in the ARC. Moreover, the VMH neurons direct their axons to the ARC, DMH, LHA, and other brainstem regions including the nucleus of the solitary tract (NTS). When energy intake is higher than energy expenditure, the expression of orexigenic neuropeptides, such as AgRP and NPY, are decreased. Opposed, when energy expenditure exceeds food intake, anorexigenic neuropeptides POMC and CART are expressed (Farooqi and O'Rahilly, 2005; Flier, 2004; Friedman, 2003; Lage *et al.*, 2008; Lopez *et al.*, 2008, 2007a,b; Martinez de Morentin *et al.*, 2010; Morton *et al.*, 2006). In addition to the mentioned hypothalamic nuclei and neuropeptides, the LHA is also involved in the regulation of energy balance by expressing orexins and melanin-concentrating hormone (MCH), neuropeptides which play an important role in orexigenic responses.

Hypothalamic Control of Energy Homeostasis

Energy homeostasis is regulated in addition to food intake by lipid metabolism and glucose homeostasis regulation. The CNS, especially at hypothalamic level, has a relevant role on energy homeostasis regulation mainly through the regulation of lipid metabolism and glucose homeostasis in peripheral organs.

Hypothalamic Control of Energy Expenditure

In addition to the regulation of food intake, the hypothalamus also controls energy expenditure. In this sense, one of the most attractive facts is the regulation of the activity of the brown adipose tissue (BAT), since it was found to be active un human adults (Cypess *et al.*, 2009; Mueez *et al.*, 2017; van Marken Lichtenbelt *et al.*, 2009). The hypothalamus requires the sympathetic nervous system to control BAT activity.

For a long time, the preoptic area (POA) has been considered the only region in the brain involved in thermoregulation (Boulant, 2000; Fuller *et al.*, 1975; Imai-Matsumura *et al.*, 1984; Satinoff *et al.*, 1976). However, we now know that other hypothalamic areas are also relevant. For instance, electrical stimulation of the VMH increased interscapular BAT temperature (Holt *et al.*, 1987; Kelly and Bielajew, 1991; Saito *et al.*, 1987; Yoshida *et al.*, 1984), being AMPK a key player in this area (Lopez *et al.*, 2016). Also the activation of neurons in the DMH and PVH stimulates body temperature (Bewick *et al.*, 2005; Cao *et al.*, 2004; Zaretskaia *et al.*, 2002). The ARC regulates also BAT thermogenesis, since the ARC orexigenic population inhibits thermogenesis and that partial loss of AgRP/NPY neurons leads to a lean, hypophagic phenotype, also characterized by sympathetic activation of BAT (Bewick *et al.*, 2005; Shi *et al.*, 2013).

Hypothalamic Control of Lipid Metabolism

The hypothalamus does not only regulate food intake, but also other components of the balance such as lipid metabolism. In the last years, a central mechanism in charge of lipid sensing has been revealed as clue in energy homeostasis regulation. Nutrients in circulation derived from the diet or from hepatic glucose synthesis and adipocyte lipolysis are sense at central levels. Alterations in this lipid sensing mechanism have been associated to obesity and comorbidities. Moreover it has been proposed that in obesity the characteristic hyperphagia is a state of resistance to the satiety effects of the lipids (Pocai *et al.*, 2005b). Based on a recent series of reports, specific circuits in the CNS are directly connected to white adipose tissue (WAT) and liver thereby directly influencing adipocyte and hepatic metabolism. Among the main circulating factors that act a central level and regulate peripheral lipid metabolism leptin and ghrelin should be mentioned.

Leptin and lipid metabolism

The anorexigenic hormone leptin acts at central level regulating peripheral lipid and glucose metabolism through neuronal pathways (Fruhbeck *et al.*, 1997; Kamohara *et al.*, 1997; Siegrist-Kaiser *et al.*, 1997). Leptin receptor is expressed in the hypothalamus, and the arcuate nuclei is the main target for leptin action. Leptin induces opposite effects on two neuronal subpopulations in the arcuate: inhibits the orexigenic NPY/AgRP-containing neurons and it stimulates the anorexigenic POMC neurons (Flier, 2004; Kalra *et al.*, 1999; Spiegelman and Flier, 2001). The activation of leptin receptor (LepR) in ARC activates the signaling cascade involving Janus kinase and signal transducer and activator of transcription 3 (Jak-STAT3) (Bates and Myers, 2004) as well as the IRS-PI3K pathway (Niswender *et al.*, 2003).

In addition to the anorexigenic action of leptin, a role in the regulation of peripheral lipid and glucose metabolism it was also shown (Fruhbeck *et al.*, 1997; Kamohara *et al.*, 1997; Siegrist-Kaiser *et al.*, 1997). The administration of leptin to experimentation animals induce lipolysis in adipose tissue (Fruhbeck *et al.*, 1998). Different studies in the last years have shown that multiple mechanisms are involved in the peripheral effect in WAT. Among the mechanisms involved in this effect central leptin affects the different pathways involved in the de novo conversion of saturated fatty acids to the monounsaturated fats in WAT (Lin *et al.*, 2003) and WAT lipogenesis (Clauson *et al.*, 2005). A decrease in stearoyl-CoA desaturase 1 (SCD-1), fatty acid synthase (FAS) and acetyl-CoA carboxylase (ACC) gene expression in WAT and liver (Gallardo *et al.*, 2007) might be related to this effect as well as the

modulation the main indicator of lipolysis in WAT, the hormone-sensitive lipase (HSL) (Tajima *et al.*, 2005). Under this context, leptin, decreases fat tissue mass and lipid accumulation through this action at central level.

Ghrelin and lipid metabolism

Opposed actions of ghrelin and leptin regarding the regulation of energy homeostasis has been described. Ghrelin hormone mainly produced in stomach stimulates food intake and increase adiposity (Billington *et al.*, 1994; Nakazato *et al.*, 2001; Tschop *et al.*, 2000). In the CNS ghrelin activates hypothalamic neurons co-expressing NPY/AgRP (Wren *et al.*, 2000) in an opposite way that leptin. In addition to its actions on appetite, central administered ghrelin regulates BAT sympathetic activity (van der Lely *et al.*, 2004). The involvement of the autonomous nervous system on central ghrelin actions in the periphery was showed to be carried out by the vagus nerve (Yasuda *et al.*, 2003). In fact, chronic central ghrelin infusion increases the expression in WAT of the main enzyme with lipogenic action (FAS, SCD-1, ACC, and LPL); while it decreases the expression of carnitoyl-palmitoyl transferase 1 (CPT-1) the main marker of fat oxidation. These central effects of ghrelin on WAT metabolism were shown to be independent of food intake (Theander-Carrillo *et al.*, 2006). It was probed that the effects of central ghrelin on WAT metabolism are leaded by the sympathetic nervous system (Theander-Carrillo *et al.*, 2006). In addition to the central actions of peripheral hormones the hypothalamic neuropeptides have a key role in lipid metabolism regulation.

Hypothalamic NPY and melanocortin system and lipid metabolism

NPY expression is regulated in an opposite way by leptin and ghrelin. The orexigenic NPY is mainly produced in the ARC. Besides the effect of central NPY on feeding and energy expenditure, it was also described a potent effect inducing de novo lipogenesis in both, liver and adipose tissue (Zarjevski *et al.*, 1994). In addition to the NPY neurons, another set of hypothalamic adjacent neurons are directly involved in lipid metabolism regulation, the neurons expressing the anorexigenic peptide POMC (Flier, 2004; Kalra *et al.*, 1999; Spiegelman and Flier, 2001). Related to this, the family of peptides derived from the posttranslational processing of POMC named melanocortins, act through a family of five members of the family of G-protein-coupled receptors (MCRs) (Cone 2005, 2006). Among those receptors, MC3Rs and MC4Rs are the most important regarding energy homeostasis. The activation of these receptors at hypothalamic level decreases food intake, body weight, and fat mass (Fan *et al.*, 1997). In addition to its effect in food intake, a role in lipid metabolism was also attributed to the melanocortin system in the CNS. The administration of melanocortin system derivates at central level has shown to stimulate lipolysis (Nogueiras *et al.*, 2007; Song *et al.*, 2005). Moreover, the activation of the CNS melanocortin system increased lipid mobilization in WAT and its blockade elicit lipid uptake and triglyceride synthesis (Nogueiras *et al.*, 2007). The sympathetic nervous system seems to be mediating the effects of CNS melanocortin system on lipid metabolism in adipose tissue (Song *et al.*, 2005) since the central activation of melanocortin system increase sympathetic nervous activity in WAT (Nogueiras *et al.*, 2007).

Hypothalamic Control of Glucose Homeostasis

Hypothalamic leptin and glucose homeostasis

The effects of leptin on energy homeostasis regulation are not only related to this action on food intake and lipid metabolism, it was also probed that leptin is directly related to glucose homeostasis. Among the effects of leptin centrally administered an improvement in insulin sensitivity was reported in animal studies (Cusin *et al.*, 1998; Rouru *et al.*, 1999; Shi *et al.*, 1998). In addition, an increase in glucose uptake in several tissues such as heart, brown adipose tissue (BAT), and muscle was found after leptin administration (Minokoshi *et al.*, 1999). The actions of leptin on glucose homeostasis might be elicited through the activation of the PI3K pathway (Morton *et al.*, 2005).

Hypothalamic melanocortin system and glucose homeostasis

The mentioned effects of leptin increasing insulin sensitivity and decreasing adiposity might be mediated by the central melanocortin system (Barzilai *et al.*, 1997). Possibly, the effects of the melanocortin on glucose homeostasis might be secondary to the mentioned effects of this system decreasing adiposity since visceral adiposity is a well-recognized risk factor for insulin resistance and diabetes. Accordingly, the central blockade of melanocortin system reduces insulin sensitivity (Obici *et al.*, 2001).

Hypothalamic NPY and glucose homeostasis

The actions of central NPY on glucose homeostasis have been revealed to be tissue specific. Supporting this it was found that central infusion of NPY increasing glucose uptake in adipose tissue probably mediated by an increase in the expression of the main glucose transporter GLUT4. Opposed, in muscle tissue the central infusion of NPY decrease glucose uptake and GLUT4 expression (Zarjevski *et al.*, 1994).

Hypothalamic insulin and glucose homeostasis

A relevant factor modulating glucose homeostasis at central level is insulin. At central level, specifically in the arcuate nuclei of the hypothalamus (ARC) the insulin receptors lead the central effects of insulin on glucoses metabolism. Immediately after food intake, insulin is secreted from the pancreatic β-cells blocking the endogenous glucose synthesis and increasing glucose uptake. When the circulating levels of insulin are decreased the central activation of insulin pathway in the hypothalamus is able for decrease

endogenous glucose production and thus regulate glucose homeostasis (Obici *et al.*, 2002). At hypothalamic level the channels ATP-sensitive potassium (KATP) are involved in the action of insulin since it was found that the activation of his channels by insulin have the capacity of decrease blood glucose levels as a consequence of an inhibition of the gluconeogenesis (Obici *et al.*, 2002; Pocai *et al.*, 2005a,b). These facts highlight the crucial role of hypothalamic insulin signaling in the maintenance of glucose homeostasis.

Gastrointestinal Hormones and Their Regulation of Food Intake

Luca Busetto, Marco Rossato, and Roberto Vettor, University of Padua, Padua, Italy

Introduction

Energy balance, the equilibrium between food intake and energy expenditure, is regulated tightly in humans at the level of the central nervous system (CNS), mostly in areas pertaining to the hypothalamus and the brainstem. Orexigenic and anorectic neurons located in the arcuate nucleus of the hypothalamus receive both central and peripheral signals, integrate this complex array of data, and regulate their activity in order to provide an appropriate coordinate response in term of eating behavior, drive for feeding and energy expenditure (Schwartz *et al.*, 2000). Peripheral signals can be divided in long-term and short-term signals (Schwartz *et al.*, 2000). Long-term signals communicate to the hypothalamus information regarding body's energy stores, endocrine status, and general health. Many of them are represented by circulating hormones, like the adipose tissue hormone leptin and the pancreatic hormone insulin. Short-term signals are believed to regulate meal initiation and termination, and mostly of them are originated in the gastrointestinal (GI) system. The GI tract can communicate with the hypothalamus both through vagal afferent nerves that innervate brain regions involved in the immediate need for food intake, and through a large number of humoral messengers produced at the GI level and sensed in the CNS, globally named as GI hormones or gut hormones (Schwartz *et al.*, 2000).

Many peptide hormones generated in the gastrointestinal (GI) tract modulate appetite in both animal and human studies (**Fig. 1** and **Table 1**) (Lean and Malkova, 2016; Steinert *et al.*, 2017). The site of production, mechanism of action and effects of the most relevant of these GI hormones will be revised in this article. Moreover, for each of these relevant hormones, information will be provided on the variations in their levels induced by obesity and by the changes induced by dietary restriction, physical exercise, and bariatric surgery (**Tables 2** and **3**). The physiology, effects and regulation of insulin and glucagon, which most important actions relate to glucose homeostasis, will be not included.

Glucagon-Like Peptide 1 (GLP-1)

GLP-1 physiology. GLP-1 is secreted primarily from entero-endocrine L cells located in the distal jejunum and ileum, and its release is stimulated by carbohydrate and fat intake (Madsbad, 2014). Secretion of GLP-1 in response to food intake occurs rapidly after food ingestion (within 10–15 min) with a second peak of secretion at 30–60 min. After release, GLP-1 is rapidly inactivated by the enzyme dipeptidyl peptidase-4 (DPP-4) with a plasma half-life of less than 2 min (Madsbad, 2014). GLP-1 receptors are widely distributed in the brain, in peripheral organs such as the pancreatic islets, and in the GI tract. GLP-1 has an important role on post-prandial glucose homeostasis stimulating glucose-induced insulin release and inhibiting glucagon release at the pancreatic level ("incretin" effect) (Willms *et al.*, 1996). At the GI level, GLP-1 delays gastric emptying with a slow nutrient absorption, that may contribute to the reduction of postprandial glycaemia, and an enhanced satiety, that may contribute to food intake reduction ("ileal brake" effect) (Madsbad, 2014). However, the most important site of action for the effects of GLP-1 on appetite is the CNS. In the brain, GLP-1 receptors are found in areas that are implicated in the control of food intake and energy balance. The central administration of GLP-1 in animals has been shown to significantly reduce food intake (Lean and Malkova, 2016) (**Table 1**).

GLP-1 in obesity. Obesity has been associated with an attenuated post-prandial GLP-1 response to test meals in several studies. Adam and Westerterp-Plantenga (2005) analyzed GLP-1 release after a standard breakfast in 30 normal-weight subjects and in 28 patients with overweight/obesity. Pre-prandial GLP-1 levels were similar in the two groups, but the post-prandial GLP-1 response was significantly blunted in patients with obesity. A flat GLP-1 post-prandial curve was also observed by Carroll *et al.* (2007) in 20 patients with obesity as compared with 19 normal-weight controls. A reduced post-prandial GLP-1 response in patients with severe obesity was also confirmed by Verdich *et al.* (2001) in 19 patients and 12 lean controls. The attenuated GLP-1 post-prandial response observed in patients with obesity has been linked to increased appetite (Adam and Westerterp-Plantenga, 2005) and increased food intake during an ad libitum lunch (Verdich *et al.*, 2001). Therefore, the defective GLP-1 regulation could be involved in the pathophysiology of obesity or in its maintenance (**Table 2**).

GLP-1 and calorie restriction. Unfortunately, the majority of the studies that examined the effects of dietary intervention with calorie restriction on GLP-1 levels demonstrated a further reduction in GLP-1 levels, accompanied by a reduced satiety and a greater appetite. Sloth *et al.* (2009) observed a reduction of fasting GLP-1 levels and greater appetite after an 8-week low-energy diet. Sumithran *et al.* (2011) monitored the circulating levels of several peripheral hormones involved in the homeostatic regulation of body weight, including post-prandial GLP-1 levels, in 50 patients with overweight or obesity treated by an 8-week very-low calorie diet followed by a 2-week weight stabilization period and a 52-week weight maintenance phase. Mean weight loss was 14% of initial body weight after weight stabilization (week 10) and 8% at the end of the maintenance phase (week 62). Mean levels of GLP-1 did not change significantly between baseline and week 10, but the GLP-1 levels at week 62 were slightly but

 doi:10.1016/B978-0-12-801238-3.66106-8

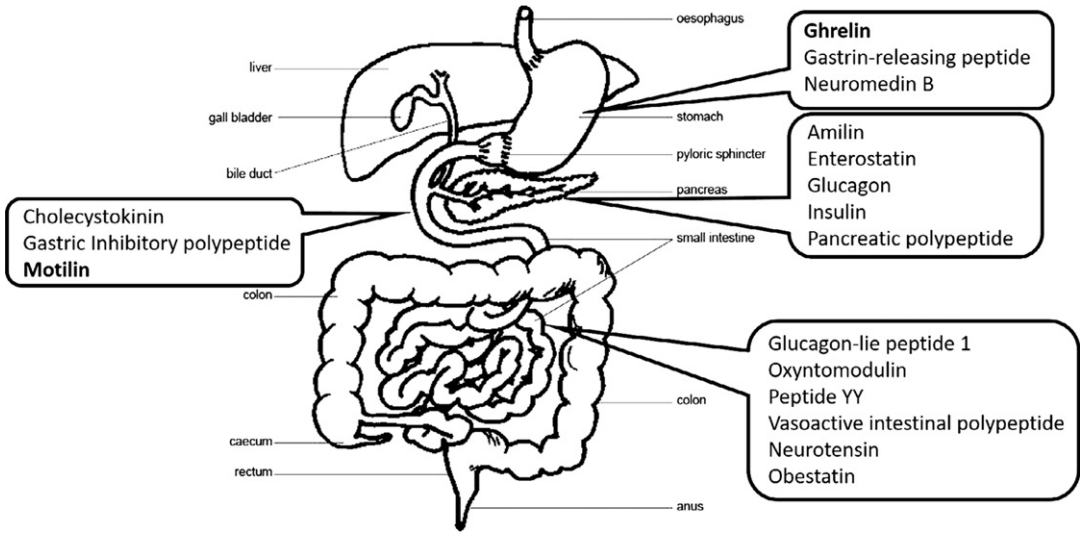

Fig. 1 Sites of production of the gastrointestinal hormones having a role in the regulation of energy balance. Most of the hormones have an anorectic activity. The few orexigenic hormones are evidenced in bold.

significantly lower than baseline levels. These studies support the view that diet-induced weight loss can result in long-term reductions in GLP-1, postulated to favor increased appetite and weight regain, thus at least in part explaining why weight loss through caloric restriction is often so difficult to achieve and/or maintain (Lean and Malkova, 2016) (**Table 2**).

GLP-1 and exercise. The effects of physical exercise on GLP-1 levels seems to go in opposite way respective to those observed after calorie restriction. A recent meta-analysis on the effects of acute exercise on the hormones related to appetite regulation reported a small acute post-exercise increase in GLP-1 levels in normal-weight individuals (Schubert *et al.*, 2014). More interestingly, Martins *et al.* (2010) examined the effect of a more prolonged 12-week aerobic exercise training (500 kcal of treadmill walking or running 5 days per week) on fasting and postprandial levels of GLP-1 in 22 sedentary patients with obesity and observed a tendency toward an increase in the delayed release of GLP-1 90–180 min after exercise. These beneficial changes may explain why long-term exercise training typically prevent weight regain (**Table 2**).

GLP-1 after bariatric surgery. The available evidences about the changes observed in GI hormones levels after bariatric surgery have been recently reviewed by Dimitriadis *et al.* (2017). Whereas laparoscopic adjustable gastric banding (LAGB) has none or very few effects on post-prandial GLP-1 levels, both sleeve gastrectomy (LSG) and Roux-en-Y gastric bypass (RYGB) in particular are followed by a substantial increase in post-prandial GLP-1 concentrations (Evans *et al.*, 2012; Tsoli *et al.*, 2013; Dimitriadis *et al.*, 2017). Reasons for GLP-1 food hyper-stimulation after surgery are not fully understood. Both the passage of more intact nutrients to the ileum through anatomical changes or increased intestinal transit (Nausheen *et al.*, 2013) and the bypassing of the upper small intestine (Rubino and Marescaux, 2004) have been advocated as potential mechanisms in different procedures. Whatever the mechanisms, taking into account the multiple effects of GLP-1 on glucose homeostasis and energy balance, the persistence of post-bariatric GLP-1 elevation is seen as one of the potential mechanisms explaining the favorable and durable effect that bariatric procedures exert on both glucose metabolism and body weight (Dimitriadis *et al.*, 2017). Indeed, weight regain occurring in some patients after bariatric surgery, RYGB in particular, may be associated to a tendency to GLP-1 levels to return to pre-operative levels (Santo *et al.*, 2016) (**Table 3**).

Gastric Inhibitory Polypeptide (GIP)

GIP physiology. GIP is released from duodenal endocrine K cells immediately upon the absorption of fat or glucose (Falko *et al.*, 1975). In mice, high-fat diet is associated to hypersecretion of GIP and extreme fat deposition with insulin resistance. In contrast, mice lacking the GIP receptor are protected from diet-induced obesity and insulin resistance (Miyawaki *et al.*, 2002). These effects are believed to be driven mostly by the peripheral effects of GIP: GIP promotes a more efficient storage of ingested fat in the adipocytes with secondary insulin resistance and hyperinsulinemia. On the contrary, the intra-cerebroventricular administration of GIP does not affect food intake (Woods *et al.*, 1981). These results indicate that there is little if any direct effect of GIP on feeding behavior.

Cholecystokinin (CKK)

CKK physiology. CCK is secreted by the duodenal and jejunal L cells in response to luminal nutrient (particularly fat) content and it was probably the first GI for which an action on food intake regulation has been discovered (Fried *et al.*, 1991; Matzinger *et al.*, 1999). CKK has multiple effects on GI system that tend to facilitate nutrient absorption, including stimulation of gall bladder

Table 1 Gastrointestinal hormones involved in appetite regulation

Hormone	*Primary source for appetite regulation*	*Propose mechanism of action on appetite*
Anorexigenic factors		
Amylin	Pancreatic β cells (co-secreted with insulin)	Delays gastric emptying; targets the hindbrain and hypothalamus
Cholecystokinin (CCK)	Duodenal/jejunal I cells	Delays gastric emptying; targets the vagus nerve, hindbrain, and hypothalamus
Enterostatin	Exocrine pancreas	Inhibits fat intake, targets the hypothalamus
Gastrin-releasing peptide (GRP)	Gastric myenteric neurons	Contributes to meal termination
Glucagon	Pancreatic α cells	Modulates gastric emptying and vagal tone
Glucagon-like peptide 1 (GLP-1)	Intestinal L cells (co-secreted with PYY, OXM)	Delays gastric emptying, promotes insulin secretion, suppresses glucagon secretion; targets the vagus nerve, hindbrain, and hypothalamus
Insulin	Pancreatic β cells	Targets the hypothalamus
Neuromedin B (NMB)	Gastric myenteric neurons	Contributes to meal termination
Neurotensin	Gastrointestinal enteroendocrine cells	Decrease in food intake is acute only
Obestatin	Stomach, intestine	Decreases food intake, slows gastric emptying
Oxyntomodulin (OXM)	Intestinal L cells (co-secreted with GLP-1, PYY)	Delays gastric emptying; targets the hypothalamus
Pancreatic polypeptide (PP)	Pancreatic F cells	Delays gastric emptying; targets the vagus nerve and hindbrain
Peptide YY (PYY)	Intestinal L cells (co-secreted with GLP-1, OXM)	Delays gastric emptying; targets the vagus nerve and hypothalamus
Vasoactive intestinal polypeptide (VIP)	Intestine, pancreas	Targets hypothalamus
Orexigenic factors		
Ghrelin	Gastric antrum and fundus	Increases gastric emptying, decreases insulin secretion; targets the vagus nerve, hindbrain and hypothalamus
Motilin	Small intestine	Increases gastric motility, targets vagus nerve

Modified from: Lean, M. E. J. and Malkova, D. (2016). Altered gut and adipose tissue hormones in overweight and obese individuals: Cause or consequence? International Journal of Obesity 40, 622–632.

contraction, enhanced pancreatic enzyme secretion and delayed gastric emptying (Lean and Malkova, 2016). Delayed gastric emptying has been considered in the past as the most important mechanism by which CCK suppresses appetite (De Graaf *et al.*, 2004). However, CCK is also present in different parts of the brain involved in the regulation of energy balance and food intake (Lean and Malkova, 2016). (**Table 1**).

CCK in obesity. Studies regarding CCK secretion in obesity reported controversial results (Steinert *et al.*, 2017). Baranowska *et al.* (2000) reported reduced fasting CCK levels in patients with obesity, but this observation was not confirmed by others (Stewart *et al.*, 2011; Brennan *et al.*, 2012). Stewart *et al.* (2011) reported delayed and reduced CCK response to an intra-duodenal oleic acid infusion in patients with overweight or obesity compared with normal weight subjects, but CCK responses to high-fat, high-carbohydrate, and high-protein meals were found to be comparable in subjects with or without obesity by Brennan *et al.* (2012). Finally, French *et al.* (1993) reported a higher CCK response to a high-fat meal in patients with obesity than in normal-weight controls (**Table 2**).

CCK and calorie restriction. In its study on the levels of GI hormones in patients with overweight or obesity treated by a very-low calorie diet followed by a weight maintenance phase, Sumithran *et al.* (2011) demonstrated a rapid reduction of post-prandial CKK levels after the first phase of rapid weight loss and the persistence of this reduction until the end of the weight maintenance period. Chearskul *et al.* (2008) confirmed a significant reduction in post-prandial CCK concentrations after a phase of rapid weight loss obtained by a very-low-calorie diet intervention in patients with obesity. These studies suggest that, beside GLP-1 reduction, also CCK lowering may be involved in increasing appetite and stimulating weight regain after diet-induced weight loss (**Table 2**).

*CCK and exercise. E*vidence regarding the effect of exercise on CCK is very limited (Lean and Malkova, 2016). Studies regarding the impact of acute exercise on CCK levels have been conducted in normal weight individuals and reported increased CCK responses immediately after exercise (Schubert *et al.*, 2014). However, more long-term studies in patients with obesity losing weight through an exercise training program failed to demonstrated any variation on either fasting or post-prandial concentrations of CCK measured at least 48 h after the last exercise session (Martins *et al.*, 2010) (**Table 2**).

CCK after bariatric surgery. Few studies examined the changes in CCK occurring after bariatric procedures (Dimitriadis *et al.*, 2017). However, a rise in the post-prandial CCK levels have been reported both after RYGB (Jacobsen *et al.*, 2012) and LSG (Mans *et al.*, 2015). Peterli *et al.* (2012) directly compared in a randomized trial hormonal changes after RYGB and LSG, and described a larger CCK increase in the LSG than in the RYGB group (**Table 3**).

Table 2 Variations in the levels of gastrointestinal hormones induced by obesity and their changes after dietary restriction or physical exercise

Hormone	*Levels in obesity*	*After diet*	*After exercise*
Anorexigenic factors			
Cholecystokinin (CCK)	=?	↓	=↑
Glucagon-like peptide 1 (GLP-1)	↓	↓↓	↑
Oxyntomodulin (OXM)	?	?	?
Pancreatic polypeptide (PP)	=↓	↑	↑
Peptide YY (PYY)	↓	↓↓	=↑
Orexigenic factors			
Ghrelin	=↑	↑↑	?

Table 3 Variations in the levels of gastrointestinal hormones after bariatric surgery procedures

Hormone	*LAGB*	*LSG*	*RYGB*
Anorexigenic factors			
Cholecystokinin (CCK)	?	↑↑	↑
Glucagon-like peptide 1 (GLP-1)	=↑	↑	↑↑
Oxyntomodulin (OXM)	?	?	↑
Pancreatic polypeptide (PP)	=	?	?
Peptide YY (PYY)	↑	↑	↑
Orexigenic factors			
Ghrelin	=	↓↓	↓

LAGB: Laparoscopic adjustable gastric banding; LSG: sleeve gastrectomy; RYGB: Roux-en-Y gastric bypass.

Peptide YY (PYY)

PYY physiology. Peptide YY (PYY) is a satiety hormone co-secreted with GLP-1 by L cells in the lower intestine (Adrian *et al.*, 1985). Fat intake is considered the strongest stimulant of PYY secretion, whereas carbohydrate intake seems to have a limited effect (Essah *et al.*, 2007). Plasma PYY is a mix of PYY(1–36), the secreted form, and PYY(3–36), the active form, which results from cleavage of PYY(1–36) by DPP-4 (Steinert *et al.*, 2017). The anorectic effect of PYY is mostly attributed to delayed gastric emptying and vagal nerve stimulation that are dose-related and dependent on the amount of fat in the meal ("ileal brake" effect) (Lean and Malkova, 2016). However animal studies showing that intra-CNS injections of PYY(3–36) reduce food intake and that peripherally administered PYY(3–36) inhibits eating even in vagotomized mice seems to suggest also the possibility of a central action (Steinert *et al.*, 2017) (**Table 1**).

PYY in obesity. Several studies documented an attenuation of post-prandial PYY response in obesity (Lean and Malkova, 2016). For example, le Roux *et al.* (2006) demonstrated attenuated post-prandial PYY release and reduced satiety in 20 patients with obesity compared with 20 normal-weight subjects. Zwirska-Korczala *et al.* (2007) also observed blunted post-prandial PYY responses in obese and morbidly obese women compared with lean control subjects. (**Table 2**).

PYY and calorie restriction. Similar to GLP-1 levels, Sloth *et al.* (2009) observed a reduction of PYY levels and greater appetite after an 8-week low-energy diet in patients with obesity. Reduction of PYY levels during energy restriction has been confirmed in patients with overweight or obesity by Sumithran *et al.* (2011). This blunted PYY response was found to be persistent over a 12-month weight maintenance phase (Sumithran *et al.*, 2011) (**Table 2**).

PYY and exercise. A small acute increase of PYY immediately after a single exercise session has been consistently reported (Schubert *et al.*, 2014). However, the results regarding more long-term effects of exercise on PYY levels are more contrasting. A sustained increase in fasting plasma PYY levels after a prolonged period of exercise was found in two pediatric (Jones *et al.*, 2009; Roth *et al.*, 2005) and one adult intervention studies (Martins *et al.*, 2010). On the contrary, Guelfi *et al.* (2013) did not found modifications in fasting or postprandial PYY levels in overweight and obese men doing endurance or resistance training (**Table 2**).

PYY after bariatric surgery. Post-prandial PYY levels appear to increase following bariatric surgery (Dimitriadis *et al.*, 2017), regardless of the type of bariatric procedure (Korner *et al.*, 2009; Tsoli *et al.*, 2013) (**Table 3**).

Oxyntomodulin (OXM)

OXM physiology. OXM is an anorectic hormone co-secreted with PYY and GLP-1 from the intestinal L cells. Its anorectic effect is mostly attributed to binding to GLP-1 and glucagon receptors (Choudhury *et al.*, 2016). OXM peripheral administration can stop weight gain in rats and cause weight loss in humans (Murphy *et al.*, 2006). However, no clear data are available about OXM levels in obesity and the effects of energy restriction or exercise (**Table 2**).

OXM after bariatric surgery. Very few studies have looked at the effects of bariatric surgery on OXM (Dimitriadis *et al.*, 2017). However, at least two small studies reported an increase of OXM levels after gastric bypass (Laferrère *et al.*, 2010; Falkén *et al.*, 2011) (**Table 3**).

Pancreatic Polypeptide (PP)

PP physiology. PP is produced in response to a meal by the F cells of the endocrine pancreas, and to a lesser extent by the exocrine pancreas, colon and rectum (Lean and Malkova, 2016). The anorectic effect of PP is believed to in part centrally mediated, and in part related to the effects of the hormone on gastric emptying (**Table 1**).

PP in obesity. Studies of PP in patients with obesity reported conflicting results, with some study showing no differences (Adamska *et al.*, 2014) and some studies demonstrating lower fasting PP levels in patients with obesity as compared to normal-weight subjects (Reinehr *et al.*, 2006) (**Table 2**).

PP and calorie restriction. An increase in PP concentrations after dietary induced weight loss has been demonstrated both in adults (Sumithran *et al.*, 2011) and in children with obesity (Reinehr *et al.*, 2006) (**Table 2**). These observations seem to suggest that PP behaves in a different manner in respect to other anorectic GI hormones that tend to reduce during energy restriction (Lean and Malkova, 2016). However, the clinical relevance of this observation may be questioned, giving that in both the above studies the appetite scores were increased and not reduced after weight loss.

PP and exercise. An acute increase of PYY immediately after a single exercise session has been reported (Schubert *et al.*, 2014). No data are available for more time-sustained effects of exercise on PP levels (**Table 2**).

PP after bariatric surgery. Information about the effects of bariatric procedures on PP levels are very scarce. No significant changes in post-prandial PP levels were observed after gastric banding (Dixon *et al.*, 2011). No information are available about the changes of PP levels after other bariatric procedures (**Table 3**).

Amylin

Amylin physiology. Amylin is co-secreted with insulin by the pancreatic β-cells and therefore meal-associated fluctuations of circulating amylin levels directly reflect changes in β-cell secretion (Lutz, 2016). Chronic administration of amylin in rats reduces body weight by reducing food intake and increasing energy expenditure (Lutz, 2016). Amylin is sensed by specific receptors located in areas of the SNC typically involved in the regulation of energy intake and energy expenditure (area postrema) and the anorectic effect of amylin is therefore believed to be mostly centrally mediated (Lutz, 2016). Moreover, amylin seems to interact with leptin at the CNS level. Interestingly, amylin may be able to reduce the leptin resistance that is commonly associated with obesity and the anorectic effect of amylin is potentiated by its co-administration with leptin (Lutz, 2016). Initial clinical studies showed that co-administration of amylin and leptin analogs pramlintide and metreleptin, was effective in lowering body weight in humans (Roth *et al.*, 2008). More information are needed about amylin levels and regulation in obesity and after weight loss.

Ghrelin

Ghrelin physiology. Ghrelin has been originally identified as the endogenous ligand of the growth hormone secretagogue receptor 1a (GHRS-1a), but its fundamental physiological role is indeed related to eating behavior: ghrelin is the most relevant orexigenic GI hormone yet discovered (Lean and Malkova, 2016). Ghrelin is secreted by specific cells in the GI tract, primarily at the gastric antrum and fundus, and its orexigenic action has been mostly attributed to the interaction of its acylated form with GHRS-1a at the hypothalamic level (Delhanty and van der Lely, 2011). Moreover, ghrelin accelerates gastric emptying (Tack *et al.*, 2006). In normal-weight individuals, ghrelin levels raise in response to fasting and decline after eating (Cummings *et al.*, 2001). Therefore, ghrelin seems to fluctuate and act in a way that is opposite to the anorectic GI hormones mentioned above (Lean and Malkova, 2016) (**Table 1**). However, the physiologic relevance of ghrelin as a stimulus for meal initiation and food intake regulator has been recently questioned by the fact that ghrelin infusion was not able to modulate appetite or spontaneous meal request in normal-weight males (Lippl *et al.*, 2012).

Ghrelin in obesity. Fasting ghrelin levels were reported to be lower in patients with obesity than in normal-weight subjects in one study (Carlson *et al.*, 2009), but this observation was not confirmed by others (Lean and Malkova, 2016). However, compared with lean subjects, patients with obesity consistently demonstrated less suppression of ghrelin levels following meals (Yang *et al.*, 2009; English *et al.*, 2002). This attenuated response to ghrelin to meals, with persistently higher flat values, has been linked to the tendency to continuous eating or "grazing" observed in some patients with obesity (Lean and Malkova, 2016) (**Table 2**).

Ghrelin and calorie restriction. Diet-induced weight loss was accompanied by alterations in ghrelin levels in several studies (Lean and Malkova, 2016). Fasting ghrelin levels increased by 17% in a group of seventy premenopausal women with overweight or obesity who had a 4.5% weight loss after a 10-week intervention program including an energy-restricted diet and moderate physical activity (Ata *et al.*, 2010). Cummings *et al.* (2002) demonstrated an elevation of 24-h ghrelin profiles and meal-related ghrelin fluctuations in 13 patients with obesity after a 6-month dietary intervention. Finally, Sumithran *et al.* (2011) described

increased post-prandial ghrelin levels in 50 patients with overweight or obesity both at the end of an 8-week very-low calorie diet and after a 52-week weight maintenance phase (**Table 2**).

Ghrelin and exercise. An acute suppression of acylated ghrelin levels in the hours immediately following a single exercise burst has been consistently reported (Schubert *et al.*, 2014). The effects of chronic exercise on ghrelin levels are more complex and less clear (Lean and Malkova, 2016). Chronic exercise was associated to increased fasting ghrelin levels, but to increased suppression of post-prandial ghrelin levels in patients with overweight and obesity (Martins *et al.*, 2010). However, no significant changes in fasting or post-prandial ghrelin levels have been observed in adults with severe obesity treated by an integrated program including exercise (Morpurgo *et al.*, 2003) or in exercising children with obesity (Kim *et al.*, 2008) (**Table 2**).

Ghrelin after bariatric surgery. Several studies demonstrated a reduction of ghrelin levels after the most commonly performed bariatric procedures (Dimitriadis *et al.*, 2017). Sleeve gastrectomy, that includes the removal of the part of the stomach where ghrelin is mostly produced, is associated to a reduction of ghrelin levels not observed after gastric banding (Yousseif *et al.*, 2014). A differential effect on ghrelin levels in comparison to gastric banding has been observed also after RYGB, with no changes after gastric banding and reduction after RYGB (Frühbeck *et al.*, 2004). Cummings *et al.* (2002) demonstrated a nearly complete suppression of 24-h ghrelin profiles and meal-related ghrelin fluctuations in five patients treated with RYGB (**Table 3**).

Conclusion

Accumulating evidences clearly demonstrated that GI hormones play an important physiologic role in regulating food intake, meals initiation and termination, and eating behavior in humans. A large number of anorectic and a few orexigenic hormones interact in a coordinate network to play this role. The balance between anorectic and orexigenic hormones seems altered in patients with obesity, where a tendency toward reduced anorectic pathways and increased orexigenic signals have been reported. Attempts to reduce body weight trough dietary restriction tend to accentuate this alteration, with a further reduction in anorectic hormones and an increase of the orexigenic ones. These diet-induced changes in GI hormones are considered one of the most important factor causing weight regain and obesity recidivism after diet-induced weight loss. A different picture may be observed after bariatric surgery, particularly after sleeve gastrectomy and gastric bypass, where anorectic hormones are stimulated and orexigenic signals suppressed. These changes may partly explain the superiority of bariatric surgery over lifestyle modifications in maintaining weight loss over time. Therefore, GI hormones regulation seem important both in physiology and in the obese state. Pharmacologic targeting GI hormone are increasingly recognized as an important tool for improving obesity management in the long term.

Body Composition

Manfred J Müller, Corinna Geisler, and Anja Bosy-Westphal, University of Kiel, Kiel, Germany

Abbreviations

2C-model	2 compartment model
4C-model	4 compartment model
AT	Adipose tissue
ADP	Air displacement plethysmography
BIA	Bioelectrical impedance analysis
BIS	Bioelectrical impedance spectroscopy
BCM	Body cell mass
BMD	Bone mineral density
BMI	Body mass index
BNP	Brain natriuretic peptide
BCA	Body composition analysis
BAT	Brown adipose tissue
BIVA	Bioelectrical impedance vector analysis
CT	Computer tomography
DHEAS	Dehydroepiandrosteronesulfate
D_2O	Deuterium
DXA	Dual-energy-absorptiometry
ECW	Extracellular water
FM	Fat mass
FFM	Fat free mass
FT3	Free tri-iodo-thyronine
FT4	Free thyroxine
ICW	Intracellular water
IGF	Insulin-like growth factor
IGFBP	Insulin-like growth factor binding protein
LST	Lean soft tissue
LBM	Lean body mass
MRS	Magnetic resonance spectroscopy
MRI	Magnetic resonance imaging
NA	Neutron activation
NaBr	Sodium bromide
PET	Positron emission tomography
PA	Phase angle
QMR	Quantitative magnetic resonance
R	Resistance
SAT	Subcutaneous adipose tissue
SMM	Skeletal muscle mass
SHBG	Sex hormone binding protein
TBK	Total body potassium
TBW	Total body water
TAT	Total = whole body adipose tissue
TSH	Thyroid stimulating hormone
TBN	Total body nitrogen
TAG	Tri-acyl-glycerol
VAT	Visceral adipose tissue
WC	Waist circumference
WAT	White adipose tissue
Xc	Reactance

Body composition analysis (BCA) differentiates body weight into different body components, organs and tissues. Body composition reflects body responses to internal (i.e., hormones, cytokines, myokines) and external (e.g., diet, physical activity, infection) determinants, it characterizes over- and malnutrition. BCA applies concepts of cellular/molecular physiology, biochemistry and experimental approaches to understand the masses and functions at different biological levels, that is, the whole body or its individual organs, tissues, cells, and molecules (Forbes, 1987; Heymsfield *et al.*, 2005, 2015). Suitable applications of BCA are (i) interpretation of body functions (e.g., energy expenditure, glucose turnover and protein synthesis in relation to muscle mass) and their disturbances in the context of individual body components and their associations and vice versa (ii) interpretation of the meaning of individual body components in the context of their functional consequences (e.g., fat mass in relation to the secretion of adipokines, inflammation, and insulin resistance) (Müller, 2013).

In clinical practice, BCA is used to describe energy stores (fat mass), "functional" body mass (i.e., the sum of oxygen consuming cells), hydration status (total body water, TBW, intracellular water, ICW, extracellular water, ECW), fracture risk (bone mineral content and density) and cardio-metabolic risks (e.g., visceral adipose tissue, VAT, and liver fat related to insulin resistance) (Müller, 2013). BCA addresses changes in energy and fluid balances (e.g., during weight gain or weight loss or in response to fluid overload or dehydration) and adds to identify clinical issues such as sarcopenia (e.g., a reduced skeletal muscle mass in the elderly), cachexia (e.g., involuntary weight loss in cancer patients) and fluid disturbances (e.g., fluid overload in patients with heart failure, liver cirrhosis or impaired renal function).

BCA is an essential part of clinical investigation and cardio-metabolic risk assessment, it characterizes overweight and malnutrition. Since individual body components add to variances of plasma hormone levels (e.g., there is a close correlation between fat mass and plasma leptin levels) and metabolism (e.g., fat free mass, FFM, is a major determinant of resting energy expenditure, REE) body components are used to explain their inter-individual variances and for adjustment of either plasma hormone concentrations or metabolism (Heymsfield *et al.*, 2012; Bosy-Westphal *et al.*, 2013a). BCA adds to characterize development and growth, aging as well as physical performance. Thus, detailed body composition data provide a sound basis for differentiated nutritional assessment, understanding endocrine and metabolic functions, defining personalized medical treatment strategies and *in depth* phenotyping in biomedical research (Müller, 2013; Prado and Heymsfield 2014; Heymsfield *et al.*, 2015).

 doi:10.1016/B978-0-12-801238-3.65167-X

Contrary to detailed BCA, primitive and crude estimates of the nutritional status such as BMI and waist circumference (WC) have a limited accuracy to characterize energy balance and physical, endocrine and metabolic functions related to weight status (Müller *et al.*, 2016a). In addition, these crude estimates have limited value in estimating individual health risks and morbidity. They may be used at the population level. In clinical practice BMI and WC are reserved for a first categorization of patients, that is, categorizing overweight and obese patients. At the population level they are used to estimate cardio-metabolic risks.

From Anatomy to Compartment Models (Fig. 1)

Human macroscopic anatomy is about appearance, position and structures of organs and tissues of the body. This knowledge is mainly based on post-mortem autopsy data (Snyder *et al.*, 1975; ICPR, 2002). By contrast, modern in vivo BCA is about models and so-called compartments. A "two compartment model" (or 2C-model) divides the body into two compartments, fat mass (FM), and FFM (Forbes 1987; Withers *et al.*, 1999; Heymsfield *et al.*, 2005; **Fig. 1**). While FFM includes cellular water, protein and minerals within adipocytes FM refers to chemical fat only, that is, energy stores with tri-acyl-glycerol (TAG) accounting for about 60%–90% of adipose tissue. FFM refers to TBW, minerals and body protein. When compared with FFM, lean soft tissue (LST) is the sum of all lean compartments, organs and tissues except bone, and includes non-adipose tissue lipids. When compared with LST lean body mass (LBM) includes bone mass.

Extending the "2C-model" refers to different levels (Heymsfield *et al.*, 2005, 2015; Müller, 2013; Müller *et al.*, 2016b). The "atomic" level includes the eleven major elements, H, O, N, C, Na, K, Cl, P, Ca, Mg, S), whereas the "molecular" relates to six components, lipid, water, protein, carbohydrates, bone minerals, and soft tissue minerals. At the "cellular" level three or four components, body cell mass (BCM), ICW, ECW, extracellular solids are described. The "tissue-organ level" comprises major tissues, adipose tissue, skeletal muscle, visceral organs, bone with further organ level components such as brain, liver, kidneys, heart, spleen. Finally, the "whole body level" divides the body into body regions, that is, head, trunk, upper and lower limbs. When compared with the "2C-model" all these models are considered as "multi-component" or "multi-compartment models" (Heymsfield *et al.*, 2005, 2015; **Fig. 1**).

Methods and Models Used for BCA (Table 1)

Methodological aspects of BCA have been extensively described (Heymsfield *et al.*, 2005; Preedy, 2012). Anthropometric methods are non-invasive, they are still used in population studies to assess for example, skinfold thickness (as an estimate of subcutaneous FM) and midarm or thigh circumference (which can be used as a measures of skeletal muscle mass after correction for subcutaneous fat). Strictly spoken, these are local or at least regional assessments of body composition resulting in a "2C-model," because they have been validated against so-called "2C-reference methods" (see below). Age-and sex-specific estimates of whole body FM are based on algorithms generated from the statistical associations between anthropometric measurements and the data obtained by the reference or gold standard method.

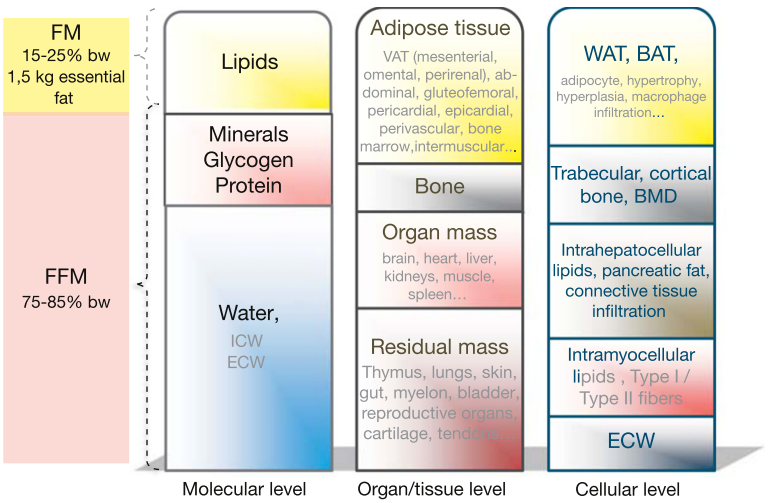

Fig. 1 From a 2-compartment model to different multi-compartment models (see text for further explanations). Abbreviations used: *VAT*, visceral adipose tissue; *WAT*, white adipose tissue; *BAT*, brown adipose tissue; *BMD*, bone mineral density; *ICW*, intra-cellular water; *ECW*, extracellular water. Adapted from Muller, M.J. (2013). From BMI to functional body composition. *European Journal of Clinical Nutrition* **67**, 1119–1121.

Table 1 Characteristics of individual methods used for body composition analysis

	Methods	*Outcomes*	*MDC, kg*	*Precision, %*
Gold standards	MRI/CT whole body, regional	AT, SAT, VAT, BAT?,MM, OM (brain, heart, liver, kidneys), ectopic fat in liver, skeletal muscle, pancreas	0.2	1,1
	4C model	FM, FFM, hydration of FFM	1	
Individual reference methods	DXA whole body, regional	lean body mass, FM, bone mass and bone mineral density	1	2
	Dilution methods D_2O, NaBr	Total body water, extra- + intra-cellular water, tissue hydration	2	1–2 (for TBW)
	Densitometry ADP, underwater weighing	Body volume and density, FM	2	2
	QMR	FM, lean tissue, free + total water	0,2	0,7
Field methods	BIA	Resistance, reactance, phase angle, BIVA	1.5	1
	Skinfolds	SAT	2–3	>5
	Ultrasound	SAT, MM thickness, OM, liver fat	?	?

MDC, minimal detectable change (fat mass, kg); prec', precision (Fat mass, %); *MRI*, magnetic resonance imaging; *CT*, computer tomography; *DXA*, dual X-ray absorptiometry; *ADP*, air displacement plethysmography; *QMR*, quantitative magnetic resonance; *BIA*, bioelectrical impedance analysis; *TBW*, total body water; *AT*, adipose tissue; *SAT*, subcutaneous adipose tissue; *VAT*, visceral adipose tissue; *BAT*, brown adipose tissue; *MM*, muscle mass; *OM*, organ mass; *FM*, fat mass; *FFM*, fat free mass.

There are a number of non-invasive and accurate methods for BCA. Different reference methods are used which differ in techniques, concepts and outcomes. At the whole body level reliable and valid measurements of body volume and thus body density (calculated as the ratio of body mass and body volume) by either underwater weighing or air displacement plethysmography (ADP) aim to assess FM and FFM (Forbes, 1987). Dilution techniques measure hydration status, that is, D_2O-dilution to assess TBW and NaBr-dilution to measure ECW. ICW is then calculated from the difference between TBW and ECW (Heymsfield *et al.*, 2015). Dual X-ray-absorptiometry (DXA) assesses bone mineral content and density (BMD), LST, and FM. LST of leg and arms (or LST of limbs) can be taken as a measure of skeletal muscle mass (so-called appendicular skeletal muscle mass; Heymsfield *et al.*, 1990; Gallagher *et al.*, 1997; Kim *et al.*, 2002). Major body elements (e.g., total body K, N, Ca, etc.) are quantified by whole body counting (e.g., in a total body K counter as total body potassium, TBK, or by neutron activation analysis, NAA, of different elements, e.g., total body nitrogen, TBN) (Heymsfield *et al.*, 2005). Today the latter two methods are of very limited use because of specialized equipment, requirements of high technical skills, high costs and a very limited availability. Quantitative magnetic resonance (QMR) technology is non-imaging and based on nuclear magnetic resonance (NMR) (Bosy-Westphal and Müller, 2015). QMR requires a low magnetic field of 67 G (or 0.0067 T). QMR measures FM, lean mass (with the exclusion of solid components mainly in the bone) and free water. Today, QMR is the most precise method for BCA (see **Table 1**). QMR estimates FM independently of FFM hydration.

Models used in BCA rely on certain assumptions, which are considered as fixed (e.g., 73.2% water content of FFM or measurements at a body temperature of 36°C or 37°C). In addition, it is usually assumed that an individual body component has a homogenous composition. These assumptions may be questioned in daily practice, for example, tissue hydration differs between children and the elderly and also between obese and normal weight patients. In addition, FFM hydration changes with weight loss and throughout the course of a clinical condition, for example, with inflammation and sepsis and in patients with liver cirrhosis. To minimize the shortcomings of individual methods, the results of different methods are combined, that is, DXA + ADP + D_2O-dilution resulting in a so-called "4-compartment-" or "4C-model" (Fuller *et al.*, 1992; Withers *et al.*, 1999; Shen *et al.*, 2005; Heymsfield *et al.*, 2015). Thus the "4C-model" avoids assumptions of a fixed composition of FFM. It is considered as a gold standard for BCA.

Detailed body composition can be assessed by imaging technologies, that is, whole-body magnetic resonance imaging (MRI) or computer tomography (CT) (Müller *et al.*, 2002; Heymsfield *et al.*, 2005; Prado and Heymsfield, 2014). MRI allows reconstruction of all organs and tissues of the body. Transversal images are taken at different distances (e.g., a slice thickness of 7–10 mm for abdominal organs). Cross-sectional organ areas are segmented by hand or automatically using a validated software. Calculation of organ and tissue volumes is based on the sum of areas multiplied by slice thickness and the distance between the scans. The accuracy of volume determination is improved by using contiguously obtained images. Organ and tissue volumes are then converted into masses by taking into account their specific densities (i.e., 0.916 for adipose tissue, 1.0414 for skeletal muscle, 1.0298 for heart, 1.05 for liver, kidneys and spleen, 1.030 for brain, 1.99 for bone corticalis adding up to a whole body density of 1.07 for males and 1.04 for females). Using CT, attenuation intervals (Hounsfield units; HU) can be used for detailed BCA at the organ/tissue level. The interval between −1001 and 191 HU covers air, gas and lung, −190 and −30 HU reflects adipose tissue and yellow bone mass, −29 and 151 HU covers soft tissue whereas cortical bone and spongiosa are defined by an interval of +151 and 2001 HU. To assess whole body subcutaneous and visceral adipose tissue (SAT, VAT) and skeletal muscle mass (SMM)

a whole body-protocol can be reduced to measurements at a single slice at lumbar vertebra 3 (L3; Schweitzer *et al.*, 2015, 2016). This site has been validated for healthy adults and the elderly. However as for longitudinal observations (e.g., during weight loss or weight gain) the variance in changes of regional fat depots limits the value of a single slice estimate (Schweitzer *et al.*, 2015).

Besides the 4C-model, MRI and CT are also considered as Gold standard methods of BCA (Müller *et al.*, 2002; Prado and Heymsfield, 2014). Comparing 4C-model data with MRI- or CT-derived estimates of body composition some differences become evident, that is, chemically defined fat mass as assessed by the 4C-model does not closely resemble the volume of adipose tissue as measured by MRI. There is a considerable inter-individual variance in these data with a fat content of adipose tissue volume varying between 60% and 90%. Thus, strictly spoken the results obtained by imaging technologies cannot be directly compared with the results obtained by the use of either a single reference methods or the 4C-model.

Magnetic resonance spectroscopy (MRS) can be used to assess fat infiltrations in liver, pancreas and skeletal muscle. Liver fat can also be measured by MRI using the 2-point Dixon method that calculates "fat-only" and "water-only" images from "in-phase" and "opposed-phase" images (Ma, 2008).

When compared to reference methods and the gold standard methods, bioelectrical impedance analysis (BIA) has become a widely applied field method for BCA (Lukaski, 2013). Individual BIA devices have been validated against the different reference methods, the "4C-model" and whole body MRI too (Bosy-Westphal *et al.*, 2013b, 2017). These validations are specific for the individual devices, the reference populations and the individual reference or gold standard methods. In a standard approach impedance is measured with a current of 100 mA at a single frequency of 50 kHz. Using multifrequency BIA or bioelectrical impedance spectroscopy (BIS) frequencies between 1 and 1000 kHz body composition is calculated from the impedance to the flow of an electric current through total body fluid. The conductive volume (V, which represents TBW or FFM) is proportional to the square length of the conductor (Ht^2) and inversely correlated to resistance (R) of the cross-sectional area ($V = \rho \times Ht^2/R$, where ρ is the specific resistance of the conductor). TBW can be further differentiated into ICW and ECW. It distinguishes excess fluid from the hydration of major body tissues (Chamney *et al.*, 2007).

Whole-body impedance is mainly based on the impedance of the distal parts of the limbs near the electrodes. Algorithms used to calculate body composition from BIA measurements are based on statistical relationships between impedance and either TBW or FFM or muscle mass. FM is then calculated from the difference between body weight and FFM. Population specificity, the reference method used to generate the BIA algorithm and the BIA device add to a nearly endless list of varying BIA algorithms published so far. Thus, using a BIA device in a clinical setting, population specificity and validation and the device used for generation of a specific BIA algorithm has to be scrutinized.

Alternatively, the use of BIA raw data has gained popularity in body composition research (Bosy-Westphal *et al.*, 2005, 2006). Resistance (R) and reactance (Xc) are standardized by body height in a bioelectrical impedance vector analysis (BIVA) to characterize hydration status and body cell mass (BCM). In a clinical setting, BIVA can be used to follow changes in hydration and BCM and thus malnutrition (e.g., in tumor patients undergoing treatment) (Norman *et al.*, 2015). In addition, the phase angle (PA) can be directly calculated from R and Xc as arc-tangent (Xc/R) $180^\circ/\pi$. PA is associated with body cell mass (BCM), changes in cellular membrane integrity and alterations in fluid balance. A low PA is used for the diagnosis of malnutrition and clinical prognosis. For device-specific BIVA and PA, reference values from different populations stratified according to ethnic, age, and body mass index (BMI) groups are available. Modern BIA techniques are valid tools to estimate body composition in healthy and euvolemic adults. In the clinical setting the use of BIA raw data has value. By contrast, using standard BIA algorithms generated in healthy subjects for BCA in patients has obvious limitations.

The accuracy and outcomes of different methods used for BCA are presented in **Table 1**.

Clinical Applications of BCA (Tables 2 and 3)

The use of appropriate models and methods in BCA depends on both, the question of interest as well as the accuracy needed to address that question (see **Tables 2** and **3**; Müller *et al.*, 2016b). As far as energy balance is concerned, FM and FFM (or LST, LBM) are suitable outcomes. While FM is a measure of energy stores FFM is the major determinant of REE. FM and FFM can be assessed appropriately by either ADP, underwater weighing or DXA. However, faced with the limited precision of either reference methods or the "4C-model," an assessment of changes in body components as an estimate of energy balance is sound at weight changes of >2 kg. By contrast, and within short-term and during controlled over- and under-feeding, QMR allows an accurate assessment of changes in energy stores (i.e., within ± 150 g changes in FM). Quantifying VAT and liver fat as part of cardio-metabolic risk assessment is brought about by MRI, CT, and magnetic resonance spectroscopy (MRS). Whole body and regional fat masses are interpreted in the context of adipokines (e.g., plasma leptin levels) and its inflammatory activity adding up to cardio-metabolic risk assessment.

The clinical phenotypes of low muscle mass and impaired muscle function, that is, sarcopenia (i.e., sarcopenia occurs at under-, normal-, overweight and in obese subjects and may also be associated with osteopenia) are characterized by skeletal muscle mass SMM, with or without increases in VAT and/or alterations in SAT and BMD together with a measure of muscle strength (e.g., as obtained by isokinetic hand-held dynamometry). This phenotype can be assessed by whole body MRI or CT together with DXA. In the case of malnutrition, FFM (or LST, LBM) and muscle mass are measured by either DXA (LST), ADP (FFM), D_2O-dilution (FFM), BIA (FFM) and/or MRI/CT (skeletal muscle mass). In malnourished patients, a PA as assessed by BIA is an estimate of poor prognosis (Bosy-Westphal *et al.*, 2006; Norman *et al.*, 2010, 2015). Osteopenia and osteoporosis are characterized by a low BMD

Table 2 Application of anthropometrics and body composition analysis in clinical problem solving

Characteristics	*Clinical problem*	*Clinical application*	*Detailed phenotyping*	*Method of choice*
1. BMI	• Overweight • Obesity • Malnutrition	• Risk assessment • Treatment (weight loss, weight gain)	Ø	Ø
2. Waist circumference	• Overweight • Obesity	Risk assessment	VAT, SAT, liver fat	MRI; CT
3. Fat mass	• Energy storage • Energy balance	Diet	Total and regional AT, SAT, VAT, BAT	MRI; CT; PET; thermo-graphy;DXA; ADP
4. Muscle mass (FFM, BCM)	• Malnutrition • Growth development • Sarcopenia • Rehabilitation	Treatment	Skeletal mus-cle (total, regional), heart muscle	DXA; MRI
5. Body water (ICW, ECW)	• De-& hyperhydration • Heart failure • Impaired renal function • Liver cirrhosis	Treatment	Edema, ascites, liver, kidney, heart	D_2O; NaBr, BIA/BIS
6. Bone mineral content	Osteoporosis	Treatment	Bone mineral density	DXA

Abbreviations used: *AT*, adipose tissue; *VAT*, visceral adipose tissue; *SAT*, subcutaneous adipose tissue; *BAT*, brown adipose tissue; *MRI*, magnetic resonance imaging; *CT*, computer tomography; *PET*, positron emission tomography; *DXA*, dual energy X-ray absorptiometry; *ADP*, air displacement plethysmography; *NaBr*, sodium bromide; *BIA*, bioelectrical impedance analysis; *BIS*, bioelectrical impedance spectroscopy.

Table 3 Body composition analysis follows the question of interest: What do we want know?

Questions	*Characteristic*	*Methods*
Energy stores?	Fat mass (FFM)	ADP, HD, DXA, BIA, QMR
Metabolic risk?	VAT, ectopic fat	MRI,MRS, CT, (DXA)
Sarkopenia?	Muscle mass	DXA, MRI, NA, BIA
Osteoporosis?	Bone density	DXA, (CT), NA
Hydration/edema?	TBW/ECW	D_2O-, NaBr-dilution, BIA
Prognosis?	Phase angle	BIA
Partitioning?	Fat mass, FFM	QMR

Abbreviations used: *FFM*, fat free mass; *TBW*, total body water; *ECW*, extracellular water; *ADP*, air displacement plethysmography; *HD*, hydrodensitometry = underwater weighing; *DXA*, dual energy X-ray absorptiometry; *BIA*, bioelectrical impedance analysis; *QMR*, quantitative magnetic resonance; *MRI*, magnetic resonance imaging; *MRS*, magnetic resonance spectroscopy; *CT*, computer tomography, *NA*, neutron activation; *naBr*, sodium bromide.

and trabecular structure as measured by either DXA or CT. Overhydration (e.g., in cardiac failure, chronic kidney or liver diseases) and dehydration (e.g., in the elderly) can be assessed by either dilution techniques (D_2O, NaBr) or multifrequency BIA/BIS.

Endocrine Correlates of Detailed Body Composition (Table 4)

Several hormones are correlated with masses and volumes of individual body components (**Table 4**). Since body components are again inter-correlated some of the associations between plasma hormone levels and body composition have to be interpreted with caution. The strongest correlations were seen between plasma leptin levels and SAT as well as between plasma testosterone and skeletal muscle mass. Thus, to explain the inter-individual variances in hormone concentrations there is need of an adjustment for body composition.

About a Reference Man and a Reference Women (Fig. 2)

The so-called *Reference Man* is a medical model used for calculation of radiation doses. Further applications relate to assessment of pharmacokinetics of drugs and modeling substrate metabolism (e.g., related to insulin resistance). The *Reference Man* is not a reference in epidemiological studies. The *1975 Reference Man* was based on characteristics of body composition which were mainly

Abbreviations used: *FT3*, free tri-iodo-thyronine; *FT4*, free thyroxine, *TSH*, thyroid stimulating hormone; *BNP*, brain natriuretic peptide; *IGF*, insulin-like growth factor; *IGFBP*, insulin-like growth factor binding protein; *SHBG*, sex hormone binding protein; *FM*, fat mass; *FFM*, fat free mass; *VAT*, visceral adipose tissue; *SAT*, subcutaneous adipose tissue; *TAT*, total = whole body adipose tissue; *SMM*, skeletal muscle mass; *TBW*, total body water; *ECW*, extracellular water; *ICW*, intracellular water. Unpublished data from the Kiel Reference Center of Body Composition. The study population includes body composition data sets obtained in 1152 healthy subjects (mean age of 30.9 years.; age range 6.1–82.0 years.; BMI range 12.3–52.7 kg/m^2; 52.3% females, 47.7% males) using reference and gold standard methods.

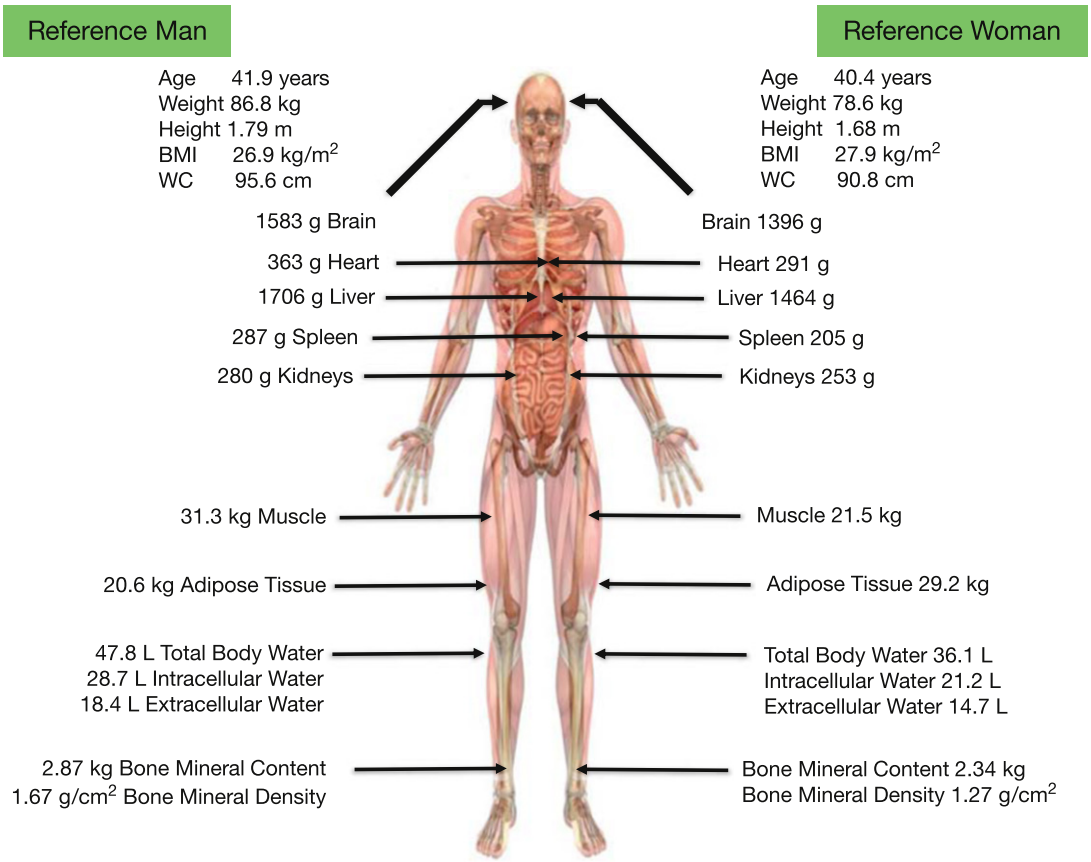

Fig. 2 The Kiel Reference Man + Reference Woman. Unpublished data from the Kiel Reference Center of Body Composition (Later *et al.*, 2010; Müller *et al.*, 2011; Bosy-Westphal *et al.*, 2013a,b). The study population includes body composition data sets obtained in 731 healthy adult subjects (mean age of 41.1 years; age range 18–82.0 years; BMI range 16.8–47.7 kg/m^2; 52.3% females, 47.7% males) using reference and gold standard methods. See text for further details.

autopsy data (Snyder *et al.*, 1975; ICPR, 2002). Faced with technological advances of in vivo BCA, new mathematical models and socio-demographic changes characterized by an increase in elderly and overweight subjects the development of a timely *Reference Man* was developed (see Later *et al.*, 2010; Müller *et al.*, 2011; Bosy-Westphal *et al.*, 2013b). To do this, the worldwide largest in vivo human body composition database in Kiel was analyzed using *in depth* body composition as assessed by gold standard methods, that is, whole body MRI and the 4-C model. **Fig. 2** represents a detailed characterized of a timely Reference Man and Reference Woman.

Summary

Body composition analysis is an integral part the assessment of patients. The structures of the body are closely related to endocrine activities, metabolism, inflammation and cardio-metabolic risks as well as nutrient, fluid and mineral balances. In addition, body composition provides the contexts to understand endocrine and metabolic variables and their changes with weight changes.

Ashley Gearhardt, University of Michigan, Ann Arbor, MI, United States

Introduction

Over the past 25 years, the prevalence of overweight and obesity has undergone a considerable increase worldwide. A study exploring overweight and obesity between 1990 and 2015 found that high BMI accounted for 4.0 million deaths globally, nearly 40% of which occurred in persons who were not obese (Collaborators, 2017). Owing to the similarities between the overconsumption of palatable foods and addictive drugs, a growing number of clinicians and scientists have suggested that excess weight may be a form "food addiction" (Davis *et al.*, 2011; Gearhardt *et al.*, 2011; Volkow *et al.*, 2017). The recent popularity of the food addiction model is reflected in the substantial increase in the number of scientific publications on food addiction (Meule, 2015) (**Fig. 1**).

Proponents of the food addiction model contend that there is sufficient neuroscience evidence to demonstrate that the intake certain energy-dense food and addictive drugs bring about similar neural responses and some argue that the identification of the neurobiological drivers of overconsumption could potentially lead to more effective treatments for obesity (Schulte *et al.*, 2016a,b). Preclinical and clinical studies using a variety of sophisticated techniques have found both drugs of abuse and hyperpalatable foods act on neural reward pathways and therefore, to some extent, support the claim that some types of overeating and obesity constitute a food addiction (Smith and Robbins, 2013).

In this article, we will critically review the applicability of the addiction model to the context of obesity. Additionally, we will provide an overview of the differences and similarities between obesity and other addictive behaviors by expounding upon the comorbidity of both conditions and their common risk factors.

Addiction Model

One possible factor that may be contributing to the rising rates of obesity and the difficulty maintaining long-term weight loss is the potential role of an addictive process in problematic eating behavior. The model of addiction that is traditionally applied to substances like, alcohol, suggests that these substances can become so reinforcing that systems involved in reward, motivation, and memory can become compulsively focused on acquiring and using the substance of abuse and

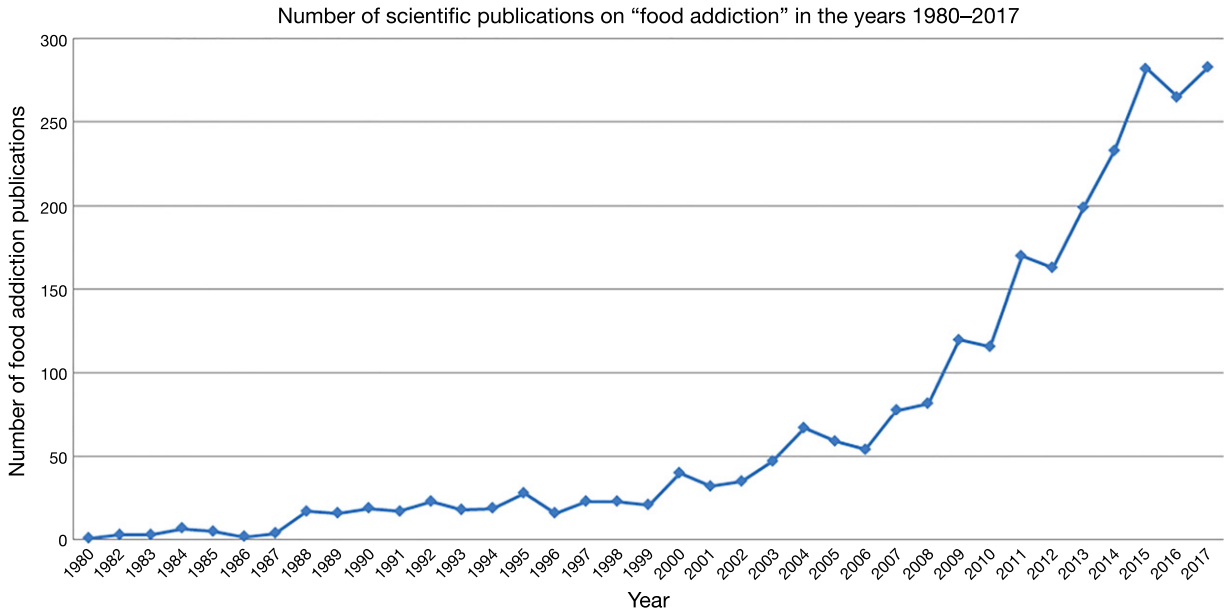

Fig. 1 Values represent the "results by year" using the search term "food addiction" in the NCBI PubMed database. Values for 2017 were extracted in November of that year.

 doi:10.1016/B978-0-12-801238-3.65411-9

addiction is the outcome (Volkow and Wise, 2005). The substance may initially be used because the individual likes the experience of consuming the substance (i.e., pleasure), but as the addiction progresses the cues that signal the availability of the substance become powerful triggers of desire. These cues can start to trigger wanting so intensely that even if the individual stops liking the experience of the substance, he/she will still compulsively consume it (Robinson and Berridge, 2001). A strong body of research suggests that certain behaviors (like gambling) can also be reinforcing enough to cause similar addiction-like changes (Potenza, 2008). Similar behavioral criteria are used to diagnose both substance and behavioral addictions, including an inability to cut down despite a desire to do so, intense cravings, and continued use despite negative consequences (APA, 2013). Withdrawal (i.e., negative affective or physical symptoms) in response to cutting down or stopping use/engagement and increased tolerance (i.e., needing more and more to get the same effects) are symptoms assessed for both substance and behavioral addictions, but these are not necessary for a diagnosis of an addiction (**Table 1**).

The modern food environment has changed drastically in the last 40 years. Highly processed foods that have high levels of intensely rewarding ingredients, such as sugar and fat, have become widely available, heavily advertised, and very affordable. One possibility is that these highly processed foods have become so intensely reinforcing, that like alcohol, cigarettes, and gambling, these foods are able to trigger an addictive process in at least some individuals. There is evidence to support this concept. First, as these highly processed foods spread around the world the rates of compulsive overeating, obesity, and health-related disease spread with them (Gearhardt *et al.*, 2011). Second, in animal models, highly processed foods are effective at engaging neural circuitry associated with addiction and to even cause addictive-like changes in the brain more rapidly than traditional drugs of abuse (Ahmed *et al.*, 2013; Oginsky *et al.*, 2016). Third, in humans, the behavioral indicators of addiction are also demonstrated in eating behavior, including an inability to cut down on the consumption of food, intense cravings for food, and continued use despite both physical and psychological consequences (Meule and Gearhardt, 2014). Humans also self-report behaviors consistent with withdrawal and tolerance, although experimental research in this domain is lacking (Schulte and Gearhardt, 2017). Importantly, these behaviors are far more likely to occur regarding highly processed foods (e.g., chocolate, pizza) than naturally occurring foods (e.g., fruits, vegetables) (Schulte *et al.*, 2015).

There are notable implications of the addiction model when applied to food. The addiction model highlights the importance of the reinforcing properties of the food and (the role of the food industry in creating highly processed foods) in compulsive overeating and the associated health consequences. This may highlight the application of the substance-focused policies that have been effective in reducing the public health consequences of addictive substances (like cigarettes) to change the environment surrounding highly processed foods. For example, restricting advertising, using zoning to reduce accessibility, and applying taxation to increase prices are all options that have been used to address cigarettes that could be considered to reduce the impact of highly processed foods (Gearhardt *et al.*, 2011). There are also treatment implications. The development of thoughtful treatment approaches that acknowledge the reinforcing nature of the highly processed foods while not unintentionally increasing rigid dietary rules and disordered eating behavior is needed. Harm reduction treatment approaches employed in substance use disorders teach people to use lower risk substances (e.g., light beer rather than liquor) in lower risk contexts (e.g., in a emotionally calm state rather than when feeling sad or angry) might be useful in the context of addictive-like eating (Schulte *et al.*, 2016b). In this case, strategies to help people consume lower risk foods that they still find reinforcing (e.g., strawberries, nuts) rather than higher risk foods (e.g., ice cream, potato chips) in lower (e.g., with supportive friends) rather than higher risk contexts (e.g., alone late at night) is a potential future direction.

Table 1 Presence of DSM-5 substance use disorders criteria across disorders

DSM-5 substance use disorders criteria	*Obesity*	*Binge eating disorder*	*Behavioral addictions*	*Healthy controls*
Substance taken in larger amount and for longer period than intended	+ +	+ + +	+ + +	+
Persistent desire or repeated unsuccessful attempts to quit	+ + +	+ + +	+ + +	—
Much time/activity to obtain, use, recover	+	+ +	+	—
Important social, occupational or recreational activities given up or reduced	+	+ +	+ + +	—
Use continues despite knowledge of adverse consequences	+ + +	+ + +	+	+
Tolerance	+	+ +	+ +	—
Characteristic withdrawal symptoms; substance taken to relieve withdrawal	+	+	+ +	—
Continued use despite social or interpersonal problems	+ +	+ + +	+ + +	—
Failure to fulfill major role obligations	—	+	+ + +	—
Use in physically hazardous situations	—	—	+	—
Craving, or a strong desire or urge to use	+ + +	+ + +	+ + +	—
Use causes clinically significant impairment	+	+ +	+ + +	—
Use causes clinically significant distress	+	+ +	+ + +	—

+ + +: very frequent; + +: frequent; +: occasional; —: not typically present.

However, there are important questions that remain to be answer regarding the addiction perspective on eating. There are questions about whether addictive-like eating more closely resembles a substance or a behavioral addiction (Hebebranda *et al.*, 2014). The behavioral addiction perspective suggests that the act of eating (rather than the food itself) may be addictive. Proponents of the behavioral addiction perspective highlight that a specific addictive ingredient in food has not been identified and the indicators of addictive-like eating are behavioral in nature. However, proponents of the substance-focused approach highlight that addictive-like eating is far more likely to occur with highly processed foods and that the research into identifying what might increase the addictive potential of a food is just beginning. Additionally, behavioral indicators are also used to identify substance addictions, thus that does not discriminate between substance and behavioral addictions. Further, eating is necessary for survival, whereas the consumption of highly processed foods is not. Thus, substance-addiction relative to behavioral addiction perspectives highlight the nature of the specific foods being consumed (Schulte *et al.*, 2017a,b). Given that substance and behavioral addictions are the result of the same mechanisms, whether addictive-like eating is seen as more of a behavioral or substance addiction may be more of a matter of semantics. Related to this question there are also debates about the best way to assess addictive-like eating. The Yale Food Addiction Scale (YFAS) applies the substance addiction criteria to the consumption of highly processed food and is the most widely used validated measure to assess this construction (Granero *et al.*, 2014; Schulte and Gearhardt, 2017). However, there are critics of the YFAS that suggest that alternative approaches would be more appropriate, including those inspired by behavioral addictions (Schulte *et al.*, 2017a,b; Ruddock *et al.*, 2017). Future research will be needed to evaluate what is the most valid approach to assessing addictive-like eating.

Comorbidity

Obesity, understood as a multifactorial and complex chronic disease, is not considered a mental disorder by the Diagnostic and Statistical Manual (DSM-5; APA, 2013). However, current scientific literature has proven its robust association with different psychiatric conditions, mostly addictions, eating disorders and mood disorders (Maremmani *et al.*, 2017). These comorbidities are understood to interfere significantly with the quality of life of people with obesity (Ivezaj *et al.*, 2017).

Substance Use Disorders

At present, the available operational information about neurobiology of addictive behaviors suggest that obesity and substance use disorders share neuronal mechanisms implicated in loss of control and overconsumption (Volkow *et al.*, 2013). It is not unexpected, therefore, that several studies have demonstrated greater rates of substance use disorders in people with obesity in comparison to healthy weight controls (Barry and Petry, 2009; Michaud *et al.*, 2017). In a recent study by Donnadieu-Rigole *et al.* (2016), the authors found a greater prevalence of cocaine, amphetamine, and cannabis use in patients with obesity in comparison to the general population.

With regards to alcohol consumption, investigators have noted that people with a family history of alcoholism, especially women, presented a 49% greater likelihood of obesity than those without this antecedent, highlighting the etiologic associations between both disorders (Grucza *et al.*, 2010). The concurrence of alcohol with obesity after bariatric surgery has also been reported in the literature (Li and Wu, 2016), and some authors suggest a possible behavioral change within the pattern of abuse that shifts from excessive food intake to the overconsumption of alcohol (Donnadieu-Rigole *et al.*, 2016).

Food Addiction and Other Behavioral Addictions

Due to the complex clinical similarity between obesity and addictions, the food addiction model has emerged as a relevant construct in the obesity field (Maremmani *et al.*, 2017). Food addiction includes representative clinical features of both, addiction to substances and behavioral addictions, chiefly a recurrent and uncontrollable involvement in behaviors in spite of the possible negative consequences (Jiménez-Murcia *et al.*, 2017). In this vein, Pursey *et al.* (2014) reported that the prevalence of food addiction in overweight and obese people ranged between 7.7% and 56.8% whereas other studies have obtained rates between 34% and 40% (Meule *et al.*, 2014; Ceccarini *et al.*, 2015). Food addiction is also found to be more prevalent in women than in men (Meule, 2012). Finally, taking personality traits into account, Jiménez-Murcia *et al.* (2017) found, in a clinical sample with gambling disorder, that those who had comorbid food addiction obtained low self-directedness levels and high scores in self-transcendence. Individuals with this personality profile tend to experience difficulties in defining vital goals and directing their behavior toward them (Cloninger *et al.*, 1998).

Regarding adolescents, Burrows *et al.* (2017) studied food addiction from an intergenerational perspective, finding a positive correlation between food addiction levels in parents and children. Moreover, the authors observed that, in the case of children, there was a significant association between food addiction and body mass index (BMI).

Taking other behavioral addictions into account, some studies suggest an association between buying disorder and BMI (Sansone *et al.*, 2013) and eating disorders, especially binge eating disorder (Müller *et al.*, 2013). In this vein, Leppink *et al.* (2016) studied the association between BMI and symptom change in patients with gambling disorder, detecting less improvements in

gambling symptomatology in participants with obesity. Despite these findings, there is a lack of empirical evidence taking the comorbidity between obesity and behavioral addictions into account.

Eating Disorders

Studies investigating eating disorder comorbidity indicate that binge-eating disorder is the most prevalent disorder in people with obesity (Kessler *et al.*, 2013). Suitable reasons as to why these two disorders are strongly linked can be explained by taking the clinical features of binge eating disorder into account. Binge eating disorder is characterized by recurrent uncontrollable overeating episodes followed by an intense perception of loss of control and in the absence of compensatory behaviors, such as purging (APA, 2013). These dysfunctional eating behaviors can, therefore, imply a significant weight increase and ultimately lead to obesity (Aviram-Friedman *et al.*, 2017; Goldschmidt *et al.*, 2018). Specifically, people with binge eating disorder are approximately 3–6 times more likely to present obesity, in comparison with people without an eating disorder diagnosis (McCuen-Wurst *et al.*, 2017). Although the clinical aspects of both disorders are becoming better explored and understood, some authors suggest that a clear distinction between obesity with and without BED needs to be formulated (Villarejo *et al.*, 2012; Aviram-Friedman *et al.*, 2017).

When examining comorbidity between food addiction and eating disorders, the prevalence of patients with eating disorders who met the criteria for food addiction, in a study by Granero *et al.* (2014), was 72.8%. Within this sample, lower food addiction prevalence was found in anorexia nervosa-restricting subtype, whereas bulimic-spectrum disorders (bulimia nervosa, binge eating disorder and anorexia nervosa-bingeing/purging subtype) showed greater comorbidity. In general, these patients presented higher dependence symptoms and a tendency to consume more high-fat/high-sugar foods than planned.

Other Psychiatric Comorbidities

In addition to the comorbidities mentioned above and the health complications associated with obesity, obesity is often closely related to high levels of psychological distress and, especially, to anxious and depressive symptomatology (Yoder *et al.*, 2017). In this line, the National Co-morbidity Survey Replication stated a prevalence rate of 20.8% for mood disorders in people with a clinical diagnosis of obesity (Kessler *et al.*, 2005). In a recent study by Donnadieu-Rigole *et al.* (2016), 18% of the participants with obesity reported one or more depressive episodes in their lifetime. In the case of adolescents with obesity, Lanza *et al.* (2015) identified a higher chance of presenting greater deviant peer affiliation and depression levels than in normal-weight adolescents. Other researchers have made the case that high scores on the Yale Food Addiction Scale may be used as a proxy measure for interrelated clinical features, including greater eating disorder severity, greater obesity severity, greater posttraumatic stress disorder (PTSD) symptoms, greater psychiatric comorbidity, as well as greater medical morbidity and mortality (Brewerton, 2017).

Shared neurocognitive deficits and personality traits in individuals with obesity and in addictive behaviors.

Research indicates a number of personality traits and neurocognitive impairments in individuals with obesity and excess food intake that are present in individuals with addictive behaviors (Volkow *et al.*, 2011). These deficits encompass cognitive domains such as decision-making, set shifting and delay discounting. Studies evaluating decision-making using behavioral measures such as the Iowa Gambling Task have linked increased BMI to poorer performance compared to healthy weight controls (Fitzpatrick *et al.*, 2013). One recent study compared Iowa Gambling Task performance in a large sample of adults with substance-use disorder, obesity, and gambling disorder, and in healthy controls, and found that all three clinical groups presented similar deficits in decision-making, suggesting the presence a shared underlying deficiency in individuals with addictive behaviors (Mallorquí-Bagué *et al.*, 2016). Similarly, the compulsive eating patterns that are characteristic of binge eating disorders have been associated with a tendency to focus on immediate gratification at the expense of larger, future rewards (Steward *et al.*, 2017b; Stojek and MacKillop, 2017). Similar heightened delay discounting attributes have also been found in individuals with gambling disorder and substance use disorders (Amlung *et al.*, 2017; Steward *et al.*, 2017a).

Personality traits play an important role both as risk and protective factors in the development and maintenance of obesity and food addiction. A recent systematic review of 70 empirical studies of obesity and personality found that neuroticism, impulsivity and sensitivity to reward appeared to be risk factors in relation to weight gain, whereas conscientiousness and self-control have a protective function (Gerlach *et al.*, 2015). Personality traits have also been shown to be a predictor of response to bariatric surgery, with one study finding that individuals with higher scores in novelty seeking and lower scores in persistence lost significantly less weight after surgery than a more successful comparison group (García-Ruiz-de-Gordejuela *et al.*, 2017). Likewise, higher food addiction severity has also been associated with poorer treatment outcomes in the case of eating disorders marked by binge eating episodes (Hilker *et al.*, 2016). Such results suggest that obesity patients with impulsive or addictive traits could potentially benefit from targeted psychological interventions (Carter *et al.*, 2016). Post-surgical interventions are especially important given that postoperative, but not preoperative, problem eating behaviors are predictors of poorer weight loss trajectories after surgery (Conceição *et al.*, 2017).

Recent studies on the etiology underlying obesity have shed more light on the factors contributing to its development and maintenance. Altered emotion regulation stands out as a common risk factor in food addiction and other addictive behaviors (Sloan *et al.*, 2017; Hardy *et al.*, 2018). An inability to regulate negative affect via emotion regulation strategies is thought to cause some individuals to find relief from emotional distress in highly palatable food (Fernandes *et al.*, 2018). Dysfunctional emotion regulation also hinders adherence to long-term goals and is believed to be interfere with weight-loss interventions (Forman and

Butryn, 2015). One functional resonance magnetic imaging (fMRI) found that young people with overweight and obesity had decreased negative functional coupling between the right anterior insula and regions in the prefrontal cortex during cognitive reappraisal, suggesting a reduced ability to regulate negative affective states (Steward *et al.*, 2016). This position is supported by the behavioral findings of another study pointing to a double vulnerability in bariatric surgery patients with food addiction. Patients with food addiction endorsed greater emotion dysregulation than those without and also presented lower levels of the personality trait self-directedness (Ouellette *et al.*, 2017).

Conclusions

Evidence from animal and human research is supportive of the classification of specific food and eating behaviors as being potentially addictive. Nonetheless, this classification remains underdeveloped and more empirical studies are required to test the validity of the food addiction phenotype. A shift in public health policy toward the food addiction model would have a major impact on how obesity is perceived by the lay public and potentially lead to increased support for measures that reduce the overconsumption of harmful foods in the general population, akin to the public health campaigns to reduce tobacco use. In this review, we have highlighted the similarities found in individuals with obesity and in addictive behaviors. However, taking into consideration the vast reach of the obesity epidemic, researchers and clinicians should be careful not to assume that the presence of obesity implies the presence of food addiction. Resources should be dedicated to identifying which individuals best fit the food addiction model and how weight-loss interventions can be tailored to their specific needs. It has yet to be tested whether individuals with food addiction benefit to greater extent from pharmacological approaches targeting the dopamine or opioid systems or whether these individuals respond better to psychological treatments focusing on the cognitive processes involved in addiction (Carter *et al.*, 2016).

Leptin☆

Rachel C Morgan and Robert V Considine, Indiana University School of Medicine, Indianapolis, IN, United States

Historical Perspective

The obese *(ob)* mutation was first described in 1950 as causing early onset (4–6 weeks) obesity and insulin resistance in mice (Ingalls *et al.*, 1950). Subsequent cross circulation experiments between mice with the *ob* mutation and those of normal weight suggested that the obese mice lacked a circulating factor that suppressed food intake (Coleman, 1978). Using positional cloning techniques, the *ob* gene and its human homolog were identified in 1994 as an adipose tissue specific gene (Zhang *et al.*, 1994). Shortly thereafter, recombinant ob protein was shown to induce weight loss in mice (Pelleymounter *et al.*, 1995; Halaas *et al.*, 1995; Campfield *et al.*, 1995), and the protein was named leptin, from the Greek root leptos meaning thin (Halaas *et al.*, 1995).

Within 1 year following the discovery of leptin and the demonstration that leptin could reduce food intake and body weight in mice, the leptin receptor was cloned (Tartaglia *et al.*, 1995). Very quickly it was proven that the leptin receptor was encoded by the *db* gene (Lee *et al.*, 1996; Chen *et al.*, 1996). It had been previously hypothesized that the *db* gene, which resulted in obesity in mice, encoded a receptor for the circulating factor regulating food intake that was missing in *ob*/*ob* mice (Coleman, 1978).

The discovery of leptin, its receptor, and actions within the brain opened novel areas of research into the central neural pathways regulating energy intake and expenditure. The cloning of leptin also replaced the perception of the adipocyte as merely a site of triglyceride storage with that of adipose tissue as a dynamic participant in the regulation of whole body metabolism.

Adipose Tissue Leptin Synthesis

The gene for leptin in both humans (*LEP*) and rodents (*Lep* replacing *ob*) encodes a 167-amino-acid protein with an amino-terminal secretory signal sequence of 21 amino acids (Zhang *et al.*, 1994). Leptin circulates in the blood as a 146-amino-acid, 16 kDa protein. Release of leptin from the adipocyte occurs primarily via a constitutive secretory pathway, although insulin may acutely increase the movement of leptin from the endoplasmic reticulum to the plasma membrane for release. Increased or decreased leptin release from the adipocyte is generally associated with a parallel change in *Lep* gene expression; thus, leptin synthesis and release appear primarily regulated by transcriptional mechanisms (Considine, 2001).

Fat Mass and Gender Determine Serum Leptin Concentration

The two major factors that determine serum leptin concentrations in humans under conditions of consistent food intake are fat mass and gender. Leptin positively correlates with fat mass in adults, children, and newborns. *LEP* gene expression is greater in the larger adipocytes present in subjects with obesity, and leptin secretion is strongly correlated with fat cell volume. Thus, the elevation in serum leptin in obesity is the result of secretion by a greater number of fat cells and increased leptin synthesis in the larger adipocytes of characteristic of these subjects (Bell and Considine, 2006).

Serum leptin is significantly greater in women than in men with the same amount of body fat (Rosenbaum and Leibel, 1999). One explanation for this finding is that women have a significantly greater subcutaneous adipose tissue mass relative to visceral adipose mass than men. *LEP* gene expression/leptin production is greater in subcutaneous than visceral adipocytes. Sex steroids also regulate leptin production. Testosterone replacement reduces serum leptin in hypogonadal men and leptin levels decrease as serum testosterone increases during pubertal development in boys. Estrogen, in combination with anti-androgens, increases leptin in male-to-female transsexuals and testosterone decreases leptin in female-to-male transsexuals, independent of changes in adipose tissue mass. In vitro, estradiol stimulates, and dihydrotestosterone inhibits, leptin production in human visceral adipose tissue pieces in culture for 48 h.

Energy Intake Regulates Serum Leptin Levels

Energy intake can regulate serum leptin concentrations independent of effects on adipose tissue mass. With standard timing for food intake (three meals per day in humans), leptin levels are reasonably constant from day to day, exhibiting a maximal daily variation of approximately 30%. However, serum leptin falls with short-term fasting (24 h) and increases within 4–5 h of

refeeding. Maintenance of euglycemia with dextrose infusion prevents the fasting-induced drop in leptin, implicating insulin and/or glucose as the nutritional signal recognized by the adipocyte for leptin synthesis (Kolaczynski *et al.*, 1996; Boden *et al.*, 1996). In a prolonged study of energy restriction (moderate and severe), changes in serum leptin were best correlated with changes in glycemia (Wisse *et al.*, 1999).

Serum leptin exhibits a diurnal profile entrained to food intake (Sinha *et al.*, 1996, Schoeller *et al.*, 1997). The peak in serum leptin occurs at ~0200 h, in both lean and obese subjects under standard living conditions. Day/night reversal shifts the peak in serum leptin by 12 h. A shift of 6.5 h in meal timing without a change in light or sleep cycles shifts the leptin peak 5–7 h, suggesting that the nocturnal peak in serum leptin is a delayed postprandial response induced by after-meal excursions in glucose and insulin. The macronutrient content of meals also regulates serum leptin levels. High-fat/low-carbohydrate meals (60%/20%) over the course of 1 day reduce leptin levels (Havel *et al.*, 1999). High-fat/low-carbohydrate meals induce smaller insulin and glucose excursions than meals of standard fat/carbohydrate content, again implicating insulin and glucose in the nutritional regulation of leptin production.

The regulation of leptin synthesis by glucose and insulin has been directly demonstrated using the euglycemic–hyperinsulinemic clamp. Serum leptin is elevated by the end of prolonged clamps (9 h) at physiologic insulin or within 4–8 h with supraphysiologic insulin concentrations in humans (Saad *et al.*, 1998; Utriainen *et al.*, 1996). The synthesis of hexosamines within the adipose tissue is one link between insulin-stimulated glucose uptake/metabolism and leptin production. In rodents, infusion of glucosamine, uridine, or free fatty acids during a 3 h euglycemic–hyperinsulinemic clamp increased muscle uridine diphosphate-*N*-acetylglucosamine (UDP-GlcNAc), muscle *Lep* gene expression, and serum leptin, compared to saline-infused controls clamped under identical conditions (Wang *et al.*, 1998). In transgenic mice overexpressing glutamine: fructose-6-phosphate amidotransferase (GFAT), the rate-limiting enzyme in hexosamine biosynthesis, serum leptin and adipose tissue *Lep* gene expression is significantly increased (McClain *et al.*, 2000). In subcutaneous adipose tissue of obese humans, UDP-GlcNAc is increased 3.2-fold compared to lean subjects and there is a significant positive relationship between adipose tissue UDP-GlcNAc and body mass index (Considine *et al.*, 2000). An increase in hexosamine biosynthesis in cultured human subcutaneous adipocytes increases leptin release and inhibition of GFAT activity reduces glucose-stimulated leptin release.

Other Regulation of Leptin Synthesis in Adipocytes

Sympathetic nervous system

Leptin-induced activation of the sympathetic nervous system is postulated to be a negative feedback signal for leptin synthesis (Haynes *et al.*, 1997; Trayhurn *et al.*, 1998). Infusion of isoproterenol in humans (to mimic sympathetic activation) significantly reduces serum leptin (Donahoo *et al.*, 1997; Pinkney *et al.*, 1998; Stumvoll *et al.*, 2000), in agreement with preclinical data showing catecholamines inhibit leptin production in cultured cells and rodent models (Considine, 2001).

PPARγ agonists

Thiazolidinediones inhibit *Lep* gene expression and leptin release in rodents, isolated adipocytes and cultured cell lines (Considine and Caro, 1997). In cultured human adipocytes, troglitazone alone had little effect on leptin production but inhibited dexamethasone-induced leptin release (Williams *et al.*, 2000). PPARγ activation resulting in inhibition of *LEP* gene expression is counterintuitive since this highly expressed transcription factor is central to the differentiation of preadipocytes to adipocytes (Cornelius *et al.*, 1994). It has been proposed that PPARγ does not bind the *LEP* promoter but instead antagonizes binding of C/EBPα to down regulate expression (Hollenberg *et al.*, 1997).

Glucocorticoids

Dexamethasone is a potent stimulus for leptin secretion in vivo and in vitro and several studies suggest that glucocorticoids synergize with insulin to increase leptin production (Fried *et al.*, 2000). However, cortisol is not an absolute requirement for leptin synthesis and it is not clear how glucocorticoids increase *LEP* mRNA as the glucocorticoid receptor does not bind the *LEP* promoter.

Leptin Signaling in the Brain

The Leptin Receptor

The hypothalamic leptin receptor (Ob-Rb, using mouse nomenclature) is a member of the class I cytokine receptor family. As with other cytokine receptors, binding of leptin to its receptor activates an associated janus kinase (JAK), which phosphorylates tyrosines within the leptin receptor itself and signal transducer and activator of transcription (STAT) proteins associated with the receptor. Phosphorylated STAT proteins dimerize and translocate to the nucleus to initiate gene transcription. STAT-3 is the major STAT protein activated by the hypothalamic leptin receptor in mice (Tartaglia, 1997; Friedman, 1998). Binding of leptin to its receptor has also been reported to activate phosphatidylinositol-3-kinase, phosphodiesterase-3B, and members of the mitogen-activated protein kinase superfamily. Low-level expression of Ob-Rb has been detected in cells other than those in the hypothalamus and it has been shown that leptin activates AMP-activated protein kinase in skeletal muscle (Bjørbaek and Kahn, 2004).

In addition to the hypothalamic leptin receptor Ob-Rb (long receptor isoform) described above, five other leptin receptors mRNAs have been identified in mice, all encoded by alternative splicing of the *Lep* gene. The extracellular domain of all leptin receptors is identical; however, the intracellular domains terminate at different lengths. Due to the truncated intracellular domain, the short leptin receptors lack the box 2 motif necessary for STAT protein interaction and these leptin receptors do not phosphorylate STATs. Ob-Ra is the most abundant and widely distributed of the short receptor isoforms, and is found on most cell types in the body. Ob-Ra is highly expressed in the choroid plexus where it functions to transport leptin across the blood–cerebrospinal fluid barrier. The Ob-Re receptor isoform, lacking an intracellular domain and a transmembrane domain, circulates in the blood of rodents as a leptin-binding protein, prolonging the half-life of the hormone. In humans, the soluble leptin receptor binding protein is generated by proteolytic cleavage of the extracellular domain of membrane bound leptin receptor (Ahima and Flier, 2000).

Leptin-Activated Hypothalamic Pathways

Leptin receptor is detectable in many areas of the CNS but is highly expressed in the arcuate, paraventricular, ventromedial, and dorsomedial nuclei of the hypothalamus, which is responsible for integration of the numerous neural signals regulating energy intake. Leptin is detectable in cerebrospinal fluid but leptin likely accesses the arcuate nucleus directly from the blood within the median eminence, which lacks the tight junctions characteristic of the blood–brain barrier. In the arcuate nucleus, leptin reduces the expression of neuropeptides that stimulate food intake and increases expression of neuropeptides that inhibit feeding. As such, leptin suppresses neuropeptide Y and agouti-related peptide expression in neurons expressing these neurotransmitters and induces the expression of α-melanocyte-stimulating hormone in proopiomelanocortin neurons. These neurons innervate other nuclei within the hypothalamus and also communicate with other areas of the brain. Leptin-binding neurons in the arcuate nucleus mediate the effects of leptin on the sympathetic nervous system and hypothalamic pituitary axes. Leptin actions in the arcuate nucleus can amplify neuronal signals of food intake from the gastrointestinal tract to the nucleus of the solitary tract in the hindbrain (Elmquist *et al.*, 1999).

Leptin Binding in the Brain Reduces Food Intake and Body Weight in Mice

The role of leptin in regulation of body weight was first demonstrated in C57BL/6 J *ob*/*ob* mice (Pelleymounter *et al.*, 1995; Halaas *et al.*, 1995; Campfield *et al.*, 1995). The lack of leptin in *ob*/*ob* mice causes hyperphagia, cold intolerance, and morbid obesity. Daily intraperitoneal injection of recombinant leptin resulted in a dose- and time-dependent decrease in body weight of *ob*/*ob* mice. Weight loss was mediated by an increase in metabolic rate and locomotor activity, as well as a reduction in food intake. Leptin also reduced body weight in lean C57BL/6 J heterozygotes (+/?) and lean wild-type mice, although much higher doses of leptin were needed. In lean mice, leptin administration had no effect on body temperature or locomotor activity but did reduce food intake. Leptin treatment lowered insulin and glucose in *ob*/*ob* mice. Since these initial experiments, many investigators have observed that leptin, either peripherally or centrally administered, effectively reduces food intake to stimulate weight loss in most animal models of obesity, with the exception of those with inactivating leptin receptor mutations.

C57BL/KsJ *db*/*db* mice are hyperphagic, morbidly obese, and diabetic due to a mutation in the hypothalamic leptin receptor gene. A nucleotide substitution (G to T) generates a new splice donor within an exon of the short receptor (Ob-Ra). This new splice donor competes with the upstream splice donor of the long form of the receptor, resulting in alternative splicing and the insertion of a premature termination signal in the long form of the receptor. The truncated long receptor protein is unable to associate with STAT proteins, interrupting JAK/STAT signaling and resulting in obesity in *db*/*db* mice. Exogenous leptin administration to C57BL/6J *db*/*db* mice does not result in weight loss at any concentration tested. A different leptin receptor mutation was identified in Zucker *fatty* (*fa*/*fa*) rats. An A-to-C substitution changes glutamine-269 to a proline in the extracellular domain of the receptor, reducing the amount of receptor on the cell surface and its capacity to signal. In obese Koletsky rats, a third receptor mutation, T2349A in codon 763 of the leptin receptor gene, creates a premature stop codon just before the transmembrane domain. Leptin treatment does not induce weight loss in either Zucker *fatty* rats or Koletsky rats (Tartaglia, 1997; Friedman, 1998).

Leptin, Synaptic Plasticity and the Hippocampus

In addition to leptin's activity in the hypothalamus modulating energy balance, leptin signaling influences function in other brain areas. The hippocampus, part of the limbic system involved in learning and memory, exhibits leptin receptor on both neurons and glial cells. Leptin deficient rodent models have display impairments in synaptic long term potentiation (synaptic plasticity) and spatial learning. Leptin regulates hippocampal excitability by modulating calcium-activated potassium channels in vitro, and improves memory processing in mice (Harvey *et al.*, 2006).

Leptin and Body Weight Regulation in Humans

Leptin and Leptin Receptor Mutations Cause Obesity in Humans

Mutations in the human *LEP* gene were first identified in children of a consanguineous Pakastani family. In these subjects, deletion of a guanine nucleotide in codon 133 produces a frameshift resulting in truncated leptin protein that is degraded by the proteasome. There is no leptin in the circulation. A third child from an unrelated family (at least five generations back) was found to have the same *LEP* gene mutation. The lack of leptin in these children causes hyperphagia and extreme early onset morbid obesity. A second *LEP* gene mutation, a C-to-T substitution in the first base of codon 105, changing arginine to tryptophan, was identified in a Turkish family. In three subjects homozygous for the mutation, serum leptin was very low but detectable. The low leptin in these subjects resulted in hyperphagia, morbid obesity, and hypogonadism. One subject also exhibited low sympathetic tone (Farooqi and O'Rahilly, 2005).

As with mutations in the *LEP* gene, mutations in the leptin receptor in humans are rare. A G-to-A substitution in the splice donor site of exon 16 has been identified in three sisters of a Kabilian family. This mutation results in a truncated leptin receptor lacking the transmembrane and intracellular domains. The mutant extracellular domain is present at high concentrations in the blood, acting as a leptin-binding protein to greatly increase serum leptin concentrations. This leptin receptor mutation results in early onset morbid obesity, hyperphagia, and hypothalamic hypogonadism (Farooqi and O'Rahilly, 2005).

Leptin Induces Weight Loss in Humans With *LEP* Mutations

Farooqi and colleagues have demonstrated that subcutaneous administration of recombinant leptin is an effective long-term therapy for obesity in the three children lacking leptin due to *LEP* gene mutations. With treatment for up to 4 years (0.01 mg kg^{-1} lean body weight), leptin therapy induced significant weight loss via a reduction in caloric intake. Weight loss in these children was associated with a reduction in insulin, serum triglycerides, and cholesterol. Leptin treatment also improved T cell proliferation and increased $CD4^+$ T cell number and function, which was severely impaired in the absence of endogenous leptin production. Adults with congenital leptin deficiency or leptin receptor mutations are prepubertal. Leptin replacement was permissive for pubertal progression of the oldest child treated (therapy started at age 10 years), but did not induce precocious puberty when younger children (3 and 4.5 years old) were treated (Farooqi and O'Rahilly, 2005). With respect to effects of leptin on neuroplasticity discussed above, leptin replacement therapy improved the rate of cognitive development in one child tested (Paz-Filho *et al.*, 2008).

Leptin Resistance

Inactivating mutations in the leptin and leptin receptor gene in humans are rare and not the cause of obesity in the general population. Rather, it has been observed that serum leptin levels are elevated in obese subjects. This observation has led to the hypothesis that obese individuals are "leptin resistant"; i.e., these subjects do not respond to the weight-reducing actions of leptin (Considine *et al.*, 1996). Leptin resistance is dependent on the premise that the major function of leptin is to oppose increases in body weight. Flier and colleagues have noted that from an evolutionary perspective, it is difficult to conceive of a mechanism that would limit food intake in times of excess. Therefore, they hypothesize that the major function of leptin is to signal the reduction in energy intake associated with fasting rather than the excess storage of energy in times of food abundance. Evidence for this proposal is derived from the observation that the reduction in leptin with fasting is associated with metabolic, hormonal, and behavioral changes promoting energy conservation and increased energy intake. Leptin administration during fasting prevents these adaptations to food restriction (Ahima *et al.*, 1996). The concept of leptin resistance is compatible with the role of leptin as a signal of energy deprivation. It is conceivable that the central nervous system in obese individuals does not properly receive or process the leptin signal generated by the adipose tissue, despite elevated serum leptin levels. This would result in metabolic adaptations to conserve energy and increase energy intake. Several explanations for leptin resistance have been put forth.

High-fat feeding in rodents decreases the effectiveness of intraperitoneal or intravenously injected leptin to induce weight loss, although the response to leptin administered directly to the brain is maintained. Therefore, high-fat feeding appears to cause a defect in access of leptin to the central nervous system (Banks *et al.*, 2006). An alternative interpretation is that the palatability of the high-fat diet provides a neural signal for increased consumption that is stronger than the signal for decreased food intake provided by intraperitoneally or intravenously administered leptin. The fact that central leptin administration could overcome this palatability signal may be the result of activation of additional neural pathways that inhibit food intake with central injection.

Suppressors of cytokine signaling (SOCS) are a group of genes rapidly activated following STAT binding in the nucleus. SOCS proteins act in a negative feedback loop to limit intracellular cytokine signaling. SOCS-3 is a potent inhibitor of leptin receptor-initiated JAK/STAT signal transduction in cultured cell lines. Leptin also induces SOCS-3 mRNA expression in the hypothalamus. SOCS-3 message is increased in leptin-binding neurons in the hypothalamus suggesting that the increased SOCS-3 expression could cause leptin resistance. Protein tyrosine phosphatase 1B also attenuated leptin receptor signaling in vitro and in vivo (Münzberg and Myers, 2005).

Leptin Therapy in Obese Adults Without Leptin Deficiency

Modest leptin-induced weight loss was achieved in obese subjects with normal adipose tissue leptin production (Heymsfield *et al.*, 1999). In this study, 47 obese subjects underwent 24 weeks of twice-daily injections of leptin (0.1–0.3 mg kg^{-1} body weight) or placebo. There was statistically significant weight loss with the highest dose of leptin tested (mean $\pm$ SD 7.1 $\pm$ 8.5 kg, $n = 8$). It is important to note that the dose of leptin needed to induce weight loss in leptin-replete subjects is greater than 10 times that needed in the children with *LEP* gene defects. As discussed above, serum leptin concentrations increase in parallel with body fat in all obese individuals who do not have a *LEP* gene mutation. This apparent "resistance" to the weight-reducing effects of endogenously produced leptin suggests that exogenous leptin administration would be ineffective in decreasing body weight. The demonstration that leptin therapy can induce weight loss in leptin-replete subjects suggests that leptin resistance is relative, and can be overcome with high-dose treatment. However, whether these subjects would become resistant to the weight loss effects of the therapeutic dose of leptin over longer treatment periods is not known.

As discussed above, Flier and colleagues suggest that the major role of leptin is to decrease with prolonged fasting/starvation and initiate processes to conserve energy and maintain body weight. Therefore, the reduction in leptin with caloric restriction during a diet would be counterproductive to the attempt to lose weight. In a controlled study in which subjects lost 10% of body weight, circulating triiodothyronine and thyroxine levels and total daily energy expenditure were reduced. Administration of recombinant leptin to these subjects normalized thyroid hormone levels and increased total energy expenditure (Rosenbaum *et al.*, 2002). These observations support a role for leptin as opposing weight loss and suggest that leptin therapy may be a useful augmentation to weight loss induced by diet and exercise or other pharmacologic treatment.

Leptin Therapy in Lipodystrophy

Lipodystrophy is a condition in which adipose tissue is either partially or fully absent. Individuals with lipodystrophy generally exhibit hypertriglyceridemia, insulin resistance, and hyperglycemia due to deposition of lipid in liver and muscle. As a consequence of the lack of adipose tissue, leptin levels are low (Chan and Oral, 2010). Leptin replacement therapy has been FDA approved for generalized forms of lipodystrophy. Leptin therapy significantly decreased fasting glucose, hemoglobin A1c, triglycerides and liver volume. Subjects also report an increase in satiation. There is some weight loss at initiation of therapy but body weight stabilizes at approximately 6 months (Meehan *et al.*, 2016).

Effect of Leptin on Other Physiologic Processes

In addition to its role in body weight regulation, leptin has been implicated as a regulatory signal in a variety of other physiological processes. Many of these functions of leptin are mediated through the central nervous system, although the presence of leptin receptors on numerous nonneural cells suggests that leptin may have direct effects on these cells and tissues.

Glucose Homeostasis and Lipid Metabolism

Leptin improves insulin sensitivity directly and independently of its effects on food intake and body weight. In rodents, insulin and glucose are reduced shortly after the initiation of leptin treatment, before significant reductions in body fat content are observed. With long-term leptin administration resulting in weight loss, insulin and glucose are reduced to a greater extent than in pair-fed controls. Intracerebroventricular leptin acutely enhances whole body glucose uptake in mice, suggesting that leptin influences insulin sensitivity through central mechanisms. Leptin therapy also reverses insulin resistance and diabetes in two different transgenic models of lipodystrophy through mechanisms not related to reductions in food intake (Morgan and Considine, 2015).

Leptin increases lipolysis in white adipose tissue both in vivo and in vitro. This effect of leptin results from centrally mediated activation of the sympathetic nervous system as well as a direct effect of leptin on adipocytes. Hyperleptinemia in rats does not result in the release of free fatty acids into the blood but rather the oxidation of fatty acids within adipocytes. Leptin has also been observed to stimulate fatty acid oxidation in rodent muscle via activation of AMP-activated protein kinase (Morgan and Considine, 2015).

In rodent models of type 1 diabetes leptin lowers glucose, HbA1c and free fatty acids. Type 1 diabetes may be considered a "relatively" leptin deficient state due to loss of insulin-stimulated leptin synthesis in adipocytes. Leptin therapy in two patients with type 1 diabetes and lipodystrophy lowered glucose, lipids and insulin requirements (Park *et al.*, 2008). Thus, there is interest in use of leptin in the treatment of type 1 diabetes.

Reproduction

Successful reproduction requires an extensive investment of energy. Leptin serves as a permissive signal that energy stores are sufficient for the increased demand for energy during reproduction. *Ob*/*ob* mice lacking leptin as a signal of energy stores are infertile. Leptin treatment reverses infertility in *ob*/*ob* mice and accelerates the onset of puberty in normal mice. During starvation,

when endogenous leptin levels in mice are low, exogenous leptin maintains LH release and estrous cycle periodicity (Hileman *et al.*, 2000). In humans, the age of menarche is inversely related to serum leptin concentrations (Matkovic *et al.*, 1997). Humans with *LEP* gene defects have hypothalamic hypogonadism and remain prepubertal. Leptin therapy in these subjects increases gonadotropin secretion and the progression through puberty (Farooqi and O'Rahilly, 2005). Overall, these observations suggest that leptin is a coordinating signal to the central nervous system that energy stores are sufficient to support the higher energy needs associated with reproduction.

Maternal serum leptin increases during pregnancy in both rodents and humans and this increase is not due solely to the increase in fat mass. Human placenta synthesizes leptin, which contributes to the elevation in maternal leptin levels during pregnancy. In rodents, the placenta also secretes soluble leptin receptor binding protein, which increases the half-life of leptin in the maternal circulation. The role of increased leptin during pregnancy is not fully understood. It is possible that the increase in leptin might regulate maternal–fetal energy metabolism or that leptin may act in a paracrine/autocrine manner on placental or fetal growth (Henson and Castracane, 2006).

Immune Function

Nutritional deprivation suppresses immune function and malnutrition predisposes to death from infectious diseases. Leptin appears to be a coordinating signal for activation/inactivation of the immune response during times of energy excess or deprivation. Leptin administration prevents the starvation-induced reduction in immune function in mice. Leptin also stimulates the proliferation of T cells in vitro, an effect mediated by direct interaction of leptin with leptin receptor isoform Ob-Rb expressed on the T cell (Lord, 2002). The number of $CD4^+$ T cells and their function was severely impaired in children lacking endogenous leptin due to *LEP* gene mutations. Leptin treatment improved T cell proliferation and activity in these children (Farooqi and O'Rahilly, 2005).

Bone Metabolism

Obesity is in general protective against bone loss and fractures. A role for leptin as mediator of this protective effect is supported by the observations that leptin administration reduces ovariectomy-induced bone loss in rats and increases bone mineral content and bone density in *ob*/*ob* mice. That these effects are the result of a direct effect of leptin on bone is inferred from observations that leptin promotes differentiation of bone marrow stromal cells to osteoblasts and promotes mineralization of these cells. Leptin also inhibits osteoclast generation from blood mononuclear cells. In contrast to observations that leptin promotes bone formation, leptin-deficient *ob*/*ob* and leptin-resistant *db*/*db* mice have significantly greater bone mass than wild-type littermates. Intracerebroventricular administration of leptin to *ob*/*ob* mice results in bone loss in these animals. A unifying hypothesis for these disparate findings is that the central effect of leptin to decrease bone formation is offset by its peripheral effects to promote bone growth. The importance of this postulate is that during periods of starvation, low leptin levels result in suppression of the hypothalamic–pituitary–adrenal and hypothalamic–pituitary–gonadal axes and bone would be lost. However, the low leptin levels in the brain then also activate pathways that protect the skeleton during starvation. The mechanisms by which the hypothalamus regulates bone formation have not been fully elucidated (Upadhyay *et al.*, 2015).

Glossary

ADA diets Dietary approach based on American Diabetes Association recommendations.
AHA/ACC/TOS American Heart Association/American College of Cardiology/The Obesity Society.
AHI Apnea-hypopnea index used to indicate severity of sleep apnea. AHI is calculated by dividing the number of pauses of breathing (apnea) by the number of hours of sleep.
BMI Body Mass Index—a measurement based on height and weight, an indicator of the degree of nutrition.
DASH Dietary approach for regulation of hypertension.
FTO gene Fat mass and obesity-associated gene, associated with reproducibly with human body mass.
HbA1c Glycated hemoglobin, an indicator of the quality of glycoregulation for the last 3 months.
HCLF High-carbohydrate, low-fat dietary regiment.
HOMA IR Homeostatic model assessment, mathematical model for insulin resistance calculation.
HRQOL Health related quality of life.
LDL Low density lipoprotein, proatherogenic cholesterol.
MET Unit equal with energy expenditure at rest.
MUFAs Monounsaturated fat acids.
NIH National Institute for Health.
OSA Obstructive sleep apnea, common disorders in obesity which compromise oxygenation during the sleep.
REM Rapid eye movement, a sleep phase.

Severe obesity as a serious public health concern requires efficacious treatment. Available drugs are not enough efficacious and bariatric surgery is effective but expensive, thus some other treatments are needed. Lifestyle interventions can help severely obese individuals to achieve long-term weight loss and to improve the risk factors for cardiovascular diseases (Unick *et al.*, 2013).

The aim of lifestyle modifications is to reduce the burden of obesity and obesity related comorbidities. Some people consider that small amount of weight loss is disappointing, but even a small amount of weight loss like 5%–10% from baseline is associated with significant benefits. Sedentary behavior is associated with a lot of metabolic and cardiovascular comorbidities like obesity, diabetes, metabolic syndrome, and cardiovascular disease (Chau *et al.*, 2015). Environmental factors such as sitting jobs, access to television and the Internet in households for which people sit for hours in front of the screen cause lower energy expenditure. U.S. population spent sitting approximately 7.7 h/day (Matthews *et al.*, 2012; Liao *et al.*, 2011). Sedentary lifestyle leading to reduction in energy expenditure although overeating of high calorie foods increases energy consumption. Patients with lower educational level and low income have several times greater chance to develop sedentary lifestyle (Konevic *et al.*, 2015). One study on large sample of older adults in United Kingdom with self-reposted TV viewing duration demonstrated that increasing in watching TV was associated with higher BMI besides other parameters for example, physical inactivity, lower socioeconomic status depression and being a smoker (Gardner *et al.*, 2014). Study conducted in United Kingdom on 3777 non obese adult participants analyzed association between TV viewing and obesity. Strong association was found between TV watching more than 6 h/day and central obesity but they did not find association between the time spent in front of TV screen and BMI > 30 kg/m^2. The possible explanation for isolated central but not overall obesity was that older people have predominantly central fat distribution.

Trying to collect the data regarding sedentary behavior a numerous authors used traditional questionnaire as the first-line tool. Disadvantage of this common method is that requiring long periods of recall. Some investigators use MET. 1 MET value is equal with energy expenditure at rest. MET has a disadvantage that cannot distinguish sitting from the standing position as well as a waking state of sleep (Owen *et al.*, 2011).

Different types of activity monitors, like accelerometry-based monitors have been used in order to measure sedentary time, or time spent in physical activity. Those accelerometer fixed to the hip could detect body position (sitting, standing, lying). Inclinometers with higher ability than accelerometer to detect change in posture had been used in another type of devices (Trost *et al.*, 2005; VAN Loo *et al.*, 2017).

In order to develop tool for objective monitoring with ability to correct errors in the self-report method physical activity measurement survey (PAMS) was conducted as NIH-funded project. 24PAR (physical activity recall) RC was acceptable to respondents because they were supposed to provide data regarding physical activity only from the previous day (Dunton *et al.*, 2009).

Specialist in behavioral epidemiology suggests six phases of research in order to advance approach to sedentary behavior. The first phase is identifying associations between sedentary behavior and health conditions, there are also adequate measures of sedentary behavior, defining prevalence of sedentary behavior across different populations, identifying the determinants of sedentary behavior, developing interventions to influence in sedentary behavior and using the relevant evidence for public health guidelines and policy (Owen *et al.*, 2010).

Change in lifestyle is the first step in management of obesity. Term "lifestyle" includes dietary habits and physical activity. In order to help patients to implement new lifestyle recommendations, physicians should be interested in patients' lifestyle history and possible contributors to weight gain. Information about previous weight reductions attempts, medical conditions and therapy and family history of obesity could be very useful in planning strategy for weight management for every patient in order to reach therapeutic goals. Desirable weight loss from baseline is 5%–10% within 6 months according the AHA/ACC/TOS guidelines (Jensen *et al.*, 2014).

The energy deficit of at least 500 kcal/day is necessary for weight loss. This deficit could be provided by calorie restriction or through physical activity. Best results achieving the patients who combine the both approach which are including in group sessions or in individual program with trained interventionist.

Usual components of weight loss program are reduced calorie-intake. At the same time or soon after the start of the dietary regime it is recommended to gradually intensify physical activity. Recommendations for childhood obesity treatment included also multi-disciplinary approach, integrated care model and family-based multicomponent behavioral therapy (Wilfley *et al.*, 2017).

Lifestyle intervention begins during the pregnancy. Pregnant women are the first in line for implementation a lifestyle intervention in order to prevent obesity. It was demonstrated that increased intake of refined-grain during pregnancy was significantly related to a greater BMI among children in 7 years of age (Zhu *et al.*, 2017).

Change in dietary habits and physical activity influences not just on metabolic obesity related disorders but also on of obstructive sleep apnea (OSA). One study analyzed OSA severity in REM (rapid eye movement) sleep, in overweight patients with diabetes type 2, during 4 years follow-up under the intensive lifestyle intervention. Lifestyle changes reduced severity of OSA, REM-AHI, and NONREM-AHI as well as HbA1c and other metabolic parameters. Weight loss was a better predictor of improving glycemic control than reductions in AHI **Fig. 1** (Shechter *et al.*, 2017).

Despite one meta-analysis from Arabic-speaking countries indicated that lifestyle modifications programs were no more effective than other treatments (Kreidieh *et al.*, 2017) the most of studies demonstrated tight connection between lifestyle intervention and improvement in metabolic and cardiovascular diseases (Shechter *et al.*, 2017; Stavropoulos *et al.*, 2017; Bloch, 2017; Davy and Melby, 2003; Gulati and Misra, 2017).

Dietary Treatment

Dietary treatment was probably the first and main therapeutic approach for obesity in the past. This treatment is based on negative energy balance caused by lower energy intake but also in change in composition of food and proper rhythm of meals. There are a numerous available commercial diets but fad or crush diets published in magazines could damage health and should be avoided. Diets have to be medically confirmed and, if it is possible, patient tailored. Long-term calorie reduction with appropriate ingestion of necessary nutrients reduces the risk for obesity comorbidities (Sofer *et al.*, 2015).

Common dietary recommendations are:

- Reducing fat, carbohydrates with high glycemic index, protein or alcohol consumption
- Smaller portion size
- Distribution of energy intake at various time of day with a largest amount of calorie was taken in the morning
- Low-calorie food
- Combining different foods

After successful diet the main issue is how to maintain the weight loss. Eating habits need to change for a long time.

During the time there were different dietary recommendations. The data indicate that improving in dietary ingredients influence on blood glucose, insulin, serum lipids, and inflammatory markers. In order to prevent vitamin and mineral deficiency

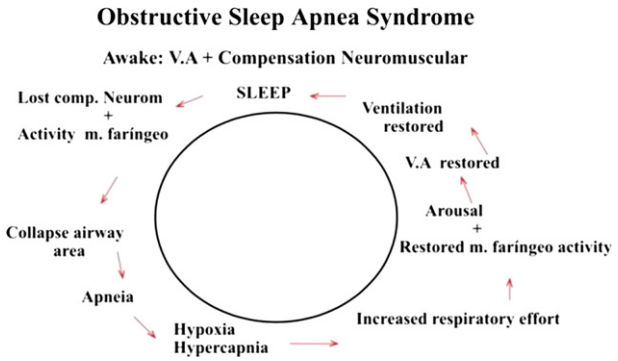

Fig. 1 Obstructive sleep apnea syndrome. From Maciel de Carvalho, T. (2015). Obstructive sleep apnea in Down syndrome children. *EC Dental Science* **2**(4), 321–327.

well balanced diet is recommended. Change in food ingredients implies more complex carbohydrates, more monounsaturated fatty acids and increasing in protein intake.

The data show that improving quality of carbohydrates (more complex carbohydrates), improving fat quality (more monounsaturated fatty acids and omega three polyunsaturated fatty acids) and increasing protein intake could improve blood glucose, serum insulin, lipids, inflammatory markers and hepatic fat, but more studies are needed (Stavropoulos *et al.*, 2017).

Traditional dietary recommendations for obesity and obesity related co morbidities include high-carbohydrate, low-fat (HCLF) regimens. Despite the positive experience with HCLF diet and scientific approval this diet for metabolic disease management, the rates of obesity and metabolic syndrome continue to rise. The Women's Health Initiative study demonstrated that the low-fat diet failed to prevent cardiovascular events, cancer and impaired glycemic control in patients with diabetes (Howard *et al.*, 2006). Dietary Guideline Advisory Committee in the United States in 2015 withdrawn recommendation for fat limitation and concluded that limiting total fat intake could not prevent obesity (Mozaffarian and Ludwig, 2015). In some populations, low-carbohydrate diet was accepted as dietary therapeutic approach for some diseases. In Japan, low-carbohydrate diet proves to be effective in patients with type 2 diabetes. NIPPON DATA 80 had shown that low-carbohydrate diet is safe, effective and strongly associated with lower mortality rate in Japanese population.

Ketogenic Diet

Ketogenic diet with extremely low carbohydrate intake, less than 50 g/day are associated with lipid profile impairment. The main concern in a low-carbohydrate diet is increase in lipid levels and cardiovascular risk (Kwiterovich *et al.*, 2003).

There is evidence that a high intake of carbohydrates may influence abnormalities associated with metabolic syndrome. A lot of studies emphasize the importance of dietary fiber intake.

Dietary fibers provide sense of fullness and prolonged satiety. Also fibers rich diet allows gradually degradation of carbohydrates and low serum glucose oscillations. Therefore, high fiber diets could delay further impairment of glucose toleration (**Table 1**) (Polovina and Micić, 2010). Eating carbohydrates last ("Carbo-last" diet) is based on facts that eating vegetables first (dietary fibers), than meat and staple food caused suppression of gluconeogenesis. Underlying mechanism of delay gastric empting in this diet is incretin effect (Kuwata *et al.*, 2016).

Mediterranean Diet

Mediterranean diet composed by olive oil, fruits, vegetables, whole grains, nuts, legumes, small amounts of diary (cheese and yogurt) and fish has proven effect in preventing diabetes (Sofer *et al.*, 2015). The same diet was not such effective in glycemic control in patients with diabetes. Possible explanation for unsatisfied glycemic control is greater fruit intake in Mediterranean diet that is recommendable for diabetic patients (Díez-Espino *et al.*, 2011). The main difference between the Mediterranean and ADA diets is in monounsaturated (MUFAs) content. MUFAs has impact on insulin sensitivity, postprandial glucose level, and lipid profile (Esposito *et al.*, 2010).

DASH

DASH trial demonstrated that an HCLF diets with 20–35 g/day dietary fiber intake (regarding recommendations of the American Dietetic Association), may be beneficial for patients with metabolic syndrome (Bloch, 2017). Another, most popular diet is low-carbohydrate, high fat diet regimens well known as Dr. Atkins' new diet revolution. Despite popularity, there is no enough scientific evidence in favor of safety and efficacy of this diet on cardiovascular health (Stevens Ohlson 2006; Davy and Melby, 2003).

Table 1 Metabolic parameters before and 12 weeks after fiber rich diet

Parameter	*Group A BD*	*Group A AD*	*P*	*Group B BD*	*Group B AD*	*P*
Waist circumference	123 ± 28.6	116 ± 23.2	<.001	129 ± 36.2	131 ± 34.6	NS
FPG	6.1 ± 0.7	5.4 ± 0.5	<.05	6.2 ± 1.1	6.2 ± 0.8	NS
Insulin	123 ± 36	86 ± 19.1	<.05	121 ± 24.2	124 ± 22.1	NS
HOMA IR	9.8 ± 3.2	5.03 ± 1.3	<.001	10.3 ± 3.1	10.8 ± 2.8	NS
HDL-c	0.96 ± 0.5	1.1 ± 0.3	<.05	0.92 ± 0.7	0.9 ± 0.1	NS
Triglycerides	2.9 ± 1.1	2.1 ± 0.6	<.001	2.7 ± 0.9	2.5	NS

BD, before diet; *AD*, after diet; *FPG*, fasting plasma glucose; *HOMA IR*, homeostatic model assessment for insulin resistance; *HDL-c*, high density lipoprotein cholesterol.
From Polovina, S. and Micic, D. (2010). The influence of diet with reduction in calorie intake on metabolic syndrome parameters in obese subjects with impaired glucose tolerance. Medicinski Pregled, 63(7–8), 465–469. Available at: http://www.ncbi.nlm.nih.gov/pubmed/21446131 [Accessed January 11, 2017].

Vegetarian Diet

Vegetarian diet is presented in two principles: vegan (do not eat animal products), lacto-vegetarian (consuming dairy products along plants), ovo-vegetarian (using eggs along plants), and lactoovo-vegetarians (eat dairy and eggs besides plants). Previous studies demonstrated that vegan diet is more successful in total cholesterol and LDL-c lowering, HBA1c reduction and reduction in diabetes drugs than standard ADA treatment although weight reduction was similar. The overall conclusion was that vegetarian diets could have positive effect on glycemic control and noninferior effect on weight reduction (Ajala *et al.*, 2013).

A communities should engage their resources in order to address obesity-related behaviors and implementation healthy eating and activity across the lifespan (HEAL) integration model (Berge *et al.*, 2017). Finally, regulatory framework must be tightened to impose taxes on sugar-sweetened beverages, oils such as palmolein, and dietary fats and limit trans fats (Gulati and Misra, 2017).

In order to achieve greater weight loss "meal replacement programs" were developed. The main characteristic of these programs is replacing normal meals with prepared meal supplements like soups, bars or vitamin-rich shakes. The meal replacement formulas provide enough energy that not causes malnutrition. Underlying mechanism of this treatment is mild ketosis induced by limited carbohydrates intake. Ketosis is a consequence of break down fat storage for energy (Proietto and Baur, 2004).

Some authors underlined the importance of time for food intake. One study showed that carbohydrates eaten just at dinner could decrease abdominal obesity and parameters of metabolic syndrome. One animal study demonstrated that time-restricted feeding improved insulin resistance, inflammation, fat content in liver, obesity and obesity related comorbidities. This study also shows that timed high-fat diet provides better satiety and significant lower ghrelin concentrations. Late main meal is associated with less weight reduction despite nutrient composition, energy expenditure, and sleep duration. Greater weight loss and waist circumference reduction was in large breakfast group due to lower ghrelin level and high satiety scores. This group is also characterized with significant improvement in HOMA IR.

The most satiating nutrient is dietary protein. Proteins could increase feeling of fullness and reduce the hunger (Jiwa *et al.*, 2015). Addition amount of protein in breakfast might help to reduce hunger in the middle of the day (Ossolinski *et al.*, 2017). Some studies conducted during Ramadan demonstrated that concentrated carbohydrate intake at dinner time, but no during the day, could be helpful for obese people or for people with metabolic syndrome. One possible underlying mechanism is increase in serum leptin at midday and feeling of satiety and reduced level of ghrelin. Adiponectin, antiinflammatory hormone, which is low in obese people, become elevated after a whole day starvation. This antiinflammatory effect reduced risk factors for metabolic syndrome (Kreidieh *et al.*, 2017).

Physical Activity

Physical inactivity is associated with increased risk for several noncommunicable diseases and one of the main causes of mortality. Increased physical activity play very important role in long-term maintaining weight loss (Catenacci and Wyatt, 2007). Current recommendations are that adults should have at least 150 min of moderate-intensity physical activity during a week (Kohl *et al.*, 2012). The represent of moderate-intensity physical activity is walking. Walking provides psychological and physical benefits, requires minimal equipment, and risk for injury is low (Baker *et al.*, 2010).

Although lifestyle interventions including physical activity and change in dietary habits, weight regain and returning to sedentary behavior are common in high number of patients. Self-monitoring or group support could be very important in maintained the intense of physical activity over a long period of time. Results from SAVE (slow the adverse vascular effects) study demonstrated that, in comparison to patient who did not use any specific strategies to apply lifestyle interventions, patients who used self-monitoring or group support had greater increase in physical activity (Lott *et al.*, 2017).

Study conducted in order to analyze association of sedentary lifestyle and obesity in EU shown that obesity prevalence was greater in those who spent more than 35 h sitting during a leisure time per week in comparison with those people who spent this time in physical activity (Martínez-González *et al.*, 1999).

There was no definitive conclusion that physical activity could facilitate greater improvement in HRQOL than diet alone. Also, there was no existing evidence that an exercise prescription without diet for may improve HRQOL in obese adults (van den Hoek *et al.*, 2017).

One animal study had shown association between that high-intensity interval in Rev-erbα and CPT1 expression and prevention of diet-induced obesity. The authors concluded that increased caloric expenditure achieved with HI interval protocol might be useful to improve lipid metabolism (Shen *et al.*, 2015).

In order to maintain weight loss increased physical activity is essential beside dietary treatment. Exercise program should be gradually built up along with cardio respiratory fitness improvement. About 30 min of walking 3/5 days per week is recommended for as a good start point. The patients could start with walking to nearby places, climbing the stairs rather than choosing escalator or elevator. For extremely obese activities in water such swimming or walking could improve fitness on the beginning. Psychologist could help obese patients to produce a long term adherence to exercise program. Adherence to the diet and physical activity vary depend of age and motivation. One nationwide survey shown that structured program in school campus may help that children accept healthy lifestyle (Proietto and Baur, 2004).

In order to support increased physical activity, self-monitoring using pedometers could be effective. One investigation implemented pedometers as motivational tools to motivated males in maintained of physical activity. This weight management

program for overweight or obese men lasted 12 weeks. The results shown that in majority of participants pedometer provide proof of progress and enabled autonomy in monitoring the program effect. Those participants that accepted pedometer as allied felt increasing competence for change. The minority of men who not achieved the physical activity goals felt pedometer as controlling. Some man continued to use pedometers after the program because they found that pedometer helps them to maintain their physical activity. The men which no longer used the pedometer were less successful in weight loss (Donnachie *et al.*, 2017).

Motivation for Lifestyle Change

During past time, there was a lot attempts to established the best therapeutic approach to motivate obese patients to lose a weight. One approach was multidisciplinary obesity treatment program (MOTP) with the idea to achieving long-term outcome regarding weight reduction and emotional state. The second objectives of this program were to analyze the influence of psychological factors on weight change. The first, intensive treatment part of this program lasted 12 weeks, included dietary counseling, exercise and cognitive behavioral therapy in order to define realistic weight goals and dysfunctional eating habits if they are existed. They were trained in emotion regulation skills. Dietetic counseling included facts about balanced diet, combination of nutrients and reduction of some ingredients. The exercise program consisted of water gymnastics, Nordic walking or weight lifting. The program included session with psychotherapist which analyzed the progress of patients. Patients and psychotherapist also evaluated obstacles to their goals. The patients visited dietician once monthly and trained doctor every 3 months. Results showed that MOTP was associated with improved obesity related psychological factors like attention, emotions, somatization, depression, and shame. These patients also experienced significant weight loss (Pjanic *et al.*, 2017).

Behavioral therapy for obesity, based on behaviorism, was introduced in 1960s. Behavior (sedentary lifestyle and overeating) influenced in occurrence of obesity. Specific educational programs are designed in order to facilitate changes in eating habits and physical activity thru modification of environmental elements and reinforcements of food intake. In next years in behavioral therapy were integrated some procedures derived from cognitive therapy. Those procedures in combination with dietary changes and exercise were recognized as weight-loss style modification (Dalle Grave *et al.*, 2013).

Conscious cognitive processes play important role in weight reduction and maintaining weight. Specific cognitive factors are associated with unhealthy eating habits, dietary treatment discontinuation, and weight loss maintenance. More than half of patients on behavioral therapy experienced weight regain after 5 years. In the first decade of 21st century Cooper developed cognitive behavioral therapy for obesity (CBT-OB) in order to address the fail in behavioral treatments used in weight loss. CBT-OB analyzed factors responsible for failure to achieve desirable weight loss and weight maintained like unrealistic weight goals and unsatisfied training in weight maintained (Dalle Grave *et al.*, 2017).

Multistep cognitive behavioral therapy for obesity may be implemented at three levels of care: outpatient, day hospital, and residential. CBT-OB incorporates the physical activity and dietary recommendations and cognitive behavioral strategies. In study with multistep CBT-OB approach, outpatient CBT-OB was leading by single therapist in group or individually. The first step was to lose weight at least 10%, and the second one was to develop a mind-set conductive to weight maintenance. Each patient was given a low-calorie Mediterranean diet and functional rehabilitation program in order to improve cardio respiratory capacities. Patients were passing thru six modules: monitoring food intake, physical activity and body weight, changing eating with 500–750 kcal deficit per day, active lifestyle, impediments to weight loss, addressing to weight loss and addressing to weight loss maintained. Patients achieved more than 10% weigh loss with no weight regain in further 12 months. Patients with binge eating disorder before hospitalization, after 3 week of residential CBT-OB showed recovering from binge eating disorder (Calugi *et al.*, 2016). Authors concluded that CBT-OB is suitable for extreme obese patients and obesity related comorbidities including the patients referred for bariatric surgery (Dalle Grave *et al.*, 2017).

Visual effect is very important for majority of people. This appearance is also highly important for obese people who wish to reduce weight.

Change in dietary habits and physical activity requires initial motivation of obese person and further, continued effort to maintained new lifestyle. One study demonstrated that computerized future self-image may be useful in weight loss, especially in female population (Jiwa *et al.*, 2015; Ossolinski *et al.*, 2017). This pilot study used application "future me" which included dietary and exercise information in order to predict BMI. One self-image from the future time points has been chosen and was printed as well as current image. Patients were also chosen to receive future self-image on the beginning of the investigation or after 8 weeks after start. Greater weight reduction was in group with delayed self-image. The possible explanation for this unrespectable result was that future self-image stimulates additional effort for further weight loss after a few weeks of weight reduction attempt (Ossolinski *et al.*, 2017).

Barriers to Behavior Change

Poor motivation, social and environmental pressure, socioeconomic status, lack of knowledge or physical limitations could be barriers to lifestyle change. The predictors of behavior compliance are older age, male sex, lower baseline BMI, and weight loss in early phase of treatment. This data suggest that program for lifestyle change should be individualized. Unrealistic expectations regarding weight reduction and negative mood could implicate lack in adherence (Burgess *et al.*, 2017). Large trial Look AHEAD

investigated possible association of degree of weight reduction and fitness with cardiovascular events. This study included 5145 overweight or obese participants with type 2 diabetes in United States who were randomized to lifestyle intervention or to diabetes education and support. Results suggest tight association between degree of weight reduction and incidence of cardiovascular disease in patients with type 2 diabetes (Look AHEAD Research Group *et al.*, 2016). This findings are the challenge for community to incorporate intensive lifestyle intervention into public health programs. One of community-based lifestyle weight loss program adapted from Look AHEAD trial is Lifestyle Interventions for the Treatment of Diabetes study (LIFT Diabetes) with reduction in CVD risk as a primary goal (Katula *et al.*, 2017).

Therapeutic treatment could be slightly difficult in obese adolescents who have an aversion to usual obesity management. Using *E*-health lifestyle intervention might be useful to reach desirable aim in this population. One study demonstrated that adolescents who participated in the *E*-health lifestyle intervention had a greater decrease in BMI then those who did not participated in this program. This program with login on a weekly basis was supported by at least one parent of adolescent. Web-based intervention encouraged healthy eating, reduced screen time and physical activity during 8 months. *E*-health intervention delivered through the internet is cost-effective and acceptable method for adolescents (Tu *et al.*, 2017).

If outpatient treatment failed in initial weight loss, inpatient management could be useful. Study conducted in one inpatient clinic, showed that 4-week inpatient program in closed group, enabled satisfied weight reduction, and maintained further weight loss during the first year after inpatient stay. Program included dietary, exercise and behavior modules. Patients who reduced weight of $>10\%$ were offered to participate in 2-week stabilization program. After dismiss patients and the clinic team maintains contact by phone or by mail. This approach could prevent weight regain (Weinreich *et al.*, 2017).

Fat mass and obesity associated protein (FTO) is one of the most important gene with impact on energy balance and foot intake. Single nucleotide polymorphisms in the FTO gen causes desire for intake energy rich foods. The effects of FTO gene on effect of lifestyle intervention are controversial although some study demonstrated that improvement in environmental factors (lifestyle) can reduced effect of FTO polymorphisms on obesity. One study showed that reduced calorie intake could help in patients with FTO risk allele (Kalantari *et al.*, 2016).

In case that lifestyle change failed in weight loss, combination of calorie restriction and some drugs could be useful. Lorcaserin with behavioral weight loss facilitates the maintenance of losses of $\geq 5\%$ of initial weight (Tronieri *et al.*, 2017).

In spite everything that has been said, some authors suggest that simply treating of obesity with the "best diet" should not solve the problem with chronic noncommunicable metabolic diseases. They also warning that weight loss should not be only one problem when low-grade inflammatory processes may be related to serious metabolic disorders (Egger and Dixon, 2014).

Summary

Change in lifestyle is the first step in management of obesity. The term "lifestyle" includes dietary habits and physical activity. Lifestyle interventions can help severely obese individuals to achieve long-term weight loss and decrease risk for cardiovascular diseases. A small amount of weight loss is associated with significant health benefits. The energy deficit of at least 500 kcal/day is necessary for weight loss. This deficit could be provided by calorie restriction or through physical activity. Best results achieving the patients who combine the both approach which are including in group sessions or in individual program with trained interventionist. There are a numerous available commercial diets but fad or crush diets published in magazines could damage health and should be avoided. Diets have to be medically confirmed and, if it is possible, patient tailored. Long-term calorie reduction with appropriate ingestion of necessary nutrients reduces the risk for obesity comorbidities. In order to maintain weight loss increased physical activity is essential beside dietary treatment. Exercise program should be gradually built up along with cardio respiratory fitness improvement. Change in dietary habits and physical activity requires initial motivation of obese person and further, continued effort to maintained new lifestyle.

Physical Activity and Exercise

Federico Mallo Ferrer, Biomedical Research Centre (CINBIO), University of Vigo, Vigo, Spain

Introduction and Definitions

The WHO defines physical activity as any bodily movement produced by skeletal muscles that requires energy expenditure —including activities undertaken while working, playing, carrying out household chores, traveling, and engaging in recreational pursuits. Meanwhile exercise is a subcategory of physical activity that is planned, structured, repetitive, and aims to improve or maintain one or more components of physical fitness. Both modalities at moderate and vigorous intensity improve health.

As defined, physical activity is a structural component of life style, independently of including planned exercise or sport. Since obesity and being overweight are regarded as an energy imbalance between consumed and expended calories, physical activity is a key factor in the pathophysiology of this disease. In fact, the WHO attributes to physical inactivity and sedentarism a key role in the development of obesity. Physical inactivity in relation to the nature of work, transportation modes in the cities, and increasing urbanization of humanity has increased in the last few decades affecting all human populations. Recent statistics (WHO report 2010) show that at least 23% of adults over 18 were not active enough (men 20% and women 35%) globally, but that proportions increase to 26% in men and 35% in women in high-income countries (vs. 12% men and 24% women in low-income countries). Those figures closely correlate with current prevalence of obesity. The reduction in physical activity in modern lifestyle is particularly due to inaction during leisure time and sedentary jobs, as predominant behaviors. In addition, this is negatively affected by the predominant passive modes of transportation inside cities and their surroundings. Much more worrying are the conditions in adolescents aged under 18, as 81% of them are insufficiently physically active (84% girls and 78% boys), not reaching the WHO recommendations. Undoubtedly, physical inactivity is a key factor that causes obesity, a disease increasing in prevalence in last decades.

Relevance of Exercise for Health

Recent reports by the WHO states that insufficient physical activity is 1 of the 10 leading risk factors for death worldwide and a key risk factor for noncommunicable diseases (NCDs) such as diabetes, cardiovascular complications and cancer. Conversely, physical activity and exercise have significant health benefits preventing NCDs. There is solid evidence demonstrating that active adults compared to inactive ones, have lower rates of all causes of mortality, coronary heart diseases, stroke, blood pressure, type-2 diabetes, risk of falls and bone fractures, breast and colon cancer, and depression. In addition, they have higher levels of muscular and cardiovascular fitness and, finally, a higher probability of maintaining normal weight and better body composition, preventing obesity and abdominal adiposity.

Worldwide, one in four adults is not active enough and more that 80% of the adolescent population are not physically active and exercise not enough. Therefore, WHO member states agreed to introduce policies to reduce insufficient physical activity by 10% by 2025, which seems a very modest objective. All those benefits are achieved irrespective of the age of the subject, however the emphasis should be on the younger, children and adolescents, as they will have the largest benefit for life (WHO report 2016).

Physical activity is the major factor for energy expenditure in physiological conditions, and a key determinant of energy needs of the body. Under exercise, there are principal changes in fuel fluxes from the body stores (adipose tissue and liver) to expending tissues (muscles, heart and brain) in a typical catabolic condition.

Beyond metabolic changes, there are physiological adaptations to the increased tissue demand. Those changes consist in redistribution of blood flow to the brain and muscles but reduced blood flow in abdominal organs and skin, increased heart expenditure, increased pulmonary ventilation, activation of sympathetic nervous system and inhibition of the parasympathetic branch, and switch of hormonal systems: reduction of insulin levels (inhibited by sympathetic nervous system), increased adrenaline, glucocorticoids, GH and blockade of the gonadotrophic axis.

Increase in heart activity inherent to exercise is one of the major factors in preserving health, keeping this muscular organ fit. Increase in pulmonary ventilation and circulation of respiratory gases, and oxygenation of tissues, also greatly contribute to maintaining trophic functions of all the organs including the brain. The brain, being the central regulatory organ of the body function, and as such having a predominant role in human health, benefits immensely from regular exercise. Exercise improves general function of the brain, mainly superior and cognitive capacities. As exercise dramatically contributes to keeping the brain and the heart in good condition, it is a warranty of having a healthy life. Mobilization of muscles and joints during exercise also have direct healthy effects on the body, improving general capacities and abilities to adapt to everyday challenges. In addition, exercise is the most important factor in maintaining bone density by avoiding the calcium loss linked to inactivity, and thus preventing bone pathology in aging. Overall, exercise is the most efficient way to prevent disease and improve health.

Metabolism at Exercise: Physiology of Exercise, Energy Expenditure, and Metabolism

Despite common belief lipids are the preferred fuel for muscles, and just at the point of intense effort carbohydrates (CHO, carbs) are more important. Different classic studies have shown at least four preferred fuels to supply muscle metabolism: intramuscular lipids, intramuscular carbs (glycogen), lipids accumulated in adipose tissue, and circulating glucose (van Loon, 2004). They are all used in moderate and vigorous exercise, although in different proportions, depending on duration and intensity of the effort. There are four physiological energy resources used during exercise: intramuscular fat, circulating triglycerides extracted from adipose tissue, muscular glycogen, and circulating glucose release from the liver on demand to supply increasing needs during exercise. The liver produces glucose from hepatic stored glycogen (about 5% of liver weight) and from de novo synthesis from other energy sources, such as as glycerol (from triglycerides), aminoacids (especially alanine), and circulating lactate. Circulating lactate is released from exercising muscles through the MCT-2 membrane transporter (Mono-Carboxylate Transporter-2) which appeared in muscle membranes during exercise. Lactate is produced in muscles by glycolysis of monosaccharides and glucose, and is then released from muscle glycogen. The liver resynthesizes glucose from lactate in a chemical cycle discovered by the Cory couple. This "lactate shuttle" is a refined process allowing the organism to keep glycemia homeostasis by using muscle glycogen during exercise, and therefore warranting the glucose supply to critical organs as the brain. Several tissues might also use lactate as primary carb surge instead of glucose, such as the heart, kidneys, gut cells and the glia and neurons of the central nervous system (Hui *et al.*, 2017). Therefore, hyperlactatemia has preserving functions in metabolic control during strenuous exercise.

A classic study (Romijn *et al.*, 1993) showed that the proportion of energy supply to the muscle by each of the four main sources deeply depends on the exercise intensity. At low intense exercise (25% of the maximum oxygen consumption VO_2max) the major energy source is plasma FFA with minor inputs from muscle triglycerides and plasma glucose. At medium intensities of exercise (65% VO_2max) muscle triglycerides (especially glycogen) are the major energy resource in the active muscles. And finally, at very high intense exercise ($>85\%$ VO_2max) the energy input from glycogen is critical, plasma glucose is also a relevant input, and in general the major source to maintain the effort are carbs in detriment of lipids. However, these high intensity exercises cannot be maintained for long periods of time unless in very well-trained athletes; most exercise in common people, and especially in overweight and obese subjects are in the range of low-to-medium intensities. Thus, and in contrary to common beliefs, lipids are the major source of energy for muscle metabolism in most of the range of exercise for humans, except very short efforts and among sportsmen and athletes. It has been previously described that lipids are the major source for exercise between 45% and 75% of VO_2max or maximal heart rate (MHR), to the misconception that outside those limits muscles use other energy substrates. All along the range of exercise intensities muscle metabolism uses lipids as a preferred resource, however, at very high intensities muscle uses glycogen or glucose to provide energy bursts for very short extreme efforts. In addition, there is a large variability in the capacity of fat oxidation between individuals, and it also depends on the type of exercise. Following this rationale, low-to-medium intense prolonged exercise will demand high amounts of lipids, and by the contrary strength training is more depending on carb supply. Combined exercises, as most team sports are, and depending on their duration, they will demand different proportions of lipids and carbs in a quite individual manner.

In fact, one of the major adaptations to training exercise includes the increase of lipid depots in the working muscular fibers. This is very important, as it allows more efficient energy production, longer duration of exercise, and better performance. In such a way, the muscles of obese subjects have lower amounts of intramuscular fat with respect to athletes. Interestingly, the increase in intramuscular fat also increases insulin sensitivity, which is characteristic in trained muscles of sportsmen.

Benefits of Exercise in Obesity and Metabolic Syndrome

Exercise alone promotes multiple changes that improve health in obese subjects. Recent studies have demonstrated that even very light exercise in heavily obese subjects greatly improves cardiovascular condition and reduces the risk of cardiovascular events to a greater extent than losing weight. Furthermore, the reduction in cardiovascular risk is proportional to the intensity and duration of exercise: vigorous exercise is better than moderate; and moderate exercise is better than light physical activity. In summary, exercise is the most reducing cardiovascular risk of those studied yet, including reduction in BMI-body weight, waist circumference or biochemical parameters (total cholesterol, LDL, etc.)

As described above, muscle incorporation of glucose becomes independent of insulin action, and that condition sustains at least several hours after finishing the exercise. It has been extensively described that the expression of GLUT-4 in the membrane surface of muscular fibers is greatly increased during exercise even with very low circulating levels of insulin.

Similarly, transmembrane transport of lipids is also increased in exercising muscles. In this case the expression of CD36/FABP4, the most important membrane lipid transporter, is greatly augmented during exercise, facilitating the lipid incorporation into muscle metabolism.

Exercise increases energy expenditure during execution but also enhances resting energy expenditure and prevents the deposit of visceral fat, increases the fat oxidation in muscle, reduces the depot of adipose tissue, and greatly increases the tissue perfusion and oxygenation. Trained subjects use a higher proportion of lipids as mitochondrial fuel in muscle during exercise performance. Exercise increases brown fat development from white adipose tissue, likely by the activation of the sympathetic nervous system.

In addition, exercise reduces insulin needs during execution and several hours afterwards, and complementary increases IGF-1 circulating levels by increasing GH secretion. All those ameliorate multiple functions in different tissues including muscles (Ana Fernandez) and brain (I torres-alemán).

Chronic exercise decreases food intake and modifies food preferences to healthy foods. In addition, exercise promotes brown fat development which is highly dependent on sympathetic nervous system activation, and enhances resting energy expenditure, reducing adiposity, especially in the abdominal organs.

Exercise improves fitness, cardiovascular function, reduces cardiovascular risk and it has a direct effect on increasing survival and life expectancy.

Exercise in Weight Loss and Maintenance

Given that physical exercise is the part of metabolic energy that may be modulated and increased by will, it should be regarded in terms of energy magnitudes as Kcal or kJ in order to control body weight. If we see the alterations in body weight in terms of energy imbalance with respect to the amount of calories eaten versus the calories expended, exercise should play a key role in strategies of weight loss and body weight maintenance. However, the real influence of exercise in both processes is typically different.

In fact, although exercise is the best way to expend calories, current exercise at medium or low intensity consumes modest amounts of energy and so we need to perform the exercise for longer times. Physical activity without caloric restriction very often promotes modest weight loss. And in fact, it is not strange that some obese even gain weight during exercise programs by an increase in muscular mass. It also takes into account that in many subjects light exercise programs increase food appetite, which may interfere with dietary restrictions, especially immediately after finishing the exercise.

On the other hand, exercise is a very efficient tool in maintaining body weight. There are several reasons to justify the effectiveness of exercise in maintenance of body weight. Firstly, certainly doing exercise by routine will balance the energy equilibria of income/expenditure in the body. Secondly, doing exercise is clearly associated with other healthy habits, reduced alcohol intake, longer times and better sleep quality, reduced smoke consumption, more equilibrated diet, and hydrating strategies. Thirdly, exercise has a direct effect on improving the physiological function and responses of many organs including heart and vessels, lungs, kidneys, gastrointestinal system, central and peripheral nervous system, muscle and skeletal system and general metabolism.

In addition, it must be emphasized that independently of the effect in weight body balance, any amount of exercise will promote some improvement in healthy parameters in overweight and obese subjects. Moreover, those obese subjects obtained larger benefits from even very low amounts of exercise, independently of final mark in body reduction or even with negligible losses. In fact, increasing physical activity is the major factor that reduces cardiovascular risk, which much more potent than weight loss or even reduction in waist circumference as a marker of abdominal obesity.

Exercise Recommendations: Modifying Factors (Age, Physiological Condition, Physical Handicaps, etc.)

Any amount of exercise and physical activity will provide some kind of benefit for health or for specific organs. However, it is not easy to give a general recommendation with respect to the most adequate exercise to reach the optimal benefits. Including exercise in the treatment of obesity would regard proposals of changes of life habits and transport and programmed exercise.

Exercise must be defined in relation to at least the following parameters: frequency, duration, intensity, type and groups of muscles intervening. Exercise restricted to upper or lower limbs, or even individual extremities might be prolonged for large times to obtain a general benefit. On the other hand, simple and current exercise (walking, swimming, etc.) involving the whole body will potentially promote great improvements in health.

In subjects over 50 years old with a previous habit of large sedentarism for long periods, there must be detailed consideration of their physical and health condition. Concurrence of comorbidities or even frank pathology is very frequent. In such a case, obesity is one of the multiple factors conditioning health of individuals. This patient might be reluctant to do any exercise, as sedentarism has always been their way of life. Recent studies have shown that they are susceptible of the highest health benefits with the lowest increase of physical activity and exercise.

WHO stratifies the population into three age groups: below 18, from 18 to 64, and above 65. In all of them exercise will bring great benefits to health, but the amounts of exercise needed are different at various ages, and since there are different recommendations to reach optimum efficiency. A general rule is to do as much exercise as tolerable at each age, and then more duration and intensity in youngsters that may be reduced with age, although there is a clear conditioning individual factor.

Preparing for Exercise: Medical Exam, Incompatibilities, Physiotherapy Reconditioning, Progressive Guided Intensity

The American College of Sport Medicine establishes that low-impact physical activities (walking, cycling, swimming, etc.) at low intensities might be initiated by any obese subjects without further evaluation. Patients with high risk or previous history of

cardiovascular events, respiratory diseases and likely morbidly obese with poor fitness and/or musculoskeletal alterations should be evaluated first as initiating exercise of moderate or vigorous intensity from almost complete sedentarism is a risky practice. Several precautions should be taken in order to get the maximum benefit of practicing exercise and sports with the lowest risk for health. In such a way, the exercise programs for the obese must be safe, effective, and motivating. Frequently, starting a physical exercise protocol needs to recondition at least several organic systems. As described above, the cardiovascular system rapidly adapts its functional parameters to actual needs, and an increased demand needs an adapting period. The same will happen with pulmonary capacities, which must increase in order to supply the exercise demand of oxygen. This might be a relevant point as pathology affecting lung functionally is rather common in obese subjects, and eventually might be a limiting factor. Obesity is associated with long periods of physical inactivity, and then the reduction of functional capacities of many muscular groups and joints. It is common to suffer muscular or joint injuries at the beginning of exercise in obese and overweight subjects, that require a sudden and disturbing interruption of the activity, a necessary period of inactivity follows a discouraging incentive that may drive to the failure of the program.

These risks are greatest at the very beginning and wane once training is a routine habit, and most will be significantly prevented by a preexercise evaluation.

A complete physical examination is mandatory, including cardiovascular explorations and complementary test (ECG, ECOCG) and spirometry. In obese subjects, especially those most sedentary or aged above 40, a cardiovascular stress test is highly recommended, and must be performed by expert professionals with experience in interpreting this kind of data.

A full skeletal examination, characterizing functional capacities of major joitns and muscular groups, will greatly contribute to the prevention of injuries. The role, not just that of a medical specialist, but also of experienced physiotherapy professionals is of extraordinary value at the beginning of the physical exercise, to identify motility problems, to supervise early stages and to recommend appropriate scaled protocols according to the physical condition and fitness of every obese subject.

Although, almost all subjects will benefit from increased physical activity adjusted to any specific clinical condition, it must be regarded to exclude those with valvular heart disease, dangerous arrhythmias, and malignant hypertension. In addition, others should be carefully supervised during the exercise program, such as those with hemoglobinopathies, exercise-induced asthma and diabetics, and those initially morbidly obese.

Table 1 displays a complete collection of pathologies that indicate a partial restriction of exercise or need specific therapeutic exercise programs.

Prescribing Exercise for Obese Subjects. Protocol for Beginners. Uncharged in Water. Progression. Fitting Objectives Looking to Health

The WHO recommends a general not specific rule of being engaged in regular physical activity for a minimum of 60 min per day for children and 150 min per week in adults. Although this protocol will bring relevant health benefits for all people, it might not be enough to reach significant reductions in body weight in overweight and obese subjects, as explained above. In fact 60 min of moderate to vigorous intensity exercise every day is the minimal proposed for children to keep healthy. And the same should be said for 150 min/week of moderate-intensity, or at least 75 min of vigorous-intensity, physical activity in adults. In fact, additional benefits will be obtained with 300 min/week of moderate intensity or 150 min/week of vigorous-intensity. In adults, it is also recommended to include muscle-strengthening activities involving two major muscular groups at least 2 days a week or more.

In terms of energy expenditure, it is a good practice to start with tolerable exercise to increase the cardio-respiratory functional capacity prior to any other objective. An increase of about 1300 kcal/week of aerobic exercise greatly improves the cardio-metabolic functional capacity and reduced cardiovascular risk in any condition. It has been also reported that an increase of more than 1500 kcal/week by resistance exercise may reduce the progression of atherosclerotic lesions, and more than 2000 kcal/week might promote the regression of coronary atherosclerotic plaques in patient with myocardium isquemia.

After a health evaluation of the subject the next step is to calculate the whole energy expenditure, in order to plan a personalized program. To that purpose it is recommended to carry out a complete survey about habits including resting time, leisure time activities, work and transportation, sleep duration and quality, and schedules for each activity and meals. Calculations may be inferred based on accepted formulas, such as Harris-Benedict and others.

Therefore, a complete plan to increase physical activity in all common life events should be created, which should also include an exercise/sport program as appropriate. WHO emphasizes that reduction of physical activity in life common actions, including work, commute, and leisure time are determinants in the whole energy expenditure, and modifying these habits would greatly contribute to the prevention of being overweight and obesity.

As seen above initiating an exercise program needs some preparation in order to achieve at least three objectives: to warrant a safe activity avoiding exercise risk, provide the best conditions to obtain an optimum health benefit, and to encourage the follow-up of the program in the long-term avoiding premature withdrawal.

As obese individuals have been usually completely sedentary for long periods, it is a good practice to start with exercise that reduces weight load as much as possible. Some options may include swimming, cycling (although perhaps not in the very first moments), and gym seated/lying activities. All those should be always supervised by a qualified exercise monitor who must understand that obese subjects are unfit, with limited joint mobility and usually low motor coordination capacities. Group

Table 1 Some therapeutic exercise routines for specific patient populations

Department	*Disease*	*Therapeutic exercise*
Cardiac (Romijn et al., 1993; van Loon, 2004)	Ischemic heart disease (CAD) Post-MI Stable angina Stable chronic heart failure (CHF) with sinus rhythm and ejection fraction of 40%	AROM; endurance training (e.g., after a 5 min warm-up, exercise until the heart rate reaches that attained at 50% of VO_2max) Training muscle strength by resistance training, which must be carried out with great caution and adjusted to each patient's physical fitness level
Pulmonary	Pneumonia Chronic bronchitis Bronchiectasis	Postural drainage exercises
	Asthma Emphysema	Breathing techniques Relaxation techniques
	Respiratory insufficiency Restrictive lung disease	Stretching exercises to mobilize respiratory muscles *Note:* The level of physical effort should be limited because exercise may provoke bronchospasm
Orthopedics	Fractures Osteoarthritis Amputations	Preoperative and postoperative exercises Isometric exercises for joints with minimal ROM ROM exercises to prevent contractures and heterotopic ossification
Burns		Passive and active exercises assisted by therapists to prevent contractures
Rehabilitation	Cervical, thoracic, and lumbar problems	Training of the Swedish Back School[a] Treatment of muscle contractures Myofascial release Flexibility training (stretching) to mobilize joints Resistance (which may include isometric exercises) and PNF training of muscle strength in muscles that have become weakened, as well as in the back extensors and abdominal muscles Graded fitness training
	Ankylosing spondylitis	Mobilization of spinal vertebrae Extension exercises
Rheumatoid arthritis		Flexibility training Gentle fitness training
Gynecology and obstetrics	Pregnancy and postdelivery	Prenatal and postnatal exercises Relaxation techniques
	After mastectomy	Training to reduce lymphedema
	Urinary incontinence	Isometric exercises to pelvic muscles

[a]The Swedish Back School derived from pioneering Swedish studies in the 1970s that measured intradiscal pressure in normal nuclei pulposi at the L3 level. The pressure at L3, measured with a subject standing erect, was found to be 100 kp/cm^2 in a male weighing 75 kg. The pressure increased to 250 kp/cm^2 when an individual was sitting bent forward and diminished to 50 kp/cm^2 when he was lying prone.
ROM, range of motion; AROM, Active range of motion.

activities may be a good initiating strategy for example: gym, dancing or trekking. This group exercise promotes additional motivation to continue the exercise program. In recent years, social networks have contributed to sharing exercise and sport goals, which in many cases is a very good reinforcement to keep doing it. Other important recommendations are to avoid very high-intensity exercise in obese subjects, emphasizing the duration and exercise frequency in sessions per week as tolerable, and to include modifications in the nutrition plan accordingly to the exercise program (meal preexercise, hydratation habits and post-exercise dieting).

Sport clothing must always be comfortable and allowing wide range mobility; appropriate shoes and socks are also very important. Using hydrating creams before and after exercise will prevent uncomfortable galls and skin inflammation especially around hips, groin, knees, and armpits.

The objectives should be initially centered in getting a better fitting with significant improvements in respiratory and cardiovascular responses, which will yield the highest health benefits. Afterwards programed exercise will be a good adjuvant of the weight-loss strategy, but never alone and always contextualized in an integrated therapeutic plan, including a diet regime, resting and sleeping recommendations, psychological support and any other therapeutic tool that may be needed.

Management of Patients with Obesity: Different Therapies and Clinical Use

The global pandemic of obesity is increasing over the past decades, becoming a major public health challenge (NCD Risk Factor Collaboration (NCD-RisC), 2017; GBD 2015 Obesity Collaborators, 2017). Obesity is directly linked to a number of different diseases including type 2 diabetes (T2D), hypertension, hyperlipidaemia, obstructive sleep apnoea (OSA), cancer as well as psychological and psychiatric morbidities (Allott and Hursting, 2015; DeMarco *et al.*, 2014; Nedeltcheva and Scheer, 2014). According to different projections, the cost of overweight and obesity to society could increase to $50 billion in 2050 if obesity rates continue to rise (National Clinical Guideline Centre, 2014). Treatment options for obesity may include non-surgical treatments and bariatric surgery (Bray *et al.*, 2016). Non-surgical treatments involve lifestyle interventions including caloric restriction, reduction of sedentary behaviors and increased physical activity as well as pharmacotherapy. However, diet therapy may have little effect on weight loss (WL) and may be relatively ineffective in treating obesity in the long-term (Bray *et al.*, 2016). Furthermore, several pharmaceutical agents approved for reducing excess adiposity (Dixon, 2016) have been unfortunately associated with low efficacy and diverse side effects (Rucker *et al.*, 2007). By contrast, surgical procedures have expanded quickly in the last decade, due to their ability to produce long-term WL, ameliorating obesity-related comorbidities and reducing long-term mortality (Sjöström *et al.*, 2004; Adams *et al.*, 2007; Frühbeck, 2015). In this sense, bariatric surgery is considered the most effective treatment for individuals with severe obesity [body mass index (BMI) $> 40.0\ kg/m^2$] or those with a BMI $> 35\ kg/m^2$ who also have important comorbidities, such as T2D, hypertension or OSA (Pi-Sunyer *et al.*, 1998; Fried et al., 2013a). In this regard, different guidelines for treating obesity and its associated comorbidities in an effective way have been developed (Fried et al., 2013b, 2014; De Luca *et al.*, 2016).

Different Techniques of Bariatric Surgery

The term bariatric surgery refers to all surgical procedures with the aim to reduce excess weight (Frühbeck, 2015). Bariatric surgery techniques began with the observation that patients with short bowel syndrome (undergoing extensive resection of a large portion of the intestinal tract) or patients after gastrectomy experienced a significant WL. The first surgeries to achieve WL were performed >50 years ago by Drs. Mason and Ito (Kremen *et al.*, 1954). However, in the past 20 years, the dramatic increase in the prevalence of severe obesity combined with relevant improvements in the efficacy and safety of bariatric surgical techniques have led to an important increase in the number of procedures annually performed. In fact, in 2013, nearly half a million procedures were performed worldwide (Angrisani *et al.*, 2015). A range of procedures is now well established with different degrees of WL achieved after surgery. Traditionally, surgeries are classified in three main groups: restrictive, malabsortive or mixed techniques (**Table 1**). Nowadays all bariatric surgery techniques are carried out by a laparoscopic approach. The selection of the type of bariatric surgery needs to be carefully considered based on the patient's characteristics and the surgeon's preferences evaluating the risks and benefits of each procedure.

Restrictive Techniques

Restrictive procedures promote a reduction in food intake by limiting the size of the stomach. Different types of restrictive WL surgery procedures include vertical banded gastroplasty (VBG), adjustable gastric banding (AGB), sleeve gastrectomy (SG) and gastric plication (GP).

Table 1 Classification of the main bariatric surgery procedures

Restrictive techniques	*Malabsortive techniques*	*Mixed techniques*
Vertical banded gastroplasty (VBG)	Jejuno-ileal bypass	Roux-en-Y gastric bypass (RYGB)
Adjustable gastric banding (AGB)	Duodenal-jejunal bypass	Biliopancreatic diversion with duodenal switch (BPD-DS)
Sleeve gastrectomy (SG)		Biliopancreatic diversion (BPD)
Gastric plication (GP)		

 doi:10.1016/B978-0-12-801238-3.65164-4

- **Vertical banded gastroplasty (VBG)** was developed by Dr. Edward E. Mason (Mason *et al.*, 1998). This purely restrictive procedure stapled vertically the upper stomach creating a small pouch along the inner curve of the stomach. The passage of food through the rest of the stomach is restricted by a plastic band, which delays the emptying of food from the pouch, causing a feeling of fullness. It was popular in the 1980s, but it has been progressively abandoned due to intractable reflux and vomiting problems after surgery (Goldberg *et al.*, 2000).
- **Adjustable gastric banding (AGB)** is one of the most commonly performed bariatric surgery in the world (Buchwald and Oien, 2009). The original technique was performed as an open procedure in Sweden, but nowadays it has been modified to become a laparoscopical technique (Miller and Hell, 2003). An adjustable silicone band is bucked around the upper stomach in a restrictive procedure. The lumen of the band is connected via a tube to a subcutaneous reservoir and injection of saline allows the band to be adjusted. Injection or withdrawal of fluid from the system via this port allows the surgeon to tighten or loosen the band depending on the patient's symptoms and the desirable degree of WL to be achieved.
- **Sleeve gastrectomy (SG)** was introduced in the early 1990s and its popularity is increasing because it is considered a secure technique with low complication rates and minor long-term nutritional deficiencies (Nguyen *et al.*, 2013). This restrictive procedure involves an 80% vertical resection of the stomach following the major curve, creating a tubular stomach. Currently, SG is considered as an acceptable option as a primary bariatric procedure with a suitable risk/benefit profile, placed between RYGB and AGB. In fact, this procedure climbed from up to 37% of total procedures between 2003 and 2013 worldwide and, in some regions, such as USA/Canada and Asia Pacific, has become one of the most frequently performed procedures (Angrisani *et al.*, 2015).
- **Gastric plication (GP)**. The current model of laparoscopic gastric placation was described by Talebpour and Amoli (Talebpour and Amoli, 2007). This procedure is based on the reduction of the size and capacity of the stomach approximately 75% by folding the stomach's lining inside itself. As compared to SG, gastric plication does not involve any gastric resection without leaving a staple line behind (Pujol Gebelli *et al.*, 2011). Moreover, no foreign body placement is included alleviating the associated problems. In addition, GP is a reversible procedure that allows revision to other bariatric surgeries (Skrekas *et al.*, 2011; Tsang and Jain, 2011). However, it must take into account that gastric plication has been recently described and further studies are needed to prove its effectiveness in long-term WL and its role in the improvement of obesity-associatedcomorbidities.

Malabsortive Techniques

Malabsortive techniques are based on the removal of small intestine portions and the diversion of biliopancreatic secretions, limiting the absorption of nutrients in the intestine. Duodeno-jejunal bypass and jejuno-ileal bypass are classified as pure malabsortive methods.

- **Jejuno-ileal bypass (JIB)** became popular in the late 1960s and early 1970s (Griffen Jr. *et al.*, 1983). The technique involves an intestinal bypass in which the proximal jejunum is anastomosed to the distal ileum, being a purely malabsortive procedure (Griffen Jr. *et al.*, 1977). This type of procedure results in extreme WL and its practice was abandoned due to the development of serious complications, such as renal failure, liver disease, fat-soluble vitamin deficiencies and malnutrition, among others (Requarth *et al.*, 1995).

Mixed Techniques

Biliopancreatic diversion, with (BPD/DS) or without (BPD) duodenal switch, and Roux-en-Y gastric bypass (RYGB) are defined as mixed procedures, being a combination of restrictive and malabsortive techniques (DeMaria, 2007).

- **Biliopancreatic diversion (BPD) and biliopancreatic diversion with duodenal switch (BPD/DS).** Biliopancreatic diversion was described by Scopinaro in 1979 (Scopinaro *et al.*, 1979). The surgery consists of a horizontal distal gastrectomy that leaves behind a functional upper stomach. This remnant stomach is anastomosed to the distal small intestine (alimentary limb). The excluded small intestine (including the duodenum, the jejunum, and part of the proximal limb) carries bile acids and pancreatic secretions (biliopancreatic limb) and it is connected to the alimentary limb at a distal ileal level. The "common limb" is the only segment of small bowel where digestive secretions and nutrients mix, leading to a delayed mixing of food with biliopancreatic secretions.

  In the biliopancreatic diversion with duodenal switch (BPD-DS) instead of distal gastrectomy, a sleeve type gastrectomy is performed and Roux limb is anastomosed not to the stomach but to the duodenum (duodenal switch), thus preserving the pylorus (Crookes, 2006) and theoretically regulating gastric emptying and reducing dumping syndrome. The BPD-DS was popularized by Marceau et al. (Marceau *et al.*, 1993) and Hess & Hess (Hess and Hess, 1998) in 1993. However, its technical complexity and long-term significant nutrient deficiencies has led to a decrease in the number of this type of surgery representing only 2% of total bariatric surgery procedures worldwide (Buchwald and Oien, 2009).
- **Roux-en-Y Gastric Bypass**. The gastric bypass was originally introduced in 1969 by Mason and Ito (Mason and Ito, 1969) and it has undergone different modifications. The most common version, the laparoscopic Roux-en-Y-gastric bypass (RYGB), represents one of the most performed bariatric operation throughout the world (Angrisani *et al.*, 2015). This includes a small

and vertically oriented proximal gastric pouch of 15–20 mL that is anastomosed to the jejunum through a gastro-jejunal anastomosis in a Roux-en-Y manner. As in BPD and in BPD-DS, three limbs appear: an alimentary limb (jejunal Roux-en-Y limb anastomosed to the stomach), a biliopancreatic limb (which transmits bile and pancreatic juices to the jejuno-jejunostomy) and a common channel limb (from enteroenterostomy and ileocecal valve).

Currently, SG and RYGB are the most commonly performed bariatric surgery techniques. However, the mechanisms of action of bariatric surgery are complex and involve multiple neuroendocrine signals that exert effects at the central nervous system as well as in peripheral organs, contributing to overall benefits of these procedures (Frühbeck, 2015).

Health Benefits of Bariatric Surgery

Important studies initiated almost three decades ago have analyzed the effect of bariatric surgery to achieve WL and the resolution of obesity-associated comorbidities (Buchwald and Oien, 2009; Courcoulas *et al.*, 2013; Schauer *et al.*, 2012; Buchwald *et al.*, 2009; Arterburn and Courcoulas, 2014; Sjöström *et al.*, 2012). A body of evidence exists showing that bariatric surgical procedures contribute to an increased body WL, an improvement in the control of comorbidities, and a better quality of life in patients with obesity compared to non-surgical treatments (Colquitt *et al.*, 2009). Although most results from different studies are limited to the first two or three years of follow-up after bariatric surgery, immense efforts have been made to evaluate the long-term effects of these surgeries (**Table 2**). Our main current knowledge about the long-term results of bariatric surgery comes from the Swedish Obese Subjects (SOS) study (Sjöström et al., 2004, 2007). This study was started in 1987 and it is the largest and longest prospective, non-randomized and interventional trial examining the effects of bariatric surgery in over 4000 subjects. Other long-term observational studies comparing bariatric procedures with non-surgical management of obesity, such as the Utah obesity study and the Longitudinal Assessment of Bariatric Surgery (LABS-2) have also demonstrated that bariatric procedures are more effective than medical or lifestyle interventions in achieving WL and the resolution of obesity-related comorbidities (Courcoulas *et al.*, 2014; Karlsson *et al.*, 2007; Kolotkin *et al.*, 2012).

Table 2 Long-term effects of bariatric surgery compared with non-surgical management

Study	*Location*	*Study Details*	*Population*	*Weight change*	*T2D remission*	*T2D incidence*
Swedish Obese Study (SOS)	Sweden	The largest and longest prospective, non-randomized study with matched controls. Started in 1987	$n = 2010$ underwent bariatric surgery: 68% VBG, 19% AGB, 13% RYGB; $n = 2037$ matched control group	The mean changes in body weight after 2, 10, 15 and 20 years were: −23%, −17%, −16% and −18% in the surgery group and 0%, 1%, −1% and −1% in the control group, respectively	After 2 years: 72% of patients with T2D were in remission. After 10 years: 50% of patients with remission of T2D had relapsed	Bariatric surgery reduced risk of developing T2D by 96%, 84% and 78% after 2, 10 and 15 years, respectively
Utah Obesity Study	Utah, USA	Prospective, observational study with matched controls. Started in 2000	RYGB: $n = 418$ Control 1: $n = 417$ bariatric surgery seekers who did not undergo surgery; Control 2: $n = 321$ population-based severely obese matched controls	Six years after surgery: −27.7%, +0.2% and 0% of their body weight in RYGB, control 1 and control 2, respectively	Six years after surgery: 62% in RYGB, 8% and 6% in control 1 and control 2, respectively	Six years after surgery incidence decreased to 2%, 17% and 15% for bariatric surgery, control 1 and control 2, respectively
Longitudinal Assessment of Bariatric Surgery (LABS)	USA	Multicenter observational cohort study. Started in 2006	$n = 2458$: 70.7% RYGB, 24.8% AGB and 4.5% other procedures	Three years after surgery: −31.5% and −15.9% of their body weight in RYGB and AGB, respectively	Three years after bariatric surgery: 67.5% of RYGB and 28.6% of LAGB experienced partial remission of T2D	Incidence of diabetes was 0.9% after RYGB and 3.2% after AGB

VBG: vertical banded gastroplasty, RYGB: Roux-en-Y gastric bypass, AGB: adjustable gastric banding.

Effects of Bariatric Surgery on Weight Loss

Long-term effect on body weight is one of the most important points to determine success after bariatric surgery. Sustained total body WL improves obesity-associated comorbidities and to date, bariatric surgery is the most effective treatment to achieve a substantial and durable WL. However, changes in body composition towards a reduced adiposity are also of great importance after bariatric surgery (Frühbeck, 2015; Gómez-Ambrosi *et al.*, 2017). A series of randomized controlled trials have provided evidence that patients lose more weight up to 5 years after bariatric surgery compared to non-surgical interventions (Gloy *et al.*, 2013).

The effectiveness of bariatric surgery was first described in a meta-analysis in which the main surgical procedures were studied. The mean percentage of excess weight loss (EWL) was 47.5% for gastric banding, 61.6% for gastric bypass, 68.2% for gastroplasty and 70.7% for biliopancreatic diversion or duodenal switch. In most cases, the WL outcomes did not differ significantly at 2 years or less compared with those at over 2 years (Buchwald *et al.*, 2004). In an additional long-term study comparing AGB and RYGB after a 10-year follow-up, patients who underwent RYGB experienced a greater percentage of mean EWL (69%) than the AGB (46%) patients. However, RYGB lead to a higher risk of developing early and long-term surgical complication rates than AGB (Angrisani *et al.*, 2013). In the same line, a recent meta-analysis of randomized controlled trials including 11 studies and 796 individuals, has demonstrated that patients lost more weight (mean difference − 26 kg) after bariatric surgery than individuals after non-surgical treatment (Gloy *et al.*, 2013). On the other hand, Camerini et al. reported a good short-term WL after AGB (BMI was 79% of preoperative value at 1 year) but BMI tended to increase over time, by approximately 0.42 BMI units per year and, at 13 years postoperatively, 60% of bands had to be removed (Camerini *et al.*, 2004).

Weight loss outcomes up to 20 years after bariatric surgery have been reported from the SOS study (**Table 2**) (Sjöström, 2013). However, in most cases a weight regain (WR) in all the surgery subgroups was observed (from the first year), although this tendency stopped after 8–10 years. In the same line, Freire et al. reported that WR increased significantly with time after surgery, specifically 14.7% after 2 years, 69.7% from 2 to 5 years, and 84.8% over 5 years (Freire *et al.*, 2012).

Another important ongoing prospective study performed in Utah, found that six years after surgery, patients who underwent RYGB experienced a significant WL compared to two different control groups (Adams *et al.*, 2012). In the LABS multicenter observational cohort, including 2458 patients, the percentage of WL for participants who underwent RYGB mostly occurred during the first year (Courcoulas *et al.*, 2013). Furthermore, a recent study has concluded that the measurement of body composition and body fat after the first and the second year after RYGB may yield clinically more relevant information about cardiometabolic risk factors than body weight, BMI and EWL (Gómez-Ambrosi *et al.*, 2017).

Thus, bariatric surgery is markedly more efficient than non-surgical treatments to achieve WL, improving quality of life and reducing mortality associated to obesity (Sjöström, 2008). However, WR and failure to sustain WL have been observed in 20–30% of patients and should be also contemplated (Meguid *et al.*, 2008). Individuals who present WR are difficult to predict pre-operatively and, consequently, diverse studies are trying to identify predictors of WR (Livhits *et al.*, 2011). The main etiological factors responsible for weight recidivism are discussed below (Karmali *et al.*, 2013; Maleckas *et al.*, 2016).

Factors responsible for weight recidivism following bariatric surgery

- *Nutritional non-compliance.* Poor diet quality, characterized by excessive calorie intake in the form of snacks, sweets and fatty foods, has been reported as one of the main factors that influence WR (Freire *et al.*, 2012). In addition, eating disturbances and the loss of control when eating are of great importance after gastric bypass, constituting risk factors for decreased WL outcomes (Kofman *et al.*, 2010). For this reason, an appropriate education and diet counseling by a multidisciplinary team are crucial.
- *Hormonal/metabolic imbalance.* Early findings have suggested that WR is associated with a hormonal imbalance. In this regard, post-prandial suppression of plasma ghrelin has been correlated with the maintenance of WL (Engstrom *et al.*, 2007), whereas high levels of this hormone in plasma after surgery have been associated with WR (Bohdjalian *et al.*, 2010). Conversely, no influence of ghrelin secretion on WL or WR has been recently described while the decreased levels of the glucose-dependent insulinotropic polypeptide (GIP) and the glucagon like peptide (GLP-1) may be important factors promoting the WR process (Santo *et al.*, 2015). Reportedly, WR is attributed to a failure to sustain elevated plasma peptide YY (PYY) concentrations (Meguid *et al.*, 2008). The hormone imbalance effect on WL has been demonstrated and diverse studies are currently developing therapeutic compounds in order to regulate this gut hormones misbalance (Bhat, 2017; Monteiro, 2011).

On the other hand, reactive hypoglycaemia caused by changes in intestinal anatomy after bariatric surgery has been described as another cause of WR, inducing an early and important insulin surge by the hypersecretion of GIP and GLP-1 (Roslin *et al.*, 2011; Salehi *et al.*, 2011). These episodes of low glucose levels may stimulate appetite, leading to a snacking or grazing eating behavior. Management of this problem is focused on changing dietary regimen in order to minimize glucose level variations and subsequent hunger (Roslin *et al.*, 2011).

- *Mental health.* Unrecognized and untreated eating and psychiatric disorders may cause WR in some patients after bariatric surgery because eating disturbances tend to persist after surgery. The frequency of grazing, which is defined as uncontrolled eating of small amounts of food (Saunders, 2004), has been positively correlated with WR (Kofman *et al.*, 2010). In this regard, patients classified as binge eaters showed an increase in their BMI compared to non-binge eaters after RYGB (Kalarchian *et al.*, 2002). Furthermore, patients with two or more psychiatric diagnoses, showed an increase in WR after RYGB (six times) relative

to those without or with 1 psychiatric diagnosis (Rutledge *et al.*, 2011). Hence, a psychological evaluation by a qualified mental health team of all patients before and after surgery is of great importance.

- *Physical inactivity.* Physical activity is closely related to WL and patients who perform physical exercise have the lowest WR incidence (Freire *et al.*, 2012). Although patients undergoing bariatric surgery are not very physically active, a recent meta-analysis has demonstrated that from a total of seventeen studies, seven have reported an increase in activity at 3–6 months, and at 11–12 months (Herring *et al.*, 2016). However, further studies are needed to clearly define the mode, frequency, duration and intensity of physical activity to provide health benefits after bariatric surgery (Coen and Goodpaster, 2015)
- *Anatomic/surgical factors.* Pouch dilatation, increase in stoma size and gastro-gastric fistula are identified as common causes of WR after gastric bypass (Heneghan *et al.*, 2012; O'Brien *et al.*, 2013) and each specific complication appears according to the type of bariatric surgery. In AGB, as the stomach is a distensible organ, able to expand to accommodate food boluses, gastric pouch may enlarge in up to 50% of patients at 4 years (Kuzmak and Burak, 1993). In RYGB, in addition to enlargement of gastric pouch, stomal dilation and the presence of a gastro-gastric fistula are important anatomic changes that reduce the effectiveness of the RYGB (Yimcharoen *et al.*, 2011; Cucchi *et al.*, 1995). Finally, some authors have suggested that gastric capacity increases after SG, with the size of the gastric sleeve being linearly correlated with post-operative BMI (Braghetto *et al.*, 2009; Weiner *et al.*, 2007). In this sense, several surgical interventions with varying efficiency have been proposed in order to reduce its adverse effects.

Bariatric Surgery in Type 2 Diabetes Remission

In the 1990s, Pories et al. reported that among 146 morbidly obese patients with T2D who underwent gastric bypass, 121 (83%) experienced a rapid and prolonged post-operative normalization of plasma glucose levels without the need for glucose-lowering medication (Pories *et al.*, 1995). The improvement or remission of T2D after bariatric surgery has been later confirmed in other studies (Schauer et al., 2012, 2014, 2017; Adams *et al.*, 2012; Carlsson *et al.*, 2012; Kashyap *et al.*, 2013). However, depending on the type of surgery performed, some differences in patient outcomes may be observed. In fact, restrictive interventions have generally demonstrated a smaller effect on T2D resolution, hypertension and dyslipidemia than mixed techniques (Frühbeck, 2015).

The SOS study described 28.4 cases per 1000 person-year in the control group whereas 6.8 cases per 1000 person-years in the bariatric surgery group diagnosed with T2D (Carlsson *et al.*, 2012). In the LABS study, among participants who had diabetes at baseline, 67.5% that underwent RYGB and 28.6% of patients undergoing AGB experienced partial remission of T2D at 3 years, achieving levels of haemoglobinA1c (HbA1c) $<6.5\%$ or fasting plasma glucose values <126 mg/dL without pharmacological therapy (Courcoulas *et al.*, 2013; Schauer *et al.*, 2014). Different randomized controlled trials have studied patients with suboptimal controlled T2D and BMI ranging from 30.0 to 39.9 kg/m^2, showing that 49% of patients who underwent RYGB achieved defined T2D management goals (HbA1c $< 7.0\%$, LDL- cholesterol <100 mg/dL and systolic blood pressure < 130 mmHg) compared with 19% of patients in the lifestyle-medical management group (Ikramuddin *et al.*, 2013).

However, despite the recognized efficacy of bariatric surgery in improving T2D, not all patients respond in the same way and not all of them experience resolution of the disease (Davies *et al.*, 2014). For this reason, the identification of risk prediction models of T2D remission after bariatric surgery constitutes a topic of great interest for clinicians and patients. Diverse studies have evaluated different parameters associated with the improvement of T2D after bariatric surgery. In 2003, Schauer et al. described that the preoperative duration of T2D, the use of insulin, as well as a high percentage of HbA1c and lower WL after surgery, were factors that influence the remission of T2D (Schauer *et al.*, 2003). Few years ago, the percentage of excess weight loss (% EWL) was suggested as the only predictor for diabetes remission (Hamza *et al.*, 2011). Young age and lower BMI have been also proposed as predictors of long-term glycaemic control (Huang *et al.*, 2011). Although several studies are in line with these findings, a reproducible risk prediction model has not been validated until now (Zhang *et al.*, 2016). Among the available systems, only two have undergone external validation, the Diabetes Surgery score (ABCD score) and the Diabetes Remission (DiaRem) score (Lee *et al.*, 2013; Still *et al.*, 2014). The ABCD score includes four categorical variables to predict the success in the remission of T2D: age, body mass index (BMI), C-peptide levels, and T2D duration. The ABCD score is a multidimensional 10-point scale, constructed with these parameters, in which greater scores indicate a better chance of T2D remission. The model has been validated in three independent cohorts (Lee et al., 2013, 2015a, b). The DiaRem score also includes four preoperative clinical variables to predict remission of T2D after RYGB: age, HbA1c levels, type of antidiabetic treatment and the use of insulin. DiaRem ranges from 0 to 22 points and it is divided into five groups corresponding to five probability-ranges for T2D remission: 0–2 points (88%–99% remission), 3–7 points (64%–88% remission), 8–12 points (23%–49% remission), 13–17 points (11%–33% remission), 18–22 points (2%–16% remission). This model has been validated in two independent cohorts (Still *et al.*, 2014).

Interestingly, the improvements in glycaemic control after surgery often occur immediately within days of the operation, independently of WL (Dirksen *et al.*, 2012; Madsbad *et al.*, 2014). In fact, due to the beneficial effects of bariatric surgery on the resolution of diabetes and other metabolic alterations, these procedures are now also considered as metabolic surgery (Frühbeck, 2015). For this reason, the eligibility criteria for metabolic surgery have been changed and new guidelines consider metabolic surgery in patients with a BMI ranging from 30.0 to 34.9 kg/m^2 with associated T2D (Moncada *et al.*, 2016; Rubino *et al.*, 2016).

Metabolic surgery

Although the mechanisms by which bariatric surgeries improve glycaemic levels remain poorly understood, different explanations have been proposed (Ashrafian *et al.*, 2010). There is evidence that a lower caloric intake significantly influences glucose metabolism (Gumbs *et al.*, 2005). Changes in secretion of gut derived hormones, such as GLP-1, PYY, oxyntomodulin, GIP and ghrelin have been also suggested as potential mechanisms (Dirksen *et al.*, 2012). Moreover, an increase in insulin secretion and sensitivity in addition to changes in neural connection between the intestine and the brain, especially the vagus nerve, might play an important role in T2D remission (Joshua *et al.*, 2009). Finally, postoperative alterations in bile acid recirculation, as well as intestinal rearrangement and changes in gut microbiota composition have been linked to improvements in the glucose metabolism (Seeley *et al.*, 2015; Vitek and Haluzik, 2016).

Taken into account the multiple mechanisms contributing to the remission of diabetes after gastric bypass, 3 main hypotheses have been proposed to understand the early, weight-independent effects of metabolic surgery: the foregut, the midgut and the hindgut hypothesis. None of these theories necessarily excludes the others, so the three hypotheses are possible and may occur at the same time (**Fig. 1**).

- *Foregut exclusion hypothesis:* This theory contends that the exclusion of a short segment of the proximal small intestine (primarily the duodenum) and the alteration of the way of ingested food after gastric bypass, results in the release of a signal or signals with anti-diabetic properties (Guidone *et al.*, 2006; Hickey *et al.*, 1998; Pories and Albrecht, 2001). Evidence for this hypothesis was provided in a non-obese diabetic rodent model (Goto-Kakizaki) where rats underwent a duodenal-jejunal bypass (DJB) (which is a stomach-preserving RYGB that excludes the proximal intestine) or a gastrojejunostomy (GJ) (without bypassing any intestine). Rats undergoing DJB showed an improved glucose tolerance, whereas rats undergoing GJ did not exhibit any improvements. When the procedures were surgically reversed, diabetes returned when the DJB was converted to a GJ and resolved when the GJ was converted to a DJB (Rubino *et al.*, 2006).
- *Midgut hypothesis:* When glucose is present in the portal vein, portal afferents communicate with the vagus nerve decreasing hunger through hypothalamic centers. Using a gastric bypass model in mice, Troy et al. concluded that this procedure promoted intestinal gluconeogenesis and stimulated the hepatoportal glucose sensor (Troy *et al.*, 2008). Consequently, gastric bypass modifies the insulin sensitivity of hepatic glucose production and food intake independently of body WL and gut hormone actions.
- *Hindgut hypothesis:* This hypothesis suggests that the rapid delivery of ingested nutrients to the distal bowel accentuates secretion of gut hormones, which are delivered from the hindgut (terminal ileum, colon and rectum) (Rubino *et al.*, 2004; Cummings *et al.*, 2007). Among these hormones are GLP-1, PYY and oxyntomodulin. These peptides can reduce food intake and their contribution to diabetes resolution has been increasingly recognized (Ashrafian and le Roux, 2009).

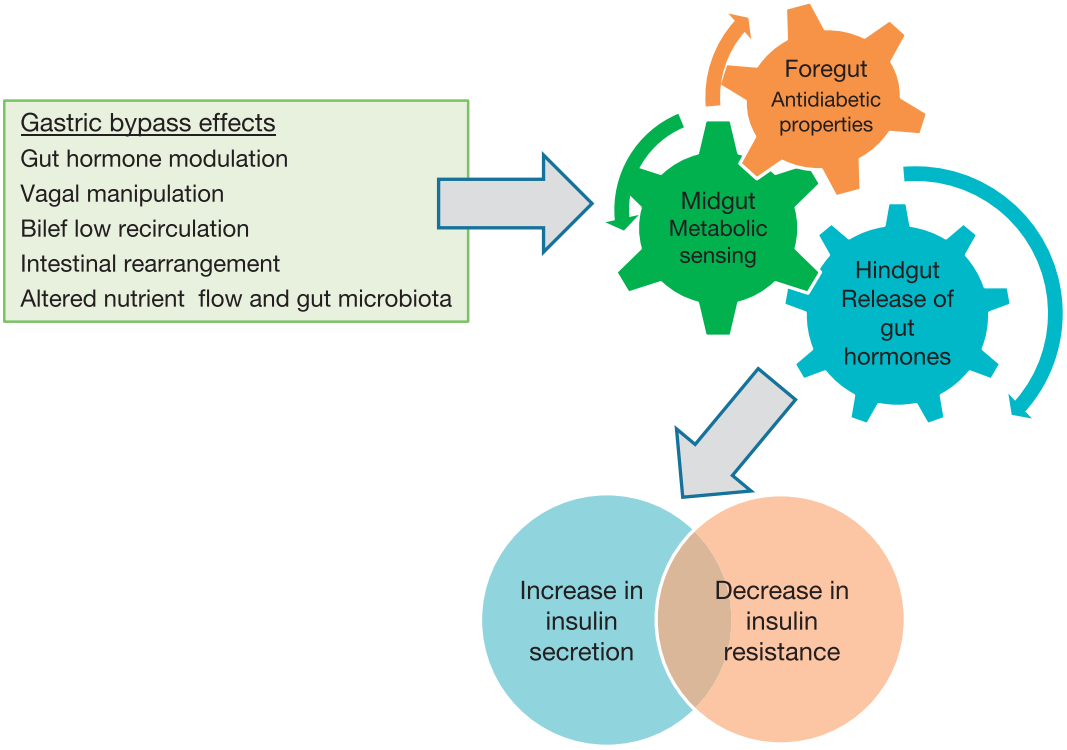

Fig. 1 Hypotheses proposed in the resolution of type 2 diabetes after gastric bypass.Diabetes resolution and hyperinsulinemia after metabolic Roux-en-Y gastric bypass.

In conclusion, weight-dependent and weight-independent mechanisms are responsible for the improvements in glycaemic control, and probably additional effects, which are still unknown, may be also participating. For this reason, further studies are required to determine the precise mechanisms of diabetes resolution after surgery.

Long-Term Cardiovascular Events after Surgery

In comparison with pharmacotherapy, bariatric surgery was associated with lower long-term cardiovascular (CV) death and lower incidence of CV events in obese adults (Sjöström *et al.*, 2012; Kwok *et al.*, 2014; Beamish *et al.*, 2016). Interestingly, bariatric surgery was also associated with a reduced myocardial infarction (MI) incidence in obese individuals with T2D, while no effect was observed on stroke incidence. Moreover, the effect of surgery in reducing MI incidence was stronger in individuals with higher serum total cholesterol and triglycerides at baseline, whereas BMI was not related with surgical outcomes (Romeo *et al.*, 2012).

Together with WL, there are different possible mechanisms that may explain the role of bariatric surgery in the reduction of CV events (Boido *et al.*, 2015). After surgery, WL is associated with reduction of visceral fat and a decreased number of adipocytes, directly modulating the levels of adipokines secretion, specifically adiponectin, leptin and C-reactive protein (CRP), which are intimately involved in the reduction of CV diseases and CV mortality (Gómez-Ambrosi *et al.*, 2017; Appachi and Kashyap, 2013). On the other hand, surgery decreases serum levels of molecules mediating endothelial dysfunction. Among them, oxidized low density lipoprotein (LDL), intracellular adhesion molecule-1 (ICAM1), endothelin-1, *E*-selectin, P-selectin and vascular endothelial growth factor A (VEGFA) have been described as markers reflecting the CV risk level (Uzun *et al.*, 2004; Pontiroli *et al.*, 2004; Garcia de la Torre *et al.*, 2008; Nijhuis *et al.*, 2007). The intervention also reduce systemic inflammation, oxidative stress, erythrocyte sedimentation rate, known to predict coronary mortality (Bacci *et al.*, 2002), as well as levels of sialic acid, PAI-1, malondialdehyde and von Willebrand factor, which have important roles in atherosclerosis development (Uzun *et al.*, 2004; Vazquez *et al.*, 2005). Recently a significant increase in HDL-cholesterol and apolipoprotein ApoA4 levels after gastric bypass has been reported being associated with a relevant improvement in hepatic insulin sensitivity (Raffaelli *et al.*, 2014). Finally, several trials have shown that liver steatosis, which is an emerging risk factor for CV disease (Calori *et al.*, 2011), decreases after bariatric surgery (Dixon *et al.*, 2006; Folini *et al.*, 2014).

In this sense, pleiotropic effects of WL achieved by surgery mediate improvements in CV events and the prevention of CV disease may depend, among other factors, on the baseline conditions of the patients. However, further research should be conducted to evaluate more effects of bariatric surgery at physiological and cellular levels, as well as the efficacy of different surgical techniques.

Other Health Benefits

Obstructive sleep apnoea (OSA)

Obesity is frequently associated with OSA, a common disorder of repetitive pharyngeal collapse during sleep, leading to oxygen desaturation and disrupted sleep (Young *et al.*, 2002; Jordan *et al.*, 2014). Bariatric surgery considerably improves or resolves the symptoms of OSA in most morbidly obese individuals (Ashrafian *et al.*, 2012). The beneficial effects of the operation on OSA may include mechanical weight-dependent and metabolic weight-independent mechanisms. These include adipokine effects, cytokine actions, altered gut hormonal release and the improvements of insulin resistance (Ashrafian *et al.*, 2012).

In the SOS study, patients with sustained WL after bariatric surgery display less severe sleep apnoea, reduced inflammatory activity, and enhanced cardiac function. In addition, persisting sleep apnoea appears to limit the beneficial effects of WL on inflammation and cardiac performance (Kardassis *et al.*, 2013). Further research is required to evaluate differences between surgical and non-surgical treatment of obesity and to determine the mechanisms underlying resolution of OSA.

Osteoarthritis and joint problems

Osteoarthritis is a very common problem in weight-bearing joints, especially in aged population and obesity has been identified as the main modifiable risk factor (Blagojevic *et al.*, 2010). The excess adipose tissue in obese individuals leads to the release of pro-inflammatory mediators, which may damage the cartilage within joints (Messier, 2008). WL reduces the risk of incident knee OA, and, in established disease, reduces symptoms, improves function and is likely to reduce disease progression. However, osteoarthritis also has a multifactorial etiology with its systemic effects being related to the adipokine profile and metainflammation (Wluka *et al.*, 2013). Recent studies have demonstrated that bariatric surgery may benefit obese patients with hip or knee osteoarthritis. However, more randomized controlled trials are needed to clarify the role and indications for bariatric surgery in these type of diseases (Gill *et al.*, 2011).

Kidney function

Obesity itself has been known to be an independent risk factor for the development of chronic kidney disease (CKD) (de Jong *et al.*, 2002). Moreover, hyperglycemia induces the production of vasodilatory prostaglandins, angiotensin II, inflammatory cytokines and reactive oxygen species, which damage the glomerulus (Caramori and Mauer, 2003). For this reason, in patients with T2D, obesity amplifies the risk for CKD (Ziyadeh, 2004).

Several studies have reported that bariatric surgery improves kidney function decreasing albuminuria proportionally to WL (Agrawal *et al.*, 2009; Iaconelli *et al.*, 2011). Moreover, the resolution of diabetes chronic disease (DKD) following RYGB in obese patients has been also described in different case report studies (Izzedine *et al.*, 2005; Perez *et al.*, 2006). It is true that to date, few analyses have examined the effects of bariatric surgery beyond the first post-operative year, but a recent 5-year prospective study has demonstrated that the improvement in glomerular filtration is maintained for up to 5 years (Neff *et al.*, 2017).

However, it should be noted that mixed procedures, such as RYGB, increase the risk for oxalate nephropathy, which could rapidly progress to end stage kidney disease (ESKD), especially in patients with long-standing diabetes and pre-existing renal insufficiency. In this sense, more controlled studies are warranted to provide with more details the effects and mechanisms of action of bariatric surgery on kidneys function (Rao *et al.*, 2014).

Factors Involved in the Metabolic Effects of Bariatric Surgery

The exact molecular, cellular and physiological mechanisms for metabolic improvements in patients who undergo bariatric surgery remain unclear. Although these procedures cause a reduction of the gastric size and a decrease in calorie absorption, these changes in the digestive tract cannot fully explain all the metabolic improvements that occur after bariatric surgery. For this reason, immense efforts are being performed to identify the mechanisms that occur across different biological systems after bariatric surgery (Dirksen *et al.*, 2012; Miras and le Roux, 2013; Abdeen and le Roux, 2015; Kohli and Diabetes, 2013; Kohli *et al.*, 2011; Ionut *et al.*, 2013).

Changes in Adipocyte-Derived Factors

Several studies have investigated the potential role of adipokines after bariatric surgery. It was clearly demonstrated that the plasma levels of adiponectin increase post-operatively (Trakhtenbroit *et al.*, 2009; Korner *et al.*, 2009) being associated with a lower risk of T2D (Li *et al.*, 2009). In contrast, other adipose-derived factors such as leptin and insulin decrease in proportion to WL achieved by bariatric surgery (Garcia de la Torre *et al.*, 2008; Trakhtenbroit *et al.*, 2009). On the other hand, inflammation in adipose tissue is known to contribute to local and peripheral insulin resistance (Reilly and Saltiel, 2017). The infiltrated macrophages of the adipose tissue constitute an important source of pro-inflammatory cytokines including tumor necrosis factor (TNF)-α, plasminogen activator 1 (PAI-1) and interleukin-6 (IL-6) (Galic *et al.*, 2010). A link between the resolution of the inflammatory state and metabolic improvements in obese subjects after bariatric surgery has been described, reducing pro-inflammatory cytokine levels and ameliorating glucose metabolism (Zhang *et al.*, 2011; Forsythe *et al.*, 2008; Hu *et al.*, 2013).

Changes in Gut-Derived Hormones

Changes in gastrointestinal hormones have been proposed as key candidates in the context of metabolic improvements after bariatric surgery. GLP-1 is an incretin secreted by L-cells in the small intestine in response to food intake (Suzuki *et al.*, 2012). GLP-1 stimulates insulin release and inhibits glucagon secretion, gastric emptying as well as food intake, leading to reduction of glycaemia and weight loss (Drucker, 2001). Moreover, PYY is also secreted by L-cells together with GLP-1 after food intake, and by acting at the arcuate nucleus of the hypothalamus decreases appetite (Batterham *et al.*, 2002). In addition, gastric bypass also modulates the secretion of other glucose-regulatory gut hormones such as oxyntomodulin and GIP. Although an increase in the secretion of these hormones improves glucose homeostasis, most of the studies reveal a non-significant modulation of their levels (Ashrafian *et al.*, 2010). Furthermore, reduced ghrelin is another of the proposed hormonal mechanisms to explain WL after surgery. Plasma ghrelin is notably reduced after SG and RYGB being this decrease dependent on the excluded gastric fundus in the surgery (Frühbeck et al., 2004a, b).

Bile Acids and Fibroblast Growth Factor 19 (FGF19)

Increased serum levels of bile acids after RYGB have been reported by different studies (Ahmad *et al.*, 2013; Nakatani *et al.*, 2009). Patti et al. demonstrated that post bile acid concentrations correlate with key metabolic parameters after RYGB, including an inverse association with 2-h post-meal glucose, triglycerides, and thyroid-stimulating hormone (TSH) levels, as well as a positive correlation with adiponectin and with the post-meal peak of GLP-1 levels (Patti *et al.*, 2009).

Gerhard et al. confirmed previous results showing that bile acids in addition to fibroblast growth factor 19 (FGF19), were higher in patients with sustained remission of T2D after RYGB (Gerhard *et al.*, 2013). In agreement with this finding, a recent study has established that FGF19 levels in obese patients increase after bariatric surgery-induced WL independently of the type of surgical procedure, but not after diet-induced WL (Gómez-Ambrosi *et al.*, 2016). FGF19 is expressed in ileal enterocytes of small intestine and colon (Fon Tacer *et al.*, 2010; Izaguirre *et al.*, 2017) and acts principally on the liver regulating negatively bile acid synthesis (Holt *et al.*, 2003). The increased serum levels of both, bile acids and FGF-19, is explained by the hepatic insulin resistance present in patients with T2D, exhibiting a decreased uptake of bile acids by the liver cells (Kohli and Diabetes, 2013).

The Role of the Gut Microbiota

The role of the gut microbiota in the context of obesity has currently attracted considerable interest to explain the beneficial effects of bariatric surgery. The gut microbiota may play a role in obesity by increasing the host's energy-harvesting efficiency (Turnbaugh *et al.*, 2006). Reportedly, RYGB restructures the gut microbiota, prompting the hypothesis that these changes may lead to WL after surgery (Furet *et al.*, 2010; Zhang *et al.*, 2009). In fact, Liou et al. have demonstrated that transfecting the gut microbiota from RYGB-treated mice to non-operated ones, resulted in WL and reduced fat mass in the recipient animals (Liou *et al.*, 2013). These results highlight the important roles of the gut microbiota after bariatric surgery and further studies are warranted to determine exactly their potential action to reduce the weight and adiposity of the host after RYGB.

In conclusion, although new studies are helping to understand the molecular mechanisms behind the bariatric surgery, more controlled studies are needed to improve the use of these procedures. Thus, bariatric surgery remains an inspiration in the search for new drug targets for WL.

Assessing the Long-Term Outcomes of Bariatric Surgery in Adolescents

The prevalence of obesity in adolescents has markedly increased worldwide across the past three decades (Ng *et al.*, 2014; Skinner and Skelton, 2014) and, as in the adult population, it is associated with preventable chronic comorbidities including hypertension, T2D, OSA, polycystic ovarian syndrome, dyslipidaemia, fatty liver disease and different musculoskeletal disorders (Rocchini, 2011; Juonala *et al.*, 2011; Shah *et al.*, 2015). Furthermore, obese children and adolescent loose self-esteem, suffer psychologically and perceive social exclusion (Russell-Mayhew *et al.*, 2012). Thus, effective treatment strategies are urgently needed.

Nowadays, obesity in adolescents is mostly managed by behavioral (diet, exercise and lifestyle modifications) and pharmacological approaches, but they are frequently limited to the short-term (Danielsson *et al.*, 2012). As a result, bariatric procedures have begun to be considered as a potential treatment option and consequently, the number of adolescents undergoing bariatric surgery is increasing worldwide (Lennerz *et al.*, 2014; Kelleher *et al.*, 2013). The guidelines from the *International Paediatric Endosurgery Group (IPEG)* state that adolescents with a BMI >40 kg/m^2 or a BMI $>$ 35 kg/m^2 combined with severe comorbidities should be considered for surgical intervention, if they have (nearly) achieved adult stature (International Pediatric Endosurgery Group (IPEG), 2009).

Inge et al. from USA (Inge *et al.*, 2017) and Olbers and colleagues from Sweden (Olbers *et al.*, 2017) have recently published two novel and important studies showing the long-term effects of bariatric surgery in adolescents. Inge et al. *(Inge* et al., *2017)* showed a substantial and durable body weight reduction as well as cardiometabolic benefits for young adults after bariatric surgery in a long-term longitudinal study including 58 adolescents (aged 13–21 years at baseline). However, some of the patients included in the study presented mild anemia, hyperparathyroidism and low amounts of vitamin B12. In this regard, they proposed that long-term health maintenance after RYGB should be focused on adherence to dietary supplements and the management of micronutrient deficiencies (Inge *et al.*, 2017). Olbers and colleagues (Olbers *et al.*, 2017) included 81 adolescents (aged 13–18 years at baseline) in their *Adolescent Morbid Obesity Surgery (AMOS)* prospective study. In the same line, adolescents with severe obesity undergoing RYGB showed a substantial WL over 5 years together with improvements in comorbidities and cardiovascular risk factors. However, gastric bypass was associated with additional surgical interventions and nutritional deficiencies. In contrast, conventional non-surgical treatment was associated with WR and a quarter of patients underwent bariatric surgery within 5 years (Olbers *et al.*, 2017).

Nevertheless, the available literature describing long-term outcomes in teenagers is still limited and it is necessary to consider some concerns related to adolescent bariatric surgery (Beamish and Reinehr, 2017). Firstly, it has to be highlighted that different side effects after bariatric surgery in adolescents have been outlined in different studies including the *Teen-Longitudinal Assessment of Bariatric Surgery (Teen-LABS)* study from the United States (Inge et al., 2014, 2016), the *AMOS* study in Sweden (Olbers *et al.*, 2012) and the *Germany Obesity Registry*, among others (Lennerz *et al.*, 2014). One of the main side effects is the dumping syndrome, which is a well-known complication of upper gastrointestinal surgery (Laurenius *et al.*, 2013) that comprises diverse symptoms such as abdominal pain, diarrhea, nausea, bloating, palpitations as well as hypotension and syncope. Secondly, all bariatric surgery techniques implicate a risk of vitamin and micronutrient deficiency that may lead to growth retardation (Becker *et al.*, 2012). Finally, the refeeding syndrome, which is an important complication after resumption of nutrition, might produce severe electrolyte imbalance and, hence, its early recognition is vital to reduce morbidity and mortality after bariatric surgery (Mehanna *et al.*, 2008). On the other hand, eating disorders and other psychiatric diseases among adolescents with severe obesity may be considered as exclusion criteria for bariatric surgery due to the suboptimal WL or even continued weight gain after bariatric procedure in these patients. Importantly, two cases of attempted suicide in the *AMOS* study and different cases of drug abusers have been reported after bariatric surgery (Jarvholm *et al.*, 2012).

Therefore, a multidisciplinary team should discuss bariatric surgery on an individual-case to assess the potential deterioration in the quality of life after the bariatric procedure. Moreover, the patients and their families must be educated regarding the benefits and risks, including the irreversibility of some procedures, potential side effects, expected changes in eating behavior and the lifelong requirement for regular medical follow-up after surgery (Beamish and Reinehr, 2017).

Complications of Bariatric Surgery

Although bariatric surgical procedures confer effective WL with a reduction in comorbid conditions, they carry substantial consequences that physicians should be aware of and consider in a pre- and post-operative assessment.

Dumping Syndrome

The dumping syndrome refers to symptoms and signs that occur when food reaches the small bowel too rapidly as a result of a defect in grinding or sieving within the stomach (Tack *et al.*, 2009). After bariatric surgical procedures that involve partial gastrectomy, such as RYGB and SG, up to 40% of patients have dumping syndrome symptoms (Banerjee *et al.*, 2013; Tzovaras *et al.*, 2012).

Symptoms normally start with food intake and they are divided into "early" and "late" symptoms (Tack *et al.*, 2009; Arts *et al.*, 2009) (**Table 3**). Early symptoms occur in response to the rapid passage of hyperosmolar contents to the duodenum, causing the move of fluid from the intravascular compartment to the intestinal lumen (Johnson *et al.*, 1962). Late dumping occurs 1 or 3 h after meal ingestion and it is caused by a reactive hypoglycaemia secondary to a hyperinsulinemia (Eloy *et al.*, 1975). Recently, the gut hormone GLP-1 has been shown to play a key role in the pathogenesis of late hypoglycaemia after gastric bypass (Salehi *et al.*, 2014).

Initial therapy for dumping consists of different dietary guidelines such as: 1) eat small and frequent meals; 2) avoid ingestion of liquids within 30 min of a solid-food meal; 3) avoid simple sugars and increase the intake of fiber and complex carbohydrates; and 4) increase protein intake (Heber *et al.*, 2010). An adequate response to the dumping syndrome is observed in 95% of cases after nutritional counseling (Zurita Mv *et al.*, 2013). However, different pharmacological therapies to slow gastric emptying and to inhibit the release of several gastrointestinal peptides involved in the development of the dumping syndrome such as somatostatin analogues, may be considered if dietary guidelines fail (Arts *et al.*, 2009; Deloose *et al.*, 2014). Finally, in difficult-to-manage patients ($<1\%$), a surgical re-intervention may be considered to reconstruct the gastric reservoir or to insert a short anti-peristaltic loop (Zurita Mv *et al.*, 2013).

Nutritional Deficiencies after Bariatric Surgery

Nutrient deficiencies constitute the most important long-term complications of bariatric surgery leading to the development of hematological, metabolic and especially neurological disorders that are not always reversible.

Unfortunately, the more effective surgical options for inducing WL are more likely to develop nutritional deficiencies. Restrictive techniques such as AGB and SG produce less frequently nutritional deficits, whereas RYGB and BPD, with a malabsortive component, are associated with higher prevalence of nutritional deficiencies. The preoperative nutritional status of the patient is another variable mainly related with nutritional deficiencies after bariatric surgery (Hammer, 2012). In addition, a common factor to all bariatric surgery techniques contributing to the occurrence of deficiencies is the reduced overall nutrient intake in the early post-operative phase (Saltzman and Karl, 2013). Specific deficiencies may require precise approaches and supplements, as described below:

Vitamin deficiencies after bariatric surgery

- Vitamin B1 (thiamine) deficiency is present in up to 49% of patients after RYGB, being the major nutritional complication (Lakhani *et al.*, 2008). Vomiting after bariatric intervention together with poor food and supplements are the principal risk

Table 3 Symptoms in dumping syndrome

Early dumping	*Late dumping*
Gastrointestinal symptoms:	**Hypoglycemia**:
Abdominal pain	Perspiration
Diarrhea	Palpitations
Bloating	Hunger
Nausea	Weakness
	Confusion
	Tremor
	Syncope
Vasomotor symptoms	

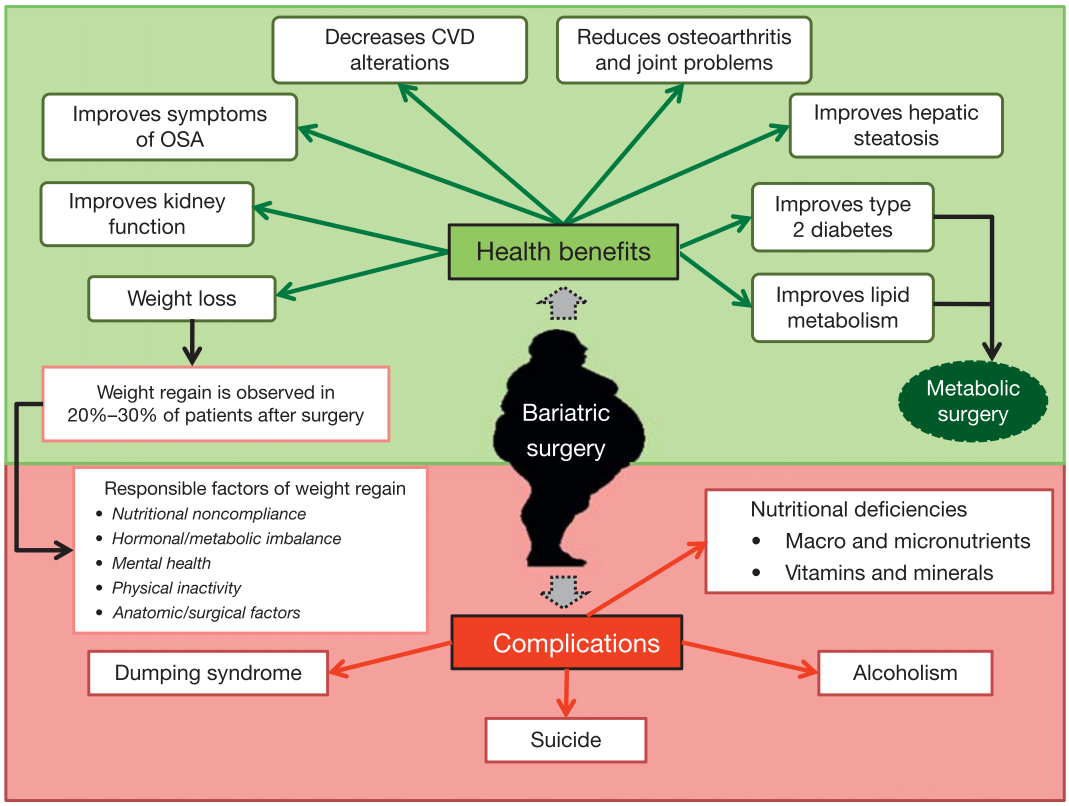

Fig. 2 The main health benefits and complications of bariatric surgery.

factors for developing thiamine deficiency (Galvin *et al.*, 2010). Clinical manifestations of thiamine lack include Wernicke's encephalopathy and Korsakoff syndrome, among others (Landais, 2014). Since thiamine deficiency may lead to irreversible neurological damage, the *European Federation of Neurological Societies* recommends a follow up of thiamine status at least 6 months post-operatively as well as a parenteral thiamine supplementation (beriberi factor) (Galvin *et al.*, 2010). In particular cases, oral thiamine supplementation after bariatric surgery may not resolve thiamine deficiency, being associated with small intestinal bacterial overgrowth and antibiotic therapy may be required (Lakhani *et al.*, 2008).

- Vitamin B12 (cobalamin) deficiency. The prevalence of the lack of vitamin B12 is 3.6% 12-months after RYGB (Clements *et al.*, 2006), rising to 61.8% at 5-years after RYGB (Dalcanale *et al.*, 2010). The mechanisms underlying vitamin B12 deficiency are the reduced intake of meat, the diminished contact of food with gastric acid and the decreased secretion of intrinsic factor (Herrmann and Obeid, 2008). Clinical manifestations include megaloblastic anemia, potentially irreversible peripheral neuropathy, as well as depression and neuropsychiatric symptoms. Effective treatment for vitamin B12 deficiency include oral, intramuscular, nasal or sublingual vitamin B12 supplementation (Herrmann and Obeid, 2008).
- Vitamin B9 (folate) deficiency. Megaloblastic anemia, weakness, anorexia and WL are potential symptoms of folate deficiency. It is of special consideration in pregnant women because maternal folate deficiency is associated with neural tube defects in newborns (American College of Obstetricians and Gynecologists, 2005). For prevention, women who are trying to become pregnant after bariatric surgery should receive 1 mg of folic acid daily, as a routine supplement (Bal *et al.*, 2010).
- Vitamin D deficiency. It is described as a common cause of calcium metabolism disorders and metabolic bone disease leading to osteoporosis and possibly fractures after surgical procedures (Johnson *et al.*, 2005). Aarts et al. described that 39% of patients exhibited vitamin D deficiency despite daily multivitamin supplementation (Aarts *et al.*, 2011). Intake of vitamin D3 or D2 should be initiated with oral vitamin D once weekly and 8–12 weeks after the start of supplementation 25-hydroxyvitamin D levels should be measured to confirm repletion (Levinson *et al.*, 2013). Moreover, in order to avoid bone fractures after bariatric surgery, measurements of calcium, vitamin D and parathyroid hormone as well as preoperative and postoperative follow-up bone mineral density measurements is recommended after bariatric surgery (Heber *et al.*, 2010).
- Vitamin A deficiency. The origin of vitamin A deficiency includes a relative deficiency of bile acids in the bypassed duodenojejunal segment as well as desconjugation of bile acids by upper gut bacterial overgrowth because fat soluble vitamins require micelle formation with bile acids to be assimilated (Hatizifotis *et al.*, 2003). Clinical manifestations include a sensation of dry eyes, reduced night vision, itching and dry hair. In case of vitamin A deficiency, the initial treatment is oral supplementation but in women who want to become pregnant, supplements of vitamin A should be carefully used because hypervitaminosis A may induce teratogenic effects (Tack and Deloose, 2014).

Mineral deficiencies after bariatric surgery

- Iron deficiency. Anemia is common after bariatric surgery, specifically after RYGB (36% of patients 1 year after RYGB) (Cable *et al.*, 2011) compared to SG (1.5% of patients 1 year after SG) (Hakeam *et al.*, 2009). The responsible factors for iron deficiency are probably the reduced intake of meat, diminished contact of food with gastric acid and decreased intestinal absorption. The risk is increased in menstruating or pregnant females (Saltzman and Karl, 2013). Treatment of iron deficiency after bariatric surgery includes either 150–200 mg per day of oral elemental iron or ferrous salt-vitamin C combination. Non-responder patients to oral iron supplements are occasionally treated with parenteral therapies (Bal *et al.*, 2012).
- Zinc deficiency. A high risk for zinc deficiency after bariatric surgery has been reported, with higher prevalence 1 year after duodenal switch than after RYGB (Bal *et al.*, 2012). Symptoms of hypozincaemia include skin eruption, nail dystrophy, alopecia, hypoalbuminaemia (in patients with severe deficiency) and glossitis. In case of deficiency, doses of 60 mg of elemental zinc are recommended. However, administration of zinc may deplete copper stores and, hence, this should be considered when administering zinc supplements (Tack and Deloose, 2014).
- Copper deficiency has been reported in up to 18% of patients after bariatric surgery usually several months after the intervention (Levinson *et al.*, 2013). Low serum copper levels can lead to anemia, neutropenia and pancytopenia (Todd *et al.*, 2004; Fuhrman *et al.*, 2000). In addition, in the past decade, neurologists reported that some patients with hypocupraemia developed a new myeloneuropathy-like disorder with splastic gain and sensory ataxia (Kumar, 2006) and the symptoms were not fully reversed with cupper therapy. On the other hand, sudden bilateral blindness has been also reported in a patient with cupper deficiency after RYGB (Naismith *et al.*, 2009) and, unfortunately, the appropriate treatment for blindness after bariatric surgery is uncertain.

Conclusions

Bariatric surgery is the most effective treatment in producing sustainable WL and improvements in obesity-related comorbidities. The positive effects obtained regarding ameliorations in T2D after bariatric surgery, have expanded the eligibility criteria for metabolic surgery. However, operated patients do not respond in the same way, with a subset of subjects showing WR, failure of sustained WL and even T2D recidivism. Although it is true that some potential responsible factors have already been described, additional studies are needed to examine plausible undiscovered effects in an effort to enhance patients' benefits. On the other hand, bariatric procedures are not without risk with nutritional deficiencies being the most important long-term complication after bariatric surgery leading sometimes to metabolic and neurological disorders, which are not always reversible. Given the uncertainties between risks and benefits of bariatric surgery, the decision to undergo surgery should be based on a high quality multidisciplinary team in order to optimize patient selection criteria and outcomes (**Fig. 2**).

Metabolic Surgery; Indications and Outcomes

Lidia Castagneto-Gissey and James Casella-Mariolo, Sapienza University of Rome, Rome, Italy
Geltrude Mingrone, Catholic University, Rome, Italy and Guy's Campus, King's College London, London, United Kingdom

Introduction

Obesity prevalence and incidence are increasing not only in developed countries but also in developing countries. Obesity is an independent risk factor for cardiovascular diseases and diabetes and it is associated with a significant increase in all-cause mortality. Lifestyle modifications are indeed effective, but the number of patients responding well to the lifestyle interventions is limited (Look AHEAD Research Group *et al.*, 2016). The response rate to bariatric surgery is good also in the long term and thus these surgical interventions are becoming more popular.

In addition to weight loss, bariatric surgery has a large number of benefits, including improved control of glycaemia, hypertension, dyslipidemia with reduced cardiovascular diseases and female cancer mortality, often independent of body weight reduction. For these reasons bariatric surgery was renamed as metabolic surgery.

In this review we report the effects of metabolic surgery on obesity and its metabolic complications.

Mortality Reduction

The Swedish Obesity Study (SOS) showed that the mortality hazard ratio adjusted for gender-, age- and risk factors was 0.71 ($P = 0.01$) for obese subjects after bariatric surgery as compared with medical treatment (Sjöström *et al.*, 2007). The mortality reduction was driven by a substantial reduction in myocardial infarctions and female cancers, while insulin resistance rather than body mass index appeared to predict which patients would benefit most (Sjöström *et al.*, 2007).

In a retrospective cohort study with an average follow-up of 7.1 years the adjusted mortality from any cause in the Roux-en-Y gastric Bypass (RYGB) group decreased by 40%, as compared with that in the control group ($P < 0.001$) (Adams *et al.*, 2007). Cause-specific mortality was in particular lower for coronary artery disease, diabetes and female cancers. However, rates of death not caused by disease, such as accidents and suicide, were 58% higher in the surgery compared to the control group ($P = 0.04$).

Type 2 Diabetes and Its Vascular Complications

Metabolic surgery can place type 2 diabetes (T2D) in remission in several patients while almost all have a substantial improvement in glycemic control. Remission of T2D is common within the short term, that is, 1–2 years after surgery, but relapse occurs in many in the longer term, although glycemic control remains much improved (Schauer *et al.*, 2012, 2017; Mingrone *et al.*, 2012, 2015; Sjöström *et al.*, 2004, 2014). Importantly, the cumulative incidence of microvascular complications at 15 years follow-up (Sjöström *et al.*, 2014) was 41.8 per 1000 person-years (95% CI, 35.3–49.5) for patients not receiving surgery and 20.6 per 1000 person-years (95% CI, 17.0–24.9) in the surgery group (hazard ratio [HR], 0.44; 95% CI, 0.34–0.56; $P < 0.001$). Macrovascular complications (Sjöström *et al.*, 2014) were observed in 44.2 per 1000 person-years (95% CI, 37.5–52.1) in patients not receiving surgery and 31.7 per 1000 person-years (95% CI, 27.0–37.2) for the surgical group (HR, 0.68; 95% CI, 0.54–0.85; $P = 0.001$).

The benefits of surgery on microvascular disease are inversely proportional to diabetes duration. Thus the longer the length of the disease the lower is the reduction of diabetic vascular complications for the group (Sjöström *et al.*, 2014), this does however not mean that patients with long standing diabetes do not benefit. The numbers needed to treat (NNT) to achieve benefit may indeed be lower when surgery is used in those with established microvascular disease secondary to T2D as their disease may be controlled and even put into remission (Iaconelli *et al.*, 2011).

At the moment only two randomized controlled trials (RCT) report data 5 years after surgical or medical interventions. Mingrone *et al.* (2015) showed 5 year diabetes remission rates (defined as a fasting glucose concentration of 5.6 mmol/L or HbA1c $<6.5\%$ [≤ 47.5 mmol/mol] without active pharmacological treatment) of 37% after Roux en Y gastric bypass (RYGB) and of 63% after biliopancreatic diversion (BPD) while none of the patients in the medical arm achieved the criteria.

Schauer *et al.* (2017) found that 28.6% in the RYGB and 23.4% in the sleeve gastrectomy (SG) arms had HbA1c $<6\%$ with or without medication, while the end point was achieved in only 5.3% of the patients in the medical arm with the use of medication. However, while the difference with the medical arm was statistically significant ($P = 0.03$) after adjustment for multiple comparisons for RYGB it did not reach a statistical significance ($P = 0.07$) for SG patients. Importantly, if we focus on glycemic control rather than remission then metabolic surgery showed substantially better improvements in comparison with medical treatment (HbA1c 6.5 ± 1.3 vs. $7.6\% \pm 1.7\%$) (Schauer *et al.*, 2017).

The results on glycemic control after metabolic surgery as average between short and long term follow-up in RCTs is summarized in **Fig. 1** (Schauer *et al.*, 2012, 2014, 2017; Mingrone *et al.*, 2012, 2015; Cummings *et al.*, 2016; Ding *et al.*, 2015; Dixon

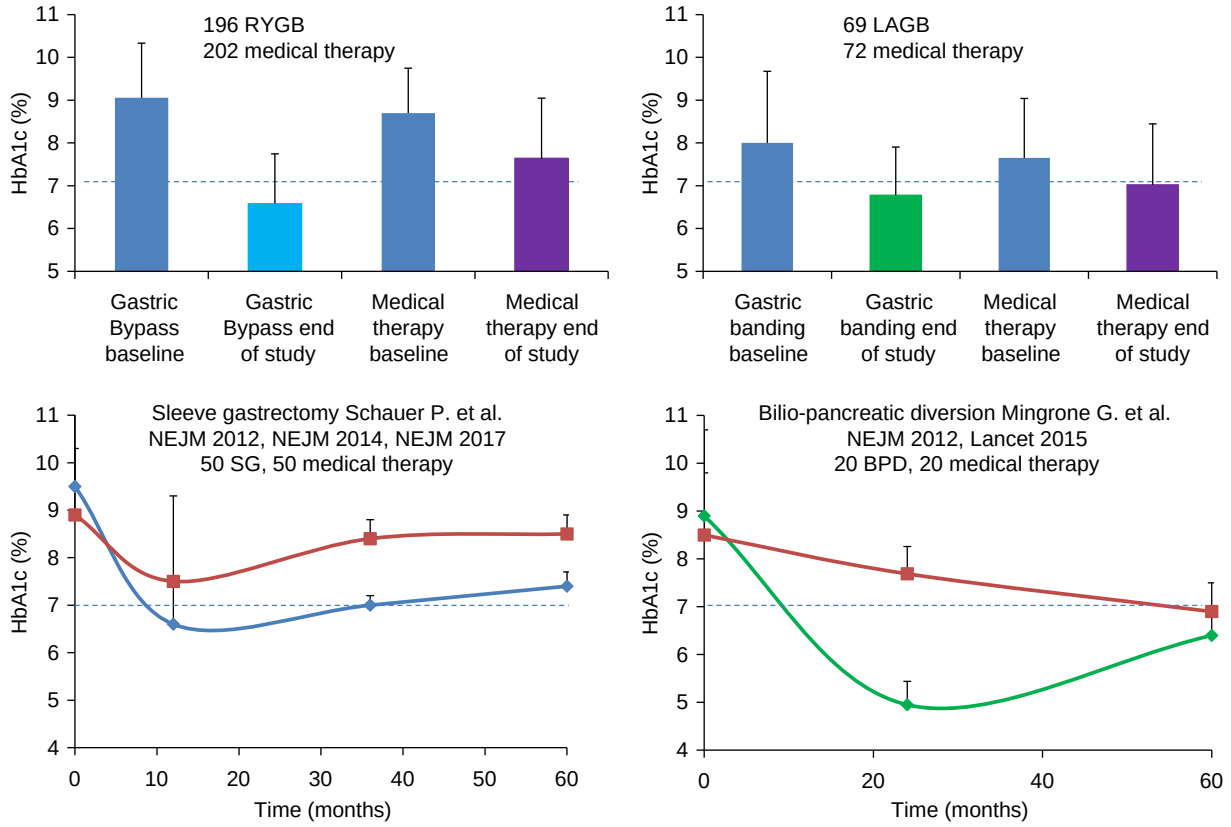

Fig. 1 End-study average glycated hemoglobin (mean ± SD) in type 2 diabetic subjects undergone bariatric/metabolic surgery ($n = 698$) or medical treatment plus lifestyle modifications ($n = 503$) from randomized controlled trials. Reference numbers are provided into brackets.

et al., 2008; Courcoulas *et al.*, 2014, 2015; Halperin *et al.*, 2014; Ikramuddin *et al.*, 2013, 2015; Liang *et al.*, 2013; Parikh *et al.*, 2014; Wentworth *et al.*, 2014).

Hypertension

Few clinical trials had hypertension improvement after bariatric surgery as primary outcome.

The Diabetes Surgery Study (Ikramuddin *et al.*, 2013, 2015) with achievement of the composite treatment goal of HbA_{1c} <7.0% (53 mmol/mol), LDL cholesterol <2.59 mmol/L, and systolic blood pressure <130 mmHg at 12 months as primary endpoint had 76% and 69% SBP reduction in the lifestyle and medical management and 82% and 80% in the RYGB group at 1 year and at 2 years respectively ($P = 0.2$). RYGB also had similar improvements ($P = 0.79$) than a program of intensive lifestyle intervention on nocturnal hypertension (Nordstrand *et al.*, 2012). The remission rate for hypertension was 19% after bariatric surgery as compared to 11% after medical treatment in the 10 years follow-up of the SOS study (Sjöström *et al.*, 2004).

Therefore, at first glance it seems that surgery isn't much better than anti-hypertensive drug treatment to improve blood pressure control, but it should be remembered that historically clinicians thought it a good idea to discontinue effective pharmacotherapy after bariatric surgery, while in more recent years surgery is now seen as an "add on therapy" and that effective pharmacotherapy should be continued to keep chronic diseases in control (Miras and le Roux, 2017). This later approach is likely to result in a reduction of dose of the medication but a substantial improvement in control of metabolic parameter (Miras and le Roux, 2014).

Hyperlipidemia

The Program on the Surgical Control of the Hyperlipidemias (POSCH) was the only RCT using a surgical approach with the primary endpoint of overall mortality linked to hyperlipidemia/atherosclerosis. Partial ileal bypass was compared with medical treatment and showed that the urgical approach normalized lipid profiles and reduced overall mortality at 18 years follow-up (Cottam *et al.*, 2006).

Ikramuddin *et al.* (2013) demonstrated in their RCT with as composite end-point HbA1c <7.0%, low-density lipoprotein cholesterol <100 mg/dL, and systolic blood pressure <130 mmHg, that 49% of patients reached the goal in the RYGB and 19% in the lifestyle-medical management arm, respectively.

We showed a highly significant ($P < 0.0001$) increase in HDL-cholesterol concentrations after RYGB (from 41.9 ± 7.2 to 56.6 ± 9.0 mg/dL) but not after dieting (Raffaelli *et al.*, 2014). Many prospective non randomized (Sjöström *et al.*, 2004; Fløl*o* *et al.*, 2017; Kothari *et al.*, 2017) and randomized (Schauer *et al.*, 2012, 2017; Mingrone *et al.*, 2012, 2015; Cummings *et al.*, 2016; Ding *et al.*, 2015; Dixon *et al.*, 2008; Courcoulas *et al.*, 2014, 2015; Halperin *et al.*, 2014; Ikramuddin *et al.*, 2013, 2015; Liang *et al.*, 2013; Parikh *et al.*, 2014; Schauer *et al.*, 2014; Wentworth *et al.*, 2014) studies have demonstrated a net improvement of plasma lipid profile after metabolic surgery, but most of these studies reduced the doses of effective statin therapies after surgery. The beneficial effect of combining surgery with lower doses statins may result in the benefits of high dose statins without the side effects (Nissen *et al.*, 2006).

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is characterized by recurrent episodes of collapse of the upper airways during sleep due to reduced airway dilator muscle tone, with consequent desaturation and sleep fragmentation leading to daytime fatigue. It is a frequent complication of overweight and obesity occurring in 41% of adults with a BMI >28 kg/m^2 (Vgontzas *et al.*, 1994) and in 78% of patients referred for bariatric surgery (Lopez *et al.*, 2008).

Although obese patients are recommended to lose weight the results of clinical trials are controversial. A very low calorie diet (VLCD) for 9 weeks in obese subjects with a BMI between 30 and 40 kg/m^2 reduced the apnoea–hypopnoea index (AHI) by 21 events/h and weight by 18 kg (Johansson *et al.*, 2011). These results seemed very promising in view of the great weight loss obtained with bariatric surgery.

Two metaanalysis of surgical interventions published in 2004 and in 2009 showed opposite results. The first demonstrated remission of OSA in 85% of patients who underwent bariatric surgery (Buchwald *et al.*, 2004), the second demonstrated that bariatric surgery reduces AHI but that most continued to need medical treatment (Greenburg *et al.*, 2009). The differences can be explained by the various definitions that were used as surgery reduces AHI substantially, but often not below the threshold where CPAP would no longer be beneficial.

A randomized controlled study comparing low energy diet (including if necessary VLCD) with gastric banding confirmed this ascertain as weight loss was 5.1 kg with dieting and 27.8 kg with LAGB and AHI decreased by 14.0 events/h (95% CI, 3.3–24.6 events/h) with dieting and 25.5 events/h (95% CI, 14.2–36.7 events/h) with surgery, but there was no statistical difference in the number of subjects where the AHI decreased below the threshold where CPAP was not indicated (Dixon *et al.*, 2012).

These results were confirmed by another RCT with primary endpoint of the number of patients fulfilling the criteria for weaning from non-invasive ventilation (NIV) after either dieting or LAGB. Again there was no significant difference between the two arms (Feigel-Guiller *et al.*, 2015) spite of a much greater weight reduction after surgery than after lifestyle modification both at 1 and at 3 years.

Sexual Dysfunction

Obesity is frequently associated with sexual dysfunction. In women early onset of obesity is often associated with menstrual irregularities, oligo- to an-ovulation and subfertility. Obesity also increases the risk of miscarriages. Polycystic ovary syndrome (PCOS) is present in 36% of women with morbid obesity while male obesity-associated secondary hypogonadism (MOSH) is observed in 64% of severely obese men (Escobar-Morreale *et al.*, 2017).

A recent metaanalysis showed that PCOS resolved in 96% of cases and that resolution of MOSH occurred in 87% of affected men after bariatric surgery (Escobar-Morreale *et al.*, 2017). Sexual function improved in 28% ($P = 0.02$) of 29 obese women in reproductive age 12 months after gastric bypass (Legro *et al.*, 2012).

The Swedish Medical Birth Register compared 670 singleton pregnancies that occurred from 2006 through 2011 in women after bariatric surgery (Johansson *et al.*, 2015) with matched control pregnancies. Post-surgery pregnancies were associated with an increased risk of small-for-gestational-age infants (15.6% vs. 7.6%; odds ratio, 2.20; 95% CI, 1.64–2.95; $P < 0.001$) and shorter gestation (273.0 vs. 277.5 days; mean difference −4.5 days; 95% CI, −2.9 to −6.0; $P < 0.001$). The authors concluded that bariatric surgery was safe but pointed to a non-significant trend to increased still births after bariatric surgery (Johansson *et al.*, 2015).

Appetite Reduction and Food Preferences

Many patients after bariatric surgery point to the most beneficial effect of the interventions being the increased satiety and reduction in hunger which allows them to lose weight and maintain weight loss (le Roux *et al.*, 2011). The profound improvements in eating behaviour are the consequences of multiple visceral signals (le Roux *et al.*, 2011) which appears to fundamentally

alter subcortical brain centres involved with appetite and reward. Whether patients eat fewer calories and shift their preferences to lower calorie dense foods remain controversial (Goldstone *et al.*, 2016).

Conclusions

A recent metaanalysis including both RCTs and observational studies showed that mortality associated with metabolic surgery is low, ranging from 0.08% to 0.35% (Chang *et al.*, 2014). Nonetheless, surgical complications are relatively frequent, 10%–17% (Chang *et al.*, 2014). In addition, long term nutritional complications are common, in fact anemia is observed in 33%–49% of patients within 2 years from surgery and calcium/vitamin D malabsorption with secondary hyperparathyroidism with bone loss is present in 8%–13% of the cases (Lupoli *et al.*, 2017).

Although globally the long term benefits of metabolic surgery exceed surgical side effects, it is desirable that less invasive approaches to the obesity epidemics can be found in the future.

Treatment: New Drugs

Silvia Garelli, Nicola Salituro, Giulia M Pontesilli, Luigi Ricciardiello, Valentina Vicennati, and Uberto Pagotto, Alma Mater Studiorum University of Bologna, Bologna, Italy

Introduction

Obesity, globally representing one of the most preventable causes of death, remains a worldwide health concern as its incidence has dramatically grown in the last 40 years. Although, our knowledge in the understanding of pathophysiological mechanisms driving to obesity has constantly advanced in the recent period, the effectiveness of interventions to limit obesity epidemic progression has been highly disappointing. As confirmed by the most recent guidelines of international societies of obesity and human nutrition, lifestyle intervention (changes in dietary pattern and physical exercise) remains the cornerstone in weight loss strategies (Williamson, 2017). However, changes in lifestyle are unanimously considered the most difficult action to be maintained lifelong by patients and consequently their effect on body weight (BW) are limited by the high attrition rate. For most people, a nutritional program to reduce BW is generally considered a prescription to be followed for a limited period, with a start and an end, rather than a road to achieving healthier nutritional habits. This misleading idea also comes from the widespread availability of "dietary" restrictive protocols (based on the exclusion of food categories, i.e., sugars, carbohydrates), being on one hand potentially dangerous and on the other, for sure, not applicable for a long time in everyday life. Furthermore, BW loss is followed by the activation of preservative biological mechanisms (e.g., ghrelin increase, reduction of energy expenditure) inducing weight regain which are the reason for failure of diet-behavioral therapy in the long-term maintenance of weight loss (Apovian *et al.*, 2015).

It is nowadays commonly well acknowledged that in selected patients, especially when changes in lifestyle become a constant failure and an irrepressible source of frustration, the surgical approach to reduce BW is strongly indicated. Indeed, to date, bariatric surgery represents the most effective and potentially definitive treatment for severe obesity and its metabolic correlates (primarily type 2 diabetes). This procedure, however, involves a certain risk and often high costs, therefore it is applicable only for patients who have a totally favorable risk/benefit ratio.

The devastating effects of obesity on health and the scarce impact of pressure on the general population to ameliorate the lifestyles paved the way, especially in the second half of the last century, to alternative therapeutic strategies to tackle obesity, increasing scientific interest in the development of antiobesity drugs. Research in the field of pharmacologic therapy of obesity has gone hand in hand with the understanding of the complex network between central and peripheral structures involved in the regulation of food intake. Hypothalamus is known to be pivotal in the regulation of homeostatic mechanisms, as it receives inputs from other areas of the brain and from the periphery in order to modulate feeding and energy metabolism (Berthoud *et al.*, 2017; Camilleri, 2015; Suzuki *et al.*, 2010). The arcuate nucleus of the hypothalamus, in particular, is the key area involved in these mechanisms, containing the orexigenic neuropeptide Y (NPY) and Agouti-related protein (AgRP) neurons and the anorexigenic melanocortin system derived from propiomelanocortin (POMC) and cocaine and amphetamine-regulated transcript (CART) producing neurons (Berthoud *et al.*, 2017). Many hormones (ghrelin, leptin, insulin, cholecystokinin, peptide YY, oxyntomodulin, and GLP-1) also have a role in the modulation of hypothalamus nuclei activity and, by influencing the AgRP/NPY pathway or the melanocortin system, they eventually control appetite (Berthoud *et al.*, 2017). To date, all approved drugs for weight management, except from orlistat, target appetite regulation mechanisms and hedonic/rewarding role of food (Apovian *et al.*, 2015).

Prescriptive Guidelines and Regulatory Authorities Point of View

In 1998 the National Institute of Health Guidelines for treatment of overweight and obesity in adults proposed that pharmacological treatment for obesity was indicated for patients with Body Mass Index (BMI) $\geq 30\ kg/m^2$ or BMI $\geq 27\ kg/m^2$ with comorbidities (type 2 diabetes, hypertension, dyslipidemia, coronary heart disease, and sleep apnea) (Anon, 1998). These criteria have been recently confirmed by both American and European Obesity Societies guidelines, that also suggested that pharmacologic therapy should be considered only after at least one attempt of nutritional intervention has proved insufficient and must be associated to continuous behavioral counseling. Interaction between these two strategies may enhance adherence to nutritional changes and physical activity, thus improving weight loss and increasing the probability of maintaining a lower BW. Moreover, as for any pharmacological treatment, an issue has been raised concerning the potential side effects produced by antiobesity drugs. A further encouragement to constantly perform periodic re-evaluation of both efficacy and side effects for each patient undergoing pharmacological antiobesity treatment has been conclusively expressed (U.S. Department of Health and Human Services—Food and Drug Administration—Center for Drug Evaluation and Research (CDER), 2007; European Medicines Agency (EMA)—Committee for Medicinal Products for Human Use (CHMP), 2016). This last recommendation, in particular, has achieved increasing importance in the last decade, after the withdrawal from the market of most antiobesity drugs for the onset of serious

 doi:10.1016/B978-0-12-801238-3.65344-8

side effects (Rodgers *et al.*, 2012). At present, United States and European regulatory drug agencies have further defined specific guidelines and standards to be followed in the development of antiobesity pharmacologic treatments. According to the American Food and Drug Administration (FDA) draft guidance, the efficacy of an antiobesity drug should be primarily defined if after 1 year/treatment the difference in weight loss between the tested drug and placebo is at least 5%, or in the same timeframe of treatment, the proportion of subjects who lose $\geq 5\%$ of baseline BW with the drug is at least 35% or approximately double the proportion in the placebo. FDA also requires that medications show evidence of improvement in metabolic biomarkers, including blood pressure, lipid levels, and glycemic control (U.S. Department of Health and Human Services—Food and Drug Administration—Center for Drug Evaluation and Research (CDER), 2007). On the other hand, the European Medicines Agency (EMA) required that after 1 year/treatment the difference in weight loss between drug and baseline BW should be at least 10% and should also be at least 5% higher than that achieved on placebo. As an alternative, EMA guideline stated that proportions of responders could be considered as an alternative primary efficacy criterion where response is more than 10% weight loss at the end of a 12-month period (European Medicines Agency (EMA)—Committee for Medicinal Products for Human Use (CHMP), 2016). As secondary endpoint, the improvement of parameters affecting cardiovascular risk (blood pressure, lipid profile, blood glucose) must be documented prior to authorization. To define the impact of the drug on glycemic control, authorities have highly encouraged studies focusing on the delay in the time of onset of diabetes from a prediabetic state as well as specific studies in diabetic cohorts. Concomitant evaluation of obesity comorbidities (sleep apnea, urinary incontinence, mood disorders, impaired fertility, functional limitation) and quality of life by distinct studies or subanalyses should be included as secondary, but not less important endpoints (U.S. Department of Health and Human Services—Food and Drug Administration—Center for Drug Evaluation and Research (CDER), 2007; European Medicines Agency (EMA)—Committee for Medicinal Products for Human Use (CHMP), 2016). Pharmacologic safety has to be taken into account in the study design of phase II–III trials. Especially, cardiovascular safety (in terms of incidence of cardiovascular events/mortality) is a pivotal requirement both in preauthorization studies (which must include a relevant proportion of patients with coexisting cardiovascular profile) and in postmarketing extended trials (U.S. Department of Health and Human Services—Food and Drug Administration—Center for Drug Evaluation and Research (CDER), 2007; European Medicines Agency (EMA)—Committee for Medicinal Products for Human Use (CHMP), 2016). The efficacy of antiobesity drugs should be evaluated after the first 3 months of therapy. If weight loss achieved $>5\%$ loss in nondiabetic and $>3\%$ in diabetic patients treatment should be continued, otherwise the drug should be discontinued and the patients should be defined as nonresponders.

Central Sympathomimetic Agents for Obesity Management

Amphetamines and their congeners were the first antiobesity drug approved by FDA at the end of the 1940s. This heterogeneous group includes norepinephrine (and possibly dopamine) releasing molecules (desoxyephedrine, phenmetrazine, diethylpropion phentermine, phendimetrazine, benzphetamine), and serotonin releasing agents (fenfluramine, dexfenfluramine). All these agents are known to increase central nervous system (CNS) activity and resting energy expenditure, and decrease appetite and food intake, thus inducing weight loss. The use of amphetamine-based drugs spread widely in United States between the 1950s and 1970s, but along with their diffusion, the report of adverse events, as well as concerns about abuse potential and transient efficacy, rapidly increased. In 1977 the FDA limited of the use of phentermine, diethylpropion, phendimetrazine, benzphetamine only for short-term treatment (from a few weeks, up to 3 months) leading to the decline in their use (Haslam, 2016; Colman, 2012, 2005; Gomez and Stanford, 2017). Interest in amphetamine congeners reemerged in 1990s after authorization of dexfenfluramine (an isomer of fenfluramine) and of the association phentermine–fenfluramine ("Phen–Fen") for long-term treatment of obesity. Unfortunately, after a few years, emerging data on pulmonary hypertension and left-sided heart-valve fibrosis and degeneration (due to the interaction with receptor 5-HT(2B) (Connolly *et al.*, 1997; Rothman *et al.*, 2000), led to the withdrawal in United States of both Phen–Fen and dexfenfluramine. Since 1999, the EMA recommended the withdrawal of all amphetamine-derived drugs (Onakpoya *et al.*, 2016). On the other hand, in the United States phentermine is nowadays the most prescribed antiobesity drug for short-term use (Hampp *et al.*, 2013). Its efficacy has been described in a short-term outcome meta-analysis of six studies (ranging from 2 to 24 weeks), which reported a mean BW loss of 6.3 kg in patients treated with 15–30 mg/day phentermine (3.6 kg over the placebo group) (Haddock *et al.*, 2002). Only one randomized, double blind, placebo-controlled trial evaluated the effects of a longer treatment with phentermine, comparing continuous (37.5 mg/day for 36 weeks) versus discontinuous (alternating phentermine and placebo every 4 weeks) therapy. Mean weight loss was -12.2% in the phentermine continuous-group, -13% in the discontinuous-group, and -4.8 in the placebo group (Munro *et al.*, 1968). The more frequent side effects are palpitation, blood pressure elevation, dizziness, insomnia, dryness of the mouth, therefore it is contraindicated in patients with cardiovascular disease, moderate/severe hypertension, hyperthyroidism, known hypersensitivity to the sympathomimetic amines, glaucoma.

Orlistat

Orlistat was the first developed and approved antiobesity agent with a completely different mechanism of action (not central but peripheral) compared to previous drugs. It is a gastric and pancreatic lipase-inhibitor which reduces the absorption of about the

30% of dietary fats (Food and Drug Administration (FDA), 2015). It is available both in the United States and Europe in 120 mg tablets (prescription only) and 60 mg tablets (as over-the-counter medicine), and the daily recommended dose is up to 120 mg thrice daily. The Xendos study compared obese prediabetic/diabetic patients treated with orlistat 120 mg or placebo: mean BW loss was significantly higher in treated patients than in placebo group both at mid- and long-term follow-up (at 1 year: −10.6 vs. −6.2 kg; at 4 years: −5.8 vs. −3 kg). Furthermore, the number patients achieving a BW loss ≥5% and ≥10% were significantly higher in orlistat treated patients than placebo both at 1 and 4 years treatment (Torgerson *et al.*, 2004). The results at 1 year were confirmed in a meta-analysis of 16 double blind randomized placebo-controlled clinical studies, reporting a mean weight loss in orlistat-treated patients of 2.9% more than placebo. In four studies of 2 years duration, both orlistat and placebo showed similar weight-regain therefore preserving the differential in weight reduction (Rucker *et al.*, 2007). Within secondary endpoints, orlistat was proven to be effective, at least in the short/mid term, in improving glycemic control (blood glucose, HbA1c) (Rucker *et al.*, 2007), insulin sensitivity (Lucas *et al.*, 2003), lipid profile (total cholesterol, high density lipoprotein—HDL cholesterol, low density lipoprotein—LDL cholesterol, triglycerides) (Hutton and Fergusson, 2004; Sahebkar *et al.*, 2017), and systolic/diastolic blood pressure (Rucker *et al.*, 2007; Siebenhofer *et al.*, 2016). Moreover, it significantly reduces the cumulative incidence rate of type 2 diabetes after 4 years treatment in patients with impaired glucose tolerance at baseline (2.9% with orlistat vs. 4.2% for placebo), corresponding to a 41% risk reduction (hazard ratio 0.593) (Torgerson *et al.*, 2004). A meta-analysis of 11 studies reported a significant reduction in the risk of developing diabetes in patients treated with orlistat alone or orlistat + diet + exercise versus standard care (hazard ratio 0.38 and 0.31, 95% CrI, respectively) (Stevens *et al.*, 2015). Treatment with orlistat is typically associated with gastrointestinal side effects: abdominal pain and discomfort, steatorrhea/oily stool, oily spotting, fecal urgency (Xenical, 2009). Due to its mechanism of action, orlistat reduces the absorption of fat-soluble vitamins: although true deficiency states have not been reported, patients receiving orlistat must be advised to take oral multivitamins (Food and Drug Administration (FDA), 2015).

Phentermine/Topiramate

Phentermine/Extended-Release Topiramate (PHEN/ER TOP), Qnexa®, was the first combination of central acting drugs approved by FDA in 2012 for long-term treatment of overweight/obesity in adults (Yanovski and Yanovski, 2014). Topiramate is an anticonvulsant drug, used also for bipolar disease and in migraine-prophylaxis (Food and Drug Administration (FDA), 2012). It is known to inhibit carbonic anhydrase activity, block voltage-dependent sodium channel, and antagonize kinate subtype glutamate receptors (Kramer *et al.*, 2011). The exact mechanisms associated with topiramate-induced BW loss are still unclear, although an anorectic action has been postulated following carbonic-anhydrase inhibition on taste and the activation of γ-aminobutyric acid (GABA)-A receptor in the lateral hypothalamus known to interact with leptin pathway (Turenius *et al.*, 2009). The observation of BW loss following administration of topiramate, led to its evaluation as a possible antiobesity agent (Bray *et al.*, 2003; Astrup *et al.*, 2004). A meta-analysis of 10 RCTs reported a significant weight loss in overweight-obese patients treated with topiramate versus placebo, furthermore patients losing ≥5% and ≥10% were significantly more in the topiramate group; interestingly, the weight-losing effect of topiramate increased with dosage and duration of treatment, while it resulted independent of the presence of diabetes (Kramer *et al.*, 2011). In diabetic subjects, topiramate monotherapy 96–192 mg compared to placebo (alone or in combination with lifestyle interventions and/or metformin or sulfonylurea), showed a significantly higher BW and BMI reduction associated to a significant reduction of HbA1c (Paravattil *et al.*, 2016). Weight-loss treatment with topiramate resulted associated to a twofold incidence of side effects (paresthesia, taste perversion, psychomotor disturbances, and hypoesthesia, memory/attentional difficulties, dizziness), especially with higher doses (greater than 96 mg/day) (Kramer *et al.*, 2011; Paravattil *et al.*, 2016). Both topiramate and phentermine were proved to reduce BW, but their use was limited by the activation of biological compensatory mechanisms and the high incidence of side effects and adverse events reported at efficient doses. Clinical studies comparing the efficacy of the two single molecules versus their combination highlighted the superiority of the association on weight reduction (Singh and Kumar, 2015). The latter achieved results at lower doses of each component (because of their complementary and synergic effect on appetite regulation and energy balance) (Bays, 2010). The authorization of PHEN/ER TOP followed a RCT conducted on 2487 overweight-obese patients with BMI 27–45 kg/m^2 and at least two metabolic comorbidities (CONQUER) (Gadde *et al.*, 2011). Diabetic subjects were included, without lower BMI limit, treated with lifestyle or metformin monotherapy. Participants were randomized at PHEN/ER TOP 15/92 mg once daily, PHEN/ER TOP 7.5/46 mg once daily or placebo, in addition to standardized counseling on diet (−500 kcal/day) and lifestyle modifications. After 56 weeks both PHEN/ER TOP groups showed significantly greater weight loss (−12.4% for PHEN/ER TOP 15/92, −9.6% for PHEN/ER TOP 7.5/46 mg, −1.6% or placebo) with a significantly higher proportion of patients achieving ≥5% and ≥10% weight reduction compared to placebo (70% in PHEN/ER TOP 15/92 mg, 62% in PHEN/ER TOP 7.5/46 mg, 21% in placebo group); a subanalysis restricted to diabetic patients showed even greater results on weight loss (Garvey *et al.*, 2014). Results on BW after 56 weeks, were confirmed in the EQUIP study, conducted on higher-BMI subjects (BMI ≥35 kg/m^2, mean BMI 42.0 kg/m^2), in whom the administration of PHEN/ER TOP 15/92 mg once daily induced significantly higher body reduction compared to PHEN/ER TOP 3.75/23 mg once daily and placebo (PHEN/ER TOP 15/92 > PHEN/ER TOP 3.75/23 mg > placebo). Furthermore, results were independent by baseline BMI (Allison *et al.*, 2012). In the CONQUER trial, the superiority of PHEN/ER TOP versus placebo concerned also significant improvements in cardiovascular risk factors (blood pressure/hypertensive treatments, waist circumference, lipid profile/lipid lowering medications, blood glucose, inflammatory biomarkers) (Gadde *et al.*, 2011); this difference was confirmed in

higher-BMI subjects between PHEN/ER TOP 15/92 mg and placebo, but not always between PHEN/ER TOP 3.75/23 mg and placebo (Allison *et al.*, 2012). Both the RCTs reported a slight improve in heart rate in PHEN/ER TOP patients compared to placebo (Gadde *et al.*, 2011; Garvey *et al.*, 2014; Allison *et al.*, 2012; Vorsanger *et al.*, 2016). Phentermine/ER Topiramate has been proved to improve glycemic control in diabetic patients: after 56 weeks, patients taking PHEN/ER TOP 15/92 mg daily exhibited greater reduction in HbA1c and greater reduction in antidiabetic medications compared to placebo; furthermore a greater portion of PHEN/ER TOP-treated subjects achieved HbA1c targets (Gadde *et al.*, 2011; Allison *et al.*, 2012; Davidson *et al.*, 2013). Concerning OSA, a RCT was conducted on 45 subjects with BMI 30–40 kg/m^2 diagnosed with moderate/severe OSA but unable or unwilling to comply with CPAP treatment, treated with PHEN/ER TOP or placebo: PHEN/ER TOP patients experienced a significant improve in apnea/hypopnea index (AHI) already at 8 weeks and further at 28 weeks, as well as in additional OSA parameters and self-assessed quality of sleep (Winslow *et al.*, 2012). Durability of Phentermine/ER Topiramate was analyzed in the SEQUEL study (an extension of the Conquer trial): after 108 weeks, the significant difference between placebo and both PHEN/ER TOP groups with respect to weight loss and cardiovascular risk factors was sustained (− 1.8% for placebo, − 9.3% for 7.5/46 PHEN/ER TOP, and − 10.5% for 15/92 mg PHEN/ER TOP). A higher percentage of subjects treated with both doses of PHEN/ER TOP experienced weight losses of 5%, 10%, 15%, and 20% when compared with placebo-treated subjects. As seen at 56 weeks, PHEN/ER TOP resulted effective in all BMI categories; interestingly, both the 7.5/46 and 15/92 mg doses were statistically similar in their effectiveness in the lower baseline BMI, whereas, for BMI 40–45 kg/m^2, the 15/92 mg group showed a significantly greater weight loss than the 7.5/46 mg group (Garvey *et al.*, 2012). Among cardiovascular risk factors: blood pressure reduction was similar between treatment arms, but PHEN/ER TOP experienced a reduction in hypertensive medications; fasting glucose, insulin concentrations, incidence of diabetes and diabetes progression rate were significantly reduced in PHEN/ER TOP groups; also, triglycerides decreased and HDL cholesterol increased more in PHEN/ER TOP groups than placebo. Phentermine/ER Topiramate is currently approved at doses of 3.75/23, 7.5/46, and 15 mg/92 mg (recommended dose) for long-term overweight/obesity management. The side effects are due to both components of the drug. The most frequently reported are dry mouth, paraesthesia (sometimes causing drug discontinuation), constipation, upper respiratory tract infection/nasopharyngitis, dysgeusia (at higher doses), depression (Gadde *et al.*, 2011; Garvey *et al.*, 2014, 2012; Allison *et al.*, 2012). Phentermine/ER Topiramate is contraindicated in pregnancy (for fetal toxicity by topiramate) (Hernández-Díaz *et al.*, 2017), glaucoma, hyperthyroidism, during or within 14 days of taking monoamine oxidase inhibitors. Heart rate, mood disorders, and suicidal ideation must be monitored during treatment (Food and Drug Administration (FDA), 2017). With regards to cardiovascular safety, the RCTs conducted so far have shown a reduction in cardiovascular risk factors with no cardiovascular events reported in treated patients. Given the previous reports of palpitation, blood pressure elevation, and cardiac injuries due to phentermine (and its consequent limitation), data on blood pressure after Phentermine/ER Topiramate indicate that the metabolic benefit overcomes the sympathomimetic effect (Vorsanger *et al.*, 2016).

Naltrexone/Bupropion

In ARC of hypothalamus, POMC neurons release anorexigenic αMSH and β-endorphin. The latter inhibits POMC neurons and decrease αMSH concentration in a negative feedback loop, thus ensuring energy homeostasis (RBS, 2017). The μ-opioid receptor subtype, bind by β-endorphin, has a key role in this mechanism, but is known to modulate hedonic control of eating too, being expressed in critical area such as nucleus accumbens and other brain regions part of the reward system (RBS, 2017). Naltrexone is a high affinity μ-opioid receptor antagonist, also used to treat alcoholism and opioid addiction. Naltrexone increases POMC neurons activity blocking β-endorphin negative feedback on the μ-receptor. Moreover, it decreases dopamine levels in the nucleus accumbens, leading to a reduction in food seeking, binge eating and preference and consumption of highly palatable, sugary and fat foods (Giuliano *et al.*, 2012). Bupropion is an antidepressant drug inhibitor of dopamine and norepinephrine reuptake (Stahl *et al.*, 2004). Through this mechanism, it stimulates POMC neurons to release αMSH, thus inducing an anorexigenic effect (RBS, 2017; Stahl *et al.*, 2004). *CONTRAVE*® (Orexigen Therapeutics, USA) is an extended release formula containing naltrexone (8 mg) and bupropion (90 mg). The drug is orally administered with an initial 4-week titration to achieve the total dose of 32 mg of naltrexone and 360 mg of bupropion (Caixas *et al.*, 2014; Anon, 2010). It should not be used in patients with uncontrolled hypertension, seizure disorders, a history of drug addiction, bulimia, anorexia nervosa (Srivastava and Apovian, 2017; Gadde *et al.*, 2017), in individuals receiving chronic treatment with opioids and in those who abruptly stopped alcohol, benzodiazepines, barbiturates, and antiepileptic drugs (Srivastava and Apovian, 2017; Gadde *et al.*, 2017). The efficacy and safety of Contrave® were established by the Contrave Obesity Research Program (COR), which included four 56-week, randomized, double-blind, placebo-controlled, phase III trials: COR-I, COR-II, COR-Diabetes, and COR-behavioral modification (BMOD) (Greenway *et al.*, 2010; Apovian *et al.*, 2013; Wadden *et al.*, 2011; Hollander *et al.*, 2013). The COR-I study involved patients with either a BMI of 30–45 or a BMI of 27 kg/m^2 and comorbidities such as controlled hypertension, dyslipidemia, or both. They were randomly assigned to be treated with either 32 mg naltrexone + 360 mg bupropion per day (NB32), 16 mg naltrexone + 360 mg bupropion per day (NB16) or placebo. Weight loss in the NB groups began early (by the 4th week) and continued for the whole trial duration. The mean percentage of weight loss was 6.1%, 5%, and 1.3% in the three groups respectively and more patients in the NB groups compared to placebo group lost 5% or more, 10% or more, and 15% or more of their BW. Better results regarding insulin resistance, fasting insulin, and glucose concentration were observed in the NB groups than in placebo, as well as a better lipid metabolism control. Participants assigned to the NB groups also showed improvements in their quality of life, as stated by higher

scores in Impact of Weight on Quality of Life-Lite (IWQOL-Lite) Questionnaire, and in their feeding behavior and relationship with food, estimated by the Control of Eating Questionnaire (COEQ) (Greenway *et al.*, 2010). The COR-II study, which had the same design and confronted patients receiving 32 mg naltrexone + 360 mg bupropion per day or placebo, confirmed the previous results, showing a significantly greater weight loss and superior improvement in glucose and lipid metabolism in treated subjects than in placebo group (Apovian *et al.*, 2013). A comparable favorable outcome was demonstrated in COR-BMOD, which added an intense group lifestyle modification program to the administered drug or placebo. Again, NB receiving patients exhibited a better weight loss and a better improvement of cardio-metabolic risk parameters than placebo treated subjects (Wadden *et al.*, 2011). The COR-Diabetes trial finally examined the safety and efficacy of the two molecules in obese patients with Type 2 Diabetes Mellitus. Confirming former results, participants treated with NB lost more weight than placebo-treated individuals, and more patients in the NB group achieved $\geq 5\%$ and $\geq 10\%$ reduction in BW. In addition, NB group showed a greater improvement in HbA1c and a higher percentage of patients achieving an HbA1c $< 7\%$ and $< 6.5\%$, in a weight loss-correlated manner. Furthermore, higher baseline HbA1c values demonstrated the greater reduction, while fasting glucose and HOMA-IR did not significantly differ between the two groups (Hollander *et al.*, 2013). The main adverse events in the NB groups were gastrointestinal, above all nausea, which tended to disappear once the total dose was reached. Headache and constipation were also reported (Greenway *et al.*, 2010; Apovian *et al.*, 2013; Wadden *et al.*, 2011; Hollander *et al.*, 2013). Neurological and psychiatric adverse events did not differ between NB and placebo groups (Gadde and Pritham Raj, 2017). Despite that, as a single case of seizure and a case of passive suicide ideation were reported, a careful screening for depression, suicidal thoughts, and personal history of seizures is necessary to exclude these conditions before drug administration (Gadde and Pritham Raj, 2017). NB may raise heart rate and blood pressure and should not be used in patients with uncontrolled hypertension. The clinical significance of the slight increase in these parameters is unclear, especially for patients with heart-related and cerebrovascular disease, since patients at high risk for cardiovascular diseases were excluded from the clinical trials above mentioned. FDA mandated a placebo-controlled, non-inferiority cardiovascular outcomes trial, however because of the unanticipated early termination of the trial, it was not possible to assess non inferiority of NB versus placebo. Accordingly, cardiovascular safety of this treatment remained uncertain and will require evaluation in a new adequately powered outcome trial (Nissen *et al.*, 2016).

Liraglutide

Liraglutide is an acylated glucagon-like peptide-1 (GLP-1) analog with a 97% homology to endogenous human GLP-1. GLP-1 is secreted by L-cells in the gut and by neurons in the nucleus tractus solitarius (Merchenthaler *et al.*, 1999; Baggio and Drucker, 2007; Drucker and Nauck, 2006) and it is a physiological regulator of glucose metabolism, as it increases insulin secretion and reduces glucagon release after meals. Furthermore, it inhibits gastric emptying and promotes satiation by acting on afferent vagal fibers. The metabolic role of GLP-1 has been exploited in the treatment of type 2 diabetes, by developing GLP-1 receptor agonists resistant to degradation by dipeptidyl peptidase-4 (DPP-4). Animal and human studies have shown that GLP-1 receptor agonists produce also significant weight loss when compared to controls, due to a direct stimulation of POMC/CART neurons in the arcuate nucleus of the hypothalamus (Baggio and Drucker, 2014). There are six GLP-1 based drugs currently approved by the agencies: albiglutide, dulaglutide, exenatide, liraglutide, lixisenatide, semaglutide. Each of these is able, by a distinct modification, to extend the duration of action of GLP-1. Once-day liraglutide 3.0 mg has been tested in obese patients with or without comorbidities and according to the results has been licensed for the treatment of obesity. The SCALE Obesity and Prediabetes study, 3731 patients with BMI ≥ 30 kg/m^2 or BMI ≥ 27 kg/m^2 associated to dyslipidemia and/or hypertension, were stratified according to prediabetes status at screening and BMI at baseline (< 30 kg/m^2 or ≥ 30 kg/m^2). After 56 weeks, patients in the liraglutide group showed a significantly greater weight loss compared to placebo (-8.0% vs. -2.6%) as well as a greater proportion of patients losing at least 5%, 10%, and 15% of baseline BW (63.2%, 33.1%, and 14.4% in lira-group vs. 27.1%, 10.6%, and 3.5% in placebo group) (Pi-Sunyer *et al.*, 2015). Interestingly liraglutide appeared less effective in patients with a BMI ≥ 40 kg/m^2 (Pi-Sunyer *et al.*, 2015), but a recent post hoc analysis showed the same results (in BW loss) between patients having BMI 27–35 kg/m^2 or ≥ 35 kg/m^2 (le Roux *et al.*, 2017). Lipid profile, systolic and diastolic blood pressure improved significantly more in the liraglutide group than in placebo, as well as the prevalence of prediabetes and the development of diabetes were significantly lower in the liraglutide group than in the placebo group (Pi-Sunyer *et al.*, 2015). The superiority of liraglutide versus placebo on BW loss as well as on glucose metabolism and diabetes incidence/development has been confirmed in the 3-year extension trial (SCALE maintenance) (Davies *et al.*, 2015); furthermore, after 160 weeks, the liraglutide group showed significantly higher regression rate from prediabetes to euglycemia (Davies *et al.*, 2015). Effects on fasting lipids and cardiovascular markers were modest with the exception of high-sensitivity C-reactive protein (Davies *et al.*, 2015). Liraglutide was also associated with improvement in health-related quality of life questionnaires score (Pi-Sunyer *et al.*, 2015; Davies *et al.*, 2015). The SCALE Diabetes study involved overweight/obese diabetic patients with poor glycemic control (HbA1c range 7%–10%), treated with diet and physical exercise alone or in combination with one to three oral hypoglycemic agents (Wadden *et al.*, 2013). The study compared treatment with liraglutide 3.0 mg, 1.8 mg and placebo for 56 weeks: the results showed a mean weight loss of 60%, 47%, and 20% respectively ($P < .001$ for any liraglutide dose vs. placebo) as well as greater reduction of BMI and waist circumference for liraglutide patients. Moreover, liraglutide was associated with significantly improved glycemic control, glucagon and proinsulin levels, proinsulin-to-insulin ratio, reduction of oral hypoglycemic agents after 56 weeks compared to the placebo group. Liraglutide 3.0 mg, but not 1.8 mg, improved systolic and diastolic blood pressure, levels of total cholesterol, very low LDL cholesterol (VLDL-C), HDL-cholesterol, and triglycerides, but no

effects were observed on LDL cholesterol or free fatty acids. Liraglutide 3.0 significantly improved quality of life in a dose dependent way (Wadden *et al.*, 2013). These results support the use of liraglutide 3 mg in patients with prediabetes or diabetes who find it difficult to achieve their HbA1c goal (Golden, 2017). Moreover, liraglutide proved to be effective in improving apnea–hypopnea index and sleeping saturation parameters in obese nondiabetic patients, after 32 weeks (Blackman *et al.*, 2016). Liraglutide has been approved for treatment of overweight/obesity in 2014 by FDA and in 2015 by EMA. It is administered subcutaneously at a 3.0 mg daily dose, achieved within 5 weeks with a weekly increase of 0.6 mg to improve gastrointestinal tolerability. The most common side effects, reported as mild or moderate in 94% of cases, involve the gastrointestinal tract (nausea, diarrhea, constipation, vomiting, dyspepsia, and abdominal pain) and in all RCTs were one of the main causes for drug discontinuation. Nausea and vomiting occurred mostly within the first 4–8 weeks of treatment, worsening as the dose increased. Gallbladder-related events (cholelithiasis and cholecystitis) were reported more frequently in liraglutide patients and led to elective cholecystectomy, followed by treatment restoration (Pi-Sunyer *et al.*, 2015; Davies *et al.*, 2015; Wadden *et al.*, 2013). Few cases of pancreatitis were reported but many patients showed increases in serum levels of lipase (only a few were greater than three times the upper limit of normal range) and pancreatic amylase (not greater than three times the upper limit of normal range). Further studies have shown that the association between increased levels of these two markers and incidence of pancreatitis and pancreatic cancer was not statistically significant (Chalmer *et al.*, 2015; Funch *et al.*, 2014). Cardiovascular safety of liraglutide 3 mg is being studied. A recent post hoc analysis on cardiovascular events reported in SCALE trials, suggested a protective cardiovascular role of liraglutide 3 mg (Davies *et al.*, 2017): in the pooled analysis, 8 cardiovascular events (both fatal or nonfatal) were reported in the liraglutide group versus 10 in the placebo group, with a hazard ratio of 0.45 (95% confidence interval (CI), 0.17–1.08). The same analysis confirmed a slight but significant increase in pulse rate associated to liraglutide treatment (Davies *et al.*, 2017). These preliminary data, together with results of the LEADER study with lower doses of liraglutide (Marso *et al.*, 2016), may suggest an even greater protective role of liraglutide 3 mg on both cardiovascular profile and events. Nevertheless, further postmarketing data on a wider population are due. Recently, semaglutide, a once-weekly GLP-1 analog has been tested in a 12 week treatment trial in obese women versus placebo showing a significant reduction in ad libitum energy intake with a corresponding loss of body weight. In addition, semaglutide in the same group of women showed reduced appetite and food cravings. Obviously, more prolonged studies are needed to derive definitive conclusions about this novel compound (Blundell *et al.*, 2017).

Lorcaserin

Serotonin (5-hydroxytryptamine, 5HT) is synthesized both peripherally and centrally, and affects food intake through different pathways. Peripherally, enterochromaffin cells and mast cells produce 5HT which binds to $5HT_3$-receptors and activates ascending vagal afferent fibers, thus increasing satiety. Centrally, 5HT is produced by neurons of the raphe nuclei and by mast cells, it binds to the $5HT_{2C}$ receptors (located on POMC neurons) and the $5HT_{1B}$ receptors (located on AgRP neurons, with inhibitory effect), inducing a synergic stimulation on POMC neuron signals and, consequently, an increase in α-MSH release and hypophagia (RBS, 2017). Lorcaserin is a selective serotonin $5HT_{2C}$ receptor agonist with minimal affinity for $5HT_{2B}$ receptors (known to be responsible of valvular heart disease and fibrosis in patients treated with fenfluramine and dexfenfluramine) (Food and Drug Administration (FDA), 2017). Lorcaserin hydrochloride is available in two oral formulations: BELVIQ, containing lorcaserin 10 mg, administered orally twice daily; BELVIQ XR, an extended release tablet containing lorcaserin 20 mg, administered once daily (Blundell *et al.*, 2017). The BLOSSOM study assessed the efficacy and safety of lorcaserin administered 10 mg twice daily (BID) or 10 mg once daily (QD) versus placebo, in patients with BMI ≥ 30 kg/m^2 or 27 $\leq$BMI > 30 kg/m^2 with comorbidities (with the exception of type 2 diabetes). After 52 weeks, the results showed a significantly greater weight loss as well as greater proportion of patients losing at least 5% of baseline BW, in both lorcaserin groups compared to placebo. In the lorcaserin groups, weight loss results were dose-dependently increased. Similarly, BMI, waist circumference and body fat significantly decreased in lorcaserin-treated subjects compared to placebo. Concerning lipid profile, lorcaserin groups did not show any significant improvements other than those secondary to weight loss. Quality of life (assessed by the Impact of Weight on Quality of Life-Lite Questionnaire score) significantly improved in patients taking lorcaserin (Fidler *et al.*, 2011). When administered to patients with type 2 diabetes for 52 weeks (BLOOM-DM study), lorcaserin significantly improved HbA1c, fasting plasma glucose and insulin resistance (assessed by HOMA-IR) as compared to placebo. Moreover, lorcaserin BID and QD groups showed a higher rate of diabetic patients achieving glycemic target (HbA1c $\leq 7\%$) and a significant reduction in the overall use of oral antidiabetic agents, as compared to placebo. Lorcaserin was associated to a higher incidence of hypoglycemia (7.4% in BID group, 10.5% QD group, and 6.3% in placebo), but no severe episode has been reported (O'Neil *et al.*, 2012). The efficacy of lorcaserin has been confirmed in the 2-years extension trial (BLOOM trial): patients treated with lorcaserin 10 mg twice daily, experienced a significantly greater weight loss compared to placebo within the first year, which sustained in the second year in a significantly higher proportion. Weight loss was associated with BMI and waist circumference reduction as well as improvement in blood pressure, fasting glucose, insulin, glycated hemoglobin, total cholesterol, LDL cholesterol, triglyceride levels and reduction of high-sensitivity C-reactive and fibrinogen levels. In the second year, both groups showed a partial weight regain, associated to an increase in glycemic parameters and lipids levels. Systolic and diastolic blood pressure, at the end of the second year, decreased slightly but significantly between baseline and the end of year 2 in lorcaserin group as compared to placebo (Smith *et al.*, 2010). The most common adverse events are headache, upper respiratory infection, nausea, dizziness, dry mouth, fatigue and back pain; the incidence of side effects increases along with the dose, and has been reported among the main causes of drug discontinuation (Fidler *et al.*, 2011; O'Neil

et al., 2012; Smith *et al.*, 2010). Lorcaserin treatment was not associated to an increase in the incidence of FDA-defined valvulopathies (Fidler *et al.*, 2011; O'Neil *et al.*, 2012; Smith *et al.*, 2010); furthermore, in the BLOSSOM study, subjects with preexisting valvulopathies and treated with lorcaserin, showed a lower increase of mitral or aortic regurgitation as compared to placebo (Fidler *et al.*, 2011). The incidence of depression and suicidal ideation was not significantly affected by lorcaserin administration (Fidler *et al.*, 2011; O'Neil *et al.*, 2012; Smith *et al.*, 2010). Serotonin syndrome or neuroleptic malignant syndrome-like reactions can occur with concurrent use of two serotonergic agents, therefore selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs) and other drugs affecting the serotonergic system, should not be prescribed to patients taking lorcaserine (Kim *et al.*, 2013). Among the five agents taken into consideration, lorcaserin is the one associated with the least incidence of adverse events, whereas naltrexone-bupropion and liraglutide are the most likely to being discontinued due to adverse events (Khera *et al.*, 2016).

Conclusions

The history of pharmacotherapy for obesity has been marked by severe restrictions from the EMA and FDA regulatory committees. However, recently, at least two novel antiobesity medications are available in Europe and the United States, together with another two still marketed in the United States with some restrictions. Today, pharmacological treatment should definitively be considered part of a comprehensive strategy of disease management, helping patients maintain compliance, reducing cardiovascular risk factors, and improving quality of life. All the currently approved drugs help patients limit food intake and achieve better compliance with the diet. Antiobesity drug mode of action has not always been completely clarified, but in general we can summarize that all prescribable drugs are able to determine a reduction in food intake by limiting hunger and food craving, as well as enhancing the sense of satiety. For the future however, it is strongly recommended that patients should be carefully examined before starting any specific antiobesity drug therapy, so that this is tailored to respond to their specific needs and conditions.

Definition of Bulimic-Spectrum Eating Disorders

The bulimic-spectrum eating disorders (BSED) include serious psychiatric nosological entities, such as bulimia nervosa (BN) and binge eating disorder (BED), which are characterized by recurrent binge eating episodes as main symptom. An episode of binge eating is defined as excessive food consumption, in a discrete period of time, accompanied by a sense of loss of control over eating.

According to the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5; American Psychiatric Association, 2013), BN is defined as an eating disorders (ED) characterized by recurrent episodes of binge eating followed by compensatory behaviors, such as fasting, dieting, excessive exercise and/or purging behaviors (e.g., self-induced vomiting, misuse of laxatives, diuretics, or enemas) to prevent weight gain. In addition, individuals with BN place a great emphasis on body shape or weight that influence their self-evaluation. Likewise, BED is also characterized by recurrent episodes of binge eating, but without inappropriate compensatory behaviors. For both disorders, binge eating episodes have to be present at least once a week for 3 months, and are also accompanied by marked distress.

Due to the caloric overconsumption, BSED are strongly associated with (or lead to) obesity (Razzoli *et al.*, 2017; Villarejo *et al.*, 2012). Obesity is considered a public health problem with worldwide epidemic consequences. It is defined by the World Health Organization (WHO) as a complex and multifactorial disease that occurs when an individual's food consumption exceeds his or her energy expenditure. Therefore, obesity is characterized by abnormal and excessive fat accumulation which, in turn, may impair health and be life-threatening.

Furthermore, BSED frequently suffer from comorbid psychiatric disorders (e.g., mood, anxiety, substance use disorders). BSED and obesity have also been associated with social and psychopathological impairments (e.g., emotional distress and negative affect), as well as with increased risk for medical comorbidities such as type II diabetes, hypertension, dyslipidemia, coronary heart disease, congestive heart failure, and various types of cancer (Mitchell, 2016). Thus, BSED are associated with increased healthcare costs in addition to reduced quality of life and increased morbidity and mortality (Ágh *et al.*, 2016).

Etiology and Prevalence

The prevalence of BSED, namely BN and BED, has increased substantially throughout the past few decades, especially in women who live in developed countries. The increasing prevalence of BSED appears to be especially related to a maladaptive, population-wide exposure to excessive cultural inducements to diet as well as an increasing idealization of thinness. Social pressure to be thin and personal internalization of this unrealistic appearance ideal contribute to the development of body dissatisfaction, which leads to increased negative affect and also reduced dietary intake in order to better conform to the appearance ideal. Finally,

negative affect and elevated dietary restriction may act as risk factors increasing the odds of developing binge eating and unhealthy compensatory behaviors (Stice, 2001).

Both BN and BED are prevalent mental disorders framed in BSED. When exploring community samples, around 1% of population suffers from lifetime BN, whereas BED lifetime prevalence ranges from 1.9% to 2.8% (Kessler *et al.*, 2013; Hudson *et al.*, 2007). Nevertheless, when the lifetime occurrence of BSED is examined in clinical samples comprising individuals with obesity, the estimated rates obtained are notably higher. In patients with obesity, BN and BED lifetime prevalence reaches up to 4.9% and 9.3% respectively (Herpertz *et al.*, 2006). These results suggest an association between BSED prevalence and BMI, being BSED prevalence higher at the same time that BMI increases. Furthermore, BSED lifetime prevalence also varies depending on the gender, appearing to be higher in women (1.5%–3.5%) compared with men (0.5%–2%) (Cossrow *et al.*, 2016; Hudson *et al.*, 2007).

Given that evidence points to a strong association between BSED and BMI, in some cases obesity could be understood as a consequence of the binge eating behaviors observed in BSED. In this regard, the percentage of obesity in people who suffer BSED is higher than in nonclinical population. In this line, BED individuals display the highest percentage of obesity (87.8%) followed by BN (33.2%) (Villarejo *et al.*, 2012), probably due to the absence of compensatory behaviors after binge episodes.

Endocrine and Medical Complications

Both BN and BED are associated with a multitude of medical complications and comorbidities. These should be kept in mind as they greatly impact on the morbidity and also mortality of these patients.

In patients with BN, several complications are directly related to the purging behavior and depend on the mode and frequency of this behavior. These encompass hypokalaemia and metabolic alkalosis. Moreover, purging leads to a loss of fluid and often results in a compensatory increase in aldosterone secretion in order to maintain blood pressure in a normal range. In combination, these changes were termed pseudo-Barter syndrome (Bahia *et al.*, 2012) and may increase the risk for edema formation after ceasing of vomiting and during volume therapy (Trent *et al.*, 2013).

When related to vomiting, these changes are due to a loss in gastric acid and potassium and often associated with gastric acid reflux (Denholm and Jankowski, 2011) and subsequent dyspepsia (Santonicola *et al.*, 2012). Local acid complications encompass alterations of the vocal cords (Ferreira *et al.*, 2010) as well as perimolysis, an erosion of dentin and enamel (Uhlen *et al.*, 2014). Moreover, acute hematemesis may occur due to a Mallory-Weiss lesion. Chronic vomiting is often associated with an enlargement of the parotid glands (Coleman *et al.*, 1998), a condition with the exact pathomechanism yet to be unraveled.

When related to laxative abuse hypokalaemia is often associated with early hyperchloraemic metabolic acidosis, whereas the metabolic alkalosis develops later due to a subsequent stimulation of aldosterone secretion. Long-term laxative abuse may lead to cathartic colon syndrome (Müller-Lissner, 1996), a motility disorder recently challenged (Müller-Lissner *et al.*, 2005). Moreover, local complications of excessive laxative use encompass diarrhea, hematochezia (Xing and Soffer, 2001) and rectal prolapse (Malik *et al.*, 1997). Lastly, when local enemas are used severe hyperphosphataemia may occur due to respective ingredients of the enema (Ori *et al.*, 2012).

Hypokalaemia and metabolic alkalosis increase the risk for cardiac arrhythmias and thereby considerably contribute to the mortality of BN (Crow *et al.*, 2009). It is important to note that when syrup of ipecac is used to induce vomiting also irreversible congestive heart failure has to be considered (Ho *et al.*, 1998) as the alkaloid-containing syrup has cumulative toxicity.

Patients with BED display a higher risk to develop obesity (Kessler *et al.*, 2013) and obesity-associated diseases including hypertension, dyslipidaemia or diabetes (Hudson *et al.*, 2010). Interestingly, the risk of developing these diseases was greater than the risk solely attributable to obesity. Moreover, binge eating disorder was also associated with chronic pain disorders (Javaras *et al.*, 2008) sleep disorders (Trace *et al.*, 2012), asthma (Alonso *et al.*, 2014), gastrointestinal symptoms (Cremonini *et al.*, 2009), reduced cardiac output (Lelli *et al.*, 2015) as well as gynecological diseases such as menstrual dysfunction (Algars *et al.*, 2014), polycystic ovary syndrome (Hollinrake *et al.*, 2007), and complications during pregnancy (Linna *et al.*, 2014). Also these associations remained visible after controlling for body mass index. Therefore, more studies are needed in order to better understand the pathomechanisms underlying these associations.

Clinical and Personality Features

Eating/Weight-Related Symptoms

Body dissatisfaction is one of the main characteristics of BSED. Individuals with BSED place an excessive emphasis on body shape or weight in their self-evaluation. Body image is continuously assessed by BSED individuals taking as reference the ideal body type established by their culture. The result of their self-evaluation frequently leads to high levels of body dissatisfaction and it negatively influences their self-esteem. In this line, an overvaluation of shape and weight seems to be associated with eating pathology severity; as well as body dissatisfaction could be considered a predictor for worsening of eating symptoms and negative affect displayed by BSED individuals (Rikani *et al.*, 2013; Kornstein *et al.*, 2016).

Another essential feature of BSED is recurrent episodes of binge eating. Although these episodes are commonly defined as a large consumption of calories in a brief period of time, BSED individuals usually tend to define binge episodes depending on the type of food consumed and their mood state while consuming, not necessarily by the actual among of

calories ingested. Some types of food, especially hypercaloric foods, are considered as forbidden to those patients and, when consumed, they constitute a binge regardless of the overall amount or caloric content consumed. For instance, a large quantity of fruits and vegetables of the same caloric amount as a candy bar could not be considered as a binge because fruits and vegetables are "good" or "safe" foods (Rushing *et al.*, 2003). Despite binge episodes are not characterized by a craving for a specific nutrient, patients frequently tend to consume hypercaloric foods that they would otherwise avoid, forbidden foods for them; however, the type of food consumed during binges may vary depending on both the patient and the moment of intake. The most frequent triggers of binge eating episodes are negative affect, interpersonal stressors, dietary restraint, boredom, and negative feelings related to body and food. Additionally, binge episodes are normally planned in order to not be interrupted by any setback such as lack of the desired food at home, and they continue until the individual feels uncomfortably and painfully full. Individuals with BSED are typically ashamed of their eating problems and attempt to conceal their symptoms. For this reason, binge eating episodes generally occurs in secrecy or as inconspicuously as possible. BSED patients also avoid some situations in which they are likely to be exposed to food or will find it difficult to control their eating, such as when eating out with others. This avoidance behavior may result in a decline of social relationships (Kornstein *et al.*, 2016; NICE, 2004; American Psychiatric Association, 2013).

Subjective feelings of loss of control during binge eating episodes and marked distress over binge eating are also part of the typical symptomatology of patients with BSED. Individuals report not being able to refrain from eating or to stop eating once started, displaying an increased reward sensitivity and impulsivity in response to food-related stimuli. In most cases, binge eating episodes are characterized by a more generalized pattern of uncontrolled eating rather than a specific feeling of loss of control. Furthermore, this lack of control might not be complete; individuals can interrupt the binge immediately in the presence of certain events, for example, if someone enters in the room. In addition, the lack of control and the marked distress that these individuals suffer from during binge eating episodes appears to increase eating disorder pathology (Kornstein *et al.*, 2016; American Psychiatric Association, 2013).

In the end, another symptom only present in patients with BN is inappropriate compensatory behaviors in order to prevent weight gain. These compensatory behaviors are commonly associated with extreme feelings of guilt and shame. Nevertheless, BN patients do not suppress their compensatory behaviors by the fear to face the consequences of their binge eating such as excessive weight gain. Individuals with BN employ several methods to compensate (vomiting, fasting, exercising, etc.), collectively referred to as purge behaviors or purging. The most common compensatory behavior is vomiting. Patients usually vomit to relieve physical discomfort and reduce the fear of gaining weight after a binge eating episode. However, sometimes they vomit after eating a small amount of food in order to loss more weight. As they repeat vomiting behaviors numerous times, individuals generally learn to induce the vomit without use any method, they finally can vomit at will. Other purging behaviors include the misuse of laxatives, diuretics and enemas, as well as fasting and excessive exercise. BN patients may abuse of exercise and it could become excessive when it significantly interferes with important daily activities, when individuals exercise at inappropriate times or in unsuitable settings, or when they exercise despite injury or other medical complications. Finally, in some cases, BN patients may take thyroid hormone or, in the case of diabetic patients, they may omit or reduce insulin doses in an attempt to avoid weight gain (NICE, 2004; American Psychiatric Association, 2013) (**Table 1**).

Related-Psychopathological Symptoms and Comorbid Psychiatric Disorders

A large body of work suggests that BSED usually co-occur with other psychopathological symptoms and mental disorders; with the most common comorbid conditions being anxiety, mood and substance use disorders as well as other eating disorders (Kaye *et al.*, 2004; Hudson *et al.*, 2007; Welch *et al.*, 2016). Previous studies also report that in some occasions these symptoms (e.g., anxiety conditions) can have their onset before the development of the BSED therefore they can also be considered vulnerability factors.

Table 1 Clinical characteristics

	BSED			
Symptomatology	BN	BED	OB	HC
Binge eating episodes	+ + +	+ + +	−	−
Purging behaviors	+ + +	−	−	−
BMI	+ +	+ + +	+ + +	+
EDI-2:drive of thinness	+ + +	+ + +	+ +	+
EDI-2: body dissatisfaction	+ + +	+ + +	+ + +	+
EDI-2: bulimia	+ + +	+ +	−	−

BSED, Bulimic-spectrum eating disorders; *BN*, bulimia nervosa; *BED*, binge eating disorder; *OB*, obesity; *HC*, healthy controls; *BMI*, body mass index; *EDI-2*, eating disorder inventory-2.

International Journal of Eating Disorders 44 (6), 488–496.

Another particular clinical concern is the elevated risk for suicide in individuals with BSED (Crow *et al.*, 2009; Franko and Keel, 2006), which is described to be high even when controlling for the presence of depressive or comorbid symptoms (Welch *et al.*, 2016).

As previously mentioned, obesity is highly associated with BSED thus it is important to explore both conditions commonalities and differences. Like BSED, obesity also co-occurs with high level of psychopathology, mainly with anxiety and mood disorders as well as stress related conditions (Erermis *et al.*, 2004). However, despite the prevalence of the specified disorders is higher in individuals with obesity than normo-weight individuals from nonpsychiatric population, when comparing patients with BSED and individuals with obesity, the latter presents fewer comorbid psychopathological symptoms (Tanofsky-Kraff *et al.*, 2004). It is also important to note that studies reveal that suicide risk and mood disorder rates are elevated regardless of the presence of comorbid obesity in BSED (Welch *et al.*, 2016).

The substantial comorbidity rates observed in BSED and obesity highlight the clinical importance of assessing and addressing the full array of symptoms that these patients present. However, more studies are required to establish the role of the described symptoms as vulnerability factors for both BSED and obesity. Additionally more controlled treatment effectiveness studies are required determine long-term effects of these conditions on secondary disorders.

Personality

Previous studies and etiologic models have highlighted the role of personality traits in the development, symptomatic expression, and maintenance of the BSED, as well as its relevance in treatment outcomes. Therefore, most studies assessing personality in these pathologies are based on the Cloninger's psychobiological model of personality, which includes seven dimensions divided into two major components of personality, temperament, and character (Cloninger *et al.*, 1993).

Temperament is defined as an inherited neuropsychological mechanism, relatively stable throughout life, and mediated by neurotransmitter functioning in the central nervous system. It is identified by four dimensions named: novelty seeking, harm avoidance, reward dependence and persistence. Novelty seeking is associated with exploratory activity and impulsive decision making. High levels of novelty seeking have been related to impulsive, excitable, dramatic, and intolerant of routine individuals. Thus, it is also related to low dopaminergic activity. Harm avoidance refers the tendency to avoid potentially threatening situations. It is related to high serotonergic activity, and is characteristic of pessimistic, fearful, insecure, frustration-prone and overly concerned individuals. Reward dependence has been associated with social approval, seeking social and emotional support from others, and emotional expression. It has been suggested that is influenced by the noradrenergic system. Finally, persistence is defined as perseverance in spite of fatigue or frustration.

Character includes those personality traits acquired through experience, related to learning, and the environment. The three character dimensions are: self-directedness, cooperativeness, and self-transcendence. Self-directedness is described as the ability of planning, control, make decisions, and adapt the behavior in accordance with goals and values. It is conceptually related to locus of control. Cooperativeness is associated with tolerance, empathy, altruism and compassion as opposed to intolerance, insensitivity or selfishness. Self-transcendence is a personality trait associated with experiencing spiritual ideas, acceptance, identification or spiritual union with nature and its origin.

The temperament and character dimensions present different combinations, being responsible of the functional organization that underlies the personality of the individuals. The personality dimensions are influenced by interaction between genetic and environmental variables, so personality develops as a complex adaptive system.

Notably, BSED patients have been frequently associated with specific personality traits such as high levels of both novelty seeking/impulsiveness and harm avoidance, low levels of self-directedness, and lack of persistence (Farstad *et al.*, 2016; Villarejo *et al.*, 2014). A recent systematic review consolidates the evidence that patients with binge eating symptoms represent a distinct phenotype within the obesity spectrum that is characterized by increased impulsivity (Giel *et al.*, 2017). This personality profile characterized by high both impulsivity and harm avoidance (correlated with neuroticism) has been conceptualized as *negative urgency*, defined as the tendency to engage in impulsive and risky behaviors when experiencing strong negative emotions or emotional distress (Racine *et al.*, 2013). Negative urgency has been significantly associated with vulnerability to stress, difficulties in problem solving and coping strategies of avoidance and, therefore, with increased lifetime prevalence of binge eating behaviors (Lee-Winn *et al.*, 2016). Likewise, low levels of self-directedness and emotion dysregulation have been also related to greater binge eating symptomatology. In addition, it has been documented that those individuals with poor self-directedness and high negative urgency are at risk for developing addictive eating patterns associated with BSED, such as food addiction (Wolz *et al.*, 2017).

Neuropsychological Features and Brain Activity

Cognitive Profiles

Cognitive functions are frequently divided into the domains of memory, attention, processing speed, language, visuospatial abilities, and executive functions. In BSED neuropsychological difficulties have specifically been identified in attention, memory, verbal function, and executive function (including inhibitory control, cognitive flexibility, decision-making, and working memory) (Lena *et al.*, 2004; Manasse *et al.*, 2015).

However, among all these cognitive difficulties, executive function impairments (with an special emphasis in decision making, response inhibition and cognitive flexibility) are the ones most broadly acknowledged for its core role in the development and maintenance of BSED (Degortes *et al.*, 2016; Lena *et al.*, 2004; Fagundo *et al.*, 2012; Smith *et al.*, 2011). Hence, current literature in BSED supports the hypothesis of an alteration on the inhibitory control-emotional regulation-executive function circuit. With this regards, different studies exploring decision making in BSED by means of the Iowa Gambling Task (IGT; a well-established measure for assessing decision making patterns) report difficulties not only in the final outcome of the task but also in the learning process when comparing it with healthy controls and general population. Additionally, response inhibition has been shown to be crucial for impulse control related to food consumption and recently linked to attentional impulsivity (Hege *et al.*, 2015). It is important to note that not only BED and BN present difficulties in response inhibition but also individuals with obesity in absence of any comorbid eating disorder. Finally, cognitive/mental flexibility has been linked to different forms of psychopathology and BSED are no exception. In this case, studies report that when the eating disorder is present together with obesity the impairment would be heightened (Mobbs *et al.*, 2011).

Consistent with this theory, it is not surprising that patients with BED or BN as well as some individuals with obesity often display cognitive problems in terms of impulsivity or regulating behavior (Schag *et al.*, 2013) which usually lead to inadequate self-control and maladaptive eating patterns. This research evidence has also contributed to the "food addiction" model which is still inconclusive but considers obesity in terms of a dysfunctional brain reward circuitry. Particularly, it has been demonstrated that individuals with obesity display similar decision making patterns to substance use disorders if assessed by the IGT (Mallorquí-Bagué *et al.*, 2016).

The cognitive impairments mentioned above have been associated with BSED and often proposed as risk and maintenance factors. However, it is essential to emphasized that in some circumstances they are also considered a consequence of the eating condition. For instance patients with obesity, in addition to their metabolic disturbances, also experience a progressive cognitive decline in certain domains. This decline could be a result of their metabolic problems or due to a direct effect of chronic inflammation in the brain which is caused by obesity in itself (Morris *et al.*, 2015; Spyridaki *et al.*, 2016; Restivo *et al.*, 2016).

Electrophysiological and Neuroimaging Techniques

Recent research has delved into neuropsychological mechanisms that could be involved in the development and maintenance of BSED. Growing evidence suggests alterations in the brain functional connectivity of patients who suffer from BSED. Several studies have employed electroencephalographic (EEG) measures to identify neuronal activity underlying attentional processing of stimuli with high temporal resolution. Results show that patients with BSED display a consistent attentional bias towards food stimuli. Specifically, BN patients show an increased visual attention to high-caloric and low-caloric food pictures during early sensory processing, which is related to attentional orienting and selection processes. Abnormal eating behaviors could be associated with this enlarged early orienting to food stimuli. On the other hand, BED patients only display an enhanced visual attention to pictures with high-caloric content during late sensory processing, which corresponds to motivated attention. These results indicate their difficulty to regulate motivated attention toward food stimuli (Wolz *et al.*, 2015). Furthermore, other results obtained in BED patients reflect an impairment of frontal control network and visual processing networks, which lead patients to be more vulnerable to food cues and lack of control with regards to over eating (Imperatori *et al.*, 2015).

Additionally, studies have also investigated neural basis of BSED employing neuroimaging techniques, which allow for identifying brain areas involved in processing of stimuli with high spatial accuracy. The evidence from neuroimaging reports structural abnormalities and neural vulnerability factors related to BSED. Findings suggest that BN patients present increased reward sensitivity to food stimuli in striatal regions; moreover, hypothalamic inputs could be overridden by top-down emotional-cognitive control regions. Both BN and BED patients show altered neural responses to food and a diminished recruitment of prefrontal cognitive control circuitry, which may contribute to the binge eating of palatable foods (Steward *et al.*, 2017). Moreover, BED patients also present corticostriatal circuitry alterations similar to those observed in individuals with substance abuse disorders; these abnormalities include altered function of prefrontal, insular, and orbitofrontal cortices and the striatum (Kessler *et al.*, 2016).

Treatment Approaches

Current treatment options for BN and BED include psychological, behavioral and pharmacological modalities. Outpatient treatment is the first-line treatment setting for these disorders (Hilbert *et al.*, 2017). The National Institute of Clinical Excellence (NICE) guideline recommends the Cognitive Behavior Therapy (CBT) as the primary first-line treatment approach for BSED. Other recommended treatment modalities include CBT guided self-help, interpersonal psychotherapy (IPT), dialectical behavioral therapy (DBT), and behavioral weight loss, as well as pharmacotherapy.

Roughly, treatment approaches for BSED should address several aspects, such as the disordered eating (reduced binge-eating), the associated psychopathology (especially depression and anxiety), the coping strategies, and the psychosocial functioning, but also the excess weight and metabolic problems for guarantying the effectiveness of the treatment (Grilo, 2017).

Psychological First-Line Treatments

NICE Guideline (Eating disorders: recognition and treatment. 23 May 2017. Retrieved from: https://www.nice.org.uk/guidance/ng69) supports the efficacy of therapist-led CBT as first-line treatment for BN and BED. The modalities of bulimia-nervosa-focused CBT (CBT-BN) and the enhance version (CBT-E) have been consistently declared as standard effective therapies. The CBT for both BN and BED adults typically consists of 16 weekly 90-min group sessions, but individual sessions are also possible if group therapy is not available or the person declines it. This therapeutic program includes psychoeducation, weekly monitoring of binge eating and compensatory behaviors, daily food intake dietaries, and identifying binge eating cues. It directly targets the normalization of eating patterns and promotes behavioral and cognitive changes in order to: reduce or remove the episodes of binge eating and purging behaviors; minimize food restriction; address the clinical characteristics and the problematic areas that underlie the disorder (e.g., body image concerns and self-esteem); promote coping styles and problem-solving strategies. In addition, it helps with relapses prevention and coping with current and future risks and triggers. For children and young people with BSED is recommended to offer the same CBT-ED treatment than for adults with the same diagnostic. As primary outcomes, the CBT model presents high short and long-term rates of remission/recovery with reductions in behavioral and cognitive ED symptoms (mainly for binge eating and purging symptomatology), but also improvements in comorbid psychopathology (Linardon and Brennan, 2017).

Evidence-based clinical guidelines and recent systematic reviews further recommend other psychological treatments, such as guided self-help treatment, interpersonal psychotherapy and dialectical behavioral therapy for BN and BED (Hilbert *et al.*, 2017). CBT self-help has also demonstrated to be efficacious (Wilson *et al.*, 2010); though overall there is less evidence for benefit. CBT guided self-help is recommended as an alternative to therapist-led CBT by most guidelines, likely for economic reasons (Hilbert *et al.*, 2017). The IPT model is considered a strong empirically-supported alternative to CBT for bulimic disorders (Linardon and Brennan, 2017). IPT is well suited for helping patients to address interpersonal difficulties which appear to be maintaining the eating disorder and therefore, facilitating its recovery (Murphy *et al.*, 2012). IPT has shown slower acting than CBT, but as effective as in the longer term (Hilbert *et al.*, 2017). Other therapeutic approaches, to a lesser extent, such as DBT (mainly focused in emotion regulation, distress tolerance and interpersonal effectiveness) has also shown promising results in reducing binge eating and associated psychopathology in BED patients, but further researches are needed to elucidate its long-term effectiveness (Iacovino *et al.*, 2012). Finally, family-based therapy was in particular recommended mostly for younger patients with BN (Hilbert *et al.*, 2017).

However, although psychological therapies have a sustained effect on bulimic symptomatology, and stopping binge eating can have effect on slowing down the course of weight gain, they fail to produce body weight loss in these patients who frequently present with obesity (Grilo, 2017).

Behavioral Treatments

Behavioral therapies based on caloric reduction and promoting physical activity, namely behavioral weight loss (BWL), are recommended for BN and BED patients with overweight/obesity. BWL is widely used to treat obesity. However, although BWL appears to be useful for weight loss, it is less effective than CBT or IPT in maintaining binge eating reduction during follow-ups (Wilson *et al.*, 2010).

Furthermore, adjuvant treatment to usual therapy, such as mindfulness, has shown preliminary usefulness and effectiveness for improving overall health, well-being, and sustainability of outcomes (Iacovino *et al.*, 2012). In other words, both mindfulness and emotion regulation strategies might be effective to address negative urgency (a key feature involved in the development of BSED) (Racine *et al.*, 2017).

On the other hand, some studies converge on the benefits of adding exercise to CBT for ED, showing both a reduction in binge-eating symptomatology and an improvement in comorbid depression and anxiety (Vancampfort *et al.*, 2013). BSED patients often report physical complications due to comorbid obesity and the sedentary lifestyle, the majority being extremely inactive (Hrabosky *et al.*, 2007; Vancampfort *et al.*, 2014b). Recent findings indicate that BED patients, when compared to obese non-BED patients and normal weight controls, are those with the greatest limitations in physical activity and self-perception. In addition, the positive effect of enhancing physical activity/exercise in these patients has been shown to be associated with improved quality of life and physical self-perception (Vancampfort *et al.*, 2014a).

Pharmacological Treatments

Pharmacotherapy cannot be indicated as the sole treatment for BSED. However, although medication is not the primary choice of treatment for BSED, is often prescribed as adjuvant to other psychological therapies. Several randomized placebo-controlled studies have demonstrated that combining CBT with some medications improves the effectiveness of treatment, especially for managing comorbid symptoms or improving treatment outcomes in certain individuals (Davis and Attia, 2017).

Antidepressant medications, especially selective serotonin reuptake inhibitors (SSRIs), are often indicated as adjuvant treatment for BSED. Particularly, fluoxetine is the most commonly prescribed drug for the treatment of BSED. Evidence-based results have shown that fluoxetine yield clinically significant results by reducing binge eating and purge episodes, even in the absence of depressive symptoms. In addition, other SSRIs have been useful in the treatment of BSED, such as citalopram, sertraline, and

fluvoxamine. Antidepressants are generally safe and well-tolerated, but they do not have the desired effect on weight loss in these patients, who are often in overweight/obesity (Davis and Attia, 2017).

The combination of CBT and topiramate (an antiepileptic medication) has also demonstrated efficacy for both BED and BN with severe symptoms, improving the efficacy of the psychotherapy, reducing binge eating and purging frequency, and producing weight changes (Appolinario and McElroy, 2004; Claudino *et al.*, 2007). However, topiramate has limited tolerability and should occasionally be withdrawn because of its adverse effects such as headache, paresthesias, dry mouth or sedation (Appolinario and McElroy, 2004).

Recently, some studies have focused on lisdexamfetamine (LDX), a stimulant of the central nervous system, as effective medication for reducing binge eating behaviors and treating comorbid symptoms (McElroy *et al.*, 2016; Bello and Yeomans, 2017). LDX has also been associated with a decreased weight in BED patients. Therefore, LDX has proved to be specially indicated for treating patients with BED. However, although LDX is generally safe and well-tolerated, it can have emergent adverse effects (e.g., dry mouth, headache or elevations in heart rate and blood pressure), so that physician should closely monitor these parameters, particularly heart rate and blood pressure, during the treatment with LDX.

On the other hand, antiobesity or weight management medications, such as Orlistat (a lipase inhibitor used to treat obesity), has been shown to be useful for achieving weight loss. However, Orlistat has revealed ineffective in reducing bulimic symptomatology (Grilo and White, 2013).

Cognitive Stimulation Interventions

Given the cognitive impairments observed in BSED, a set of new treatment techniques for improving attention, memory, language and or/executive functions have been created as to complement the effect of first line treatments (i.e., psychotherapeutic treatments and pharmacological treatments) (Treasure *et al.*, 2015). With illness (i.e., BN, BED) and obesity progression, cognitive secondary changes underlying rigid eating habits and addictive-like changes and brain abnormalities develop and in turn reinforce the illness; thus it is important to work on new treatment approaches that target these changes (**Fig. 1**).

Different cognitive stimulation interventions have been proposed for disorders that present cognitive impairments, such as cognitive remediation (CR) or the use of brain simulation (deep brain stimulation (DBS), transcranial magnetic stimulation (TMS), transcranial direct current stimulation (TDCS). However, these treatment approaches are still in their early stages when it comes to BSED and more research is needed before they can be consistently validated and established as treatment. Still, a brief summary of the current knowledge on the field of BSED and cognitive stimulation interventions is provided bellow.

Cognitive remediation

CR is a type of rehabilitation treatment that offers exercises with the aim of reducing cognitive deficits by improving attention, memory, language and executive functions. Notably, two randomized controlled trials report significant improvements with a version of CR for obesity (CR-OB) that specially addresses executive function impairments (Raman *et al.*, 2014; Smith and Whittingham, 2017). Thus, CR-OB has been suggested as a good therapeutic approach for enhanced executive function and weight loss in obese adults. Finally, although CR also has the potential to be a good approach to complement first line treatments in BN and BED, more studies are needed before it can robustly be endorsed.

Brain stimulation (internal and external)

Deep brain stimulation (DBS; a neurosurgical technique to target dysfunctional brain circuits using electrical impulses through the implantation of a brain pacemaker into the cortex), repetitive transcranial magnetic stimulation (rTMS; via the generation of an electromagnetic field from a coil it generates magnetic stimulation of the cerebral cortex) and transcranial direct current stimulation

Fig. 1 Cognitive stimulation interventions.

(tDCS; via the placement of electrodes onto the scalp, applies low current to a target area of the cortex in order to modulate neural excitability) have emerged as a valid neuromodulation form with reversible means of altering brain circuitry in different mental health conditions. In eating disorders the target circuits involve reward, inhibition and mood regulation (Treasure *et al.*, 2015).

With regards to rTMS, promising findings have been found when targeting the dorso medial prefrontal cortex (DMPFC) in patients with treatment resistant BN (Downar *et al.*, 2012) and some other studies point toward lowers cue-induced food craving after high-frequency rTMS of the left dorso lateral prefrontal cortex (DLPFC) in people with a bulimic eating disorder and may reduce binge eating (Van den Eynde *et al.*, 2010). Some significant results are also observed with patients with no eating disorder but food craving (Lowe *et al.*, 2017). Unfortunately, research in BSED and tDCS is still lucking evidence to report conclusive results. Finally despite noninvasive techniques (i.e., rTMS, tDCS) need further investigation before they can be considered for clinical practice, there is sufficient available data suggesting that DBS may become an acceptable therapy for patients with treatment-resistant obesity (Göbel *et al.*, 2017) as well as promising results for neuromodulation and BN and BED (Lutter, 2017).

Introduction

Lipodystrophy is defined as a clinical entity characterized by an abnormal distribution of adipose tissue in the body. The use of the term lipodystrophy in clinics is associated with alterations such as total or partial lipoatrophy, although in some patients lipohypertrophy occurs at some anatomical sites in association with lipoatrophy at other sites. Obesity or lipomatosis, which involve altered distribution of hypertrophied adipose tissue only, are not included in the term "lipodystrophy" as commonly used in clinics. Apart from human immunodeficiency virus (HIV)-associated lipodystrophy, lipodystrophies occur very infrequently. Because of its rarity, the prevalence of these syndromes is very difficult to determine; a recent study (Chiquette *et al.*, 2017), based on the evaluation of several electronic databases of medical records and the review of Literature published from 1946 to 2012 in Europe, has estimated that the prevalence of the main lipodystrophy subtypes is approximately 1.3–4.7 cases/million, with partial lipodystrophies occurring more frequently (2.84 cases/million) than generalized lipodystrophies (less than 1 case/million). Lipodystrophies are classified as congenital (mostly monogenic diseases) and acquired, although ongoing research tends to identify sometimes a genetic component in lipodystrophies originally classified as acquired forms. **Table 1** shows the classifications of lipodystrophies (modified from Brown *et al.*, 2016).

Congenital Lipodystrophies

Since 1996, more than 15 genes have been found to be related to different subtypes of lipodystrophies. The most widely reported are those causing type 1 and type 2 congenital generalized lipodystrophy (CGL) and type 2 familial partial lipodystrophy (FPLD), with approximately 500 cases reported in the literature, while the other subtypes are rarer.

CGL (Berardinelli–Seip Syndrome)

CGL (**Fig. 1**) is a recessive entity characterized by a near-complete lack of fat, starting at birth or childhood depending on the causative gene (*AGPAT2*, *BSCL2*, *CAV1*, or *PTRF*) (Agarwal et al., 2003a; Garg, 2004). These children are born with a triangular and coarse face. During the first years of life, the musculature is very well-defined, which later appears as muscular hypertrophy, mainly affecting the calves. Additionally, during the first few years, hypertrichosis frequently observed, which can affect the whole body. Severe acanthosis nigricans, achocordons, acromegaloid features, and flebomegaly are common characteristics, as are a voracious appetite and accelerated growth. At onset, patients present hepatomegaly with liver steatosis, which over time can evolve into cirrhosis, and sometimes to splenomegaly and lymphadenopathy. Most patients have umbilical hernia or umbilical prominence. The practical absence of leptin leads to a voracious appetite. The growth rate is accelerated, although the final size is expected for parental stature, and these individuals exhibit a higher bone age. Basal energy expenditure is increased. Patients also have hypertriglyceridemia, which can lead to episodes of acute pancreatitis early in life. As a result of extreme insulin resistance, nonketotic diabetes mellitus may appear at puberty or later and is often very difficult to control. Hyperinsulinemia, hypoleptinemia, and hypoadiponectinemia are common laboratory findings. High-density lipoprotein-cholesterol (HDLc) concentrations are typically low. Hepatomegaly, which results from liver steatosis, leads to abdominal distention, and increased liver enzymes.

Women may present with clitoromegaly, polycystic ovarian syndrome (PCOS), hirsutism, and menstrual disorders, being gestation exceptional. Sexual function in men is normal and they are fertile, although some cases of hypogonadism have been reported (Jiang *et al.*, 2014). In some subtypes, fat is also absence from the bone marrow. The marked absence of fat, acromegaloid traits, and acanthosis nigricans cause significant social stigmatization (Garg, 2011; Rochford, 2010; Vantyghem *et al.*, 2012).

According to the causative gene, there are specific conditions which can be useful for diagnosis. The lack of fat is more severe in type 2 CGL, which also affects mechanical adipose tissue (Simha and Garg, 2003). Mental retardation has been associated with type 2 CGL (Van Maldergem *et al.*, 2002), and a variant associated with the *BSCL2* gene causes a lethal neurodegenerative condition in the second childhood has been reported (Guillén-Navarro *et al.*, 2013). Twenty-five percent of type 1 and type 2 CLG presents hypertrophic cardiomyopathy. Lytic cystic lesions in appendicular bones have been associated with type 1 CGL (Fleckenstein *et al.*, 1992), although the risk of fractures is not increased, while myopathy, skeletal abnormalities, cardiac arrhythmia, and esophageal dysmotility are the hallmarks of type 4 CGL (Rajab *et al.*, 2010). Without adequate treatment, the life span of these patients is reduced, and death is typically related to diabetes complications or hepatic cirrhosis.

 doi:10.1016/B978-0-12-801238-3.65165-6

Table 1 Classification of lipodystrophies

Congenital
- Generalized
  - Type 1 congenital generalized lipodystrophy (*AGPAT2*)
  - Type 2 congenital generalized lipodystrophy (*BSCL2*)
  - Type 3 congenital generalized lipodystrophy (*CAV1*)
  - Type 4 congenital generalized lipodystrophy (*PTRF*)
  - *PPARG*-associated congenital generalized lipodystrophy
  - Leprechaunism (Donoue syndrome)
- Partial
  - Type 1 familial partial lipodystrophy (unknown genes)
  - Type 2 familial partial lipodystrophy (*LMNA*)
  - Type 3 familial partial lipodystrophy (*PPARG*)
  - Type 4 familial partial lipodystrophy (*PLIN1*)
  - Type 5 familial partial lipodystrophy (*CIDEC*)
  - Type 6 familial partial lipodystrophy (*LIPE*)
  - *AKT2*-linked lipodystrophy
  - Partial lipodystrophy, congenital cataracts, and neurodegeneration syndrome (*CAV1*)
- Systemic
  - Progeria syndromes
    - Hutchinson–Gilford progeria syndrome (*LMNA*)
    - Nestor–Guillermo progeria syndrome (*BANF1*)
    - Type A mandibuloacral dysplasia (*LMNA*)
    - Type B mandibuloacral dysplasia (*ZMPSTE24*)
    - MDPL syndrome (*POLD1)*
    - Werner syndrome (*RECQL2*)
    - Atypical Werner syndrome and Atypical Progeroid syndrome (*LMNA*)
    - Bloom syndrome (*RECQL3*)
    - *PCYT1A* lipodystrophy
    - SHORT syndrome (*PIK3R1*)
    - Marfan syndrome with neonatal progeroid syndrome-like lipodystrophy (*FBN1*)
    - Cockayne syndrome (*ERCC6, ERCC8*)
    - Neonatal progeroid syndrome
    - Keppen–Lubinsky syndrome (*KCNJ6*)
    - Ruijs–Aalfs syndrome (*SPRTN*)
    - *CAV1*-associated neonatal onset lipodystrophy syndrome
    - Neonatal progeroid syndrome
  - Autoinflammatory syndromes
    - Nakajo–Nishimura syndrome (*PSMB8*)
    - JMP syndrome (*PSMB8*)
    - CANDLE syndrome (*PSMB8*)

Acquired
- Generalized
  - Acquired generalized lipodystrophy (Lawrence syndrome)
- Partial
  - Acquired partial lipodystrophy (Barraquer–Simons syndrome)
  - HIV-associated lipodystrophy
  - Lipodystrophy associated with total body radiation and hematopoietic stem cell transplantation
- Localized
  - Caused by drug injections
  - Lipodystrophy semicircularis
  - Centrifugal lipodystrophy
  - Panniculitis-associated lipodystrophy

Modified from Brown, R. J., Araujo-Vilar, D., Cheung, P. T., et al. (2016). The diagnosis and management of lipodystrophy syndromes: a multi-society practice guideline. Journal of Clinical Endocrinology and Metabolism 101, 4500–4511.

The pathogenetic mechanisms leading to adipose tissue loss are not well-known. In cases with mutations in *AGPAT2*, it is thought neutral lipids cannot be stored in the adipocyte lipid vacuole, as this gene encodes 1-acylglycerol-3-phosfate *O*-acyl-transferase 2, an enzyme that catalyzes the passage of lysophosphatidic acid to phosphatidic acid. The *BSCL2* gene encodes for seipin, an endoplasmic reticulum resident protein believed to play an important role in the formation of lipid droplets, in adipogenesis, and in the synthesis of membrane phospholipids (Cartwright and Goodman, 2012; Salo *et al.*, 2016; Wang

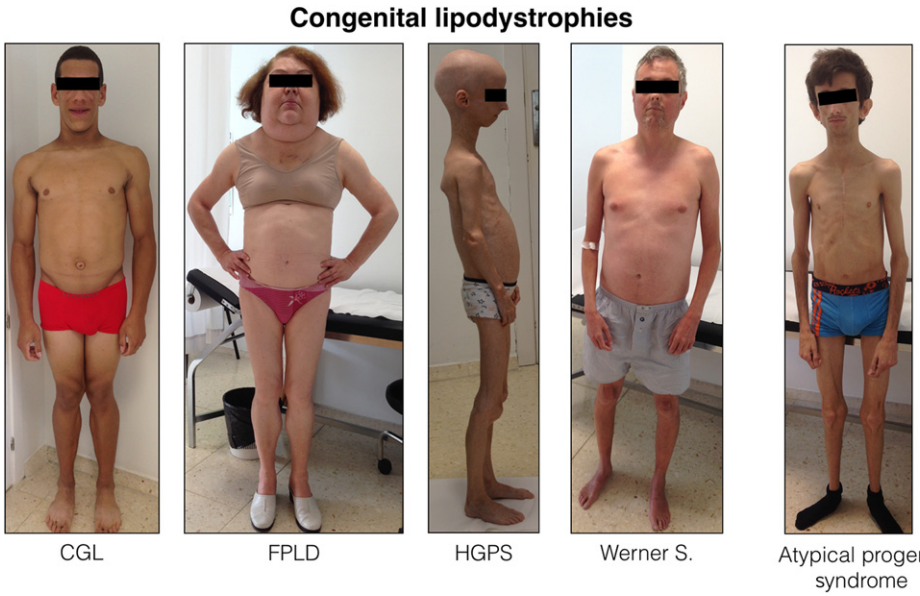

Fig. 1 Examples of congenital lipodystrophies. CGL: Congenital generalized lipodystrophy. Male, 16 years old, shown a generalized absence of body fat from birth, herculean aspect, acromegaloid facies, acanthosis nigricans, and umbilical protrusion. FPLD: A 55-year-old female with familial partial lipodystrophy due to mutation in *LMNA*, showing loss of fat in limbs and hips, and an accumulation of adipose tissue on face and neck. HGPS: A 16-year-old female with the classic phenotype of Hutchinson-Gilford progeria. Werner S: A 36-year-old male with Werner syndrome due to a mutation in *RECQL2*, with a short stature, aging appearance, early graying, and loss of adipose tissue in extremities. Atypical Progeria Syndrome: A 16-year-old male with a de novo mutation in *LMNA*. He shows short stature, aged facies, generalized lipoatrophy, and articular contractures. This patient had severe dilated cardiomyopathy requiring cardiac transplantation at 12 years of age.

et al., 2016). Both CAV1 and PTRF encode proteins resident in the caveola of the plasma membrane. Caveolin 1 binds to fatty acids and moves them to lipid droplets, which are necessary for the transport of triglycerides into adipocytes. PTRF, also known as cavin, is involved in the biogenesis of caveolae and regulates the expression of caveolin 1 and 3. Caveolas are formed from the lipid rafts of the cell membrane and consist of phospholipids, glycosphingolipids, and caveolin-1. Endocytosis of the caveolae forms caveolin vesicles that can fuse with the lipid droplets to translocate fatty acids to them (Garg, 2011; Rochford, 2010).

Familial Partial Lipodystrophy

This disorder was described by Dunnigan et al. (1974), and is a group of Mendelian disorders characterized by a loss of subcutaneous adipose tissue, affecting the limbs, buttocks, and hips (Garg, 2004). The loss of subcutaneous fat in the abdomen is variable. In general, fat accumulates on the face, buttocks, underarms, and labia majora, while visceral fat is preserved. The phenotype appears characteristically in women at the onset of puberty, while in men, because of the characteristic distribution of adipose tissue, it may go unnoticed for many years. Patients present muscular hypertrophy, which is generally more pronounced in calves, and phlebomegaly. Insulin resistance appears early (Araújo-Vilar *et al.*, 2003), leading to the onset of acanthosis nigricans. Leptin levels are relatively low, but not undetectable. These patients have hypertriglyceridemia with low HDLc and a higher risk of developing insulin-resistant diabetes mellitus. Hepatomegaly and high liver enzymes are also common in relation to hepatic steatosis or nonalcoholic steatohepatitis. Both metabolic and cardiovascular complications (ischemic heart disease and stroke) occur during adulthood, and are more common in women than in men (Hegele, 2001). The "classical" phenotype is characteristically associated with mutations in codon 482 of the *LMNA* gene, in which lipodystrophy is more severe and other clinical manifestations are more obvious. In other cases with mutations in other codons of the *LMNA* gene or in other genes (vide infra), lipodystrophy is less obvious and is referred to as "atypical forms" (Garg *et al.*, 2001). Additionally, higher rates of PCOS, hirsutism, miscarriages and stillbirths (Vantyghem *et al.*, 2008), gestational diabetes, hypoplastic breasts, and rough hands with short fingers have been reported. The presence of encapsulated lipomas even in lipoatrophic areas (Araújo-Vilar *et al.*, 2012) and muscular pain have been reported. In some cases, episodes of acute pancreatitis and eruptive xanthomas have been reported to be associated with severe hypertriglyceridemia (Garg, 2011; Vantyghem *et al.*, 2012). The prognosis is better than for other lipodystrophies, and it is conditioned by the metabolic and cardiac complications.

To date, six loci have been identified, although in more than 50% of the cases the responsible gene is unknown. These genes are: LMNA, PPARG, AKT2, CIDEC, PLIN1, and LIPE (Brown *et al.*, 2016). Except for mutations in CIDEC and LIPE, in which the disorder is autosomal recessive, other FPLD forms follow an autosomal dominant pattern of inheritance (or co-dominant in the case of *LMNA* mutations).

Type 1 FPLD

Notably, the type 1 FPLD or Köbberling variety, the most common subtype, has not been associated with mutations in any gene to date (Guillín-Amarelle *et al.*, 2016; Lotta *et al.*, 2017). Although some pedigrees shown a clear autosomal dominant pattern of inheritance, the disease is likely oligogenic or polygenic (Lotta *et al.*, 2017). This subtype is characterized by a loss of adipose tissue that mainly affects the buttocks and extremities, with characteristic accumulation of both subcutaneous and visceral fat in the abdomen (Guillín-Amarelle *et al.*, 2016). It is important to note that the absence of fat in the limbs and hips manifests in childhood or adolescence. Because of this particular fat distribution (typical male pattern), only women are diagnosed. They are typically obese and have a waist/hip ratio greater than 1, often present with diabetes mellitus, hypertriglyceridemia and, in some cases, acanthosis nigricans. Episodes of acute pancreatitis related to hypertriglyceridemia are not uncommon, and the prevalence of cardiovascular disease is high. Plasma levels of leptin are in line with body mass index (BMI).

Type 2 FPLD

Mutations in *LMNA* give rise to the "classical" form of type 2 FPLD (FPLD2) or Dunnigan disease (**Fig. 1**) when located at codon 482. Although mutations have been described in nearly all exons of this gene, most mutations occur in exons 8, 9, 10, and 11, which encode for the carboxy-terminal globular end of lamin A. FPLD2 is the most frequent form of genetic lipodystrophy with a molecular diagnosis and has been reported in more than 300 patients. Cardiac alterations have also been described, ranging from disorders in the conduction system to valvulopathies. Mutations in LMNA may cause other conditions such as Emery–Dreifuss muscular dystrophy, familial dilated cardiomyopathy, Charcot–Marie–Tooth disease, or atypical Werner syndrome, among others. Overlapping syndromes of lipodystrophy and some of these disorders have also been reported (Worman *et al.*, 2009).

The mechanisms by which a mutation in *LMNA* causes a loss of adipose tissue are not fully understood. It is unclear which of the multiple roles attributed to the nuclear lamina is involved in the selective alteration of adipogenesis, such as the maintenance of the nucleus form and structure, transcriptional regulation, function and positioning of nuclear pores, or organization of heterochromatin (Paulsen *et al.*, 2017). The predicted pathogenetic mechanisms include those related to a dysfunction of the transcription factors involved in adipogenesis. Some authors have proposed that, as in Hutchinson–Gilford progeria (vide infra), mutations in LMNA causing FPLD would result in an accumulation of prelamin A, the immature form of lamin A; excess of this immature lamin A may "kidnap" certain essential proteins in the adipocyte maturation process such as SREBP1c. Another proposed mechanisms are malfunction of the Wnt-beta-catenin pathway in relation to peroxisome proliferator-activated receptor-γ function. Finally, given the involvement of the nuclear lamina in the nucleus reordering process during mitosis, mutations in this gene lead to premature senescence of mesenchymal stem cells. Why adipose tissue is affected rather than other tissues remains unclear (Garg, 2011; Rochford, 2010; Vantyghem *et al.*, 2012; Worman *et al.*, 2009; Handelsman *et al.*, 2013; Hegele *et al.*, 2007; Araújo-Vilar *et al.*, 2009).

Type 3 FPLD

Approximately 30 cases of type 3 FPLD have been reported. This type is caused by mutations in the *PPARG* gene, and differs from the classical form of FPLD2 in that in the former the lipodystrophic condition is less severe and can appear at any age; however, insulin resistance with conditions such as hyperinsulinemia, diabetes mellitus, acanthosis nigricans, PCOS, and hirsutism are more severe or appear earlier, including hypertension, which is typically severe. Ischemic heart disease occurs earlier than in FPLD2. Lipodystrophy in these patients affects more to the distal regions of the limbs than proximal regions. Unlike FPLD2, this form of partial lipodystrophy does not always show accumulation of fat in the face. There may also be excess abdominal fat, both visceral and subcutaneous. As a monogenic form of metabolic syndrome, hypertriglyceridemia, low HDLc levels, and hepatic steatosis are common. In some cases, a pseudo-acromegaloid appearance has been described, as well as episodes of acute pancreatitis. Muscle enzymes may be elevated without a clear explanation. Plasma levels of leptin are in the normal-low range for BMI, while adiponectin levels are significantly low. Responsible mutations are often missense in heterozygosis, and mutations in the promoter and de novo have been described. The mechanisms responsible for lipodystrophy-related mutations in the *PPARG* gene are easier to understand, as this gene encodes a key transcriptional factor in adipogenesis. The mutated forms of the receptor function either by a "dominant negative" mechanism or by haploinsufficiency (Garg, 2011; Rochford, 2010; Vantyghem *et al.*, 2012).

Type 4 FPLD

Type 4 FPLD, which has been reported in five families (Gandotra *et al.*, 2011; Kozusko *et al.*, 2015), is a disorder due to mutations in the *PLIN1* gene that codes for perilipin 1, a component of lipid droplets. This protein is essential in the uptake and release of lipids. Affected patients present fat loss from infancy, which mainly affects the limbs and buttocks, without accumulation of fat in the neck. Compared with other forms of FPLD, lipodystrophy is more homogeneous. It is frequently associated with hypertrophy of the calves, acanthosis nigricans, insulin resistance, alterations in glucose metabolism, hypertriglyceridemia, tendency to have hypoleptinemia, hypoadiponectinemia, hepatic steatosis, and PCOS. Adipose tissue contains smaller adipocytes and shows macrophages infiltration and fibrosis. In adipocytes, lipid droplets are smaller, with less accumulation of triglycerides and increased basal lipolysis. The mutations identified in *PLIN1* give rise to an aberrant protein and its pathogenetic mechanism is associated with haploinsufficiency (Garg, 2011; Vantyghem *et al.*, 2012).

Type 5 FPLD

Type 5 FPLD is due to a missense mutation in the CIDEC gene, which encodes a member of the cell death-inducing DNA fragmentation factor-like effector family. This subtype is an autosomal recessive disorder with only one case has been described in an Ecuadorian woman of 19 years of age. She presents with insulin resistance, diabetes mellitus, acanthosis nigricans, hypertriglyceridemia with secondary pancreatitis, hypertension, hepatic steatosis, and partial lipodystrophy. Lipodystrophy was confined only to the buttocks and lower limbs, remaining unaltered the rest of the adipose depots (Rubio-Cabezas *et al.*, 2009). CIDEC encodes for a protein that is a component of lipid droplets, and its deficiency reduces fat mass, playing important roles in apoptosis, and giving rise to adipocytes with multiloculated lipid vacuoles (Garg, 2011; Vantyghem *et al.*, 2012).

Type 6 FPLD

Type 6 FPLD is a recessive disorder due to mutations in the LIPE gene, which encodes the hormone-sensitive lipase E. Mutations in this gene give rise to a late-onset FPLD. Two pedigrees have been reported so far, one of which was associated with multiple symmetric lipomatosis (Farhan *et al.*, 2014; Zolotov *et al.*, 2017). The phenotype becomes evident at up to 30 years of age with a progressive reduction of subcutaneous fat in the lower limbs and fat accumulation in the neck, abdomen, clavicular regions, axillae, labia majora, back, and area below the triceps. These patients can develop insulin-resistant diabetes, hepatic steatosis, hypertriglyceridemia, hypercholesterolemia, hyperadiponectinemia, and high levels of creatine kinase. One patient showed mild proximal muscle weakness and dystrophic changes in muscular biopsy.

To date, only a single pedigree bearing a missense mutation in the AKT2 gene has been reported to be associated with partial lipodystrophy (Tan *et al.*, 2007). These patients also have diabetes mellitus and severe insulin resistance, and the lack of AKT in adipocytes causes severe lipodystrophy in mice (Shearin *et al.*, 2016). However, because the lipodystrophic phenotype was not described in detail, no differences from other types of FPLD can be established. The AKT2 gene (murine thymoma-oncogene homolog-2) encodes a protein belonging to a subfamily of serine/threonine kinases containing SH2-like (Src homology 2-like) domains involved in glucose metabolism, postreceptor signaling of insulin and adipocyte differentiation (Garg, 2011; Rochford, 2010; Vantyghem *et al.*, 2012).

Progeria Syndromes

Hutchinson–Gilford progeria syndrome

This is the classic form of premature aging and is associated with de novo mutations in the *LMNA* gene (**Fig. 1**). The disease characteristically begins to manifest after the first year of life. Patients present growth retardation, low stature, alopecia, osteolysis, facial aging characteristics, disproportionately large head, "pinched" nose, joint stiffness, dentition abnormalities, whistle voice, osteoporosis, and generalized lipodystrophy affecting the limbs, face, and trunk, while preserving intraabdominal depots. Other features are prolonged prothrombin times, elevated platelet counts and serum phosphorus levels, low-frequency conductive hearing loss, and functional oral deficits. Cardiovascular studies have revealed diminishing vascular function with age, including elevated blood pressure, reduced vascular compliance, decreased ankle-brachial indices, and adventitial thickening. Patients typically die before age 15 years because of myocardial infarction or stroke (Merideth *et al.*, 2008). The most frequent mutation causing Hutchinson–Gilford progeria syndrome (HGPS) is a de novo C-to-T transition resulting in a silent gly-to-gly change at codon 608 within exon 11 (G608G) (De Sandre-Giovannoli *et al.*, 2003; Eriksson *et al.*, 2003). This mutation was shown to activate of a cryptic splice site within exon 11 of *LMNA*, causing production of a protein product with 50 amino acids deleted near the C terminus (named as LaminΔ50 or progerin). The cellular hallmarks of HGPS include nuclear blebbing, loss of peripheral heterochromatin, defective epigenetic inheritance, altered gene expression, and senescence (Goldman *et al.*, 2004). It has been proposed that abnormal farnesylation of progerin plays a role in the cellular phenotype in HGPS cells. HGPS-induced pluripotent stem cells (iPSCs) showed the absence of progerin, and lacked the nuclear envelope and epigenetic alterations; however, upon differentiation of HGPS iPSCs, progerin and nuclear abnormalities were restored. These studies identified DNA-dependent protein kinase catalytic subunit (PRKDC) as a downstream target of progerin. The absence of nuclear PRKDC holoenzyme was correlated with premature aging (Liu *et al.*, 2011). In contrast, HGPS skin fibroblasts show a loss chromatin compartmentalization at later passages because of the loss of H3K27 trimethylation in gene-poor regions, gain of H3K27 trimethylation in gene-rich regions, and detachment of chromatin from the lamina (McCord *et al.*, 2013). Another pathogenetic mechanism involved in lipodystrophy-associated HGPS is disruption of the mechanistic target of rapamycin pathway, which leads to abnormal autophagy, altered proliferative rate, and downregulation of genes that regulate adipogenesis (Charar and Gruenbaum, 2017).

Mandibuloacral dysplasia

Mandibuloacral dysplasia (MAD) is an extremely rare autosomal recessive disorder that occurs in early childhood (2–4 years) and is characterized by multiple musculoskeletal abnormalities (progressive osteolysis of the distal phalanges and clavicles and mandibular hypoplasia, which cause retrognatia and stepped shoulders), progeroid features (cutaneous atrophy with marked superficial vasculature and mottled hyperpigmentation, thin "pinched" nose and hair loss), delayed teething and enclosure of the cranial sutures, dental crowding, joint stiffness, lipodystrophy with insulin resistance, hypertriglyceridemia, low HDLc, and impaired glucose metabolism. There are two types of lipodystrophy: A (partial loss of fat in limbs preserving that of the neck and trunk) and B (generalized). MAD may be due to mutations in *LMNA* (type A) (Novelli *et al.*, 2002) or in *ZMPSTE24* (type B) genes

(Agarwal et al., 2003b). The latter gene encodes for a zinc-metalloprotease involved in the posttranslational processing of prelamin A. A deficiency in *ZMPSTE24* will result in the accumulation of toxic farnesylated prelamin A in cells. MAD due to mutations in *LMNA* has been reported in approximately 30 patients, whereas less than a dozen of patients have been reported with mutations in *ZMPSTE24* (Garg, 2011; Vantyghem *et al.*, 2012; Worman *et al.*, 2009).

Werner syndrome

This recessive syndrome (**Fig. 1**) is due to mutations in the RECQL2 gene (Yu *et al.*, 1996), which codes for a DNA helicase. Patients present short stature, late-onset progeroid features (second childhood-adolescence), such as premature graying, cataracts, cutaneous signs of scleroderma and osteoporosis. In addition, these patients present lipodystrophy affecting the trunk, face, and extremities associated with insulin resistance and diabetes, acute voice, bird face with beaky nose, hypogonadism, limb muscle atrophy, calcification of blood vessels and premature death (3rd–4th decade) related to cardiovascular disease or cancer. Malignancy is frequent in these patients (10%), with nonepithelial cancers (osteosarcoma, soft tissue sarcoma, melanoma) more frequent than in the general population (Goto *et al.*, 1996). The characteristic features are short stature, aged appearance, thin limbs, and robust trunk (Hegele *et al.*, 2007). The mutant *RECQL2* gene triggers a sequence of premature expression of inhibitors of DNA synthesis and other genes, with resulting in inhibition of DNA synthesis and early cellular senescence (Thweatt and Goldstein, 1993).

Atypical Werner syndrome and atypical progeroid syndrome

Some missense mutations in heterozygosis and, generally de novo, in the *LMNA* gene give rise to other subtypes of premature aging different than the classic HGPS. In all cases, lipodystrophy is present, albeit to varying degrees, from generalized forms to partial forms affecting only the distal extremities of the limbs. The clinical features of these disorders in some cases coincide with other entities related to *LMNA* mutations, such as HGPS, LDPF2, MAD, Emery–Dreiffus muscular dystrophy, or familial-dilated cardiomyopathy, suggesting that more than independent clinical entities are different forms of presentation of the same disorder, modulated by unknown factors (endogenous and/or exogenous). Additionally, the same mutation can cause different clinical features.

The so-called atypical Werner syndrome shows similar clinic features as the classic form of this syndrome, although there are some differences. In general, the onset of early signs (early graying) typically occurs at earlier ages and disease progression is often more accelerated in atypical forms than in the classical form. Insulin resistance is typically present and patients may develop diabetes. Some cases associated with dyslipidemia, hepato-splenomegaly, cardiomyopathy, joint contractures, and leucomelanodermic papules have been reported; however, there is high phenotypic heterogeneity. Generally, these patients commonly present with short stature, premature graying, lipodystrophy, and aged appearance.

Atypical progeroid syndrome (APS) (**Fig. 1**) has been linked to the following mutations in *LMNA*: T10I, A57P, L59R, R133L, L140R, S143F, E145K, V169fsX176, D300N, E578V, and R644C. Although most are de novo mutations in heterozygosis, in some cases mutations were transmitted in an autosomal dominant manner affecting two generations. These cases present progeroid signs, such as short stature, beaked nose, premature graying, partial alopecia, nasal voice, and cutaneous lesions (spotted hypopigmentation and sclerodermatous changes, especially on the dorsum of the hands and feet), but not acanthosis nigricans. Other features that may appear are: mandibular hypoplasia, mild clavicular resorption, acro-osteolysis, dental crowding, and ojival palate. Some patients experience contractures affecting the elbows, wrists, knees, and ankles. Valvulopathies and dilated cardiomyopathy have also been reported in over 50% of cases. Patients with greater lipodystrophy develop diabetes mellitus with severe insulin resistance, hypertriglyceridemia, and hepatic steatosis. All women of childbearing age show poor breast development, but their menses were regular, although premature ovarian failure has been reported in some cases. Marrow fat is always preserved. Although the phenotype is heterogeneous, it can be distinguished from HGPS and MAD. In contrast to these two syndromes, APS shows no acro-osteolysis or minimal involvement of the distal phalanges, and mandibular hypoplasia is rare and mild. Alopecia is minor. The onset of clinical manifestations is later than in HGPS or MAD, and survival is greater compared to HGPS. However, it is often extremely difficult to discriminate between APS and atypical Werner syndrome (Garg *et al.*, 2009; Guillín-Amarelle *et al.*, 2015).

Nestor–Guillermo progeria syndrome

This entity is an autosomal recessive disorder caused by mutations in the *BANF1* gene; to date, only two cases have been reported (Cabanillas *et al.*, 2011). Nestor–Guillermo progeria syndrome presents numerous similarities with LMNA-associated progeria syndrome, but is considered a chronic progeria. This disorder begins to manifest from 2 years of age, with growth retardation, short stature, partial alopecia but preserving eyebrows and eyelashes, ocular protrusion, generalized lipodystrophy, severe osteolysis affecting the jaws, clavicles, ribs and phalanges, dental crowding, joint stiffness, delayed closure of fontanelles, loss of nasal bridge, aging appearance with dry and wrinkled skin, spotted pigmentation, severe scoliosis, and valvulopathies. Analytical studies revealed only vitamin D2 deficiency and severe hypoleptinemia. Unlike HGPS and MAD, these patients did not present metabolic alterations, hepatic steatosis, or atherosclerosis.

The *BANF1* gene encodes for barrier-to-autointegration factor 1 (BAF), which is involved in nuclear envelope assembly. BAF interacts with DNA and different proteins, including lamin A. Immunofluorescence studies of primary fibroblasts from these patients revealed abnormalities in nuclear morphology (herniations), which were similar to those observed in other laminopathies. Particularly, the location of lamina A was unaffected, but that of emerine was not (Cabanillas *et al.*, 2011). In conclusion,

mutations in this gene, which forms part of the nuclear membrane protein framework, cause abnormal distribution of nuclear lamina components in a manner similar to that in other progeroid disorders associated with *LMNA* mutations.

Neonatal progeroid syndrome

This disorder, also known as Wiedemann–Rautenstrauch syndrome, follows a pattern of autosomal recessive inheritance. Its molecular basis is unknown, although it has been suggested that the syndrome can be caused by disturbed RNA polymerase III subunit A (POLR3A) functioning (Paolacci *et al.*, 2017). Affected children are characterized by intrauterine growth retardation, failure to thrive, short stature, progeroid appearance with cranial deformities, hypotonia, variable mental impairment, and death in childhood (Hegele *et al.*, 2007). Lipodystrophy is almost generalized, and in some cases paradoxical accumulation of fat around the buttocks and anogenital area and on the flanks have been reported (O'Neill *et al.*, 2007; Arboleda *et al.*, 1997). Recently (Garg *et al.*, 2015), two patients with some features resembling neonatal progeroid syndrome but with longer survival were reported with mutations in the *CAV1* gene.

MPLD syndrome

MPLD is an autosomal dominant disorder due to de novo mutations in the *POLD1* gene characterized by mandibuloacral hypoplasia, deafness, progeroid manifestations, nondescent tests and male hypogonadism, metabolic abnormalities including insulin resistance and diabetes mellitus and generalized lipodystrophy (Weedon *et al.*, 2013). The disease appears in early childhood with poor growth and thin limbs caused by loss of subcutaneous adipose tissue. Sensorineural deafness occurred later. Facial features included beaked nose, prominent eyes, crowded teeth, small mouth and uvula, and long eyelashes in some cases.

PCYT1A lipodystrophy

Only two subjects have been reported to suffer this rare recessive condition (Payne *et al.*, 2014), which is due to mutation in *PCYT1A* encoding choline phosphate cytidylyltransferase-1α. Lipodystrophy is generalized and observed mostly in the limbs. Patients show insulin resistance, diabetes mellitus, hypertriglyceridemia, low HDLc, and liver steatosis during childhood. Characteristically, patients have growth failure and short stature.

SHORT syndrome

SHORT is the acronym of S = stature; H = hyperextensibility of joints or hernia (inguinal) or both; O = ocular depression; R = Rieger anomaly; T = teething delay. In this autosomal dominant syndrome, nonprogressive lipodystrophy is manifested mostly by a lack of subcutaneous fat in the face, chest, and upper extremities, relatively sparing the legs, generalized thin stature, and sometimes by local loss of fat resulting in small cutaneous pits on the elbows or buttocks (Koenig *et al.*, 2003). All patients presented with relatively short stature compared with their families. Other features are triangular face, prominent forehead, deep-set eyes, hypoplastic or thin alae nasi, small chin, and large ears. Mild midfacial hypoplasia gives the patients the impression of apparent prognathism despite micrognathia. The thin, wrinkled skin and readily visible veins intensify the progeroid impression (Koenig *et al.*, 2003). Rieger anomaly may manifest at birth with congenital glaucoma and cloudy cornea (Brodsky *et al.*, 1996) or total absence of the iris stroma. Despite speech delays in childhood, mental status appears to be normal or only slightly subnormal (Gorlin *et al.*, 1975). The disorder is caused by heterozygous mutation in the *PIK3R1* gene (Thauvin-Robinet *et al.*, 2013), which encodes for phosphoinositide-3-kinase regulatory subunit-1, a lipid kinase that phosphorylates the inositol ring of phosphatidylinositol and related compounds.

Bloom syndrome

Bloom syndrome is an autosomal recessive pediatric disorder caused by mutations in *RECQL3*, which encodes RecQ helicase (Ellis *et al.*, 1995). This syndrome is characterized by growth deficiency, telangiectasia, altered skin pigment, photo-sensitivity, hypertrichosis, polydactyly, predisposition to malignancy, and chromosomal instability. Lipodystrophy affects fat accumulation in the limbs and abdomen. Diabetes may be present.

Other progeroid syndromes

Other progeroid syndromes such as Cockayne syndrome (CS) and Keppen–Lubinsky syndrome present with severe mental retardation, seizures, and generalized lipodystrophy. CS is a recessive disease characterized by a marked failure to thrive, cachectic dwarfism, microcephaly, ataxia, mandible prognathism, and deep-set eyes with congenital cataracts, progressive pigmentary retinopathy, and sensorineural hearing loss among other features; the patients typically die in the second decade of life. CS is a genetically heterogeneous disorder, and certain types show some overlap with specific forms of xeroderma pigmentosum, although these patients show no significant increase in skin cancer. CS is caused by mutations in *ERCC8* or ERCC6 genes, which are part of the nucleotide excision repair pathway, a complex system that eliminates structural DNA lesions (Troelstra *et al.*, 1992). In Keppen–Lubinsky syndrome, the patients show poor postnatal growth, microcephaly, and aged facial appearance because of their tightly adherent facial skin, with open mouth and large prominent eyes (Masotti *et al.*, 2015).

Autoinflammatory Syndromes

This term encompasses Nakajo–Nishimura syndrome (Kitamura *et al.*, 2011), JMP syndrome (joint contractures, muscular atrophy, microcytic anemia, and panniculitis-induced lipodystrophy) (Garg *et al.*, 2010) and CANDLE (chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature) syndrome (Torrelo *et al.*, 2010). All these disorders are recessive disorders related to mutations in *PSMB8*, which encodes for proteasome subunit beta 8. Immunoproteasome-mediated proteolysis generates immunogenic epitopes presented by major histocompatibility complex class I macromolecules. Mutations in *PSMB8* may trigger auto-inflammatory responses, leading to infiltration of lymphocytes and other immune cell to adipose tissue, and consequently, adipocyte loss (Garg, 2011; Vantyghem *et al.*, 2012).

These recessive disorders begin in childhood and lipodystrophy can be generalized or partial, affecting the face and limbs. JMP is characterized by joint contractures, muscular atrophy, microcytic anemia, and panniculitis-induced lipodystrophy. Other features include intermittent fever, hypergammaglobulinemia, increased sedimentation rate, hepato-splenomegaly, and calcification of the basal ganglia. For CANDLE syndrome, five patients have been reported to present childhood onset with recurrent fevers and violaceous annular plaques on the eyelids and lips, evolving through childhood to a loss of subcutaneous fat in the face and upper limbs. The cases also had edematous purplish eyelids, hepato-splenomegaly, arthralgias, microcytic anemia, increased sedimentation rate, and calcifications in the basal ganglia. These features likely represent the initial forms of presentation of JMP syndrome (Garg, 2011).

Acquired Lipodystrophies

Acquired Generalized Lipodystrophy (Lawrence Syndrome)

This is a rare disorder (**Fig. 2**) characterized by the disappearance of adipose tissue throughout the body and is associated with diabetes mellitus, hypertriglyceridemia, and hepatomegaly (Lawrence, 1946). Unlike CGL, it does not manifest from birth but develops after childhood or adolescence. This is a rare disease that affects women more frequently than men. Fat loss occurs throughout the body, including characteristically the sole of the feet and the palm of the hands. Loss of adipose tissue is typically gradual and slow, beginning in particular parts (often face and extremities) of the body before

Fig. 2 Example of acquired generalized lipodystrophy (Lawrence syndrome). Woman at 3 and 13 years of age. Fat loss started at 6 years. There is generalized loss of fat with well-defined musculature and abdominal prominence caused by severe hepatomegaly due to hepatic steatosis.

generalizing to other parts over months or years, although sometimes the process may last only a few weeks. In addition to adipose tissue involvement, severe hypertriglyceridemia is frequent, which is sometimes responsible for episodes of pancreatitis and eruptive xanthomas. Other metabolic disorders include diabetes mellitus, insulin resistance, hyperinsulinemia, and hypoleptinemia (Misra and Garg, 2003). Reproductive capacity is preserved. Hepatomegaly, sometimes associated with cirrhosis, is a consequence of triglyceride deposition. In some patients, kidney tubular lipidosis and focal glomerular sclerosis have been reported. Etiology and pathophysiology of the disease is poorly understood; panniculitis as well as concomitant autoimmune diseases have been associated with several cases.

Acquired Partial Lipodystrophies

Barraquer–Simons syndrome

Accquired partial lipodystrophy (APL) (**Fig. 3**), also named Barraquer–Simons syndrome or cephalothoracic lipodystrophy, was described at the beginning of the 20th century by Barraquer and Simons (Misra *et al.*, 2004). Since then, approximately 200 cases have been reported. Although it is considered an acquired form of lipodystrophy, in 2006, APL was suggested to be associated with mutations in the *LMNB2* gene (Hegele *et al.*, 2006).

APL is a disorder that begins in childhood, although it may also appear later in life, sometimes after a viral infection. It affects females more frequently than males. Fat loss occurs in the head, neck, shoulders, upper limbs, thorax, and upper abdomen. On the face, loss of fat predominately affects the temples and cheeks. In the upper limbs, superficial veins are prominent and the loss of adipose tissue gives an appearance of extreme muscles. In women, after puberty, fat is deposited on the hips and thighs. Fat deposits have also been described in the breasts and scattered areas of the body. Fat in the gluteal region, bone marrow, orbits, and mediastinal region is not affected. Intermuscular, intraperitoneal, and perirenal fat is also normal. Fat loss may occur over a limited period (1–2 years), although it can also occur periodically for several years. Unlike other types of lipodystrophy, APL is rarely associated with insulin resistance, dyslipidemia, diabetes mellitus, or menstrual disorders. Patients with Barraquer–Simons syndrome tend to have low serum complement three levels, and in some cases presence of C3 nephritic factor. A characteristic feature is its association with mesangiocapillar glomerulonephritis, which affects approximately one-third of patients (Misra *et al.*, 2004).These patients typically do not present clinical evidence of renal disease or anomalies in renal function up to 10 years after the loss of adipose tissue begins.

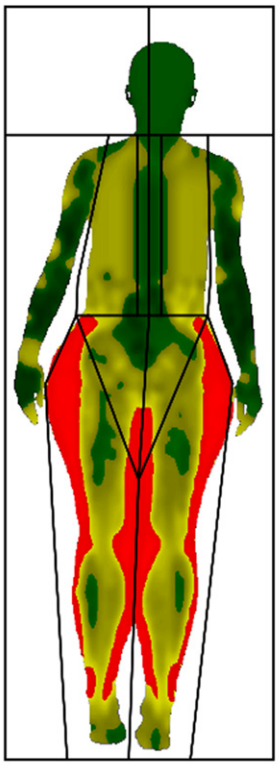

Fig. 3 Example of acquired partial lipodystrophy (Barraquer–Simons syndrome). Dual-energy X-ray absorptiometry (DEXA) image of a 38-year-old woman with cephalon-caudal acquired partial lipodystrophy. Loss of fat in the upper body and accumulation of adipose tissue in hips and lower extremities (in *red*) is observed.

Autoimmune diseases and antinuclear and anti-DNA antibodies have been detected in several patients. The morbidity and mortality of this disorder is fundamentally related to kidney involvement and autoimmune diseases with which it is often associated.

Lipodystrophy associated with HIV infection

Lipodystrophy in human immunodeficiency virus type 1 (HIV-1)-infected patients is an adipose tissue redistribution disorder commonly associated with comorbidities such as systemic metabolic alterations, dyslipidemia, and cardiovascular disease (Grinspoon and Carr, 2005; Villarroya *et al.*, 2005; Caron-Debarle *et al.*, 2010). Morphological changes and metabolic disturbances among HIV-1-infected patients were first described in the mid-1990s with the introduction of combination antiretroviral therapy (Carr and Cooper, 2000). Since then, HIV-1-associated lipodystrophy syndrome (HALS) has described as a syndrome characterized by loss and/or accumulation of fat in different adipose tissue depots. Mainly, lipoatrophy occurs in the peripheral area (loss of subcutaneous fat from the face, arms, buttocks, and legs) (**Fig. 4**), may be mixed with lipohypertrophy in the visceral area (fat accumulation on the abdominal area), and/or is located in specific lipoma areas, that is, accumulation of dorsocervical fat ("buffalo humps") (Milinkovic and Martinez, 2005).

HALS is primarily considered to be an adverse effect of a chronic inflammatory state due to HIV-1 virus infection and therapy treatment. Antiretroviral drug toxicity is not limited to a specific drug or a class of drugs, although new antiretroviral drugs are thought to be less prone to induce lipodystrophy (Srinivasa and Grinspoon, 2014). In early reports, HALS was reported to affect up to half of HIV-infected patients receiving antiretroviral therapy (Carr *et al.*, 1998). According to the UNAIDS report on the global AIDS epidemic (UNAIDS.org, 2016), the prevalence of people living with HIV globally was estimated as 36.7 million in 2016. The number of HIV-infected patients on antiretroviral therapy has been continuously increasing, reaching 17.0 million people in 2016. Thus, acquired lipodystrophy in HIV-infected patients is by far the most prevalent type of lipodystrophy (Garg, 2004). The progressive substitution of some antiretroviral drugs, mainly nucleoside analog inhibitors of viral reverse transcriptase (typically thymidine analogs such as stavudine), for other less toxic drugs has substantially reduced the development of overt lipoatrophy (i.e., facial lipoatrophy) in HIV-infected patients, and, in the short-term, the appearance of new lipodystrophy cases is less frequent when last-generation drugs are used for antiretroviral therapy.

The pathophysiology of HALS appears to be multifactorial and several key pathophysiological factors associated with HALS have been identified. These include mitochondrial dysfunction, adipocyte differentiation disturbances, high adipocyte lipolysis, proinflammatory milieu, and adipocyte apoptosis in lipoatrophic adipose tissue (Giralt *et al.*, 2011). However, adipose tissue disturbances vary by anatomical location and lipodystrophy status. Thus, visceral adipose tissue from HIV patients on antiretroviral treatment show unaltered adipogenesis and milder induction of proinflammatory markers (Gallego-Escuredo *et al.*, 2013). In contrast, acquisition of a distorted white-to-brown adipose phenotype with mitochondrial alterations but absence of local inflammatory status was reported to occur in enlarged dorsocervical subcutaneous adipose tissue ("buffalo humps") (Guallar *et al.*, 2008; Bérériat *et al.*, 2011; Torriani *et al.*, 2012). Additionally, adipose tissue dysfunction expands to involve systemic

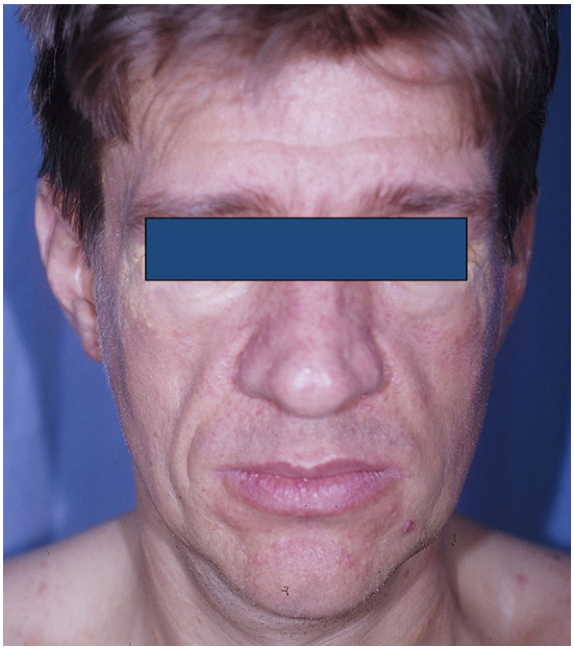

Fig. 4 Example of facial lipoatrophy in lipodystrophy associated with HIV infection. Facial lipoatrophy in a HIV-infected patient after 5 years receiving highly active antiretroviral therapy of first generation (stavudine + lamivudine + indinavir). metabolic homeostasis through alterations in endocrine functions of adipose tissue (i.e., frequent low levels of circulating leptin and adiponectin), enhanced production of proinflammatory cytokines, and excess free fatty acid release due to lipolysis (Lagathu *et al.*, 2005; Giralt *et al.*, 2011; Paruthi *et al.*, 2013). Several research groups have identified the deleterious action of diverse antiretroviral drugs as important factors in eliciting these alterations in adipose tissue (Villarroya *et al.*, 2005; Caron-Debarle *et al.*, 2010; Erlandson and Lake, 2016). Moreover, HIV-1 infection-related events (HIV-1-encoded proteins, local inflammation in adipose tissue) contribute directly to the complex development of HALS by affecting adipocyte biology (Giralt *et al.*, 2006).

While the prevention of HALS may be addressed by choosing drugs with poor toxicity, treatment options for HALS once established remain scarce. Switching the antiretroviral drug regimen is a potential mechanism for preventing or minimizing lipodystrophy, but peripheral lipoatrophy is difficult to reverse (Lake and Currier, 2013). A few small studies of leptin replacement therapy in HIV patients with lipoatrophy demonstrated improvements in visceral adiposity and metabolic parameters, but did not observe improved peripheral lipoatrophy (Paruthi *et al.*, 2013). Reduced visceral adipose mass without loss of insulin sensitivity or exacerbation of lipoatrophy has been reported in HIV patients treated with rosiglitazone and/or growth hormone analogs (Falutz, 2011; Glesby *et al.*, 2013). Mediterranean diet may have protective effects on both HALS lipodystrophy and its metabolic complications (Tsiodras *et al.*, 2009). Finally, autologous fat transplant and subdermal fillers are recognized treatment options for facial lipoatrophy (Lake and Currier, 2013).

Lipodystrophy in adults associated with total body radiation and hematopoietic stem cell transplantation in childhood

Several reports have described a pattern of higher visceral and lower subcutaneous fat among patients who have undergone radiotherapy, including childhood cancer survivors and those who received hematopoietic stem cell transplantation (Adachi *et al.*, 2017; Wei *et al.*, 2015; Adachi *et al.*, 2013). Such lipodystrophy adds to the high risk of developing endocrinopathies and metabolic derangements as late complications after hematopoietic stem cell transplantation. Because of the lower lean mass of patients, this syndrome is referred to as "lipodystrophic and sarcopenic" (Adachi *et al.*, 2013). In these patients, lipoatrophy is remarkable in the gluteal regions and extremities, whereas fat is preserved in the cheeks, neck, and abdomen. This is associated with increased deposition of visceral fat, insulin resistance, and hypertriglyceridemia. These features resemble those of FPL2.

Localized lipodystrophies

These forms of lipodystrophy are characterized by subcutaneous fat loss in a small area of the body, in contrast with the generalized or partial (but not local) forms of lipodystrophy described earlier.

Localized lipodystrophy caused by drugs

Abnormal reactions in subcutaneous fat to drugs, mainly insulin injection in patients with diabetes, have been reported (Radermecker *et al.*, 2007). Injected insulin may cause lipohypertrophy (a lipomatous development secondary to lipogenic effect of insulin) or lipoatrophy, which is considered an adverse immunological side effect of insulin action (Ma *et al.*, 2012). Insulin injection-induced lipoatrophy typically occurs in children and young type 1 diabetic patients. Lipoatrophy is becoming progressively uncommon with the availability of newer insulin analogs, whereas lipohypertrophy remains prevalent (Hussein *et al.*, 2007). Moreover, injected pegvisomant, a growth hormone antagonist used to treat acromegaly, has been reported to cause lipohypertrophy at the abdominal wall, at the site of injections, in some patients (Bonert *et al.*, 2008). These primary localized lipoatrophies usually resolve spontaneously and are not associated with systemic disorders. Education of patients about rotating injection sites and switching of injection area appears the most beneficial to avoid local lipodystrophy as a consequence of insulin or pegvisomant injections in affected patients. Localized subcutaneous lipoatrophy is also a common adverse effect of repeated intramuscular corticosteroid injection (Hamidou *et al.*, 1991; Avilés-Izquierdo *et al.*, 2006) and also resolves spontaneously, although cosmetic treatment using poly-L-lactic acid (Brodell and Marchese Johnson, 2014) or hyaluronic acid fillers (Di Gregorio and D'Arpa, 2016) have been reported.

Semicircular lipoatrophy

Semicircular lipoatrophy (also called "lipoatrophia semicircularis") is an infrequent condition characterized by semicircular depressions of subcutaneous adipose tissue in the anterolateral thighs (Hodak *et al.*, 1990). It mainly affects office workers and is considered an occupational disease. Skin and underlying muscles remain intact. The origin of this peculiar form of lipoatrophy is unknown, but repeated mechanical microtraumatisms and localized pressure on the affected thighs, and even electromagnetic fields have been proposed (Linares-García *et al.*, 2015). Reports of semicircular atrophy involve mainly women, and it has been proposed that the anatomical adipose constitution of women's thighs predisposes that a persistent mechanical pressure originates a relative impaired circulation on a tenuous perfused tissue, and induces the development of this type of lipoatrophy (Herane *et al.*, 2007). Recent studies claim that avoiding exposure to mechanical pressure (office table edges) improves the incidence of new cases as well as the recovery of affected individuals (Reinoso-Barbero *et al.*, 2013).

Centrifugal lipodystrophy

Centrifugal lipodystrophy ("lipodystrophia centrifugalis abdominalis infantilis") is a localized form of lipodystrophy affecting young children. Most of the patients are Japanese, Korean, or Chinese, although a few cases of Caucasian patients have been reported (Imamura, 2012). Patients usually develop depressed lesions, with loss of subcutaneous adipose tissue, during the first 3–4 years of life in the groin or axilla, often surrounded by slight erythematous appearance. The depressed lesions extend

centrifugally to involve the abdominal or chest walls. In most cases, such enlargement spontaneously ceases after a few years and most patients show spontaneous improvement after the cessation of enlargement before reaching adulthood. The etiopathology of this alteration is unknown.

Panniculitis-associated lipodystrophy

This is a rare condition, also called lipoatrophic panniculitis, lipophagic lipoatrophic panniculitis, and annular lipoatrophic panniculitis of the ankles (Corredera *et al.*, 2011; Shen *et al.*, 2010), in which permanent local lipoatrophy in children follows inflammatory panniculitis (Peters and Winkelmann, 1980). In patients, circumferential bands of lipoatrophy are often observed on the arms and legs. The causes of this disease are unknown, but it has been associated with autoimmune phenomena. It has been hypothesized that inflammatory signals arise locally from panniculitis target adipocytes and promote lipoatrophy (Levy *et al.*, 2017).

Acknowledgments

The authors wish to acknowledge the support of grants from Fondo de Investigaciones Sanitarias, Instituto de Salud Carlos III (PI14/00063 to M.G.), Fundación Mutua Madrileña (to. D.A-V), Ministerio de Economía y Competitividad (SAF2014-55725 to F. V.), Spain, co-financed by the European Regional Development Fund (ERDF), and Generalitat de Catalunya (2014SGR-141). M. G., F.V., and D. A-V. are members of the "Adipoplast" research network supported by Ministerio de Economica y Competitividad (BFU2015-70454-REDT), Spain. Thanks are given to Dr. P. Domingo (Department of Infectious Diseases, Hospital Universitari Arnau de Vilanova, Lleida, Spain) for scientific discussions and providing us with the HIV lipodystrophy patient picture. We thank Gemma Moreno for editorial support.

GI Hormone Development (Families and Phylogeny)☆

Anders H Johnsen, Copenhagen University Hospital, Copenhagen, Denmark

Glossary

Genome The complete gene complement of an organism.
Paleontology The scientific study of life in the geologic past; it involves the analysis of plant and animal fossils.
Phylogeny The evolutionary history of a species.

Introduction

Most peptide hormones identified in humans and other mammals have relatives in all major vertebrate classes. The assignment of such relationships is based primarily on structural similarities, but the site (organ) of production and functional characteristics may be also considered. However, caution is also warranted since, for example, function of structurally conserved hormones may have changed during evolution. In this article, only peptide hormones are described.

The phylogeny of species has been established by compilation of many kinds of information, mainly from paleontology and anatomy (**Fig. 1**). But important clues have also been obtained from comparison of the sequences of key proteins, such as a number of enzymes, with structures so crucial that only small variations are allowed (Feng *et al.*, 1997). Thus, the degree of dissimilarity of these structures can aid in the evaluation of their evolutionary distances. However, the peptide hormones are rather short, so variation of their structures cannot be used to evaluate evolution. In contrast, the hormone structures can be investigated in relation to the established phylogeny of the species to evaluate the constraints, or lack thereof, that have governed the changes in the sequences. Some hormone structures appear to be so conserved that they have hardly changed at all within vertebrates (e.g., pituitary adenylate cyclase-activating polypeptide (PACAP)), whereas others have changed to such a degree that the relationship is hardly recognizable from fish to human (e.g., growth hormone-releasing hormone (GHRH)). When amino acid sequences of proteins and peptides of different species are compared, it should also be remembered that the information is obtained from living representatives of the classes. These modern forms may have changed further since their divergence as separate species several hundred million years ago. Thus, comparing sequences provide only circumstantial evidence about the situation at the time when the divergence occurred (Holmgren and Jensen, 2001; Hoyle, 1998).

Peptide hormones and neuropeptides are not restricted to vertebrates. In fact, the number of regulatory peptides in some invertebrate species may far exceed that observed in mammals and other vertebrates. Nevertheless, there are surprisingly few genuine invertebrate relatives of the known vertebrate hormones. There have been many indications that homologues to vertebrate hormones have been detected in invertebrates. However, most of these reports were based on antibody recognition. Antibodies are powerful tools for detection, visualization, and quantification, as well as many other purposes, when the epitope of the binding partner is known to be identical to the original antigen or can be assumed with high probability to be so. But assuming that there is such a degree of identity between an epitope and antigen from different species is often not justified. Thus, many apparently positive reactions may be due to cross-reactivity of the antibody with unrelated peptides or proteins that by chance show structural similarities to the hormone in question. The opposite situation has also been observed: the antibody is so specific that single amino acid substitutions that may be without any functional consequences can abolish the reaction with the antibody in part or in total. Thus, observations in one species based on antibodies raised against peptides from another species must be evaluated with caution, since both false-positive and false-negative results can occur.

During evolution, duplication of genes and exons followed by substitutions, insertions, and deletions has been an important mechanism for the creation of new peptides that acquire new functions. Two major rounds of whole genome duplications (WGD) occurred during the evolution of vertebrates, one at the beginning of the "Cambrian explosion" (approximately 500 million years ago) and one in the early Devonian, 2R, (approximately 450 million years ago), to produce up to four copies of the original genome. In fish, a third duplication, 3R, appears to have occurred in the late Devonian (approximately 300 million years ago). In the salmonid lineage even a fourth duplication occurred around 100 million years ago (Berthelot *et al.*, 2014). Many of the duplicated gene products developed into new proteins with new functions, thus giving rise to distinct families of proteins (e.g., regulatory peptides), with family members having related or even very distant functions.

☆*Change History*: May 2018. The sections "The PP-fold Family," "The Cholecystokinin/Gastrin Family," "The Tachykinin Family," "The Gastrin-Releasing-Peptide/Bombesin/Neuromedin B Family," "Motilin and Ghrelin" have been updated with references. The remaining sections have been updated to varying degrees, including new references and the PACAP/Glucagon introduction has been transformed into a table.

This article is an update of Anders H. Johnsen, GI Hormone Development (Families and Phylogeny), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 168–172.

 doi:10.1016/B978-0-12-801238-3.99430-3

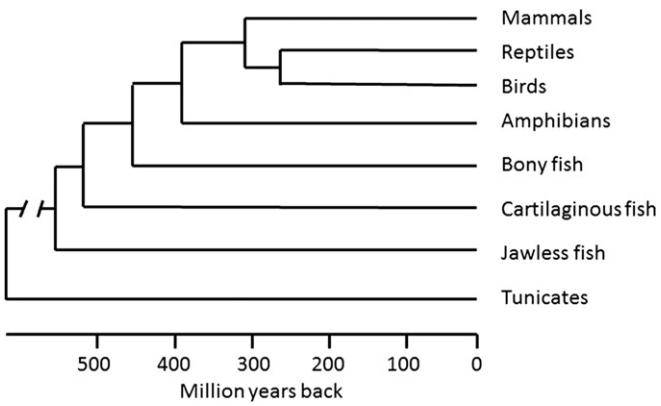

Fig. 1 Evolutionary relationship of the chordate classes. Apart from the tunicates (or urochordates), the remaining classes are vertebrate animals. The lengths of the horizontal lines indicate the period when the respective classes are assumed to have segregated.

Many of the gastrointestinal hormones can clearly be classified as belonging to families originating from a common ancestor. Others appear as singular peptides although they can be traced to most vertebrate classes. The following discussion of the relationships between specific peptides and peptide families considers mainly solid structural information and to some extent function and anatomical origin. Also, only hormones from the Chordata (including tunicates) are considered.

An interesting aspect of evolution is the coevolution of peptide ligands and their receptors (Jiang *et al.*, 2014), which however will not be further addressed in this article.

Hormone Families

The PACAP/Glucagon Superfamily

The PACAP/glucagon superfamily includes 10 structurally related hormones in human, encoded by six genes, see **Table 1**.

PACAP-like subfamily

The PACAP subfamily can be traced back to tunicates, in which PACAP and GHRH have been identified; actually, there are two different precursors in tunicates, each coding for both peptides. Most likely they segregated already during the first round of whole genome duplication. Interestingly, PACAP has been extremely well conserved from tunicate to human, whereas the structure of GHRH is highly variable and even between different mammals there is a low degree of similarity.

The glucagon family

Glucagon, GLP-1, and GLP-2 have been detected in all vertebrate classes, but not (yet) in tunicates. The three peptides are derived from a common precursor and this organization has been conserved from jawless fish to mammals. The differential expression of the three peptides is tissue specific. Glucagon is highly conserved in all vertebrates while both GLP-1 and GLP-2 appear to be considerably more variable (Irwin, 2001, 2009).

GIP, PHM/PHI, secretin, and VIP

GIP has been identified in mammals, birds and reptiles and secretin while PHM/PHI have been identified only in mammals and birds. Whether they are represented in the other vertebrate classes remains an open question. In contrast, VIP has been detected in all vertebrates except jawless fish. Furthermore, the structure of VIP is highly conserved with only minor variations allowed at nine positions of the 28-residue peptide (Cardoso *et al.*, 2010).

The PP-Fold Family

The PP-fold family of peptides derives its name from a structural characteristic of all the members: a hairpin-like fold with an extended proline helix containing three proline residues, a turn, and an α-helix with two tyrosine residues that fit in between the three proline residues. The family consists of neuropeptide Y (NPY) and peptide YY (PYY), present in all vertebrate classes, pancreatic polypeptide (PP), found only in tetrapods, and a pancreatic peptide Y (PY), found in some fish. NPY and PYY most likely originate from duplication of a common ancestor before the development of the jawless fish. NPY displays a high degree of sequence conservation, whereas PYY is more varied. The occurrence of PP only in tetrapods suggests that it is the result of yet another gene duplication that occurred before the emergence of the amphibians. The sequence variability of PP is quite high, with only 50% identity between mammals, birds, and amphibians. PY constitutes a special case and probably arose from a duplication of the PYY gene unrelated to the duplication event that generated PP (Larhammar *et al.*, 1993; Conlon, 2002).

Table 1 Members of the PACAP/glucagon superfamily

Name	*Short name*	*Gene (mammals)*
Pituitary adenylate cyclase-activating polypeptide	PACAP	A
PACAP-related peptide	PRP	A
Glucagon	–	B
Glucagon-like peptide-1	GLP-1	B
Glucagon-like peptide-2	GLP-2	B
Peptide histidine-methionine (or -isoleucine)	PHM (or PHI)	C
Vasoactive intestinal peptide	VIP	C
Growth hormone-releasing factor	GHRH	D
Secretin	–	E
Glucose-dependent insulinotropic peptide	GIP	F

The Cholecystokinin/Gastrin Family

Cholecystokinin (CCK) and gastrin constitute a small family comprising only these two members. They are characterized by a common amidated C-terminal tetrapeptide sequence, which also constitutes the minimal structure necessary for biological activity of both peptides. Hence, it appears most likely that CCK and gastrin have evolved from a common ancestor. Cionin, isolated from *Ciona intestinalis*, a representative of the tunicates, which occupy a key position at the transition to vertebrates, also contains the characteristic tetrapeptide sequence and thus represents the oldest genuine member of the CCK/gastrin family thus far known, dating the emergence of these peptides back to at least 500 million years ago. The CCK/gastrin family is represented throughout the entire chordate phylum, including cartilaginous and bony fish, amphibians, reptiles, birds, and mammals (Johnsen, 1998; Baldwin *et al.*, 2010). A duplication of the ancestral gene appears to have occurred at 2R giving rise to two peptides most likely homologous to CCK and gastrin and a third duplication occurred at the level of cartilaginous fish to produce two CCKs (Dupré and Tostivint, 2014). At the amphibian level, the two separate peptide systems have been shown to exert distinct physiological gastrin and CCK actions. Interestingly, while CCK is well conserved in all vertebrate species, the gastrins vary more and the mammalian gastrins at first sight appear as a distinct group with little similarity to the nonmammalian gastrins outside the invariant C-terminal tetrapeptide. However, closer examination reveals that even if a major structural change was introduced at the transition to mammals, there exists a clear evolutionary relationship between mammalian and nonmammalian gastrins (Johnsen, 1998).

The Tachykinin Family

The tachykinins share a C-terminally amidated pentapeptide, -Phe-Xaa-Gly-Leu-Met-amide, where Xaa can vary among a few possible amino acids. In mammals, the family comprises four peptides encoded by two genes: preprotachykinin A, encoding substance P (SP), neurokinin A (NKA), and neuropeptide γ (NPγ, which is an N-terminally extended form of neurokinin A); and preprotachykinin B, encoding neurokinin B. SP, NKA, and NPγ have been identified in most vertebrate classes, whereas NKB has been identified only in mammals and a frog (Amphibia). NKA (a decapeptide) has been highly conserved and SP (an undecapeptide) somewhat less so. Interestingly, SP from amphibians shows less identity to the mammalian form than SP from the phylogenetically more distant fish. However, the peptides are rather short and even if many tachykinins from nonmammalian vertebrates have been identified, almost no genes for these tachykinins have been discovered (Zhou *et al.*, 2012). Thus, solid conclusions regarding the evolution of the tachykinins are difficult to make, but there is no doubt that the tachykinins constitute a family, that they must have arisen from a common ancestor, and that their diversity must have been brought about by exon duplication, gene duplication, and point mutations.

The Somatostatin Family

In mammals, the somatostatin (SS) family contains two members, somatostatin (known since 1973) and the neuropeptide, cortistatin, which shows a high degree of similarity to somatostatin. The bioactive forms of somatostatin are somatostatin-14 and the N-terminally extended somatostatin-28. Somatostatin-14 is highly conserved, being identical in all vertebrates from jawless fish to mammals. In addition to genuine somatostatin (SS1), most, if not all, investigated vertebrate species express a second gene, SS2, very similar to preprosomatostatin-I. It has been suggested that the duplication of the original somatostatin gene occurred early in evolution, predating or concomitant with the development of the chordates. Subsequently, the third round of duplication in the stem lineage leading to bony fish after divergence from the line leading to tetrapods has resulted in the occurrence of no less than at total of six SS-related peptides, SS1–6 (Tostivint *et al.*, 2013).

The Gastrin-Releasing-Peptide/Bombesin/Neuromedin B Family

Gastrin-releasing peptide (GRP) has been identified in all major vertebrate classes except jawless fish. It consists of 22 (goldfish) to 29 (rat) amino acid residues and has an invariant C-terminal octapeptide sequence in all species. Neuromedin B, which shows similarity to GRP, has been identified only in mammals and a toad (Amphibia) and is encoded by a separate gene. The bombesins constitute an interesting subgroup, all being isolated from the skin of amphibians, where they may serve protective purposes, and also arising from independent genes. Since only GRP is known to exist in many vertebrate classes, it is not possible to further elaborate on the phylogeny of these peptides (Baldwin *et al.*, 2007).

Motilin and Ghrelin

Motilin is produced in endocrine cells of the upper intestine. Since the identification of porcine motilin in 1972, motilin has been identified in a number of mammals but in only one nonmammalian species, the chicken. The mature form of motilin consists of 22 amino acid residues and between human and chicken there are seven substitutions, although most are conservative. Thus, little can be said about the evolution of motilin. In 1999–2000, a new GHRH was identified independently by two groups and was designated ghrelin and prepromotilin-related peptide, respectively. Since then ghrelin has been identified in all vertebrate classes and there are ample evidence that motilin and ghrelin are phylogenitically related (He *et al.*, 2011).

Galanin

Galanin is a widespread neuropeptide and is also common in the gut. Since its discovery in 1983, galanin has been identified in a number of species representing all major vertebrate classes. It comprises 29 (or 30, in human) amino acid residues, of which the 14 N-terminal residues are identical in all species investigated. Despite repeated efforts to discover related peptides, none were found until 1999, when galanin-like peptide (GALP) coded by a separate gene (Lawrence and Fraley, 2011), was isolated from hypothalamus based on its stimulation of galanin type 2 receptors. Thirteen residues (positions 9–21) of GALP are identical to the N terminus of galanin. GALP has been identified only in mammals (human, pig, and rat). Recently, a mass spectrometry peptidomic analysis of the central nervous system of the ascidian, *Ciona intestinalis*, identified 33 peptides, 26 of which were novel (Kawada *et al.*, 2011). Among these a galanin/GALP-like peptide was identified by a highly conserved 12-amino acid sequence. Based on additional criteria the peptide was designated Ci-GALP, and thus it represents the first non-mammalian GALP and extends the galanin/GALP-family back the protochordates.

Glossary

Endocrine cell Type of cell that produces a signal that reaches the target via the blood circulation.

Fluorescence Emission of light of longer wavelength (e.g., visible light) following the absorption of light of shorter wavelength (e.g., ultraviolet light).

Histochemistry Defined chemical reactions performed directly in tissue sections and visualized in the microscope.

Immunohistochemistry The process of selectively detection of antigens (e.g., proteins) in cells of a tissue section using antibodies specifically binding to these antigens.

Paracrine cell Type of cell that produces a signal that is aimed at reaching neighboring cells by direct contact or diffusion.

Reducing capacity Ability of a cell to convert certain metal ions to free metal precipitate that can be visualized in the microscope. Reducing substances include amines, such as catecholamines and serotonin.

Secretory granules Particles composed of peptide hormones, and also amines, that are stored in membrane-bound vesicles in the cytoplasm before release.

Introduction

Endocrine (neuroendocrine or enteroendocrine) cells of the gastrointestinal (GI) tract belong to the dispersed neuroendocrine system, composed of cells that are widely distributed in the body, regardless of their embryologic derivation (Tischler, 1989). They are found within the mucosa all along the GI tract. Taking into account the size of the GI tract, the endocrine cells together constitute a prominent endocrine organ. In fact, calculations have made it clear that the endocrine cells of the GI tract form the largest endocrine organ in the body, and furthermore, harbor the greatest number and variety of endocrine cell types and hormones (Ahlman and Nilsson, 2001). The different endocrine cell types along the GI tract although diverse, have several histochemical and ultrastructural features in common. They produce hormone peptides, biogenic amines or neuroregulatory substances. After their synthesis in the endoplasmic reticulum, the endocrine cells are capable of packaging and storing these products into dense core vesicles (also named secretory granules) in the Golgi apparatus. (Vazquez-Martinez and Gasman, 2014). Therefore, one of the ultrastructural characteristic is the presence of membrane-bound secretory granules, which vary in size, shape and electron density (Capella *et al.*, 1976; Buffa *et al.*, 1978). There are several histochemical and immunohistochemical methods distinguishing endocrine from non-endocrine cells.

Historical Annotation

The first descriptions of the cells known as endocrine cells in the GI tract were published more than a century ago. In 1879 chromaffin cells and osmiophilic cells and in 1897 acidophil cells with basally located granules were described. The term enterochromaffin (EC) cell was first used in 1907. In 1914 Masson introduced a silver impregnation technique to demonstrate argentaffin cells, based on their capacity to form silver precipitates from a silver nitrate solution. It was also suggested at that time that the cells were endocrine. During the following years, several other staining methods were developed. Friedrich Feyrter in his classical work on disseminated endocrine cells, published in 1938, described these cells as "clear cells." In 1952 the endogenous substance ("enteramine") in the argentaffin/chromaffin cells capable of reducing ionic silver and chromium to the corresponding metallic precipitate was identified as 5-hydroxyptamine (5-HT or serotonin), (**Table 1**).

Interestingly, in 1912 it had already been observed that the GI tract was rich in cells with morphology similar to that of the EC cells, but lacking endogenous reducing substances. For several years, these cells were thought to be progenitors of EC cells. The presence of such non-EC endocrine cells was confirmed in several studies during the 1940s and 1950s. These studies have shown that endocrine cells even of non-EC type could be argyrophil, capable of forming silver precipitate, when an exogenous reducing agent was used. In fact, it turned out that the vast majority of endocrine cells in the GI tract were argyrophil. A similar to Bodian stain originally described in 1936 in neurons, was introduced by Grimelius, to detect argyrophil cells in 1968 and modified in 1980 (Grimelius, 2008). An important histochemical advancement in the early 1960s was the possibility of demonstrating monoamines, such as catecholamines and 5-HT (and their immediate amino acid precursors), by fluorescence microscopy taking advantage of the ability of these amines to

form fluorescent conjugates with formaldehyde vapors under certain conditions (the Falck-Hillarp technique). Using this technique, it was found that the endocrine cells in the GI tract had the capacity to form fluorogenic monoamines, such as dopamine and 5-HT, on administration of the corresponding amine precursor (L-DOPA and 5-hydroxytryptophan, respectively) and to store large amounts of them in their secretory granules. Based on these properties the cells have been referred to as APUD (Amine Precursor Uptake and

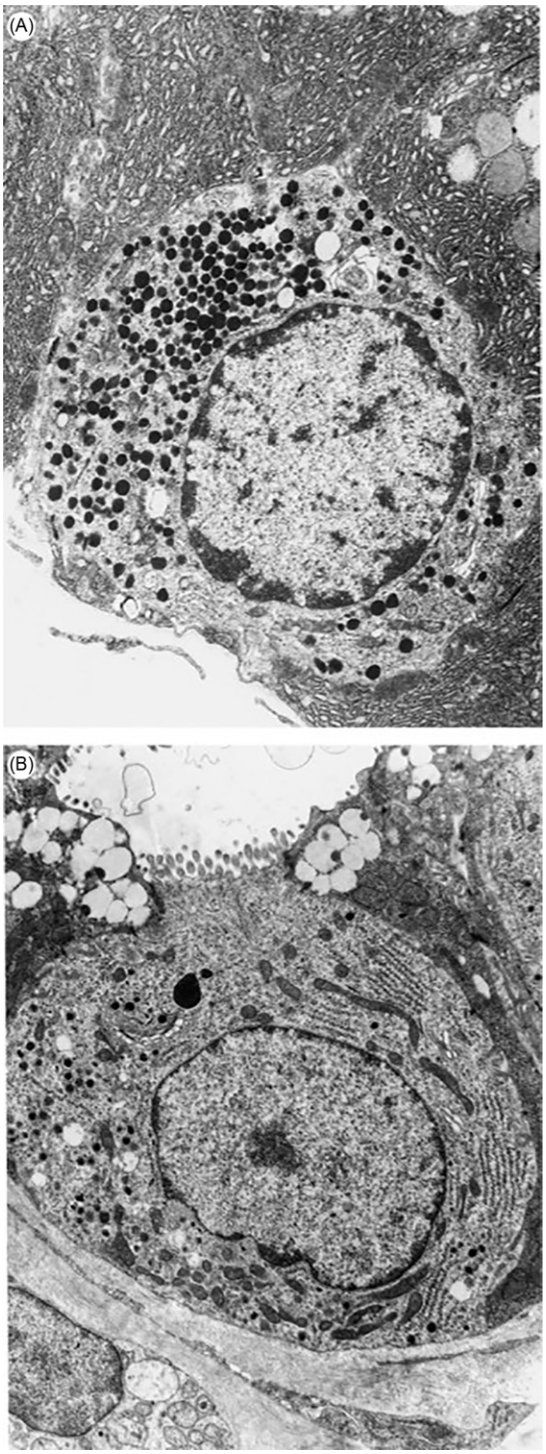

Fig. 3 Electron micrographs illustrating (A) an endocrine cell of closed type (A-like cell) in the acid-producing mucosa and (B) an open endocrine cell in the antral mucosa (G cell) of the rat stomach. Note numerous microvilli at the lumenal surface.

Decarboxylation). Given that amine-handling properties, as well as some other histochemical features are similar to those of neurons it was long thought that the GI endocrine cells have an embryonic neuroectodermal origin, deriving from neural crest (Pearse, 1969). Currently, the experimental evidence strongly supports their endodermal origin (Lloyd, 1990).

During the past few decades, immunocytochemistry, with the use of antibodies against individual hormones or other specific neuroendocrine cell markers, has become the most important technique for distinguishing the individual endocrine cell populations with respect to their cellular morphology, their regional and topographic distribution, and their function. Conversely, there

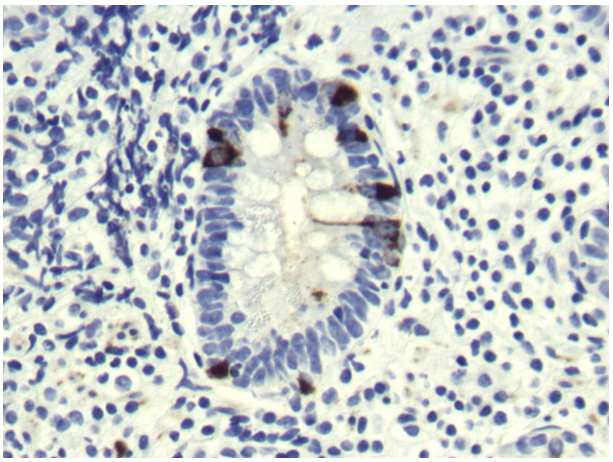

Fig. 4 Gastric gland harboring randomly distributed endocrine cells. Immunohistochemistry for chromogranin A highlights the attenuated thin cell processes towards the lumen surface (25 ×).

are cell populations that differ in their hormone content, but nevertheless share both light microscopic features and secretory granule appearance. Several broad-spectrum immunohistochemical markers have been introduced to detect and localize endocrine cells. Chromogranin A and synaptophysin represent the most important for diagnostic pathology (**Fig. 1**). Chromogranin A, a matrix-soluble glycoprotein, is member of the granin family of secretory proteins that are ubiquitous to the endocrine cells and neurons (Feldman and Eiden, 2003). Synaptophysin, a 38 kDa, is matrix-soluble glycoprotein molecule, component of the membrane presynaptic vesicle membrane, is also found diffusely in the cytoplasm of endocrine cells (**Fig. 2**). Neuron specific enolase (NSE) is a very sensitive, but not very specific marker for neuroendocrine cells (Lloyd, 1990). Other general markers, although nonspecific, include the protein cell product 9.5 (PGP-9.5), a soluble protein originally isolated from the brain, the Leu 7 (CD57), the 7B2 protein, the synaptic proteins (SNAP-23, SNAP-25, Rab3A) and the neural cell adhesion molecule (NCAM/CD56). Specific immunohistochemical markers are designated to reveal the exact type of hormonal product in endocrine cells. Holgate *et al.* (1983) introduced in 1983 the immunogold'silver technique for light microscopy and later on, the method was modified for application to electron microscopy ultrathin sections (Holgate *et al.*, 1983; Lackie *et al.*, 1985). Using specific antibodies conjugated with colloidal gold particles (from 5 to 15 nm), this technique can specifically detect the hormone peptide products concentrated within the secretory granules of endocrine cells.

The in situ hybridization technique allows demonstrating the presence of mRNA sequences specific for a peptide hormone or the biogenic amine, using isotopic or nonisotopic labeled complementary mRNA probes. However, besides the intensive research made during the last decades using histochemical, immunohistochemical and molecular techniques, and electron microscopy, some populations of endocrine cells remain yet undefined in terms to which hormone are linked.

General Morphological Features

Endocrine cells of the GI tract are tall columnar cells within the crypts and their apical cytoplasmic process forming microvilli that extend towards the luminal surface (**Fig. 3**). They are often found isolated from one another interspersed by non-endocrine epithelial cells. They are located within the deeper half, of mucosa and comprise only a small minority (< 1%) of the overall epithelial cell population. Some endocrine cells have a very characteristic appearance. They display a flask-shaped with a narrow, often quite elongated neck reaching the lumen and thus of open type. By electron microscope, microvilli represent a specialized sensory apparatus that detects changes in the lumen and respond to luminal stimuli by releasing their hormonal product thus, modulating endocrine cell secretion. (El-Salhy *et al.*, 2017). The cytoplasmic process often seems to be directed towards the base of the crypt. Interestingly, there are several indications that such widely distributed cells may serve to influence cells in their vicinity, in addition to the role of delivering their products by exocytosis to the blood circulation. Such cell-to-cell interaction refers to as paracrine function. Under confocal laser scanning microscopy they also show alone pseudopod-like basal process approximately 50–70 μm long, extending from these cells and form an interface between the mucosal epithelium and the lamina propria. These processes resembling a synapse appear to interact with neighboring cells and might be involved in their paracrine function (Sundler *et al.*, 1989; Bohórquez *et al.*, 2011). A general morphological characteristic of the endocrine cells in the upper, acid-producing part of the stomach (i.e., the corpus or fundus) is that they are "closed" in that the apical end of the cell does not reach the gland lumen. In the antrum, on the other hand, the vast majority of cells do reach the lumen via a narrow neck (**Figs. 3** and **4**). One possible explanation for this morphological difference is that open cells respond to lumenal stimuli (e.g., nutrients, pH changes), whereas closed cells are sensitive to other types of stimuli (e.g., distension, temperature changes, neuronal, and hormonal messengers). Therefore, it is conceivable that these cells serve both endocrine and paracrine functions (Sundler *et al.*, 1989). With respect to genuinely endocrine cells, it has been argued that each such population should have a restricted distribution along

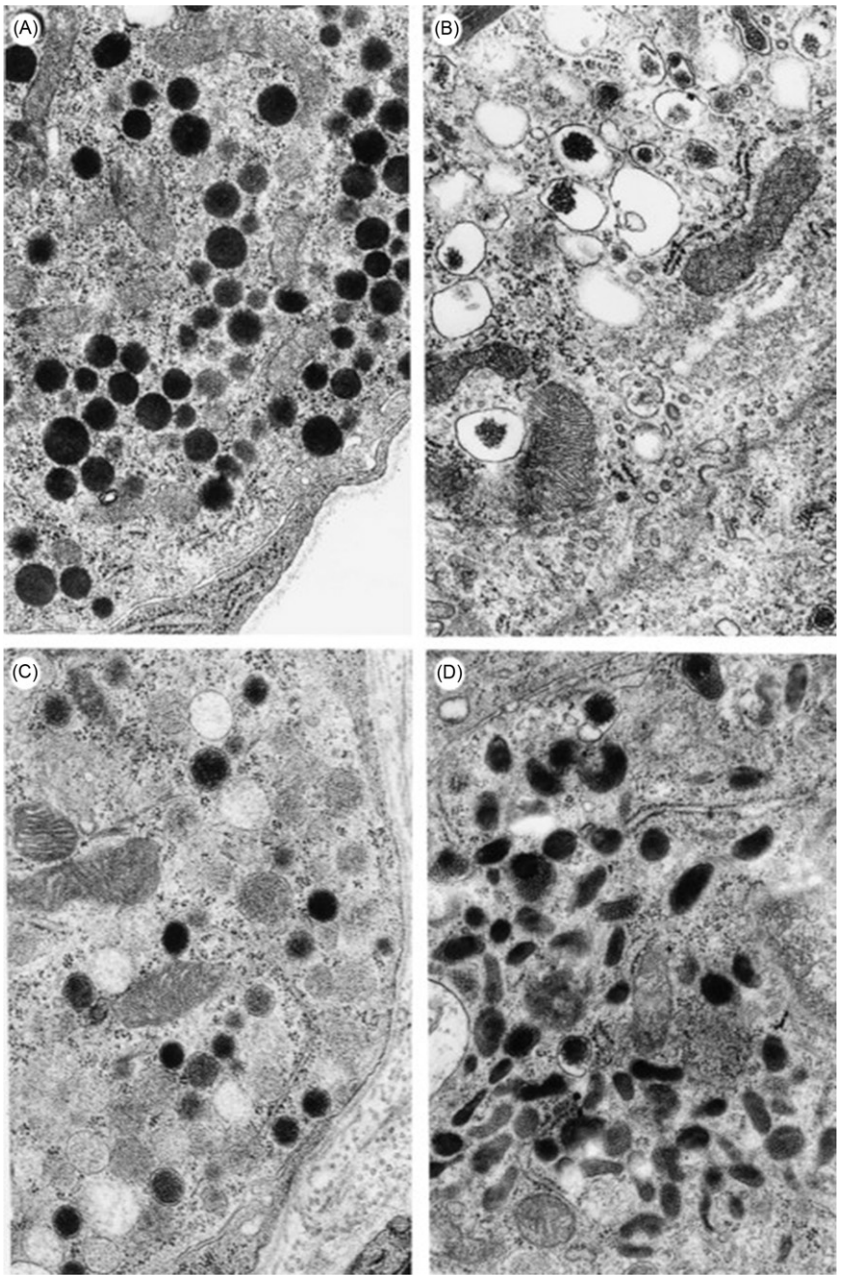

Fig. 5 Electron micrographs of secretory granules of endocrine/paracrine cells in the rat stomach. (A) A-like cell. The granules are round and highly electron-dense. (B) ECL cell. Note granule pleomorphism.

the GI tract in order for the target cells to be able to respond to a circulating messenger in a meaningful way. Apparently, endocrine cells have a multi-messenger capacity, considerably more powerful as transmitters of information than might be anticipated by the traditional and now discarded one-cell, one-messenger hypothesis (Tischler, 1989). By electron microscope, the endocrine cells show similarities and differences regarding the size, electron density, distribution, morphology and pleomorphism of secretory granules (exemplified in **Fig. 5**). Typically, the secretory granules accumulate at the base of the cell, but may sometimes be more diffusely distributed, although they are always confined to the cytoplasm and never in the nucleus.

Interaction to Nervous System

The endocrine cells of the GI tract exhibit both endocrine and neuron-like characteristics. In fact, several biogenic amines or hormone peptides are fount to both endocrine cells and neurons. In addition, the endocrine cells have a basal cytoplasmic process

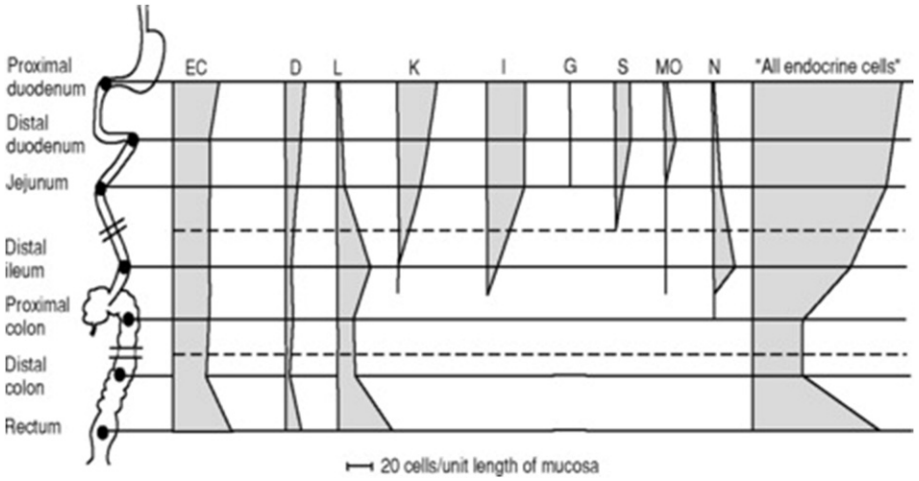

Fig. 6 Schematic diagram illustrating the distribution and relative frequency (number of cells/unit length of mucosa) of several different populations of endocrine cells in the human intestine. Data are based on immunocytochemical observations using hormone antibodies. (*Left*) *Black dots* on the outline of the intestine indicate tissue sampling sites. (*Right*) A compilation of the data. Note that some cell types are distributed throughout the intestine, whereas other cell types have a more restricted distribution. Note also that the rectum is almost as rich in endocrine cells as the duodenum.

that refers to us neuropods, indicating that these cells have the necessary elements for synaptic transmission. Therefore, the GI hormones released in the lamina propria could act locally by paracrine mode on neighboring cells or neurons, by endocrine mode through the circulating blood, or by afferent and efferent synaptic transmission (El-Salhy *et al.*, 2017).

Distribution, Types and Nomenclature

The endocrine cells arise in all segments of the GI tract except for the esophagus. As a rule their regional distribution and frequency is characteristic almost for each cell type (Sundler *et al.*, 1989). Thus, certain cell types are restricted to, or greatly predominate, in the stomach. Others are confined to the upper small intestine and still others predominate in the distal small intestine and/or the large intestine (**Fig. 6** and **Table 2**). Intestinal endocrine cells are predominately located within its deeper half, and comprise approximately 1% of the entire gut epithelial population. They often lie isolated from one another interspersed by non-endocrine epithelial cells, facing the GI lumen (Buffa *et al.*, 1978; Sternini *et al.*, 2008). A few cell types are distributed all along the GI tract. Traditionally, endocrine cells of the GI tract are named with an alphabetical letter, according to their origin. However, due to a huge amount of accumulated information provided by the extensive use of immunohistochemistry as well as to the discovery of

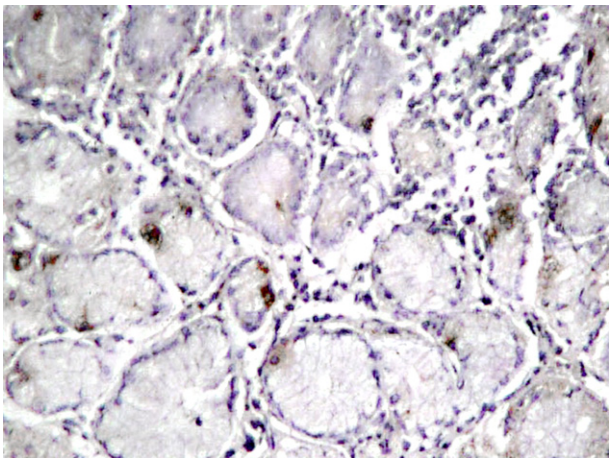

Fig. 7 Immunohistochemistry reveals scattered gastrin-producing cells distributed among non-endocrine cells within the glands in the gastric mucosa (10 ×).

new peptides, it is better to characterize a certain endocrine cell after its principal secretory product. The GI endocrine cells are divided into at least 15 different types depending on their morphology, specific regional distribution and hormonal peptide or amine substances they produce and secrete. These include a variety of about 50 hormone peptides or signaling molecules, including somatostatin (D cells), gastrin (G cells), serotonin (EC cells), histamine (ECL cells), vasoactive intestinal peptide (VIP) (D_1 cells), cholecystokinin (CCK) (I cells), glucose-dependent insulinotropic peptide (GIP) (K cells), glucagon-like peptides (GLPs) and peptide YY (PYY) (L cells), and ghrelin (P/D_1 cells). Upon stimulation, the hormone products, which are stored in secretory granules, are secreted by exocytosis at the basolateral membrane into the interstitial space. They exert their functional activity locally or on distant targets after release to bloodstream (Sternini *et al.*, 2008). Two or more hormones can be detected in the same type of endocrine cell and may be co-localized in the same secretory granule as well (Egerod *et al.*, 2012).

Stomach

Based on various histochemical techniques, immunohistochemistry, and electron microscopy, with special emphasis on the morphological features of the secretory granules (**Fig. 5**), at least seven endocrine cell types have been described in the stomach. They comprise G cells, D cells, EC cells, enterochromaffin-like (ECL) cells, and two types of cells with small granules and designated P cells and D_1 (P/D_1 or X/A like) cells (**Table 2**). Additionally, in certain species, notably carnivores such as dogs and cats, "true" glucagon-producing A cells, being well-known constituents of the pancreatic islets, are also present in substantial numbers in the stomach. The gastrin-producing G cells are exclusively found in the antrum of the gastric mucosa, where they are located within a zone at the upper part of the glands (**Fig. 7**). Ultrastructurally, these cells contain secretory granules 150–300 nm in diameter, distributed mostly in the basal portions of the G-cell cytoplasm and the apical portion of the cell reaches the glandular lumen (Lloyd, 1990). The somatostatin producing D cells, are found throughout the GI tract but contrastingly are found in much lower numbers, making up around 3%–5% of the endocrine cell population in the lower GI tract. The D cells in the stomach are diffusely distributed all over the stomach in all species. These spindle shaped cells, very often have a slender apical cytoplasmic process that can have a shorter wider basal extension of nerve fiber-like appearance, ending with a knob-like swelling filled with granules (**Fig. 8**). The secretory granules range from 300 to 400 nm in diameter (Lloyd, 1990). The D cells have been found to often make direct contact with G cells in the antrum and with parietal cells in the acid-producing part of the gastric mucosa. This contact is usually established via the cytoplasmic processes of the D cells. These features, together with the wide distribution of the cells both within the GI tract and outside of it (the pancreatic islets in particular), have contributed to the designation of the D cells as paracrine cells. Cells containing small granules (P and D_1 cells), like the D cells, seem to occur all over the stomach. VIP producing D_1 cells are widely distributed throughout the length of the gut mucosa including the stomach, never being numerous at any site (Bloom *et al.*, 1975; Said, 1975; Buffa *et al.*, 1977; Bryant and Bloom, 1979). Leptin-secreting P cells are localized in the stomach. Leptin directs the central nervous system to adjust food intake (Kelesidis *et al.*, 2010). The endocrine cells greatly predominate in the antrum in certain mammals, such as rodents, whereas in the stomach of human and many larger mammals they also occur in the acid-producing part of the stomach in quite high numbers. The ECL histamine-producing cells are the largest endocrine cell population in the stomach. They constitute one—and possibly the only—gastric endocrine cell type that is confined to the acidic gastric mucosa, upper part (corpus fundus or body), (**Table 3**). This seems to be the case in all vertebrate species examined, from fish to human, but in different percentages. The secretory granules have a very characteristic ultrastructure, which at least in part, seem to be related to the histamine production by these cells.

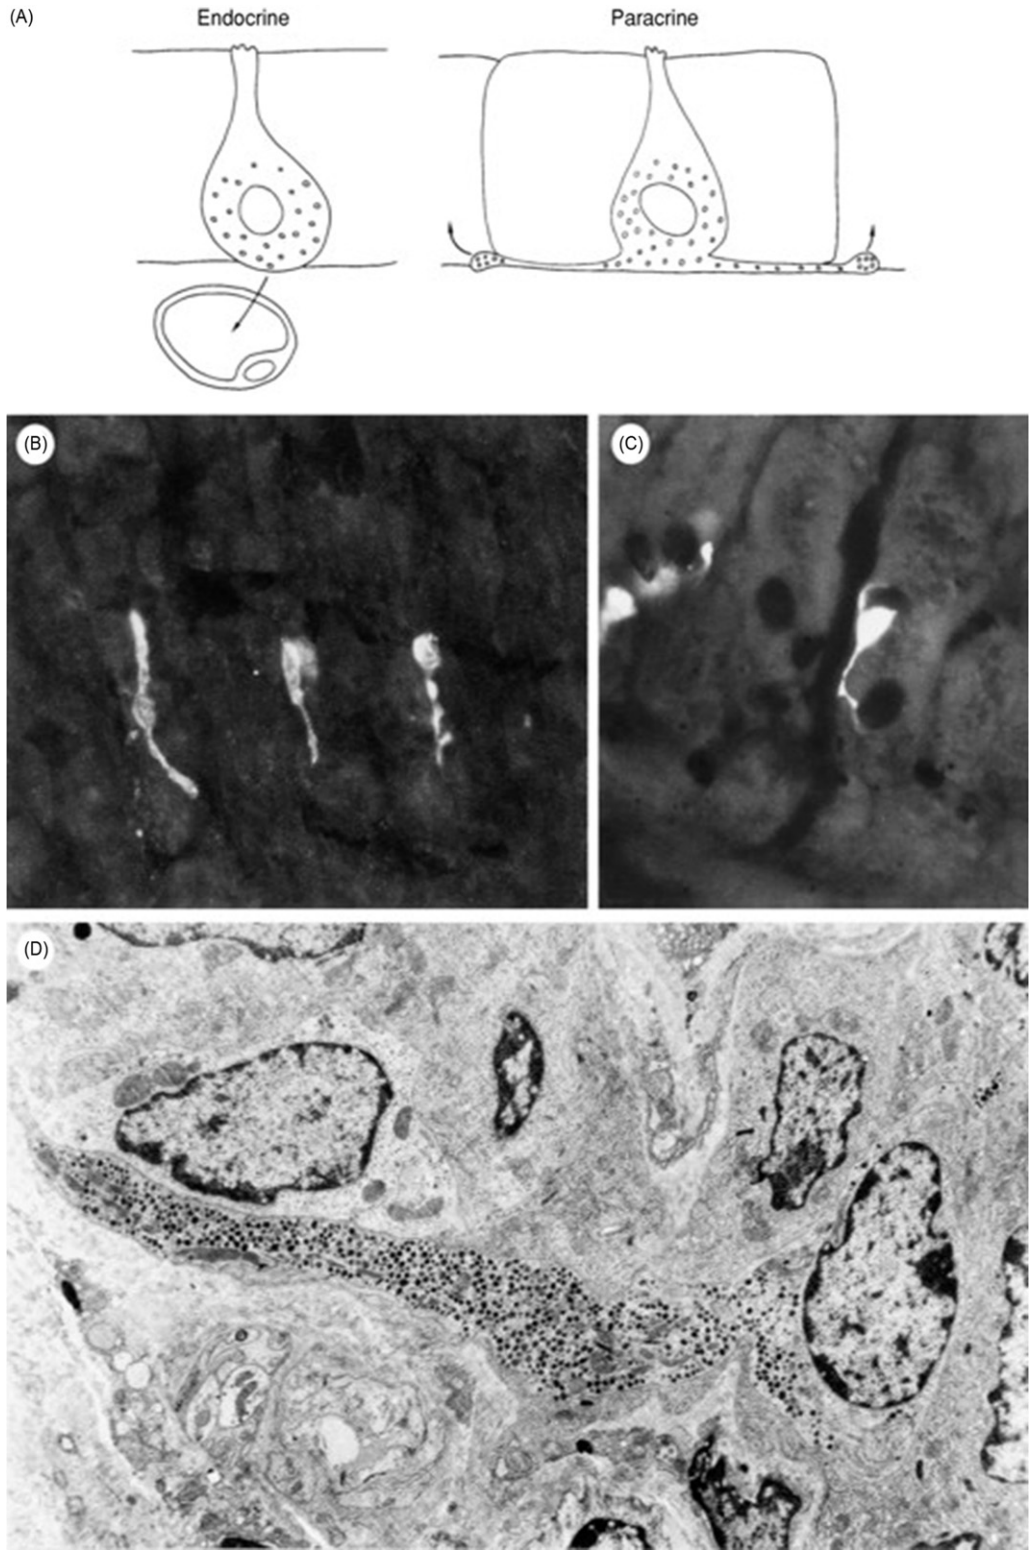

Fig. 8 (A) Schematic morphological distinction between endocrine and paracrine cells. (B and C) D cells of rat gastric mucosa (somatostatin immunofluorescence). (B) The cells issue long, slender cytoplasmic processes, sometimes ending in a knob-like swelling. (C) D cell process ending on a G cell (stained black by gastrin immunoperoxidase). (D) Electron micrograph showing a D cell process filled with secretory granules. The process runs along the base of the gland epithelium near the top of the figure.

Table 3 Relative frequency of different endocrine cells in gastric oxyntic mucosa of human and rat

Cell type	*Human (%)*	*Rat (%)*

D_1 + A-like (X) + P + cells	14	24
Somatostatin cells	26	10
EC cells	25	0

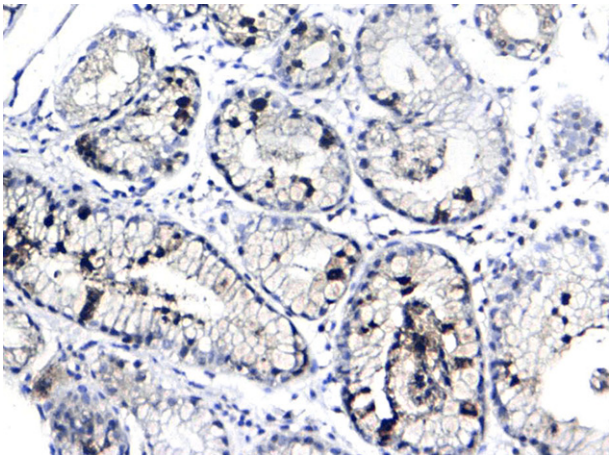

Fig. 9 Ghrelin-producing cells localized by immunohistochemistry within the glands of the gastric mucosa (10 ×).

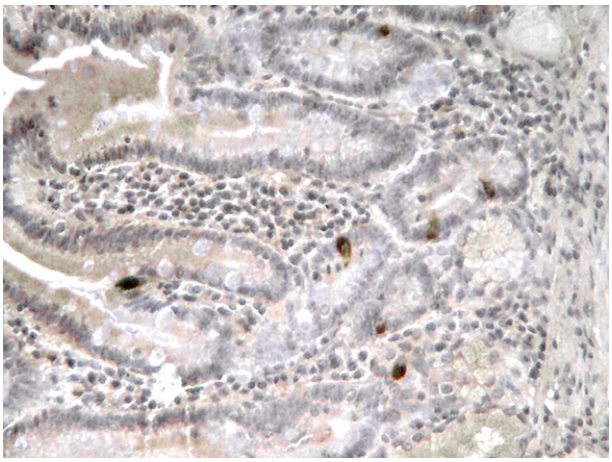

Fig. 10 Immunohistochemical detection and distribution of somatostatin-producing cells within normal cell of the small intestinal mucosa. They are mostly lying isolated from one another, interspersed in non-endocrine epithelial cells (10 ×).

The peptide ghrelin is produced by well-defined as P/D_1 cells in humans, which in the past had been labeled differently in various mammals, as A-like cells in rats and X-like type in dogs. X/A-like cells are primarily found in the oxyntic part of the gastric mucosa, accounting for 20%–30% of the oxyntic endocrine cells and therefore represent the second most abundant gastric endocrine cell type (Rindi *et al.*, 2004). They may also occur in smaller numbers in the distal non-acid-producing part (antrum, pylorus) of the stomach. The ghrelin immunoreactive cells in the antrum are distinct from the gastrin cells, the serotonin-containing EC cells and the D cells. Ghrelin producing cells represent the main source of circulating ghrelin as demonstrated by the sharp decline of ghrelin levels following gastrectomy (Jeon *et al.*, 2004) (**Fig. 9**). Ghrelin, among its numerous functions, stimulates appetite and increases food intake by stimulating the production of neuropeptide Y (NPY) and promotes fat storage (Wren *et al.*, 2001). For this reason, it is termed the "hunger hormone." Ghrelin, P/D_1 type cells contain characteristic round, compact, electron-dense secretory granules with a mean diameter 147 ± 30 nm (Rindi *et al.*, 2002).

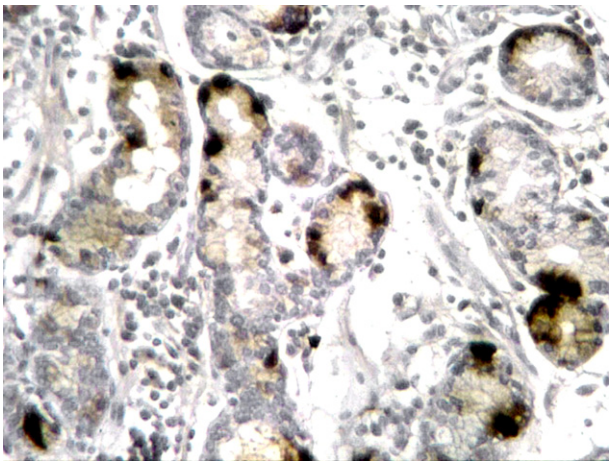

Fig. 11 Endocrine cells in the glands of the small intestine immunopositive for cholocystokinin (10 ×).

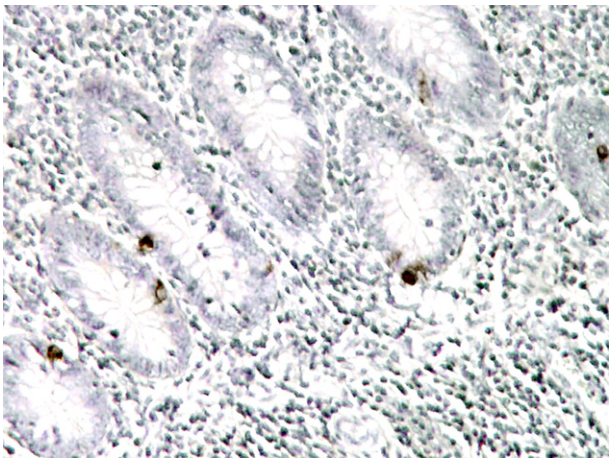

Fig. 12 Scattered serotonin-producing cells are detected by immunohistochemistry among mucin producing columnar cells in the glands of the large bowel mucosa (10 ×).

Small Intestine

The endocrine cells are characteristically flask-shaped with a narrow, often quite elongated neck reaching the lumen and thus of open type. The secretory granules accumulate at the base of the cell, but may sometimes be more diffusely distributed, although they are always confined to the cytoplasm. The classification and naming of the intestinal endocrine cells were for a long time based primarily on the size and morphology of the secretory granules. Accordingly, the cells were categorized as, for example, S (small granules), I (intermediate-size granules), and L (large granules) cells (**Table 2** and **Fig. 6**). Subsequent immunohistochemical observations about the cellular localization of various hormones complicated matters and resulted in attempts to retain the letter classification, the inevitable renaming of some cells, and the addition of hormonally classified cells that did not fit into previous classifications. Thus, the classification of endocrine cells in the small intestine is often a mixture of letter naming and naming based on the hormone content of the cells. The EC cells are distributed throughout the small intestine with maximal numbers in the duodenum. The somatostatin producing D cells also occur throughout the small intestine, with the highest frequency in the duodenum including Brunner's glands, and gradually in smaller numbers distally (**Fig. 10**). The gastrin producing G cells, in addition to gastric mucosa, are also found in the duodenal mucosa and in Brunner's glands of the duodenal bulb (Lloyd, 1990). Some cell types are more restricted in their regional distribution. Thus, S cells, I cells, K cells, and M cells predominate in the duodenum and upper jejunum and are only rarely found in the ileum. The opposite is true for L cells and N cells, which predominate in the ileum, but are scarce in the duodenum (Rindi *et al.*, 2004; Egerod *et al.*, 2012). According to ultrastructural criteria, P cells are also present in the small intestine, with a distribution mainly in the upper part. One cell type with very large granules has been reported to occur throughout the human small intestine. The secretin-producing S cells are present in the duodenum and jejunum of most mammalian species. These cells have granules 180–220 nm in diameter and show positive immunoreactivity for secretin. The I cells, are also located in the duodenum and jejunum. They secrete CCK in response to the

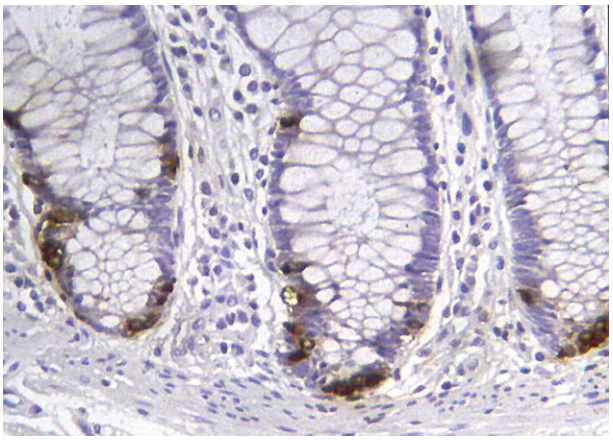

Fig. 13 Immunohistochemical localization and distribution of endocrine cells within the mucosal glands in the large intestine, detected by chromogranin A (25 ×).

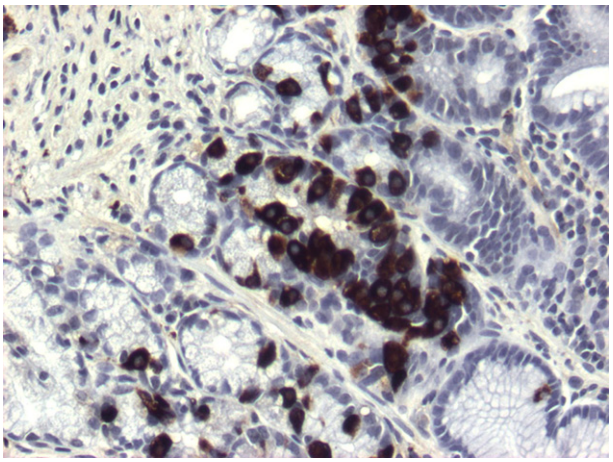

Fig. 14 Chromogranin A immunohistochemistry reveals hyperplasia of endocrine cells, characterized by occupation of a large portion of glands in the gastric mucosa. More than three endocrine cells accumulate in a continuous lining and are packed together (40 ×).

emptying of the stomach contents into the duodenum (**Fig. 11**). The secretory granules of these cells measure from 250 to 300 nm (Lloyd, 1990). Secretin is co-expressed with CCK in endocrine cells of the small intestine. K cells are predominantly found in the duodenum and jejunum. The K cells secrete gastric inhibitory peptide (GIP) and L cells glucagon-like peptide-1 (GLP-1). A population of K/L cells has been found to secrete both GIP and GLP-2. The L cells secrete GLP-1, GLP-2, and PYY, which delay gastric emptying and oxyntomodulin, which inhibits gastric emptying. In the intestine, L cells occur especially in the duodenum and are rare proximal to the terminal ileum. They are found in all parts of the crypts, but with some predominance in the basal portion. Glicentin and enteroglucagon immunoreactivity has also been identified in these cells. They have secretory granules of 250–300 nm in diameter (Lloyd, 1990). M (or MO) cells occur in both upper and low parts of the small intestine and secrete molitin. The N cells are found in the jejunum. They release neurotensin and control smooth muscle contraction. In addition to oxyntic gastric mucosa, ghrelin is also produced by P/D_1 type endocrine cells of the jejunum and low part of the small intestine. The secretin-producing S cells are present in the duodenum and jejunum. They contain secretory granules 180–220 nm in diameter (Lloyd, 1990).

Large Intestine

The large intestine also harbors endocrine cells of several different kinds, although it seems that the number and the variety of different populations are less diverse than in the small intestine. Interestingly, the endocrine cells are collectively more numerous in the rectum than in the colon, as calculated in the human gut (**Fig. 6**). At least five different endocrine cell populations can be distinguished in the large intestine. It is notable that there is a marked overlap in the distribution of certain endocrine cell populations between the distal small intestine and the large intestine (**Table 2**). Thus, EC cells and L cells are quite numerous also

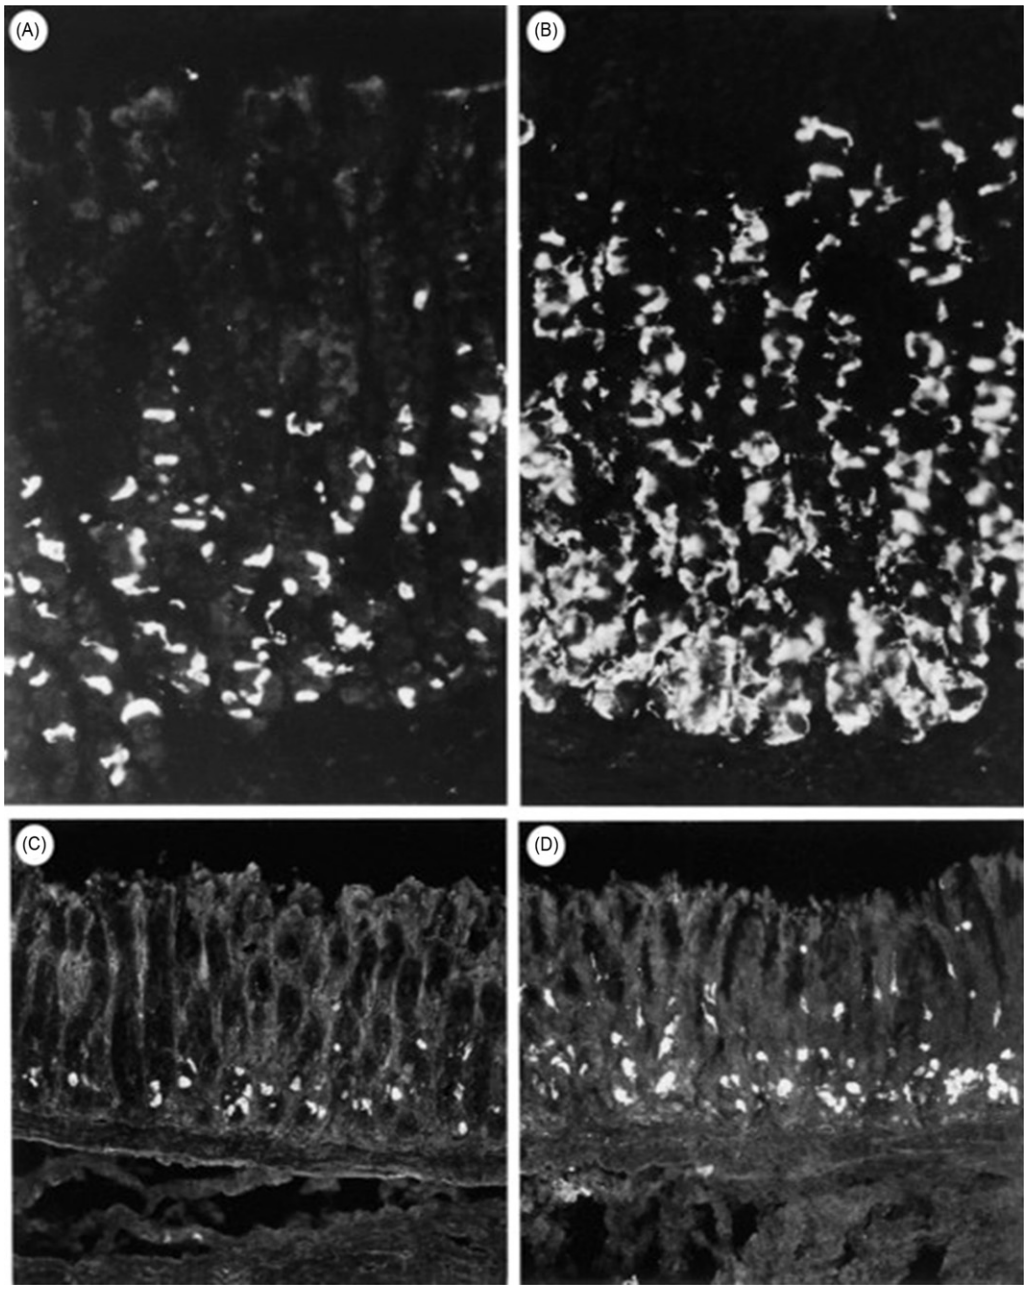

Fig. 15 Endocrine cell plasticity illustrated by the marked hyperplasia of rat ECL cells (B) and G cells (D) on pharmacological blockade of acid secretion for 8 weeks. Acid blockade causes G cell activation and hyperplasia with hypergastrinemia, which in turn brings about activation of the ECL cells with increased histamine secretion and, with time, proliferation. ECL cells are visualized with histidine decarboxylase immunofluorescence and G cells are visualized with gastrin immunofluorescence.

in the large intestine. N cells, on the other hand, are only rarely found in the large intestine and D cells are also clearly fewer in number here than in the small intestine. Overall, 95% of the body's serotonin content is found within the GI tract. The serotonin secreting EC cells are abundant, distributed in all parts of the GI tract, populating the gastric antrum, duodenum, jejunum, ileum and appendix, the colon and rectum (**Fig. 12**). They account for the largest population making up over 70% of the endocrine cells in the proximal large bowel, which falls to around 40% in the rectum (Cristina *et al.*, 1978; Sjölund *et al.*, 1983). By electron microscopy the EC cells are approximately 8 μm in size with triangular or pyramidal shape and display a slender apical process often extending to the luminal surface. They secretory granules measure approximately 150–500 nm in diameter (Buffa *et al.*, 1978; Spiller, 2008). Findings from experimental studies suggest that serotonin released by endocrine cells is, at least in part, neurally regulated. D cells are also clearly found, but fewer in number than in the small intestine making-up around 3%–5% of the endocrine cell population (Buffa *et al.*, 1978; Cristina *et al.*, 1978; Sjölund *et al.*, 1983). They represent the least common endocrine

cell type in colon and rectum (Fig. 13). The ultrastructure of D cells is relatively uniform in the large intestine with one elongated apical extension and one shorter, wider basal extension. This differs from the overall appearance of D cells in the stomach. The secretory vesicles of D cells are approximately 200–400 nm in diameter. Ghrelin is also produced, although in much lower amounts, in large bowel. The L cells constitute the second largest population of large intestine, their frequency rising from proximal to distal, reaching approximately 14% of the endocrine cell numbers in the rectum (Cristina *et al.*, 1978; Sjölund *et al.*, 1983). They secrete glicentin, which inhibits gastric emptying, oxyntomodulin and GLP-1, GLP-2 (Gunawardene *et al.*, 2011). L cells have characteristic morphology with a bottle or flask shaped configuration. They often display an open morphology with a beaded process running along the base of the epithelium and an apical protrusion of cytoplasm extending to the luminal surface and forming microvilli (Capella *et al.*, 1976; Sjölund *et al.*, 1983). Under electron microscopy, the secretory vesicles occur adjacent to the basolateral membranes and are approximately 150–300 nm in diameter. Secretin-producing S cells, motilin-secreting M cells and neurotensin-producing N cells are absent from the large intestine (Rindi *et al.*, 2004).

Concluding Remarks

As is obvious from the data presented here, there is some confusion and remaining uncertainties as to the classification and naming of endocrine cells in the GI tract. This is due to the fact that endocrine cells sharing staining characteristics with cells occurring outside the GI tract, notably, the pancreatic islets, which are known by the "islet" name. This applies to islet A cells and D cells. Another problem arose when an ultrastructurally defined cell type, for example, the L cell, was later found to comprise at least two functionally distinct cell populations, one producing proglucagon-derived peptides (retaining the L cell designation) and another producing neurotensin (renamed N cells).

Another problem is related to the I cell. Obviously, several functionally distinct endocrine cell populations fall into this somewhat vague category. Thus, CCK cells, K cells, and M cells are all "I" cells, but with the current possibilities of a more detailed functional classification, the hormone name, or its short name, is gradually replacing the original letter name. Furthermore, EC cells are distributed widely throughout the GI track. They are probably not one single cell type, but rather several functionally distinct populations, unified merely because they produce large amounts of serotonin. This view is favored by available ultrastructural data showing different types of granules in EC cells in different regions of the gut, and sometimes even in different EC cells within the same region, together with the fact that certain regulatory peptides are restricted to subpopulations of EC cells only.

Finally, it should be mentioned that there is a remarkable potential for plasticity in gut endocrine cell systems. This is perhaps most readily observed in the stomach, where each of the endocrine cell populations has a restricted regional distribution and the cells are more frequent per unit area. Thus, marked hyperplasia of G cells and ECL cells (within their normal regional boundaries) evolves within some time (days to a few weeks) after, for example, profound pharmacological blockade of acid secretion (Figs. 14 and 15) and ECL cell hypoplasia after, for example, removal of the G cells (antrectomy).

GI Hormones Outside the Gut: Central and Peripheral Nervous Systems☆

Graham J Dockray, University of Liverpool, Liverpool, United Kingdom

Glossary

Classical neurotransmitters Neurotransmitters that are released by calcium-dependent exocytosis of small clear synaptic vesicles and act at postsynaptic membranes often at receptors that are ion channels, for example, nicotinic acetylcholine, γ-aminobutyric acid type A receptor, serotonin type 3, and *N*-methyl-D-aspartate-type glutamate receptors.

Cotransmission Production of multiple transmitters by a single neuron and their interaction at a common cellular target; may include classical transmitters and neuropeptides that are also gut hormones.

Neuropeptides Biologically active peptides synthesized in neurons, sequestered into secretory vesicles, and released on neuronal stimulation. Their actions are mediated by G protein coupled-receptors, which may be on cells distant to the release site.

Regulatory peptides A generic term to cover biologically active peptides that may function as hormones, paracrine or autocrine agents, and neurotransmitters. Typically, peptides are produced from larger precursors, are stored in secretory vesicles, are released by exocytosis, and act at G protein-coupled receptors.

Introduction

The three main gut hormones discovered in the early 20th century, gastrin, secretin, and cholecystokinin (CCK), were thought for many years to be exclusively concerned with the regulation of digestion. However, the availability of rapid and specific methods for the identification, localization, and estimation of these peptides in the 1970s prompted rigorous studies of their distribution outside the gut (Dockray, 2014). These studies came at a time when it was becoming clear that the main gut hormones belonged in families of structurally related peptides and that different family members may in any case be expressed outside the gastrointestinal tract. Three of the earliest relevant findings were that (1) CCK occurred in high concentrations in brain; (2) a secretin-related peptide, vasoactive intestinal polypeptide (VIP), was widely distributed in CNS and PNS neurons; and (3) the hypothalamic peptide, somatostatin, was found in many endocrine cells of the gut and pancreas. Since then, more peptides have been characterized as gut hormones and several of these have been shown to occur in CNS or PNS neurons. Conversely, some peptides first identified as neurotransmitters have subsequently been identified as putative gut hormones. Although there are many examples of gut hormones in CNS or PNS neurons, there are also several important groups of neuropeptides whose presence in gut endocrine cells, or roles as gut hormones, is unlikely or unclear; these include the opioid peptides (e.g., enkephalins), the tachykinins (e.g., substance P), the super-family of peptides terminating in –Arg-Phe-amide, and calcitonin gene-related peptide.

Evolutionary Relationships

Regulatory Peptides

It is thought that the role of peptides as intercellular molecular messengers emerged early in evolution (Hokfelt *et al.*, 2000). Subsequently, the genes encoding regulatory peptides duplicated and diverged to produce families of structurally related peptides. Different members of the same family may be expressed in neurons, endocrine cells, glial cells and other cells or tissues including amphibian skin glands, myofibroblasts and tumors. The gene encoding a specific regulatory peptide may also be expressed by multiple cell types. These patterns may themselves change during evolution, giving rise to species differences in cellular expression.

Receptors

Hormonal and neurotransmitter peptides typically act at G protein-coupled receptors (GPCRs). GPCRs constitute a large family of structurally related proteins that are thought to have also evolved by the duplication and divergence of ancestral genes. Multiple GPCRs may exhibit differential affinity for the various members of regulatory peptide families. The receptors may themselves be expressed by multiple cell types including CNS or PNS neurons and nonneuronal cells, for example, secretory cells or smooth muscle cells.

☆*Change History*: March 2018. Graham Dockray updated reference.

This article is an update of Graham J. Dockray, GI Hormones outside the Gut: Central and Peripheral Nervous Systems, in Encyclopedia of Endocrine Diseases, Edited by Luciano Martini, Elsevier, New York, 2004, Pages 194–198.

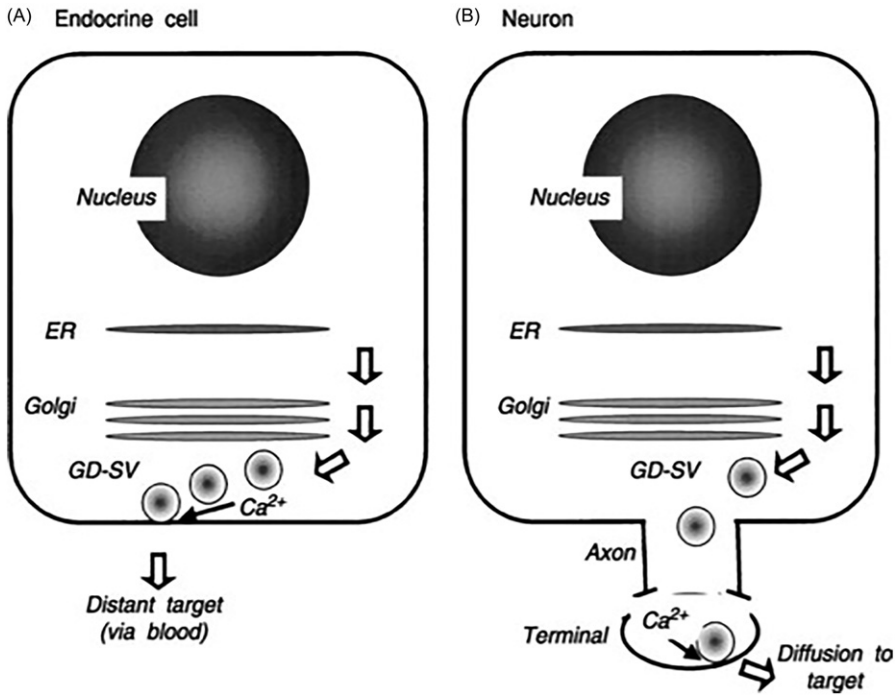

Fig. 1 Schematic representation of the intracellular progression of hormonal peptides produced by gut endocrine cells (A) and by central or peripheral neurons (B). In both cases, mRNA is translated at the endoplasmic reticulum (ER) and precursor peptides progress through the Golgi complex; mature peptides are stored in Golgi-derived secretory vesicles (GD-SV) and released by calcium-dependent exocytosis. Peptide released at the basolateral membrane of endocrine cells is conveyed to target cells via the circulation. In neurons, secretory vesicles progress along the axon to nerve terminals for release; in this case, the secreted peptide typically diffuses to its target cells, although peptides released into the hypothalamo-hypophyseal portal vessels are an exception.

Criteria for the Identification of Gut Hormones in PNS or CNS Neurons

Evidence for the presence of gut hormones in PNS and CNS neurons should be based on the following lines of evidence: (1) expression of the gene identified by techniques such as reverse transcription-polymerase chain reaction, Northern blot analysis, and in situ hybridization and confirmation by cloning and sequencing of the relevant cDNA; (2) the presence of the relevant peptide determined by radioimmunoassay or ELISA, preferably using antibodies to several epitopes, coupled with high-performance liquid chromatography and confirmation by bioassay, chemical isolation, and amino acid sequencing; and (3) demonstration of cellular origins by immunocytochemistry, preferably using multiple antibodies to several epitopes. Localization of neuropeptides may be a useful way of distinguishing subsets of neurons already identified by the presence of classical transmitters and for this purpose double-labeling immunocytochemistry is useful. There may be problems with the specificity of particular antibodies. For these reasons, the interpretation of studies based on the use of a single experimental method, for example, immunohistochemistry, or using a single primary antibody, should be approached with caution.

Cellular Aspects

Regulatory peptides produced in gut endocrine cells, CNS or PNS neurons are, in each case, generated by mRNA translation at the rough endoplasmic reticulum (Fig. 1). The product (prepropeptide) is usually biologically inactive and is rapidly converted to a precursor peptide (propeptide) that progresses through the Golgi complex and is sequestered in secretory vesicles that bud from the *trans*-Golgi network. During transit through the Golgi complex, or in secretory vesicles, the propeptide is subject to any of a variety of different posttranslational modifications. These may include glycosylation, Tyr sulfation, and Ser phosphorylation (all of which occur in the Golgi complex), cleavage of the peptide chain, or COOH-terminal α-amino amidation (which occurs in secretory vesicles). The patterns of posttranslational modification of a specific peptide may differ in neurons and endocrine cells. The Golgi-derived secretory vesicles often possess electron-dense cores and their morphology is characteristic of particular cell types. These vesicles are distinct from the small, clear, synaptic vesicles that recycle at nerve terminals and contain classical transmitters such as acetylcholine, monoamines, γ-aminobutyric acid (GABA), and glutamate. Expression of the genes encoding gut hormones is physiologically regulated, but different mechanisms may regulate the expression of these genes in PNS or CNS neurons.

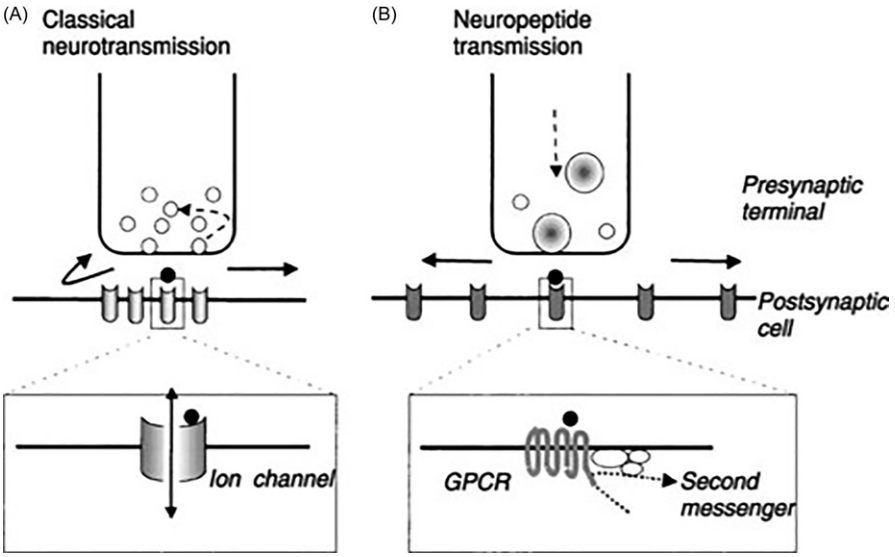

Fig. 2 Schematic representation of some events involving neurotransmission by classical (A) and neuropeptide (B) transmitters. Classical transmitters are stored in small, clear synaptic vesicles that are recycled at the nerve terminal. There are reuptake mechanisms for the neurotransmitter, which is resequestered in these vesicles. Receptors for classical transmitters are concentrated in the postsynaptic membrane and are often ion channels. In contrast, neuropeptides are located in Golgi-derived dense-cored vesicles and after secretion they are degraded by proteolysis either locally or elsewhere after diffusion away from the release site. Neuropeptides typically act at G protein-coupled receptors (GPCR) to trigger second-messenger responses; the receptors may be diffusely distributed on postsynaptic cells and may be some distance from the release site. (●) Putative transmitter.

Cotransmission

Increased intracellular Ca^{2+} leads to exocytosis of both Golgi-derived (neuropeptide-containing) and synaptic vesicle populations (Fig. 2). The actions of neuropeptides are exerted at GPCRs, which are not exclusively localized to postsynaptic membranes or even to neurons. As a consequence, peptides may act over longer distances and for longer times than classical neurotransmitters. Where both neuropeptide and classical transmitters act on the same postsynaptic cell, there may be interactions between them (Hokfelt *et al.*, 2000). For example, increased or decreased sensitivity to the classical transmitter may be mediated by neuropeptides.

Overview of Gut Hormones Expressed by PNS Neurons

Representatives of the gut hormone families are commonly expressed in the major divisions of the autonomic nervous system. In postganglionic parasympathetic neurons, the secretin-like peptides VIP, peptide histidine isoleucine amide (PHI), and pituitary adenylate cyclase-activating peptide (PACAP) are commonly expressed, whereas in postganglionic sympathetic neurons, neuropeptide tyrosine (NPY) is commonly expressed. The enteric nervous system, which is sometimes considered to be a third division of the autonomic nervous system, is an abundant source of neuropeptides, including VIP, CCK, and NPY (Furness, 2000). Many primary afferent neurons express neuropeptides; some of those belonging to the main families of gut hormones (VIP, NPY) are up-regulated after nerve damage. Gut hormonal peptides are not generally found in somatic efferent neurons.

Overview of Gut Hormones Expressed by CNS Neurons

The expression of neuropeptides is a property of very many CNS neurons. Gut hormones or related peptides, for example, somatostatin, CCK, and NPY, are expressed in hypothalamic neurons, where they may act in local circuits or in the control of pituitary hormone release after secretion into hypothalamo-hypophyseal portal vessels. In addition, these and other gut hormones are found in many other CNS regions, including cerebral cortex, hippocampus, brainstem, and striatum.

Major Gut Hormone Families and Their Expression in CNS and PNS Neurons

The following brief sketches are grouped on the basis of peptide families that include at least one member that is produced and released by gut endocrine cells and at least one that is produced and released by CNS or PNS neurons (for more detailed accounts see Walsh and Dockray, 1994).

The Cholecystokinin/Gastrin Family

The *CCK* gene is expressed in intestinal I-type endocrine cells and in many CNS neurons and some PNS neurons. There are differences in posttranslational processing that account for the reported variation between neurons and endocrine cells in the major form of CCK present. In cerebral cortical neurons, CCK may occur together with GABA and in some nigrostriatal neurons it occurs with dopamine. Gastrin originates from pyloric antral G cells and may be found in small amounts in hypothalamus. The CCK1 (also called CCK-A) receptor has high affinity for CCK and low affinity for gastrin; it is expressed in pancreas, gallbladder, and some CNS and PNS neurons. The CCK2 (also called gastrin-CCK-B) receptor has high affinity for both gastrin and CCK and is found on parietal and enterochromaffin-like cells in the stomach and many CNS neurons. The main function that has been ascribed to CCK in the brain is inhibition of food intake. In addition, CCK is thought by some to be associated with anxiety or panic attacks and it may modulate noxious sensations.

The Secretin/Glucagon/VIP/PHI/PACAP/GIP Superfamily

The superfamily of structurally related peptides that includes the classical gut hormones secretin and glucose-dependent insulinotropic peptide (GIP) and the pancreatic hormone glucagon also includes major neuropeptide transmitters such as VIP, PHI, and PACAP. In the case of glucagon, there is good evidence that a single precursor molecule may yield several different products through alternative posttranslational processing. In the pancreatic islet alpha cells, glucagon itself is a primary product; in intestinal L cells, glucagon-like peptide-1 (GLP-1) and GLP-2 are primary products (but not glucagon). CNS neurons resemble intestine more closely than pancreas in the processing of the glucagon precursor; one possible role for the CNS GLPs is in the control of food intake. Two members of the family that seem to be predominantly expressed in neurons, and not endocrine cells, are VIP (the precursor of which also gives rise to the related peptide PHI) and the closely related peptide PACAP.

Somatostatin

Somatostatin-producing endocrine (D) cells are found throughout the gastrointestinal tract and in the islets of Langerhans. In these systems, somatostatin acts locally as a paracrine inhibitor of secretion from nearby cells, for example, G cells in the pyloric antrum and beta cells in the pancreas. In addition, somatostatin is produced in hypothalamic neurons and functions as an inhibitor of growth hormone secretion from the anterior pituitary. It is also found in enteric neurons, sympathetic neurons, and some somatic afferent neurons.

Neurotensin

Neurotensin was first isolated from the hypothalamus and then discovered to be produced in N-type endocrine cells of the ileum and colon, where it is a putative mediator of the ileal brake in the gut. Neurotensin has been identified in multiple CNS neurons; interactions with dopamine have been identified and possible actions as an anti-psychotic agent reported.

The Peptide YY/NPY/Pancreatic Polypeptide Family

Peptide YY is named for the presence of tyrosine residues (Y in the single-letter notation) at both the COOH– and NH_2-terminal positions. It is normally produced in endocrine cells of the ileum and colon. Putative hormonal actions include the inhibition of pancreatic secretion, intestinal transit, and food intake. There is little evidence for neurotransmitter functions, although the 3-36 fragment of PYY acts at Y2 receptors expressed by vagal afferent neurons to inhibit gastric emptying and food intake. The closely related NPY is widely expressed in CNS and peripheral neurons. One of its most striking actions is the stimulation of food intake on injection into the hypothalamus. In addition, it is present in sympathetic postganglionic neurons and may modulate responses to noradrenaline. Another member of the family is pancreatic polypeptide, produced in the islets of Langerhans; its functions as either a hormone or a neurotransmitter remain uncertain.

Ghrelin and Motilin

The related peptides ghrelin and motilin are produced in gastric and small intestinal endocrine cells, respectively. They are distinct from other gut hormones in that they are released from these cells during fasting. Ghrelin is a naturally occurring ligand for an orphan receptor (GHS) originally identified as a putative mediator of growth hormone secretion. Small amounts of ghrelin are

thought to be produced in the hypothalamus. It is a powerful stimulant of food intake; the peptide released from the stomach may stimulate food intake by delivery to the hypothalamus through the circulation or by acting on vagal afferent neurons to suppress the action of satiety factors such as CCK and PYY3-36.

Glossary

Carcinoma Malignant epithelial neoplasm; when composed by neuroendocrine tumor cells is defined as neuroendocrine carcinoma and implies poorly differentiated morphology (NEC) and a rapidly progressive clinical behavior.

Dysplasia Disordered epithelial growth; when for neuroendocrine cells in the gut mucosa it refers to clustered moderately atypical neuroendocrine cells above the basal membrane.

Hyperplasia Increased cell numbers; when for neuroendocrine cells in the gut mucosa it refers to increased number of typical neuroendocrine cells above the basal membrane.

Neoplasia Abnormal mass (tumor) of transformed cells with uncontrolled proliferation and death, either clinically benign and malignant; when composed by neuroendocrine tumor cells is defined as neuroendocrine neoplasm (NEN) and implies malignant clinical behavior.

Neuroendocrine cell Gut epithelial cell specialized in producing hormones and other bioactive substances.

Tumor Epithelial neoplasm with well differentiated morphology; when composed by neuroendocrine tumor cells is defined as neuroendocrine tumor (NET) and implies slowly progressive clinical behavior.

Definition of the Subject

Nonneoplastic and neoplastic growths of the neuroendocrine cells of the gastrointestinal tract are lesions made by abnormal accumulation of neuroendocrine cells and are classified as hyperplastic, dysplastic or neoplastic epithelial cell changes.

History and Histogenesis

Cells belonging to the so-called diffuse neuroendocrine system (DNES) of the gut (**Table 1**) (Solcia *et al.*, 1998) attracted the attention of scientists in the second half of the 19th and early 20th centuries since their ability to interact with chromium salts (chromaffinity) and to reduce silver ions in the absence (argentaffinity) or in presence (argyrophilia) of reducing agents. In parallel, a nonconventional, epithelial tumor of the intestine with slow-growing attitude, the "carcinoid" (carcinoma-like), was described and soon was proven to be composed by argentaffin cells. Gut neuroendocrine cells express common antigens like chromogranin A, neuron specific enolase (NSE) and synaptophysin (defined as general markers of neuroendocrine differentiation) as well as specific hormones (defined as cell-specific markers of neuroendocrine differentiation) (**Table 1**). In the small intestine neuroendocrine cells may express more than hormone, like intestinal secretin cells coexpressing serotonin and GIP cells coexpressing enteroglucagon. In addition, they produce a number of trophic factors and abundantly express the somatostatin receptor subtype 2 (SSR2).

Gut neuroendocrine cells may undergo cell-cycle deregulation resulting in proliferation and tumor growth, as demonstrated in hereditary conditions like multiple endocrine neoplasia syndromes type 1 and 2 (MEN1 and 2) in man and after genetic manipulation in mice. Proliferating or transformed gut neuroendocrine cells may variably express the same antigens as their normal counterpart depending on their differentiation status. Expression of the somatostatin receptor subtype 2 (SSR2) in neuroendocrine tumor cells is important for both diagnostic and therapeutic applications.

Nonneoplastic Growths of Gut Euroendocrine Cells

Nonneoplastic growths of gut neuroendocrine cells have been reported in the stomach, the duodenum and occasionally in the ileum and colon (Rindi *et al.*, 2010b).

☆*Change History*: April 2018. Guido Rindi, Frediano Inzani and Enrico Solcia updated the abstract, the glossary, the subject definition, the whole text according to the current World Health Organization classifications and the references for further reading.

This article is an update of Guido Rindi and Enrico Solcia, GI Tract, General Pathology of Endocrine Growths, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 216–219.

Modified from Solcia, E., Capella, C., Fiocca, R., Sessa, F., Larosa, S. & Rindi, G. 1998. Disorders of the endocrine system. In: Pathology of the gastrointestinal tract. In: Ming SC, G. H.(ed.) Pathology of the gastrointestinal tract. 2 ed. Philadelphia: Williams and Wilkins.

Stomach

Nonneoplastic growths are restricted to proliferation of histamine-producing enterochromaffin-like (ECL) cells in the corpus/fundus and of gastrin-producing (G) and somatostatin-producing (D) cells in the antrum/pylorus. Hypergastrinemia-promoted ECL cell hyperplasia is categorized as *diffuse* (increase in neuroendocrine cells of more than twice the standard deviation as compared to age/sex-matched controls), *linear* (sequences of five or more cells inside the basement membrane of the gastric gland), *micronodular* (clusters of five or more neuroendocrine cells up to 150 μm in diameter) and *adenomatoid* (collection of five or more micronodules adherent to each other but with interposition of basement membranes and thin strands of *lamina propria*). Dysplasia is characterized by 150–500 μm lesions formed by moderately atypical neuroendocrine cells and defined as *enlarged micronodules* (nodules of $\geq$150 μm), *adenomatous micronodules* (collections of at least five micronodules), *fused micronodules* (disappearance of the intervening basal membrane between adjacent micronodules) and *microinfiltrative lesions* (microinfiltration of the *lamina propria* by neuroendocrine cells filling the space in between glands).

G cell hyperplasia is defined as an increase of gastrin cell number (above 140) when counted per linear millimeter of mucosa in 5 μm thick histological sections. It may be associated with reduced somatostatin (D) cell count resulting in elevated G/D cell ratio.

Long-standing hyperchlorhydria associated with duodenal G cell tumor may result in increased D cells of the antrum and reduced G/D cell ratio.

Small intestine

Similar to the stomach hyperplastic changes classified as diffuse (>2 times SD), linear ($\geq$5 cells; 2 chains/mm) and micronodular ($\geq$5 cells; size 30–90 μm) are identified in the duodenum as composed by either G od D cells (Anlauf *et al.*, 2005, 2007). On the same line, lesions between 90–120 μm in size are defined as dysplasia.

Increased numbers of somatostatin D cells are observed in the duodenum/ileum of patients with coeliac disease, as well as increased neuroendocrine cells in idiopathic inflammatory bowel conditions.

Neoplasia

General

Neuroendocrine neoplasms of the gut are found at any level of the gastrointestinal tract (**Table 2**). According to recent epidemiological data, in western countries neuroendocrine neoplasms more commonly display an age-standardized rate of about 1/100,000 per anatomical site of the gut, more frequently occur in the colorectum, followed by the small intestine and stomach of females at increasing incidence with age.

The diagnosis of neuroendocrine tumors is based on the identification of their characteristic morphology, the expression of markers of neuroendocrine differentiation and grading. Grading is defined by the World Health Organization (WHO) (Rindi *et al.*, 2010a; Kloppel *et al.*, 2017) and the American Joint Committee on Cancer (AJCC) (Woltering *et al.*, 2017) in three tiers by the mitotic index per 10 high power fields (G1, <2 mitosis; G2, 2–20; G3, >20) and Ki67 proliferation index in percent of tumor

Table 2 Tumor type, distribution and cell features of the neuroendocrine neoplasms of the gastrointestinal tract

Tumor type	*Preferred site*	*Main cell type*	*Hormonal products*
NET	Stomach body/fundus	ECL	Histamine 5HT/5HTP
"	Antrum, duodenum, jejunum	G	Gastrin
"	Duodenum, jejunum	D	Somatostatin
"	Jejunum, ileum, coecum, appendix	EC	Serotonin*
"	Colon, rectum	L	Glicentin, PP, PYY
Gangliocytic paraganglioma	Duodenum	PP, D	PP, Somatostatin
NEC	Stomach, intestine	proto-endocrine	none

ECL: Enterochromaffin-like cell; EC: enterochromaffin; 5HT: 5-hydroxytryptamine (serotonin); 5HTP: 5-hydroxytryptophan; PP: pancreatic polypeptide; PYY: peptide Tyrosine Tyrosine; *: substance P, tachykinins and other peptides.

cells (G1, <3%; G2, 3%–20%; G3 > 20%). According to the current WHO and AJCC classifications, gut neuroendocrine neoplasms are classified as:

- neuroendocrine tumors, NET G1-G3, displaying well differentiated morphology;
- neuroendocrine carcinomas, NEC, by default G3, displaying poorly differentiated morphology.

Staging tools are also provided for each anatomical gut site by both WHO and AJCC.

Neuroendocrine Tumor, NET

Neuroendocrine tumors, NETs are generally characterized by bland histological and cytological features, low cytological atypia, low mitotic index and diffuse expression of general markers of neuroendocrine differentiation. Cell specific markers are in general observed in tumor cell subpopulations. The degree of atypia and the occasional presence of spotty necrosis progresses with the grade progression.

The clinical behavior of NETs correlates directly with grade and stage, the higher the worse.

Stomach

ECL cell NETs

By far the most frequent neuroendocrine tumor of the stomach, ECL cell tumors display strong argyrophilia by silver impregnation techniques, immunoreactivity for chromogranin A and vesicular monoamine transporter 2 (VMAT2), and no or focal immunoreactivity for ghrelin, serotonin, gastrin and somatostatin. The largest fraction of gastric NENs are NET G1-G2, usually at low stage (stage I and II) at diagnosis in more than 60% of surgical series (Solcia *et al.*, 1986; La Rosa *et al.*, 2011).

Three clinico-pathologic subtypes (Rindi *et al.*, 1993, 1999) are defined as: type I, associated with diffuse chronic atrophic gastritis of autoimmune or A type (A-CAG); type II, associated with hypertrophic gastropathy (HG), usually in conjunction with MEN1 and Zollinger–Ellison syndrome (ZES) and type III or sporadic, not associated with specific gastric pathology. Of the three subtypes, type I tumors are the most frequent (70%–80% of published series), occur in elderly female patients and, though multiple and multicentric, are small and limited to mucosa and submucosa and display an excellent survival. Type II tumors are rare (~6% of published series), multiple and multicentric usually display a good prognosis, though metastases may be present and rare cases with aggressive course have been described. By converse the solitary type III tumors are less frequent (~15% of published series), raise in male patients, are larger and, in general, display a more aggressive behavior with frequent metastases and malignant course. Of note, type III tumors may associate with the so-called "atypical carcinoid syndrome" due to histamine and/or 5-hydroxytryptophan hypersecretion.

Other tumor types

Exceedingly rare gastrin G cell NETs have been reported in the antrum similar to rare D cell tumors of both oxyntic and antral mucosa. None of such tumors usually associate with any hyperfunctional syndrome.

Intestine

Gastrin G cell NETs

Gastrin G cell tumors raise in the duodenum or upper jejunum of male patients. When "functioning" they can be defined as gastrinomas, are cause of the ulcerogenic ZE Syndrome and frequently associate with MEN1. Though small in size, G cell tumors, especially when functioning, frequently metastasize especially to local lymph nodes. G cell NETs are usually G1 or, rarely, G2 and at low stage (stage I or II) at diagnosis in more than 50% of surgical series (Vanoli *et al.*, 2017).

D cell NETs

Somatostatin D cell tumors are rare tumors of the duodenum (preferentially at the ampulla of Vater) and upper jejunum in patients of the fifth decade. Often associating with type 1 neurofibromatosis and only rarely with diabetes and/or gallstones, may

be defined as "functioning," though the complete somatostatinoma syndrome (diabetes mellitus, diarrhea, steatorrhea, hypo- or achlorhydria, anemia and gallstones) has been described for pancreatic D cell tumors only. Intestinal D cell tumors are often malignant and may metastasize to both local lymph nodes and the liver. D cell NETs are usually G1 or, rarely, G2 and usually at low stage (stage I or II) at diagnosis in more than 50% of surgical series (Vanoli *et al.*, 2017).

Ganglioneuromatous paraganglioma

Rare tumors composed by neuroendocrine cells, mature ganglion cells and Schwann-like spindle cells, develop in the submucosa of the periampullary duodenal region in middle aged patients. In general, ganglioneuromatous paragangliomas display benign behavior, though local lymph node metastases of the neuroendocrine component have been reported in occasional cases (Vanoli *et al.*, 2017).

Serotonin EC cell NETs

Most serotonin EC cell tumors develop in the intestine, though with decreasing frequency in the ileum, coecum, appendix, jejunum, duodenum, distal colon and rectum. Intestinal EC cell NETs may run a relatively aggressive behavior since often multiple (small intestine), of large size (colon) and deeply infiltrating the intestinal wall, with frequent lymph-node metastases. A typical carcinoid syndrome due to unregulated release of serotonin and other active substances by tumor EC cells may associate, though depending on the establishment of liver metastases. By converse, appendix EC cell tumors, in spite of the deep wall invasion often observed, in general run a benign course. EC cell NETs are usually G1 or, rarely, G2, invariably at high stage (stage III or IV) at diagnosis in more than 90% of surgical series (Jann *et al.*, 2011; Norlen *et al.*, 2012).

Glicentin/PYY L cell NETs

L cell tumors most frequently develop in the colon and rectum and rarely in other sites of the intestine and appendix. The majority of L cell tumors are small, do not associate with any hyperfunctional syndrome and run a benign course (Fiocca *et al.*, 1980). Usually L cell NETS are G1 or, rarely, G2, and at low stage (stage I or II) at diagnosis (Weinstock *et al.*, 2013).

Neuroendocrine carcinoma, NEC

Neuroendocrine carcinomas, NECs are clinically aggressive carcinomas, poorly differentiated in morphology, reported to occur at any site of the gut of patients of the seventh decade. Neuroendocrine carcinomas display solid structure, abundant necrosis, composed by small to intermediate cells with severe cellular atypia, high mitotic index, faint but diffuse chromogranin A expression and intense and diffuse expression of synaptophysin and NSE. Additional features include high Ki67 index and p53 accumulation at immunohistochemistry, while cell-specific neuroendocrine markers are absent. The majority of NEN are high staged (stage III or IV) at diagnosis. Similar to undifferentiated carcinomas, neuroendocrine carcinomas run a very aggressive course.

Gastrin☆

Graham J Dockray, University of Liverpool, Liverpool, United Kingdom

Glossary

Gastric acid secretion Hydrochloric acid produced by parietal cells in the stomach in concentrations up to 130 mM; secretion is stimulated by gastrin, histamine, and acetylcholine and is inhibited by somatostatin.

Gastric endocrine cells Cells of the gastric epithelium specialized for secretion at their basolateral membrane of regulatory peptides and amines; various populations of cells producing gastrin, somatostatin, or serotonin occur in the pyloric antral part of the stomach, and cells producing histamine, somatostatin, or ghrelin occur in the body of the stomach.

Gastric epithelial cell proliferation Division of stem cells located in the isthmus region of gastric glands; proliferation is stimulated by growth factors and gastrin; cells leaving the cell cycle migrate up or down gastric glands and differentiate into the major gastric epithelial cell types.

Gastric innervation Either nerve fibers running in the vagal or splanchnic nerve trunks to the stomach or neurons with cell bodies in the myenteric or submucous plexus of the gastric wall; various neuronal populations may have sensory, motor, or interneuron functions.

Histamine Released by enterochromaffin-like cells in the body of the stomach and stimulates acid secretion; synthesis, storage, and release of histamine all are regulated by gastrin.

Gastrin is a hormone produced mainly by specialized endocrine (G) cells of the pyloric antral part of the stomach and is secreted in response to food in the stomach. It acts on histamine-secreting enterochromaffin-like cells and acid-secreting parietal cells in the body of the stomach to increase acid secretion. It may also regulate proliferation of epithelial cells in the stomach and other parts of the gastrointestinal tract. Gastrin secretion is inhibited by gastric acid, probably via the paracrine mediator somatostatin. When acid secretion is reduced (in patients with pernicious anemia or individuals treated with proton pump inhibitors), plasma gastrin is elevated. There is also increased plasma gastrin in patients with gastrinoma (Zollinger–Ellison syndrome). The main receptor for gastrin is the cholecystokinin (CCK)-2 (or gastrin–CCK_B) receptor.

Introduction

The idea that gastric acid secretion might be regulated by a hormone was suggested by John Sidney Edkins in 1905. He showed that extracts of the stomach stimulated acid secretion and named the active substance "gastrin." Edkins was influenced in his thinking by the work of William M Bayliss and Ernest Starling, who had shown earlier that an active factor from the small intestine, secretin, stimulated pancreatic secretion. For many years, it was unclear whether gastrin was identical to histamine given that histamine is also abundant in the stomach and stimulates acid secretion. The relationship was clarified by the chemical characterization of gastrin by Rod Gregory and Hilda Tracy and by the demonstration that gastrin releases histamine from enterochromaffin-like (ECL) cells of the gastric corpus.

The Gastrin Gene and Progastrin

A single gastrin gene encodes a precursor peptide of 101 residues in humans. *Gastrin* gene expression is increased by food in the stomach and is inhibited by gastric acid. The main product of mRNA translation, preprogastrin, is rapidly converted to progastrin in the endoplasmic reticulum. Further conversion of progastrin occurs during passage along the secretory pathway.

Progastrin and Its Products

Progastrin may be sulfated at a tyrosine residue in position 86, and phosphorylated at a serine residue in position 96, during passage through the trans-Golgi network (Fig. 1). Progastrin is then sequestered in secretory vesicles, where it may be cleaved by

☆*Change History*: December 2017. Graham J Dockray updated the text.

This article is an update of Graham J. Dockray, Gastrin, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 97–100.

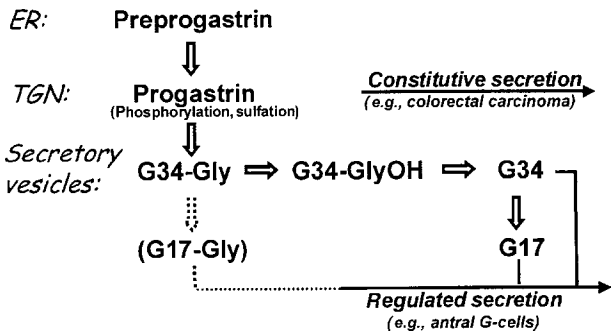

Fig. 1 Schematic representation of the biosynthesis of gastrin. Preprogastrin is translated in the endoplasmic reticulum (ER) and is converted there to progastrin, which translocates through the Golgi complex to secretory vesicles. In the trans-Golgi network (TGN), progastrin may be phosphorylated on Ser-96, sulfated on Tyr-86, or both. In secretory vesicles, it is cleaved to yield a COOH-terminal Gly peptide of 34 residues (G34-Gly), which may then be converted by COOH-terminal α-amidation to G34 or cleaved to G17-Gly. In pyloric antral G cells, G17 and (to a lesser extent) G34 are the main products of regulated secretion. In some tumor cells, progastrin may be secreted by the constitutive pathway direct from the TGN to the cell surface.

enzymes of the prohormone convertase family. Biosynthetic intermediates with a COOH-terminal glycine residue (Gly-gastrins) provide substrates for the enzyme peptidyl α-amino mono'oxygenase, which yields COOH-terminally amidated gastrins (Fig. 1) (Dockray *et al.*, 2001). The amidated gastrins are typically peptides of 17 and 34 amino acid residues (G17 and G34), both of which occur as tyrosine-sulfated and unsulfated peptides. G34 corresponds to an NH_2-terminal extended form of G17. Human gastrin (G) cells normally secrete mainly amidated gastrins, but small amounts of both progastrin and Gly-gastrins may also be released. The COOH-terminal pentapeptide amide of G17 (–Gly–Trp–Met–Asp–Phe–NH_2) is identical to that in the related hormone cholecystokinin (CCK).

Circulating Forms and Metabolism

The concentrations of amidated gastrins in the plasma of normal fasting humans are generally less than 30 pM. A mixed meal increases gastrin concentrations up to about threefold. The major circulating form of gastrin in humans is G34; however, this form is typically $<10\%$ of gastrin stored in G cells. In humans, it is cleared with a half-life of approximately 35 min, compared with approximately 7 min for G17. The difference in clearance accounts in part for the tendency of G34 to accumulate in plasma.

The G Cell and Its Control

G cells are found in the pyloric antral mucosa of all mammalian species. In humans, there are also some G cells in the duodenum. After a meal, gastrin is released in response to gastric luminal stimuli (mainly protein, peptides, and amino acids) and in response to nervous stimuli (Fig. 2). One candidate neurotransmitter regulating the G cell is gastrin-releasing peptide (GRP), which is a mammalian relative of the amphibian skin peptide bombesin. Gastric acid inhibits gastrin release, producing a negative feedback loop. Therefore, decreases in gastric acid secretion, either through disease (e.g., gastritis) or by drug treatment (e.g., proton pump inhibitors), tend to increase gastrin release. The effects of acid are mediated by release of somatostatin from D cells in the antrum, which then suppresses the G cell by a paracrine mechanism (Fig. 2). In patients with *Helicobacter pylori*, there is a tendency for

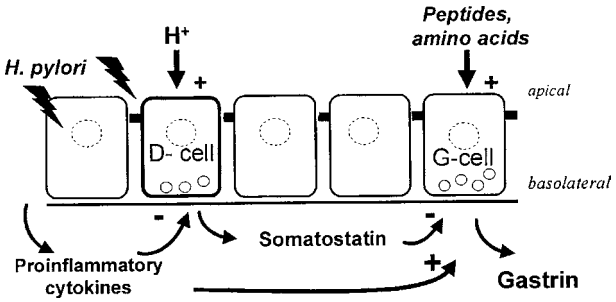

Fig. 2 Schematic representation of cellular relationships in the pyloric antral epithelium. The release of gastrin from G cells is stimulated by peptides and amino acids in the gastric lumen and by neurotransmitters (not shown). Acid releases somatostatin from D cells, and this inhibits gastrin release. In the presence of the gastric bacterium *Helicobacter pylori*, proinflammatory cytokines may inhibit D cells and stimulate G cells and so enhance gastrin release indirectly and directly.

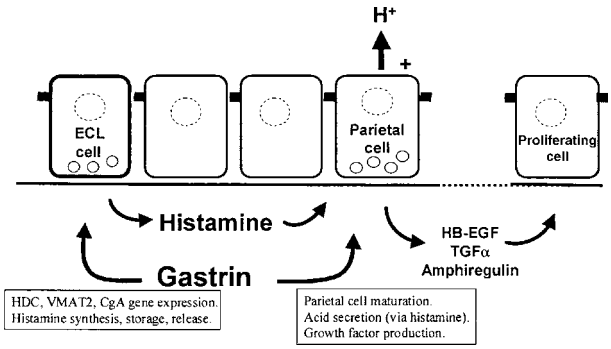

Fig. 3 Schematic representation of some effects of gastrin in the gastric corpus. Gastrin stimulates histamine release from enterochromaffin-like (ECL) cells, and this in turn stimulates acid secretion from parietal cells. In ECL cells, gastrin also increases the production of histidine decarboxylase (HDC), which makes histamine from histidine; vesicular monoamine transporter type 2 (VMAT2), which sequesters histamine in secretory vesicles; and chromogranin A (CgA), which is co-stored with histamine. ECL cell numbers are regulated by gastrin. Parietal cells may also respond directly to gastrin. In addition to acute effects on acid secretion, gastrin controls the maturation of parietal cells and stimulates the production of growth factors, particularly members of the epidermal growth factor (EGF) family, including heparin-binding EGF, transforming growth factor (TGF)-α, and amphiregulin, which increase proliferation of other cells in the epithelium.

increased gastrin release. This is attributable to proinflammatory cytokines that are thought to act partly by inhibiting D-cell function and partly by directly stimulating G cells (**Fig. 2**).

Gastrin Receptors

The effects of gastrin are exerted at CCK2 receptors (also known as gastrin–CCK_B receptors). These are found on gastric parietal and ECL cells, some smooth muscle cells, and some central nervous system (CNS) neurons. This receptor has high affinity for peptides with the C-terminal sequence –Try–Met–Asp–Phe–NH_2; the C-terminal amide is essential for activity. Both gastrin and CCK therefore exhibit high affinity at CCK2 receptors. However, gastrin is the main ligand for receptors on parietal and ECL cells because its plasma concentrations are roughly 10 times higher than those of CCK. However, CCK is the main ligand for CNS receptors because there is abundant CCK, but little or no gastrin, in the brain. The CCK2 receptor belongs to the family of G protein-coupled receptors, characterized by seven transmembrane domains. It acts via the $G\alpha_{q/11}$ group of G proteins to increase intracellular calcium concentrations and protein kinase C activity. Several antagonists have been generated, including YF476 (netazeptide) and L-740,093.

The Physiology of Gastrin

Acid Secretion

The primary action of gastrin is the stimulation of acid secretion. The question of whether gastrin acts directly on the acid-producing parietal cells or indirectly via histamine release from ECL cells has been the subject of intense debate. It is now generally thought that gastrin acts mainly via histamine release from ECL cells (**Fig. 3**). Immunoneutralization of circulating gastrin, or administration of CCK2 receptor antagonists, inhibits gastric acid responses to food. In mice in which the gastrin or CCK2 receptor genes have been deleted by homologous recombination, there is a loss of acid secretion that is refractory to acute stimulation by gastrin, histamine, or cholinergic agonists (Hinkle and Samuelson, 1999). However, acid secretory capacity can be restored by infusion of gastrin, indicating a role for this hormone in maturation of the parietal cell as well as in acute secretory responses after a meal.

ECL Cells

Gastrin increases the expression of several genes in ECL cells that are important for histamine synthesis and storage; these include histidine decarboxylase (HDC), which makes histamine from histidine; vesicular monoamine transporter type 2 (VMAT2), which transports histamine into secretory vesicles; and chromogranin A, which is co-stored with histamine in secretory vesicles (**Fig. 3**). In addition, gastrin increases ECL cell number. In patients with prolonged increases in plasma gastrin, there is a tendency for ECL cell hyperplasia.

Proliferation

Gastrin increases the proliferation of epithelial cells in the stomach. Apart from ECL cells, it is not clear whether proliferating cells express the CCK2 receptor. Therefore, proliferative responses are thought to be due to release of growth factors, including those of the epidermal growth factor (EGF) family (**Fig. 3**) (Dockray, 1999).

Motility

Gastrin contracts smooth muscle and may regulate gastrointestinal motility, but the physiological significance of these effects is still uncertain.

Central Nervous System

There are abundant CCK2 receptors on CNS neurons, but it is thought that the related peptide CCK is the main ligand for these receptors. There is little evidence to suggest that circulating gastrin released from antral G cells in mammals influences CNS function.

Gastrin in Gastrointestinal Disease

Elevated plasma gastrin concentrations occur in patients with gastrin-secreting tumors of the pancreas (Zollinger–Ellison syndrome, gastrinoma) and are associated with increased acid secretion and intractable peptic ulcer. There are also high plasma gastrin concentrations in patients with pernicious anemia, which is attributable to autoimmune destruction of parietal cells and loss of acid inhibition of the G cell. In these patients, and also in patients with mutations of the *menin* gene (i.e., multiple endocrine neoplasia type 1), hypgastrinemia is associated with ECL cell neuroendocrine (carcinoid) tumors. In patients with pernicious anemia, these may resolve after removal of gastrin by antrectomy.

Moderately elevated plasma gastrin concentrations also occur in some patients infected with *H. pylori* (**Fig. 2**). When the infection is limited to the antrum, increased gastrin release may lead to increased acid secretion and duodenal ulcer.

The *gastrin* gene is also expressed in colorectal carcinoma, but the main products of expression are progastrin and Gly-gastrin (**Fig. 1**). There is some evidence that these are growth factors for colon tumor cells. They do not act at CCK2 receptors, and the relevant receptor is still uncertain. There is also evidence that gastrin may play a role in tumors of the pancreas, stomach and esophagus (Rozengurt and Walsh, 2001; Hayakawa *et al.*, 2016).

Two strategies are presently being explored for inhibiting the actions of gastrin. A CCK2 receptor antagonist (netazepide) has been shown to be useful for treatment of gastric neuroendocrine tumors in patients with hypergastrinemia (Boyce *et al.*, 2016). An immunoneutralization strategy using a vaccine promoting antibodies directly to the N-terminus of G17 and G17Gly is being explored for treatment of patients with pancreatic cancer.

Cholecystokinin (CCK)☆

Nori Geary*, Weil Medical College of Cornell University, New York, NY, United States

Glossary

Gastrin A gastrointestinal polypeptide hormone produced by enteroendocrine cells of the gastric antrum that stimulates gastric acid secretion.

G Protein-coupled receptor A family of cell surface receptor proteins consisting of seven transmembrane regions; the intracellular region interacts with GTP-binding proteins that, on ligand binding, transduce signals within the cell, leading to a cellular response (e.g., secretion, motility, growth).

Lamina propria The intestinal lamina propria is the layer separating the intestine's epithelial-cell layer and muscle-cell layers; it is composed extra-cellular fluid, connective tissue, capillaries, lymphatic vessels, and myofibroblasts that support the villi, and it contains numerous nerve endings and immune cells; enteroendocrine cells secrete directly into the lamina propria.

Microvilli Finger-like extensions along the apical surface of intestinal mucosal cells; enterocyte microvilli increase the absorptive surface of the cell; enteroendocrine cell microvilli allow potential intra-luminal stimuli greater exposure to receptors.

Myenteric plexus Also known as Auerbach's plexus, a system of nerves and ganglia lying within the longitudinal and circular muscle layers of the intestine; its nerves innervate numerous targets, including the myenteric externa, mucosa, and sympathetic prevertebral ganglia.

Pylorus The region of circular smooth muscle surrounding at the junction of the stomach and duodenum; pyloric contractions are critical regulators of gastric emptying.

Sphincter of Oddi The region of circular smooth muscle at the distal end of the common bile duct and pancreatic duct as they enter into the duodenum; when constricted, this sphincter prevents flow of bile and pancreatic juice into the duodenum and restricts reflux of duodenal contents back into the bile and pancreatic ducts.

Submucosal plexus A network of nerves and small ganglia found in the submucosa of the intestine; comprised of outer and inner layers; controls intestinal secretion, motility and vasodilation; primary sensory nerves contained in this plexus, which also communicates with the myenteric plexus.

Cholecystokinin (CCK) is a peptide produced and secreted by enteroendocrine cells of the upper small intestine and by neurons in the gastrointestinal tracts and brain. It has several functions. Gastrointestinal CCK, the subject of this article, is the major hormone responsible for stimulating pancreatic enzyme secretion and gallbladder contraction, contributes to meal-ending satiation, slows gastric emptying, and affects intestinal motility.

Introduction

Cholecystokinin (CCK) is a peptide hormone produced by enteroendocrine cells of the upper small intestine. It is secreted during and after ingestion of meals. It was discovered in 1928 as the third gastrointestinal hormone (after secretin and gastrin) by Ivy and Oldberg, who found that intestinal extracts could stimulate gallbladder contraction in dogs and named the substance cholecystokinin ("cholecyst" [gallbladder] and "kinin" [to move]). In 1943, Harper and Raper noted that a similar extract, which they named "pancreozymin," stimulated pancreatic enzyme secretion. Not until CCK was purified and its amino acid sequence was determined by Jorpes and Mutt in 1968 was it clear that CCK and pancreozymin were the same hormone. The original name, cholecystokinin, is now used.

Molecular Forms

Hormonal CCK circulates predominantly in a 58 amino-acid form (CCK-58) (Rehfeld *et al.*, 2007; Stengel *et al.*, 2009). In contrast, neuronal CCK is an eight amino acid peptide, CCK-8. The biologically active region of CCK resides in its carboxyl terminus, which is identical in all forms of CCK: -Gly-Trp-Asp-Met-Phe-NH2. This terminal sequence is identical to that of gastrin, so that gastrin

 doi:10.1016/B978-0-12-801238-3.95866-5

has some weak CCK-like activity, and CCK has some weak gastrin-like activity. CCK is produced from a single gene that encodes a 115 amino acid preprohormone. In humans, the CCK gene is located on chromosome 3, NC_000003.12. CCK expression developmentally regulated in a tissue-specific fashion. In the intestine, the CCK gene is expressed prenatally and is regulated postnatally primarily by the frequent exposure of CCK cells to nutrients.

Distribution

Cholecystokinin cells are gastrointestinal endocrine cells (enteroendocrine cells) that are scattered throughout the mucosa of the small intestines, with the density greatest in the duodenum and proximal jejunum and least in the ileum. Early electron microscopy results suggested that CCK was synthesized and released by a unique enteroendocrine cell type, called I-cells (Polak *et al.*, 1975). Recent data, however, indicate that many enteroendocrine cells that express and secrete CCK also express and secrete other peptides, including ghrelin, GLP-1, PYY, GIP, neurotensin, and secretin.

The apical surface of enteroendocrine CCK cells is open to the lumen of the intestine. Like enterocytes, these enteroendocrine cells possess microvilli that increase the exposed surface area, thereby increasing exposure to intra-luminal stimuli. The apical surface of CCK cells express a variety of nutrient receptors that control CCK secretion. CCK is released through the basal aspect of the CCK cells into the intestinal lamina propria, where it may act on nearby cells or diffuse into intestinal capillaries and be carried via the hepatic portal vein and liver into the systemic circulation.

CCK is also present in vagal (cranial nerve 10) efferent neurons in the abdomen. In the intestine, vagal efferent CCK neurons synapse upon postganglionic cholinergic neurons that stimulate smooth muscle contraction. Vagal efferent CCK neurons also innervate the islets of Langerhans of the endocrine pancreas. In addition, CCK is present in neurons of the myenteric and submucosal plexi of enteric neurons within the gastrointestinal tract.

CCK is expressed by many neurons in the central nervous system (CNS), including the cerebral cortex, olfactory bulb, several hypothalamic nuclei, the thalamus, hippocampus, amygdala, ventral tegmental area, substantia nigra, nucleus of the solitary tract, and more. CNS CCK, which is mainly CCK-8, may have roles in learning and memory, anxiety, analgesia, and other functions. For a review of CNS CCK and its functions, see Beinfeld (2013).

CCK Receptors

CCK exerts its biological actions by binding to cell-surface receptors on its target tissues. Gastrointestinal CCK receptors are expressed widely in the pancreas, gallbladder, stomach, pylorus, lower esophageal sphincter, intestines, vagal afferent neurons, enteric and peripheral nerves and the central nervous system. Two types of CCK receptors have been identified. CCKAR (CCK "alimentary" receptors; sometimes called CCK-1 receptors) predominate in the periphery and appear to mediate most of intestinal CCK's effects. Full activation of the CCKAR requires the seven carboxyl terminal amino acids and sulfation of the tyrosine located seven amino acids from the terminus. CCKBR (CCK "brain" receptors; sometimes called CCK-2 receptors) are identical to the gastrin receptor and predominate in the central nervous system. Both receptors are G-protein-coupled, seven-membrane-spanning proteins (Wank *et al.*, 1994; Kopin *et al.*, 1992). The human CCKAR gene is located on chromosome 4, NC_000004.12, and the human CCKBR gene, on chromosome 11, NC_000011.10.

CCK Release

Intestinal CCK cells release CCK in response to ingestion of proteins, lipids and carbohydrates (Steinert *et al.*, 2017). On a calorie basis, lipids are the most potent secretagogues, proteins intermediate, and carbohydrates least. Secretion is stimulated by the detection of the products of digestive hydrolysis of proteins and triglycerides by specialized receptor molecules on the apical surface of intestinal CCK cells (**Table 1**). Fatty acids with chain length $\geq$ 12C stimulate CCK secretion much more than fatty acids $<$12C; less saturated long-chain fatty acids may be more potent secretagogues than more saturated fatty acids. Carbohydrate digestion may not be required, as inhibition of carbohydrate hydrolysis did not affect CCK secretion. In addition to these direct nutrient effects, CCK is secreted indirectly by CCK-releasing factors such as "pancreatic monitor peptide" and "intestinal luminal CCK-releasing factor" (Miyasaka *et al.*, 1989; Wang *et al.*, 2002), at least in rodents. Such releasing factors are ordinarily degraded by pancreatic proteases. After a meal, however, the proteases bind preferentially to ingested proteins, allowing more releasing factors to reach the CCK cells and stimulate secretion. There may also be neural inputs to CCK cells that affect CCK secretion. As a result of all these controls of secretion, plasma levels of CCK increase from basal levels ($\sim$1–3 pMol) within about 10 min of the onset of a mixed-nutrient meal, reach a peak of $\sim$5–8 pMol 30–60 min after meal onset, and return to basal after 3–5 h (Eysselein *et al.*, 1990; Rehfeld, 1998).

The table is based on the evidence of receptor expression in mice, rats or humans; see Steinert *et al.* (2017) for details. Abbreviations: CASR, calcium-sensing receptor; CD36, thrombospondin receptor; FFAR, free-fatty acid receptor; GNAT3, guanine nucleotide-binding protein, alpha transducing 3; LPAR5, lysophosphatidic acid receptor 5; SLC15A1, solute carrier family 15 (oligopeptide transporter), member 1; TAS1R1, taste receptor, member 1; TAS1R2, taste receptor, member 2; TAS1R3, taste

Table 1 Nutrient receptors expressed by enteroendocrine CCK cells

Receptor	*Nutrient sensed*
CASR	Calcium
CD36	Fatty acids
FFAR1	Fatty acids
FFAR4	Fatty acids
LPAR5	Lipids
GNAT3	Sugars, bitter
LPAR5	Lipids
SLC15A1	Peptides, amino acids
TAS1R1/TAS1R3	Glutamate, sugars
TAS1R2/TAS1R3	Bitter, sugars

receptor, member 3.; T1R1/T1R3; note that abbreviations are for the human genes, although many of the receptors indicated have been identified on the respective enteroendocrine cells so far only in mice or rats. Names and abbreviations are current recommendations of the National Library of Medicine of the United States (www.ncbi.nlm.nih.gov/gene/).

Modes of Action

Neural CCK appears to act as in a neurocrine mode; that is, it is a neurotransmitter that is released from a presynaptic CCK neuron into a narrow synaptic cleft and diffuses the short distance to receptors on the post-synaptic neuron. Intestinal CCK was long assumed to act in a classical endocrine mode; that is., secreted CCK reached distant target tissues via the circulation. Animal research indicates that this is only part of the story, and that intestinal CCK probably has three additional, local modes of action that do not involve transport via the blood. First, it appears to act in a paracrine mode. This involves diffusion of CCK released into the intestinal lamina propria to CCK receptors on neighboring nonneural cells. Second, CCK act in a mixed neuroendocrine-paracrine mode, in which it diffuses to reach CCK receptors on vagal and other nerve endings in the lamina propria. Third, recent discoveries by Liddle and his colleague indicate that CCK may act in an additional neurocrine-like mode following release from axon-like cytoplasmic extensions of the enteroendocrine cells, called neuropods (Bohorquez *et al.*, 2015). These neuropods end mainly in close apposition to glial cells of the enteric nervous system. Ultra-structural data suggests that these appositions have a synapse-like function. The neuropod mode of action presumably provides for more specific and rapid cell-to-cell signaling than other local modes or the endocrine mode. The convention is to continue to identify signaling molecules that have local as well as endocrine modes of action hormones.

Biological Actions of CCK

Potential biological functions of hormones and neurotransmitters are identified by administration of hormones in pharmacological doses or patterns, by transgenic gene-deletion ("knock-out") models, or other similarly gross methods. Proof of endogenous function is more difficult and requires fulfillment of several exacting criteria. The most difficult of these involve measurement and mimicry of endogenous levels and patterns of hormone or neurotransmitter levels at their sites of action and reversal of the action of the hormone or neurotransmitter by antagonism of receptor function within its dynamic range. When the receptors are freely accessible to the blood, blood levels of hormones are considered adequate to assess hormone levels at the site of actions. This would not be the case, for example, for assessing the actions of peripheral hormones within the brain, which is functionally separated from the circulating hormones by the blood-brain barrier.

A classic series of experiments by Liddle and his colleagues (Liddle *et al.*, 1985, 1989) demonstrated conclusively that Ivy and Oldberg's (1928) hypothesis that CCK stimulates gallbladder contraction was correct. These investigators, first, measured plasma CCK after a mixed-nutrient meal and found a close relationship between the increase in plasma CCK and gall bladder contraction, which was visualized ultrasonically; second, found a CCK infusion dose that mimicked these plasma levels; third, found that such CCK infusions were sufficient to stimulate gall bladder contraction in the absence of food intake; and, fourth, found that pretreatment with a selective and potent CCKAR antagonist completely blocked the meal-stimulated gall bladder contractions. Thus, CCK is a physiological controller of human meal-related gall bladder contraction.

Similar experiments involving tests of infusions of "physiological" CCK doses or CCK receptor antagonists in healthy humans indicate that intestinal CCK is also a physiological controller of pancreatic exocrine secretion, relaxation of the sphincter of Oddi, pyloric contraction, gastric and duodenal motility, gastric emptying, at least of liquid foods, and meal-ending satiation (Hildebrand *et al.*, 1990; Konturek *et al.*, 1990; Steinert *et al.*, 2017). As a result of its effect to slow gastric emptying, CCK also contributes to the physiological regulation of meal-related plasma glucose levels (Steinert *et al.*, 2017). Most of the functions

mentioned are mainly or wholly CCKAR-mediated, except CCK's pancreatic actions, which are predominately CCKBR-mediated. Other effects remain under investigation in animals and humans.

CCK's satiation effect is especially interesting. Although many peripheral hormones are hypothesized to contribute to the physiologic control of eating, at present only CCK has fulfilled both the physiological dose and the antagonist criteria (Steinert *et al.*, 2017). Studies in rodents indicate that CCK satiation is mediated by vagal afferents (Smith *et al.*, 1985), that it physiologically modulates the potent eating-stimulatory effect of hypothalamic AgRP neurons (Beutler *et al.*, 2017), and that in females, CCK satiation is modulated by estrogens (Asarian and Geary, 2013). In a sample of obese patients, allelic variations in CCK were related to increased predisposition to eat overly large meals (de Krom *et al.*, 2007). The potential of several CCKAR agonists as anti-obesity therapies is currently under investigation in preclinical studies.

Clinical Aspects

CCK has several diagnostic uses, including to stimulation of gallbladder contraction for radiographic tests of the gallbladder function and, together with secretin, as a challenge test of pancreatic exocrine insufficiency.

CCK injections are sometimes used to stimulate gallbladder contraction in order to reduce gallbladder sludge and prevent gallstone formation in patients undergoing parental alimentation.

Meal-related secretion of CCK is markedly blunted in patients with and bulimia nervosa (Geracioti and Liddle, 1988), but the causes of this and its potential significance to the pathophysiology of bulimia nervosa are unknown. Low blood levels of CCK sometimes occur in patients with celiac disease or other conditions that delay gastric emptying. The defect in CCK secretion in celiac disease is likely due to loss of function of small intestinal CCK cells that are affected by the disease.

It is not known whether CCK deficiency has pathophysiological consequences, nor are there known diseases of cholecystokinin excess.

Pancreatic Polypeptide (PP)☆

Dana K Andersen, National Institutes of Health, Bethesda, MD, United States
F Charles Brunicardi, University of California Los Angeles, Los Angeles, CA, United States

Glossary

Diabetes mellitus A metabolic disease in which there is a deficiency or absence of insulin secretion by the pancreas.
Gastric antrum A dilated portion of the lower end of the stomach, between the body of the stomach and the pyloric canal.
Hypoglycemia A condition in which the concentration of glucose in the blood is abnormally low.
Pancreatogenic diabetes A form of secondary diabetes due to disease, injury, or absence of the exocrine pancreas.

Introduction

After early studies in animals suggested a role of PP as a late-phase anti-digestive hormone with inhibitory effects on exocrine secretion and choleresis, subsequent studies in animals and man have demonstrated that PP is a gluco-regulatory peptide. Since our previous review of this subject (Kono *et al.*, 2004), new research has further supported the possible therapeutic role of PP. This article summarizes the properties of PP and the studies that support its potentially important clinical role in glucose homeostasis. Therapeutic opportunities that may result from an improved understanding of the physiology of PP in diabetes and other clinical conditions are also highlighted.

Structure, Synthesis, and Distribution

PP is a 36-amino-acid straight-chain peptide with a free NH_2 terminus and a COOH-terminal tyrosine amide with a characteristic 'hairpin fold' (**Fig. 1**). In 1968, J. R. Kimmel and colleagues discovered PP during purification of insulin from the pancreatic extracts of chickens. The peptide, first named avian PP, was later extracted from bovine, porcine, and human pancreatic tissue by R. E. Chance and co-workers. The peptides isolated from different mammalian species differ by only one or two residues (Lin and Chance, 1974). In man, the hormone is secreted from specialized cells called F cells or PP cells that are predominantly located in the ventral (uncinate) process of the pancreas (Gates and Lazarus, 1977) (**Fig. 2**). As shown by L. Orci (1976), PP cells account for 10%–15% of the total islet cell population, and outnumber both alpha and delta cells. They are found in the islets and in clusters throughout the exocrine pancreatic tissue. In some species, such as the dog, a few PP cells are found in the gastric antrum (Gersell *et al.*, 1979). In addition, antibodies to PP react with a population of neurons in both the central and peripheral nervous systems.

PP is a member of the 'PP family' of structurally related regulatory peptide hormones. Other peptides include peptide YY (PYY) and neuropeptide Y (NPY). As their names suggest, the peptide members share considerable amino acid sequence homology, but are found in

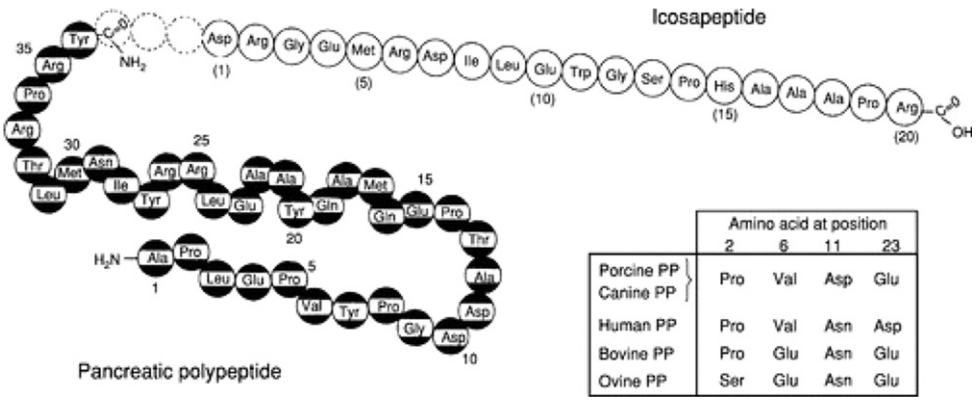

Fig. 1 Pancreatic polypeptide is a 36-amino-acid peptide that is secreted by the F cells of the islet. There is significant homology across species.

Table 1 Alterations in PP levels

Elevated levels in:	Normal aging
	Type 2 diabetes (Obesity accompanied by glucose intolerance)
	Early stage type 1 diabetes
	Neuroendocrine (islet cell) tumors
Deficient levels in:	Type 3c diabetes due to chronic pancreatitis, cystic fibrosis, proximal or total pancreatectomy
	Late stage Type 1 diabetes
	Diabetic autonomic neuropathy
	Vagal denervation

widely disparate locations, including the pancreas (PP), the distal gut (PYY), and the central nervous system (NPY). The circulating levels of PP have been found to vary with a number of normal and pathologic conditions in humans (**Table 1**). The presence of a family of G protein-coupled receptors specific for the PP family called Y receptors has been confirmed and the population of high affinity hepatic Y4 receptors has been shown to vary inversely with the circulating levels of PP (Seymour *et al.*, 1998).

In addition to the liver, the Y receptor family has been found to be expressed in the intestine, spinal cord, adrenal gland, in ganglia of the midbrain and brain stem, and in the vas deferens. At least 5 sub-types of Y receptors have been identified, and the PP family of peptides cross-react with different members of the Y receptor family with variable affinity (Berglund *et al.*, 2003). PP has the greatest affinity for the Y4 receptor sub-group, and Y4 receptors have been found in the gastro-entero-hepatic system, the brain, and the cardiovascular system (Bard *et al.*, 1995).

Pharmacokinetics and Metabolism

The half-life of exogenously administered PP in the vascular system is 5–7 min (Floyd *et al.*, 1978). The metabolic clearance rate and volume of distribution do not change significantly when blood concentrations of the peptide are increased. Sustained elevations of PP after a meal cannot be accounted for by a low metabolic clearance rate, but rather indicate that the peptide is continuously released in the postprandial period to maintain the high level.

PP levels are elevated in patients with chronic renal failure. A close inverse correlation exists between the glomerular filtration rate and serum PP levels, which suggests that the kidney may play a dominant role in the clearance of PP from the circulation.

Regulation of Secretion

PP is promptly released into the blood following a meal. The response to food is generally biphasic, with plasma concentrations rising four- to sixfold above basal levels beginning within 5 min after food ingestion. The initial release lasts 30–60 min and is followed by a secondary response lasting up to 5 h. Protein is the most potent enteral stimulator of PP release, closely followed by fat, whereas glucose has a lesser effect (Floyd *et al.*, 1978).

Vagal mechanisms are not only the most powerful stimulators of PP secretion, but also are required for nearly all other stimuli of the PP cell. Central vagal activity can be increased either by sham-feeding, a rather specific but mild stimulation, or by hypoglycemia, a less specific but stronger stimulus. The PP response is eliminated by vagotomy and can be abolished by atropine, even at very small doses. The presence of an intact PP response to ingested nutrients has therefore been taken as an indication of vagal integrity, or as a test for incomplete vagotomy (Glaser *et al.*, 1980).

After sham-feeding, PP concentrations remain elevated for hours, even though the stimulus may last for only 15 min. Cessation of electrical vagal stimulation is followed by a rapid decline of plasma PP concentrations with a half-life of 5.5 min, similar to the half-life of exogenously administered PP. Thus, hypoglycemia or sham-feeding causes prolonged activation of the 'vagal center' responsible for PP secretion. This phenomenon may be an important aspect of the prolonged PP secretion detected after a meal.

The isolated perfused human pancreas model has been used to investigate the neural regulatory mechanism of the endocrine pancreas. In this model, human pancreata are procured from heart-beating organ donors. Following organ procurement, the pancreas is perfused via the splenic artery and the effluent is collected from the splenic vein. Electrical stimulation of the neural plexus along the splenic artery can be performed in the presence or absence of selective neural blockers and hormonal responses in the venous effluent can be examined. In this model, cholinergic stimulation with combined perfusion of phentolamine and propranolol (α- and β-adrenergic antagonists) during splanchnic nerve stimulation causes a marked stimulation of PP release, consistent with the vagal dependency of *in vivo* PP release (Brunicardi *et al.*, 1988). Activation of α-adrenergic fibers causes strong suppression of PP secretion and activation of β-adrenergic fibers causes mild stimulation.

PP release may also be mediated by enteric hormonal agents such as cholecystokinin (CCK), secretin, bombesin, and gastric inhibitory polypeptide (GIP). Intravenous infusion of cerulein, an analogue of CCK, stimulates an increase in plasma PP levels in humans and infusions of 20% pure CCK in humans achieve similar results. The most potent stimulus for PP release on a molar basis in dogs is pure CCK, followed by octapeptide of CCK and synthetic human gastrin. Phenylalanine and tryptophan, instilled into the duodenum, cause a significant increase in PP levels. Duodenal acidification also releases PP, but the response is significantly less than that obtained by infusion of the two amino acids. The mechanism of PP release by phenylalanine and tryptophan appears likely to involve the intermediate release of CCK, which in turn stimulates the release of PP. Oleate and liver extract, both strong releasers of CCK, also stimulate the release of significant amounts of PP when infused into the intestine of dogs. These findings suggest that endogenously released CCK plays an important role in the prolonged or so-called intestinal phase of PP release.

Gastro-Entero-Hepatic Actions of PP

The basal secretion of pancreatic fluid and protein is modestly inhibited by physiologic doses of PP in dogs and in humans. Therefore PP has been proposed as a post-digestive hormone which serves as a 'brake' or reversal agent for meal-stimulated secretion (Hazelwood *et al.*, 1973). At physiologic doses, PP inhibits secretin- and cerulein-stimulated pancreatic protein and bicarbonate secretion in dogs. Secretin- and CCK-stimulated pancreatic secretion of trypsin was markedly inhibited and bicarbonate output was less markedly, but significantly, inhibited by PP. In humans, PP inhibited secretin-stimulated pancreatic secretory volume and enzyme concentration, but had no effect on pancreatic fluid bicarbonate concentration.

PP infusion does not affect gastric acid or pepsin secretion or the plasma levels of insulin, glucagon, secretin, gastrin, glucose, or lipids in normal man (Bloom *et al.*, 1978). Additionally, there are no signs or symptoms of cardiovascular or gastrointestinal alterations in healthy persons receiving intravenous infusion of PP. In dogs, pharmacologic doses of PP had no effect on steady-state bile flow but did cause choledochal resistance and relaxation of the gallbladder. Basal and stimulated output of bilirubin is inhibited significantly by PP infusion at physiologic levels.

Satiety, Obesity, and Hyperphagia

A number of studies suggest that PP may play a role in feeding and obesity and, therefore, in glucose metabolism. R. L. Gingerich and co-workers observed that the amount of PP in the pancreas is elevated in hyperglycemic, obese mice. Subsequently, R. J. Gates and N. R. Lazarus (1977) reported reversal of hyperphagia, obesity, and glucose intolerance after administration of PP in obese, hyperphagic mice and concluded that the abnormalities seen were due to a deficiency of PP release.

B. Glaser and colleagues (1988) studied the relationship of PP levels with both obesity and glucose intolerance in humans. Obese subjects with normal oral glucose intolerance demonstrated low basal and low stimulated levels of PP compared to age-matched controls. Obese subjects with abnormal oral glucose tolerance demonstrated elevated basal levels of PP, however, and an exaggerated PP response to stimulation.

W. B. Zipf and colleagues (1990) observed that obese children with Prader–Willi syndrome were PP-deficient and that their hyperphagia was reduced by PP administration. PP administration to normal dogs has also been shown to induce weight loss. A 14-day continuous subcutaneous infusion of PP resulted in a 3.5% loss of body weight in 20 kg dogs allowed normal access to food. The weight loss was reversed within 4 weeks after cessation of the PP infusions (YS Sun *et al.*, 1986). Other investigators have found elevated levels of PP in patients with bulimia. A satiety effect of NPY has also been observed by several investigators and laboratory and clinical studies continue to explore the possible role of PP and NPY as satiety-inducing agents. Despite positive results of experiments in rodents and non-human mammals, PP has yet to be shown as an anorexigenic agent in man. The role of PP is also being investigated in patients undergoing bariatric surgery.

Regulation of Insulin Action

The liver occupies a central role in the regulation of glucose metabolism. The ability of the liver to produce glucose during times of fasting or stress, and to take up glucose after feeding, is essential for metabolic homeostasis and PP appears to play an important role in the hepatic response to insulin. A study by Y. S. Sun and colleagues (1986) examined pancreatogenic diabetes in a canine model of chronic pancreatitis created by pancreatic duct ligation. The hyperinsulinemic–euglycemic glucose clamp technique and radioisotopic methods were used to quantify hepatic and nonhepatic insulin-stimulated glucose turnover. Hepatic glucose production in normal animals was suppressed by insulin, but dogs with chronic pancreatitis demonstrated far less insulin-induced suppression of hepatic glucose production. This insulin resistance could be demonstrated only in the liver and not in nonhepatic tissue. Furthermore, it occurred only in animals with impaired meal-stimulated PP secretory activity. Thus, PP deficiency was uniformly associated with profound hepatic insulin resistance.

In subsequent experiments, the same animals were restudied at varying time points during continuous subcutaneous infusion of bovine PP. The hepatic insulin resistance previously observed in PP-deficient animals was corrected after PP administration (**Fig. 3**). Serial glucose tolerance tests, performed over 28 weeks after the PP infusion period, demonstrated that glucose tolerance was significantly improved posttreatment, as compared to pretreatment values.

Seymour *et al.* (1995) studied hepatocyte insulin-binding characteristics to determine whether insulin receptor function or expression is altered by PP. Maximal insulin-binding capacity was significantly lower in hepatic tissue from animals with chronic pancreatitis than from control, sham-operated animals (**Fig. 4**). This loss of high-affinity binding sites was observed in the liver but not in skeletal muscle. PP administration in animals with chronic pancreatitis resulted in significantly greater hepatic insulin-binding capacity than was observed after vehicle administration alone and approximated that of the control (nonpancreatitic) group. During glucose tolerance tests performed immediately prior to the procurement of tissues, the magnitude and duration of the serum glucose elevation following an intraduodenal dextrose challenge were reduced by PP administration in animals with pancreatitis.

Serum immunoreactive insulin levels were not altered by PP administration, but the restoration of high-affinity insulin-binding sites produced by exogenously administered PP suggested alterations in the expression of hepatic insulin receptors. Subsequent studies by this group showed that diminished hepatic insulin receptor gene expression seen in PP-deficient animals is reversed by exogenous PP administration (Spector *et al.*, 1997).

The glucoregulatory effect of PP therefore appears to reside in its role in the expression of the hepatic insulin receptor protein. Diminished PP levels are associated with a loss of high-affinity insulin receptor sites on hepatocytes, which creates a state of hepatic insulin resistance. Although other factors may play a role in the hepatic insulin resistance that characterizes pancreatogenic diabetes, a loss of insulin-binding sites due to the reduced expression of hepatic insulin receptor protein appears to be the primary mechanism of PP's glucoregulatory role. Replacement of PP by exogenous administration reverses the hepatic insulin resistance and at least partially corrects the abnormal hepatic glucose production (Cui and Andersen, 2011).

Evidence for the Role of PP as an Adjunct to Insulin Therapy

The artificial endocrine pancreas, used clinically, is simple in its concept. A sensor electrode measures the level of blood glucose. This information is fed into a small computer that energizes an infusion pump, and from a small reservoir, controlled amounts of insulin enter the patient's circulation. K. Hanazaki and colleagues (2001) developed a new artificial pancreas with a multiple-chamber injection pump to facilitate infusion of not only insulin, but also PP. The addition of PP decreased insulin requirements

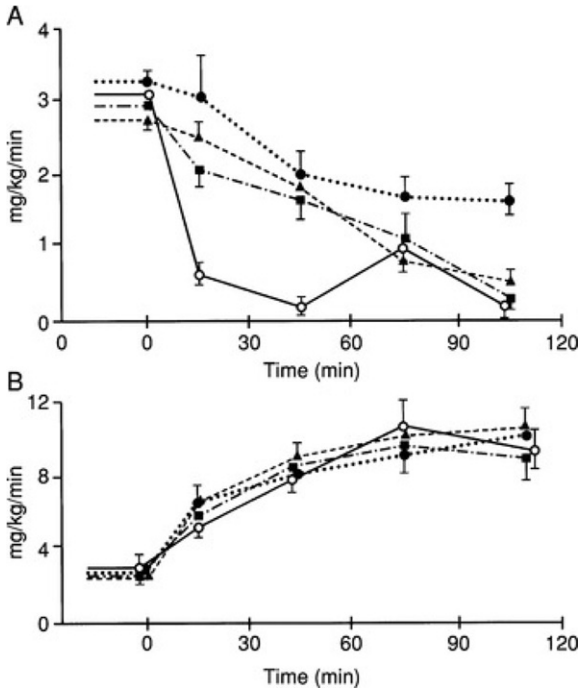

Fig. 3 (A) Hepatic glucose production rates. The responses of dogs with chronic pancreatitis at days 6 (▲) and 11 (■) of continuous subcutaneous PP infusion were significantly lower than the pretreatment response (•) by paired analysis compared to control, sham operated animals (○) ($P<0.05$). (B) The overall glucose disposal rates achieved by insulin infusion in these studies. Reprinted from Sun *et al.* (1986), with permission.

in pancreatectomized dogs during a 72 h trial period. This observation suggested that PP, or a PP-receptor agonist, may become a useful adjunct in the treatment of diabetes.

To determine whether the addition of PP would reduce the insulin requirements in Type 1 (T1D) and Type 3c (T3cD) diabetics who were using an insulin pump, Rabiee *et al.* (2011) conducted a pilot study in which a randomized, blinded 72 h infusion of either PP or saline was administered subcutaneously in 7 T1D and 3 T3cD subjects. The average blood glucose levels, measured by a blinded continuous glucose monitor, were not different during the PP and saline infusions, as the subjects followed their usual algorithm for adjustment of their insulin infusions. The amount of insulin required for the same degree of glucose control was significantly less during the second and third day of the PP infusion (**Fig. 5**). Insulin sensitivity, calculated from the amount of insulin infused corrected for the mean glucose levels, increased 34–45% during the PP infusion period compared to the saline infusion period. Furthermore, the improvement in insulin sensitivity was seen not only in all of the T3cD subjects, but in 5 of the 7 T1D subjects as well. Further studies of the potential role of PP as an adjunct to insulin therapy are in progress.

The Role of PP in Pancreatogenic Diabetes

Pancreatogenic diabetes, or T3cD, is defined by the American Diabetes Association and the European Association for the Study of Diabetes as a form of secondary diabetes due to exocrine disease of the pancreas. This includes chronic pancreatitis, proximal or total pancreatectomy, cystic fibrosis, hemochromatosis, 'tropical' fibrocalcific pancreatitis, pancreatic cancer, pancreatic trauma, and agenesis of the pancreas. Chronic pancreatitis accounts for 75–80% of T3cD, according to a study by Hardt *et al.* (2008) of almost 2000 diabetic patients referred to an academic medical center in Germany. In their population, T3cD accounted for 8% of the entire population of diabetics, and half of the T3cD patients has been previously misdiagnosed as T2D or, less commonly, as T1D (**Fig. 6**).

Patients with severe chronic pancreatitis have a profound meal-stimulated PP secretory deficiency compared to normal subjects (**Fig. 7**) (Sive *et al.*, 1978, Valenzuela *et al.*, 1979). During an initial, baseline hyperinsulinemic–euglycemic clamp study, F.C. Brunicardi *et al.* (1996) found a pattern of profound hepatic insulin resistance similar to that seen in the canine studies in PP-deficient chronic pancreatitis patients (**Fig. 8**). Glucose clamp studies were repeated during the final 2 h of an 8 h intravenous infusion of bovine PP, which replicated physiologic serum concentrations of postcibal immunoreactive PP (750–1000 pg ml^{-1}). Hepatic responses to insulin in PP-deficient patients were restored to normal by PP (**Fig. 8**). However, insulin-stimulated glucose disposal in normal control subjects was not altered by the PP infusion. There was no PP-induced alteration in serum insulin or

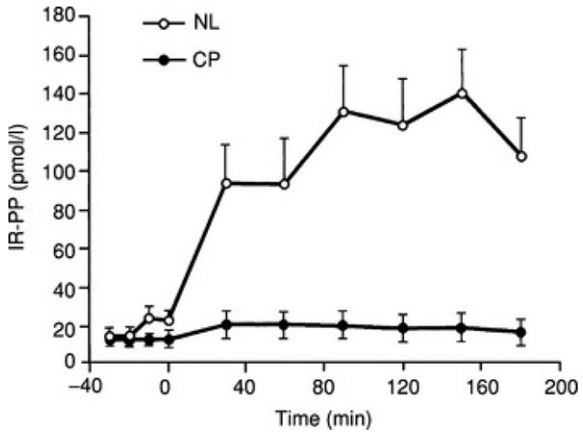

Fig. 7 PP response to test meal. Immunoreactive PP (IR-PP) responses in normal control subjects (NL, $n=6$) and patients with chronic pancreatitis (CP, $n=5$) accompanied by PP deficiency. Test meal was administered at 0 min. Reprinted from Brunicardi *et al.* (1996), with permission.

glucagon concentrations in either of the experimental groups. These data indicate that PP replacement was successful in reestablishing the normal hepatic response to insulin. A third set of glucose clamp studies was performed 1–2 months after the PP administration. Hepatic glucose output in response to insulin in PP-deficient patients had returned to near-baseline values, which confirmed the etiologic role of PP deficiency in the hepatic resistance to insulin.

An oral glucose tolerance test (OGTT) was administered to the subjects in Brunicardi's study on the day after the clamp experiment, and the mean plasma glucose levels from the OGTT performed before, 1 day after, and 1 month after the PP infusion are shown in **Fig. 9**. In every subject in whom mean plasma glucose levels were abnormally high in the baseline study, glucose levels were lower immediately after the 8 h PP infusion. These findings indicate that the enhancement of hepatic insulin sensitivity by PP in PP-deficient subjects contributed to an improvement in their glycemic response to oral glucose.

Seymour *et al.* (1988) examined glucose turnover in patients with a remote history of pancreatectomy. In these subjects, proximal pancreatectomy and distal pancreatectomy were distinguished from one another, since only the former was associated with a loss of PP secretory activity and low circulating PP levels (**Fig. 10**). Three hyperinsulinemic–eugycemic clamp studies were performed in each subject, separated by at least 1 month. An 8 h intravenous PP infusion was administered before the second study. PP-deficient, proximal pancreatectomy subjects demonstrated an impairment in hepatic insulin responses in the first study and required significantly smaller glucose infusions than normal control subjects to maintain euglycemia during insulin infusion (**Fig. 11**). This insulin resistance was completely reversed by PP administration during the second clamp study, but was evident again during the final infusion study in the absence of PP. No alteration in peripheral glucose disposal was observed with either pancreatectomy or PP administration.

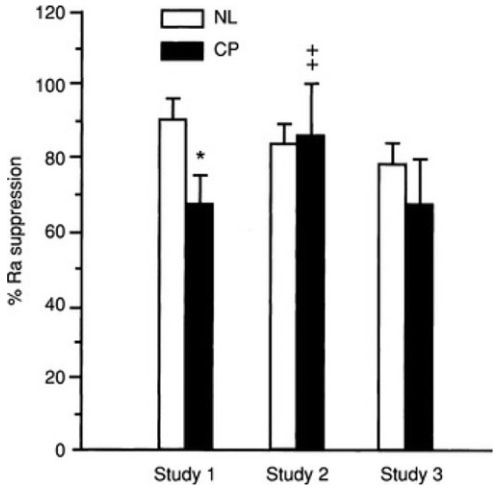

Fig. 8 Percentage suppression of RA (rate of glucose appearance) during hyperinsulinemic–euglycemic clamps for studies 1, 2, and 3 for normal subjects (NL, $n=6$) and CP patients (CP, $n=5$). Study 1 (baseline) showed significant ($*p<0.05$)resistance to insulin-mediated suppression of hepatic glucose production. Study 2 was performed during the last 2 hr of an 8 hr infusion of bovine PP; the suppression of hepatic glucose production by insulin was significantly increased from baseline ($+p<0.05$). Study 3 was performed one month later. Reprinted from Brunicardi *et al.* (1996), with permission.

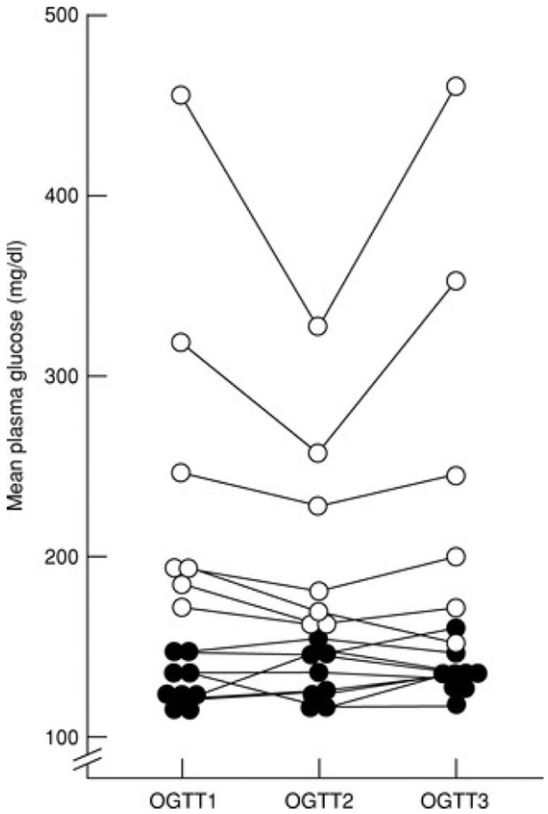

Fig. 9 Mean plasma glucose concentration during 180 min after 40 g m^{-2} oral glucose tolerance test (OGTT) in chronic pancreatitis patients ($n=10$) and controls ($n=6$). Open circles indicate impaired or diabetic status during the initial OGTT. Filled circles indicate normal or nondiagnostic status during the initial OGTT. OGTT 2 was performed 18 h after an 8 h infusion of bovine PP (2 pmol kg^{-1} min^{-1}). OGTT 3 was performed 1 month later. Eighteen hours after PP infusion, every patient with an impaired or diabetic OGTT showed a lower mean plasma glucose response. Reprinted from Andersen (1990). Fig. 11 Glucose infusion rate (mg kg^{-1} min^{-1}) during the final hours of a 2 h insulin infusion in normal control (open squares), non-PP-deficient resection (filled circles), and PP-deficient resection (filled squares) subjects. The glucose infusion requirement for PP-deficient subjects was significantly greater during the PP infusion study than during the control study ($P<0.03$). Reprinted from Seymour *et al.* (1988), with permission.

These studies provide strong evidence for a metabolic role of PP in the regulation of hepatic glucose metabolism, and suggest that PP might have benefit as a therapeutic agent in T3cD. Administration of PP requires continuous infusion either intravenously or subcutaneously due to the short half-life of the peptide, however. Therefore, efforts have been explored to find a method to protect PP from rapid degradation to prolong its bioavailability. K. Bellman-Sickert and colleagues (2011) showed that acetylation with fatty acids (lipidation) or polyethylene glycol (PEGylation) of PP results in a prolonged circulation half-life due to prevention of renal degradation. A. Banerjee and H. Onyuksel (2013) incorporated human PP in PEGylated phospholipid micelles and showed improved insulin sensitivity and glucose tolerance in a rat model of T3cD due to chronic pancreatitis. Further efforts are underway to create a modified peptide, a delivery vehicle for preventing degradation of the peptide, or a durable Y4 receptor agonist, for therapeutic trials.

Clinical Implications of Alterations in PP Secretion

Diabetes mellitus

Mean basal concentrations of plasma PP are elevated in normal aging and in T2D (**Fig. 12**). PP levels are particularly elevated in type 2 (adult onset, non-insulin-dependent) diabetic patients, which may represent a compensatory response to a loss of sufficient insulin synthesis or the development of insulin resistance. Recent studies by C. W. Chia *et al.* (2014) indicate that the elevation in PP levels in T2D is secondary to increased levels of GIP, which is tropic to PP secretion. Early type 1 diabetic patients may also exhibit high levels of PP before they experience loss of islet responsiveness due to the progression of disease.

Pancreatogenic or type 3c diabetes differs from both T1D and T2D in several respects (**Table 2**). T3cD rarely, if ever, results in ketoacidosis, but can be associated with labile blood glucose levels and frequent episodes of iatrogenic hypoglycemia. This specific pattern of abnormal glucose homeostasis is likely caused by the simultaneous deficiencies in insulin, glucagon, and PP secretion.

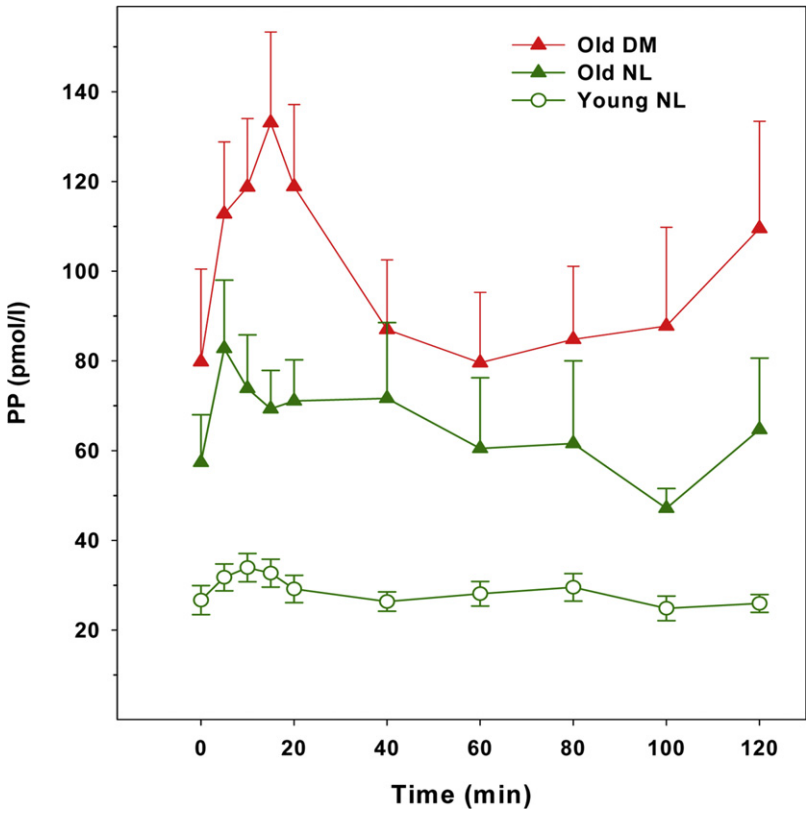

Fig. 12 Serum PP responses to 75 g of glucose ingested at time = 0 in 10 healthy young (age younger than 40 years; NL Young), 19 healthy elderly (age greater than 65 years) with normal glucose tolerance (NL Old), and 21 elderly subjects with T2DM (DM Old). Data are shown as mean ± SE. Reprinted from J. T. Magruder, D. Elahi, and D. K. Andersen. Pancreas **40** (2011) 339-351, with permission.

Table 2 Types of diabetes mellitus

Parameter	*Type 1 IDDM Autoimmune*	*Type 2 NIDDM Obesity-related*	*Type 3c pancreatogenic Prior pancreatic disease*
Ketoacidosis	Common	Rare	Rare
Hyperglycemia	Severe	Usually mild	Mild
Hypoglycemia	Common	Rare	Common
Peripheral insulin sensitivity	Normal or increased	Decreased	Increased
Hepatic insulin sensitivity	Normal	Normal or decreased	Decreased
Insulin levels	Low	High	Low
Glucagon levels	Normal or high	Normal or high	Low
PP levels	High early, Low late	High	Low
Typical age of onset	Childhood or adolescence	Adulthood	Any

Note. IDDM, insulin-dependent diabetes mellitus; NIDDM, non-insulin-dependent diabetes mellitus; PP, pancreatic polypeptide. (From Slezak and Andersen 2001)

Therefore, a loss of PP responsiveness to ingested nutrients discriminates T3cD from T2D, and is a marker for pancreatogenic diabetes. As described by Y. F. Cui and D. K. Andersen (2011), this form of diabetes requires special attention in its management.

Chronic pancreatitis

Chronic pancreatitis is a complex pathologic state consisting of lifelong exocrine and endocrine derangement. Endocrine dysfunction manifests itself as diabetes mellitus, but multiple hormone deficiencies have been demonstrated. Meal-stimulated levels of circulating immunoreactive PP are especially affected by advanced chronic pancreatitis, so much so that the measurement of PP levels has been suggested as the best endocrine screening procedure for the diagnosis of chronic pancreatitis by Rickels *et al.* (2013). In PP-deficient states such as chronic pancreatitis, there is demonstrable hepatic resistance to insulin, which can be reversed by the administration of PP (**Fig. 8**).

Pancreatic surgery

K. Inoue and colleagues confirmed the abolishment of PP responses to ingested nutrients in patients after pancreaticoduodenectomy. In the study by Seymour *et al.* (1988), healthy, young (age less than 30 years) male patients who had undergone pancreatic resection for trauma and who had a deficient PP response as a consequence of their pancreatic resection had a measurable impairment of hepatic insulin sensitivity (**Fig. 11**). This effect was not associated with impaired glucose tolerance, however, when insulin and glucagon secretory function was present. Although 100% of patients are PP deficient after pancreaticoduodenectomy, only 50% are diabetic. Therefore PP deficiency, per se, in the setting of adequate beta-cell function does not cause overt disease.

The risk of pancreatogenic diabetes is increased when proximal pancreatectomy is performed in older patients, however, or when near-total or total pancreatectomy is performed. The development of duodenum-preserving pancreatic resection techniques by H. G. Beger and colleagues, and by C. F. Frey, has been shown to be associated with improved glucose tolerance postoperatively. The preservation of glucose tolerance with operative techniques that spare part or all of the PP-rich region of the pancreas further supports the role of PP in glucose homeostasis (Slezak and Andersen, 2001).

Islet-cell transplantation, either by allo-transplantation or by auto-transplantation after total pancreatectomy, is also associated with an impaired PP response and PP deficiency. Disruption of the cholinergic innervation of the islet is thought to be involved in the mechanism.

Summary

PP release is both hormonally and neurally mediated and both exaggerated or diminished PP responses are valuable indicators of the integrity of the neuro-entero-pancreatic system. Although subtle effects on pancreatic exocrine function and choleresis are associated with PP, its major role appears to be that of a glucoregulatory hormone. It remains to be determined whether PP plays a role in food ingestion as a satiety mediator in man, but its most consistent function appears to be that of a regulator of hepatic insulin action, through its mediation of hepatic insulin receptor protein synthesis. A deficient PP response to ingested nutrients appears to be a useful marker to distinguish T3cD from T2D, and replacement of PP in PP deficient patients improves hepatic insulin sensitivity and glucose homeostasis. Therapeutic opportunities are being explored with the use of methods to extend the half-life of PP. In the future, PP analogues, as well as PP-receptor agonists or antagonists, are likely to become useful clinical tools.

Peptide YY (PYY)

Peter Holzer and Aitak Farzi, Medical University of Graz, Graz, Austria

Glossary

Bariatric surgery Surgical intervention to reduce food intake and induce weight loss in obese people, involving a variety of procedures to diminish the size of the stomach or bypass the stomach.

Biologically active peptide A chain of amino acids joined by peptide bonds, the sequence of amino acids and the tertiary structure of the molecule determining the biological properties and function of the peptide.

Enteroendocrine cells Hormone-producing endocrine cells interspersed between epithelial cells of the gastrointestinal mucosa.

Pancreatic α-cells Endocrine cells in the pancreatic islets of Langerhans expressing glucagon, peptide YY, glucagon-like peptide 1 and glucagon-like peptide 2.

Y receptors Receptors located in the cell membrane, which when activated by peptide YY, pancreatic polypeptide or neuropeptide Y elicit a cellular response.

PYY and Y Receptors

Peptide YY (PYY) is an amidated peptide that was identified by Tatemoto and Mutt (1980) and named after the tyrosine (Y) residues constituting each end of its amino acid chain (Field *et al.*, 2010). It belongs to a family of biologically active peptides that also includes pancreatic polypeptide (PP) and neuropeptide Y (NPY). As these peptides share the PP fold (hairpin fold) as common tertiary structural motif, they are also referred to as PP-related peptides. PYY, NPY, and PP are all composed of 36 amino acids and exhibit high sequence homology, 70% of the amino acid residues being identical in PYY and NPY and 50% in PYY and PP (Pedragosa-Badia *et al.*, 2013). The N-terminus of PYY (like that of NPY) is readily truncated by dipeptidyl peptidase 4 (DPP-4) (EC 3.4.14.5), yielding the fragment PYY(3–36) which is the major postprandial circulating form of PYY (Mentlein *et al.*, 1993; Medeiros and Turner, 1994). Other enzymes such as aminopeptidase-P and endopeptidase-24.11 also contribute to the degradation of the peptide.

The structural commonalities between the PP-related peptides explain why their biological actions are brought about by binding to a group of rhodopsin-like (class A) G protein-coupled receptors (GPRs) termed NPY or, in brief, Y receptors. In mammals, 5 Y receptor subtypes have been identified: Y1, Y2, Y4, Y5, and y6. The y6 receptor is commonly written in lower case because it is a pseudogene in humans, but functional in mouse, rabbit and some other mammals (Alexander *et al.*, 2017). The receptor originally named Y3 receptor has later been identified as the CXCR4 chemokine receptor (Alexander *et al.*, 2017). The Y receptor subtypes display differential affinities for the different members of the PP-related peptide family and their fragments (Alexander *et al.*, 2017). While PYY and NPY do not markedly differ in their selectivity for the Y1, Y2 and Y5 receptor subtypes, PYY (3–36) is a preferred agonist at Y2 receptors and PP a preferred agonist at Y4 receptors (Alexander *et al.*, 2017).

The differential affinities of PYY, NPY and PP to the Y receptor subtypes are not only the result of different structural homologies between the ligands but also of grossly varying sequence identities of the receptors (Pedragosa-Badia *et al.*, 2013). Once activated, the Y receptors are typically coupled to pertussis toxin-sensitive $G_{i/o}$ proteins, transduction through which leads to inhibition of adenylate cyclase, diminution of cAMP formation, and modulation of Ca^{2+} and K^{+} channels (Pedragosa-Badia *et al.*, 2013). In addition it has been reported that coupling of Y2 and Y4 receptors to G_q proteins can increase inositol 1,4,5-phosphate production via activation of phospholipase C-β (PLC) (Pedragosa-Badia *et al.*, 2013).

Expression of PYY in Gut, Pancreas and Brain

PYY was originally isolated from the porcine intestine, and the gastrointestinal tract (GIT) is the prime source of this peptide in the body although appreciable amounts of PYY are also expressed in the pancreas and brain. In the GIT, enteroendocrine L cells are the predominant source of PYY, these cells appearing very early during ontogeny, which suggests that this hormone is relevant to the development of the GIT (Boey *et al.*, 2007; El-Salhy *et al.*, 2013). The topographic distribution of PYY in the gut differs markedly between different vertebrate species. While in lower vertebrates the peptide is concentrated in the upper GIT, PYY-expressing enteroendocrine cells occur in all parts of the small and large intestine of the rat. This pattern is again different in primates in which low levels of PYY are present in the stomach and its concentration increases along the alimentary canal such that the highest density of PYY-immunoreactive enteroendocrine cells is found in the rectum (Field *et al.*, 2010; El-Salhy *et al.*, 2013; Persaud and Bewick, 2014). In mice and humans about 50% of the colorectal L-cells contain PYY which in these cells is co-expressed with pro-glucagon products such as glicentin, glucagon-like peptide 1 (GLP-1) and GLP- 2 and copackaged in the same secretory granules (Cox, 2007; Persaud and Bewick, 2014). Apart from its predominant expression by enteroendocrine cells, PYY

 doi:10.1016/B978-0-12-801238-3.65827-0

has also been localized to enteric neurons in the stomach of several mammalian species including rat, cat, ferret and pig, which are different from those expressing NPY (Boey *et al.*, 2007; Cox, 2007).

Since the gut and the pancreas share a common embryological origin, it is not surprising that PYY is also expressed in pancreatic endocrine cells in which the peptide appears during the earliest stage of pancreatic islet cell precursor differentiation (Persaud and Bewick, 2014). A large proportion of the early PYY-positive cells in the islets of Langerhans also contain glucagon (α-cells) and insulin (β-cells) and, later in development, PYY is also found in cells that express somatostatin (δ-cells) and PP (F cells) (Persaud and Bewick, 2014). Although this co-expression pattern is altered in adulthood, about 40% of the pancreatic glucagon cells (α-cells) are descendants of PYY-positive cells, with PYY being in addition expressed by subpopulations of PP cells and the other islet cell types (Boey *et al.*, 2007; Persaud and Bewick, 2014). As is true for the intestinal L-cells, the pancreatic α-cells containing glucagon and PYY also co-express GLP-1 and GLP-2. These observations are consistent with the view that PYY plays a role in the differentiation, growth, development and regulation of islet endocrine cells (Boey *et al.*, 2007; Persaud and Bewick, 2014). The expression of PYY in cells of the exocrine pancreas has not yet been well characterized.

Although PYY is primarily an endocrine peptide, it is also expressed by neurons of the central nervous system (CNS), apart from enteric neurons in the stomach of some mammalian species. In contrast, the expression of PYY mRNA in sympathetic neurons has not been confirmed in a study using in situ hybridization (Pieribone *et al.*, 1992). In the CNS, PYY has been localized to neurons of the spinal cord, brainstem, pons and hypothalamus (Boey *et al.*, 2007; Shi *et al.*, 2015). Specifically, PYY is found in neurons of the gigantocellular reticular nucleus of the rostral medulla wherefrom they project to the lateral parabrachial nucleus, the nucleus of the solitary tract, the dorsal vagal complex and the hypoglossal nucleus (Glavas *et al.*, 2008; Gelegen *et al.*, 2012; Alhadeff *et al.* 2015). Unlike in the circulation, the predominant form of PYY found in the brain is full-length PYY(1–36) (Gelegen *et al.*, 2012).

Circulating PYY and PYY(3–36)

PYY released from endocrine cells in the GIT and pancreas can, on the one hand, have a local paracrine effect on neighboring cells and, on the other hand, exert endocrine effects on remote cells which it reaches via the blood stream. The role of intestinal PYY in the temporal and spatial coordination of postprandial digestion and in the regulation of food intake, energy homeostasis and behavior requires the peptide to be released into, and distributed by, the circulation. Fasting plasma levels of PYY are under the influence of several factors including exercise, body weight status, adiposity level and ethnicity, whereas sex and age have little effect (Cooper, 2014).

The plasma levels of PYY are lowest in the absence of food intake and start to rise within 15 min of a meal through release from the intestinal L cells. PYY entering the circulation is relatively rapidly attacked by DPP-4 and in part hydrolysed to PYY(3–36), the predominant postprandial form of PYY in plasma, which potently stimulates Y2 receptors and, to some extent, Y5 receptors in the periphery and brain (Cox, 2007; Alexander *et al.*, 2017). The initial increase in circulating PYY concentration occurs long before food has reached the L cells in the lower GIT, which indicates that a neuronal or endocrine mechanism operating during the cephalic phase of digestion stimulates the L cells (Cox, 2007; Cooper, 2014). Maximal plasma concentrations of PYY in humans are observed 1–2 h postprandially when the nutrients have arrived at the L cells, and elevated levels are maintained for up to 6 h (Cooper, 2014; Persaud and Bewick, 2014).

The postprandial release of PYY is proportional to energy intake but also modified by the macronutrient composition of the diet, as intraluminal lipid hydrolysis as well as a high-protein diet enhance the effect of food intake on PYY release (Cox, 2007; Field *et al.*, 2010; Cooper, 2014). In addition, the composition of fatty acids from dietary fat has an impact, given that both the size ($\geq$C12) and nature of fatty acids are of relevance: polyunsaturated and saturated fatty acids evoke a greater PYY response than monounsaturated fatty acids (Cox, 2007; Cooper, 2014). PYY-releasing enteroendocrine cells sense the presence of digested nutrients in the lumen of the GIT by a variety of nutrient-selective receptors. Particular GPRs expressed by L cells are involved in the effect of free fatty acids and certain bacterial fermentation products to release PYY as well as GLP-1 and GLP-2 (Cox *et al.*, 2010; Spreckley and Murphy, 2015). Short chain fatty acids (SCFAs) generated from indigestible carbohydrate fibers by the intestinal microbiota, such as butyric and propionic acid, bind to free fatty acid receptor 1 (FFA1, previously known as GPR40), FFA2 (previously known as GPR43), FFA3 (previously known as GPR41), FFA4 (previously known as GPR120) and hydroxycarboxylic acid receptor 2 (previously known as GPR109A) and in this way stimulate enteroendocrine L cells in the lower GIT (Samuel *et al.*, 2008; Bindels *et al.*, 2013; Tan *et al.*, 2014; Psichas *et al.*, 2015; Spreckley and Murphy, 2015; Brooks *et al.*, 2016; Moodaley *et al.*, 2017).

While the majority of circulating PYY is derived from the intestinal L cells and pancreatic endocrine cells, there may also be some contribution from leukocytes. Thus, PYY can be expressed by human peripheral blood mononuclear cells as shown by PYY mRNA and peptide expression (Holler *et al.*, 2014). Once these cells have differentiated into macrophages in vitro, treatment with lipopolysaccharide causes down-regulation of peptide YY mRNA levels (Holler *et al.*, 2014). Any functional implication of this finding awaits to be explored.

Effects of PYY on Digestive Activity

PYY subserves several roles in the regulation of digestion, which it exerts both via a paracrine and endocrine route, depending on the expression of different Y receptor subtypes by the gastrointestinal effector systems. The effects of both PYY and PYY(3–36) on

gastrointestinal motility are of an inhibitory nature, these actions being mediated by 3 major Y receptor subtypes: Y1 receptors on enterocytes, myenteric and submucosal neurons and endothelial cells, Y2 receptors on myenteric and submucosal neurons, extrinsic primary afferent nerve fibers, and Y4 receptors on enterocytes (Cox, 2007; Wang *et al.*, 2010; Holzer *et al.*, 2012). Plasma concentrations approximately equivalent to postprandial levels inhibit gastric acid secretion, delay gastric emptying, inhibit the cephalic phase of gallbladder contraction as well as pancreatic exocrine secretion, promote intestinal fluid and electrolyte secretion by inhibition of their secretion, and prolong the mouth-to-cecum transit time (Field *et al.*, 2010). The inhibition of gastric acid secretion involves Y1 and Y2 receptors and is mediated both by an action in the brainstem and stomach, while the effect of PYY (3–36) to increase gastric pressure via stimulation of Y2 receptors does not involve the vagus nerve (Holzer *et al.*, 2012). PYY released by SCFAs (administered exogenously or produced by the intestinal microbiota) inhibits gastrointestinal motility and electrolyte and water secretion by neural and non-neural mechanisms (Cox, 2007; Holzer *et al.*, 2012).

In physiological terms, PYY is thought to be a major mediator of ileal and colonic brakes which are set into operation when macronutrients able to release PYY from L cells reach the lower gut: the brakes slow gastric emptying and intestinal transit, which in conjunction with the antisecretory action of PYY facilitates nutrient absorption (Cox, 2007; Holzer *et al.*, 2012). The inhibitory effect of PYY and PYY(3–36) on colonic transit in the mouse is brought about by Y2 receptors on the enteric nervous system (Wang *et al.*, 2010; Tough *et al.*, 2011), and there is evidence that PYY and related peptides exert a tonic influence on gastrointestinal motor and secretory activity (Tough *et al.*, 2011; Holzer *et al.*, 2012). Colonic transit is tonically accelerated by Y1 receptor stimulation and tonically inhibited by Y2 receptor stimulation, while secretory activity in the human and mouse colonic mucosa is blunted by epithelial Y1 and neuronal Y2 receptors (Tough *et al.*, 2011; Holzer *et al.*, 2012).

Effects of PYY on Pancreatic Function

PYY shares some of the incretin-like effects of GLP-1, a gut hormone frequently co-expressed by enteroendocrine L cells (Cox *et al.*, 2010). These cells sense the presence of luminal nutrients by the use of various nutrient-selective GPRs, which in turn leads to the release of PYY and GLP-1. Activation of one of these nutrient-selective GPRs, the acylethanolamine receptor GPR119, inhibits epithelial electrolyte secretion in the human and mouse colon in a glucose-sensitive fashion, these effects being mediated by PYY and Y1 receptor stimulation. At the same time, GPR119 agonism improves glucose tolerance, an effect that is absent in PYY knockout mice (Cox *et al.*, 2010).

These findings of an incretin-like effect of enteroendocrine PYY are in keeping with ample evidence for a role of pancreatic PYY in insulin regulation and glucose homeostasis. Such an antidiabetic function of endogenous PYY has been deduced from the glucose intolerance and hyperinsulinemia observed in PYY knockout mice. This observation is consistent with an inhibitory effect of PYY on insulin secretion both in vitro and in vivo (Bertrand *et al.*, 1992; Boey *et al.*, 2007; Loh *et al.*, 2017). The ability of intravenously administered PYY to attenuate glucose-stimulated insulin secretion in rodents is primarily mediated by Y1 receptors on β-cells and δ-cells in the islets of Langerhans but may also involve parasympathetic vagal output from the brainstem (Boey *et al.*, 2007; Loh *et al.*, 2017). A crucial role of the Y1 receptor in β-cell regulation has been confirmed by the finding that inhibition of Y1 receptor signaling improves islet function and delays the onset of chemically induced diabetes in mice (Loh *et al.*, 2017). In this context it is important to consider, however, that Y receptor signaling mediates not only the effect of PYY, but also that of PP, on pancreatic cell function.

In contrast, PYY(3–36) is little active in inhibiting insulin secretion, which is attributed to the absence of Y2 receptors in the pancreas (Boey *et al.*, 2007; Persaud and Bewick, 2014). Inhibition of Y1 receptor function in pancreatic islets, both genetic and pharmacological, accelerates the normalization of hyperglycemia in mice with chemically induced diabetes (Loh *et al.*, 2017). Manipulation of Y1 receptor function in pancreatic islets thus emerges as a potential therapeutic target in treating metabolic diseases. While, on the one hand, impaired Y1 receptor signaling may play a role in the development of metabolic diseases such as obesity and hyperinsulinemia, inhibition of Y1 receptor signaling may prove to be a useful approach to boost β-cell function under conditions where insulin secretion is limited (Loh *et al.*, 2017).

There is some evidence for additional effects of PYY in regulating insulin secretion and activity. Peripheral administration of PYY(3–36) or a Y2 receptor-selective agonist to mice improves glucose tolerance by increasing plasma insulin levels, an effect that is associated with increased GLP-1 secretion from enteroendocrine L cells (Chandarana *et al.*, 2013). PYY(3–36) may in addition regulate glucose homeostasis by improving insulin sensitivity (Persaud and Bewick, 2014). Taken all data together, PYY(1–36) produced locally in the pancreas appears to provide a paracrine brake to the various stimulant inputs that β-cells receive, thus ensuring sensitive regulation of insulin release. In contrast, circulating PYY(3–36) improves glucose tolerance through an incretin-like effect mediated by GLP-1 release from enteroendocrine L cells (Persaud and Bewick, 2014).

Apart from regulating insulin secretion and sensitivity, PYY emerges to have a beneficial impact on pancreatic endocrine function by enhancing β-cell mass in the islets of Langerhans (Persaud and Bewick, 2014; Shi *et al.*, 2015). Transgenic mice overexpressing PYY in islet β-cells exhibit enhanced insulin levels and improved glucose tolerance, which are due to increased β-cell mass and function (Shi *et al.*, 2015). This effect is unlikely to involve Y1 receptors because prolonged treatment of mice with a Y1 receptor antagonist likewise increases islet size and β-cell proliferation (Loh *et al.*, 2017). In addition, PYY is able to protect islet β-cells from apoptosis. Thus, ablation of PYY-expressing cells in adult mice disrupts islet architecture and causes β-cell destruction, followed by the development of insulin-dependent diabetes (Sam *et al.*, 2012). A role of PYY in providing trophic support to β-cells is corroborated by the observation that β-cell loss following PYY cell ablation or chemically induced diabetes is prevented

by stimulation of Y1, but not Y2, receptors (Sam *et al.*, 2012). The protective influence of PYY on islet β-cells may be of clinical potential, given that replenishment of β-cell mass is a key aim of novel therapeutic interventions in diabetes (Persaud and Bewick, 2014).

Inhibitory Effect of PYY(3–36) on Food Intake

The postprandial release of PYY from enteroendocrine L cells together with its inhibitory effects on gastrointestinal transit and food intake has attracted considerable interest because of the potential of this peptide to arrest weight gain and attenuate obesity. The pertinent action is thought to take place preferentially in the CNS, which attributes the major postprandial form of PYY in the circulation, PYY(3–36), an important messenger role between the gut and brain. As a result, many studies have addressed the role of PYY(3–36) and the Y2 receptor, which PYY(3–36) prefers, in modulating feeding behavior and initiating satiety. The initial observation that systemic administration of PYY(3–36) diminishes food intake and weight gain in rodents (Batterham *et al.*, 2002) was contested by other investigators (Tschöp *et al.*, 2004) who were unable to replicate this finding. The discrepancy was in part attributed to different experimental stress levels. Although human obesity is not associated with abnormal plasma levels of PYY and PYY(3–36) (Pfluger *et al.*, 2007), later studies have affirmed that PYY(3–36) diminishes food intake in both rodents and humans (Koda *et al.*, 2005; Field *et al.*, 2010; Steinert *et al.*, 2010; Stadlbauer *et al.*, 2013a; Shi *et al.*, 2017). The anorectic effect of PYY(3–36) is seen in both lean and obese subjects and in higher doses is associated with nausea and vomiting (Field *et al.*, 2010). This aversive reaction to systemic PYY(3–36), which appears to be brought about by stimulation of the chemotrigger zone in the area postrema, can be avoided by local administration of PYY(3–36) into the oral cavity, which in mice activates only brain areas known to regulate food intake (Hurtado *et al.*, 2013).

Food intake is inhibited by PYY(3–36) both via a stimulant effect on Y2 receptors directly on vagal afferent neurons (Koda *et al.*, 2005; Iwasaki *et al.*, 2013) and an interaction with Y2 receptors in the hypothalamus (Holzer *et al.*, 2012). This is consistent with the ability of PYY(3–36) to gain access to the brain via circumventricular organs such as the area postrema and subfornical organ (Dumont *et al.*, 2007) but also to permeate the blood-brain barrier to a certain extent (Nonaka *et al.*, 2003). In addition, PYY (3–36) can activate Y2 receptors in the oral cavity, presumably on afferent cranial nerve fibers, which signal via the brainstem to hypothalamic satiety centers where they inhibit food intake without causing taste aversion, an adverse reaction seen following systemic administration of PYY(3–36) (Hurtado *et al.*, 2013).

With the emergence of the gut microbiota as a relevant factor in gut-brain communication, PYY and other hormones of the enteroendocrine cells have also been recognized as messengers of gut microbiota-brain interaction. Microbial metabolites and fermentation products such as SCFAs have a direct impact on enteroendocrine cells that express various fatty acid-sensitive GPRs (Holzer *et al.*, 2012; Clarke *et al.*, 2014). SCFAs are known to promote satiety and to lower hunger and energy intake, an effect that is associated with enhanced release of GLP-1 and PYY from the gut. Through their biological activities, PYY and GLP-1 transform microbial signals into satietogenic and metabolic effects (Cani *et al.*, 2009; Delzenne *et al.*, 2011; Brooks *et al.*, 2016). In addition to SCFAs, bacterial proteins such *E. coli* stationary phase proteins are able to increase plasma PYY levels and to suppress food intake when injected systemically (Breton *et al.* 2016). The implication of microbial factors in gut hormone regulation of food intake and satiety is further corroborated by the finding that the expression of FFA2 (GPR43), FFA3 (GPR41), PYY, GLP-1 and cholecystokinin, another intestinal satiety-inducing peptide, is decreased in germ-free mice (Duca *et al.*, 2012). In the hypothalamus of germ-free mice, the expression of orexigenic factors such as NPY is increased, while anorexigenic neuropeptides are down-regulated (Schéle *et al.*, 2013).

Within the brain, PYY(3–36) reduces food intake primarily via activation of Y2 receptors in the arcuate nucleus of the hypothalamus, which is an important center for integrating peripheral and central signals in the control of appetite and energy homeostasis (Chee and Colmers, 2008). The arcuate nucleus contains at least two populations of neurons that are relevant in this respect: orexigenic neurons expressing NPY and agouti-related protein (AgRP) and anorexigenic neurons expressing pro-opiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART) (Chee and Colmers, 2008; Holzer *et al.*, 2012; Lau and Herzog, 2014). These neurons issue projections to various areas of the hypothalamus (including the paraventricular nucleus) and reciprocally inhibit the orexigenic/anorexigenic tone exerted by NPY/AgRP neurons and POMC/CART neurons, respectively (Chee and Colmers, 2008). The anorectic effect of PYY(3–36) was originally thought to be mediated by presynaptic Y2 receptors on NPY/AgRP neurons in the arcuate nucleus, inhibiting their orexigenic action, and by stimulating/disinhibiting POMC/CART neurons (Batterham *et al.*, 2002). Later investigations showed, however, that PYY(3–36) inhibits POMC/CART neurons through activation of postsynaptic Y2 receptors and that POMC/CART neurons are not essential for transducing the anorectic effect of PYY(3–36) (Ghamari-Langroudi *et al.*, 2005).

Further analysis has identified additional neuronal pathways in the brain that may be relevant to the satiation caused by PYY (3–36). Infusion of PYY(3–36) into the hepatic portal vein of rats has been found to activate neurons not only in the hypothalamic arcuate and paraventricular nuclei but also in the nucleus tractus solitarii, the central area of the amygdala and the nucleus accumbens but not in the area postrema and parabrachial nucleus (Stadlbauer *et al.*, 2013a). Functional magnetic resonance imaging shows that infusion of PYY(3–36) to human subjects has a differential effect on neuronal activity within hypothalamic, corticolimbic and higher cortical brain regions, depending on the plasma concentrations of the peptide (Batterham *et al.*, 2007). In particular, the study results show that PYY(3–36) switches food intake regulation from a homeostatic (hypothalamic) to a hedonic reward-related state reflected by activity in corticolimbic brain areas (Batterham *et al.*, 2007).

Emerging evidence indicates that not only exogenous PYY(3–36) but also endogenous PYY subserves a role in the regulation of food intake, appetite and satiety. Co-administration of PYY(3–36) and GLP-1(17–36) amide to fasted human subjects has an anorectic effect similar to that observed following a meal (De Silva *et al.*, 2011). This modification of energy intake is associated with activation of brain regions implicated in appetite control (e.g., nucleus accumbens, orbitofrontal cortex and insula) as visualized by functional magnetic resonance imaging (De Silva *et al.*, 2011). It follows that postprandial satiety is brought about by a combined action of the two anorectic gut hormones PYY and GLP-1 (De Silva *et al.*, 2011), a finding that also implies that combined activation of PYY and GLP-1 signaling may be a more efficacious anti-obesity treatment regimen than either hormone alone. This inference is supported by another study in which co-infusion of GLP-1 and PYY(3–36) was found to synergize in reducing energy intake by healthy male subjects (Schmidt *et al.*, 2014). Co-infusion was accompanied by slightly increased nausea and a decrease in plasma ghrelin, but neither of these factors could explain the reduction in energy intake (Schmidt *et al.*, 2014).

It is relevant to note in this context that attenuation of food intake is not the only effect which PYY(3–36) can induce in the brain because, owing to its limited selectivity for Y2 receptors, it can also stimulate other Y receptor subtypes. This is true for the action of PYY in the lateral parabrachial nucleus of the brainstem in which PYY-expressing neurons originating from the gigantocellular reticular nucleus play a role in the regulation of energy homeostasis (Alhadeff *et al.* 2015). Microinjection of PYY(1–36) or PYY(3–36) into this nucleus increases food intake, an effect that is primarily mediated by Y1 receptors, although Y2 and Y5 receptors are also present in this region (Alhadeff *et al.* 2015). Y5 receptor signaling has in fact been shown to counteract the anorectic effect of PYY(3–36) (Shi *et al.*, 2017).

The effect of PYY(3–36) to reduce appetite and food intake in rodents and humans and to attenuate weight gain in rodents attributes this peptide a potential role in treating obesity. Its presumed benefit as an anti-obesity drug, however, is challenged by the narrow therapeutic index, given that nausea and vomiting may occur when administered at higher doses. The ability of PYY (3–36) to activate Y receptors other than Y2 receptors is also a drawback, given that stimulation of Y1 receptors in the lateral parabrachial nucleus stimulates food intake (Alhadeff *et al.* 2015). Although systemic administration of PYY(3–36) to obese human subjects causes an acute reduction of food intake, no significant body weight loss was achieved following a 12-week treatment with the peptide administered intranasally (Gantz *et al.*, 2007). Chronic subcutaneous infusion of PYY(3–36) to mice leads in fact to a Y5 receptor-dependent increase in food intake and body weight (Shi *et al.*, 2017). In humans there is limited information on the long-term efficacy and safety of PYY(3–36) administration. Several options have been considered to overcome the limitations in pharmacokinetic properties, receptor selectivity, efficacy and adverse effect profile of PYY(3–36). Nausea and vomiting seem to be related to rapid absorption and access of the peptide to its effector sites following systemic (subcutaneous, intravenous) or intranasal administration, while oral formulations enabling the peptide to survive the gastric passage seem to be less prone to cause sickness (Steinert *et al.*, 2010; De Silva and Bloom, 2012). The design of highly Y2 receptor-selective and long-acting derivatives of PYY, the refinement of the administration routes, and the combination of PYY preparations with GLP-1 analogues (Steinert *et al.*, 2010) may be further approaches to novel anti-obesity therapies.

PYY as a Mediator of Weight Loss Caused by Bariatric Surgery

Alterations in the secretion of PYY along with other gut hormones are associated with the weight loss caused by bariatric surgery, which provides further evidence for a physiological role of this gut hormone in the regulation of food intake and energy homeostasis. Bariatric surgery is able to achieve substantial and permanent weight loss, especially if it includes an element of gastrointestinal bypass, such as Roux-en-Y gastric bypass (Field *et al.*, 2010). Observations that postprandial PYY(3–36) levels appear to be reduced in obese patients compared to healthy volunteers suggest that obesity is a state of PYY(3–36) deficiency (Meek *et al.*, 2016). Following bariatric surgery, both fasting and postprandial levels of PYY increase, an effect that may persist for a long period (Meek *et al.*, 2016). Weight loss after Roux-en-Y gastric bypass is most prominent in patients who exhibit the greatest postprandial rise of PYY and other L cell-derived hormones (Field *et al.*, 2010). These observations have been confirmed and extended in mice suffering from diet-induced obesity and subjected to bariatric surgery. After surgical intervention, the obese mice lost weight and exhibited enhanced expression of PYY in the colon (Chandarana *et al.*, 2011). In addition, both fasting PYY and postprandial PYY and GLP-1 levels in the circulation increased after bariatric surgery. Since the effect of bariatric surgery to cause body weight loss was absent in PYY knockout mice, it appears as if PYY is an important contributor to the weight loss following surgical intervention (Chandarana *et al.*, 2011).

Implications of PYY in Mental Processes and Pain

Apart from regulating ingestion and energy homeostasis, gut hormones are increasingly emerging to have an impact on emotional-affective behavior and mental homeostasis (Holzer *et al.*, 2012). Seen from an evolutionary point of view, co-regulation of appetite and emotional state is an important strategy for survival, given that anxiety and/or depression would be an adverse condition when there is a need to seek food (Holzer *et al.*, 2012). This argument is supported by the activity profile of ghrelin which is released from the upper GIT under conditions of hunger and reduces both anxiety-like and depression-related behavior (Lutter *et al.*, 2008). The activity profile of PYY, which is released under fed conditions, is different, given that the mental status of human subjects treated with PYY(3–36) after a meal is changed to a hedonic state (Batterham *et al.*, 2007). This ability of PYY to promote

hedonic behavior is in keeping with the observation that knockout of PYY increases depression-like behavior but does not alter anxiety (Painsipp *et al.*, 2011). The site where the antidepressant effect of PYY takes place and the Y receptor subtypes that mediate this effect await to be elucidated.

Experimental and clinical studies have shown that peripheral administration of PYY(3–36) alters not only the activity of hypothalamic centers involved in feeding control but has also an impact on neuronal activity in the brainstem, in corticolimbic and higher cortical brain regions (Batterham *et al.*, 2007; De Silva *et al.*, 2011; Stadlbauer *et al.*, 2013a). In line with these findings, PYY(3–36) influences a wide spectrum of behavioral and cognitive functions that are pivotal for basic processes of perception and judgment, including central information processing, working memory, and behavioral responding to novelty (Stadlbauer *et al.*, 2015). Specifically, systemic administration of PYY(3–36) inhibits social interaction without affecting innate anxiety, impairs performance in particular learning and memory tasks and, at a high dose, disrupts sensorimotor gating in the form of a prepulse inhibition deficit (Stadlbauer *et al.*, 2013b). Some of these behavioral disturbances are prevented by dopamine D2 receptor antagonism (Stadlbauer *et al.*, 2013b). In addition, intraperitoneally injected PYY(3–36) increases novel object exploration and enhances the motor responses to indirect and direct dopamine receptor agonists (Stadlbauer *et al.*, 2014). These behavioral alterations are associated with activation of neurons producing γ-aminobutyric acid in the dorsal and ventral striatum (nucleus accumbens and caudate putamen) (Stadlbauer *et al.*, 2014). Taken all findings together, PYY-mediated signaling from the gut to the brain may affect a variety of mental processes, but the physiological and pathophysiological relevance remains yet to be delineated.

While NPY has been implicated in nociception, a potential role of PYY in pain sensitivity has remained largely unexplored, although the expression of this gut hormone is altered in functional and inflammatory bowel disorders. It is hence worth noting that visceral pain-related behaviors in response to chemical irritation of the colon are significantly exaggerated in PYY knockout mice (Hassan *et al.*, 2017). This observation has been confirmed with a peripherally active Y2 receptor antagonist. In addition, PYY knockout mice are more sensitive to somatic thermal pain compared to wild-type animals (Hassan *et al.*, 2017). These results indicate that endogenous PYY has the potential to diminish visceral chemical pain, an effect that seems to be mediated by peripheral Y2 receptors.

Pathophysiological Implications of PYY

While any implication of PYY in neuropsychiatric disorders awaits to be explored, the peripheral PYY system has been found to be disturbed in a number of gastroenterological and metabolic diseases. In most cases, changes in PYY expression and release appear to be secondary disturbances that take place in response to the pathophysiological conditions caused by the disease (El-Salhy *et al.*, 2013). This applies to gastrointestinal diseases/disorders such as irritable bowel syndrome (IBS), inflammatory bowel disease (IBD), celiac disease, systemic sclerosis, and post-intestinal resection state. In contrast, the changes in the PYY system seen in chronic idiopathic slow transit constipation may be one etiological factor of the disease (El-Salhy *et al.*, 2013). In this condition, the number of PYY cells and tissue concentrations of PYY in the colon are increased in some patients in whom the excess of PYY might decrease secretion of water and electrolytes and strengthen the ileal brake (El-Salhy *et al.*, 2013). In general, the pathophysiological aberrations of the PYY system may, on the one hand, contribute to the development of symptoms present in IBS, IBD, gastroenteropathy in long-standing diabetes and slow transit constipation and, on the other hand, reflect attempts to compensate for the primary disturbances associated, e.g., with celiac disease, systemic sclerosis and post-intestinal resection state (El-Salhy *et al.*, 2013).

The density of PYY cells in the colon of both IBS patients with constipation and IBS patients with diarrhea is down-regulated, and this change is proposed to be secondary to alterations in the serotonin and cholecystokinin systems (El-Salhy *et al.*, 2013). In contrast, the number of PYY-positive cells is reported to be increased in the large intestine of post-infectious IBS patients who have a history of gastroenteritis or other infections (El-Salhy *et al.*, 2013). In ulcerative colitis and Crohn's disease, the two major forms of IBD, the expression of PYY in the colon is decreased, a change that extends to the ileum of patients with Crohn's disease (El-Salhy *et al.*, 2013). Down-regulation of colonic PYY is also observed in two rodent models of IBD, that is, in the colitis associated with interleukin-2 knockout and in dextran sulfate sodium-induced colitis (El-Salhy *et al.*, 2013).

In celiac disease, both basal and postprandial plasma levels of PYY are elevated, a perturbation that normalizes within 8 months on a gluten-free diet. The changes in the endocrine cell system in the small intestine of patients with celiac disease are thought to be reactions to the marked decrease in intestinal absorptive area, resulting in diarrhea and steatorrhea (El-Salhy *et al.*, 2013). The elevated levels of circulating PYY may represent an attempt to slow down the intestinal transit and increase intestinal absorption. The finding that patients with diarrhea due to other causes, such as chronic destructive pancreatitis and infectious gastroenteritis, also have high plasma levels of PYY support this assumption (El-Salhy *et al.*, 2013). A similar relationship may explain why the plasma levels of PYY are increased in patients with systemic sclerosis that suffer from fat malabsorption and diarrhea (El-Salhy *et al.*, 2013).

The gastroenteropathy in long-standing diabetes manifests itself in manifold symptoms including nausea, vomiting, diarrhea, constipation and abdominal pain and is thought to result from gastrointestinal dysmotility and a disturbance of secretion/absorption. In patients with long-standing diabetes type 1 the number of rectal PYY cells is significantly higher than in healthy volunteers (El-Salhy *et al.*, 2013). A similar increase in the number of colonic PYY cells and the colonic tissue concentration of PYY has been found in a murine model of diabetes type 2 (db/db mice). However, in a murine model of diabetes type 1 (non-obese

diabetic mice) and another model of diabetes type 2 (ob/ob mice) the number of colonic PYY cells and the tissue level of PYY are diminished (El-Salhy *et al.*, 2013). The discrepancy in these findings is explained by differences in the duration of the diabetic state, given that the alterations in the PYY system may reflect secondary and compensatory reactions to the gastrointestinal disturbances that manifest themselves during the course of disease (El-Salhy *et al.*, 2013).

Surgical resection of the stomach results in elevated levels of circulating PYY, which may reflect an adaptive attempt to slow down gastric transit (El-Salhy *et al.*, 2013). Basal and postprandial levels of PYY are increased after a massive small bowel resection in the dog, an intervention which in piglets results in an increase in colonic PYY cells. A rise of basal and postprandial PYY concentrations has likewise been observed in patients subjected to small bowel resection, mainly due to Crohn's disease, or resection of the colon. Further analysis has shown that, following resection of a considerable part of either the small or large intestine, PYY synthesis and release increase as an adaptive response to slow the rapid gastrointestinal transit and to facilitate nutrient and electrolyte absorption (El-Salhy *et al.*, 2013).

This selection of pathophysiological implications illustrates the potential of the PYY system as a target for therapeutic intervention. Selective agonists or antagonists for the Y receptors operated by PYY would be of therapeutic benefit in those conditions in which changes in PYY activity contribute to the manifestation of disease symptoms. These indications also include attempts to enhance β-cell mass in diabetes and to prevent/reduce obesity. Given the complex endocrine and neuronal regulation of those physiological processes in which PYY plays a role, it will be a challenge to develop Y receptor ligands with sufficient bioavailability, selectivity, efficacy and safety.

Glucagon and Glucagon-Like Peptides☆

Daniel M Kemp and Joel F Habener, Massachusetts General Hospital, Boston, MA, United States and Harvard University, Boston, MA, United States

Glossary

Apoptosis A highly regulated intracellular process resulting in the programmed death, destruction, and clearance of a cell.

Differentiation The process by which cells develop into a particular phenotype or functional end-point by specific alterations in their gene expression profiles.

Hyperglycemia A physiological state of abnormally elevated levels of plasma glucose.

Insulinotropic The ability to potentiate insulin expression and secretion.

Introduction

The biologic activity of the hormone glucagon was first encountered in the 1920s in crude preparations of insulin derived from pancreas extracts and was considered to be a hyperglycemia-producing contaminant in the extract (Lefèbvre, 2011). Glucagon was later isolated from pancreatic extracts, purified, and characterized and its physiological role in glucose regulation was established. Since that time, the development of improved techniques and experimental tools has allowed researchers to further understand the biologic properties of glucagon and of its closely related peptide family members, glucagon-like peptide-1 (GLP-1) and glucagon-like peptide-2 (GLP-2) (Kieffer and Habener, 1999). As is the case in all fields of biological research, the advent of modern molecular and cellular biology has allowed for a precise resolution of the biosynthesis and biological activities of these peptides. This article discusses the biology of glucagon and the glucagon-like peptides.

Genetic Evolution

Glucagon, GLP-1, and GLP-2 are distinct peptide hormones closely related in their amino acid sequences, as shown in **Fig. 1** (Kieffer and Habener, 1999). However, each of these peptide hormones plays diverse roles in the regulation of energy homeostasis. They are encoded by the transcription of a single preproglucagon gene, which in humans consists of six exons and five introns, spans 9.4 kb, and is located on chromosome 2 (Drucker *et al.*, 2017). The preproglucagon mRNA is translated into a proglucagon precursor protein that is then differentially cleaved into functional peptide hormones in a tissue-specific manner. As each hormone is encoded by a separate exon within the gene, it is likely that these three peptides initially evolved from a triplication of one exon that encoded an original glucagon-like peptide. This replicative step within the proglucagon gene occurred prior to the diversification of vertebrates more than 500 million years ago and the amino acid sequences of these peptides appear to have independently evolved in an episodic manner. These events probably reflect an evolutionary change in the functions of the hormones, such that in humans, glucagon, GLP-1, and GLP-2 display distinct tissue-specific expression patterns and biological functions.

Regulation of Expression

Not only are glucagon, GLP-1, and GLP-2 encoded by a single gene, but each peptide is derived from a single mRNA sequence and, furthermore, from a single peptide precursor (proglucagon) (Kieffer and Habener, 1999; Drucker *et al.*, 2017). Consistent with their divergent biological functions, however, the biosynthesis and secretion of these hormones are tissue-specific. To achieve selective expression, a distinct set of prohormone convertase enzymes directs the posttranslational modification of proglucagon to generate glucagon, GLP-1, or GLP-2 in a cell-type-dependent manner. Whereas the main product of posttranslational processing in alpha cells of the endocrine pancreas is glucagon, in enteroendocrine L cells of the gut GLP-1 and GLP-2 are the main gene

☆*Change History*: April 2018. Daniel M Kemp and Joel F Habener added abstract. Edited section "Glucagon", added text to sections "GLP-1", "GLP-2", and "Inactivation of GLPs" and updated "References".

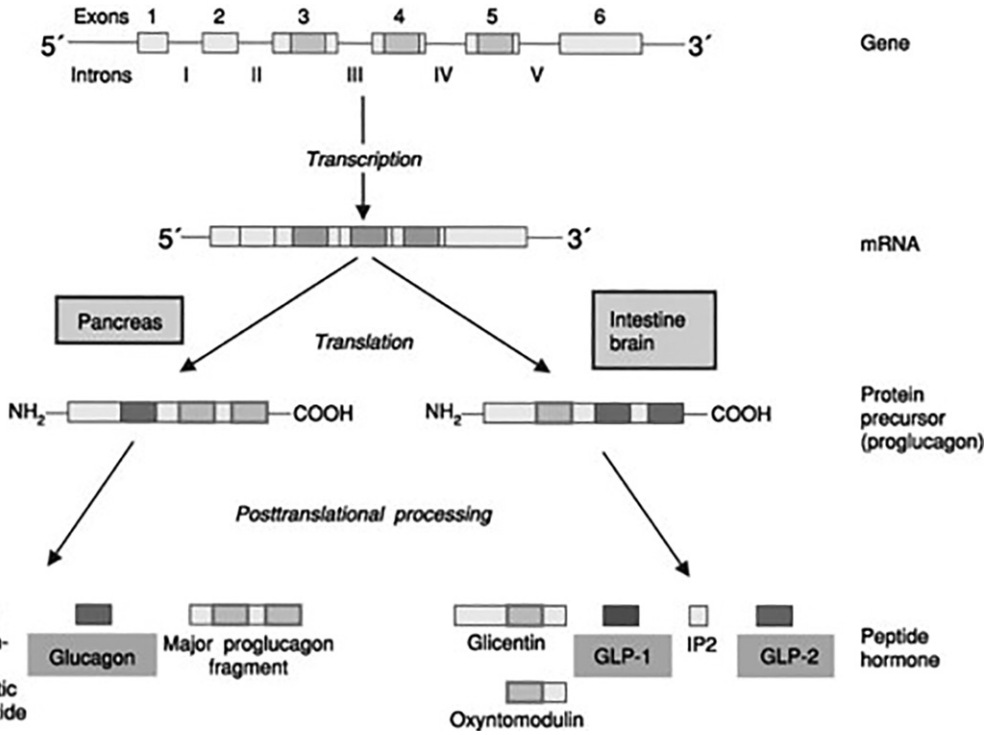

Fig. 2 Tissue-specific processing of the preproglucagon gene.

products. The steps in the expression of the preproglucagon gene are outlined in Fig. 2. Several other potentially bioactive peptides are generated from proglucagon such as oxyntomodulin and IP2 (intervening peptide 2) (as shown in Fig. 2). In addition, two small peptides (five and nine amino acids) with potential anti-oxidant activities and that increase insulin sensitivity, are derived from the C-terminus of GLP-1 (Tomas and Habener, 2010).

Intra-islet Paracrine Cross-talk Signaling Between Alpha and Beta Cells

The close anatomical physical proximity of alpha and beta cells in the islets bespeak local intra-islet paracrine interactions between these two cell types (Bosco *et al.*, 2010). Indeed, recent studies have clearly shown that chemical injury to insulin-producing beta cells sends signals to glucagon-producing alpha cells resulting in the cleavage of proglucagon into GLP-1. The GLP-1 so produced acts locally on beta cells to promote their regeneration and to inhibit apoptosis (Stanojevic and Habener, 2015; Habener and Stanojevic, 2013). Impaired glucagon receptor signaling in beta cells results in a marked hyperplasia of the alpha cells. Further, complete loss of beta cells induces the trans-differentiation of alpha cells into beta cells (Collombat *et al.*, 2010; Stanojevic and Habener, 2015; Habener and Stanojevic, 2013).

Hormone Receptors and Cell Signaling

The functional effects of glucagon and the GLPs are mediated by specific receptors located within the plasma membrane of target cells (Campbell and Drucker, 2013; Gromada *et al.*, 2007; Kieffer and Habener, 1999). Like the peptide hormones, the hormone-specific receptors share extensive amino acid sequence homology and form part of a closely related subfamily of receptors as part of the larger superfamily of G protein-coupled receptors. This superfamily is distinguished by the tertiary structure of its members, comprising seven transmembrane domains, and the coupling to trimeric G proteins. The coupling to the stimulatory G protein G_s, the activation of adenylyl cyclase, and the subsequent increase in the intracellular production of cyclic AMP (cAMP) constitute the most established functional responses elicited by all the members of the glucagon receptor subfamily. This uniform response in

intracellular function suggests that the divergent physiological effects of glucagon, GLP-1, and GLP-2 are due primarily to tissue-specific expression of the receptors, whereby cAMP imparts distinct cellular functions due to the equally diverse array of gene expression patterns in different cell types. Furthermore, temporal and tissue-specific patterns of secretion of the hormones themselves play a critical role in initiating the appropriate functional response. Notably, in the pancreatic beta cell, in which GLP-1 and glucagon receptors are expressed, both glucagon and GLP-1 stimulate insulin secretion, mediated at least in part by cAMP. Paradoxically, however, insulin gene expression is inhibited by glucagon and stimulated by GLP-1. This contradiction suggests that more subtle distinctions in receptor signaling exist, leading to differential intracellular responses to the two hormones, glucagon and GLP-1.

Physiology

Glucagon

The glucagon receptor is widely expressed and can be found in the liver, adipose tissue, heart, kidney, pancreatic islets, stomach, small intestine, thyroid, and skeletal muscle (Campbell and Drucker, 2013; Gromada *et al.*, 2007). Although contradictions in the specific expression pattern exist, likely due to the sensitivity of detection techniques between laboratories, the less ambiguous targets with high receptor levels correspond to the most well-established physiological actions of glucagon. The hepatocyte is a primary target cell of glucagon to which it is exposed when the hormone is released into the portal vein following secretion from the pancreatic alpha cells. Glucagon increases glucose output from the liver, an effect that results from inhibition of glycogen synthesis and stimulation of both glycogenolysis and gluconeogenesis (**Table 1**). Evidence suggests that these effects of glucagon are mediated by cAMP, although the glycogenolytic effect of glucagon may occur via a cAMP-independent mechanism. It is not surprising, therefore, that glucagon helps to maintain hepatic glucose output and thereby to sustain blood glucose levels during fasting. There exists a general consensus that the hyperglycemic activity of glucagon represents the first line of defense against hypoglycemia. Accordingly, stimulants of glucagon secretion from alpha cells include the presence and actions of factors at times when the body requires glucose for sustenance (during fasting) or fuel (during exercise).

The interplay between insulin and glucagon provides a tightly controlled equilibrium in blood glucose concentration. Insulin stimulates glucose uptake into fat and muscle cells and also inhibits glucagon expression and secretion from alpha cells. Thus, during periods when plasma insulin levels are low, such as during periods of fasting and exercising, plasma glucagon levels are elevated. The anatomical structure of the pancreatic islets of Langerhans further reflects this mechanistic action of insulin on glucagon secretion. Morphological studies have shown that in a given islet, the microcirculation goes from the core to the mantle. This circumstance suggests that in vivo, peripheral alpha cells are exposed to high concentrations of insulin released from the more centrally located beta cells in the islets. Thus, insulin and glucagon function inversely to regulate blood glucose levels.

Dysregulation of glucagon by a breakdown in the intra-islet insulin–glucagon relationship appears to be a substantial component in the pathogenesis of diabetes. As a result of insufficient insulin secretion, plasma glucagon levels are elevated in type 1 (insulin-dependent) diabetes and also to a lesser extent in type 2 (non-insulin-dependent) diabetes, thereby exacerbating the hyperglycemic state. This effect is further heightened when plasma glucagon levels fail to be suppressed following a meal and postprandial hyperglycemia ensues. Both excessive glucagon production and failure of insulin production and action are believed to contribute to the hyperglycemia of diabetes (Unger and Cherrington, 2012). It is compelling to speculate, therefore, that agents that are able to antagonize glucagon action or secretion may be of value in the treatment of patients with diabetes.

Paradoxically, a major feature of long-term diabetes is the impaired glucagon response to insulin-induced hypoglycemia, a condition of impairment that is almost universally present after 5 years of duration of type 2 diabetes. Studies have shown that hyperinsulinemia, which may be caused by insulin therapy and insulin resistance, can impair glucagon release resulting in a loss of counter-regulation and the induction of hypoglycemia (Mellman *et al.*, 1992). These examples serve to emphasize the finely balanced hormonal balance that characterizes the normal physiological state of glucose homeostasis.

Consistent with the role of glucagon in providing the body with usable energy, additional established targets of glucagon action are the adipocyte and skeletal myocytes (**Table 1**). Although studies of the effects of glucagon on adipose tissue and other tissues are difficult to evaluate owing to the rapid breakdown of the peptide by proteolytic activity associated with these cells, substantial evidence demonstrates that glucagon induces lipolysis, stimulates the release of glycerol and free fatty acids in adipocytes, and

Table 1 Actions of Glucagon

↑ Hyperglycemia
↑ Glycogenolysis

↓ Glucagon secretion

stimulates glycogenolysis in myocytes. Therefore, glucagon could qualify as the "hormone of fuel need" rather than just a "hormone of glucose need."

GLP-1

The major secreted and bioactive form of GLP-1 from entero-endocrine L cells is a truncated isopeptide cleaved from the full 37-amino-acid peptide. Cleavage of the six N-terminal amino acids of GLP-1(1–37) to form GLP-1 (7–37) and removal of the glycine residue at position 37 followed by amidation of the exposed arginine at position 36 generate GLP-1(7–36)amide (Kieffer and Habener, 1999; Campbell and Drucker, 2013). The most significant physiological function of GLP-1 is the stimulation of the synthesis and secretion of insulin from pancreatic islet beta cells (**Table 2**). The mechanism of action of GLP-1 is a potentiation of glucose-induced insulin secretion. In the absence of glucose, GLP-1 fails to stimulate insulin secretion, whereas at elevated glucose concentrations, GLP-1 stimulates secretion at a rate that exceeds that induced by glucose alone and thus potentiates secretion in a glucose-dependent manner. Notably, the secretion of GLP-1 from L cells is stimulated by glucose (and other nutrients) following oral ingestion. Thus, the temporal release of GLP-1, coincident with enhanced blood glucose levels, cooperates synergistically to provide a highly sensitive insulin-releasing mechanism. GLP-1 is thus regarded as a "glucose competence factor." (Holz *et al.*, 1993) As described above, insulin suppresses plasma glucagon levels and activates glucose uptake and metabolism, thus returning blood glucose levels to normal following a meal and maintaining glucose homeostasis in general. In this regard, insulin and GLP-1 play an important role in preventing hyperglycemia.

Evidence for additional mechanisms of action of GLP-1 in lowering blood glucose levels have emerged; GLP-1 has been shown to augment insulin-mediated glucose uptake in patients with diabetes. Extra-pancreatic targets of GLP-1 actions, particularly those of adipose and skeletal muscle tissues, are under investigation. It seems possible that a novel GLP-1 receptor mediates these effects of GLP-1 on adipose tissue and skeletal muscle, as well as liver. There is also evidence that small peptides of 5 and 9 amino acids, cleaved from the C-terminal end of GLP-1, exert anti-oxidant actions on peripheral tissues and thereby increase their insulin sensitivity (Tomas and Habener, 2010).

Additional functions of GLP-1 include the suppression of glucagon secretion and the inhibition of gastric emptying (by inhibiting intestinal motor activity in response to nutrients in the distal gut) and of meal-stimulated gastric acid secretion. A role for GLP-1 in feeding behavior has also been identified. Centrally administered GLP-1 inhibited both feeding and drinking activity in rats, suggesting that GLP-1 may be a central neurotransmitter that modulates visceral functions. Finally, in addition to the detection of pluripotent stem cells within the pancreas, some evidence suggests that GLP-1 stimulates the proliferation and differentiation of these stem/progenitor cells into beta cells (Habener, 2001; Cho *et al.*, 2014). Accordingly, GLP-1 may have a role in the embryonic development of the endocrine pancreas.

Because of its multifunctional profile GLP-1 is in use as for the treatment of diabetes mellitus (Ahrén, 2013; Sandoval and D'Alessio, 2015). By enhancing both the means to secrete insulin (by incretin action and differentiation of new beta cells), the functional ability of insulin to induce glucose disposal, and to reduce appetite, GLP-1 receptor agonists have proven to be effective in controlling blood sugar levels in diabetic patients (Drucker *et al.*, 2017; Sandoval and D'Alessio, 2015).

GLP-2

GLP-2 is synthesized in the enteroendocrine L cells (along with GLP-1) and in the brainstem and hypothalamus of the central nervous system (Drucker and Yusta, 2014). GLP-2 may act on the hypothalamus to curtail appetite and food intake. However, the regulation and function of GLP-2 in the intestinal system are better understood than those of GLP-2 in the central nervous system.

Initially, several lines of evidence suggested the importance of GLP-2 in maintaining the functional integrity of the gastrointestinal epithelium (Drucker and Yusta, 2014). Examples included the coincidence of intestinal injury and inflammatory bowel disease with elevated levels of circulating GLP-2 and patients with glucagon-secreting tumors who presented with small bowel villus hyperplasia (**Table 3**). It was subsequently shown that administration of GLP-2 to mice leads to induction of intestinal epithelial proliferation. Furthermore, following treatment of mice and rats with exogenous GLP-2 for 7–10 days, a marked increase in villus height and small bowel mass and a smaller increment in small bowel length are observed. GLP-2 also appears to slow the

Table 3 Actions of GLP-2

↓ Food intake (appetite)
↓ Gastric motility
↓ Enterocyte and crypt apoptosis

ingestion and transit of food through the gastrointestinal tract, while increasing the absorption of nutrients from the small intestine.

As with glucagon and GLP-1, the tissue-specific effects of GLP-2 action are closely reflected by the expression profile of the GLP-2 receptor, which is predominantly found in the stomach, jejunum, ileum, and colon (Drucker and Yusta, 2014). Although GLP-2 presumably exerts direct effects on cells expressing its putative receptor, some physiological effects of GLP-2 in the intestine are believed to be exerted indirectly in an autocrine, paracrine, or endocrine manner by stimulating the release of as yet unknown factors from GLP-2 receptor-positive cells. This hypothesis arose due to conflicting data regarding the exact tissue distribution of the GLP-2 receptor. Whereas one group observed that binding of labeled GLP-2 localized diffusely along the villous epithelium, others have reported the absence of the receptor among several intestinal epithelial cell lines. Thus, because the localization profile of the GLP-2 receptor is not known with certainty, the mechanism of the pleiotropic biological actions of GLP-2 in the gut, such as modulation of gastric motility, small bowel permeability, and both crypt cell proliferation and apoptosis, is speculative. However, GLP-2 has proven to be effective in the clinical treatment of short bowel syndrome by allowing for a reduction in the frequency of parental nutrition (Jeppesen, 2012).

Apart from its intestinal functions, GLP-2 is also expressed and received in the brain. Receptors were located in the hypothalamus and in certain cell groups in the cerebellum, medulla, amygdala, and hippocampus. Although studies of GLP-2 action in the brain are just beginning, a functional role of GLP-2 appears to be in the regulation of food intake. Pharmacological and behavioral studies indicate that GLP-2 acts as a specific transmitter that may inhibit feeding behavior and has potential long-term effects on body weight homeostasis.

Inactivation of GLPs

The active half-life of both GLP-1 and GLP-2 is regulated by dipeptidyl peptidase IV (DPP IV/CD26), an extracellular soluble or membrane-anchored protease, which cleaves the two N-terminal amino acids and subsequently inactivates the hormones, with respect to their known functions (Mentlein, 1999). This potent inactivation restricts the circulating bioactive half-lives to 2–3 min in vivo. Particularly high levels of expression of DPP IV are found in the kidney, lung, liver, and jejunum. The expression of DPP IV in endothelial cells of the blood vessels, and the presence of small amounts of DPP IV as a soluble enzyme in the blood, results in close contact with circulating substrate and added rapidity of peptide inactivation. Consequently, specific DPP IV inhibitors are of special interest for physiological investigations and are in use as a treatment of type 2 diabetes and improvement of mucosal regeneration. Studies have shown that prolonged activation of GLP-1 by DPP IV inhibitors results in a potentiation of the insulinotropic effect of GLP-1 in vivo and administration of GLP-2 to DPP IV-deficient rats markedly increased the bioactivity of GLP-2, resulting in a significant increase in small bowel weight. A second approach to enhance the bioactive half-life of the GLPs is the synthesis of DPP IV-resistant analogues of the GLPs for pharmacological administration. Several of these analogues are currently in clinical use and others are late stage development for use in the treatment of type 2 diabetes.

Glucagon Like Peptide 2 (GLP-2)☆

Georgios K Dimitriadis, University of Warwick Medical School, Coventry, United Kingdom and Imperial College London, London, United Kingdom
Alexander D Miras, Imperial College London, London, United Kingdom

Introduction

Glucagon-like peptide 2 (GLP-2) is a 33-amino acid peptide created by specific posttranslational proteolytic cleavage of proglucagon in a process that also liberates the related Glucagon-like peptide 1 (GLP-1). GLP-2 is produced by the intestinal endocrine L cell and by various neurones in the central nervous system. Intestinal GLP-2 is cosecreted along with GLP-1 upon nutrient ingestion. GLP-2 appears to have a role in stimulating gut hypertrophy by ileal cell hyperplasia and reducing apoptosis and has been used therapeutically in patients with short bowel syndrome (Estall and Drucker, 2003; Martin *et al.*, 2005). The actions of GLP-2 are transduced by the GLP-2 receptor (GLP2R), which is localized within the gastrointestinal GI) tract to enteroendocrine cells, sub-epithelial myofibroblast cells, and in the neurons of the enteric nervous system. The main site of action for the hormone peptide is the GI tract (where the peptide exerts trophic properties). In addition to promoting expansion of the GI mucosal surface area, GLP-2 has been shown to affect gastrointestinal motility in humans and rodents. In fact, it inhibits gastric emptying (Nagell *et al.*, 2004), decreases gastric fundic tone leading to enhanced gastric capacity (Amato *et al.*, 2009). Besides reducing intestinal transit in vivo (McDonagh *et al.*, 2007), GLP-2 additionally reduces small and large intestinal motility in vitro (Amato *et al.* 2010; Cinci *et al.*, 2011).

Physiology

GLP-2 is a pleiotropic hormone with a wide range of actions and interactions with other systems. It exerts its main biological effects in energy homeostasis, intestinal mucosal adaptation to enteral refeeding, small-intestine susceptibility to mucosal injury and intestinal host–microbiota interaction (Drucker and Yusta, 2014). It is released in response to stimulation by intake of luminal nutrients, such as glucose, fatty acids and dietary fiber (Brubaker, 2006). GLP-2 however, circulates at low basal levels in the fasting period too, and plasma levels rise rapidly after food ingestion. Renal clearance and enzymatic inactivation, control the elimination of bioactive GLP-2. GLP-2 is cleaved to inactive GLP-2 (3-33) by DPP-IV; consequently, the half-life of intravenous GLP-2 is very short, about 7 min in healthy humans (Hartmann *et al.*, 2000). Although, GLP-2 (3-33) may act as a weak agonist at pharmacological concentrations (Shin *et al.*, 2005); it is however able to act as a competitive antagonist of the GLP-2 receptor (GLP2R) in rodents (Thulesen *et al.*, 2002; Shin *et al.*, 2005; Baldassano *et al.*, 2009, 2013). Dipeptidyl-peptidase (DPP)-IV-resistant GLP-2 analogues, such as [Gly2]-GLP2 (teduglutide), exhibit greater bioactivity relative to the native molecule, due to their longer circulating half-lives (Tavares *et al.*, 2000; Baldassano and Amato, 2014).

GLP-2 promotes energy absorption within the GI tract through nonspecific and specific adaptation. In fact, it induces crypt cell proliferation and inhibition of apoptosis, resulting in an increase of villous height and in the expansion of the absorptive mucosal surface in the small and large intestine (Drucker and Yusta, 2014). Evidence from studies on humans and animal models suggests that GLP-2 also plays a role in lipid absorption. Indeed, GLP-2 facilitates intestinal absorption of lipids (Meier *et al.*, 2006; Hsieh *et al.*, 2009) and enhances and regulates chylomicron secretion from the intestine (Hsieh *et al.*, 2009). The GI responses to GLP-2 are mediated via GLP-2R, a member of the glucagon/secretin G protein coupled receptor superfamily that is located on enteric (Bjerknes and Cheng, 2001; Baldassano *et al.*, 2009) and vagal nerves (Nelson *et al.*, 2007), sub-epithelial myofibroblasts (Ørskov *et al.*, 2005) and a subset of intestinal epithelial cells (Thulesen *et al.*, 2000).

GLP-2 is cleaved to inactive GLP-2 (3-33) by DPP-IV; consequently, the half-life of intravenous GLP-2 is very short, about 7 min in healthy humans (Hartmann *et al.*, 2000). Although, GLP-2 (3-33) may act as a weak agonist at pharmacological concentrations (Shin *et al.*, 2005); it is however able to act as a competitive antagonist of the GLP-2 receptor (GLP-2R) in rodents (Thulesen *et al.*, 2002; Shin *et al.*, 2005; Baldassano *et al.*, 2009, 2013). Then DPP-IV-resistant GLP-2 analogues, such as [Gly2]-GLP2 (teduglutide), exhibit greater bioactivity relative to native molecule, due to their longer circulating half-lives (Tavares *et al.*, 2000; Baldassano and Amato, 2014). Teduglutide is currently licensed and available for the management of adult patients with short bowel syndrome under specialist follow-up.

☆*Change History*: April 2018. Dr Georgios K Dimitriadis and Dr Alexander D Miras prepared the updated manuscript and the new manuscript is entirely different than the original by Lovshin and Drucker.

This article is an update of Julie Lovshin and Daniel J. Drucker, Glucagon-like Peptide 2 (GLP-2), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 225–228.

GLP-2 and Glucose Homeostasis

To date, the role of GLP-2 in glucose homeostasis has not been fully elucidated. However, evidence from studies in GLP-2R KO mice have shown that global deficiency is not crucial for glucose equilibrium in healthy or lean mice with diabetes and is not associated with changes in fasting glucose, glucose tolerance or plasma glucagon (Bahrami *et al.*, 2010). Furthermore, chronic exposure to a GLP-2R antagonist (3-33), used to study the physiological actions of GLP-2 did not affect glucose or insulin levels and β-cell mass in rodents. This has led us to believe that endogenous GLP-2 has no role in glucose homeostasis in the normal state. In addition, changes in glucagon levels or glycaemia have not been reported following acute or chronic GLP-2 or teduglutide administration in patients with short bowel syndrome (Drucker and Yusta, 2014). It is well established that GLP-2 does not exhibit any insulin-releasing properties (Schmidt *et al.*, 1985; Ørskov *et al.*, 1988). On the contrary, intravenous GLP-2 infusion has been demonstrated to increase glucagon secretion in healthy, nonobese human subjects both in physiological and pharmacological plasma concentration (Meier *et al.*, 2006) or in patients with T2DM (Lund *et al.*, 2011). GLP-2R has been localized to α-cells in both human and rat islets by means of immunohistochemistry as well as real-time qPCR (de Heer *et al.*, 2007).

In contrast, full-length GLP-2R mRNA transcripts have not been detected in RNA from murine islets, and GLP-2 does not increase plasma glucagon levels in mice (Bahrami *et al.*, 2010). The discrepancy could be attributed to different species; however, caution should be taken in ruling out a glucagonotrophic role of GLP-2 in mice. In fact, recent research have demonstrated that GLP-2R is more widely expressed than it was estimated (Angelone *et al.*, 2012; El-Jamal *et al.*, 2014). Therefore, it is necessary to explore the presence and localization of GLP-2R in the pancreatic islets using validated GLP-2R antibody and the opportune positive and negative controls to yield to conclusive results. In any case, GLP-2 glucagonotrophic properties could suggest that the endogenous or exogenous peptide exacerbates hyperglycemia conditions related to diabetes. Nevertheless, glucagon hypersecretion induced by oral glucose, which is typical of patients with T2D (Knop *et al.*, 2007), is not a consequence of exaggerated secretion or effect of GLP-2 (Lund *et al.*, 2011), and GLP-2R global absence in genetically obese mice increases glucagon secretion and hyperglycemia (Bahrami *et al.*, 2010). Therefore, the importance of GLP-2 in the control of glucagon secretion in different species and in diverse pathological conditions related to glucose impairment requires further elucidation.

New evidence obtained from GLP-2R tissue-specific KO mice indicates that GLP-2R in POMC neurons is essential for suppressing hepatic glucose production (Shi *et al.*, 2013). Indeed, mice lacking GLP-2R selectively in POMC neurons display impaired postprandial glucose tolerance and hepatic insulin resistance (by increased gluconeogenesis), suggesting a physiological significance of GLP-2 neural action in glycaemic control. Moreover, intracerebroventricular infusion of GLP-2 increases glucose tolerance and insulin sensitivity and suppresses basal hepatic glucose production through GLP-2R activation in POMC neurons (Shi *et al.*, 2013). Therefore, GLP-2 has been proposed as a crucial neuroendocrine signal for glucose homeostasis (Guan, 2014). It will be crucial to determine whether CNS GLP-2R is a key contributor to glycaemic control and insulin sensitivity also in humans.

GLP-2 and Energy Homeostasis

Because no changes in body weight or in the daily food intake have been observed in GLP2 (3-33)- or Gly2-GLP-2-treated mice in comparison with untreated animals, an indirect effect mediated by an anti-obesity action has not been supported (Baldassano *et al.*, 2016). Reduced adiposity could contribute to the preservation of insulin sensitivity because the adipose tissue has a considerable influence on systemic glucose homeostasis through secretion of adipocytokines (McArdle *et al.*, 2013). Interestingly, GLP-2R mRNA expression has been detected in mouse mesenteric adipose tissue (El-Jamal *et al.*, 2014); however, its functional significance is still unknown. It is important to characterize whether GLP-2 increases glucose incorporation in adipocytes when their response to insulin is impaired by obesity conditions. In fact, although there are conflicting reports regarding the alterations in the basal glucose uptake, most reports provide evidence that insulin-induced glucose incorporation is suppressed in the obese state (Talior *et al.*, 2003; Sancho *et al.*, 2006; Crowe *et al.*, 2008), and as GLP-2 rapidly increases intestinal hexose absorption (Cheeseman, 1997; Au *et al.*, 2002), suggesting that it could contribute to clearance of plasma glucose through an action on adipocytes. In addition, or alternatively, GLP-2 might influence and modulate the quality and quantity of secreted adipokines and the inflammatory state of adipose tissue.

There are various studies assessing the effects of Roux-en-Y Gastric Bypass (RYGB) on GLP-2 regulation. Taqi *et al.* in an experimental study, demonstrated a significant increase in GLP-2 levels after gastric bypass in rats (Taqi *et al.*, 2010). LeRoux *et al.*, in a human prospective study, demonstrated a significant increase in the postprandial levels of GLP-2 after RYGB, with a secretion peak observed 6 months after the procedure (LeRoux *et al.*, 2010) Cazzo *et al.*, in a human prospective study, observed a significant increase in the GLP-2 levels 12 months after surgery and demonstrated that this increase was significantly correlated with aspects of satiety regulation (Cazzo *et al.*, 2017). Comparing individuals who underwent RYGB and vertical sleeve gastrectomy (VSG), Romero *et al.* observed in a prospective study that both procedures led to a significant increase in the postprandial levels of GLP-2 6 weeks after surgery, without significant difference between the two evaluated procedures (Romero *et al.*, 2012). Cummings *et al.*, in an experimental study, demonstrated a significant increase in the GLP-2 levels in rats after VSG (Cummings *et al.*, 2012). Evidence suggests that GLP-2 postoperatively increases, and this change may be potentially related to weight loss stabilization, late

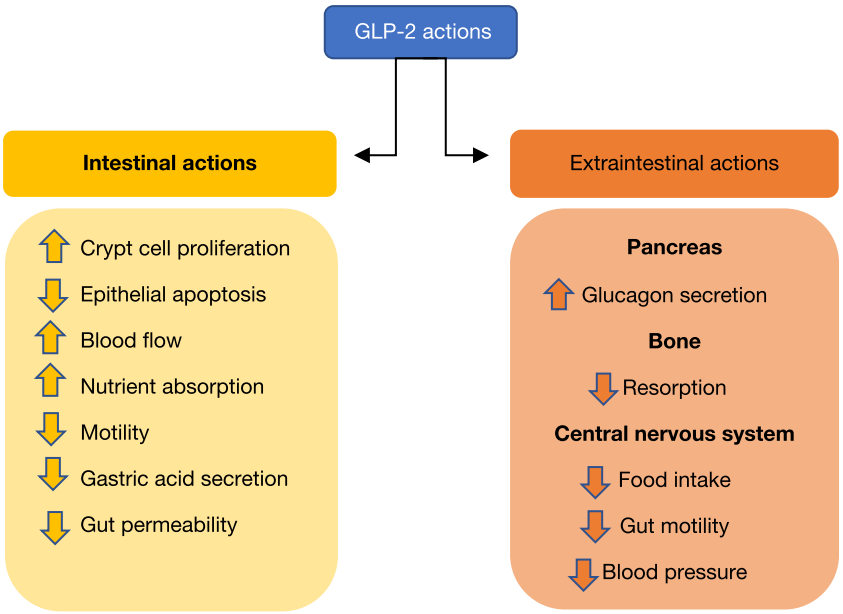

Fig. 1 Intestinal and extraintestinal actions of GLP-2.

reduction of diarrhea and malabsorption, partial compensation of effects on bone mineral metabolism, minimization of the consequences of bacterial overgrowth and satiety regulation (Fig. 1).

Conclusion and Perspective

Recent advances in our understanding of gut biology following bariatric surgery highlight the role of GLP-2 in promoting control and insulin sensitivity in the animal model, particularly in conditions associated with energy excess such is obesity. Results from human studies so far remain inconclusive; therefore, future research in this area is crucial to underpin the role of GLP-2 in preventing human insulin resistance and, in turn, the development of T2DM. The potential mechanisms driving the beneficial effects of GLP-2 receptor activation remain elusive. More work is necessary to understand the role of GLP-2 and its potential synergistic effect with other anorexigenic peptides in T2DM and obesity management.

Enterochromaffin-Like Cells

Apostolos V Tsolakis, Karolinska Institute, Stockholm, Sweden and Karolinska University Hospital, Stockholm, Sweden

Anatomy and Histology of the Stomach

The stomach is a dilated portion of the gastrointestinal tract in which the bolus of the food received from esophagus undergoes mechanical and chemical reduction to form chyme. Anatomically the stomach is divided into four regions: the cardia, fundus, corpus (body), and pylorus. The functional units of the stomach are the gastric glands, three to seven of which empty into the bottom of a single gastric pit. The mucosa of the fundus and corpus comprises the major histological compartment of the stomach. It contains numerous parietal cells that produce hydrochloric acid (oxyntic mucosa) and intrinsic factor. Furthermore, it consists of chief cells that produce pepsinogen, mucus secreting cells, as well as endocrine cells. A fraction of the latter cells are responsible for histamine production. The pylorus has a different glandular conformation. Its cells besides producing and secreting mucus can also synthesize, store and secrete gastrin.

Gastric Endocrine Cells

The history of gastric endocrine cells started with Heidenhain in 1870 when he observed cells in the gastric mucosa of dogs and rabbits that stained with dichromate solutions (Heidenhain, 1870). In 1906, Ciaccio introduced the term "enterchromaffin" (EC) cells as he noticed that their staining properties were similar to those of the adrenal chromaffin cells (Ciaccio, 1906). In 1914, Masson showed that the aforementioned cells had the ability to reduce ammoniacal silver salts without adding reducing agents and termed them "argentaffin" to describe this feature (Masson, 1914). An indoleamine called enteramine was initially purified from rabbit gastric mucosa by Vialli and Erspamer and later characterized as 5-hydroxytryptamine (5-HT) by Erspamer and Asero that showed that it is the argentaffin/chromaffin product of the EC cells (Erspamer and Asero, 1952). The last authors recognized that 5-HT is identical to serotonin, which had been isolated, in 1948, by Rapport *et al.* (1948). Gastrin was the first peptide hormone to be detected in epithelial cells of the gastric mucosa (McGuigan, 1968) termed as "G" cells, a type of cells shown to be characteristic of the antral-pyloric glands in the gastric mucosa (Sasagawa *et al.*, 1970). Håkanson and Owman were the first to describe a large population of dopamine containing, green fluorescent epithelial cells in the gastric oxyntic mucosa of rats, by means of fluorescence microscopy. The cells were morphologically similar to yellow fluorescent, serotonin containing EC cells of the pyloric mucosa, and the term "enterochromaffin-like" (ECL) was introduced. A portion of these cells was found to contain histamine by using the fluorescence histochemical *o*-phthalaldehyde technique (Hakanson and Owman, 1967). Further ultrastructural studies of the murine oxyntic mucosa revealed that the predominant population of endocrine cells in the oxyntic mucosa consists of ECL cells (Capella *et al.*, 1971). G and ECL cells comprise the largest endocrine cell population of the oxyntic mucosa, followed by ghrelin cells which are ultrastructurally similar with the previously described P/D_1 cells (Kojima *et al.*, 1999; Rindi *et al.*, 2002). Somatostatin-producing (D cells) and serotonin producing (EC cells) are present in the entire gastric mucosa (D'Adda *et al.*, 1989). The volume density of all endocrine cells in the normal human oxyntic mucosa accounts 1.2% $\pm$ 0.4% of the total mucosal epithelial volume (D'Adda *et al.*, 1989).

In the human gastric mucosa, the above five different endocrine cell types have been identified and characterized (**Table 1**) (Rindi *et al.*, 2002; Solcia *et al.*, 1975; Simonsson *et al.*, 1988). They are divided in "closed" and "open" type cells (Fujita and Kobayashi, 1977; Kobayashi *et al.*, 1971). The "closed" type pattern consists of cells thought to be involved in paracrine and/or endocrine regulatory mechanisms (Solcia *et al.*, 1975; Bordi *et al.*, 1983). On the contrary, the "open" type of endocrine cell is provided with apical cytoplasmatic extensions that project into the glandular lumen with short microvilli. These structures represent the anatomical cornerstone for the gastric endocrine cell response to stimuli from the gastric gland content (Solcia *et al.*, 1975).

Table 1 Characteristics of the human gastric endocrine cells

Cell type	*Main product*	*Distribution*	*Relative incidence (%)*	*Size of secretory granule (nm)*	*Neoplasia*
ECL	Histamine	Fundus/corpus	40–50	160–300	ECL-CCs
P/D_1	Ghrelin	Whole stomach	20–30	110–180	Ghrelinoma[a]
D	Somatostatin	Whole stomach	10–20	200–400	Somatostatinoma[a]
EC	Serotonin	Whole stomach	10–20	150–500	EC cell carcinoid[a]
G	Gastrin	Pylorus	40–60	150–350	Gastrinoma[a]

[a]Very rare cases have been reported in the gastric mucosa.

ECL, enterochromaffin-like; *EC*, enterochromaffin; *ECL-CC*, enterochromaffin-like cell carcinoid.

ECL Cell

The ECL cells are located in the basal part of the gastric pits in the vicinity of parietal cells (Fujiwara *et al.*, 1999) and comprise approximately 40%–50% of all human gastric endocrine cells (Solcia *et al.*, 2000). They are argyrophilic and can be identified by light microscopy using silver impregnation techniques such as Grimelius (Lundqvist *et al.*, 1990) and Sevier-Munger (Solcia *et al.*, 1975), and also by chromogranin A (CgA) immunostaining (Hakanson *et al.*, 1986). Ultrastractural studies have shown that this spherical cell type structures, which is 8–10 μm in diameter, contains numerous secretory granules (Capella *et al.*, 1971; Hakanson *et al.*, 1971a, 1993; Rubin and Schwartz, 1979; Helander, 1981; Delwaide *et al.*, 1991; D'Adda *et al.*, 1991; Andersson *et al.*, 1992; Chen *et al.*, 1996). At present, there is no commercial antibody against histamine for immunohistochemical identification of ECL cells in routine formalin-fixed sections, because its preservation requires a specific fixation procedure. Histamine can be demonstrated in Carnoy-fixed paraffin sections by *o*-phthalaldehyde (Hopwood, 2002). However, these cells can be visualized indirectly by an antibody raised versus a protein involved in the transport of histamine within the granules, vesicular monoamine transporter-2 (VMAT-2) (Erickson *et al.*, 1996; De Giorgio *et al.*, 1996). Accumulation of histamine in the granules of ECL cell is dependent on V-type ATPase and VMAT-2 (Merickel and Edwards, 1995; Dimaline, 1996). The granular H^+ gradient is established by V-type ATPase, which is pumping H^+ into the granules (Forgac, 1999; Nishi and Forgac, 2002). To maintain electro neutrality VMAT-2, which is localized at the vesicular membrane, transfers H^+ outside the granules counter transporting histamine.

The ECL cell expresses subtype somatostatin receptor-2 (Reubi *et al.*, 1992; Prinz *et al.*, 1999), cholecystokinin-B/Gastrin receptor (CCK-B/gastrin receptor) (Wank *et al.*, 1992) and pituitary adenylate cyclase-1 (PAC-1) receptor (Zeng *et al.*, 1998a, 1999a), which represent targets for the relevant hormones and play an important role in gastric acid release. In addition, gastrin has trophic effects on ECL cells in humans and experimental models (Solcia *et al.*, 1993; Bordi *et al.*, 1995; Nilsson *et al.*, 1993). Besides gastrin, helicobacter pylori infection and consequent inflammation have been suggested to induce ECL cell growth. Helicobacter pylori lipopolysaccharide may stimulate ECL cell histamine release and proliferation (Kidd *et al.*, 1997).

ECL Cell and Gastric Acid Release

It is well described, that gastrin is released in response to aromatic amino acids in the lumen of the antrum (DelValle and Yamada, 1990) and reaches the ECL cell via the vascular system. GRP (bombesin) (DuVal *et al.*, 1981) and acetylcholine (Zeng *et al.*, 1996) are two other factors that stimulate gastrin release. Gastrin influences, mainly, gastric acid secretion by stimulating ECL cells via CCK-B/Gastrin receptor, which results to calcium mobilization (Zeng *et al.*, 1999b). When activated by gastrin, the ECL cell responds with increased production and release of histamine, as well as with activation of histidine decarboxylase (HDC) and increase of its mRNA expression (Dartsch *et al.*, 1999; Bjorkqvist *et al.*, 1999; Kitano *et al.*, 2000). The stimulation of HDC transcription by gastrin is mediated by protein kinase C, indirect activation of c-fos and c-jun and stimulation of MAP kinase (Zhang *et al.*, 1996; Hocker *et al.*, 1997a,b). Simultaneously, the gene expression of VMAT-2 is stimulated (Watson *et al.*, 2001) and the CgA promoter is activated (Hocker *et al.*, 1998). Histamine is synthesized by enzymatic decarboxylation of the amino acid histidine by HDC (Viguera *et al.*, 1994), and then stored in secretory granules until its release (Hakanson *et al.*, 1971a,b; Prinz *et al.*, 1999). Once released, histamine interacts with H_2 receptors on parietal cells (Hakanson *et al.*, 1978). Thus, histamine serves as the most important direct stimulus for parietal cells to secrete gastric acid. Then histamine is degraded in various ways. In man, the major pathway includes methylation and oxidative deamination producing 1, 4-methyl imidazole acetic acid (MeImAA) that is excreted into the urine. In this way approximately 40%–60% of histamine is degraded. Around 4%–8% of histamine can undergo methylation and be excreted as methylhistamine. Another substantial fraction (around 20%–40%) of histamine is not methylated and produces the metabolite imidazole acetic acid, which is mainly conjugated to ribose. Finally, a small portion (1%–3%) of histamine is excreted unmetabolized (Granerus *et al.*, 1966).

It has also been proved that pituitary adenylate cyclase activating polypeptide-27 (PACAP-27), which is a neural sympathetic mediator and mediates the cephalic phase of acid secretion (Zeng *et al.*, 1999a; Pisegna *et al.*, 2000; Sandvik *et al.*, 2001; Lindstrom *et al.*, 2001), also plays an important role to gastric acid secretion. PACAP-27 binds to the PAC-1 receptor subtype, which is expressed in ECL cells and induces histamine release through a calcium dependent pathway (Zeng *et al.*, 1999a,b; Pisegna *et al.*, 2000; Lindstrom *et al.*, 2001). Other stimulants proved to evoke histamine secretion from ECL cells are acetylcholine (Zeng *et al.*, 1996), epinephrine and VIP (Prinz *et al.*, 1993; Hakanson *et al.*, 2001). Ghrelin has also been suggested to increase gastric acid secretion (Masuda *et al.*, 2000; Date *et al.*, 2001), whereas galanin, somatostatin, PYY and PGE_2 exhibit inhibitory action on the ECL cell (Zeng *et al.*, 1998a, b; Prinz *et al.*, 1993, 1994; Lindstrom and Hakanson, 2001).

Hyperplasia and Dysplasia of the Gastric Endocrine Cells With Focus on ECL Cell

G-, ECL-, Ghrelin-, and D-cell hyperplasia have been described in the gastric mucosa (Solcia *et al.*, 1988, 1991; Tsolakis *et al.*, 2008). The first three cell types are the most common to undergo hyperplasia which occurs in patients with type A chronic atrophic gastritis (A-CAG). In this autoimmune type of gastritis the body generates antibodies against the parietal cells causing megaloblastic anemia. *Helicobacter pylori* infection has also been described to cause ECL-cell hyperplasia (Solcia *et al.*, 2000). Hypergastrinemia under the concept of Multiple Endocrine Neoplasia 1/Zollinger–Ellison syndrome (MEN1/ZES) can induce both ECL

and ghrelin cell hyperplasia (Tsolakis *et al.*, 2008; Solcia *et al.*, 2010). Four patterns of endocrine cell hyperplasia have been described: simple or diffuse, linear, nodular and adenomatoid (Solcia *et al.*, 2000). Simple or diffuse pattern is termed as increased density of endocrine cells, more than twice the standard deviation as compared to age and sex matched controls. The linear pattern includes linear sequences of five or more endocrine cells along the basement membrane of the gastric glands. Nodular pattern is defined as clusters of five or more endocrine cells forming a nodule. The adenomatoid hyperplasia pattern is the less common and is termed as the collection of five or more nodules of endocrine cells adherent to each other with interposition of basement membrane and thin strands of lamina propria.

Dysplastic or precarcinoid ECL cell lesions are growths between 150 and 500 nm in size that escape endoscopic observation and are scattered in the mucosa. The cells are relatively atypical with features of enlarging or fusing micronodules, or newly formed stroma (Solcia *et al.*, 2010). Despite the fact that these are considered precursor lesions of enterochromaffin-like cell carcinoids (ECL-CCs) they do not infiltrate beyond the muscularis mucosa (Solcia *et al.*, 1986, 1988, 1991, 2010). Nodules that become bigger than 0.5 mm are classified as microcarcinoids (Solcia *et al.*, 2010).

Gastric Neuroendocrine Tumors and Enterochromaffin-Like Cell Carcinoids

According to the WHO 2010 classification the well differentiated gastric neuroendocrine tumors (GNETs) are divided in type I, II, III ECL-CCs, as well as in non-ECL-CC type (Solcia *et al.*, 2010). **Table 2** summarizes the characteristics of ECL-CCs.

Well Differentiated Gastric Neuroendocrine Tumors

Type I ECL-CCs

Type I ECL-CCs have been reported to represent the majority (approximately 75–80%) of GNETs with a female preponderance (M:F ratio, 1:2.5) (Solcia *et al.*, 2010). The incidence of type I ECL-CCs is rising which can be explained by the improved diagnosis of neuroendocrine tumors, doctors' awareness and the increased number of endoscopies performed. However, their overall incidence remains low at around 0.3 cases per 100,000 population, being more common in elderly women (Lawrence *et al.*, 2011; Tsikitis *et al.*, 2012). These tumors develop in $<1\%$ of patients with A-CAG involving the corpus-fundus mucosa. The destruction of parietal cells results to achlorhydria which in its turn causes hypergastrinemia as a secondary response of pyloric G cells (Solcia *et al.*, 2010; Rappel *et al.*, 1995). The long standing hypergastrinemia exerts a trophic effect to ECL cells that ends to ECL-CCs under a hyperplasia–dysplasia–neoplasia sequence. Patients with type I ECL-CCs may also be accompanied with pernicious anemia and other autoimmune diseases (**Table 3**) (Thomas *et al.*, 2013; Modlin *et al.*, 2003). These tumors are usually small, often multiple with relatively uniform cells arranged in small clusters or trabecules (Solcia *et al.*, 2010; Rappel *et al.*, 1995). Most lesions are located in the mucosa, sometimes also in the submucosa, but only rarely with a deeper invasion into the gastric wall (Solcia *et al.*, 2010; Modlin *et al.*, 2003; Rindi *et al.*, 1999). Endocrine cell hyperplasia (ECL- and G-cell) is a constant feature and dysplastic growths are frequently observed (Solcia *et al.*, 1988, 2010; Rindi *et al.*, 1996). The patients are usually asymptomatic, and the diagnosis is often accidental during gastroscopy performed for dyspepsia or megaloblastic anemia. Genetically, these lesions are monoclonal, when assessed by the pattern of X-chromosome inactivation. This fact indicates that type I ECL-CCs are true neoplasms in spite of their indolent nature (D'Adda *et al.*, 1999). However, angioinvasion, lymph node- and distant metastases have also been described (Rindi *et al.*, 1999; Grozinsky-Glasberg *et al.*, 2013).

Type II ECL-CCs

Type II ECL-CCs (M:F ratio, 1:1) account 2%–10% of all GNETs and develop in patients with hypergastrinemia due to gastrin-producing tumor(s) under the ZES/MEN-1 (Solcia *et al.*, 2010; Modlin *et al.*, 2003; Rindi *et al.*, 1999; Feurle, 1994; Peghini *et al.*, 2002). Hypertrophic, hypersecretory gastropathy represent characteristic diagnostic findings (Solcia *et al.*, 2010). The tumors, usually multiple, are associated with ECL cell hyperplasia and/or dysplasia (Rindi *et al.*, 1996). In contrast to the type I ECL-CCs,

Table 2 Characteristics of ECL-CCs

	Type 1 ECL-CCs	*Type II ECL-CCs*	*Type III ECL-CCs*
Percentage of GNETs	75%–80%	2%–10%	10%–15%
Sex preponderance	Female	Equal	Male
Associations	Autoimmune gastritis	MEN1/ZES	None
Localization	Fundus/corpus	Fundus/corpus/(antrum)	Fundus/corpus/antrum
Tumor size	<1 cm	<1 cm	>2 cm
Histopathology	Hyperplasia/dysplasia/neoplasia	Hyperplasia/dysplasia/neoplasia	Normal adjacent mucosa
Biological behavior	Slow growth, rarely metastasizes	Slow growth, may metastasize	Aggressive
Gastrin levels	↑–↑↑	↑–↑↑–↑↑↑	Normal
Gastric acid output	Low or absent	High	Normal
Prognosis	Excellent	Very good	Poor

Table 3 Related autoimmune diseases in a cohort of 111 patients with type I ECL-CCs as presented in a multicenter study (Thomas *et al.*, 2013)

Disease	n	*Percentage (%)*
B12 deficiency	47	42.3
Hashimoto's thyroiditis	41	36.9
Diabetes mellitus type 1	7	6.3
Multinodular goiter	6	5.4
Rheumatoid arthritis	4	3.6
Sjögren's	3	2.7
Systemic lupus erythematosus	3	2.7
Addisson's disease	1	0.9
Vitiligo	1	0.9
Grave's disease	1	0.9

the surrounding of the ECL-CC mucosa has no signs of A-CAG (Solcia *et al.*, 2010). Type II ECL-CCs are mainly located in the corpus-fundus but they can also be identified in the antrum (Bordi *et al.*, 2001). Taking in consideration the lesions' malignant potential type II ECL-CCs are intermediately placed in this respect, between these of type I and type III (Solcia *et al.*, 2010; Modlin *et al.*, 2003; Rindi *et al.*, 1999; Modlin and Tang, 1996).

Type III ECL-CCs

The type III ECL-CCs are also called "sporadic" due to the absence of any specific gastric pathology (no association to hypergastrinemia or A-CAG) (Solcia *et al.*, 2010). They constitute approximately 10%–15% of all GNETs and are observed mainly in males (M:F ratio, 2.8:1) (Solcia *et al.*, 2010; Modlin *et al.*, 2003). They are usually single but occasional multiple lesions have also been described (Solcia *et al.*, 2010; Modlin *et al.*, 2003; Rindi *et al.*, 1996; Moriyama *et al.*, 2003). Most of the tumors are large, and have already metastasized at diagnosis; on that basis they are considered to represent the most malignant type of ECL-CCs (Solcia *et al.*, 2010; Modlin *et al.*, 2003; Rindi *et al.*, 1999). Minute carcinoids of this type are reported to give regional lymph node metastasis (Shinohara *et al.*, 2003).

Non-ECL-CCs

The non-ECL-CCs constitute a group of uncommon tumors that may present with symptoms related to the substance they produce. Serotonin- (Rindi *et al.*, 1999; Quinonez *et al.*, 1988), gastrin- (Soule *et al.*, 1976), ACTH-producing (Hirata *et al.*, 1976; Tsuchiya *et al.*, 2005), and ossifying lesions (Yamagishi *et al.*, 2004) are some examples that have been described in the literature. Recently a new entity of GNET has been described and termed ghrelinoma (Tsolakis *et al.*, 2004).

Glossary

Aprepitant (Emend, MK-869, L-754,030) A nonpeptide NK_1 receptor antagonist used in clinical practice for the prevention of postoperative nausea and vomiting and chemotherapy-induced nausea and vomiting. In addition to the antiemetic action, aprepitant exerts antipruritic effects and it is a broad-spectrum anticancer compound.

Fosaprepitant (Ivemend) It is a prodrug of aprepitant that exerts an antitumor action. Fosaprepitant (intravenous use), via the action of ubiquitous phosphatases, is rapidly converted to aprepitant.

Nonpeptide NK_1 receptor antagonists They are brain-penetrant and are not degraded by peptidases. Aprepitant, fosaprepitant and rolapitant are the only NK_1 receptor antagonists used in clinical practice. Nonpeptide NK_1 receptor antagonists are safe and well tolerated.

Peptide NK_1 receptor antagonists (SP analogue antagonists) In the SP molecule, L-amino acids are replaced by D-amino acids. They are not brain-penetrant, are rapidly degraded by peptidases, have a toxic action and show a poor potency.

Introduction

Substance P (SP) is an 11-amino-acid peptide with the primary structure Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met, which contains a C-terminally α-amidated methionine residue. SP is a member of the biosynthetically and evolutionarily related tachykinin family of regulatory peptides that are characterized by common structural features and a shared spectrum of biological activities. Neurokinin A (NKA), neurokinin B (NKB), and hemokinin-1 (HK-1) peptides also belong to this family. SP is derived from the *TAC1* gene. This gene contains seven exons and the sequence encoding SP is contained in exon 3. The primary RNA transcript of *TAC1* is spliced to produce four types of mRNA (α-TAC1, β-TAC1, γ-TAC1, and δ-TAC1) each of them encode a single-copy of the peptide; β-TAC1 and γ-TAC1 also encode NKA; β-TAC1 the neuropeptide K and γ-TAC1 the neuropeptide γ. After the posttranslational proteolytic processing of the protachykinin protein precursor, SP can be further processed, producing SP fragments (SP (1–4), SP (1–7)) with biological activities.

Tachykinins exert their biological actions through three metabotropic receptors belonging to the G-protein-coupled receptor family: neurokinin-1 (NK_1), NK_2, and NK_3. These receptors are encoded respectively by the *TACR1*, *TACR2*, and *TACR3* genes. In humans, the *TACR1* gene has been located on chromosome 2 and spans 45–60 kb, and it is contained in five exons. SP, NKA, and NKB bind to the three NK receptors. The affinity of the NK_1 receptor for NKB and NKA is, respectively, 500- and 100-fold lower than for SP. Thus, the NK_1 receptor binds the peptide with the highest affinity, so this receptor is often termed the SP receptor. This receptor also shows a high affinity for HK-1 (in nonneural tissues, HK-1 is a potent ligand for the NK_1 receptor). HK-1 induces the proliferation of cells (e.g., B cells, T-cell precursors) and angiogenesis, decreases blood pressure and exerts an antiapoptotic effect.

Historical Introduction

The presence of a vasodilator compound in extracts of horse brain and intestine that also stimulated the motility of the rabbit intestine in the presence of atropine was first reported by von Euler and Gaddum in 1931. A crude preparation of this material was obtained and the active component was shown to be peptidic in nature and was referred to as substance P (P for powder). SP resisted all attempts at purification and structural characterization until 1971, when Chang and Leeman demonstrated that an 11-amino-acid peptide isolated from an extract of bovine hypothalamus on the basis of its potent sialagogic effect in rats was identical to the factor of von Euler and Gaddum. Since then the NK_1 receptor antagonists aprepitant (oral administration), fosaprepitant (prodrug of aprepitant, intravenous use) and rolapitant (oral administration/intravenous use) are used for the prevention of chemotherapy-induced nausea and vomiting (CINV) and postoperative nausea and vomiting (PONV). To date, these drugs are the only NK_1 receptor antagonists used in clinical practice.

☆*Change History*: May 2018. Miguel Muñoz and Rafael Coveñas updated the abstract and the entire text. Table 1 was updated by adding new biological activities and disease correlations. The references appearing in "See Also the Following Articles" and in "Further Readings" were deleted: updated references were added in both sections. The terms appearing in the Glossary were deleted and new terms were added.

This article is an update of J Michael Conlon, Substance P, In Encyclopedia of Endocrine Diseases, edited by L Martini, Elsevier, New York, 2004, Pages 339–342.

Distribution of Substance P and the NK_1 Receptor

Substance P

In the higher mammals, SP is localized in neurons of the central and peripheral nervous systems. SP-containing cell bodies and fiber networks are widely distributed in the human brain, with the highest concentrations being in the substantia nigra, striatum, hypothalamus, globus pallidus, and medulla oblongata. SP is highly concentrated in the superficial layers (laminae I–III) of the dorsal horn of the spinal cord, where most primary afferent fibers terminate. Colocalization of the peptide with neurokinin A and calcitonin gene-related peptide in unmyelinated primary afferent C-fibers has been demonstrated.

Within the gastrointestinal tract, most of the SP-containing neurons are of intrinsic origin with cell bodies occurring in both myenteric and submucous nerve plexi. In the gut, the coexistence of SP and NKA occurs in fibers of the afferent neurons, in neurons of the enteric nervous system and in immune and enterochromaffin cells of the mucosa. SP-containing neurons originating in the myenteric plexus project within the plexus itself and to the underlying circular smooth muscle layer and to the submucous ganglia and mucosa. Colocalization of SP and enkephalins in such nerve fibers in the human stomach and intestine has been described. Neurons in the submucous plexus project predominantly to the mucosal layer and SP is frequently colocalized with acetylcholine. SP fibers in the mucosa are particularly numerous in humans. The gastrointestinal tract is also innervated by extrinsic SP-containing fibers that originate primarily from dorsal root ganglia.

In the pancreas, a sparse distribution of SP fibers, which are probably of extrinsic origin, innervate blood vessels and acini and such fibers are also found surrounding acini and along blood vessels in the salivary glands. In the hepatobiliary system, immunoreactive fibers are found in the parenchyma of the liver and hepatic vasculature and are localized to the ganglionated and mucosal plexi of the gallbladder. In the trachea and bronchi, extrinsic SP-containing nerve fibers are found within the smooth muscle layer and around local ganglion cells and, in the nasal mucosa, within and under the epithelium and around arterioles, venules, and exocrine glands. In the human heart, SP fibers are found in close proximity to arterioles and are localized to the adventitia and to the border between the adventitia and media in a wide range of blood vessels. Within the urogenital system, immunoreactive nerve fibers of extrinsic origin are present in the urinary bladder throughout the ureter close to smooth muscle cells and around blood vessels in the kidney cortex often close to renal tubules and glomeruli. The female (uterus, oviduct, and vagina) and male (seminal vesicle, testis, epididymis, and vas deferens) genital organs are also innervated by extrinsic SP fibers.

SP is also located in cells that do not belong to the nervous system (e.g., endothelial, smooth muscle and Leydig cells, fibroblasts, platelets, and placenta cells) and in the body fluids (e.g., breast milk, cerebrospinal fluid, and blood). The synthesis and release of SP by cells of the immune system (monocytes, lymphocytes, eosinophils, and macrophages) have been reported and SP fibers innervate thymus, spleen, lymph nodes, and bone marrow. In malignant cells, the expression of both SP and the NK_1 receptor is increased. Human tumor cells (e.g., breast and lung carcinoma, melanoma) express the peptide, which is located in both the cytoplasm and nucleus. It seems that SP is released into the blood vessels from the tumor mass. In human gastric tumor samples, an increased nuclear localization of SP has been reported in cancer cells when compared to human gastric normal cells. Consistent with the rapid rate of clearance from the circulation (half-life <1 min), the plasma concentration of SP in healthy subjects is very low (<10 fmol/mL). However, elevated concentrations of circulating SP are often seen in patients with carcinoid tumors, particularly metastatic tumors of the midgut region.

NK_1 Receptor

The NK_1 receptor (also named tachykinin 1 receptor) is widely distributed in the central and peripheral nervous systems of mammals (e.g., spinal cord, medulla oblongata, striatum, hippocampus, and cerebral cortex). In peripheral tissues, NK_1 receptors are present on human pulmonary arterial blood vessels, on circular and longitudinal smooth muscle throughout the human gastrointestinal tract, and over ganglia of the myenteric plexus. These receptors have been also located in the placenta, thyroid gland, endothelial cells, immune cells (e.g., dendritic cells, macrophages, monocytes, and lymphocytes) and in platelets. The occurrence of NK_1 receptors in spleen, in thymus, on arterioles and venules of the lymph nodes, and on T lymphocytes provides further evidence for an involvement of SP in immunoregulation. The potent vasodilator action of SP is mediated primarily by binding to NK_1 receptors on the endothelium of peripheral arterial blood vessels. The potent sialagogic effect of SP is consistent with the high concentration on NK_1 receptors on rat submaxillary gland. In the urogenital system, NK_1 sites are expressed on blood vessels in the urinary bladder, uterus, and ureter; in the skin, NK_1 sites are present at high density in postcapillary venules in the dermis and in keratinocytes (SP controls the production of proinflammatory cytokines by these cells). In the gut of rodents, NK_1 receptors were observed in the smooth muscle, interstitial cells of Cajal, inhibitory, excitatory and secretomotor neurons and in epithelial and immune cells. The activation of the NK_1 receptors located on the intrinsic primary afferent neurons of the submucosal and myenteric plexus, interstitial cells of Cajal and on the muscle cells, facilitated the gastrointestinal motor activity. In the case of the interstitial cells of Cajal this stimulation enforced motility by prolonging the duration of the slow waves originated in these cells. In the enteric nervous system, NK_1 receptors located on the inhibitory motor pathways are involved in the depression of the motor activity via release of adenosine triphosphate and nitric oxide.

The NK_1 receptor shows different active conformations and each of them has a different affinity for distinct agonists/antagonists. This receptor is highly conserved along the species and contains seven putative hydrophobic α-helical transmembrane domains (showing three extracellular and three intracellular loops with the possibility for a four intracellular loop due to the

palmitoylation of cysteine); its C-terminus (intracellular) contains putative threonine/serine phosphorylation sites (once phosphorylated induces the desensitization of the receptor when it is repeatedly activated by SP), whereas its N-terminus (extracellular) contains potential asparagine glycosylation sites. SP (the conserved COOH-terminal sequence is required for the activation of the receptor) binds to residues 178–183 (Val-Val-Cys-Met-Ile-Glu) which are located in the middle of the second extracellular loop, whereas the third intracellular loop binds to the G protein. NK_1 receptor antagonists bind between the third and sixth transmembrane domains.

The glycosylation/phosphorylation of the NK_1 receptor influences the NK_1 receptor signaling. SP generates second messengers and affects many signaling pathways controlling the cell function: activation of phospholipases A_2/C, protein kinases A/C and adenylyl cyclase, synthesis of diacylglicerol/inositol triphosphate/arachidonic acid, mobilization of intracellular Ca^{++}, generation of thromboxane/leukotrienes, phosphorylation of myosin regulatory light chain, and activation of Rho-associated protein-kinase (ROCK). SP, via the NK_1 receptor, transactivates the epidermal growth factor receptor (EGFR) leading to the activation of mitogen-activated protein kinases (MAPK), extracellular signal-regulated kinases (ERK) 1 and 2, DNA synthesis and proliferation. SP exerts and antiapoptotic effect involving the Janus kinase 2 (JAK-2) and phosphoinositide 3-kinase (PI3K)-mediated activation of the antiapoptotic molecule Akt (protein kinase B). SP activates p38, promotes the synthesis of proinflammatory cytokines (e.g., interleukin-6, interleukin-8) and activates proinflammatory transcription factors (e.g., nuclear factor kappa B (NF-κB) by mechanisms in which the activation of the Rho family kinases is involved).

The NK_1 receptor shows two isoforms: the full-length (407 amino acids, 46 kDa molecular mass; present mainly in the brain) and the truncated isoform (311 amino acids without its C-terminus tail; it is mainly located in peripheral tissues, although in the nucleus accumbens, cerebellum, locus coeruleus and cingulated cortex the truncated isoform was observed). Both isoforms show a different functional significance due to the different signaling capability. The full-length induces the slow growth of cancer cells, whereas the truncated ones (the oncogenic isoform of the NK_1 receptor) mediates the malignancy/growth of tumor cells and stimulates the synthesis of cytokines, which upregulate the truncated form. The full-length isoform is phosphorylated and interacts with β-arrestins, which are involved in desensitization/internalization/endocytosis of the receptor. This receptor activates ERK1/2 and NF-κB and promotes the expression of interleukin-8. However, after stimulation of the truncated form, the expression of interleukin-8 was inhibited. SP, via cytokines, promotes the activation of NF-κB, which slightly increases the full-length isoform but upregulates the truncated ones. An NF-κB binding site has been located in the promoter of the *TACR1* gene and this promoter contains binding sites for other transcription factors (e.g., Oct2, Sp1, and AP1), which regulate many inflammatory genes. In airway epithelial cells, via MAPK/ERK and JAK/STAT pathways, the leukemia inhibitory factor favors the expression of the NK_1 receptor. In pancreatitis, the NK_1 receptor is upregulated in acinar cells and this is mediated by JNK and, in colonic epithelial cells, SP activated the JAK/STAT pathway and promoted the release of prostaglandins.

SP induces a clathrin-dependent internalization of the NK_1 receptor, the SP/NK_1 receptor complex is internalized into endosomes and then SP is degraded and the NK_1 receptor returns to the cell surface (this occurs during a brief exposure to low concentrations of SP). After a maintained exposure with a high concentration of SP (e.g., this occurs during the inflammatory processes), the NK_1 receptor is ubiquitinated and degraded. The loss of the C-terminal threonine/serine residues is crucial for G protein-coupled receptor kinase interaction and β-arrestin recruitment for receptor internalization. The truncated isoform is able to prolong the responses after the binding of SP, because its internalization and desensitization are altered (the truncated form has a reduced efficiency regarding both processes because is not phosphorylated and does not interact with β-arrestins). The truncated form increases its tumorigenic potential due the diminished endocytosis/desensitization of this form. In colitis-associated cancer the expression of the truncated isoform is related to the progression from quiescent colitis to dysplasia and cancer and it is increased in colonic epithelial cells from patients suffering colitis-associated cancer. However, the full-length is not affected. The truncated isoform was overexpressed in human hepatoblastoma cells but negligible levels of the truncated isoform were found in nonmalignant cells. The overexpression of the truncated form induced the transformation of breast cancer cells, but not the full-length.

Physiological Roles

The principal biological actions of SP are summarized in **Table 1**. The undecapeptide controls cell function via neuroendocrine, endocrine, paracrine and/or autocrine processes. It is well established that SP acts as a neurotransmitter in primary afferent sensory neurons and is involved in the perception of pain. The release of SP from small-diameter sensory "pain" fibers into the dorsal horn of the spinal cord following intense peripheral stimulation promotes central hyperexcitability and increases sensitivity to pain. Intrathecal injection of SP in mice elicits behaviors suggestive of pain sensation. However, in rats, intracerebroventricularly administered SP displays a clear-cut antinociceptive activity in the hot plate test, which is abolished by treatment with the opioid antagonist, naloxone. It has been suggested that proteolytic conversion of SP to its (1–7) fragment is a prerequisite for development of the analgesic action. This fragment also inhibited grooming and aggressive behavior. Knockout mice lacking expression of the *TAC1* gene exhibit a surprisingly healthy phenotype and a normal response to mildly painful stimuli, for example, the tail flick assay, but the response to moderate to intense pain was significantly reduced. Similarly, mice with a targeted deletion of the NK_1 receptor for SP were healthy and fertile and responded normally to acute painful stimuli but were unable to develop fully the stress-induced analgesia of control animals.

Table 1 A summary of the principal biological actions of substance P with correlations to human diseases

Organ system	*Biological activity*	*Disease correlation*
Central nervous system	Neurotransmitter/neuromodulator function	Migraine
		Riley–Day syndrome
		Emesis
		Alcohol addiction
		Depression/anxiety
		Seizures
	Nociception	Neuropathic pain
	↑ Neurogenic inflammation	Parkinson's disease
		Huntington's disease
		Alzheimer's disease
	↑ Permeability of blood-brain barrier	Traumatic brain injury
	Bacterial infection	Bacterial meningitis
	Viral infection	Viral encephalitis
	Parasitic infection	Neurocysticercosis
	Mitogenesis of tumor cells	Astrocytoma/glioma
Cardiovascular system	Vasodilation	Carcinoid flush
	Plasma extravasation	
	Tachycardia	
	↑ Cardiac output	
		Pulmonary arterial hypertension
		Vascular anomalies
	↑ Neurogenic inflammation	Viral-myocarditis
	Viral infection	
Blood	Platelet aggregation	Thrombosis
	↑ Neurogenic inflammation	Sepsis
	Bacterial infection	
	HIV	AIDS
	Mitogenesis of tumor cells	Acute lymphoblastic leukaemia B and T cells
	Immunoregulation	
Respiratory system	Bronchoconstriction	Asthma
	Vasodilation	
	↑ Vascular permeability	
	↑ Mucus secretion	
	↑ Neurogenic inflammation	Bronchiolitis
	Viral infection	Respiratory syncytial virus
		Pulmonary arterial hypertension
	Mitogenesis of tumor cells	Small and nonsmall lung cancer, larynx cancer
Salivary glands	↑ Salivation	
Gastrointestinal tract	↑ Peristalsis	Hirschprung's disease
	↑ Water and electrolyte secretion	Ulcerative colitis
	↑ Blood flow	Crohn's disease
	↑ Neurogenic inflammation	
	Mitogenesis of tumor cells	Gastric and colon cancer
Pancreas	↑ Exocrine secretion	
	Mitogenesis of tumor cells	Pancreatic cancer
Hepatobiliary system	↓ Bile secretion	Cholestasis
	↑ Gallbladder motility	
	↑ Neurogenic inflammation	Hepatitis
		Hepatotoxicity
	Mitogenesis of tumor cells	Hepatoblastoma, cholangiocarcinoma
Urogenital system	↑ Motility of ureter and bladder	Urinary incontinence
	↑ Blood flow and motility of uterus	
	Renal vasodilatation	
	Placenta function	
	↑ Neurogenic inflammation	Abortus
	Mitogenesis of tumor cells	Endometrial adenocarcinoma
Musculoskeletal system	↑ Neurogenic inflammation	Arthritis
	↑ Blood flow to skeletal muscle	
	Mitogenesis of tumor cells	Osteosarcoma
Skin	↑ Neurogenic inflammation	Dermatitis, pruritus
	Mitogenesis of tumor cells	Melanoma

(*Continued*)

Table 1 Continued

Organ system	*Biological activity*	*Disease correlation*
Ocular system	↑ Neurogenic inflammation	Keratitis
	Mitogenesis of tumor cells	Retinoblastoma
Oral system	Nocicepcion	Dental pain
	↑ Neurogenic inflammation	Pulpitis
		Oral liquen planus
	Mitogenesis of tumor cells	Oral squamous cell carcinoma, keratocystic odontogenic tumor

SP increases the firing of striatal neurons and promotes the release of methionine-enkephalin, dopamine and acetylcholine; the peptide also controls the nigrostriatal dopamine release and, after infusion of SP into the substantia nigra, an increase in rearing, sniffing and grooming was reported. The administration of SP into the ventral tegmental area increased rearing and locomotion and its infusion into the nucleus accumbens exerted memory-promoting effects. In the amygdala, the level of SP was higher in males than in females and after castration the level of SP decreased. SP controls the release of anterior pituitary hormones (e.g., growth hormone, prolactin) and in the hypothalamus acts as an orexigenic substance, promoting gain.

Intra-cerebroventricular injections of SP in rats and mice induce a wide range of behavioral responses, including increased grooming and scratching (behavioral defense), increased hindlimb rearing, decreased aggressive behavior, an enhancement of inhibitory avoidance learning, anxiety and respiratory and cardiovascular responses (e.g., increase in blood pressure, heart rate, hindlimb vasodilation, and visceral vasoconstriction). Intra-arterial infusions of SP in humans result in a fall in diastolic blood pressure, an increase in heart rate, and an increase in cardiac output, due mostly to a greater stroke volume. The peptide is a powerful vasodilator in humans with high-dose (70 pmol/kg/min) infusions, producing a bright red flushing of the skin, particularly in the neck and face, with a subjective feeling of warmth. Intra-dermal injections of SP in humans produce flare, wheal, and itching that are related to the release of histamine and an increase in capillary permeability. An antipruritic effect has been reported when the NK_1 receptor antagonist aprepitant was administered.

In macrophages and eosinophils, the expression of both NK_1 receptors and SP is upregulated during the inflammatory processes. In these processes, SP is involved in the recruitment of leukocytes (e.g., eosinophils) and stimulates the synthesis of inflammatory cytokines by monocytes. In the gastrointestinal tract, the peptide facilitates the activation and recruitment of granulocytes and mast cells. SP promotes white cell endothelial adhesion and platelet aggregation (thrombus formation), vasodilation and increases capillary permeability and plasma extravasation. The peptide, acting on the NK_1 receptors located in the endothelial cells, augments in the intestine the blood vessel permeability, facilitating the extravasation of leukocytes and plasma proteins. Lymphocyte T cells express SP and the NK_1 receptor during infection/inflammation and the peptide controls the proliferation of these cells and the release of cytokines. SP, via the NK_1 receptor, promotes the release of cytokines and increases the cytotoxicity of the natural killer cells. SP also regulates the functional activity of neutrophils (e.g., release of cytokines, bacterial phagocytosis, and ROS generation).

In macrophages of the lung, hypoxia processes upregulated the expression of NK_1 receptors. This has been also observed in the same cells of smokers. In the rat, SP promotes the release of the endothelial growth factor/tumor necrosis factor-alpha by mast cells and the release of histamine from these cells after a stressful stimulus. In this rodent, immobilization stress promoted the release of SP in the medial nucleus of the amygdala, but the central administration of an NK_1 receptor antagonist blocked the stress-induced anxiogenic behavior.

SP and NKA coexist in extrinsic afferent neurons and in intrinsic enteric neurons. In the enteric nervous system, tachykinins are involved in the slow postsynaptic excitation, contributing to the communication between intrinsic primary afferent neurons and inhibitory motoneurons. The precise actions of SP on the motility of the gastrointestinal tract are species-dependent, but in vitro the peptide generally evokes a contractile response on tissues from all regions and in vivo is a strong stimulator of peristalsis by a mechanism that involves both a direct action on smooth muscle and a release of acetylcholine from cholinergic neurons. SP stimulates the secretion of water and electrolytes from the mucosa of the small intestine and colon of various mammals and produces an increase in short-circuit current in the guinea pig colon that is indicative of net ion transport across the tissue. In the human colon, the stimulation of the NK_1 receptor increased the mucosal ion transport. SP, released from the intrinsic primary afferent neurons of the myenteric and submucosal plexus, facilitated the secretion of chloride. In the jejunal mucosa of monkeys infected with the protozoan parasite *Cryptosporidium parvum* (induces a diarrheal disorder), the upregulation of both SP and the NK_1 receptor has been reported and this system is also involved in glucose malabsorption and increased secretion of Cl^-. The release of SP from afferent fibers innervating the stomach and gut and from intrinsic fibers of the submucous ganglia supplying submucosal arteries produces vasodilation, leading to an increase in blood flow in the mesenteric artery. A cytoprotective role for the gastric mucosa has been proposed for the SP released from primary afferent terminals.

Intra-arterial infusions of SP in dogs weakly stimulate basal output of pancreatic juice, amylase, and bicarbonate, whereas in the isolated rat pancreas, the peptide inhibits cholecystokinin-induced amylase release and secretin-induced flow and, at high concentrations, weakly stimulates the release of insulin, glucagon, and somatostatin. SP is also expressed in human sperm and, via

the NK_1 receptor, the peptide increased sperm motility. SP is also observed in the epididymis, stimulating the motility of the sperm. Prostate contraction is also mediated by the NK_1 receptor.

Pathophysiology and Disease

The involvement of SP in human disease is summarized in **Table 1**. A link between SP and nociception has been clearly established. Cerebral and pial arteries are richly innervated by SP fibers and it has been suggested that neurogenic inflammation within the cerebral tissues leading to the release of SP may be involved in the pathogenesis of acute migraine and cluster headaches. Both SP and the NK_1 receptor are upregulated in the inflammatory processes. Similarly, the inflammatory response to trauma in the eye may be due to a release of SP. Patients with reduced sensitivity to pain and temperature, as in Riley–Day syndrome, are associated with a marked depletion in the SP content of the medulla oblongata and substantia gelatinosa of the spinal cord. In mice, the genetic deletion of NK_1 receptors prevented mechanical hyperalgesia in the colon and NK_1 receptor antagonists reduced in the jejunum/colon of rodents the induced hypersensitivity to distension. In rodents, these antagonists also blunted the pancreatitis-evoked abdominal hyperalgesia. In rats, after an experimental cystitis or colitis, the expression of the NK_1 receptor was upregulated in the dorsal horn of the spinal cord. This also occurred in the pancreas (acute pancreatitis), in neurons of the spinal cord (chronic stress), and in the cingulate cortex (HIV-positive patients). In the latter patients, the level of SP was also increased in the blood and this peptide increased HIV replication in macrophages/mononuclear phagocytes; this mechanism being mediated by the NK_1 receptor.

An involvement of SP in the pathophysiology of neurodegenerative diseases is indicated by the significant decrease in the concentration of the peptide in the substantia nigra and globus pallidus of patients with Huntington's disease and Parkinson's disease. A similar decrease in the SP content in the cerebral cortex and hippocampus has been found in patients with Alzheimer's disease.

The deletion of the NK_1 receptor blocked stress symptoms induced by pain. In rodents, SP antagonists suppressed anxiety-related behaviors and mice with selective deletion of the gene encoding SP or the NK_1 receptor showed a decrease in such behaviors. The NK_1 receptor antagonists AV608 decreased pain ratings and anxiety in women with irritable bowel syndrome. In this syndrome, a decrease in the binding of an NK_1 receptor PET agonist was observed in the brain. Changes in the levels of SP and NK_1 receptors have been reported in schizophrenia and bipolar disorders. SP is also involved in acute brain injury; the peptide promoted the death of neurons and the development of vasogenic edema. SP also increased the immune response of glial cells.

In the periphery, a role for SP in the pathogenesis of rheumatoid arthritis is suggested by the observations that joints that develop severe arthritis are densely innervated by SP-containing fibers and concentrations of the peptide in synovial fluid are increased. NK_1 receptors are also found on synovial endothelial cells in patients with rheumatoid arthritis. In the serum, these patients also showed an increased level of SP. Thus, tachykinins derived from hyperactive afferent nerve endings in the arthritic joints may promote the chronic inflammatory processes.

In the gastrointestinal tract, SP-containing fibers are almost absent from the aganglionic colons of patients with Hirschprung's disease. In conditions of chronic inflammatory bowel disease, such as ulcerative colitis and Crohn's disease, there is an increase in the concentration of SP in the inflamed mucosa together with a marked increase in the expression of SP-selective NK_1 receptor sites in the arterioles and lymphatic tissue. In the mucosa of patients suffering from ulcerative colitis/Crohn's disease, the secretory response mediated by SP was blunted when NK_1 receptor antagonists were used. This action was also observed in rodents suffering from oesophagitis, colitis or pancreatitis when an NK_1 receptor antagonist was administered. The intestinal inflammation mediated by *Clostridium difficile* toxin A was also blocked when NK_1 receptor antagonists were used. NK_1 receptors are expressed in fibroblasts of patients with Crohn's disease and, in these cells, SP promoted the synthesis of collagen (fibrosis). In the intestinal inflammation, SP plays a dual action: promotes inflammation but also mediates repair (e.g., fibrosis, protects colonocytes from apoptosis). The increase in vascular permeability mediated by SP is amplified in inflamed tissue because the inflammation downregulated the activity of the neutral endopeptidase that control the level of the extracellular SP (in normal tissues, this endopeptidase maintains low the level of the extracellular SP, limiting its proinflammatory effect).

SP is a potent stimulator of histamine release from mast cells in the intestines of nematode-infected rats. In the pseudo-membranous colitis due to the infection with *Clostridium difficile* an overexpression of the NK_1 receptor has been reported. A decrease in the SP-innervation of the colonic circular muscle was observed in children suffering a slow transit constipation. In adult patients suffering from the same problem, the response of the colonic circular muscle to NK_1 receptor agonists was enhanced. NK_1 receptor antagonists inhibited stress-induced defecation and corrected the muscular hyperresponsiveness and hypomovility produced by pain, inflammation and anaphylaxis and also exerted antiobesity effects. It seems that SP, via the NK_1 receptor located in the adipose tissue, mediates obesity. Stress activates NK_1 receptors located in the intestine and spinal cord, leading to motility disorders, and hyperalgesia. After surgical manipulation of the intestine, fibrous adhesions occurred in the abdominal cavity. During this manipulation, SP, via the NK_1 receptor, promoted the formation of these adhesions, whereas NK_1 receptor antagonists decreased them.

In the airways, the SP/NK1 receptor system has been involved in allergic hyperreactivity. In the nasal secretion of coughing subjects, a high level of SP has been reported. In patients with cystic fibrosis, airway seromucous glands did not respond to SP, whereas in normal patients SP promoted an increased secretion.

SP, via the NK_1 receptor, is a mitogen in normal/cancer cells. The synthesis of SP in neoplastic tissue has been described for a range of neuroendocrine tumors. The peptide has been detected at relatively low concentrations in pheochromocytomas, medullary carcinomas of the thyroid, and small-cell lung carcinomas. Much higher concentrations are found in carcinoid tumors, particularly those arising in the midgut region and their metastases. It is generally accepted that the etiology of the marked cutaneous vasodilation and tachycardia seen in the carcinoid flush is multifactorial but SP (and other tachykinins) released by tumor tissue into the circulation has been implicated in some, but not all, patients. SP facilitates colitis-associated cancer (in which the NK_1 receptor is overexpressed) and the mitogenesis of cancer cell lines derived from human colonic and gastric adenocarcinomas. These actions were inhibited by NK_1 receptor antagonists. In a rat model of colitis-associated colon cancer, these antagonists decreased microscopic/macroscopic damages. An overexpression of the NK_1 receptor occurs in tumor cells in comparison with normal cells. In malignant tissues, the expression of the mRNA NK_1 receptor was higher than that found in benign tissues. It seems that the number of NK_1 receptors is related to the degree of malignancy. This means that a specific treatment (using NK_1 receptor antagonists, for example aprepitant which is a broad-spectrum anticancer compound) against cancer cells is possible. The safety of aprepitant is known: the IC_{100} for cancer cells is 60 μM but the IC_{50} for noncancer cells is 90 μM. In human trials, 300 mg/day of aprepitant was well tolerated. The NK_1 receptor has been observed in many human cancer cell lines (e.g., oral, gastric, colon and pancreatic carcinomas, neuroblastoma, glioma, melanoma, retinoblastoma, osteosarcoma, hepatoblastoma, and acute lymphoblastic leukemia). In these cells, the NK_1 receptor was observed in the plasma membrane and in both nucleus and cytoplasm. In tumor cells, SP via the NK_1 receptor, promotes (1) mitogenesis (the mitogen-activated protein kinase signaling (MAPK) pathway is activated (including p38MAPK and ERK1/2); upon activation, ERK1/2 is translocated into the nucleus inducing the proliferation of cells and promoting an anti-apoptotic effect; this requires the presence of the epidermal growth factor receptor); (2) cell migration (changes in cellular shape, including blebbing, which is crucial for cancer cell infiltration and metastasis); (3) angiogenesis (by increasing the mitogenesis of endothelial cells, the tumor blood flow is increased and this mechanism helps to the development of the tumor; in most tumors, a high density of SP and NK_1 receptors has been located in intra- and peri-tumor blood vessels); (4) the breakdown of glycogen (Warburg effect: tumor cells show a glycolytic rate up to 200 times higher than that of normal tissues or origin. SP facilitates the glycogen breakdown and the glucose obtained augments the metabolisms of tumor cells), and (5) an antiapoptotic effect (mediates by the formation of a β-arrestin-dependent scaffolding complex; NK_1 receptor antagonists increase apoptosis). All the above effects are blocked by NK_1 receptor antagonists. SP, via the NK_1 receptor, promotes the release of interleukins, taurine and glutamate from astrocytoma cells and increases the phosphorylation/activity of Akt (protein kinase B); this activation suppresses the apoptotic mechanisms. NK_1 receptor antagonists block the activity of Akt, inducing apoptosis. The immuno-blockade of SP induced cancer cell death and decreased the levels of both epidermal growth factor receptor 2 (HER-2) and EGFR. NK_1 receptor antagonists, in a concentration-dependent manner, induced the apoptosis of tumor cells and a synergic action against tumor cells has been reported for the combination of cytostatic drugs and NK_1 receptor antagonists. A synergy also occurs between ritonavir (blocks the HIV protease activity) but not acyclovir, cidofovir and maraviroc, and the NK_1 receptor antagonist aprepitant against human glioma cells. NK_1 receptor antagonists decrease the side-effects of both radiation therapy and cytostatics. In cancer cells, the NK_1 receptor is involved in the viability of these cells (tumor cells need the NK_1 receptor for their own survival and depend of the potent mitotic signal mediated by SP. The overexpression of NK_1 receptors in tumor cells neutralize their own pathways leading to cell death).

A clear relationship occurs between chronic inflammation and the risk to develop cancer. In both cancer and chronic inflammation, the SP/NK_1 receptor system is overexpressed. Cancer originates from chronically inflamed tissue (e.g., gastrointestinal tract) and patients suffering pancreatitis (in which the mRNA NK_1 receptor expression is upregulated) showed a high risk to develop pancreatic cancer. SP induces the proliferation, migration and invasion of gastric cancer cells, whereas NK_1 receptor antagonists exert an antitumor action against colon cancer stem cells and human pancreatic, gastric, colon, and hepatoblastoma cells.

SP is involved in viral infection, replication and proliferation (e.g., herpes virus, measles virus, respiratory syncytial virus, encephalomyocarditis virus, and human immunodeficiency virus) and NK_1 receptor antagonists exerted antiviral effects. The SP/NK_1 receptor system is also involved in severe bacterial infection (sepsis, meningitis), in colostasis/pruritus, in the control of alcohol intake (in the mouse, the deletion of the NK_1 receptor blocked alcohol consumption; this deletion also diminished the rewarding effect of opioids), in smoking (inhaled cigarette smoke promoted the release of SP leading to the neurogenic inflammation and an increase in the generation of ROS; the activation of the NK_1 receptor promoted the formation of ROS which was decreased by NK_1 receptor antagonists), in seizure and in neurodegeneration (NK_1 receptor antagonists may be a novel neuroprotective strategy).

In the bronchi of patients with asthma an increase in the expression of NK_1 receptor has been reported and these patients were hyperresponsive to SP. Airway epithelial cells expressed SP, the airway SP release is controlled by the nerve growth factor and corticosteroids downregulated the expression of the NK_1 receptor in airway myocytes. Increased levels of SP were reported in people attempting suicide, major depression, fibromyalgia, and schizophrenia. In the urinary bladder of patients with multiple sclerosis, an increased density of SP-immunoreactive fibers has been reported and it has been involved to the detrusor overactivity observed in these patients.

A wide range of antagonists (peptide and nonpeptide) for the NK_1 receptor have become available for potential use as therapeutic agents. In humans, NK_1 receptor antagonists (e.g., aprepitant, fosaprepitant) exert an antiemetic action by blocking the emetic reflex at the brainstem. Both antagonists are currently used in clinical practice for the prevention of postoperative vomiting and nausea and chemotherapy-induced vomiting and nausea. Moreover, in vitro and in vivo, both antagonists (in a concentration-

dependent manner) showed an antitumor action. In general, NK_1 receptor antagonists are selective, potent, well tolerated, and safe. In irritable bowel syndrome patients, the administration of mono-tachykinin receptor antagonists did not inhibit gastrointestinal pain, but the use of an antagonist (DNK333) showing affinity by the three tachykinin receptors increased the rate of satisfactory relief from abdominal pain and discomfort in women suffering diarrhea-predominant irritable bowel syndrome. The SP/NK_1 receptor system is involved in many pathologies in which this system is upregulated and hence NK_1 receptor antagonists could be used for the treatment of these pathologies. NK_1 receptor antagonists have different chemical compositions but they share their affinity for the NK_1 receptor. Peptides (e.g., SP) are released when cells are strongly activated and/or under pathological conditions. It seems that NK_1 receptor antagonists have not effect in normal conditions and they will only act on deranged systems with increased SP release. Pharmacological therapy may be exploited due to the many pathologies mediated by the SP/NK_1 receptor system.

Gastrin and Cancer

Gastrin is synthesized from its precursor, preprogastrin, processed into progastrin and gastrin peptide fragments by enzymatic cleavage. There are several forms of gastrin, the two major ones being G34 and G17. The final modification forms the mature gastrin peptide, or amidated-gastrin. Gastrin is synthesized and secreted mainly from gastrin-containing cells (G-cells) in the antral mucosa, and to a lesser degree from endocrine cells of the nonantral stomach, duodenum, jejunum, ileum, pancreas and outside the gastrointestinal tract (GIT) (e.g., in the brain, adrenal glands, respiratory tract, and reproductive organs). Gastric pH is a major determinant of gastrin secretion. Increased gastric acid in the stomach (during fasting) inhibits its release, whereas a high gastric pH (or meal digestion) provides a strong stimulus for its secretion. The G-cells are also regulated by two counterbalancing hormones, the stimulatory gastrin-releasing peptide, and the inhibitory somatostatin (Edkins, 1905; Rehfeld, 1998).

The receptors for gastrin and cholecystokinin (CCK) are related and constitute the "CCK/Gastrin receptor family.". Two classic types of receptors have been characterized: CCK-A receptor (previously CCK-1R), having affinity mainly for CCK, and CCK-B receptor (previously CCR-2R) which is the main receptor for gastrin. Both are classical G protein-coupled receptors. Gastrin activation of the CCK-B receptor, via the mitogen activated protein kinases (MAPK) pathways (including the ERK1/2 pathway), mediates cellular processes, including cell proliferation (partly through EGFR transactivation), and gastrin dependent genes transcription (Smith *et al.*, 2016). CCK-B receptors are highly expressed in different cancer tissues, including gastric, pancreatic, colon, and lung carcinomas.

Gastrin is the major regulator of gastric acid secretion. The acid-secreting parietal cell possesses receptors for acetylcholine, histamine (secreted from ECL cells), and gastrin, all of which being able to stimulate acid secretion. The ECL cell also receives stimulatory signals from gastrin, to secrete histamine, which in turn also stimulates the parietal cell (Hersey and Sachs, 1995; Sachs and Prinz, 1996).

Gastrin is an important growth factor for the GIT development (Smith *et al.*, 2017). Studies in the past decades have focused on evaluating the proliferative effect of gastrin (and its precursors), and their role in cancer development. Hypergastrinemia is observed in patients with atrophic gastritis, pernicious anemia, Zollinger–Ellison syndrome (and gastrinoma), and in patients treated with proton pump inhibitors (Hayakawa *et al.*, 2016).

In the stomach, elevated gastrin levels are known to increase the risk for ECL cell hyperplasia, and rarely the development of neuroendocrine tumors (NETs) (mainly in patients with genetic background) (Hayakawa *et al.*, 2016). Gastrin was also associated with increased risk of gastric adenocarcinoma localized in the corpus of the stomach, and with a worse prognosis (Fossmark *et al.*, 2015). Hypergastrinemia has been associated with increased risk for colon cancer and pancreatic cancer, however studies in both animals and humans suggest that gastrin is not mutagenic by itself, but rather increases the risk in subjects with precancerous lesions or high risk genetic mutations, by its pro-proliferative effect. With the wide use of gastric acid suppressing proton pump inhibitors (PPIs), it has been speculated that the elevation of serum gastrin caused by these medications could increase the risk of pancreatic cancer and other cancers arising from tissues with CCK receptors. In large population studies of patients with *Helicobacter pylori* infection, those with elevated gastrin levels had a fourfold increase in colorectal cancers (Thorburn *et al.*, 1998), but other conditions characterized by elevated gastrin concentrations levels such as atrophic gastritis, pernicious anemia and Zollinger–Ellison syndrome did not result in gastrointestinal adenocarcinomas, implying the need of an additional carcinogenic factor such as APC gene or precancerous colonic polyps to trigger carcinogenesis (Smith *et al.*, 2016; Thomas *et al.*, 2003).

In the fetal pancreas, gastrin is thought to have a role in the growth and differentiation of the GIT. It becomes silenced after birth, but reappears in premalignant pancreatic lesions, and in pancreatic cancer cells stimulating growth in an autocrine mechanism, while inducing its own transcription by activating the CCK receptor. This process of re-expression is thought to be mediated by micro-RNAs. There is also a significant increase in CCK-B receptor expression in the cancer cells, compared to the normal pancreas. Several mutations of the receptor have been described. One variant of mutated receptor, with alternative splicing of the forth intron, inducing the addition of 69 amino acids in the receptor site involved in cell proliferation signaling, has been termed CCK-C receptor (CCK-cancer). Downregulation of the mutant receptors was shown to inhibit growth (Smith *et al.*, 2004). It is estimated that the CCK-C receptor is present in about 40% of patients with pancreatic carcinoma, and is probably associated with worse prognosis, even without elevated gastrin levels (Smith *et al.*, 2015). The germline mutation of the specific receptor is

☆*Change History:* April 2018. Inbal Uri, Kristallenia Alexandraki, Simona Grozinsky-Glasberg updated the literature on each hormone, and added for each hormone the possible therapeutic implications.

This article is an update of Andrew D. Gilliam and Susan A. Watson, GI Hormones in Cancer, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 189–193.

found in other cancers. On the other hand, when gastrin expression is downregulated with RNA interference in human pancreatic cancer cells, growth of the primary cancer is inhibited and metastases do not occur.

The CCK receptors have been described also outside the GIT, for example, in small cell lung cancer, with CCK-B receptor having the main involvement in malignant cell proliferation, partially via an EGFR dependent manner (Smith *et al.*, 2016).

Since gastrin was shown to stimulate the growth of several malignancies, there have been attempts to decrease gastrin's proliferative activity, by targeting the gastrin molecule, or blocking the interaction with the CCK-BR (Smith *et al.*, 2017).

Therapeutic Implications

- *Blockade of CCK receptors*—Several antagonists for the CCK-B receptor have been developed, with high potency in preclinical studies for reversal of tumor cell growth. Netazepide (YF476) is evaluated in patients with type 1 gastric NETs (Boyce *et al.*, 2017), Gastrazole (JB5008) and Z-360 have been used in patients with pancreatic cancer (Chau *et al.*, 2006; Meyer *et al.*, 2010), both with preliminarily good results, but further studies are needed. Ceclazepide (TR2-A) is a new benzodiazepine derived CCK-B receptor antagonist, in preclinical development (Boyce *et al.*, 2016).
- *Polyclonal antibody stimulator (PAS)*—An immunogen containing 9-amino acid epitope from the aminoterminal sequence of gastrin-17, in conjugation with diphtheria toxoid, formerly called G17DT or gastrimmune, elicits the production of antibodies directed to gastrin-17 and gly-gastrin. In animal models it was shown to decrease tumor growth and metastases. Several clinical trials have been conducted, in patients with gastric carcinoma, pancreatic carcinoma, colorectal cancer, and type 1 gastric NET, with survival benefit in patients demonstrating good antibody titer response (Smith *et al.*, 2017; Rocha-Lima *et al.*, 2014; Gilliam *et al.*, 2012; Tieppo *et al.*, 2011).

Gastrin-Releasing Peptide (GRP)/Bombesin and Cancer

Bombesin is a 14-amino acid peptide, isolated from the skin of the frog *Bombina bombina*. Two mammalian bombesin-related peptides and their receptors were described, involved in physiological and pathophysiological processes. Gastrin-releasing peptide (GRP) is a 27-amino acid peptide, processed from preproGRP, a 148-amino acid peptide; neuromedin-B (NMB), is a decapeptide, processed from preproNMB, a 76-amino acid precursor.

There are three receptors in the bombesin-receptor family; NMB-receptor (NMBR)-bombesin-receptor subtype 1 (BRS-1), GRP-receptor (GRPR)-bombesin-receptor subtype 2 (BRS-2), and bombesin-receptor subtype 3 (BRS-3), with its natural ligand yet unknown.

The bombesin-related peptides are secreted from many tumors, and function as autocrine growth factors, activating their own receptors on the tumor cells. They were found to stimulate the growth and differentiation of tumor cells, mediated by transactivation of tumor EGFR or HER2. GRPR is overexpressed by tumors of the prostate, breast, colon, small cell and nonsmall cell lung carcinoma, head and neck squamous cell tumors, pancreas, gliomas, meningiomas, and neuroblastomas. NMBR is overexpressed by tumors of the lung, pancreas, colon, bronchial and intestinal NETs. BRS-3 is also expressed by tumors of the lung, pancreas, pituitary, ovary, prostate and neuroendocrine tumors (NETs) (Moreno *et al.*, 2016).

There is great interest in using bombesin analogues for imaging of tumors expressing BnRs, similarly to what is widely used today with somatostatin analogues in NETs expressing somatostatin receptors. In the past, only BnR agonists were used, assuming there is major role for the internalization if the ligand, for optimal response. However, recent studies showed similarly good results using BnR antagonists (Strosberg *et al.*, 2017; Sancho *et al.*, 2011).

Therapeutic Implications

- *Bombesin-receptor (BnR) antagonists*, mainly for GRPR, have been studied and showed effect on the growth of several tumors. However, a phase 1 trial of GRPR antagonist (RC-3095) in 25 patients with solid tumors, failed to show any objective response (Schwartsmann *et al.*, 2006; Kelley *et al.*, 1997).
- A novel approach is the combination of BnR antagonists with other cytotoxic agents, with promising results, however with increased toxicity. For example, the combination of BnR antagonist with EGFR antagonist have potentiating effect on tumor growth in head and neck squamous cell cancers, medulloblastoma and lung cancer (Moody *et al.*, 2016a); the combination of GRPR antagonist with 5-FU in colon cancer produce greater inhibition of growth (Rick *et al.*, 2012).
- BnR ligands have also been coupled to several compounds and cytotoxic agents, used together to deliver the drugs to the BnR overexpressing tumor cells. These include coupling of BnR agonists or antagonists to the radioisotopes Y90 or Lu177 (Reynolds *et al.*, 2016), coupling to chemotherapeutic agents like doxorubicin (Wang *et al.*, 2016), coupling to gold nanoparticles (Hosta-Rigau *et al.*, 2010; Chanda *et al.*, 2010), cytotoxic toxins (Moody *et al.*, 2008), agents that activate the immune system (Zhou *et al.*, 2006), and other agents.

- Another approach receiving increasing attention is silencing of the BnR using small interfering (si) RNA, which may be delivered to the tumor cells by conjugation to BnR ligands, showing promising results in ovarian cancer cells, neuroblastomas, prostate cancer cell lines, and others (Rellinger *et al.*, 2015; Langer *et al.*, 2002; Fang *et al.*, 2009).

Somatostatin

Somatostatin is a tetradecapeptide (somatostatin-14) acting through five different somatostatin receptor (SSTR) subtypes 1,2,3,4 and 5. Different receptor subtypes are coupled to different intracellular transmission cascades in a cell type-dependent manner. Somatostatin has been detected in the nerves and cell bodies of the central and peripheral nervous systems, including the autonomous nervous system of the GIT and the D cells (the majority) of the pancreas and mucosa of the stomach and intestine. Somatostatin is an inhibitory regulator peptide, and considered as the universal endocrine switch off-hormone (Thomas *et al.*, 2003). Somatostatin inhibits the release of GH and somatomedin C and all known GI hormones as well as the gastric acid secretion and gut's motility, intestinal absorption, and pancreatic bicarbonate and enzyme secretion, and selectively decreases splanchnic and portal blood flow. Somatostatin may exert cytostatic (G_1-phase cell arrest) or cytotoxic (apoptosis induction) effects, depending on the receptor subtype expressed on the target cell, inhibiting the growth of normal and neoplastic tissues. Hence, somatostatin inhibits the growth of the GI mucosa and normal pancreas indirectly by inhibiting trophic hormones or directly through interaction with the SSTR2. Because of the short half-life of somatostatin and the need of continuous intravenous infusion, long-acting somatostatin analogues (SSAs) were developed such as octreotide long-acting release (LAR) and lanreotide autogel targeting mainly SSTR2 and less SSTR5 and SSTR3 receptor subtypes, while pasireotide targets mainly SSTR5 and less SSTR1, SSTR3 and SSTR2. SSAs can be used as first line antiproliferative treatment in patients with slow growing gastro-entero-pancreatic (GEP)-NETs (Alexandraki *et al.*, 2017). Octreotide is useful to ameliorate symptoms associated with hormonal-over-producing tumors such as intractable diarrhea in the case of carcinoid syndrome, in the management of inoperable bowel obstruction, pancreatic and enterocutaneous fistulas. Side effects of these agents consist mainly of gastrointestinal complaints, cholelithiasis, and effects on glucose metabolism (Grozinsky-Glasberg *et al.*, 2008).

Moreover, radiolabeled SSAs have been employed for the localization of primary and metastatic tumors expressing SSTR, as a diagnostic tool but its use as treatment with radiopharmaceuticals known as peptide receptor radionuclide therapy (PRRT) is a promising therapy in tumors expressing SSTR.

Therapeutic Implications

- Somatostatin may inhibit cell proliferation in the mucosa of the normal GIT and antagonize the trophic activity of gastrin, particularly in the fundus and antrum of the stomach. An inhibitory effect of somatostatin in the jejunum and ileum has been also suggested, and apparently blocking endogenous somatostatin allowed increased proliferation of the normal pancreas (Thomas *et al.*, 2003).
- Clinical trials have been performed to assess SSAs effects in the growth of endocrine and nonendocrine cancers. Despite their beneficial role for the former tumors (on both hormonal hypersecretion and tumor growth), their role on the latter cancers is equivocal with rather negative results. However, the discovery of new SSAs may suggest encouraging results for a somatostatin-directed therapy (medical or radiopeptide) when the presence of SSTR is documented (e.g., in prostate or breast cancer, with neuroendocrine features) (Wachter *et al.*, 2014; Surcel *et al.*, 2015).

Cholecystokinin (CCK)

Cholecystokinin (CCK) is a peptide related to gastrin, normally produced in the I-cells of the duodenum. Its physiologic activities include inducing gallbladder contraction, enhancing the secretion of pancreatic enzymes, increasing bowel motility, and inhibiting gastric emptying, as well as trophic effects on the pancreas and GI mucosa; both gastrin and CCK are the ligand of the CCK receptor (Smith *et al.*, 2016; Thomas *et al.*, 2003).

As mentioned above, two classic types of CCK receptors have been cloned and characterized, CCK-A receptor predominant type in the normal murine pancreas (previously known as CCK-1R) and CCK-B receptor (previously known as CCK-2R) predominant type in the normal human pancreas (Smith *et al.*, 2016).

CCK receptor is markedly overexpressed in pancreatic cancer. As it was mentioned earlier for gastrin, similarly CCK is not mutagenic, but both may increase cancer risk when they display high concentrations in a subject with a precancerous lesion such as a pancreatic intraepithelial neoplasia and a KRAS mutation (Carriere *et al.*, 2009). Moreover, high CCK blood levels from dietary fat have been shown to promote the growth of pancreatic cancer in animal models; subjects with chronic pancreatitis have elevated CCK blood levels and increased risk for pancreatic and other cancers that possess CCK receptors. In 74% of surgical specimens from human pancreatic cancer high levels of α-amidated gastrin and its precursor were detected while CCK was not (Goetze *et al.*, 2000). At the contrary, CCK immunoreactivity was reported in some pancreatic cancer surgical specimens but tumor production of

CCK did not influence growth of the tumor. Summarizing, both CCK and gastrin peptides may be present in malignant tissue but only the re-expression of endogenous gastrin stimulates pancreatic cancer growth by an autocrine mechanism (Smith *et al.*, 2016).

Gastrin or CCK-stimulated cancer growth was found to be mediated only through CCK-B receptor. CCK-C receptor as mentioned before has been reported in up to 40% of patients with pancreatic cancer and its presence was associated with a more aggressive course with shortened survival. Downregulation of the CCK-B receptor in pancreatic cancer cells results in apoptosis and halts cell proliferation by interference with intracellular signaling. CCK receptors have been described in other GI malignancies including gastric cancer and colon cancers as well as outside the GIT, with abundant expression of both CCK-A and CCK-B receptors in lung cancer (Staley *et al.*, 1990, 1989).

Therapeutic Implications

- Before the documentation that CCK-B receptor isotype is the main mediator of cancer growth a CCK receptor antagonist failed to demonstrate a clinical benefit for advanced pancreatic cancer, but the specific factor was a CCK-A receptor antagonist (Abbruzzese *et al.*, 1992). Hence, netazepide (YF476) has been developed and used to treat patients with type 1 gastric NENs. Moreover, a nonselective CCK receptor antagonist, proglumide, arrested the progression of pancreatic intraepithelial neoplasias in an animal model implying that selective CCK receptor antagonists may prevent pancreatic cancer development in high risk subjects (Smith *et al.*, 2016, 2014).

Neurotensin (NT)

NT is a tridecapeptide localized in the central nervous system (predominantly hypothalamus and pituitary, involved in the regulation of luteinizing hormone and connected to the dopaminergic system), and in endocrine cells of the jejunal and ileal mucosa (Thomas *et al.*, 2003; Galoian and Patel, 2017). In hypothalamus it induces multiple effects, such as hypothermal and increased locomotor activity, whereas in the intestine it supports smooth muscle contraction in the small intestine.

NT act through NT receptor (NTR) and is released in response to increased intraluminal fats, with numerous functions in the GIT, including stimulation of pancreatic and biliary secretion, inhibition of gastric and small bowel motility, facilitation of fatty acid translocation from the intestinal lumen, and growth of the gastric antrum (minimal effect), small bowel (pronounced effect), colon (medium effect), and pancreas (Smith *et al.*, 2016). NT is produced from preproneurotensin that contains both NT 1–13 and the related peptideneuromedin N. Neuromedin N comprises the C-terminal portion of the proneurotensin peptide after NT is removed. NT 1–13, the major product of proneurotensin in the ileum and brain, is cleaved in the inactive NT 1–8 and the biologically active NT 9–13. On the other hand, substance P, muscarinic agonists (carbachol), catecholamines, and BBS/GRP stimulate NT release.

NT has been shown to contribute to carcinogen-induced gastric cancer in animal models (Thomas *et al.*, 2003). NT stimulates pancreatic cancer proliferation as shown in human pancreatic cell lines while 75%–90% of pancreatic adenocarcinomas expressing NTRs. NT is considered a cancer promoting mitogen in colon cancer, stimulating growth of certain human colon cancer cell lines expressing high levels of NTRs both in vitro and in vivo. Since intraluminal fat is a potent stimulus for NT release, an etiologic association between fat and colon carcinogenesis may imply a role for NT, which increases colon cancer proliferation.

Lastly, NTS/NTSR also shows potential of being utilized as a diagnostic biomarker for cancers as well as targets for functional imaging.

Therapeutic Implications

Blockade and modulation of the NTS/NTSR signaling pathways appears to reduce colorectal cancer growth in cell cultures and animal studies (Qiu *et al.*, 2017).

- A possible role for NT was suggested for lung carcinomas, as seen in small cell lung carcinomas (SCLC) cell lines and confirmed by a beneficial effect of a NTR antagonist.
- NT stimulates also the proliferation of prostate cancer cells, particularly through the NTR subtype NTR 3, during conditions of prostate cancer androgen insensitivity, providing support for the potential use of NTR antagonists as potential therapy for a subset of prostate cancers that continue to grow after androgen withdrawal.

Ghrelin

Ghrelin, a 28-amino-acid peptide, is the natural ligand for the growth hormone secretagogue receptor (GHS-R). It is secreted mainly from the stomach and duodenum, however lower amounts are found in the pancreas, pituitary, kidney, and placenta. A

limited region of the arcuate nucleus of the hypothalamus contains small amounts of ghrelin (Kojima *et al.*, 1999; Korbonits *et al.*, 2004).

The ghrelin receptor (GHS-R) is a member of a G protein-coupled receptor. Two forms of the receptor exist, GHS-R1a that modulated most physiologic actions of ghrelin, and GHS-R1b that has been regarded as a nonfunctional receptor. In the brain, GHS-R1a expression is highest in the hypothalamus, but it is also found in the dorsal motor nucleus of the vagus and parasympathetic preganglionic neurons. In peripheral tissues, GHS-R1a is found in the anterior pituitary, islet cells of the pancreas, thyroid, adrenal glands, and heart (Müller *et al.*, 2015; Muccioli *et al.*, 2007; Leung *et al.*, 2007).

Ghrelin has many physiological functions, including hormonal secretion regulation (of GH, ACTH, prolactin, gonadal hormones), energy balance, motility and secretion of the GIT and the pancreas, etc.

Ghrelin and its receptors were found to be expressed in malignant tumors of the kidney, pancreas, thyroid, lung, breast, prostate, ovary, stomach, colorectal cancer, and pituitary adenoma, and in distant metastases (Lin and Hsiao, 2017). On one hand, ghrelin was found to promote tumor proliferation through several signaling pathways, including the PI3K/AKT/mTOR (through phosphorylation of AKT and mTOR), Ras/RAF/ERK, JAK/STAT, and Src kinase (Zhu *et al.*, 2017). On the other hand, also antiproliferative effects have been reported.

- The PI3K/AKT/mTOR signaling pathway activation is associated with the development and progression of GISTs, suggesting ghrelin has a role in the pathogenesis of these tumors (Zhu *et al.*, 2017).
- Ghrelin was shown to promote pancreatic cancer cell migration and invasion via the GHRS/PI3K/Akt pathway activation, which is blocked by ghrelin receptor antagonist.
- Similar influence is observed with colorectal cancer cells.
- In renal cell carcinoma patients, ghrelin was found to be an independent predictor in correlation with poor prognosis and metastatic disease (Lin and Hsiao, 2017). In breast-cancer cell lines ghrelin inhibits proliferation. There is increased ghrelin expression in well differentiated, compared with poorly differentiated breast cancer, and ghrelin expression was found to be correlated with better prognosis (Grönberg *et al.*, 2017).

The role of ghrelin as promoter or inhibitor of cancer is not fully clear, and it differs between cancers. Suggested theory is that some actions are mediated through other unknown receptor subtypes. Exploring the possible antiproliferative effect of ghrelin analogues or antagonists, will require characterization of individual tumors, and personalized approach.

Glucagon Like Peptide-2 (GLP-2)

GLP-2 belongs to the glucagon superfamily of peptides, with the shared precursor proglucagon. They are expressed in the nervous system (central and peripheral), pancreas and intestine. Proglucagon undergoes different posttranslational processing in different cell type, by tissue specific enzymes. While glucagon and GLP-1 have a role in glucose metabolism, GLP-2 mainly enhances cellular proliferation.

The GLP-2 receptor is a G-protein coupled receptor, expressed in the hypothalamus, brainstem, lung, and GIT. GLP-2 is secreted from the intestinal L-cells, and was shown to act in an autocrine mechanism, by binding to its receptor on the L-cells, and stimulating its own secretion. The receptor binding initiates the PI3K/AKT/mTOR pathway, and also ligands for ErbB and its related signaling pathway, enhancing intestinal growth. There is also an association with increased IGF-1 activity; IGF-1 increased GLP-2 receptor expression, and GLP-2 increased IGF-1 receptor expression.

GLP-2 was shown to improve intestinal wound healing through the transforming growth factor β (TGF-β) pathway, to stimulate proliferation of colon cancer cell lines, and to induce vascular endothelial growth factor (VEGF) and TGF-β1 (Kannen *et al.*, 2013).

A systematic review assessing the potential risk of intestinal neoplasia in patients receiving treatment with GLP-2, did not confer an increased risk of intestinal neoplasia in patients or animals, but a small number of patients was studied. However, GLP-2 treatment was shown to promote tumor growth, in animals with a preinduced cancer (Ring *et al.*, 2017).

Therapeutic Implications

- Therapies targeted at the tumor signaling pathways, like multiple tyrosine kinase inhibitors, increased survival of patients with colorectal carcinoma, when combined with chemotherapy. This is the rational for blocking the GLP-2 activity and its related signaling pathways, by using antibodies against GLP-2 or its receptor, or targeting the prohormone convertases involved in proglucagon cleavage.
- Another suggested use of GLP-2 in the treatment of colon cancer, is as a chemosensitizer, by increasing IGF-1 expression and promoting the cancer cells toward proliferation, making them more susceptible to chemotherapy (Kannen *et al.*, 2013).

Vasoactive Intestinal Peptide (VIP)

VIP is produced by various cells, but its primary location is within neurons; this peptide is expressed in the peripheral and central nervous systems, as well as in certain tumors. VIP shares 68% homology with pituitary adenylate cyclase activating polypeptide (PACAP) as a member of secretin-glucagon-VIP peptide family.

Its biologic actions are mediated through the members of the class II/class-B secretin-like receptors VPAC1, VPAC2, PAC1. VIP-receptors have been found in 60% of lung-carcinoma-cells, with VIP, pro-VIP and COOH-terminal-extended forms frequently found (Vona-Davis and McFadden, 2007). Both VIP- and PACAP-receptor antagonists inhibit the growth of SCLC-cells, while a VIP-analog acting as antagonist inhibited lung cancer growth and had synergistic inhibitory-effects with chemotherapeutic agents.

Breast-cancer cells have VIP/PACAP receptors in up to 100% of cases and have high densities of VPAC1 and its mRNA, and VPAC1, VPC2, and PAC1 are reported in breast-cancer tumors. Furthermore, the addition of a VPAC inhibitor to various breast-cancer cell lines, potentiated the ability of taxol to inhibit proliferation.

VIP/PACAP receptors are present in 88%–100% of prostate cancers, each of the three subtypes are found in different studies, however the predominant subtype is VPAC1 as opposed to normal prostate tissue in which for the PAC1-receptor predominates.

VIP/PACAP receptors are reported in 96% of colon adenocarcinoma and specifically, 35% of well-differentiated had VPAC1, 65% of moderately differentiated and 87% of poorly differentiated tumors.

PAC1 receptors were present in 81%–100% in various human gliomas, and in 20% of meningiomas VPAC1 and VPAC2 receptors were also found in glioma cell lines, with the VPAC1-receptor localized strongly to the nucleus, and there was a positive correlation between the degree of VPAC1 nuclear localization and glioma grade.

Almost all neuroblastoma tumor cells possess at least one of the VPAC/PAC-receptors, with VPAC1-receptors reported in 60%–100%, VPAC2 in 31% and PAC1 in 60%–100%. Both VIP/PACAP have an effect on the growth/differentiation of various neuroblastoma tumor cells along with the induction of the differentiation and neuritogenesis.

Pancreatic ductal cancer was found to express in approximately 65% VIP/PACAP receptors. VIP hypersecretion by neural tumors such as ganglioblastomas/neuroblastomas in children or by pancreatic-tumors (VIPomas), causes Verner–Morrison syndrome characterized by large volume watery diarrhea, hypokalemia and achlorhydria. VIPoma cells express both VPAC1 and VIP, raising the possibility of an autoregulatory effect on the tumor cells.

The overexpression of VPAC/PAC receptor has been studied in other tumors such as pheochromocytomas, neuroendocrine tumors, choriocarcinoma and gastric, cervical or renal cancers (Moody *et al.*, 2016b).

Peptide YY (PYY)

PYY is a 36-amino-acid peptide, synthesized as prepropeptide, homologous to pancreatic polypeptide (PP) and neuropeptide Y (NPY). PYY co-localizes with glucagon and glucagon-like products within endocrine L-cells of the intestinal mucosa and to a lesser extent in alpha cells of the pancreas. PYY inhibits small bowel fluid and electrolyte secretion, contraction of the gallbladder, gastric emptying and intestinal transit, regulating gastrointestinal motility, while it stimulates the proliferation of small bowel and colonic mucosa (Thomas *et al.*, 2003), acting on the gut and pancreas by regulating growth, digestion and absorption (Vona-Davis and McFadden, 2007).

Experiments in human pancreatic cancer cell lines with PYY analogs, showed that PYY, can inhibit pancreatic cancer growth but it was not determined whether the pancreatic cancers express receptors for PYY (Tseng and Liu, 2002).

Therapeutic Implications

- While decreased expression of PYY seems to be relevant to the development and progression of colon adenocarcinoma, the treatment with PYY decreases growth in pancreatic and breast tumors, most likely through a reduction in intracellular cAMP (Baldassano *et al.*, 2017).
- Synthetic analogs of PYY have been developed that are potent inhibitors of the proliferation of pancreatic cancer along with improving of the patients' nutritional status and have been studied as hormonal adjunct in the chemotherapy of pancreatic adenocarcinoma (Vona-Davis and McFadden, 2007).

Somatostatin Receptor Expression in Gastrointestinal Tumors

Eleftherios Chatzellis, 251 Hellenic Air Force and VA Hospital, Athens, Greece
Gregory Kaltsas, National and Kapodistrian University of Athens, Athens, Greece

Glossary

Cyclic AMP (cAMP) Adenosine-3′,5′-cyclic monophosphate, a derivative of adenosine triphosphate (ATP), is a second messenger important for intracellular signal transduction.

Immunohistochemistry The staining of cells in vitro with antibodies raised against unique antigens contained in or on the cell surfaces.

Neuroendocrine neoplasms (NENs) Tumors that originate from endocrine cells in endocrine organs (pituitary, thyroid, pancreas) or from neuroendocrine cells in disseminated endocrine tissues such as lung or gastrointestinal system. They often secrete high levels of biologically active hormones or neurotransmitters that produce characteristic symptoms and disease.

Reverse transcription polymerase chain reaction (RT-PCR) A variant of polymerase chain reaction (PCR) is a technique commonly used in molecular biology to detect RNA expression.

Introduction

Somatostatin (SST) was discovered almost half a century ago (Brazeau *et al.*, 1973), after being isolated from rat hypothalamic extracts and was named from its ability to inhibit pituitary growth hormone (GH) release (somatotropin release-inhibiting factor). Soon it was realized that this cyclic oligopeptide hormone is abundantly distributed, exhibiting various physiological actions, such as inhibition of hormone secretion by the pituitary gland (not only GH but also adrenocorticotropic hormone, prolactin, and thyroid stimulating hormone (TSH)), inhibition of insulin and glucagon secretion by the endocrine pancreas, inhibition of motility and exocrine secretion in the gastrointestinal tract, regulation of motor, cognitive, and sensory functions in the central nervous system and pain transmission in the peripheral nervous system (Reubi and Schonbrunn, 2013). Due to its broad antisecretory potency, SST was used early on to treat patients with hormone-producing tumors such as pituitary adenomas, neuroendocrine neoplasms (NENs) causing carcinoid syndrome, and islet-cell pancreatic tumors (insulinomas, gastrinomas, and glucagonomas), even before its mechanism of action was elucidated.

In humans, SST exists in two forms, 14 and 28 amino acids in length, generated by alternative proteolytic processing from a single precursor (pre-prosomatostatin) which is encoded by a gene on chromosome 3. It was also the first human peptide to be produced by bacterial recombination (Itakura *et al.*, 1977), but the short half-life (<3 min) of the native hormone was one of the main reasons limiting its routine clinical use. Production and commercial availability of somatostatin analogues (SSAs) resistant to degradation, with extended half-life (octreotide, lanreotide, and pasireotide) particularly in their long acting formulations that facilitated monthly administration (octreotide and pasireotide LAR, lanreotide autogel), considerably expanded their application in clinical practice (**Fig. 1**).

SST Receptors and Signaling

SST and its analogues exert their action by binding to somatostatin receptors (SSTRs) which belong to the seven-transmembrane domain G-protein-coupled receptors superfamily. Five distinct SST receptor genes, named sstr1 to sstr5, were cloned and located in chromosomes 14, 17, 22, 20, and 16, respectively (Hoyer *et al.*, 1995). The sstr2 gene protein product can be alternatively spliced to generate two receptor proteins, SSTR2A and SSTR2B, which differ in length (SSTR2B is shorter) and their cytoplasmic carboxy-terminal sequences (Vanetti *et al.*, 1992). Human tissues contain the SSTR2A variant almost exclusively, whereas both forms have been identified in rodents. SSTR5 also exists as truncated isoforms with four or five transmembrane domains (sst5TDM4 and sst5TDM5) (Duran-Prado *et al.*, 2009); distribution and physiological functions of truncated SSTR5 variants are not yet known, but they have been linked with pituitary tumor resistance to SSA treatment (Cordoba-Chacon *et al.*, 2011) and pancreatic NEN (pNEN) aggressiveness (Sampedro-Nunez *et al.*, 2016). Native SST has high affinity for all SSTR types; however, the available synthetic SSAs show restricted affinity profiles. Octreotide and lanreotide have high affinity for SSTR2 and low affinity for SSTR3 and SSTR5. Pasireotide (SOM230) displays a broader affinity spectrum with higher affinity for SSTR5 and to a lesser extent for SSTR1, SSTR2, and SSTR3, while multireceptor ligands with high affinity for all five known SSTRs have been produced such as KE108 (**Table 1**).

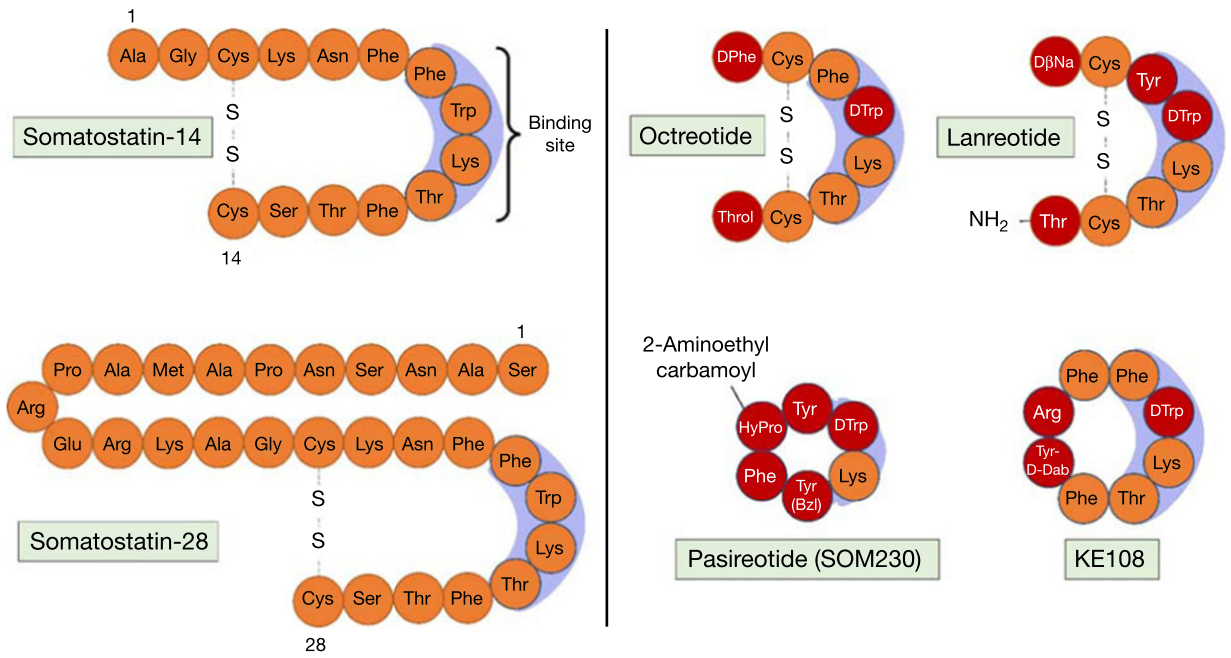

Fig. 1 Amino acid structures of native somatostatin (SS-14 and SS-28) and the somatostatin analogues discussed.

Table 1 Affinity of native somatostatin and its analogues for different SSTR subtypes

Ligand	*Binding affinity for each SSTR (IC_{50}, nM)*				
	SSTR1	*SSTR2*	*SSTR3*	*SSTR4*	*SSTR5*
Somatostatin 14	2.26	0.23	1.43	1.77	0.88
Somatostatin 28	1.85	0.31	1.3	ND	0.4
Octreotide	1140	0.56	34	7030	7
Lanreotide	2330	0.75	107	2100	5.2
Pasireotide	9.3	1	1.5	>100	0.16
KE108	2.6	0.9	1.5	1.6	0.65

Lower values represent higher affinity. Data were obtained from membrane-binding studies using cells transfected with individual receptor subtypes and may depend on the conditions of the assay used. *ND*, not determined.

Modified from Grozinsky-Glasberg, S.; Shimon, I.; Korbonits, M.; Grossman, A. B. Somatostatin Analogues in the Control of Neuroendocrine Tumours: Efficacy and Mechanisms. Endocr. Relat. Cancer 2008, 15, 701–720; Veenstra, M. J.; De Herder, W. W.; Feelders, R. A.; Hofland, L. J. Targeting the Somatostatin Receptor in Pituitary and Neuroendocrine Tumors. Expert Opin. Ther. Targets 2013, 17, 1329–1343.

Binding of a SST ligand to SSTRs leads to intracellular activation of different second messenger pathways resulting in inhibition of hormone secretion and tumor growth (Fig. 2). The antisecretory action of SSTRs is mediated by coupling to Gi/Go proteins, which subsequently leads to inhibition of adenylyl cyclase and reduction of cyclic AMP (cAMP). In addition, activation of the Gi/Go reduces intracellular calcium by inhibiting calcium channels directly and indirectly by opening potassium channels which results in membrane hyperpolarization and inhibition of calcium influx through voltage-dependent calcium channels (Patel, 1999). The simultaneous reduction of both second messengers (cAMP and calcium) by SST results in a synergistic inhibitory effect on hormone exocytosis. The antiproliferative effect of ligand-activated SSTRs results from activation of protein tyrosine phosphatases that induce growth arrest through inhibition of mitogen-activated protein kinase and apoptosis via induction of p53 and Bax (Pyronnet *et al.*, 2008; Sharma and Srikant, 1998). There are also indirect antiproliferative effects of SSTR activation, through inhibition of secretion of paracrine growth factors and trophic hormones, inhibition of angiogenesis, and modulation of the immune system (Woltering, 2003).

Following ligand activation, SSTRs are phosphorylated and β-arrestins are recruited leading to uncoupling of the receptor from the second messenger pathway, thereby interrupting signaling. Subsequently, the receptor–ligand complex can be internalized, and the receptor can then relocate to the cell membrane (recycling), or enter lysosomal degradation. For each receptor subtype, this trafficking process is different. The internalization of the SSTR2, SSTR3, and SSTR5 occurs to a much higher extent after SST exposure than that of SSTR1 or SSTR4. After endocytosis, SSTR2 and SSTR5 recycle to the plasma membrane, whereas SSTR3 is predominantly degraded by lysosomes and downregulated. It should also be noted that when different SSAs act as ligands the receptor trafficking process is not the same as when native SST activates the receptor. For example pasireotide internalizes SSTR3 more effectively than octreotide, but for SSTR2 it does so to a much lesser extent (Csaba *et al.*, 2012; Lesche *et al.*, 2009).

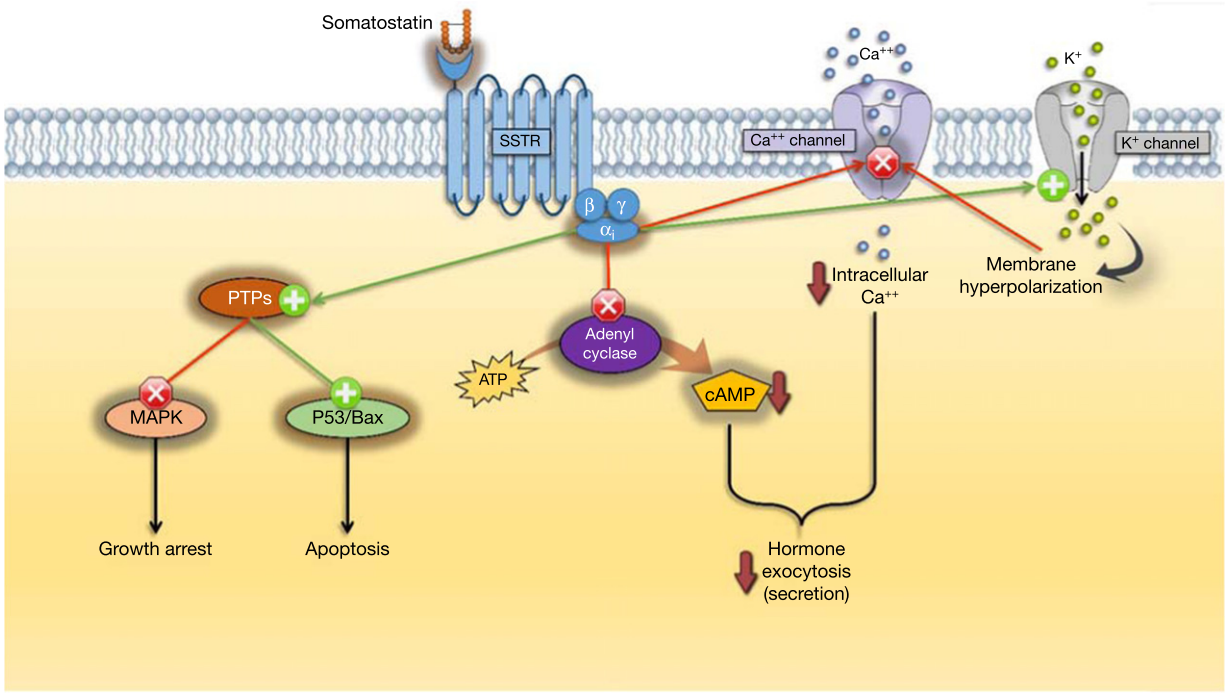

Fig. 2 Somatostatin receptor modulation of signaling cascades leading to changes in hormone secretion, apoptosis, and cell growth.

Methods of SSTR Detection In Vitro

Before discussing the current knowledge on SSTR expression in gastrointestinal tumors, a short review of the different methods available to determine SSTR at the tissue level is essential to critically appreciate the available research data. Several methods have been used to determine the expression of SSTR in vitro. All of them have intrinsic limitations and advantages, and therefore, the most robust data can be generated by the combination of two or more of them. **Table 2** lists a comparative representation of the most relevant detection methods.

Autoradiography

SSTR tissue localization had originally been demonstrated by means of autoradiography using radiolabeled SSTR ligands (i.e., ^{125}I–Tyr^{3}-octreotide) that is still considered the gold-standard method (Reubi *et al.*, 1987). This method has the unique property of identifying the presence of "functionally active" receptors; however, it is affected by low reproducibility, is only applicable to high-quality frozen material, and does not recognize the SSTR subtype expressed, unless using highly subtype-specific ligands.

SSTR mRNA Detection

Several other studies tried to identify SSTR expression in normal tissue and tumors by means of detecting mRNA expression by in situ hybridization, northern blot, or reverse transcription polymerase chain reaction (RT-PCR) (Papotti *et al.*, 2002). However, mRNA expression from tissue extracts (especially in RT-PCR) is variably affected by signals from SSTR-expressing cells different from those that represent the target of the measurement. Normal and nontumoral tissues (blood vessels, nerves, lymphocytes, as well as nontumoral endocrine cells) located adjacent to a receptor-negative tumor sample may erroneously suggest tumor positivity. Another inherent limitation of this method lies on the fact that receptor mRNA levels may not directly reflect levels of functional receptor protein, and the quality of the frozen tissue sample is again a relevant component for obtaining adequate results.

SSTR Protein Detection

In parallel with mRNA determination, several researchers aimed at detecting SSTRs by immunohistochemistry (IHC) using SSTR-specific antibodies against the N- or the C-terminus of the protein (Hofland *et al.*, 1999). Advantages of IHC include SSTR localization, recognition of the specific SSTR subtypes, a high cost/benefit ratio and reproducibility and lastly,

Table 2 Comparison between the different methods of SSTR detection on tissues

	Autoradiography	*mRNA expression*	*Immunohistochemistry*
SSTR localization	✓	–	✓
Identification of SSTR subtype	–[a]	✓	✓
Mapping of functional SSTRs	✓	–	–
Low cost	–	–	✓
Sensitivity	✓	✓	–[b]
Specificity	✓	–[c]	✓
Tissue material	Frozen only	Frozen only	Frozen and paraffin-embedded[d]
Applicability in clinical practice	–	–	✓

[a]Identification of SSTR subtypes is possible if SSTR-subtype specific ligands are used.
[b]Sensitive antibodies are inherently difficult to be produced and quantification of positivity is not standardized.
[c]Results may be contaminated by SSTR expression of adjacent normal cells.
[d]Can be applied on biopsy or FNA (fine-needle aspiration) material and not exclusively on resected tissues.

applicability on paraffin-embedded tissues facilitating investigation on retrospective archival material or even fine needle aspiration or biopsy samples of inoperable tumors. Conversely, the major caveat of IHC has been the inherent difficulty to develop highly sensitive and specific SSTR antibodies. Recently, the development of monoclonal antibodies (UMB-1) against SSTR2, the most predominantly expressed SSTR subtype, and against SSTR5 (UMB-4), have shown reliable correlation with the established autoradiography method, with only minor discrepancies (Korner *et al.*, 2012; Lupp *et al.*, 2011). However, since these antibodies only identify epitopes other than the SST binding domain of the receptor, they do not actually map the active SST-binding sites which represent the molecular targets for the clinical application of SSAs. In addition, lack of standardized quantification of positive staining is considered a relative disadvantage of IHC, although several scoring systems have been proposed (Volante *et al.*, 2007). In general, a fine membranous staining is considered the most specific, although a cytoplasmic staining may be a result of receptor internalization, especially in the case of patients treated with SSAs (Reubi *et al.*, 2010).

More recently, several studies have suggested a potential prognostic value of in vitro SSTR subtyping, associating SSTR2 expression with better outcomes in patients with NENs treated with SSAs (Asnacios *et al.*, 2008; Kim *et al.*, 2011; Corleto *et al.*, 2009; Okuwaki *et al.*, 2013). The same effect has also been observed for SSTR5 expression (Wang *et al.*, 2017; Song *et al.*, 2016). Recently, detection of SSTR2 and SSTR5 with IHC was demonstrated on circulating tumor cells from NEN patients, providing an intriguing biomarker for evaluating SSTR-targeted therapies (Childs *et al.*, 2016). Future studies are needed to validate SSTR determination at the tissue level, as a useful complementary approach for better definition of therapeutic strategies in patients affected by NENs.

Distribution of SSTRs

SSTR Expression in Normal Tissues

As implied earlier by the various SST actions in humans, SSTR expression has been confirmed in many normal tissues, including the brain, pituitary, pancreas, gastrointestinal system, thyroid, adrenal, kidney, and the immune system. All SSTR subtypes are found in different parts of the brain, while SSTR2 and SSTR5 are the main receptors found in the adenohypophysis with SSTR1 and SSTR3 being expressed at lower levels. SSTR1 is expressed in the jejunum and stomach and SSTR2 in the kidney. In the pancreas, α-cells express mainly SSTR2, β-cells SSTR1 and SSTR5, and δ-cells SSTR5. The adrenals express SSTR2 and SSTR5. In the immune system, lymphocytes express SSTR3 and thymus SSTR1, SSTR2 and SSTR3. Liver expresses SSTR1 and SSTR2. SSTR4 is present in the lung, pancreas, and heart. Although SSTR subtypes are expressed in a complex tissue-specific pattern, SSTR2A appears to be the most abundant receptor subtype (Reubi, 2003).

SSTR Expression in Tumors

A wide range of different tumors overexpress SSTRs, as compared to originating normal cells. The underlying stimuli that induce this overexpression as well as the functional meaning for the biology of tumor cells have not been conclusively explained. It is possible that the upregulation of SSTRs serves as homeostatic growth inhibitory response to the deregulated tumor cell proliferation in an autocrine/paracrine way (Msaouel *et al.*, 2009). These tumors include pituitary adenomas (in particular GH- and TSH-producing adenomas), gastroenteropancreatic NENs (GEP-NENs) and lung NENs, pheochromocytomas, and paragangliomas. Tumors of the nervous system, such as medulloblastomas, meningiomas, and neuroblastomas, also express SSTRs at high density. Furthermore, nonneural tumors and non-NENs can also express SSTRs, although clearly at a lower incidence and/or density than NENs. Such tumors include breast, prostate, hepatocellular and gastric carcinomas, lymphohematological malignancies, lung small cell, and renal cell carcinomas (Hasskarl *et al.*, 2011). Finally, it should also be mentioned that inflammatory

diseases such as sarcoidosis, rheumatoid arthritis, inflammatory bowel disease, thyrotoxic orbitopathy, and various retinal diseases are associated with increased SSTR expression.

Particularly for GEP-NENs, SSTR overexpression is considered a common histopathological feature offering unique opportunities for application of diagnostic and therapeutic modalities. Expression patterns in GEP-NENs display a wide heterogeneity between different NEN types and even between patients harboring the same tumor type, or even between cell populations within the same lesions. It has also been shown that metastatic sites can exhibit different SSTR expression profiles when compared with the primary tumor (Nasir *et al.*, 2006; Hofman and Hicks, 2012; Kaemmerer *et al.*, 2015). More than one SSTR subtype are usually present, but the most prominent subtype found in these tumors is SSTR2 followed by SSTR1 and SSTR5, whereas SSTR3 is less frequent and SSTR4 is poorly expressed. pNENs (including gastrinomas, glucagonomas, VIPomas) and intestinal NENs express SSTR2 in 80%–100% of cases, whereas insulinomas have a lower incidence of SSTR2 expression (50%–70%) (Reubi and Waser, 2003). By contrast, insulinomas often express SSTR1 or, alternatively, SSTR5 together with or instead of SSTR2. SSTR expression also correlates with the level of tumor differentiation, since well-differentiated GEP-NENs usually express a greater density and number of receptors than do poorly differentiated neoplasms, an observation which is useful for therapeutic decisions (Reubi *et al.*, 1990). **Table 3** summarizes the frequency of SSTR expression in various GEP-NENs reported by researchers using all three described detection methods.

Rarely some NENs arising primarily in the duodenum and pancreas can also secrete increased amounts of SST causing a constellation of symptoms related to the physiologic actions of SST (such as steatorrhea, cholelithiasis, hyperglycemia, and weight loss), known as the somatostatinoma syndrome (Soga and Yakuwa, 1999). Only about 10% of patients with somatostatinomas (tumors containing immunoreactive granules with SST) experience functional symptoms, and in those the primary tumor is usually located in the pancreas. On the contrary, somatostatinomas arising from the duodenum, particularly in the ampullary and periampullary area, rarely cause secretory symptoms and are frequently associated with neurofibromatosis type 1 (Von Recklinghausen's disease). In symptomatic patients, treatment with SSAs, although it may seem paradoxical, is effective in symptom relief, since these tumors also express SSTRs (Angeletti *et al.*, 1998).

SSTR Detection In Vivo

SSTR overexpression in GEP-NENs has constituted the basis for diagnostic imaging using scintigraphy with radio-labeled SSAs and has been applied in clinical practice for in vivo demonstration of SSTR presence in these tumors (somatostatin receptor imaging—SRI). Receptor internalization following binding with such a radiopeptide leads to retention and accumulation of radioactivity in tumor cells allowing macroscopic visualization with devices that capture emitted γ-radiation (γ-cameras). The same principle can be utilized to bind ligands with α- or β-emitting isotopes, permitting selective radiotherapy of the tumor-expressing SSTRs in vivo (peptide receptor radionuclide therapy).

The first commercially available agent for SRI, ^{111}In-DTPA-D-Phe^{1}-octreotide, was officially introduced in 1994 (Octreoscan), and its use to visualize various SSTR-positive tumors and tissues became the "gold standard" in the localization, staging, and follow-up in patients with NENs, especially in conjunction with single-photon emission computed tomography (SPECT). The sensitivity and specificity of Octreoscan, in the diagnosis of intestinal NENs, including primary foci and metastatic lesions, are 71%–96% and 76%–95%, respectively (Kwekkeboom *et al.*, 1993). In order to overcome the limitations of Octreoscan, such as the high cost of ^{111}In (a cyclotron-produced radionuclide) and the suboptimal physical features of this radioisotope (poor image resolution and high radiation dose to the patient), labeling SSAs with ^{99m}Tc led to development of a new radiopharmaceutical, ^{99m}Tc-EDDA/HYNIC-TOC (Tektrotyd), with superior imaging features (Hubalewska-Dydejczyk *et al.*, 2006).

Further development of SSAs for use in SRI, like DOTA-D-Phe^{1}-Tyr^{3}-octreotide (DOTATOC), DOTA-D-Phe^{1}-Tyr^{3}-Thr^{8}-octreotide (DOTATATE), and DOTA-1-Nal^{3}-octreotide (DOTANOC) opened the prospect for convenient radiolabeling with ^{68}Ga for PET/CT (positron emission tomography/computed tomography) imaging. DOTATOC and DOTATATE display a very high affinity for the SSTR2, low or negligible affinity for SSTR3 and SSTR5, and no significant affinity for SSTR1 and SSTR4. On the contrary, DOTANOC has not only a higher affinity to SSTR3 and SSTR5 but also binds more avidly to SSTR2. PET/CT using ^{68}Ga-labeled SSAs enables molecular imaging of NENs and their metastases with very high diagnostic sensitivity and specificity. The accuracy of ^{68}Ga-DOTATOC PET (96%) was found to be significantly higher than that of computerized tomography (CT) (75%) and ^{111}In-DOTATOC SPECT (58%) (Gabriel *et al.*, 2007). It could detect more lesions than SPECT and CT, but also was true positive where SPECT results were false negative, visualizing small tumors or tumors bearing only a low density of SSTRs and more metastatic foci in the lymph nodes, liver, and bones (Kowalski *et al.*, 2003). In addition, it provides superior resolution, low radiation burden (10–12 mSv), faster protocol times (60–90 min) and quantitative, reproducible data (by means of determining standardized uptake values). More recently, novel tracers (^{64}Cu-DOTATATE) using ^{64}Cu, an isotope characterized by better spatial resolution and longer half-life than ^{68}Ga, exhibited similar patient-based sensitivity compared to ^{68}Ga-DOTATOC but detected significantly more lesions (Johnbeck *et al.*, 2017).

The role of SST receptor antagonists has also been investigated recently with promising results. Potent SST receptor antagonists, known to poorly internalize after binding with SSTRs, can visualize tumors in vivo as well or even better than agonists. This is because agonists preferably recognize the active state of receptors, whereas antagonists bind with high affinity to both active and inactive receptor states. Because receptors are primarily in the inactive state in cells, agonist binding will represent a fraction of what can be labeled with an antagonist (Ginj *et al.*, 2006; Cescato *et al.*, 2008; Wild *et al.*, 2010).

Several studies have confirmed that SRI correlates strongly with tissue expression of SSTRs (Diakatou *et al.*, 2015; Kaemmerer *et al.*, 2011; Miederer *et al.*, 2009); however, caution should be taken, since all aforementioned imaging modalities are not disease specific but receptor specific. Thus, in order to be able to interpret their results, the underlying tumor biology must be taken into account. A negative scan may indicate absence of the SSTR subtypes that the radiolabeled ligand recognizes, tumor regression or tumor dedifferentiation. Correlation with anatomical imaging is always mandatory. A negative Octreoscan should also not be an excluding factor for the decision to administer SSA treatment (Sevilla *et al.*, 2016). In fact, patients with negative Octreoscan have been shown to respond to SSAs (Hillman *et al.*, 1998), while in the PROMID study which evaluated the effect of Octreotide in the control of tumor growth in patients with metastatic midgut NENs, patients with negative Octreoscan were responsive to octreotide (Rinke *et al.*, 2009). After all, Octreoscan and other SRI modalities verify whether an uptake of the radiolabeled SSA is present and not whether SSTRs are expressed. Factors like the size of the lesion in relation with the spatial resolution of the imaging method, as well as the signal intensity measured in Krenning scale (lower than, equal to, or greater than normal liver tissue; or higher than normal spleen or kidney uptake: grades 1, 2, 3, and 4, respectively), suggest that results considered as negative may not represent the true SSTR expression on microscopic level.

Conclusion

SST and its receptors are broadly expressed in the human body where they exert many physiological actions. Moreover, they can be expressed in many pathological tissues and particularly with high density in GEP-NENs. As soon as the high expression level of SSTRs in NENs was documented, SSAs were developed to control hypersecretion and tumor growth, but it also brought upon a revolution in the role of nuclear medicine in the diagnosis and therapy of such patients. This was indeed paralleled by the development of various radiopharmaceuticals targeting not only SSTRs but also other peptide receptors and metabolic pathways unique for this type of tumor cells. In recent years, knowledge on the physiology of SST and its receptors has exploded, with the elucidation of many of the molecular details involved in SST receptor signaling and regulation. First-generation SSAs (octreotide and lanreotide) were developed at a time when far less was known about the SST receptor family and are now rediscovered by unveiling of their diverse and complex interactions with the various subtypes of SSTRs. Novel second-generation SSAs such as pasireotide only emphasize the need to develop more effective SST receptor-directed agents. Further elucidation of SST receptor pharmacology will provide new opportunities to design more sophisticated means to target these receptors in an individualized and effective way, both in terms of developing diagnostic tools and of manipulating receptor signaling as a therapeutic strategy.

Gastrointestinal Neuroendocrine Tumor Syndromes (GI NETS)☆

Robert T Jensen, National Institutes of Health/National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, United States

Glossary

Carcinoid syndrome A clinical syndrome characterized by diarrhea, flushing, asthma, and heart disease caused by ectopic release of bioactive peptides/amines by a carcinoid tumor (almost always metastatic to liver).

Gastrointestinal neuroendocrine tumors (NETs) Composed of carcinoid tumors and pancreatic neuroendocrine tumors derived from the diffuse neuroendocrine system of the gastrointestinal (GI) tract. They share neuroendocrine cell markers and pathologic and biologic features, and they frequently ectopically secrete hormones/amines that cause a clinical syndrome.

Pancreatic neuroendocrine tumor (panNET) syndrome Clinical syndrome caused by ectopic secretion of bioactive peptides by a GI endocrine tumor, frequently located in the pancreas. Characteristically named after the hormone ectopically secreted (e.g., insulinoma, gastrinoma, glucagonoma, and VIPoma).

Somatostatin A naturally occurring neuropeptide/hormone that occurs as a 14- or 28-amino acid form in the GI tract and central nervous system and that frequently has inhibitory effects on biologic processes (i.e., growth, secretion, and hormone release). Synthetic analogues (octreotide and lanreotide) are frequently used to inhibit ectopic release of bioactive substances and growth of NETs. Radiolabeled analogues are used to localize NETs using somatostatin receptor scintigraphy and to treat widespread metastatic disease.

Gastrointestinal neuroendocrine tumor (GI NET) syndromes are clinical syndromes caused by the release of biologically active peptides/amines by GI neuroendocrine tumors (Ito et al., 2013a). NETs comprise carcinoid tumors and pancreatic neuroendocrine tumors (panNETs) and are derived from amine- and peptide-producing cells of the diffuse neuroendocrine system

Introduction

GI NETs are also classified as APUDomas (amine precursor uptake and decarboxylation), as are medullary thyroid carcinomas, melanomas, and pheochromocytomas, because they share various cytochemical, pathologic, and biologic features (**Table 1**) (Klimstra, 2016). These tumors were originally proposed to have a common embryonic origin from neural crest cells but subsequent studies showed that this was not the case. All NETs share a number of common features (Klimstra, 2016). However, the different clinical syndromes have important differences and there are a number of differences between carcinoids and panNETs.

Pathology/Tumor Biology of NETs

By light microscopy, NETs are generally composed of monotonous sheets of small round cells with uniform nuclei and only a few mitoses in most cases. Their presence is generally suspected by routine histology but established by specific immunohistological staining for common cellular proteins (**Table 1**). Historically, silver staining was used; currently, immunolocalization of the secretory protein chromogranin (A, B, C), the cytosolic protein neuron-specific enolase, or the membrane protein synaptophysin is generally used (Klimstra, 2016).

By electron microscopy, NETs have numerous electron-dense granules (>80 nm) and small clear vesicles that correspond to synaptic vesicles of neurons. NETs synthesize numerous growth factors, peptides, and bioactive amines that may be ectopically released and cause a clinical syndrome (**Table 2**). The diagnosis of a given NET syndrome is based on clinical findings and cannot be made from the immunocytochemical analysis. Furthermore, pathologists cannot generally distinguish between benign and malignant NETs unless metastases or invasion are present. NETs are now graded into three grades depending on the NETs differentiation (G1, G2 = well-differentiated vs. G3-G3-NET, well-differentiated, G3-NEC (neuroendocrine carcinoma)-poorly differentiated), and their preoperative rates assessed by Ki-67 or determining the mitotic index by counting mitoses (Klimstra, 2016; Singhi and Klimstra, 2018). Numerous recent studies demonstrate that prognosis is worse with increasing grade (G1 better G2 better than G3) as is also the case for increasing category in the TNM classification. These classifications/grading (ENETs, WHO,

☆*Change History*: May 2018. Robert T. Jensen updated all parts in this article.

This article is an update of Robert T. Jensen, Gastrointestinal Neuroendocrine Tumor Syndromes (GI NETS), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 111–124.

Table 1 General characteristics of gastrointestinal neuroendocrine tumors (NETs) (panNETs and carcinoids) (Klimstra, 2016;Singhi and Klimstra, 2018)

Share general neuroendocrine cell markers, including
Chromogranins (Cgs) (A, B, C) are acidic monomeric-soluble proteins found in the large secretory granules. CgA is most widely used
Neuron-specific enolase (NSE) is the γ–γ dimer of the enzyme enolase and is a cytosolic marker of neuroendocrine differentiation
Synaptophysin is an integral membrane glycoprotein (38 kDa) found in small vesicles of neurons and neuroendocrine tumors
Pathologic similarities
All NETs show amine precursor uptake and decarboxylation (APUDomas)
Ultrastructurally, they have dense-core secretory granules ($>$80 nm)
Histologically, they appear similar with most having few mitoses and uniform nuclei
Frequently, they synthesize multiple peptides/amines, which can be detected immunocytochemically but may not be secreted
The presence or absence of clinical syndrome or type cannot be predicted by immunocytochemical studies
Histological grading classifications predict biologic behavior. Only invasion or metastases establish malignancy
A common TNM classification and grading system is used for both carcinoids and panNETs NETs
Similarities of biologic behavior
They secrete biologically active peptides/amines, which can cause clinical symptoms
They generally have high densities of somatostatin receptors, which are used for both localization and treatment

UICC) are now essential for the proper management of all NET patients because they not only have prognostic significance, they also can affect the choice of therapy (Klimstra, 2016; Singhi and Klimstra, 2018).

panNETs are classified according to the specific clinical syndrome they cause or, if no clinical syndrome occurs, as nonfunctional (Ito *et al.*, 2013a; Metz and Jensen, 2008) (**Table 2**). Nonfunctional panNET in the strict sense is a misnomer because these tumors frequently secrete multiple peptides (pancreatic polypeptide, CgA, and neurotensin); however, they do not cause a specific clinical syndrome. The symptoms caused by nonfunctional panNETs are due to the tumor per se (Ito *et al.*, 2013a; Metz and Jensen, 2008).

Carcinoid tumors are frequently classified by location of origin (foregut, midgut, or hindgut) because they share histochemical, functional, and biologic characteristics within these areas (Jensen *et al.*, 2016) (**Table 3**). Foregut carcinoids generally have low serotonin (5-HT) content, are argentaffin negative on silver staining, synthesize several hormones, and occasionally secrete ACTH or 5-hydroxytryptophane (5-HTP) causing an atypical carcinoid syndrome. Midgut carcinoids are generally argentaffin positive, have high serotonin content, frequently multihormonal, rarely secrete 5-HTP or ACTH, and most frequently cause carcinoid syndrome when they metastasize (**Table 3**). Hindgut carcinoids (transverse colon to rectum) are argentaffin negative; rarely contain serotonin, 5-HTP, and ACTH or cause carcinoid syndrome; contain numerous peptides; and frequently metastasize to bone. Most carcinoids (70%) occur in one of four sites—bronchus, jejunum/ileum, rectum, or appendix—although they can occur in any tissue (Jensen *et al.*, 2016) (**Table 3**). Overall, the GI tract is the most common site for carcinoids (74% of cases), and the respiratory tract the second most common site (25% of cases).

The frequency of NETs varies according to whether they are symptomatic. The incidence of clinically significant panNETs is 10 cases/1 million population/year. Their relative incidence is insulinoma, gastrinoma, and nonfunctional (0.5–2.5 cases/1 million/year) $>$ VIPomas (2–8 times less common) $>$ glucagonomas (17–30 times less common) $>$ somatostatinomas. In autopsy studies, 0.5%–1.5% of all cases have panNETs, with $<$1 in 1000 symptomatic. In recent series of panNETs, the nonfunctional panNETs makeup as much as 66%–85% of cases because they are increasingly found when patients are asymptomatic detected when being investigated for nonspecific complaints (Ito *et al.*, 2013a; Metz and Jensen, 2008). Clinically significant carcinoids occur in 7–13 cases/1 million/year and malignant cases at autopsy in 21–84 cases/1 million/year.

Both panNETs and carcinoids can show malignant behavior. With panNETs, 50%–100% are malignant, except for insulinomas, in which $<$10% are malignant (Ito *et al.*, 2013a; Metz and Jensen, 2008). (**Table 2**). With carcinoid tumors the percentage that are malignant varies with different locations (**Table 3**). A number of factors are predictive of tumor aggressiveness and/or survival for NETs (**Table 4**). The presence of liver metastases is the most important prognostic factor. Primary tumor size is also an important predictor. The factors in **Table 4** need to be considered when determining the aggressiveness of treatment of NETs.

Until recently, the molecular pathogenesis of NETs was largely unknown because common oncogenes (*ras*, *fos*, etc.) and common tumor suppressor genes (retinoblastoma gene, *p53*) were usually not mutated. Recent studies provide evidence that various chromosomal gains and losses as well as alteration in the chromatin remodeling genes (ATRX/DAXX), *HER2/neu* oncogene, *MEN-1* gene, and *p16INK4a* and overexpression of growth factors (epidermal growth factor, vascular endothelial growth factor, insulin-like growth factor-1, and transforming growth factor-2) and their receptors may be important in the pathogenesis (Jensen *et al.*, 2016) (**Table 4**). An increased understanding of their molecular pathogenesis may lead to newer treatments as well as have prognostic significance.

Specific Pancreatic Neuroendocrine Tumor Syndromes

Functional panNETs almost always present with symptoms due to the specific hormone ectopically secreted. Nonfunctional panNETs present with symptoms due to the tumor per se and usually present late in the disease course with advanced metastatic disease. Treatment of functional panNETs requires strategies directed at controlling the hormone-excess state as well as at the

Table 2 Gastrointestinal NET syndromes

Syndrome	*Biologically active peptide (s) secreted*	*Incidence (new cases/10^6 population/year)*	*Tumor location*	*Malignant (%)*	*Main symptoms/signs*
Established specific functional syndrome					
panNET					
Zollinger–Ellison syndrome (ZES, gastrinoma)	Gastrin	0.5–1.5	Duodenum (70%) Pancreas (25%) Other sites (5%)	60–90	Pain (79%–100%) Diarrhea (30%–75%) Esophageal symptoms (31%–56%)
Insulinoma	Insulin	1–2	Pancreas (>99%)	<10	Hypoglycemic symptoms (100%)
VIPoma (Verner–Morrison syndrome, pancreatic cholera, WDHA)	Vasoactive intestinal peptide	0.05–0.2	Pancreas (90%; adult) Other (10%; neural, adrenal, periganglionic)	40–70	Diarrhea (90%–100%) Hypokalemic (80%–100%) Dehydration (83%)
Glucagonoma	Glucagon	0.01–0.1	Pancreas (100%)	50–80	Rash (67%–90%) Glucose intolerance (38%–87%) Weight loss (66%–96%)
Somatostatinoma	Somatostatin	Rare	Pancreas (55%) Duodenum/jejunum (44%)	>70	Diabetes mellitus (63%–90%) Cholelithiases (65%–90%) Diarrhea (35%–90%)
GRFoma	Growth hormone-releasing hormone	Unknown	Pancreas (30%) Lung (54%) Jejunum (7%) Other (13%)	>60	Acromegaly (100%)
ACTHoma	ACTH	Rare	Pancreas (4%–16% all ectopic Cushing's)	>95	Cushing's syndrome (100%)
[a]Causing carcinoid syndrome	Serotonin ?Tachykinins	Rare (43 cases)	Pancreas (<1% all carcinoids)	60–80	Same as carcinoid syndrome above
Carcinoid tumor					
Carcinoid syndrome	Serotonin, possibly tackykinins, motilin, prostaglandins	0.5–2	Midgut (75%–87%) Foregut (2%–33%) Hindgut (1%–8%) Unknown (2%–15%)	95–100	Diarrhea (32%–84%) Flushing (63%–75%) Pain (10%–34%) Asthma (4%–18%) Heart disease (11%–41%)
Possible specific functional panNET syndrome					
panNET secreting calcitonin	Calcitonin	Rare	Pancreas (rare cause of hypercalcitonemia)	>80%	Diarrhea (50%)
panNET secreting renin	Renin	Rare	Pancreas	Unknown	Hypertension
No functional syndrome					
PPoma/nonfunctional	None	1–2	Pancreas (100%)	>60	Weight loss (30%–90%) Abdominal mass (10%–30%) Pain (30%–95%)

[a]panNET, pancreatic neuroendocrine tumor.

panNETs per se because they are frequently malignant. Unfortunately, these tumors are not curable by surgery due to the extent of the disease; therefore, both treatment aspects cannot adequately be dealt with by curative resection.

Zollinger–Ellison Syndrome (Ito *et al.*, 2013a)

Zollinger–Ellison syndrome (ZES) is only briefly discussed here because it is included in a separate article in this encyclopedia.

Table 3 Carcinoid tumor location, frequency of metastases, and association with carcinoid syndrome

	Location (% of total)[a]	*Incidence of metastases*[a]	*Incidence of carcinoid syndrome*[b]
Foregut			
Esophagus	<1	67	—
Stomach	3.8	31	9.5
Duodenum	2.1	—	3.4

Rectum	10	14	—

[a]From 5468 cases studied from 1973 to 1991 reported by I. M. Modlin (1997).
[b]From 4349 cases studied from 1950 to 1971 reported by J. D. Godwin (1975).

Clinical Features and Diagnosis (Ito *et al.*, 2012a; Roy *et al.*, 2000)

ZES is a clinical syndrome caused by ectopic secretion of gastrin by a panNET (gastrinoma) that results in gastric hypersecretion. The acid hypersecretion characteristically causes peptic ulcer disease (often severe and refractory), diarrhea, or esophageal reflux disease (Roy *et al.*, 2001) (**Table 2**). The diagnosis is made by demonstrating inappropriate secretion of gastrin by assessing fasting gastrin levels, gastric pH and in some cases by secretin testing.

Pathology/Pathogenesis

Almost all the presenting symptoms are due to the effects of gastric hypersecretion because they disappear when the acid secretion is treated. Sixty to ninenty percentage of gastrinomas are malignant. Most gastrinomas (60%–90%) are found in the duodenum, followed by the pancreas (10%–40%). Other intra-abdominal sites include mesentery, lymph nodes, liver and ovary. Approximately 20%–25% of ZES patients have multiple endocrine neoplasia type 1 (MEN-1) (Gibril *et al.*, 2004).

Treatment (Ito *et al.*, 2013b; Jensen and Norton, 2017)

Acid hypersecretion can be controlled medically in almost every patient. Proton pump inhibitors (PPIs) are the drugs of choice because of their long duration of action. Histamine H2 receptor antagonists are also effective but frequent (every 4–6 h) high doses are usually needed. Long-term surgical cure is possible in 30% of patients with ZES without MEN-1 but is rare (<1%) in patients with ZES with MEN-1.

Insulinomas (Falconi *et al.*, 2016; Jensen *et al.*, 2016; Mathur *et al.*, 2009; Metz and Jensen, 2008)

Insulinomas are neuroendocrine tumors of the pancreas thought to be derived from the β cells of the islets that ectopically secrete insulin, which results in hypoglycemia.

Clinical Features

The most common symptoms are due to the effects of hypoglycemia on the central nervous system (neuroglycemic symptoms), including confusion, headache, altered consciousness, and even seizure (**Table 5**). Many patients also have symptoms due to excess catecholamine release, including sweating or tremulousness. Attacks characteristically occur during fasting.

Table 4 Molecular Abnormalities and Prognostic Factors in NETs (Jensen et al., 2016)

I. Molecular abnormalities

panNETs

HER2/neu (*erbB-2*) expressed in 100% GAS

MEN1 gene LOH, 46%; mutation, 42% GAS/10% INS

$p16^{INK4a}$, 30% gene abnormality

TGF-α/EGFR, 72% IHC +

IGF-1/IGFR-1, 70% PCR +

Loss of 1p (21%), 3p (8%–47%), 3q (8%–41%), 11q (21%–62%), 6q (18%–68%), Y (45%). Gains at 17q (10%–55%), 7q (16%–68%), 4q (33%), 18 (up to 45%)

Alterations in the VHL gene [deletion, methylation]; presence of FGFR4-G388R single-nucleotide polymorphism

ATRX/DAXX mutations in 43%, MEN 1 mutations in 44%, mTor mutations (14%); uncommon in midgut GI-NETs (0%–2%)

Loss of ATRX/DAXX or positive for alternative lengthening of telomeres

Carcinoids

MEN-1 gene LOH, 36%; mutation, 10%

$p16^{INK4a}$, 33% gene abnormality

TGF-α/EGFR, 85% IHC +

IGF-1/IGFR-1, 40%–80% IHC +

VEGF, 79% IHC +

GI-NETs (carcinoids)—loss of 18q (38%–88%), >18p (33%–43%), >9p, 16q21 (21%–23%). Gains at 17q, 19p (57%), 4q (33%), 14q (20%), 5 (up to 36%)

Both carcinoids and panNETs

Alterations in common oncogenes (*ras*, *fos*, etc.) or common tumor suppressor (p53, Rb) uncommon in well-differentiated forms

II. Prognostic factors

panNETs

Ha-Ras oncogene or *p53* overexpression

Female gender

MEN-1 syndrome absent

Laboratory findings (increased chromogranin A in some studies; gastrinomas, increased gastrin level)

Chrom. changes: chr 1q, 3p, 3q, or 6q LOH [$P = 0.0004$], EGF receptor overexpression [$P = 0.034$], gains in chr 7q, 17q, 17p, 20q

Alterations in the VHL gene [deletion, methylation]; presence of FGFR4-G388R single-nucleotide polymorphism); loss of ATRX/DAXX or positive for alternative lengthening of telomeres($P < 0.001$); high nuclear survivin expression ($P < 0.01$)

PHLDA3 LOH; Altered miRNA expression (Inc miRNA-21,miRNA-196)

Carcinoid tumors

The presence of carcinoid syndrome

Laboratory results: urinary 5-HIAA level ($P < 0.01$), plasma neuropeptide K ($P < 0.05$), serum chromogranin A ($P < 0.01$)

The presence of a second malignancy

Male gender ($P < 0.001$)

Older age ($P < 0.01$)

Mode of discovery (incidental > symptomatic)

Molecular findings (TGF-α expression ($P < 0.05$), chr 16q LOH or gain chr 4p ($P < 0.05$), gain in chr 14, loss of 3p13, loss of succinate dehydrogenase expression (ileal carcinoid), upregulation of Hoxc6), molecular profiling category(mutations, epigenetic changes, copy number-Small intestinal NETs)

Both carcinoid tumors and panNETs

Performance status ($P < 0.04$)

Symptomatic presentation ($P < 0.05$)

The presence of liver metastases ($P < 0.001$)

Extent of liver metastases ($P < 0.001$)

The presence of lymph node metastases ($P < 0.001$)

Rapid rate of tumor growth

Elevated serum alkaline phosphatase levels ($P = 0.003$)

Depth of invasion ($P < 0.001$)

Primary tumor site ($P < 0.001$)

Primary tumor size ($P < 0.005$)

High serum chromogranin A level ($P < 0.01$)

Presence of one or more circulating tumor cells ($P < 0.001$)

Various histologic features

Tumor differentiation ($P < 0.001$)

High growth indices (high Ki-67 index, PCNA expression)

High mitotic counts ($P < 0.001$)

Vascular or perineural invasion

Flow cytometric features (i.e., aneuploidy)

Vessel density (low microvessel density, increased lymphatic density)

Visual disturbances (diplopia, blurred vision)	59
Confusion	51
Altered consciousness	38
Weakness	32
Transient motor defects, hemiplegia	29
Dizziness	28
Fatigue	27
Inappropriate behavior	27
Speech difficulty	24
Headache	23
Seizure	23
Syncope	21
Adrenergic	
Sweating	43
Tremulousness	23
Hunger, nausea	12
Palpitations	10

Pathology/Pathophysiology

Almost all insulinomas (>99%) occur in the pancreas. Insulinomas are usually small (40% <1 cm), solitary, and distributed evenly throughout the pancreas. In adults with hyperinsulinism with islet disease, 86% have an insulinoma, 5%–15% have adenomatosis, nesioblastosis occurs in 4%, and hyperplasia occurs in 1%. Insulin is normally synthesized and stored in islet β cells. It is derived from proinsulin, which consists of a 21-amino acid α chain and a 30-amino acid β chain connected by a 33-amino acid connecting peptide (C-peptide). In normal subjects, <25% of serum insulin is proinsulin, whereas >90% of patients with an insulinoma have an elevated serum proinsulin.

Diagnosis/Differential Diagnosis

Whipple's triad, published in 1933, was long used as the diagnostic criteria for insulinoma and consists of the occurrence of hypoglycemic symptoms, hypoglycemia (blood glucose <50 mg/dL), and relief of symptoms following glucose injection.

Table 6 Causes of spontaneous hypoglycemia

Postprandial (reactive) hypoglycemia
Functional: recognizable anatomic lesion
Alimentary hyperinsulinoma, usually secondary to previous gastric surgery such as Billroth gastrectomy
Secondary to mild diabetes
Idiopathic
Due to specific hepatic enzyme deficiencies
Hereditary fructose intolerance (infants, children)
Galactosemia (infants, children)
Familial fructose and galactose intolerance (rare)
Fasting hypoglycemia
Organic hyperinsulinism: specific anatomic lesion present
Pancreatic islet disease
Insulinoma, single or multiple
Microadenomatosis with or without macroscopic adenomas
Carcinoma
Hyperplasia
Nesidioblastosis
Nonpancreatic tumors
Severe congestive heart failure
Severe renal insufficiency in noninsulin-dependent diabetes
Due to hepatic enzyme deficiencies or decreased hepatic glucose output (primarily in infants, children)
Glycogen storage diseases
Glycogen synthetase deficiencies
Other enzyme deficiencies (fructose-1,6-diphosphate deficiencies)
Endocrine hypofunction
Anterior pituitary (usually in infants, children)
Adrenocortical (Addison's disease)
Diffuse acquired liver disease
Ethanol
Severe malnutrition, sepsis
Due to exogenous agents (factitious)
Sulfonylureas, biguanides
Insulin administration
Ingestion of ackee fruits (hypoglycine)
Other drugs (aspirin, pentamidine)
Functional hypoglycemia with no persistent anatomical defect
Autoantibodies to insulin receptor
Spontaneous autoimmune anti-insulin antibody syndrome
Transient hypoglycemia on infancy

Unfortunately, this triad is not specific for insulinoma (Table 6). The diagnosis requires the establishment of hypoglycemia (<40 mg/dL) at the time of an elevated fasting plasma insulin level. The usual method of diagnosing insulinoma is to perform a fast of up to 72 h, with assessment of serum glucose, insulin, and C-peptide every 4–8 h. If at any time the patient becomes symptomatic, the test should be terminated by giving glucose after obtaining the previously mentioned serum measurements. During the first 24 h, 70%–80% of patients with insulinomas develop symptoms, and 98% of patients develop symptoms by 48 h. In nonobese normal subjects, blood insulin values should decrease to <6 μM/mL if blood decreases to ≤ 40 mg/dL and the ratio of insulin to glucose (mg/dL) is <0.3. Some investigators also require elevated serum C-peptide and proinsulin levels and/or insulin: glucose ratio >0.3 for an insulinoma diagnosis. A frequently used set of criteria to make the diagnosis of insulinoma include: blood glucose levels (≤ 2.2 mmol/L (≤ 40 mg/dL); concomitant insulin levels ≥ 6 U/L (≥ 36 pmol/L; ≥ 3 U/L by ICMA); C-peptide levels ≥ 200 pmol/L; proinsulin levels ≥ 5 pmol/L; β-hydroxybutyrate levels ≤ 2.7 mmol. There are numerous causes of hypoglycemia besides insulinoma, including pancreatic islet disease and factitious use of insulin or hypoglycemic agents (Table 6). Combinations of proinsulin levels, C-peptide levels, assessment of antibodies to insulin, and sulfonylurea levels may be required to make the correct diagnosis.

Treatment

Only 5%–15% of insulinomas are malignant; therefore, after tumor localization studies, surgery should be performed. Between 75% and 95% of patients are cured by surgery. Prior to surgery, hypoglycemia is usually controlled by frequent, small meals and the use of diazoxide (150–800 mg/day). Diazoxide controls symptoms in 50%–60% of patients. Other drugs used to control the

Table 7 Clinical characteristics of patients with VIPoma syndrome

Hypercalcemia	41–50
Hyperglycemia	18–50

hypoglycemia include verapamil and diphenylhydantoin. Long-acting somatostatin analogues such as octreotide are effective in 40%–50% of patients. However, in some patient's octreotide may worsen the hypoglycemia. The preferred tumor localization studies include computed tomography (CT) scan to exclude liver metastases and endoscopic ultrasound. Somatostatin receptor scintigraphy (SRS) using ^{111}In-penetreotate, which is the preferred imaging modality in all other NETs, is frequently negative (40%–70%) in patients with insulinomas due to low numbers of somatostatin receptors. However, ^{68}Ga DOTATE PET/CT is increasingly being used more because it is more sensitive. Endoscopic ultrasound is particularly sensitive for locating insulinomas because they are almost all pancreatic in localization. A newer method which shows promising high sensitivity, however it is not yet approved or generally available, involves the use of radiolabeled GLP1 receptor ligands, a receptor that is frequently over-expressed by insulinomas.

VIPomas (Ito *et al.*, 2013a; Metz and Jensen, 2008)

VIPomas are neuroendocrine tumors that occur primarily in the pancreas, secrete excessive amounts of vasoactive intestinal peptide (VIP), and cause a distinct syndrome characterized by large-volume diarrhea, hypokalemia, and dehydration (**Tables 2** and **7**). This syndrome is also called the Verner–Morrison syndrome, pancreatic cholera, or WDHA syndrome (watery diarrhea, hypokalemia, and achlorhydria; **Table 2**).

Clinical Features

The mean age of occurrence is 49 years; however, the syndrome can also occur in children. The principal symptoms are large-volume diarrhea leading to dehydration, acidosis, and hypokalemia. Other symptoms/signs due to the actions of VIP include flushing, hypochlorhydria, hyperglycemia, and hypercalcemia. Steatorrhea is uncommon (16%). The diarrhea is characteristically secretory in nature (persists during fasting).

Pathology/Pathophysiology

VIP is a 28-amino acid neuropeptide normally present in the GI tract and central nervous system. It causes stimulation of small intestinal chloride secretion, has effects on smooth muscle contractility, inhibits acid secretion, and has vasodilatory effects, which explain many of the symptoms of the VIPoma syndrome. In adults, 80%–90% of VIPomas are pancreatic, whereas in children the syndrome is usually caused by ganglioneuromas/ganglioblastomas. VIPomas are usually solitary, with 50%–75% in the pancreatic tail, and 40%–70% of patients have liver metastases at diagnosis.

Diagnosis/Differential Diagnosis

The diagnosis requires the demonstration of an elevated plasma VIP level and the presence of large-volume diarrhea. Almost all patients have a stool volume >1 L/day (most have a volume >3 L/day), and it is proposed that the diagnosis be excluded if the volume is not >700 mL/day. A number of other causes of large-volume diarrhea can be excluded by fasting the patient. Other diseases that can cause fasting large volume diarrhea include Zollinger–Ellison syndrome, chronic laxative abuse, systemic mastocytosis, diabetic diarrhea, AIDS, carcinoid syndrome, and, rarely, medullary thyroid cancer.

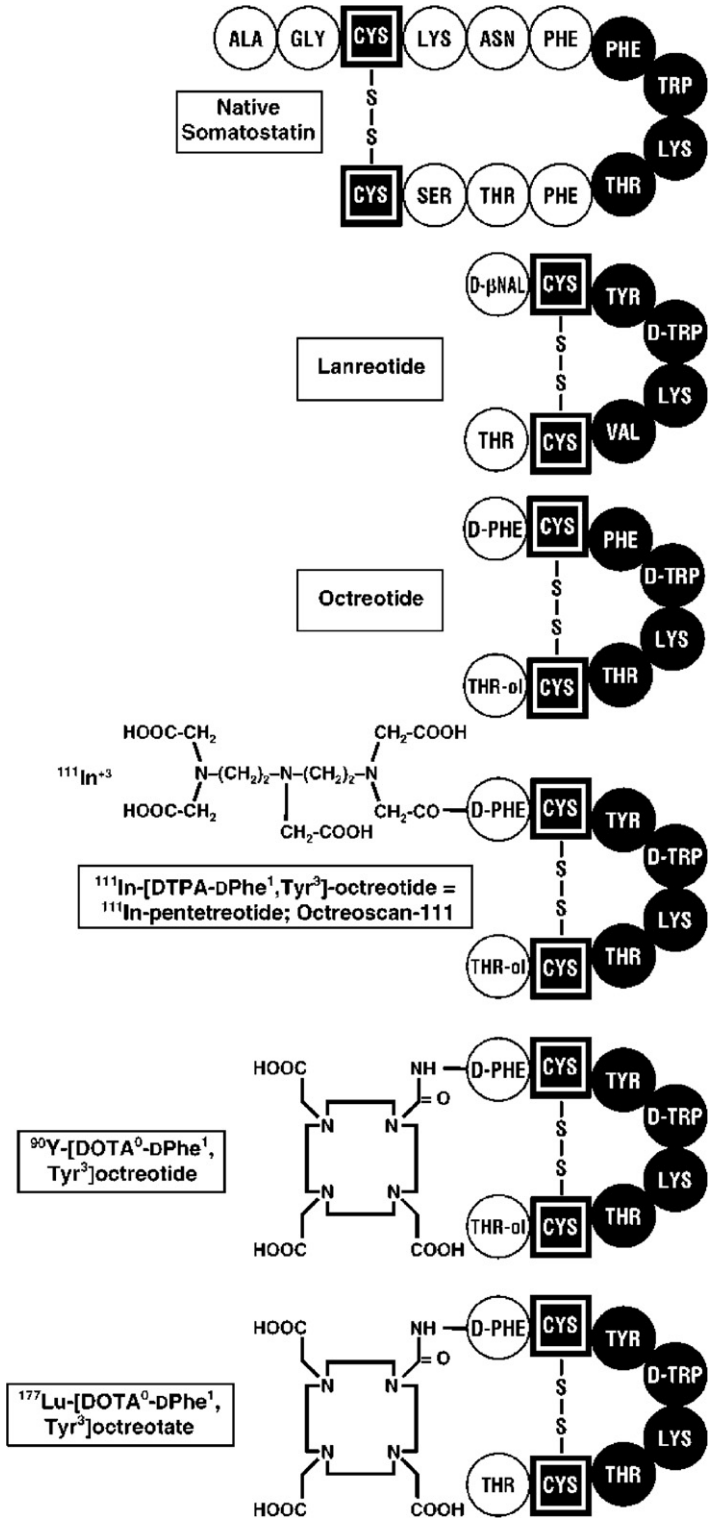

Fig. 1 Structure of somatostatin and synthetic analogues used for diagnostic (tumor localization) or therapeutic indications in patients with neuroendocrine tumors. The indium (^{111}In), yttrium (^{90}Y), or lutetium (^{177}Lu) compounds are used for therapeutic purposes. DOTA-1,4,7,10-tetra-azacylododecane-*N*,*N*′,*N*″, *N*‴-tetra-acetic acid.

Table 8 Frequency of clinical symptoms and laboratory findings in patients with glucagonoma

	Frequency (%)
Clinical symptoms	
Dermatitis	64–90
Diabetes/glucose intolerance	38–96
Weight loss	56–96
Glossitis/stomatitis/cheilitis	29–40
Diarrhea	14–15
Abdominal pain	12
Thromboembolic disease	12–35
Venous thrombosis	24
Pulmonary emboli	11
Psychiatric disturbance	0–17
Laboratory abnormality	
Anemia	33–90
Hypoaminoacidemia	26–100
Hypocholesterolemia	80

Treatment

The most important first step in treatment is to control the diarrhea and correct the dehydration, hypokalemia, and acidosis. Patients may require >5 L/day of fluid and >350 mm/day of potassium when the diarrhea is not controlled. Octreotide will control the diarrhea in 85%–90% of VIPoma patients. In nonresponders or patients who have become refractory, combinations of octreotide and glucocorticoids may be helpful. Other drugs that may help in individual patients include clonidine, indomethacin, lithium, phenothiazine, loperamide, lidamidine, propanolol, and metoclopramide.

In 40%–70% of adult patients with VIPoma, diffuse metastatic disease in the liver is present initially; therefore, surgical cure is not possible. For these patients, long-acting somatostatin analogues such as octreotide or lanreotide (**Fig. 1**) are the drugs of choice for treatment. If these fail or tumor growth continues, treatment with chemoembolization, hepatic embolization, or chemotherapy or radiolabeled somatostatin analogues (**Fig. 1**) may be helpful. If the majority of the metastatic disease in the liver can be safely resected, cytoreductive surgery may be of value in helping to control the symptoms of the hormone-excess state.

VIPomas similar to other NETs, overexpress somatostatin receptors in 80%–100% of well differentiated forms (comprise 80%–95% of all NETs). In addition to this over-expression being used to image these tumors by somatostatin receptor imaging (SRI), it is also being used to direct cytotoxic agents, particularly ^{177}Lu labeled somatostatin analogues (PRRT, peptide radioreceptor therapy). This approach is increasingly being used to treat NET patients with advanced, progressive disease and it has been reported to be particularly helpful in some functional NET syndromes, including VIPomas and carcinoid syndrome.

Glucagonomas (Jensen *et al.*, 2016; John and Schwartz, 2016; Metz and Jensen, 2008)

Glucagonomas are neuroendocrine tumors of the pancreas that ectopically secrete excessive amounts of glucagon and cause a syndrome characterized by a dermatitis (migratory necrolytic erythema), glucose intolerance or diabetes, and weight loss (**Table 8**).

Clinical Features

Glucagonomas usually occur in middle-aged and elderly populations. Migratory necrolytic erythema usually starts as an erythematous area typically at perifacial or intertriginous areas, such as the groin, buttocks, or thighs. It subsequently becomes raised and bullae form and break, resulting in eroded areas. The skin lesions may wax and wane and frequently precede the diagnosis of glucagonoma (mean, 6–8 years). Hypoaminoacidemia is a characteristic feature of glucagonomas, with plasma amino acid levels decreasing to $<25\%$ of normal, especially glycogenic amino acids such as alanine and glycine. Weight loss is another prominent feature of this syndrome and is not seen early in other panNETs unless malabsorption is present, suggesting that it is an intrinsic feature of this syndrome. Experimental studies support the conclusion that a novel anorectic substance, independent of glucagon, is released by these tumors and is responsible for the weight loss. Other prominent symptoms/clinical findings include glossitis or stomatitis, glucose intolerance or diabetes that may precede the diagnosis by years, predisposition to thromboembolism and anemia (**Table 8**).

Pathology/Pathophysiology

Glucagonomas are characteristically diagnosed late in their course and are usually large (average, 5–10 cm), and 50%–80% have evidence of metastatic spread at diagnosis, usually to the liver (43%–80%). Glucagonomas are usually single tumors and 50%–80% occur in the pancreatic tail.

Glucagon is a naturally occurring, 29-amino acid peptide characteristically released by the pancreatic A cells. Most of the findings of the syndrome are compatible with the known actions of glucagon stimulating glucogenolysis and gluconeogenesis and affecting gut secretion and motility. The exact pathogenesis of the migratory necrolytic erythema remains unclear and has been attributed by some to hypoaminoacidemia or to nutritional deficiencies such as zinc.

Diagnosis/Differential Diagnosis

The diagnosis is established by demonstrating an elevated plasma glucagon level (normal level is usually <150 ng/L). Plasma glucagon levels usually exceed 1000 ng/L in glucagonoma patients (90%), and in patients with symptoms/laboratory findings of glucagonoma (**Table 8**), a level >1000 ng/L is diagnostic. Other conditions can also cause elevated plasma glucagon levels, including pancreatitis, hepatic failure disease, renal failure, Cushing's syndrome, prolonged fast, or familial hyperglucagonemia. Except for cirrhosis, these disorders usually do not cause increases in plasma glucagon levels >500 ng/L. Recently new diseases are described that can cause hyperglucagonemia and can mimic glucagonomas. Mahvash disease is due to an inactivating mutation (homozygous P86S mutation) of the human glucagon receptor. It is associated with the development of α-cell hyperplasia, hyperglucagonemia, and the development of nonfunctioning pNETs. More recently, additional patients with other inactivating mutations of the human glucagon receptor have been described with similar findings, which has lead to the suggestion that a hepato-pancreatic feedback regulation of the cells, possibly involving amino acids, may exist in humans. A second disease called glucagon cell adenomatosis can also mimic glucagonoma syndrome and is characterized by the presence of hyperplastic islets staining positive for glucagon instead of a single glucagonoma.

Treatment

Diffuse hepatic metastases are usually present at diagnosis (in up to 80% of patients), so curative surgical resection is usually not possible. Surgical debulking or other antitumor treatments may be of palliative benefit. The drugs of choice are the long-acting somatostatin analogues (octreotide and lanreotide) (**Fig. 1**), which improve the rash in 75%–80% of patients and may improve the weight loss, pain, and diarrhea but usually do not improve the diabetes/glucose intolerance.

Somatostatinoma Syndrome (Jensen *et al.*, 2016; Metz and Jensen, 2008)

The somatostatinoma syndrome is caused by a neuroendocrine tumor of the GI tract that ectopically secretes excess amounts of somatostatin (**Fig. 1**), which frequently causes diabetes mellitus, gallbladder disease, diarrhea, and steatorrhea (**Table 9**). There is no general agreement on what constitutes a somatostatinoma, and there is no distinction in the literature regarding the presence of a somatostatinoma and/or the somatostatinoma syndrome. In the literature, the term somatostatinoma is generally used to mean a GI neuroendocrine tumor possessing somatostatin-like immunoreactivity, and it may (11%–45%) or may not (55%–89%) be associated with clinical symptoms due to ectopic release of somatostatin (**Table 9**). Because of this confusion, the term

Table 9 Clinical and laboratory findings in patients with somatostatinomas with or without somatostatinoma syndrome

somatostatinoma syndrome is used here to indicate a panNET-releasing somatostatinoma, which causes clinical symptoms, and the term somatostatinoma is used to indicate a panNET containing somatostatin immunoreactivity.

Clinical Features

The mean age of onset is 51–53 years. In one large review ($N = 173$), only 11% of all somatostatinomas in the literature were associated with the somatostatinoma syndrome. The principal clinical features of the somatostatinoma syndrome are gallbladder disease, diabetes mellitus, diarrhea, weight loss, and steatorrhea. The frequency of these symptoms depends on the location of the somatostatinoma (**Table 9**). Each symptom characteristic of the syndrome is reported more frequently with pancreatic than intestinal somatostatinomas. Recently the existence of whether a clinical somatostatinoma syndrome actually occurs has been called into question. This occurred because in one review of a large number of patients with patients with duodenal/pancreatic NETs, in the proportion of which showed predominant somatostatin expression, none had the somatostatinoma syndrome. However, in a number of other studies, a proportion of the patients with somatostatin positive pancreatic or duodenal NETs had number of the proposed features of the somatostatinoma syndrome, although the full constellation of symptoms was uncommon.

Pathology/Pathophysiology

Somatostatin is a naturally occurring tetradecapeptide (**Fig. 1**) found widely in the central nervous system and GI tract, where it functions as a neurotransmitter or has paracrine or autocrine actions. In general, it is a potent inhibitor of processes, including the release of numerous hormones, gastric and intestinal pancreatic secretion, and absorption. The hypochlorhydria, diabetes, steatorrhea, and gallbladder diseases that occur in somatostatinoma syndrome are caused by the known inhibitor effects of somatostatin.

Somatostatinomas occur in the pancreas in 56%–74% of cases and are mainly found in the pancreatic head. In most of the remaining cases, they are found in the intestine, with 90% in the duodenum, particularly in the periampullary area. They are usually solitary, large tumors (mean, 3.6–4.9 cm), and 53%–84% have metastatic spread at diagnosis (usually to the liver). They are frequently associated with neurofibromatosis I (von Recklinghausen's disease).

Diagnosis/Differential Diagnosis

In most cases in the literature, somatostatinomas have been found incidentally either at the time of cholecystectomy or during endoscopy. The presence of psammoma bodies in a duodenal neuroendocrine tumor should raise this possibility. Duodenal somatostatinomas are associated with von Recklinghausen's disease. Most of these patients do not develop the somatostatinoma syndrome and have normal plasma somatostatin levels. The diagnosis of the somatostatinoma syndrome requires the demonstration of an elevated plasma somatostatin level.

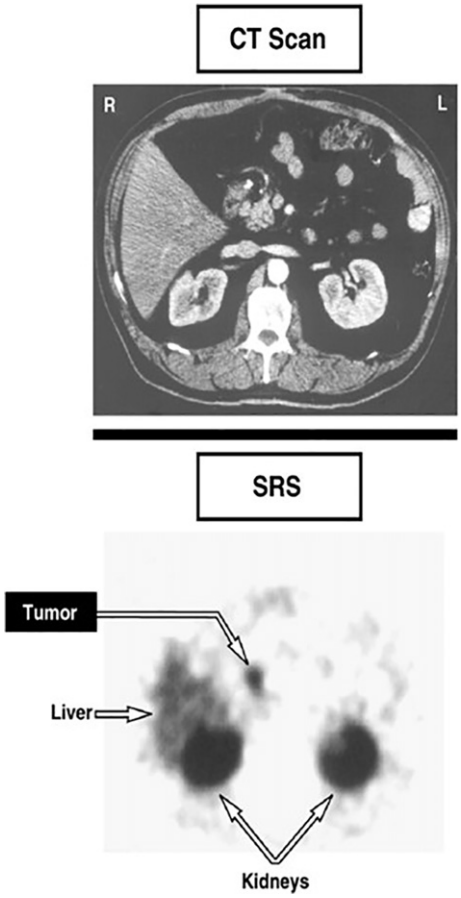

Fig. 2 Computed tomography (CT) scan (*top*) and somatostatin receptor scintigraphy (SRS) (*bottom*) of a patient with a pancreatic neuroendocrine tumor (gastrinoma). This patient previously had a duodenal tumor removed. The CT scan was negative, whereas the SRS showed a tumor medial and anterior to the right kidney. At surgery, a panNET was found in a metastatic lymph node in the periduodenal area. This case illustrates the greater sensitivity of SRS compared to conventional imaging studies.

Treatment

Symptoms of the somatostatinoma syndrome are improved by administration of long-acting synthetic somatostatin analogues such as octreotide/lanreotide (**Fig. 1**). Pancreatic tumors (70%–92%) and intestinal tumors (30%–69%) are associated with liver metastases at presentation and antitumor treatment is frequently needed.

GRFomas and Other Rarer Functional panNET Syndromes (Ito *et al.*, 2013a)

GRFomas are neuroendocrine tumors that ectopically secrete growth hormone-releasing factor (GRF). GRF is a 44-amino acid peptide that stimulates growth hormone release. GRFomas occur in lung (47%–54%), panNETs (29%–30%), small intestinal carcinoids (8%–10%), and other sites (12%). The symptoms are those of acromegaly and the mean age of patients is 38 years. The acromegaly is indistinguishable from classical acromegaly due to a pituitary adenoma. Pancreatic GRFomas are usually large (mean, >6 cm) and liver metastases are present in 39% of cases. They should be suspected in a patient with acromegaly with an abdominal tumor, MEN-1, or hyperprolactinemia, which occurs in 70% of GRFomas. The diagnosis is established by performing plasma assays for GRF and growth hormone. Surgery is the treatment of choice if possible. Symptoms can be controlled in $>75\%$ of patients by long-acting somatostatin analogues, such as octreotide or lanreotide (**Fig. 1**).

Cushing's syndrome due to a panNET occurs in 4%–16% of all patients with ectopic Cushing's syndrome. It occurs in 5% of patients with sporadic gastrinomas and is associated with hepatic metastases and a poor prognosis. Paraneoplastic hypercalcemia due to a panNET releasing PTH-related peptide is rare. These tumors are usually large and malignant. panNETs secreting calcitonin may cause a specific syndrome associated with diarrhea (**Table 2**). panNETs also cause the carcinoid syndrome (**Table 2**). These are characteristically large and malignant (68%–88%) and may cause an atypical carcinoid syndrome because they lack DOPA decarboxylase. A renin-producing panNET was described in a patient presenting with hypertension (**Table 2**). Ghrelin is a 28-amino acid peptide with a number of metabolic functions. Although expression has been demonstrated in most panNETs, in a one

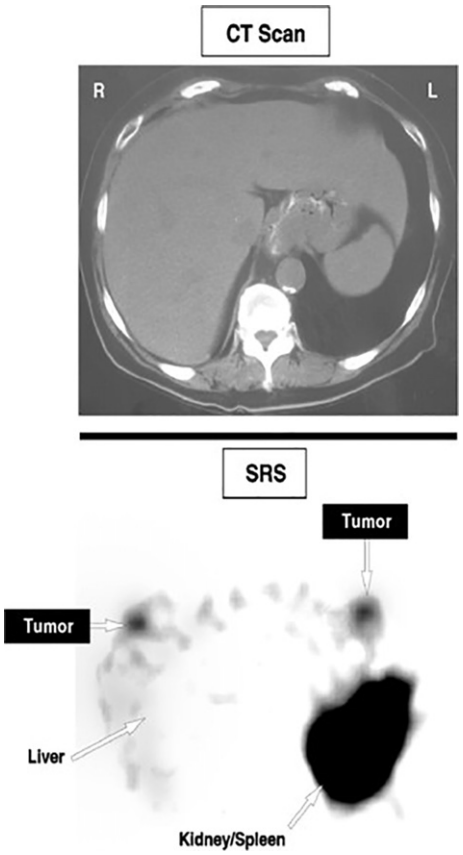

Fig. 3 Computed tomography (CT) scan and somatostatin receptor scintigraphy (SRS) of a patient with a metastatic panNET to the liver. The CT scan showed no liver lesions, whereas the SRS showed two hepatic metastases (one in the *right* lobe and one in the *left* lobe). This case illustrates the increased sensitivity of SRS compared to conventional imaging studies for localizing hepatic metastases.

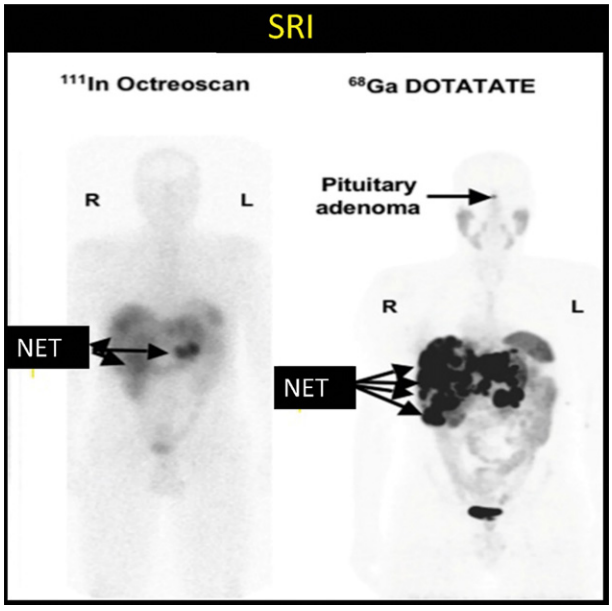

Fig. 4 Increased sensitivity of SRI with ^{68}Ga-DOTATATE PET/CT over SRS with [^{111}In-DTPA-DPhe^{1}] octreotide (Octreoscan) in a patient MEN1 with a pNET with liver metastases.

study only 1 of 24 patients (4%) with a panNET had an elevated plasma ghrelin level. This patient was asymptomatic, suggesting that no specific syndrome is associated with ectopic release of ghrelin by a panNET. A number of other very rare panNET syndromes involving a few cases (less than five) have been described; these include a panNET secreting erythropoietin, resulting in polycythemia; panNETs secreting IGF-II, causing hypoglycemia; a panNET secreting cholecystokinin (CCKoma) which can mimic ZES clinically with patients presenting with severe peptic ulcer disease, diarrhea, weight loss and gallstones, but with a normal fasting gastrin panNETs secreting enteroglucagon, causing small intestinal hypertrophy, colonic/SI stasis, and malabsorption.

Nonfunctional panNETs (Falconi *et al.*, 2012, 2016; Imamura *et al.*, 1992; Jensen *et al.*, 2012)

Nonfunctional PANNETs are neuroendocrine tumors of the pancreas that secrete no products or the secreted products do not cause a distinct functional syndrome. The symptoms from these tumors are therefore due entirely to the tumor per se (i.e., pain, jaundice, weight loss, etc.). Nonfunctional panNETs frequently secrete chromogranin A (CgA) (80%–100%), CgB (90%–100%), pancreatic polypeptide (PP) (58%), and the α-subunit of hCG (40%), and many secrete other hormones such as neurotensin, ghrelin or calcitonin. These tumors characteristically present late in the disease course. In a number of recent series an increasing proportion of NF-panNETs are asymptomatic (up to 50%) and are found at screening for various nonspecific symptoms. Characteristically, NF-panNETs are generally large (72% > 5 cm) and invasive, and hepatic metastases are usually present (64%–92%), although in the more recent series the asymptomatic ones are frequently small (<2 cm)and not metastatic. The most common symptoms are abdominal pain (30%–50%), jaundice (20%–35%), weight loss, fatigue, and bleeding. In 10%–15% of cases, they are found incidentally. The diagnosis is established by histology with appropriate neuroendocrine tumor immunohistochemistry and by assessing plasma hormone levels/clinical symptoms. Plasma PP is increased in 22%–71% of patients, CgA levels are increased in 80%–100%, and in patients with a pancreatic mass without a functional syndrome, this finding suggests that a nonfunctional panNET is present. In the older series where these patients generally presented late in the disease course curative surgical resection is rarely possible, and treatment needs to be directed against the malignant panNET. Currently the treatment of patients with asymptomatic NF-panNETs is controversial with some advocating a wait and watch with surveillance, while other propose resection.

Functional Syndromes Due to Carcinoid Tumors

Carcinoid tumors can cause a specific functional syndrome, the carcinoid syndrome, or occasionally can release biologically active peptides that cause the specific panNET syndromes discussed previously. Because carcinoids are also malignant (**Table 3**), specific treatments need to be directed at both the carcinoid tumor and the functional syndrome it produces.

Carcinoid Syndrome (Ito *et al.*, 2018)

The carcinoid syndrome is caused by a neuroendocrine tumor, usually present in the gastrointestinal tract in the midgut region, ectopically secreting bioactive amines/peptides, which results in a clinical syndrome characterized by diarrhea, flushing, asthma/wheezing, and, occasionally, heart disease (Ito *et al.*, 2018) (**Table 10**).

Clinical Features (Ito *et al.*, 2018)

The mean age at presentation is 57 years, but it occurs over a wide age range (9–91 years) (**Table 10**). The principal symptoms are diarrhea and flushing, which occur in up to 73% of cases initially and 84% during the course of the disease. The flush is usually of sudden onset, associated with a deep red to violaceous erythema of the upper body, and often associated with a feeling of warmth and occasionally with lacrimation, pruritis, or diarrhea. It may be precipitated by food, exercise, alcohol, or drugs, particularly serotonin reuptake inhibitors. Carcinoid syndrome is usually caused by metastatic midgut tumors. Flushing with midgut tumors and bronchial or gastric carcinoids may differ in duration, associated symptoms (salivation and lacrimation), and skin color. Diarrhea usually occurs with flushing (85% of cases) and is usually watery and of small volume (60% < 1 L/day). Steatorrhea is present in 67%, and in 50% of patients it is >15 g/day of fecal fat. Cardiac manifestations occur in 11% initially and 14%–41% during the disease course (**Table 10**), and they are due to endocardial fibrosis, primarily on the right side (tricuspid > pulmonary), but they can also occur on the left side. Fibrosis results in valve constriction and up to 80% of patients develop heart failure. Pellagra-like symptoms (2%–25%) and symptoms due to increased fibrotic tissue (i.e., retroperitoneal fibrosis, Peyronie's disease, and intraabdominal fibrosis) are unusual features of this disease.

A life-threatening complication of the carcinoid syndrome is the development of a carcinoid crisis (Ito *et al.*, 2018). This is most frequently seen in patients with high 5-hydroxyindoleacetic acid (5-HIAA) levels and may be provoked by anesthesia, endoscopy, stress, surgery, a radiological procedure, or a biopsy. Patients develop intense flushing, diarrhea, abdominal pain, hypotension, and cardiac abnormalities. If not adequately treated, it can be fatal.

Pathology/Pathobiology (Ito *et al.*, 2018; Klimstra, 2016)

Carcinoid symptoms occurred in 8% of 8876 patients with carcinoid tumors. Carcinoid syndrome occurs only when tumor-secreted products reach the systemic circulation in sufficient concentrations. In 91% of cases, this occurs due to liver metastases, and in the remainder it occurs due to retroperitoneal invasion by gut or pancreatic tumors or due to lung, testis or ovary carcinoids with direct access to the systemic circulation. Midgut carcinoids account for 60%–67% of cases of the carcinoid syndrome, foregut tumors account for 2%–33%, hindgut accounts for 1%–8%, and an unknown primary accounts for 2%–15%.

One of the main secretory products of carcinoid tumors is serotonin (5-HT), and overproduction occurs in 90%–100% of patients with carcinoid syndrome. Serotonin is thought to primarily mediate diarrhea by its effects on gut motility and intestinal secretion. However, prostaglandins and tachykinins (substance P, K; neuropeptide K) may also be important in causing diarrhea in some patients. Patients with the carcinoid syndrome have accelerated colonic motility with a shortened transit time as well as a possible secretory/absorptive alteration that is compatible with the known actions of serotonin in the gut mediated primarily through 5-HT_3 and, to a lesser degree, 5-HT_4 receptors. Serotonin receptor antagonists (especially 5-HT_3 antagonists) relieve the diarrhea in many, but not all, patients. A tryptophan 5-hydroxylase inhibitor, telotristat (LX-10310), which inhibits serotonin synthesis in peripheral tissues, caused a decrease in bowel movement frequency in 40%–50% of patients with the carcinoid syndrome (Ito *et al.*, 2018; Kulke *et al.*, 2014).

Flushing is not relieved by serotonin antagonists nor by the tryptophan 5-hydroxylase inhibitor, telotristat (LX-10310), which inhibits serotonin synthesis in peripheral tissues. In patients with gastric carcinoids flushing can be caused by histamine hypersecretion. Tachykinins are released during flushing and may be important in its mediation. Both histamine and serotonin may be responsible for the wheezing/asthma as well as the fibrotic reactions characteristic of this disease. The heart disease is likely due to the actions of serotonin because it is similar to that seen with appetite-suppressant drugs (e.g., fenfluramine) that have high affinity for serotonin receptors.

Patients may develop a typical or atypical carcinoid syndrome. The typical syndrome is due to a midgut tumor over-synthesizing serotonin from tryptophan. The atypical syndrome occurs when there is a deficiency in the enzyme required to convert 5-HTP to 5-HT and there is overproduction of 5-HTP. The atypical syndrome is more likely to occur with foregut carcinoids.

Diagnosis/Differential Diagnosis (Ito *et al.*, 2018)

The diagnosis of carcinoid syndrome requires measurement of urinary or plasma serotonin or its metabolites. The measurement of urinary 5-HIAA is most frequently performed. Generally, the urinary 24-h 5-HIAA excretion rate is assessed when this diagnosis is suspected; even though studies report an overnight urinary collection is just as accurate. Assessment of plasma and platelet serotonin levels and plasma 5-HIAA, if available, may provide additional information and/or substitute for the 24 h urinary 5-HIAA study. Platelet serotonin levels are more sensitive than urinary 5-HIAA but are not generally available. A single plasma 5-HIAA determination is recently reported to have similar sensitivity/specificity to that with the 24-h urinary 5-HIAA assessment and because it avoids the problem of incomplete or improper collections as seen with urinary collections, it may be generally useful. It however, could be affected by renal disease. False positives may occur if a patient eats serotonin-rich foods (bananas, walnuts, pecans, and pineapple) or takes certain medications (L-Dopa, cough syrups with guaniforesin, and salicylates). If an atypical carcinoid syndrome is suspected, urinary 5-HIAA may be only slightly elevated, and other metabolites of tryptophan such as 5-HTP should be considered. Serum CgA levels are elevated in $>50\%$ of patients with carcinoid tumors, and the level correlates with the tumor extent. However, serum CgA levels lack specificity for carcinoids because they can occur with other NETs, including panNETs. Furthermore, potent acid antisecretory drugs such as proton pump inhibitors (PPIs) (omeprazole and related drugs) can elevate serum CgA levels; the elevation occurs rapidly (3–5 days) with continued use, and the elevated levels overlap with the levels seen in many patients with NETs. Plasma neuron-specific enolase levels are also used as a marker of GI-NETs (carcinoids) but are less sensitive than CgA, being increased in only $<50\%$ of patients. Newer markers have been proposed including pancreastatin (a chromogranin A breakdown product), and activin A. Activin A is not affected by proton pump inhibitors; however, its sensitivity and specificity are not established. Plasma activin elevations are reported to correlate with the presence of cardiac disease with a sensitivity of 87% and specificity of 57%. Plasma levels of N-terminal pro Brain Natriuretic Peptide also correlate with carcinoid heart disease severity.

Flushing can be caused by other conditions, including systemic mastocytosis, reactions to alcohol or glutamate, effects of drugs, and menopause. These need to be excluded.

Treatment (Ito *et al.*, 2018)

Treatment consists of avoiding conditions that precipitate attacks and treatment of wheezing with bronchodilators, treatment of heart failure with diuretics, and treatment of diarrhea with antidiarrheal agents, such as loperamide or diphenoxylate. If symptoms persist, somatostatin analogues (octreotide and lanreotide) (**Fig. 1**) or serotonin receptor antagonists are the drugs of choice. Somatostatin analogues control symptoms in 80% of patients with flushing or diarrhea, and 70% show a $>50\%$ decrease in urinary 5-HIAA. Approximately 40% of patients show some resistance after 4–6 months and doses may have to be increased.

Sustained-release preparations, such as octreotide-LAR (long-acting release) and lanreotide-PR (prolonged release), are widely used because they can be given less frequently. Octreotide-LAR is usually given monthly and lanreotide-PR every 10–14 days as opposed to the usual preparation of octreotide/lanreotide that is given subcutaneously every 6–12 h. Somatostatin analogues can be given to both treat and prevent carcinoid crises. Prior to a possible precipitating event, such as surgery, anesthesia, or stress, it is recommended that octreotide be administered.

Side effects from the somatostatin analogues occur in 40%–60% of patients with subcutaneous analogues. Pain at the injection site and GI side effects (discomfort, nausea, diarrhea, and cramping) are the most common. They are usually short-lived and do not interrupt treatment. Long-term complications include an increased incidence of gallstones/biliary sludge (52%), steatorrhea, and worsening glucose tolerance. Interferon-α may also control symptoms in some patients.

A recent phase 3 prospective, double-blind study demonstrates that the peripheral tryptophan hydroxylase inhibitor, telotristat, can be effective at controlling the diarrhea in many of these patients.

Carcinoid heart disease is associated with a decreased mean survival and therefore, it should be sought for and carefully assessed in all patients with carcinoid syndrome. The use of transthoracic echocardiography is important in establishing the diagnosis of carcinoid heart disease and determining the extent and type of cardiac abnormalities. Treatment with diuretics and somatostatin analogues can reduce the negative hemodynamic effects and secondary heart failure. It currently is not established whether long-term treatment with these drugs or with the tryptophan hydroxylase inhibitor, telotristat, when it becomes available, will stop and/or reverse the progression of carcinoid heart disease.

Surgery should be performed if possible; however, almost all patients with carcinoid syndrome have metastatic disease in the liver and curative resection is not possible. Treatment directed against the tumor may be needed.

NET Tumor Localization (Dromain *et al.*, 2016; ElGuindy *et al.*, 2017; Ito and Jensen, 2016, 2017) (Figs. 1–4)

Tumor localization is needed for all management phases of both panNETs and carcinoid tumors (Falconi *et al.*, 2016; Ito and Jensen, 2016, 2017). Both the localization of the primary tumor and the determination of the location and extent of metastatic disease are required to appropriately manage these patients. Conventional imaging studies (CT, magnetic resonance imaging (MRI), ultrasound, and angiography) and somatostatin receptor imaging (SRI) are widely used (**Figs. 1–4**) (Ito and Jensen, 2017; Sundin *et al.*, 2015, 2017). For SRI, originally somatostatin receptor scintigraphy (SRS) was used with ^{111}In-penetreotide and SPECT/CT detection, but it is being rapidly replaced by ^{68}Ga DOTATATE PET/CT which has a greater resolution resulting in higher sensitivity and high specificity (Ito and Jensen, 2017; Sundin *et al.*, 2017) (**Fig. 4**). For panNETs, endoscopic ultrasound is also widely used. Bronchial carcinoids are usually detected by chest X-ray and assessed by CT. Rectal, duodenal, colonic, and gastric carcinoids are usually detected by GI endoscopy.

Both panNETs and carcinoids frequently (90%–100%) overexpress somatostatin receptors, which have a high affinity for radiolabeled somatostatin analogues (**Figs. 1–4**) that can be used to localize them. Because of its greater sensitivity compared to that of conventional imaging studies and its ability to localize a number of tumors throughout the body simultaneously, SRI is the imaging modality of choice for localizing all primary and metastatic NET tumors except insulinomas (Ito and Jensen, 2017; Sundin *et al.*, 2017) (**Figs. 2** and **3**). Insulinomas are usually small and have a low density of somatostatin receptors, with the result that SRI is positive in only 12%–50% of patients with insulinomas. GLP1 based radionuclide imaging has recently be shown to be both sensitive and specific in identifying insulinomas. In contrast, SRI is positive in 73%–100% of patients with carcinoids and 60%–100% of patients with panNETs other than insulinomas. SRI is positive in almost all patients with well-differentiated NETs, but in a lower percentage with poorly differentiated NETs (G3-NEC).

Figs. 2 and **3** show two examples of the ability of SRS to image a primary panNET and metastatic disease in the liver when conventional imaging studies were negative. For panNETs localized in the pancreas, endoscopic ultrasound is highly sensitive, localizing 73%–100% of insulinomas, which occur almost exclusively within the pancreas. SRS occasionally gives false positives (12% in one study) because normal and abnormal cells can have increased somatostatin receptors such as granulomas, thyroid disease, and activated lymphocytes (abscess and infection). Furthermore, SRS does not provide information on tumor size or the exact location of metastases, and a CT scan or MRI are frequently used to provide this information. **Fig. 4** shows the greater sensitivity of SRI with ^{68}Ga DOTATATE PET/CT over ^{111}In-penetreotide and SPECT/CT detection.

Treatment of Advanced Diffuse Metastatic Disease in Patients With Malignant NETs (Ito *et al.*, 2012b, 2016; Kunz *et al.*, 2013; Pavel *et al.*, 2016)

Of the numerous prognostic factors identified for NETs (**Table 4**), the presence and the extent of the hepatic metastases are the most important in almost every study. For patients with gastrinomas, 5-year survival is 98%–100% without liver metastases, 78% with limited metastases in one lobe, and 16% with diffuse metastases. For carcinoid tumors without liver metastases, 5-year survival is 80%–90%, and with diffuse metastases it is 50%. A number of treatments are reported to be effective, including various liver-directed therapies (embolization, chemoembolization, radioembolization); chemotherapy; cytoreductive surgery (removal of all visible tumor); treatment with biologics (somatostatin analogues, α-interferon); tyrosine kinase inhibitors (sunitinib); mTOR

inhibitors (everolimus); radiotherapy using radiolabeled somatostatin analogues to target the tumor (PRRT) (**Fig. 1**), and liver transplantation.

Specific Antitumor Treatments

The recent validation of the prognostic value of the different classification and grading systems (World Health Organization (WHO), European Neuroendocrine Tumor Society (ENETS), the American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC)) are resulting in them playing an essential role to stratify patients into different risk groups and also in influencing the type of therapy (Klimstra, 2016; Singhi and Klimstra, 2018). A particular important prognostic factor is whether the NET is well differentiated (G1/G2) or poorly differentiated (<1% of all NETs) (G3). Well-differentiated NETs have a 5-year survival of 60%–80%, whereas poorly differentiated NETs have a 5-year survival of only 0%–15%.

Unfortunately, cytoreductive surgery is only possible in 10%–20% of patients who have limited hepatic metastases, allowing surgical removal of at least 90% of visible tumor. Although it is reported to provide palliative treatment, there are no control studies to support this conclusion. However, studies suggest that it may increase survival; therefore, cytoreductive surgery is recommended, if possible.

Chemotherapy for metastatic carcinoids is generally disappointing, with response rates of 0%–40% with various two to three drug combinations (Angelousi *et al.*, 2017; Metz and Jensen, 2008; Pavel *et al.*, 2016). With panNETs, chemotherapy has been more successful, with response rates of 30%–70%. The regimen of choice for many years for panNETs was streptozotocin and doxorubicin, however recent studies demonstrate the combination of temozolomide (TMZ) with capecitabine is effective in panNETs and thus it is receiving attention as a possible alternative to streptozotocin based therapy. An important distinction in patients with pNETs is whether the tumor is well differentiated (G1/G2) or poorly differentiated (G3). The chemotherapeutic approach is different for these two groups. Whereas the current regimen of choice for patients with well-differentiated pNETs is the combination of streptozotocin and doxorubicin with or without 5-fluorouracil, this is not the case for poorly differentiated NETs. The classification systems have therapeutic implications because it is proposed to treat the G3 NET tumors similar to treatment for well-differentiated G2 tumors, whereas for G3 NEC tumors (poorly differentiated G3), treatment with cisplatin-based regimens with etoposide or other agents (vincristine, paclitaxel) is recommended. The response rates with this protocol are 40%–70%; however, responses are generally short-lived (<12 months). This chemotherapy regimen can be associated with significant toxicity including GI toxicities (nausea, vomiting), myelosuppression.

Unfortunately, chemotherapy in almost never curative and has substantial toxicity. Therefore, it is generally reserved for patients with rapidly growing panNETs who fail other treatments.

Long-acting somatostatin analogues (**Fig. 1**) and α-interferon rarely decrease tumor size (i.e., 0%–15%); however, these drugs have prominent tumoristatic effects, stopping growth in 50%–90% of patients with NETs. Studies suggest that they are particularly effective in slower growing tumors. It has not been proven that these agents extend survival; however, because of the availability of long-acting formulations (e.g., one injection of somatostatin/month), their low toxicity, and their long-term effectiveness in some patients, they are the antitumor agents of choice. Recently large randomized double-blind phase 3 trials have supported the effectiveness of long-acting somatostatin analogues for extending progression free survival in patients with panNETs and carcinoids (Caplin *et al.*, 2014; Yao *et al.*, 2011).

Molecular targeted medical treatment with either an mTOR inhibitor (everolimus) or a tyrosine kinase inhibitor (sunitinib) is now approved treatment in the United States/Europe for patients with metastatic unresectable panNET, each supported by a phase 3, double-blind, prospective, placebo-controlled trial (Raymond *et al.*, 2011; Yao *et al.*, 2011). In addition, a recent phase 3 double -blind study (RADIANT-4) (Yao *et al.*, 2011) demonstrated the effectiveness of everolimus in in advanced, nonfunctional NETs of the lung or GI-Tract. In this study involving patients with advanced, progressive well differentiated, NF-lung/GI-NETs, everolimus significantly ($P < 0.000001$) improved progression-free survival and this has led to FDA approval for its use in patients with these tumors in the United States.

Hepatic embolization or chemoembolization (i.e., chemotherapy with embolization) can decrease tumor bulk and help control the symptoms of the hormone-excess state. This approach is usually reserved for patients who have disease largely confined to the liver, who have a patent portal vein, and who fail treatment with other modalities. Selective internal radiation therapy (SIRT) using yttrium-90 (^{90}Y) glass or resin microspheres is a relatively newer approach being evaluated in patients with unresectable NET liver metastases. The response rate varied from 50% to 70% (partial or complete), tumor stabilization occurred in 20%–40%, 60%–100% had symptomatic improvement, and overall survival varied from 25 to 70 months.

Somatostatin receptor-directed cytotoxicity using radiolabeled somatostatin analogues that are internalized by somatostatin receptors (Kwekkeboom and Krenning, 2016) (**Fig. 1**) overexpressed on the NET are being widely investigated. The following are being evaluated for treatment: ^{111}indium (^{111}Ln)-labeled compounds, which emit gamma rays, internal conversion, and Auger electrons; ^{90}yttrium-coupled analogues, which emit high-energy β particles; and ^{177}lutetium (^{177}Lu)-coupled analogues, which emit both. The ^{177}Lu and ^{111}In compounds have respectively been shown to stabilize disease in 41% and 40% and decrease tumor size in 38% and 30% of patients with advanced metastatic NETs. Recently results from a double-blind, prospective, randomized trial (NETTER-1 Study) demonstrate the efficacy and safety of PRRT in patients with advanced inoperable, progressive midgut GI-NETs (carcinoids). In this trial which included patients with metastatic, progressive midgut carcinoids, a marked increased in progressive-free survival ($P < 0.0001$) was seen with PRRT treatment with a ^{177}Lu-labeled-somatostatin-analog, with an

acceptable safety profile and with a suggestion of an improved survival (Strosberg *et al.*, 2017), although final survival analysis is not yet complete. This study is now under review at the FDA in the US and is not approved for general use at present. The ENETS 2016, NANETS, Nordic 2010, and European Society for Medical Oncology (ESMO) guidelines list PRRT as an experimental or investigational treatment at present.

Liver transplantation, although largely abandoned for most metastatic tumors, is still a consideration for patients with metastatic NETs because of their slower growth. In 103 cases of malignant NETs (43 carcinoid, 48 panNETs), liver transplantation achieved 2- and 5-year survival rates of 60% and 47%, respectively. Liver transplantation has been suggested for younger patients with metastatic NETs limited to the liver.

Gastrinomas☆

Robert T Jensen, National Institutes of Health/National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, United States

Glossary

Gastrin A hormone of 17 or 34 amino acids that is produced primarily in G cells of the gastric antrum and regulates gastric acid secretion and proliferation of cells of gastric oxyntic mucosa.

Multiple endocrine neoplasia type 1 (MEN1) An inherited disorder characterized by hyperplasia/tumors of multiple endocrine organs (parathyroid > pancreatic endocrine tumors (PETs) > pituitary) and present in 20% to 25% of patients with Zollinger–Ellison syndrome; caused by abnormality in the MEN1 gene on chromosome 11q13, which encodes for a 610-amino acid nuclear protein, MENIN.

Zollinger–Ellison syndrome (ZES) Clinical syndrome caused by gastrinomas secreting excess gastrin (e.g., severe peptic disease, acid hypersecretion).

Introduction

In 1955, R. M. Zollinger and E. H. Ellison at Ohio State University described two patients with intractable peptic ulcer disease (PUD) due to massive gastric acid hypersecretion and non-beta islet cell tumors of the pancreas (Zollinger and Ellison, 1955). Zollinger and Ellison proposed that the tumors were secreting an ulcerogenic substance. In 1961, R. A. Gregory reported the extraction of a gastrin-like substance from a patient with Zollinger–Ellison syndrome (ZES), and in 1969, Gregory reported the acid secretagogue to be gastrin, a hormone released under normal physiological conditions (e.g., meal ingestion, low acid levels in the stomach) from gastric antral G cells (Gregory *et al.*, 1969). The main circulating form contains 17 amino acids (G-17) or an N-terminally extended form (G-34), although gastrinomas also have other precursor forms (e.g., progastrin, COOH glycine-extended forms). Patients with ZES have high serum levels of gastrin (hypergastrinemia), and this causes continuous secretion of acid from the parietal cells as well as inducing growth of the gastric mucosal cells, especially the parietal cells and gastric enterochromaffin-like (ECL) cells of the oxyntic mucosa. In addition to causing clinical symptoms due to the gastric acid hypersecretion, 60%–90% of gastrinomas are malignant (Metz and Jensen, 2008).

Clinical Features (Roy *et al.*, 2000)

The mean age at presentation is in the fifth decade of life, and the presenting symptoms are almost always due to the consequences of the gastric hypersecretion. Abdominal pain due to PUD and diarrhea due to the acid hypersecretion are the most common symptoms. Esophageal disease (e.g., heartburn, stricture), nausea, vomiting, and bleeding, either alone or in combination, are not infrequent (**Table 1**). Only late in the course of the disease does the tumor per se generally cause symptoms (e.g., weight loss, pain). The diagnosis is characteristically delayed 5–7 years from onset of symptoms because early ZES is usually mistaken for idiopathic PUD. Approximately one-fourth of patients have ZES as part of the familial syndrome, multiple endocrine neoplasia type 1 (MEN1), which is almost invariably associated with hyperparathyroidism, frequently with renal stones (Gibril *et al.*, 2004). In a certain proportion of patients, the ZES diagnosis is delayed sufficiently and the disease is severe enough to cause complications of PUD as important symptoms (e.g., bleeding, perforation, esophageal stricture).

Pathophysiology/Pathology

In almost all patients all of the initial symptoms listed in **Table 1** are due to the gastric acid hypersecretion. Usually, only late in the disease course with advanced disease are there any symptoms due to the growth of the gastrinoma per se.

Gastrinomas were originally reported to be non-beta cell tumors of the pancreas, but currently approximately 50%–90% are found in the duodenum, 10%–30% in the pancreas, and the remainder in other sites (**Table 1**). One controversial area is whether primary gastrinomas occur in abdominal lymph nodes. A long-term National Institutes of Health (NIH) study suggests that 10%–11% of all primary gastrinomas may occur in lymph nodes (Norton *et al.*, 2003). Other unusual intra-abdominal sites

☆*Change History:* April 2018. All changes by Robert T Jensen.

Liver metastases only	>3	4–14
Lymph node metastases only	16	4–23

include the gastric antrum, biliary tract or liver, mesentery, ovary, and spleen. Extra-abdominal gastrinomas also occur rarely (<0.5%) in the cardiac intraventricular septum and due to a small cell lung cancer secreting gastrin. In the duodenum, 57% of the gastrinomas occur in the first portion and 31% occur in the second portion. Most patients have localized disease at presentation (83%) with no liver metastases, although 17% have or develop liver metastases (Jensen *et al.*, 2006). Approximately one-third of patients have a primary tumor only found at surgery, one-third have a primary tumor with lymph node metastases, one-fourth have a primary tumor with liver metastases, and one-fifth have either only liver metastases (3%) or only lymph node metastases (19%) (**Table 2**). At surgery, 60%–90% of gastrinomas occur within the "gastrinoma-triangle," which is an area formed by the junction of the cystic/common bile ducts posteriorly, the junction of the second/third parts of the duodenum inferiorly, and the junction of the pancreatic neck/body medially (Stabile *et al.*, 1984). This occurs because of the high frequency of duodenal gastrinomas now being detected which were missed previously.

All gastrinomas, like other pNETs and carcinoid tumors, are now classified as neuroendocrine tumors (NETs). A number of different classification systems have been proposed for staging and grading NETs and were developed by the World Health

Organization (WHO), European Neuroendocrine Tumor Society (ENETs) Union for International Cancer Control (UICC). These are now required to manage patients with NETs, because they have prognostic value and are can dictate different therapeutic approaches in some cases. These classification systems are based on the degree of tumoral differentiation (good vs. poor), tumor size, tumor invasion, and tumor extent. The tumor grading, reflects tumoral cell proliferation rate, is particularly important and involves establishing which of three different grades the tumor is in. The three grades vary in proliferative indices including mitotic rate and Ki 67. Currently for GI-NETs/pNETs low grade-G1 is <2 mitoses/10-HPF or Ki67 $< 3\%$; intermediate grade-G2 is 2–20 mitosis/10-HPF or Ki67 3%–20% and high grade-G3 is >20 mitosis/HPF or Ki67 $> 20\%$).

Molecular Pathogenesis of Gastrinomas

Similar to other gastrointestinal neuroendocrine tumors (NETs) (e.g., carcinoids, pancreatic endocrine tumors, PETS), mutations in common oncogenes (e.g., ras, c-Jun, 1-fos) are uncommon in gastrinomas, as are alterations in common tumor suppressor genes (e.g., retinoblastoma, p53). However, recent studies show that mutations in both the p53 pathway and the retinoblastoma (RB) pathway occur in pNETs. The Rb pathway can be inactivated in many pNETs (including gastrinomas) by amplification of genes encoding the cyclin-dependent kinases Cdk4/Cdk6. Another study found the p53 pathway was altered in 70% of pNETs through aberrant activation of its negative regulators-MDM2 (mouse double minute 2 homolog), MDM4, and WIPI (WD-repeat protein interacting with phosphoinosides).

In approximately 20%–25% of patients with ZES have Multiple Endocrine Neoplasia type 1 syndrome (Wermer syndrome) (MEN1/ZES). MEN1 is an autosomal dominant disorder due to mutations in the MEN1 gene on chromosome 11 (11q13) (Jensen *et al.*, 2008). The MEN1 gene has 10-exons encoding for a 610 amino acid protein, MENIN. MENIN is a nuclear protein that interacts with a large number of proteins such as JunD; nuclear factor-kB(NF-kB), FANCD2 (a DNA-repair-factor), NM23, SMAD3; RPA2 (a DNA-processing-factor); the AP1-transcription factor, nucleoside diphosphate kinase, cytoskeletal-associated proteins, and various histone-modifying enzymes. Mutations in the MEN1 gene occur in one-third of sporadic gastrinomas. A recent study reported results of exomic sequencing of 10 sporadic pNETs, and found the MEN1 gene was the most frequently altered gene. MEN1 gene mutations occurred in 44% followed in frequency by mutations in 43% in genes encoding for two subunits of a transcription/chromatin remodeling complex consisting of DAXX (death-domain associated-protein) and ATRX (a-thalassemia/mental retardation syndrome X-linked), followed by mutations in mToR pathway genes (15%).

Recent studies provide evidence for the importance in pNETs/gastrinomas of alterations in p16/MTS1 tumor suppressor gene (50%–90%), DPC4/Smad gene (20% in pNETs), amplification of the HER-2/neu proto-oncogene, mTor/Akt/PI3K pathway, as well as increased expression of a number of growth factors and/or their receptors. A number of recent studies provide evidence that the mToR/Akt/PI3K pathway is particularly important for mediating the growth of pNETs. This evidence includes the success of the mTOR inhibitor, everolimus, in extending disease-free survival in patients with advanced pNETs (Yao *et al.*, 2011).

Comparative genomic hybridization (CGH) and genomic-wide allelotyping studies report that chromosomal gains/losses occur frequently in most pNETs, including in gastrinomas. The frequency of these changes differs between GI-NETs (carcinoids) and pNETs, supporting the conclusion that they have a different pathogenesis. In pNETs, allelic losses occur most frequently at chromosomal locus 1p (20%–75%), 1q (20%–90%), 3p (40%–96%), 11p (30%–50%), 11q (30%–70%), and 22q (40%–95%). With pNETs, chromosomal gains occur most frequently at 17q (10%–55%), 7q (15%–70%), and 4 q (33%). A number of these alterations are associated with malignant behavior including deletions at chromosome 1, 3p, 6, 11q, 17p and 22p, and gains on chromosome 4, 7, 14q, Xp.

Results are reported from a number of studies in which pNETs were studied using microarrays to assess gene expression profiles. Results from eight studies in pNETs have been summarized and they demonstrate a wide variation in the number of genes upregulated or downregulated. It is not clear which specific gene changes are important in the molecular pathogenesis of the pNET.

Diagnosis/Differential Diagnosis

The diagnosis remains elusive, with a 4- to 7-year delay in diagnosis from onset of symptoms (**Table 1**). This delay occurs because ZES is uncommon (1–3 new cases/1 million population/year) and its presentation closely mimics common disorders: idiopathic PUD (2300 cases/1 million population/year), idiopathic gastroesophageal reflux disease (GERD), which occurs in 3%–4% of the population and drug-induced PUD. The widespread use of proton pump inhibitors (PPIs) is both complicating and delaying the diagnosis of ZES (Corleto *et al.*, 2001). This is occurring because PPIs are potent acid suppressants that, in contrast to histamine H2-receptor antagonists, can control symptoms in patients with ZES at doses usually used for GERD/PUD in non-ZES patients, thereby masking the diagnosis. Furthermore, PPIs can cause hypergastrinemia in patients without ZES, and this can complicate the diagnosis of ZES in these patients. The diagnosis of ZES should be particularly suspected in patients with PUD with diarrhea, endocrinopathies, family history of PUD or endocrinopathies, and/or recalcitrant PUD disease as well as in patients with PUD without *Helicobacter pylori* or with PUD complications. The first step in establishing the diagnosis is made by measuring fasting gastrin levels which are elevated in 90% to 98% of patients (Berna *et al.*, 2006b). If the fasting gastrin level is elevated, gastric fluid pH should be assessed and

the fasting gastrin should be repeated. If the gastric pH is <2.0 and the fasting serum gastrin is elevated, it is supports the diagnosis that ZES is present (Berna *et al.*, 2006b; Roy *et al.*, 2001). If the fasting gastrin is elevated >10-fold with a gastric pH <2, ZES is confirmed when there is no previous history of gastric resection. Unfortunately, two-thirds of patients have fasting gastrin levels increased <10-fold (101–999 pg/mL), and a number of other conditions can mimic ZES in this range (e.g., *H. pylori* infection, gastric outlet obstruction, antral G-cell hyperplasia/hyperfunction, chronic renal failure, short bowel syndrome). These can be excluded by both measuring a basal gastric secretory rate for 1 h and performing a secretin test (Berna *et al.*, 2006a). The secretin test yields no false positives except in patients with achlorhydria or taking PPIs, and it is positive in 94% of patients with ZES (≥120 pg/mL increase post secretin) in this fasting gastrin range. The calcium stimulation test is now rarely used with the recent availability of secretin again. One of the main difficulties in establishing the diagnosis of ZES is that in most patients the PPI has to be stopped or withheld (e.g., PPIs × 1 week, histamine H_2 antagonists × 1 day) to obtain a gastric pH <2. This can be dangerous in a true ZES patient (Poitras *et al.*, 2012) and therefore is best performed by referring the patient to gastrointestinal unit with expertise in the diagnosis and treatment of ZES (Ito *et al.*, 2012a; Metz, 2012).

Tumor Localization

Localizing the primary tumor, as well as determining the extent of the tumor, is essential for all management steps (Ito *et al.*, 2013a; Jensen *et al.*, 2006). It is necessary to determine whether surgical exploration should be undertaken, the extent of possible resection, and the location of the primary tumor (to enhance the possibility of cure), as well as to assess changes in tumor size with patients with advanced metastatic disease, either in response to antitumor treatment or in determining the need for it. The most sensitive imaging modality at present is to use somatostatin receptor imaging (SRI) (Ito and Jensen, 2017). This was developed when it was realized that almost all gastrinomas, as well as most well differentiated pNETs and carcinoids, overexpress somatostatin receptors and thus can be imaged using radiolabeled somatostatin analogues (Krenning *et al.*, 1993). Until recently this was generally performed using somatostatin receptor scintigraphy (SRS) with [^{111}In-DTPA-DPhe^1]-octreotide (**Figs. 1** and **2**) with detection with single photon emission computed tomography (SPECT). SRS is more sensitive than all conventional imaging modalities combined (e.g., computed tomography, CT, magnetic resonance imaging, MRI, ultrasound), but it does not give reliable information on tumor size (**Figs. 2** and **3**). Therefore, a CT scan with contrast is also recommended. Recently the use of ^{68}Ga-DOTATATE has been approved in the United States and most countries because it has greater sensitivity and specificity that SRS (**Fig. 4**) and is now the procedure of choice for SRI imaging (Ito *et al.*, 2013a; Ito and Jensen, 2017). Endoscopic ultrasound is recommended by some but rarely localizes duodenal tumors; therefore, it is helpful in a minority of the patients. For the rare patients with negative SRI, functional/localization studies measuring gastrin gradients with angiography are occasionally used.

Management

General

Treatment needs to be directed at controlling the gastric acid hypersecretion initially and long term as well as directed at the gastrinoma per se (Falconi *et al.*, 2016; Jensen *et al.*, 2006; Metz and Jensen, 2008). It is also important to determine whether the patient has ZES due to the presence of MEN1 because this requires additional treatment strategies. MEN1 is generally recognized by a careful family and personal history for endocrinopathies (especially hyperparathyroidism, pituitary disease, and other pancreatic endocrine tumors (PETs) and assessment for these endocrinopathies by appropriate hormonal assays. The hyperparathyroidism is usually present prior to ZES onset and is best diagnosed by measuring serum ionized calcium levels and plasma-intact PTH (**Table 3**).

Control of Acid Hypersecretion

Many patients with ZES have basal acid secretory rates elevated more than fivefold and can rapidly develop complications due to the gastric acid hypersecretion if it is not controlled both acutely and for the long term (Ito *et al.*, 2013b; Jensen *et al.*, 2006; Roy *et al.*, 2001). PPIs (e.g., omeprazole, lansoprazole, pantoprazole, rabeprazole, esomeprazole) are now the mainstay of treatment, starting at a dose equivalent to 60 mg per day of omeprazole. Patients with MEN1, severe GERD, or previous gastric acid-reducing surgery should be started on this dose given twice a day. With time, the dose can be decreased in most patients. During periods when parenteral antisecretory drugs are needed, intravenous PPIs (intravenous pantoprazole in the United States) are now the drugs of choice. Oral or intravenous histamine H_2 receptors can be used, but high, frequent oral dosing is needed and if needed parenterally, continuous intravenous infusions are recommended. Total gastrectomy is rarely used today and is reserved for the rare patient who cannot take oral medication (**Table 3**) (Ito *et al.*, 2013b; Jensen *et al.*, 2006; Roy *et al.*, 2001).

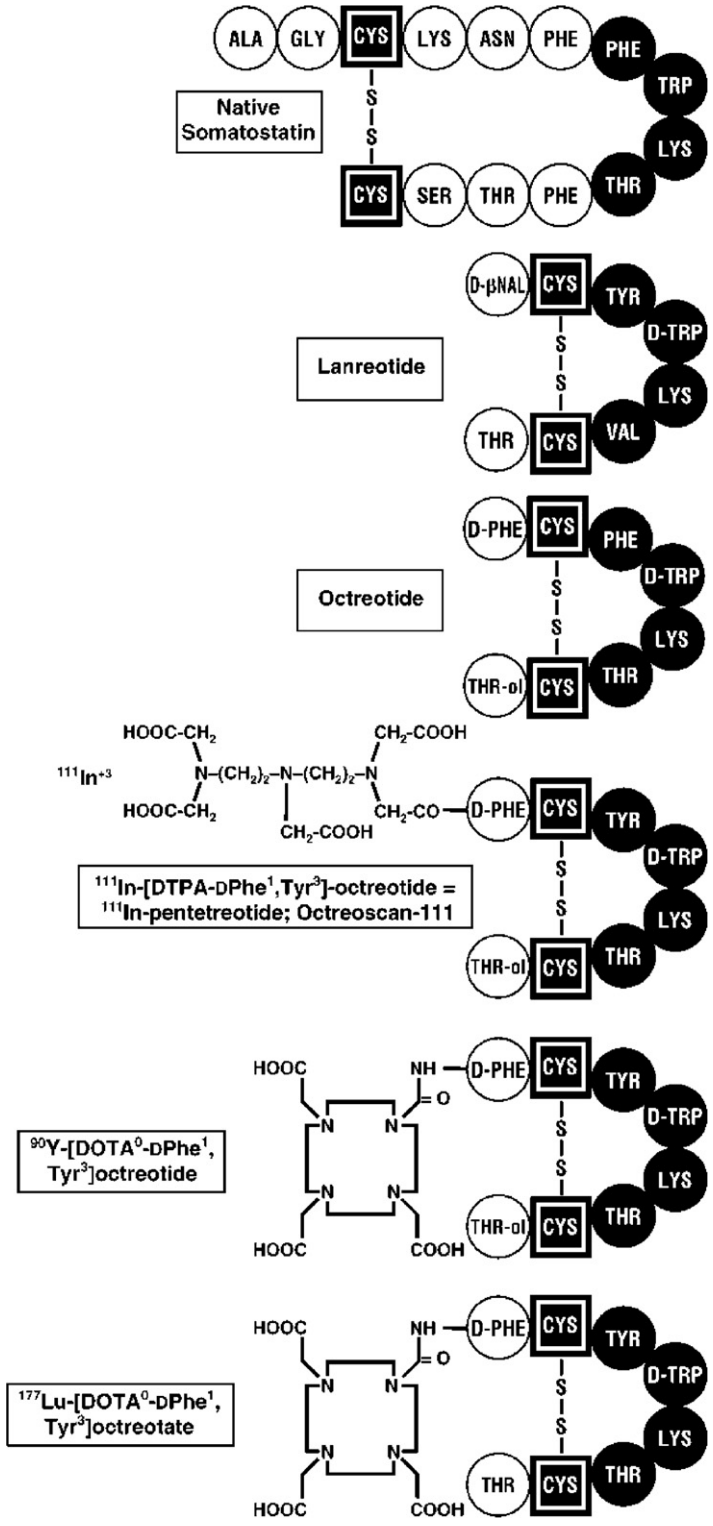

Fig. 1 Structure of somatostatin and synthetic analogues used for tumor localization or radiotherapy.

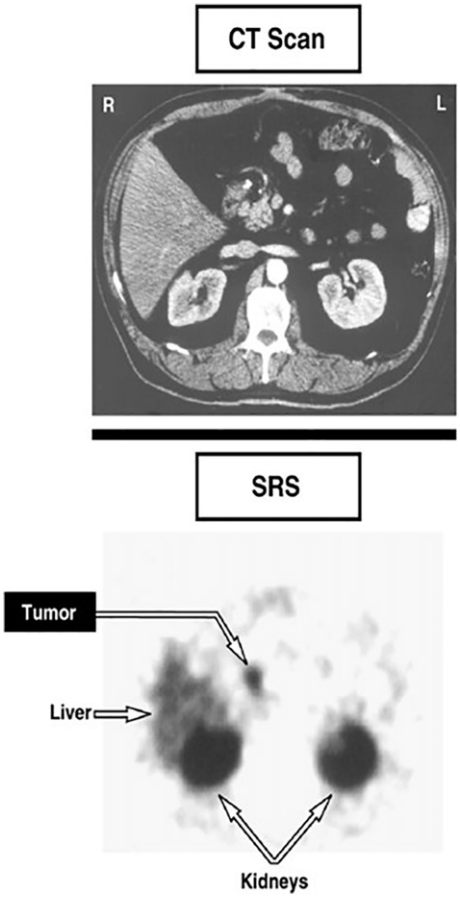

Fig. 2 Comparison of the ability of CT scan and SRS to localize a primary gastrinoma in a patient with ZES. Only the SRS is positive, showing its greater sensitivity.

Treatment of the Gastrinoma

Surgical

In all patients with sporadic ZES (without MEN1), without liver or distant metastatic disease, and without concomitant illnesses that shorten life expectancy or increase the risk of surgery, exploratory laparotomy by a surgeon experienced in the treatment of this disease should be performed (Falconi *et al.*, 2016; Jensen *et al.*, 2006). Enucleation of pancreatic head/body tumors should be performed. If needed, distal pancreatectomy for pancreatic tail lesions should be performed. Whipple resection is generally not recommended. In 5%–15% of patients with advanced disease with liver metastases, cytoreductive surgery should be considered if $>90\%$ of the visible tumor can be removed.

In patients with MEN1/ZES, the type of surgery and when it should be performed are controversial because these patients cannot be cured generally without aggressive resections such as Whipple resections, but still have an excellent long-term prognosis (Jensen and Norton, 2017). We recommend exploration when any lesion >2 cm in diameter is imaged because numerous studies demonstrate that tumor size is a strong prognostic factor for metastatic spread to the liver, which is associated with decreased survival. Lymph node metastases are frequent, even with small duodenal gastrinomas, but have not been shown to be associated with decreased survival.

Medical

Patients with metastatic gastrinoma in the liver have a decreased survival rate (Weber *et al.*, 1995; Yu *et al.*, 1999). Studies show that survival is especially decreased in the 40% of patients with a rapidly growing metastatic tumor. In this subset of patients, antitumor treatment is indicated. Long-acting somatostatin analogues, such as octreotide–LAR (**Fig. 1**) (given once monthly) is now the recommended initial treatments (Falconi *et al.*, 2016; Ito *et al.*, 2012b; Jensen *et al.*, 2006). Somatostatin analogues cause a decrease in tumor size in only 15%–20% of patients; however, they cause a cessation of growth in 50%–70% of patients and continue to remain effective for years in many patients. Chemotherapy (e.g., streptozotocin, doxorubicin $\pm$5-fluorouracil,

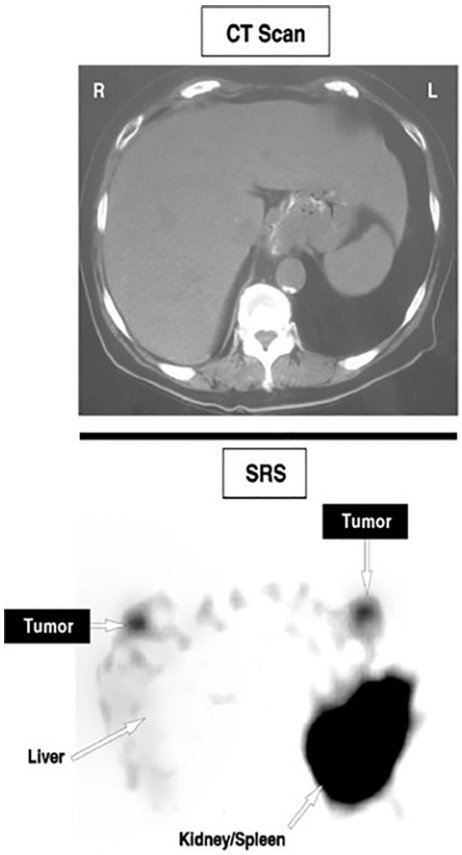

Fig. 3 Comparison of the ability of CT scan and SRS to localize metastatic disease in the liver in a patient with ZES. Only the SRS localizes a metastasis in the left lobe, showing its greater sensitivity.

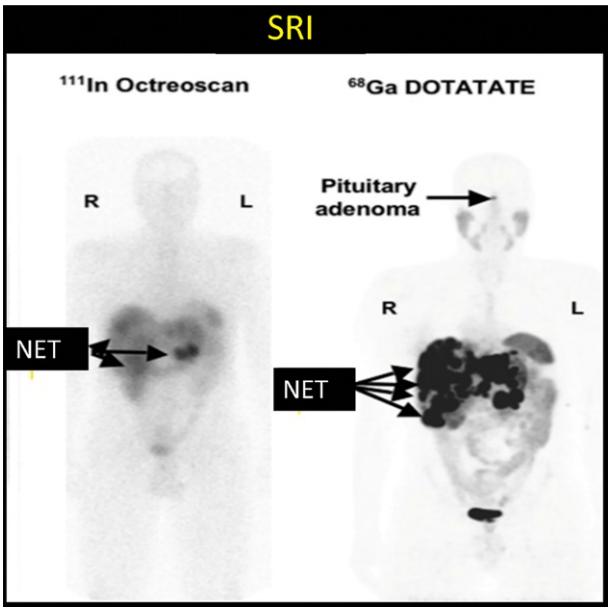

Fig. 4 Increased sensitivity of ^{68}Ga-DOTATATE PET/CT over SRS with [^{111}In-DTPA-DPhe^{1}] octreotide (Octreoscan) in a patient MEN1 with a pNET with liver metastases.

temozolomide with capecitabine) causes a decrease in tumor size in 5%–50% of patients but has significant toxicity and has not been shown to extend life in patients with gastrinomas. Both everolimus and sunitinib have been shown in large randomized trials to extend PFS (progression free survival) in patients with advanced pNETs and can also be used (Falconi *et al.*, 2016; Ito *et al.*,

Table 3 Management of ZES

Treatment of gastric acid hypersecretion
Drugs of choice: PPIs (e.g., omeprazole, lansoprazole, pantoprazole, rabeprazole, esomeprazole)
PPIs control acid secretion >99%
Histamine H_2 receptor antagonist less effective (frequent, high doses needed)
Total gastrectomy (needed only in rare patient who cannot take oral drugs)
Treatment of gastrinoma
In patients without MEN1 (75%) (sporadic ZES)
Surgery cures 60% in short term (<1 year); 30%–35% at 5 years postresection
At surgery, routine duodenotomy, routine removal of lymph nodes from gastrinoma triangle area and intraoperative ultrasound needed, with tumor enucleation used most frequently
Aggressive resection (Whipple procedure) rarely needed
In patients with MEN1/ZES (25%)
Tumor enucleation rarely (<1%) curative given that 60%–80% of gastrinomas are duodenal in location, multiple, and/or with lymph node metastases (50%–70%)
Surgery generally recommended if tumor is imaged ≥2–3 cm. otherwise observation

Note: PPIs, proton pump inhibitors.

2013a; Raymond *et al.*, 2011; Yao *et al.*, 2011). Peptide radioreceptor therapy (PRRT) is effective in patients with advanced NETs and is now approved for use in the United States and number of other countries.

Conclusion

Gastrinomas are an uncommon cause of PUD, but if diagnosed, the gastric acid hypersecretion can be controlled in every patient. The natural history of the gastrinoma is becoming an increasingly important determinant of long-term survival, so the typical 5-year delay in diagnosis remains a major challenge to instituting treatment early in the disease course in many patients. Furthermore, studies suggest that the widespread use of PPIs may further delay the diagnosis of ZES.

Introduction

Incidence

The incidence of pancreatic neuroendocrine neoplasms (pNENs) has increased from around 0.1/100.000 in 1988 to more than 0.5/100.000 in 2008 according to the SEER registry (Kuo and Salem, 2013). Small nonfunctioning pNENs (<1–2 cm) are more frequently discovered incidentally due to the widespread use of improved high-quality imaging techniques (Falconi *et al.*, 2012, 2016). The incidence of pancreatic neuroendocrine carcinomas (pNECs) is also increasing due to the increased awareness of pathologists applying specific stains for chromogranin A (CgA) and synaptophysin if a pNEC is suspected (Falconi *et al.* 2012, 2016; Ilett *et al.*, 2015; Jensen *et al.*, 2012). However, staining for CgA may be negative in pNEC.

WHO Classification

pNENs are as gastrointestinal NENs classified according to the WHO 2010 classification (**Table 1**). The classification was revised in the WHO 2017 classification for pNECs as they according to differentiation was divided into G3 neuroendocrine tumors (pNETs) for well differentiated pNENs and G3 pNECs for poorly differentiated pNENs.

Functional Classification of pNENs

pNENs are divided into functioning (20%–30%) and nonfunctioning tumors (70%–80%). The functioning pNENs release hormones that give rise to specific syndromes, whereas the nonfunctioning tumors do not cause hormone-related symptoms even though they may be immunohistochemically reactive for hormones or secrete inert hormones such as pancreatic polypeptide (PP). Most of the small incidentalomas as well as pNECs are nonfunctioning. Few nonfunctioning tumors may over time become functioning and give hormone specific symptoms (Jensen *et al.*, 2012).

Immunohistochemical Neuroendocrine Markers

In general, pNENs stain for CgA, synaptophysin, and pancreatic polypeptide (PP). In addition, tumors may stain for the cell specific hormone synthesized in the tumor cell for example, insulin or gastrin. However, a positive staining for a specific hormone does not imply that the tumor can be classified as a functioning pNEN unless it causes specific endocrine symptoms. pNECs may be negative for CgA and PP and rarely stain positive for tumor specific hormones.

Mutations in ATRX (alpha thalassemia mental retardation gene) and DAXX (death-domain-associated protein) are mutually exclusive and target genetic alterations in well differentiated pNENs whereas Rb (retinoblastoma) targets genetic alterations in pNECs.

Table 1 WHO 2010 classification

Grade	*NET G1*	*NET G2*	*NEC G3 (small/large cell)*
Mitotic count	<2	2–20	>20
Ki67 proliferation	≤2	3–20	>20
Distribution	35%	40%	25%

NETs, Neuroendocrine tumors; *NECs*, neuroendocrine carcinomas.

☆*Change History:* April 2018. Ulrich Knigge, Mikkel Andreassen, Birgitte Federspiel, Carsten Palnæs Hansen, Andreas Kjær, and Seppo W. Langer rewrote the article.

This article is an update of Vincent Marks, Pancreatic Islet Cell Tumors, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 486–487.

 doi:10.1016/B978-0-12-801238-3.95812-4

The stroma of pNETs is usually a delicate fibrovascular or hyaline stroma. In insulinomas the stroma is often characterized by amyloid deposition. pNECs most often have a similar gross presentation as a ductal adenocarcinoma and microscopically they, in contrast to pNETs, often show cellular pleomorphism, solid growth pattern, necrosis, and an often desmoplastic stroma with large vessels.

Hereditary Tumor Syndromes

pNENs may in some patients be part of a hereditary syndrome (Jensen *et al.*, 2008). They are autosomal dominant diseases and present one to two decades earlier than sporadic pNENs. A family history should be obtained from patients with pNENs and a relevant hormonal screening should be performed. If indicated a mutation analysis should be performed following patient acceptance.

Multiple endocrine neoplasia type 1 (MEN-1) presents most frequently with parathyroid and pituitary adenomas and pancreatico-duodenal NETs and more rarely with broncho-pulmonary, adrenal, and thymic NETs. Nonfunctioning or functioning pancreatico-duodenal NETs are found in up to 80% of patients with MEN-1. They have a more indolent behavior than the sporadic pNENs.

von Hippel-Lindau Disease (VHL) comprises cerebral hemangioblastoma, retinal angioma, renal cell carcinoma, pNETs, and pheochromocytoma. The incidence of pNENs, which are solid or cystic nonfunctioning tumors, is around 15%.

Neurofibromatosis type 1 (NF-1; von Recklinghausen's disease) presents with café-au lait macules, neurofibromas, skin-fold freckling, iris Lisch nodules, and bone dysplasia. Nonfunctioning somatostatinomas located at the papilla of Vater are found in up to 10%. Gastrointestinal stromal tumors are reported in a few of the patients with NF-1 and somatostatinoma. Up to 50% occur as a sporadic disease.

Tuberous sclerosis complex (TSC) presents with hamartomas in several organs. Functioning and nonfunctioning pNENs are found in a minor percentage.

Functioning pNENs

Insulinomas account for 10%–15% of pNENs. They are usually <20 mm in size, evenly distributed in the pancreas, diagnosed in the fourth–fifth decade and slightly more common in females. Around 90% are benign. About 5% are associated with MEN-1. The malignant insulinomas are larger with a Ki67-index $>10\%$, sporadic and most have metastasized at diagnosis (Jensen *et al.*, 2012).

The hypersecretion of insulin causes attacks of hypoglycemia which again may cause symptoms as confusion, headaches, behavioral and visual disturbances, and may end in coma. The hypoglycemia induced stimulation of the adrenergic system causes sweating, tremor, palpitations, and irritability. Due to these symptoms patients may be referred to neurological or psychiatric clinics. To relieve symptoms the increased glucose consumption may cause a considerable increase in body weight. The diagnostic delay is 3–5 years from start of symptoms.

Gastrinomas account for 10% of pNENs. The vast majority are located within the "gastrinoma triangle" including the duodenum and the pancreas located to the right of the superior mesenteric vessels. About 75% are located in the duodenum. MEN-1 syndrome is seen in 20% of the patients and the gastrinomas are most frequently found in the duodenum, often as multiple tumors and may also be associated with nonfunctioning tumors in the pancreas. In patients with sporadic gastrinomas the age at diagnosis is 45–60 years and one to two decades younger in patients with MEN-1. More than 50% of the pancreatic gastrinomas are malignant with metastases to regional lymph nodes or the liver at diagnosis. The duodenal gastrinomas and gastrinomas in relation to MEN-1 have a more indolent behavior and only 15%–20% of the patients have regional lymph node metastases at diagnosis.

The Zollinger–Ellison syndrome (ZES) is caused by a gastrin-induced stimulation of gastric acid secretion, which results in recurrent gastro-duodenal peptic ulcers, gastritis, dyspepsia and gastro-esophageal reflux disease in 80%–90% of the patients. *Heliobacter pylori* negative patients with recurrent dyspepsia and peptic ulcers should be suspected of having a gastrinoma. Complications such as peptic ulcer bleeding or perforation are rarely seen today due to the frequent use of proton pump inhibitors (PPI), which also prevent the acid-induced diarrhea. Due to acidification of the duodenal contents, pancreatic enzymes are inactivated and bile deconjugation diarrhea is seen in around 50% of the gastrinoma patients. In 10% diarrhea is the only symptom. Even tumors <1 cm in size may cause the ZES (Jensen *et al.*, 2012).

Glucagonomas are rare, usually malignant tumors that are evenly distributed in the pancreas. At diagnosis most tumors are >2 cm and have often spread to regional lymph nodes and the liver. They may be related to MEN-1. pNETs may stain positive for glucagon without elevated plasma glucagon and the presence of the glucagonoma syndrome.

The glucagonoma syndrome presents with diabetes, necrolytic migratory erythema, stomatitis, glossitis, anemia, fatigue, weight loss, thrombosis, hypoaminoacidemia. All symptoms may not be present simultaneously. Plasma glucagon is elevated >5-times normal level (Jensen *et al.*, 2012).

VIPomas (Vasoactive intestinal peptide; Verner–Morrissons syndrome; WDHA) are rare and evenly distributed in the pancreas, but may also develop from paragangliomas (10%). Most are malignant with disseminated disease at diagnosis. Few VIPomas are related to MEN-1. Plasma VIP is increased.

Symptoms include watery diarrhea, hypokalemia, achlorhydria (50%), metabolic acidosis, flushing (20%), hypercalcaemia (50%), glucose intolerance (50%). Severe watery diarrhea and hypokalemia may require constant iv fluid infusion and electrolyte substitution (Jensen *et al.*, 2012).

Somatostatinomas are rare and occur in the pancreas (60%) or the duodenum (40%). The pancreatic somatostatinomas are malignant often with disseminated disease at diagnosis whereas the duodenal somatostatinomas are solitary and usually have a benign behavior. The pancreatic somatostatinomas may be related to MEN-1, while the duodenal somatostatinomas may be related to NF-1. Plasma somatostatin is elevated in pancreatic somatostatinomas but rarely in the duodenal tumors (Jensen *et al.*, 2012).

The pancreatic somatostatinomas may present with diabetes mellitus, steatorrhoea/diarrhea, weight loss, abdominal pain, and bile stones (somatostatinoma syndrome). However, all symptoms are never seen simultaneously.

The duodenal somatostatinomas have no endocrine symptoms but may cause symptoms due to occlusion of the common bile duct.

Other very rare functioning pNENs may secrete ACTH, GHRH, serotonin, PTH-RP, calcitonin cholecystokinin, LH, renin, erythropoietin. The increased secretion of ACTH, growth hormone releasing hormone (GHRH), serotonin and PTH-RP leads to Cushing syndrome, acromegaly, carcinoid syndrome and hypercalcemia, respectably (Jensen *et al.*, 2012).

Nonfunctioning pNENs

Nonfunctioning pNENs are evenly distributed in the gland and in most cases have a Ki67 index between 3% and 20%. Around 20% are G3 pNEC with a Ki67 $>$ 20%. They are generally large and have metastasized to regional nodes and the liver in more than 50% of the patients. Symptoms are with abdominal pain (35%–78%), weight loss (20%–35%), anorexia, nausea (45%), and jaundice (17%–50%) (Falconi *et al.*, 2012). About 20% of nonfunctioning pNETs are seen in relation to MEN-1 (Falconi *et al.*, 2012).

With the development of more sensitive imaging techniques, asymptomatic nonfunctioning localized pNETs $<$1–2 cm are more frequently found incidentally. Whether these small nonfunctioning tumors have a benign or malignant behavior is uncertain.

Biochemical Diagnosis

Chromogranin A

CgA is the best validated circulating general marker of well differentiated NENs including pNENs (Modlin *et al.*, 2010a). CgA is present in the large secretory granules that store peptide hormones throughout the neuroendocrine system. Increased plasma levels of CgA are observed in around 80% of functioning and nonfunctioning pNENs, with the exception of insulinomas where only a minority of patients have increased CgA levels. Day to day variation of CgA is around 25%. Level of CgA is related to tumor burden, and in case of a large tumor burden levels can increase to more than 100 times upper normal range (Modlin *et al.*, 2010a). Changes in CgA may reflect tumor progression or regression and thereby the effect of treatment. Poorly differentiated pNECs (Ki-67 $>$ 20%) can lose the secretory capacity with subsequent normal levels of CgA (Ilett *et al.*, 2015).

An elevated plasma CgA without the presence of a NEN is often found in patients with renal failure, hepatic failure and inflammatory diseases. Hypochlorhydria/achlorhydria in for example, chronic atrophic gastritis and treatment with proton pump inhibitors (PPI), is also associated with increased levels of CgA (Modlin *et al.*, 2010a).

Biochemical Diagnosis of Functioning pNENs

The diagnosis of functioning pNENs is based on relevant clinical symptoms and signs together with an inappropriate elevation of a specific pancreatic hormone.

Insulinomas

Plasma glucose below 2.2 mmol/L together with inappropriately high levels of proinsulin ($>$5 pmol/L), insulin ($>$36 pmol/L), and c-peptid ($>$200 pmol/L) suggests insulinoma. The final diagnosis is based on Whipples triad (1: symptoms of hypoglycemia, 2: plasma glucose $<$2.2 mmol/L, and 3: relief of symptoms after glucose infusion) during a 72 h fasting test (Jensen *et al.*, 2012).

Gastrinomas

Fasting serum gastrin is an excellent screening test for diagnosing gastrinomas with a very high sensitivity. However, elevated gastrin has a low specificity for gastrinoma since reduced gastric acid secretion for whatever reason will lead to hypergastrinemia. Thus, a diagnosis of gastrinoma is based on hypergastrinemia together with low gastric pH. Gastric pH $<$2 and gastrin above 10 times upper normal range is highly suggestive of a gastrinoma. Around 40% of gastrinoma patients fulfill these criteria (Berna *et al.*, 2006b). In the remaining patients with less elevated serum gastrin provocative tests are needed. The most common used test is the secretin test, in which the patients receive an iv bolus of secretin with subsequent repeated measurements of serum gastrin for 30 min (Berna *et al.*, 2006a). Secretin stimulates secretion of gastrin from gastrinomas but not from the antral G-cells. Hence, a

rise in serum gastrin indicates the presence of a gastrinoma. However, there is no specific diagnostic cut-offs, and numerous criteria have been proposed for a positive secretin provocative test.

VIPomas, glucagonomas, somatostatinomas, and other very rare functioning pNENs will present with elevated fasting plasma levels of the respective tumor hormone and related symptoms (Jensen *et al.*, 2012).

Circulating Tumor Cells, Circulating DNA, and Circulating mRNA

The diagnostic and prognostic role of circulating tumor cells, tumor DNA, and tumor mRNA in cancer has been increasingly investigated in recent years. There are some promising scientific data on the use of in particular circulating mRNA as a biomarker in patients with NENs. However, more data are needed before these new technics can be recommended for clinical use (Oberg *et al.*, 2016; Zatelli *et al.*, 2017).

Imaging

Information on localization and spread is always of importance for treatment planning and monitoring of therapy. Currently, the modalities used include functional imaging with somatostatin-receptor imaging (SRI) using nuclear medicine methods as well as morphological imaging using computed tomography (CT), magnetic resonance imaging (MRI) or endoscopic ultrasound.

SRI is based on the overexpression of somatostatin receptors, in particular subtype 2 (SST2), on NENs (Binderup *et al.*, 2008). In general >90% of NETs, including pNETs, express SST2 with the exception of insulinomas where only 70% are SST2 positive. Previously, SRI was performed using gamma camera imaging with SPECT and the tracer 111In-octreotide. However, PET tracers mostly labeled with ^{68}Ga are now implemented in most NET centers. The most commonly used PET tracers are ^{68}Ga-DOTATATE, ^{68}Ga-DOTATOC, and ^{68}Ga-DOTANOC (Johnbeck *et al.*, 2014), which when performed as a PET/CT have a sensitivity and specificity above 90% (Geijer and Breimer, 2013; Sundin *et al.*, 2017; Treglia *et al.*, 2012; Yang *et al.*, 2014). However, for insulinomas the sensitivity was only 26% (Sharma *et al.*, 2016). Accordingly, SRI PET/CT is therefore now considered the primary imaging modality in noninsulinoma pNETs and should be performed as preoperative staging (Falconi *et al.*, 2016). Occasionally, small pNETs may be overlooked using SRI PET/CT due to the limited spatial resolution on ^{68}Ga-PET. However, recently a new ^{64}Cu-labeled PET tracer, ^{64}Cu-DOTATATE, was evaluated for detection of NETs (Pfeifer *et al.*, 2012, 2015). ^{64}Cu has the advantage of a shorter positron range and thereby a better spatial resolution than ^{68}Ga and ^{64}Cu-DOTATATE seems to have a better lesion detection rate than ^{68}Ga labeled tracers (Johnbeck *et al.*, 2017). Accordingly, this tracer may prove valuable for lesions not found using ^{68}Ga-labeled tracers for SRI. In contrast, there is probably no need for ^{18}F-DOPA or ^{11}C-5-HTP PET as their superiority was based on comparison with SPECT SRI (Kjaer and Knigge, 2015).

SRI is often negative in pNECs and FDG-PET/CT may be used instead. FDG-PET/CT is positive in around 50% of NENs, but it is an excellent prognostic marker as NEN patients with a positive FDG-PET/CT have a poorer survival than patients with a negative FDG-PET/CT (Binderup *et al.*, 2010).

For insulinomas, specific PET tracers that bind to the glucagon-like peptide 1 (GLP-1) receptor may be of value (Eriksson *et al.*, 2014) and clinically applicable (Velikyan *et al.* 2017). However, more data are needed. Also, these tracers are only available in few centers.

The use of CT alone, which should preferentially be performed as a three-phase CT with iv contrast and bolus tracking, has a reported mean sensitivity of 82% and specificity of 96% (Sundin *et al.*, 2017).

Although MRI could be used in line with CT, the availability, cost and longer scan time is in most centers limited to challenging cases. MRI has a mean sensitivity of 79% and specificity of 100% (Sundin *et al.*, 2017). In addition to standard morphological imaging, MRI has the ability to perform diffusion-weighted imaging (DWI) which reflects the restricted interstitial space in cancer tissue limiting the diffusion of water. Parametric DWI with ADC values (apparent diffusion coefficient) has been shown to be a marker of malignancy and to correlate with Ki67 in pNETs (Wang *et al.*, 2011).

Finally, endoscopic ultrasound with its possibility of fine-needle aspiration has a role for detection and cytological confirmation of pNENs. The method is highly operator dependent and therefore exact numbers on performance are difficult to obtain (Falconi *et al.*, 2016).

Interventional Treatment

Radical surgery is the only treatment that may cure patients with pNENs. Major surgical complications are significantly lower in high volume centers and patients can usually be treated with a mortality rate close to nil. Common pancreatic operations include pancreaticoduodenectomy (Whipple procedure), distal pancreatectomy with resection of the gland to the left of the mesenteric vessels, and a total pancreatectomy. Total pancreatectomy has earlier been avoided due to difficult diabetic control (brittle diabetes), but with modern insulin treatment and substitution with pancreatic enzymes a total pancreatectomy is widely accepted. Even aggressive surgery with curative intent in locally advanced tumors including nearby organ involvement may lead to a 5-year survival of up to 80% (Fischer *et al.*, 2008).

Enucleation of tumor is an option in benign pNETs, preferably insulinomas, but the risk of postoperative fistulas is up to 30% (Brient *et al.*, 2012). However, enucleation of a benign pNET in the head of the gland may sometimes be preferred rather than a pancreaticoduodenectomy, if the tumor is less than 2 cm and if the two main pancreatic ducts can be left intact. Malignant tumors and tumors with uncertain behavior should never be enucleated due to uncertain radicality. A central pancreatic resection with anastomosis to the cephalic and caudal parts of the gland is favored by some centers to conserve glandular tissue.

Special consideration should be offered pNENs in patients with MEN1. Patients usually have multiple tumors in the gland, and in case of gastrinomas, in the duodenum as well, where they account for the major part. Long time follow up has shown, however, that even though metastases to local lymph nodes are present, liver metastases are seldom seen, if tumors are less than 2 cm. Therefore, operation is only advisable when tumors exceed 2 cm to avoid hepatic metastases (Falconi *et al.*, 2016). An even lower propensity to distant metastases has been observed in patients with Von Hippel-Lindau disease and pNENs, for which reason these tumors should be followed.

The occasional finding of small nonfunctioning pNENs (incidentalomas) has increased in line with the frequent use of improved CT and MRI scans. Most incidentalomas are probably benign and may be observed rather than resected. ENETS guidelines advise expectancy if tumor is found incidentally, is less than 2 cm and remains unaltered in size. A CT or MRI scan every 6 months is mandatory, EUL is not recommended due to inter- and intraobservation variability. If tumor increases in size more than 0.5 cm or exceeds 2 cm in diameter, operation is advised (Falconi *et al.*, 2012).

Other investigators have warned against this procedure, since metastases have been recorded in patients with incidentalomas less than 2 cm. Expectancy should only be offered elderly patients as well as patients with severe comorbidity, and close follow-ups with CT or MRI scan and a biopsy for estimation of Ki67 proliferation index is indicated.

pNETs with multiple metastases are seldom curable, but operation may still be an option, if metastases are few and resectable, or if debulking may relieve the patient from local and/or endocrine symptoms. Resection of the primary tumor with radical resection of liver metastases has survival rates of up to 76% in well-differentiated tumors (Ki67 $< 5\%$) compared to a 5-year survival of 30%–40% in untreated cases (Partelli *et al.*, 2015). However, tumor recurrence is up to 75% within 2 years after surgery.

The rate of cure is higher in patients with liver metastases from functioning pNENs than nonfunctioning (90% vs. 40%) (Bagante *et al.*, 2017). Resection of the primary together with major synchronous liver surgery should be avoided due to increased complications and mortality. Hence liver resection should be postponed to a second operation.

Resection of a primary pNET in the presence of nonresectable hepatic metastases is controversial. Contrary to small intestinal NENs, ENETS guidelines do not recommend palliative resection of pNETs. However, studies have shown that palliative resection of the primary in the setting of nonresectable metastatic disease may increase survival, but data are from retrospective and heterogeneous cohorts (Keutgen *et al.*, 2016). Only patients with localized pNECs (G3 tumors, Ki67 $> 20\%$) are candidates for surgery. However, most have distant metastases at diagnosis and should follow oncologic protocols.

Conventional ablative techniques such as radio-frequency ablation (RFA) and microwave ablation (MWA) can be used to treat liver metastases, but should be avoided in pNETs due to the risk of injury to the pancreatic duct, the superior mesenteric vessels, and duodenum. Ablative techniques for treatment of hepatic metastases from pNETs should only be used in palliation or in combination with liver resection to conserve liver tissue. RFA is restricted to metastases <4 cm in diameter and <8–10 metastases in total. The effect of RFA is reduced in metastases close to the major intrahepatic vessels due to heat loss. Microwave ablation is a nonthermal procedure and metastases up to 7 cm and close to the hepatic vessels can be treated (de Baere *et al.*, 2015; Pavel *et al.*, 2012).

Irreversible electroporation (IRE) is another nonthermal ablative therapy based on the delivery of high-voltage electric current through electrodes positioned adjacent to the tumor. This causes irreversible injury to tumor cells but with conservation of vessels, nerves, and ductal structures. IRE can be used in the palliative treatment of pNETs and liver metastases.

Liver metastases have their blood supply from the hepatic arteries. Liver embolization via the hepatic arteries results in tumor necrosis and can be performed as bland- or chemo-embolization in patients with numerous liver metastases not suited for surgical resection or ablation (Pavel *et al.*, 2012). Embolization can be repeated but is contra-indicated in patients with occlusion of the portal vein (liver failure), previous Whipple operation or biliary-intestinal anastomosis (infection and liver abscess) and relatively contra-indicated if the hepatic tumor burden is $>75\%$ of the total liver volume. Selective internal radiation therapy (SIRT) with 90Y-microspheres is another option for treatment of liver metastases. Radiological tumor response rates are seen in 60% (Pavel *et al.*, 2012).

Medical Treatment

Low-Grade pNETs

A somatostatin analog (SSA) is first-line therapy for symptom control and antitumor treatment in functioning and nonfunctioning pNETs. It may also be used as add-on therapy in combination with other antiproliferative therapies. Octreotide and lanreotide are considered equally effective for symptom control. In general, long-acting formulations (octreotide LAR 30 mg/4 weeks; lanreotide autogel 120 mg/4 weeks) are used over a medium- to long-term period. Symptomatic and biochemical response is seen in the majority of the patients (Modlin *et al.*, 2010b; Pavel *et al.*, 2016). Dose escalation may be required and can be achieved by shortening the injection interval from 4 to 3 weeks with long-acting SSA (Al-Efraij *et al.*, 2015).

In nonfunctioning pNETs, treatment with lanreotide autogel results in superior progression-free survival (PFS) compared to placebo (24 vs. 18 months) (Caplin *et al.*, 2014). Treatment with SSA is therefore indicated in functioning and nonfunctioning pNETs with Ki67-index $<10\%$. Side effects of SSA are usually mild, and may include abdominal pain, diarrhea, flatulence, nausea, injection site reactions, and development of bile stones (Modlin *et al.*, 2010b).

Interferon alpha (IFN) may reduce tumor growth and hormone-induced symptoms. The dose should be titrated individually ranging between 3 and 5 MU SC three to five times weekly for recombinant IFN and 50–150 μg SC weekly for pegylated IFN. IFN may be used as an add-on to SSA. Side-effects to IFN include flu-like symptoms and fatigue. Patients with autoimmune diseases or a history of mental disorder should not be treated with IFN (Pavel *et al.*, 2006).

Streptozocin (streptozotocin, STZ) in combination with 5-fluorouracil (5FU) is often used as first-line chemotherapy for advanced pNETs with Ki67 index above 10%. It is administrated as a 5-day induction course followed by 1-day infusions every third week. Response rates of up to 40% with PFS of up to 20 months and median survival of 2 years have been reported. STZ is nephrotoxic. 5FU may be replaced by doxorubicin. However, due to the risk of cumulative cardiotoxicity and the resulting limited possible treatment time, this option is rarely used (Janson *et al.*, 2014; Moertel *et al.*, 1980).

Temozolomide may also be considered in the treatment of advanced pNETs with Ki67 $>$ 10%, either as monotherapy or in combination with capecitabine. Retrospective data showed a response rate of 70% and PFS of 18 months with the combination of temozolomide and capecitabine (Strosberg *et al.*, 2011). In a retrospective analysis of patients who received various temozolomide-based treatments, one-third experienced partial response with a median PFS of 14 months (Kulke *et al.*, 2009). Toxicity is usually mild with nausea and hematological toxicity.

The targeted therapies, everolimus (mTor inhibitor), and sunitinib (multikinase VEGFR inhibitor) are both approved antiproliferative therapies in progressive pNETs, and thus represent different treatment options next to SSA and systemic chemotherapy. In two prospective, randomized trials, treatment with these agents doubled the PFS from approximately 6–12 months compared to placebo in patients with progressive well and moderately differentiated pNETs (Raymond *et al.*, 2011; Yao *et al.*, 2011).

The toxicity profile of the two agents are different and therefore may influence the choice of treatment: Common side effects associated with everolimus are stomatitis, rash, diarrhea, hyperglycaemia, and fatigue, whereas patients on sunitinib may experience rash, diarrhea, nausea, vomiting, asthenia, hypertension, and fatigue.

High-Grade pNECs

Untreated, patients with metastatic G3 pNECs (Ki67 $>$ 20%) have very short expected survival time. Treatment with cis- or carboplatin and etoposide has for long been the mainstay in advanced NECs, including pNECs. The treatment is associated with an objective response rate above 30%, disease control in two thirds of the patients with a median of 4–5 months, and an overall survival time of median 10–14 months. Side-effects include emesis, bone marrow suppression, nephro- and neurotoxicity and may be both dose limiting and serious. A Ki67 index below 50%–55% is usually associated with a lower objective response rate to platinum-based chemotherapy. Hence, other regimens could be considered, such as temozolomide- or 5FU-based therapies (Sorbye *et al.*, 2013).

There are no established second-line therapies for pNECs. Temozolomide-based therapy, irinotecan, topotecan, and 5FU-bases combinations (FOLFIRI/FOLFOX) have showed moderate efficacy and may thus be considered, taking performance status and organ function into consideration (Hentic *et al.*, 2012; Strosberg *et al.*, 2010).

The aggressive behavior of pNECs warrants consideration of adjuvant therapy after radical surgery. Although definite data are missing, four to six cycles of cis/carboplatin and etoposide should be considered (Sorbye *et al.*, 2013). Prophylactic cerebral irradiation is not recommended.

Specialized Symptomatic Treatment

Insulinomas

Diazoxide (50–600 mg/day) may control attacks of hypoglycemia by inhibition of insulin release from the beta-cells. However, diazoxide has side-effects such as edema and weight gain. Somatostatin analogs may prevent hypoglycemia, but may in some cases also worsen hypoglycemia. In selected patients, everolimus has been shown to prevent hypoglycemia. Glucocorticoid or growth hormone administration may reduce severe hypoglycemia. Some patients require continuous glucose infusion to keep blood glucose levels normal (Jensen *et al.*, 2012).

Gastrinomas

Proton pump inhibitors (PPI) are the first line of treatment in patients with the Zollinger–Ellison syndrome. Often high and frequent dosing is required to control gastric acid secretion. Treatment should not be paused as ulcer perforation or bleeding may occur. SSA may be added to the PPI treatment with significant symptomatic effect by inhibition of the gastrin secretion (Jensen *et al.*, 2012).

In rare functioning pNETs such as glucagonomas, VIPomas and somatostatinomas, treatment with somatostatin analogs may significantly diminish the hormone induced symptoms. Treatment with long acting SSA may be supplemented with short acting

octreotide or interferon alpha. Patients with uncontrollable symptoms from a VIPoma may require continuous electrolyte infusion (Jensen *et al.*, 2012).

Peptide Receptor Radionuclide Therapy

Somatostatin SST2 receptors are expressed in >90% of NETs. This is utilized in peptide receptor radionuclide therapy (PRRT) with the beta-emitter ^{90}Yttrium (^{90}Y -DOTATOC) or the beta- and gamma-emitter ^{177}Lutetium (^{177}Lu-DOTATATE). Prerequisites of PRRT are a higher up-take in tumors and metastases than physiologic liver up-take, a normal kidney function, limited amount of bone metastases and a Ki67 < 30%. PRRT with ^{90}Y are given in two to three cycles with 6–8 weeks interval and ^{177}Lu in 4 cycles with 8 weeks interval. Additional cycles depend on bone marrow and renal toxicity. Following PRRT complete response is seen in <5%, partial response in 10%–35%, minor response + stable disease in 50%–80% and progressive disease in 10%–20%. A tardive response may be seen 6–12 months after PRRT. The median PFS is 15–30 months and the median OS 30–50 months. Pancreatic NETs seem to respond better than small intestinal NETs (Kjaer and Knigge, 2015). Concomitant treatment with somatostatin analogs may have an additive effect on PFS and OS (Strosberg *et al.*, 2017).

Temporary or persistent renal toxicity is seen in about 35% of the patients. Risk factors of kidney damage are hypertension, diabetes mellitus, and previous chemotherapy. Bone marrow toxicity is seen in about 80%, less than 10% severe. Kidney and bone marrow toxicity is more rare in patients treated with ^{177}LU than with ^{90}Y. Development of myelodysplastic syndrome or leukemia is seen in less than 1% of patients (Kjaer and Knigge, 2015).

Follow-up

All patients with functioning and nonfunctioning pNENs should have life-long clinical follow-up at a specialized NET Center. An exception is radically resected benign insulinomas (Knigge *et al.*, 2017).

Imaging with thoraco-abdominal-pelvic CT or abdominal-pelvic MRI is performed every 6–12 months for G1/G2 pNETs. For G3 pNECs thoraco-abdominal-pelvic CT is performed every 3–6 months. In patients with curatively treated G3 pNECs CT/MRI is maximally performed for 5 years. If recurrence or progression occurs tumor biopsy is often required for a new Ki67 determination, as tumors may undergo a more malignant transformation. If positive on somatostatin receptor imaging (SRI) at diagnosis, SRI may be performed every other year, but the significance of SRI has not been evaluated.

Patients with radically resected solitary G1/G2 insulinomas only require one follow-up with measurement of insulin, C-peptide, pro-insulin, and chromogranin A after 3–6 months. Further follow-up is only required if symptoms recur. Patients with nonresected or metastatic G1/G2 insulinomas should have follow-up as described below.

Patients with other resected, nonresected or metastatic G1/G2 functioning tumors (e.g., gastrinomas, glucagonomas, VIPomas, somatostatinomas) should have clinical follow-up with relevant blood samples every 3–6 months. This includes tumor specific hormones and CgA. In patients with gastrinoma vitamin B12, ionized calcium, and PTH should also be measured. Gastric pH measurement or secretin test may be performed, if symptoms recur in resected patients.

Patients with nonfunctioning resected, nonresected or metastatic G1/G2 NETs should have clinical follow-up with CgA measurement every 3–6 months.

All patients with G3 NECs independent of resection should have clinical follow-up with CgA and relevant hormones every third month.

Prognosis

The prognosis for pancreatic NENs depends on dissemination and pathologic grade (Ki67). Other factors are advanced age, bone metastases and rapid progression of liver metastases. Furthermore, patients with a positive FDG-PET have a poorer survival.

Functioning pNETs

Patients with benign insulinomas are cured after radical resection. In malignant insulinomas with liver metastases the OS is less than 2 years. The OS of gastrinoma patients with local disease is almost 100% after resection but the presence of liver metastases reduces the 5-year survival to 45%.

In patients with rare functioning tumors survival is equivalent to survival in patients with nonfunctioning NETs (Jensen *et al.*, 2012).

Nonfunctioning pNETs

The 5-year survival rate is around 43% and the median OS is 38 months. In patients with localized disease, regional and disseminated disease the median OS is 124, 70, and 23 months, respectably (Falconi *et al.*, 2012; Yao *et al.*, 2008).

pNECs

For patients with pNECs the median OS is 10–20 months (Sorbye *et al.*, 2013).

Peptide Neurotransmitters and Smooth Muscle in the Gut☆

JR Grider, KS Murthy, and GM Makhlouf, Virginia Commonwealth University, Richmond, VA, USA

Glossary

Circular muscle layer Innermost layer of smooth muscle in which individual muscle cells are oriented radially. Contraction of this muscle decreases the diameter of the gut and increases intraluminal pressure.

Enteric nervous system A network of two ganglionated neural plexuses contained wholly within the wall of the gut; also called the intrinsic nervous system.

Excitatory motor neuron Neuron of the enteric nervous system that projects into the muscle layer and releases a neurotransmitter that causes contraction of muscle.

Inhibitory motor neuron Neuron of the enteric nervous system that projects into the muscle layer and releases a neurotransmitter that causes relaxation of muscle.

Interneuron Neuron of the enteric nervous system that projects to other neurons of the enteric nervous system and releases a neurotransmitter that modulates the activity of other enteric neurons.

Longitudinal muscle layer Outermost layer of smooth muscle in which individual muscle cells are oriented along the oral–anal axis. Contraction of this muscle layer shortens the gut.

Myenteric plexus One of the two ganglionated plexuses of neurons that comprise the enteric nervous system. This plexus is located between the inner circular and outer longitudinal muscle layers.

Sensory neuron Neuron that is activated by a stimulus, such as stretching of the gut wall or chemical stimulation of the mucosa, and that in turn activates other neurons within the enteric nervous system.

Introduction

The debate initiated at the beginning of the 20th century regarding the relative importance of hormones and nerves in the gut was concluded at the end of the century with the recognition that peptide and nonpeptide neurotransmitters are the main regulators of function in the gut. Six peptide hormones [gastrin, cholecystokinin (CCK), secretin, motilin, and the glucose-dependent insulinotropic peptides (GIP) and glucagon-like peptide-1 (GLP-1)] are undoubtedly physiological, but their secretion is regulated, and their actions are usually mediated or modulated by enteric neurotransmitters. Two of these hormones, CCK and motilin, play physiological roles in smooth muscle. All other muscular functions are regulated by neurotransmitters, including tone and sphincteric activity, electrical and mechanical rhythmic activity, and the initiation and termination of intestinal peristaltic activity. Two neurally mediated functions have been attributed to circulating CCK: (i) postprandial stimulation of gall bladder contraction and sphincter of Oddi relaxation and (ii) activation of the sensory limb of a long reflex arc that inhibits gastric tone and slows emptying. Gall bladder contraction is largely mediated by CCK-induced release of acetylcholine (ACh) from cholinergic neurons, whereas sphincter relaxation is mediated by release of inhibitory neurotransmitters [vasoactive intestinal peptide (VIP) and nitric oxide (NO)] from noncholinergic neurons.

Motilin is the only hormonal or neural peptide whose main function is interdigestive. It is released in cycles that coincide with the start of the migrating myoelectric complex. Peaks of circulating motilin coincide with phase 3 of the cycle, a short period of intense motor activity that sweeps residual contents of the intestine caudad. Immunoneutralization of circulating motilin disrupts phase 3 activity; conversely, infusion of motilin in concentrations that mimic circulating levels triggers premature phase 3 activity. Neural activity can modulate motilin levels and motor activity, but the precise mechanisms are not known.

Peptide Neurotransmitters and Smooth Muscle Activity

Neural Organization

Neurons of the enteric nervous system, especially neurons of the myenteric plexus, modulate the intrinsic electrical and mechanical properties of smooth muscle. They constitute the final relay to smooth muscle cells and interstitial cells of Cajal; the latter appear to be interposed between motor nerve terminals and smooth muscle cells in some regions of the gut. Extrinsic adrenergic and peptidergic neurons in pre- and paravertebral ganglia synapse with and modulate the activity of enteric neurons.

Neurons of the myenteric plexus located between the circular and longitudinal smooth muscle layers fall into two broad categories. Approximately 25% contain VIP and/or its homologue, pituitary adenylate cyclase activating peptide (PACAP), often found together with neuronal nitric oxide synthase (nNOS). More than 60% contain ACh, often found together with the

☆*Change History:* February 2015. JR Grider, KS Murthy, and GM Makhlouf updated Section text and added Figures, Table and references.

This article is an update of John R. Grider, Karnam S. Murthy, Gabriel M. Makhlouf, Peptide Neurotransmitters and Smooth Muscle in the Gut, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 579-584.

tachykinins, substance P (SP) and neurokinin A (NKA); the latter are derived from the same precursor, β-protachykinin. VIP neurons also contain a homologous peptide derived from the same precursor designated PHI in animals or PHM in humans. There is little or no overlap between neurons of these two categories. Acetylcholine and the tachykinins are the major excitatory motor neurotransmitters, whereas VIP and its homologs and NO are the major inhibitory neurotransmitters. The term inhibitory refers to their ability to inhibit (i.e., relax) smooth muscle tone and rhythmic electrical and contractile activity.

Pharmacology of Neurotransmitters

VIP, PACAP, and PHI/PHM

Receptors for these peptides are present on both smooth muscle cells and neurons. VIP and PACAP interact with $VPAC_2$ receptors on smooth muscle cells, which are coupled via G_s to stimulation of cAMP formation and inhibition of muscle tone and rhythmic activity. Neural VIP/PACAP receptors are present in two locations: on nerve terminals, where they act as autoinhibitory receptors to suppress further neurotransmitter release, and on cholinergic/tachykinin motor neurons that innervate the longitudinal muscle layer: activation of these receptors upon release of VIP and PACAP from a subpopulation of myenteric interneurons stimulates release of ACh and tachykinins and induces longitudinal muscle contraction.

The discovery of VIP (and related peptides) in myenteric motor neurons, and its release from these neurons by electrical field stimulation leading to relaxation of circular smooth muscle that was selectively suppressed by VIP antiserum or VIP antagonists entitled it to consideration as an inhibitory neurotransmitter. The subsequent discovery of nitric oxide synthase in the same or adjacent neurons, and the release of NO from these neurons by electrical field stimulation leading to muscle relaxation that was selectively inhibited by NOS inhibitors raised the possibility that VIP and NO act as functionally linked inhibitory (relaxant) co-transmitters. It soon became clear that the linkage between VIP and NO was more complex: NO produced in nerve terminals regulates: 1) ICC and smooth muscle cell activity, and 2) VIP release in the same or adjacent nerve terminals; 3) VIP, in turn, regenerates NO in target smooth muscle cells by activating a distinct constitutive, Ca^{2+}/calmodulin-dependent NOS. The signaling cascade that leads to this outcome is detailed below (**Fig. 1** and **Table 1**). Evidence for this dual source of NO was derived from studies in neuronal preparations (i.e., isolated myenteric plexus and enriched synaptosomes) devoid of smooth muscle cells, and in isolated smooth muscle preparations devoid of neural elements. Studies on whole muscle tissue preparations can lead to flawed interpretations unless the dual source of NO and the role of VIP are taken into consideration.

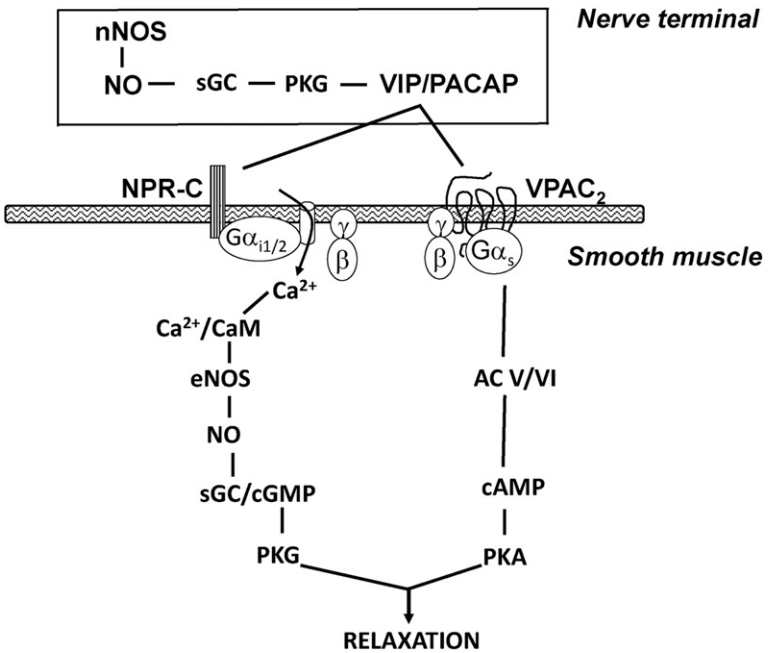

Fig. 1 Model depicting interplay of NO and VIP/PACAP in nerve terminals and smooth muscle cells. NO produced by nNOS in nerve terminals stimulates VIP/PACAP release in the same or adjacent nerve terminals via a pathway involving activation of soluble guanylate cyclase (sGC), formation of cGMP, and activation of cGMP-dependent protein kinase (PKG). VIP and PACAP release can occur independently of NO at higher intensities of nerve stimulation. In smooth muscle cells, VIP and PACAP interact with cognate $VPAC_2$ receptors and with the single-transmembrane natriuretic peptide receptor NPR-C, which is abundantly expressed in smooth muscle cells of the gut. Interaction with $VPAC_2$ receptors coupled to G_s leads to activation of adenylate cyclase V/VI, cAMP formation, and activation of PKA. Interaction of VIP and PACAP with NPR-C initiates a cascade involving $G_{i1/2}$-dependent Ca^{2+} influx, activation of a Ca^{2+}/calmodulin-dependent constitutive NOS, generation of NO, and activation of the sGC/cGMP/PKG pathway. PKA and PKG act together to cause relaxation and sustained hyperpolarization.

Table 1 Effect of various agents on signaling cascades activated by VIP and PACAP in isolated smooth muscle cells

	GDPβS	*PTx*	*Nifedipine*	*Calmida- zolium*	*L-NNA*	*LY83583*	*KT-5823*	*Myr-PKI*
Ca^{2+}	I	I	I	Nil	Nil	Nil	Nil	Nil
NO	I	I	I	I	I	Nil	Nil	Nil
cGMP	I	I	I	I	I	I	Nil	Nil
cAMP	I	Nil	Nil	Nil	Nil	Nil	Nil	Nil
Relaxation	I	P/I	P/I	P/I	P/I	P/I	P/I	P/I

NO stimulates VIP release from myenteric neurons: Studies on the myenteric plexus isolated from guinea pig, rabbit, and opossum intestine showed that NO added exogenously or produced endogenously by myenteric neurons stimulates VIP release, whereas VIP added exogenously has no effect on NO production. VIP release was abolished by the NOS inhibitor, N^G-nitro-L-arginine (L-NNA), as well as by the soluble guanylyl cyclase (sGC) inhibitor, LY83583, and the cyclic GMP-dependent protein kinase (PKG) inhibitor, KT5823. A similar NO/sGC/PKG pathway triggered by NO donors or cGMP analogues was shown to elicit VIP release from enriched synaptosomes of rat intestine, whereas exogenous VIP had no effect on NO production.

VIP stimulates NO production in isolated smooth muscle cells: The ability of VIP to stimulate NO production has now been demonstrated in smooth muscle cells isolated from various regions of the gastrointestinal tract (gastric fundus, small intestine, colon, esophageal and internal anal sphincters) in several species including human, dog, rabbit, opossum, guinea pig, rat, and mouse. VIP-stimulated NO production is inhibited by NOS inhibitors (e.g., L-NNA) and the VIP antagonist VIP10-28, but is not affected by oxyhemoglobin, which neutralizes extracellular NO, clearly implying that VIP-stimulated NO production originates in smooth muscle cells.

The receptor with which VIP and PACAP interact to generate NO in smooth muscle cells has been identified as the natriuretic peptide receptor C (NPR-C), a single-transmembrane receptor which is widely expressed in smooth muscle cells of the gut and is coupled to G_{i1} and G_{i2}. Detailed cellular and molecular studies have shown that interaction of VIP or PACAP with NPR-C leads to $G_{i1/2}$-dependent activation of eNOS and stimulation of NO formation in smooth muscle cells. The signaling pathway depicted in **Fig. 1** and analyzed in **Table 1**, is initiated by $G_{i1/2}$-dependent Ca^{2+} influx, and Ca^{2+}/calmodulin-dependent activation of a constitutive NOS (eNOS) and NO formation. NO activates sGC leading to cGMP formation and activation of PKG. Interaction of VIP and PACAP with $VPAC_2$ receptors initiates a parallel pathway involving sequential activation of adenylyl cyclase, cAMP formation, and activation of PKA. Both pathways converge to regulate muscle relaxation. With few exceptions, all actions attributed to VIP in this summary review are applicable to PACAP: both peptides interact with equal affinity with $VPAC_2$ receptors and NPR-C. The G protein-activating domain of NPR-C has now been identified as a 17-amino acid sequence in the middle region of the intracellular domain and comprises two arginine residues at the N-terminal and a B-B-X-X-B motif, where B and X are basic and non-basic residues, at the C-terminal [R^{469}*RNHQEESNIGKHRELR*^{485}]. Recent reconstitution studies in COS-1 cells and Xenopus oocytes confirm the ability of VIP, ANP, and the selective NPR-C ligand, cANP(4-23) to compete for binding to NPR-C. In cells from kidney, aorta, and heart that normally express NPR-C, natriuretic peptides activate eNOS via NPR-C.

The table summarizes evidence for the signaling cascades depicted in **Fig 1**. As expected, GDPβS inhibits all responses mediated by G protein-coupled receptors, whereas pertussis toxin (PTX), nifedipine, the calmodulin inhibitor calmidazolium, and L-NNA inhibit responses mediated by G_i-coupled NPR-C. LY83583 (cGMP inhibitor), KT5823 (PKG inhibitor), myristoylated PKI (PKA inhibitor). All inhibitors block only one pathway and elicit only partial inhibition (p/I, 45–55% inhibition) of relaxation. Together PKA and PKG inhibitors abolish relaxation. Oxy-hemoglobin had no effect implying that NO was generated within the muscle cells.

A cautionary note: A study by Lefebvre and coworkers (J.M.C. Dick et al, Br. J. Pharmacol. 129: 751–763, 2000) appeared to show that relaxation elicited by VIP in isolated smooth muscle cells was inhibited by both L-NNA and 1400 W, an inhibitor of inducible NOS (iNOS). The effect of 1400 W in this study was probably non-specific, since 1400 W also inhibited relaxation elicited by a wide variety of unrelated agents including isoprenaline, forskolin, sodium nitroprusside, and ANP (see Table 2 of this reference). It is worth noting that smooth muscle cells isolated from inflamed organs often express iNOS; in order to avoid introducing artefacts, it is essential to study smooth muscle cells isolated only from uncontaminated tissues.

Linkage of VIP release and NO production in innervated muscle strips: The two properties outlined above (VIP-stimulated NO production in muscle cells and NO-stimulated VIP release from nerve terminals) are reflected when measurements are made in innervated muscle strips. In circular muscle strips of rabbit gastric fundus, NO stimulated VIP release and elicited relaxation in a concentration-dependent fashion (threshold: 0.1 nM NO). Conversely, VIP stimulated NO production and elicited relaxation in a concentration-dependent fashion (threshold: 10 pM VIP). NO production stimulated by VIP was abolished and relaxation was partly inhibited ($\sim$50%) by L-NNA; oxyhemoglobin had no effect implying that NO generated by the action of VIP in smooth muscle cells did not traverse the extracellular space. Residual relaxation reflected the ability of VIP to interact with $VPAC_2$ receptors and elicit relaxation via a cAMP/PKA pathway.

Role of VIP and NO in inhibitory neurotransmission: *Inhibitory junction potential* (*IJP*): Smooth muscle of the gut exhibits sustained tone on which are superposed rhythmic contractions determined by the amplitude and frequency of slow waves that originate in pacemaker cells (ICC), located at the boundaries of the circular muscle layer. Muscle tone is determined by excitatory and inhibitory neurotransmitters diffusing from nerve terminals (varicosities) to regulate ionic channel activity and initiate receptor-

mediated signaling cascades in smooth muscle cells. The precise location of some channels cannot be determined because smooth muscle exists in a syncytium coupled electrically to ICCs and fibroblast-like PDGFRα^+ cells. Inhibitory neural input predominates in some locations (e.g., murine colonic circular muscle) where it attenuates tone and phasic activity: these are unmasked in the presence of tetrodotoxin, NOS inhibitors, or VIP antagonists and antisera. Excitatory neural input in the form of an excitatory junction potential or EJP depolarizes membrane potential, and enhances Ca^{2+} influx and the amplitude or frequency of corresponding rhythmic contractions. Inhibitory neural input in the form of an inhibitory (i.e., hyperpolarizing) junction potential or IJP has the reverse effect.

Inhibitory junction potentials (IJPs) consist of three components: an initial fast, high amplitude hyperpolarization, a slower, lower amplitude hyperpolarization, followed by a sustained low amplitude hyperpolarization of long duration. The three phases appear to reflect the release of purinergic (ATP or a preferential $P2Y_1$ agonist), nitrergic (NO), and peptidergic (VIP/PACAP) neurotransmitters. Recent studies have shown that the initial fast, high amplitude component reflects $P2Y_1$-mediated activation of small-conductance, Ca^{2+}-activated K^+ channels (SK channels) located in PDGFRα^+ cells, which are electrically coupled via gap junctions to ICCs and smooth muscle cells. The second nitrergic component reflects NO release from nerve terminals and/or VIP-mediated NO release from smooth muscle cells; suppression of this component by NOS inhibitors does not distinguish between these two sources of NO. The last long-duration component (evident in esophageal and internal anal sphincter muscle) represents a direct effect of VIP on smooth muscle cells, since it can be reproduced by exogenous VIP, is suppressed by VIP antagonists, and is absent in $VIP^{-/-}$ animals. This component also is sensitive to NOS inhibitors suggesting that it may reflect in part the ability of VIP to stimulate NO production in smooth muscle cells. Recent studies suggest that neuronal NO activates preferentially ICCs, from where the electrical signal is relayed to smooth muscle cells. This challenging hypothesis remains controversial and appears to preclude signaling by NO and VIP in smooth muscle cells.

Interplay of VIP and NO during nerve stimulation: *relaxation of tone*: The transient nature of IJPs does not permit concurrent measurements of NO and VIP. Thus, while pharmacological analysis of IJPs demonstrates the participation of both NO and VIP, it does not offer decisive evidence for their functional linkage. The latter is easily demonstrable in preparations where relaxation of resting tone is induced by electrical field stimulation. Defective experimental techniques such as the use of contractile agents to raise muscle tone have led to conflicting results, mainly because these agents stimulate protein kinase C, which in turn inactivates smooth muscle NOS.

Exclusive reliance on NOS inhibitors to discern the source of NO, without direct measurement of NO and VIP, leads to flawed conclusions. To avoid this pitfall, Jin et al. made concurrent measurements of VIP release, NO production, and muscle relaxation in gastric muscle strips from rabbit and rat fundus, combined with judicious use of inhibitors to identify the dual source of NO and demonstrate the interplay of VIP and NO in mediating relaxation of resting tone induced by a wide range of electrical field stimulation (EFS; 0.025-16 Hz; 3–960 pulses). The results obtained in both species were similar and only those obtained in rabbit are outlined below. EFS caused frequency-dependent increase in VIP release, NO production, and muscle relaxation, all of which were significant at the lowest stimulus (0.025 Hz/3 pulses). L-NNA abolished NO production at all frequencies; abolished VIP release and relaxation at frequencies below 0.5–1 Hz, and partly inhibited VIP release ($\sim$50%) and relaxation ($\sim$70%) at the highest frequency (16 Hz). Thus, both VIP release and relaxation were entirely dependent on NO at lower frequencies, and only partly dependent on NO at higher intensities of stimulation. Residual relaxation in the presence of L-NNA represented the effect of VIP acting directly on muscle cells via NO-independent mechanisms. The VIP antagonist, VIP10-28, abolished NO production and muscle relaxation at frequencies below 0.5–1 Hz, and partly inhibited NO production ($\sim$80%) and muscle relaxation (44%) at 16 Hz. Oxyhemoglobin inhibited VIP release and muscle relaxation, especially at low frequencies implying that some of the NO mediating VIP release traversed the extracellular space to adjacent VIP-containing nerve terminals. Thus, recognizing the ability of NO to regulate VIP release and of VIP to stimulate NO production in muscle cells is essential in interpreting their respective roles in inhibitory neurotransmission. Inhibition of relaxation by NOS inhibitors cannot be attributed solely to suppression of neuronal NO production, since NOS inhibitors also suppress VIP release stimulated by NO in nerve terminals as well as NO production stimulated by VIP in smooth muscle cells. Similarly, inhibition of relaxation by VIP10-28 cannot be attributed solely to inhibition of VIP's action on muscle cells via a $VPAC_2$/cAMP/PKA pathway, since VIP10-28 also blocks the ability of VIP to cause relaxation in muscle cells by generating NO via interaction with NPR-C and activation of the cGMP/PKG pathway.

Analysis of the peristaltic reflex confirms the interplay of VIP/PACAP and NO under physiological conditions, that is where neural simulation is applied by radial stretch or mucosal stroking (see below). Both types of stimuli elicit caudad muscle relaxation accompanied by VIP and PACAP release and NO production. NOS inhibitors (L-NNA) abolish NO production and partly inhibit VIP and PACAP release and relaxation. VIP10-28 strongly inhibits NO production and relaxation. As discussed above, the pattern clearly illustrates the interplay of VIP/PACAP and NO and further underlines the caution required in interpreting the effect of inhibitors, particularly NOS inhibitors.

SP and NKA

SP and NKA interact preferentially with NK_1 and NK_2 receptors on smooth muscle cells and nerve terminals. NKB, the preferred ligand for NK_3 receptors, is the product of a precursor that is virtually absent from the gut. NK_1 and NK_2 receptors are coupled via G_q to IP_3-dependent Ca^{2+} release and contraction in circular muscle and to arachidonic acid-mediated Ca^{2+} influx and Ca^{2+}-induced Ca^{2+} release in longitudinal muscle. The receptors stimulate ACh release from cholinergic neurons and induce a contraction that is superimposed on the direct contraction.

Enkephalin and Dynorphin

Opioid neurons of the myenteric plexus release a variety of peptides derived from two precursors: proenkephalin, which yields [Met]enkephalin and C-terminally extended derivatives, and prodynorphin, which yields α- and β-endorphin and dynorphin-17; the latter is processed to smaller dynorphin fragments and eventually to [Leu]enkephalin. [Met]enkephalin and its derivatives are much more abundant than dynorphin and its derivatives in the gut. Three opioid receptor types (μ, δ, and κ) are present on circular smooth muscle cells only where they mediate contraction. In addition, μ receptors on cholinergic neurons mediate inhibition of ACh release, and δ receptors on inhibitory neurons mediate inhibition of NO, VIP, and related peptides. The neural receptors are most relevant functionally, particularly δ receptors on inhibitory neurons. When opioids are injected *in vivo* or added to smooth muscle strips *in vitro*, they produce a transient increase in muscle tone by direct action on smooth muscle cells and a sustained increase in rhythmic, nonpropulsive contractile activity that reflects the suppression of a predominant inhibitory neural input.

Somatostatin

Somatostatin is present exclusively in a small population of myenteric interneurons, where it serves as a relay in the peristaltic reflex. Although somatostatin receptors that mediate contraction are present on circular muscle cells, they lack functional relevance in the absence of muscle innervation by somatostatin neurons.

CGRP

In the stomach, CGRP-containing nerve fibers are extrinsic primary afferent fibers, whereas in the intestine and colon they are both extrinsic and intrinsic; the latter mediate the peristaltic reflex induced by mucosal stimuli. CGRP is present in other neurons, but its function is unknown. CGRP receptors on muscle cells are reported to cause direct relaxation.

In summary, neurotransmitters of functional importance are the excitatory motor neurotransmitters, ACh and tachykinins; the inhibitory motor neurotransmitters, NO, VIP and its homologues; the modulatory neurotransmitters, opioids and somatostatin; and the sensory neurotransmitter, CGRP. Excitatory motor neurotransmitters depolarize and inhibitory motor neurotransmitters hyperpolarize membrane potential. At an appropriate threshold, depolarization opens voltage-sensitive Ca^{2+} channels, resulting in Ca^{2+} influx, an increase in both tone and the amplitude or frequency of rhythmic contractions. Hyperpolarization affects mainly rhythmic activity, which is either decreased or suppressed, but can affect tone in regions where membrane potential is already depolarized.

The Peristaltic Reflex: Interplay of Motor, Modulatory, and Sensory Neurotransmitters

The functional role of peptide and nonpeptide neurotransmitters is best exemplified by their coordinated release during the intestinal peristaltic reflex (Fig. 2). The reflex can be evoked by mechanical or chemical stimulation of the mucosa (stroking or pH change) and by radial muscle stretch. The reflex consists of a descending phase, during which circular muscle relaxes and longitudinal muscle contracts caudad to the site of stimulation, and an ascending phase, during which circular muscle contracts and longitudinal muscle relaxes. Two types of *in vitro* preparations have been used to study the reflex that permit simultaneous measurement of mechanical response and neurotransmitter release. In one preparation, a hollow segment of intestine is stretched at the caudad or orad end, and mechanical response is measured as the medium is sampled for neurotransmitter release. In the other, the segment is opened and pinned as a flat sheet, separated into three compartments. The reflex is evoked by stimulation in the central compartment, while mechanical response and neurotransmitter release in each compartment is measured.

Neurotransmitter Release during the Ascending and Descending Phases of the Reflex

A precise pattern of neurotransmitter release occurs with each phase. During the descending phase, there is an increase in the release of VIP, PACAP, NO, and somatostatin and a decrease in the release of [Met]enkephalin. The pattern of release reflects the role of these neurotransmitters in mediating the descending phase. Thus, release of VIP, PACAP, and NO from the nerve terminals of motor neurons innervating circular muscle mediates descending (caudad) relaxation of this layer. Release of the same neurotransmitters from interneurons that synapse with and activate ACh/tachykinin motor neurons that innervate longitudinal muscle mediates reciprocal contraction of this layer. The increase in the activity of VIP/PACAP/NOS motor neurons and interneurons is caused by a decrease in the tonic inhibitory influence of opioid ([Met]enkephalin) interneurons, which in turn is caused by an increase in the activity of somatostatin interneurons. Thus, as the reflex is evoked sensory input is relayed to somatostatin interneurons coupled to opioid interneurons, which in turn are coupled to VIP/PACAP/NOS motor neurons and interneurons (Fig. 2).

A reverse pattern of neurotransmitter release accompanied by an increase in SP and NKA release occurs during the ascending phase and determines the contraction of circular muscle and relaxation of longitudinal muscle. There is little direct inhibitory input to longitudinal muscle, at least in small animals. Contraction and relaxation of this muscle reflect, respectively, the increase and decrease in ACh and tachykinin release from motor neurons (Fig. 2).

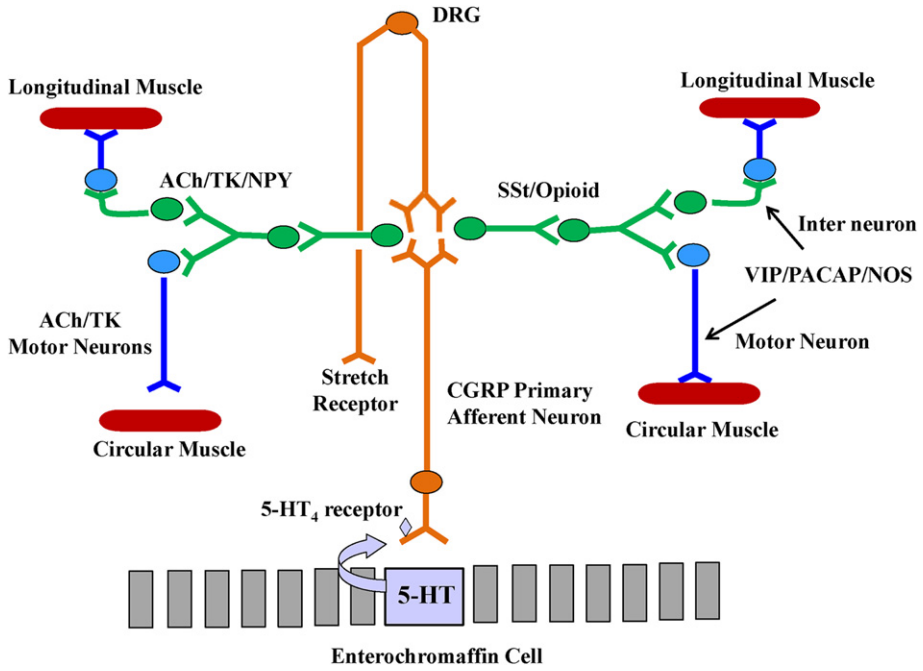

Fig. 2 Model illustrating the regulation of intestinal peristaltic reflex. Mucosal stimulation causes the release of 5-HT, which acts on a 5-HT_4 receptor on intrinsic primary afferent CGRP neurons. Mechanical distension of the gut wall activates extrinsic primary afferent CGRP neurons with cell bodies located in the dorsal root ganglion (DRG). Both afferent neurons activate the same reflex pathway. The descending or caudad pathway is mediated by somatostatin (SSt) and opioid peptide interneurons coupled in series to (i) VIP/PACAP/NOS motor neurons, which innervate the circular muscle layer and cause descending relaxation of circular muscle, and (ii) VIP interneurons coupled to ACh/tachykinin (TK) motor neurons, which innervate the longitudinal muscle layer and cause descending contraction of longitudinal muscle during circular muscle relaxation. The ascending or orad pathway is less well defined but involves cholinergic interneurons and results in activation of ACh/TK motor neurons, which innervate the circular muscle layer and cause ascending contraction of circular muscle, and inhibition of ACh/TK motor neurons, which innervate the longitudinal muscle layer and cause ascending relaxation of longitudinal muscle during circular muscle contraction.

The Sensory Limb of the Peristaltic Reflex

Two distinct populations of sensory neurons mediate the peristaltic reflex evoked by muscle stretch and mucosal stimulation. After nerve degeneration following surgical or chemical (using capsaicin) ganglionectomy, the reflex can be evoked by mucosal stimulation but not by muscle stretch. Conversely, after the mucosa is removed while maintaining intact extrinsic innervation, the reflex can still be evoked by muscle stretch. Thus, mucosal stimulation activates intrinsic sensory neurons with terminals in the mucosa and cell bodies in the myenteric plexus, whereas circular muscle stretch activates sensory neurons with nerve terminals in circular muscle and cell bodies in the dorsal root ganglia. The main sensory neurotransmitter in extrinsic and intrinsic neurons is CGRP, and its effect is relayed to the same circuits of interneurons and motor neurons that mediate the ascending and descending phases of the reflex.

The mechanism by which CGRP-containing intrinsic sensory neurons are activated is unique in that it involves release of 5-hydroxytryptamine (5-HT) from the mucosa. In both humans and experimental animals, mucosal stimulation releases 5-HT from enterochromaffin cells, one of two large stores of 5-HT in the body. 5-HT acts on 5-HT_4 receptors located on mucosal sensory nerve terminals, causing release of CGRP (Fig. 2). The addition of 5-HT or a selective 5-HT_4 agonist to the mucosal surface releases CGRP from capsaicin-sensitive sensory neurons and triggers the peristaltic reflex. Selective 5-HT_4 antagonists block CGRP release and the peristaltic reflex evoked by mucosal stimulation or by the addition of 5-HT to the mucosa. Both 5-HT_4 and CGRP antagonists suppress the ascending and descending phases of the reflex and the release of corresponding neurotransmitters. No release of 5-HT is seen when the peristatlic reflex is evoked by radial muscle stretch. Although the reflex has been traditionally viewed as a stereotypical response to intestinal distension (radial muscle stretch), it is unlikely that this represents the normal physiological modality. The mere passage and chemical composition of digesta appear to be the main physiological triggers of the reflex and propulsion of intestinal contents.

Propagation of the Reflex

The caudad propagation of the reflex leads to propulsion of intestinal contents. The velocity of propulsion is readily measured *in vitro* using synthetic fecal pellets inserted into the orad end of the segment without distending the lumen. 5-HT_4 agonists added to the lumen of the segment accelerate the velocity of propulsion, whereas 5-HT_4 antagonists have the opposite effect. Elimination

of the inhibitory influence of opioid neurons on VIP/PACAP/NOS neurons with opioid antagonists (particularly δ receptor antagonists) accelerates propulsion. The suppression of opioid activity greatly potentiates the ability of 5-HT to accelerate propulsion, such that a combination of near-threshold concentrations of a 5-HT_4 agonist and an opioid δ antagonist produces near-maximal stimulation of propulsion. The remarkable effect of this combination suggests that it may have therapeutic potential, and highlights the importance of understanding the physiological interplay of peptide neurotransmitters and their regulators.

Pituitary Tumors Associated With Multiple Endocrine Neoplasia Syndromes

Liliya Rostomyan, Adrian F Daly, and Albert Beckers, University Hospital Center of Liège, Liège, Belgium

Introduction

Pituitary adenomas are typically sporadic and the various subtypes include prolactinomas (50%–55%), clinically non-functioning pituitary adenomas (NFPA) (20%–25%) that primarily originate from gonadotrope cells, pure growth hormone (GH) secreting pituitary adenomas or mixed GH and prolactin secreting pituitary adenomas (15%–20%), corticotropinomas (5%) and TSH-secreting pituitary adenomas (1%). The prevalence of clinically relevant pituitary adenomas is about 1:1000 (Daly *et al.*, 2006b). Pituitary adenomas can occur in a familial context in 5%–6% of cases, mainly as familial isolated pituitary adenomas (FIPA), in which pituitary adenomas are the only tumoral presentation or as part of multiple endocrine neoplasia type 1 (MEN1) syndrome (Beckers *et al.*, 2013). Rare genetic forms of pituitary adenomas include Carney complex (CNC), MEN4, the "3PAs" syndrome (paraganglioma/pheochromocytoma/pituitary adenoma association) and X-Linked Acrogigantism (X-LAG) syndrome. Some characteristics of the inherited forms of pituitary adenomas can distinguish them from sporadic tumors; however, these characteristics can vary between individuals and within families. This heterogeneous clinical expression must be kept in mind during investigation and follow-up.

Recent progress in the genetics of endocrine tumors has resulted in an increased recognition of the genes that predispose to the development of pituitary adenomas in the context of multiple neoplasia syndromes (Beckers *et al.*, 2012) and as isolated familial forms (Daly *et al.*, 2006a; Trivellin *et al.*, 2014). In addition, some apparently sporadic forms of pituitary adenomas can also arise on a genetic basis. As a consequence, a better understanding of some molecular mechanisms of pituitary tumorigenesis can offer the possibility of meaningful genetic screening among the at-risk population (**Table 1**). Awareness of these complex syndromes can facilitate a more timely diagnosis, while helping to direct appropriate screening and follow-up of patients and clinically unaffected mutation carriers.

Multiple Endocrine Neoplasia Type 1 (MEN1)

MEN1 is the main multi-organ syndromic condition associated with pituitary adenomas. This is an autosomal dominant condition involving about 2.7% of all PAs in some series. MEN1 can present as a sporadic form or in a familial setting. In MEN1, pituitary adenomas usually occur in association with other endocrine and non-endocrine tumors. MEN1 related disease usually becomes clinically evident in adolescents and in young adults, and >95% of patients develop at least one manifestation of the disease by the age of 50 (Verges *et al.*, 2002).

Primary hyperparathyroidism (PHPT) is the most common (95%–98% of cases) and often the first manifestation. Gastro-enteropancreatic neuroendocrine tumors (NETs) (30%–70% of cases) are the second most frequently encountered tumor in MEN1 and include mostly gastrinomas, insulinomas, and non-functioning tumors (Wautot *et al.*, 2002; Thakker, 2014).

Table 1 Recognized genetic causes of pituitary adenomas occurring in a familial, syndromic or inherited context

Condition	*Gene*	*Physiopathology*	*Phenotype*
MEN1	*MEN1* (Chr11q13)	Decrease of menin function	All pituitary tumor types
MEN4	*CDKN1B* (Chr12p13)	Lack of tumor suppression	Only acromegaly and Cushing's disease to date
Carney complex	*PRKAR1A* (Chr17q22–24)	1A regulatory subunit of protein kinase A expression/function alteration	GH and GH/prolactin secreting adenomas
McCune–Albright syndrome	*GNAS1* (Chr20q13.3)	Activation of the stimulatory alpha-subunit (Gsα) of protein G	Pituitary hyperplasia and adenomas, acrogigantism or Cushing syndrome
3PAs	*SDHA*, *SDHB*, *SDHC*, *MEN1*, *MAX*	Decreased activity of SDH, MAX	Often aggressive macroadenomas secreting prolactin or GH
Pituitary blastoma	*DICER1* (Chr14q32.13)	Alteration of DICER1 activity	Potential for hypersecretion of ACTH and young onset Cushing disease
FIPA	*AIP* (Chr11q13.32) in 15%–20% of cases	Various	All pituitary adenoma subtypes involved. *AIP* mutation cases include somatotropinomas, prolactinomas, mixed GH/prolactin tumors, non-secreting adenomas, TSH-omas
X-LAG	*GPR101* (ChrXq26.3 microduplications and mosaicism)	Increased expression of GPR101, GHRH and GH secretion	Early onset acrogigantism, somatotropinomas/somatotrope hyperplasia with prolactin secretion

 doi:10.1016/B978-0-12-801238-3.66169-X

Pituitary adenomas are diagnosed in 40% of MEN1 patients. Most of these tumors are prolactinomas (50%–60%), followed by other functioning pituitary adenomas (somatotropinomas in 10% and corticotropinomas in 5%) and NFPA (5%–15%) (Burgess *et al.*, 1996). PAs with mixed hormonal secretion and pituitary hyperplasia have been also reported in MEN1 (Thakker, 2014). In about 17% of cases the pituitary tumor is the initial manifestation of MEN1 (Verges *et al.*, 2002).

When compared with sporadic cases, MEN1-associated pituitary adenomas develop at a younger age and present with more aggressive features. They are more likely to manifest as large prolactinomas (85% are macroadenomas) with more frequent local compression symptoms, and resistance to treatment with dopamine agonists (Verges *et al.*, 2002; Wautot *et al.*, 2002; Beckers *et al.*, 2003). However, GH-secreting adenomas have also been reported in MEN1 from a very young age that could lead to abnormal growth acceleration and tall stature in these patients (Stratakis *et al.*, 2000). In some cases, MEN1 pituitary carcinomas have also been described (Philippon *et al.*, 2012; Vroonen *et al.*, 2012).

Other less frequent components of MEN1 syndrome include adrenal cortical lesions (25%–40%), carcinoids (10%), bronchopulmonary and thymic neuroendocrine tumors (2%) and pheochromocytomas (<1%), as well as non-endocrine lesions such as angiofibromas (80%), collagenomas (70%), and lipomas (20%–30%) (Thakker *et al.*, 2012; Thakker, 2014).

The *MEN1* gene consists of 10 exons, coding for the 610 amino acid nuclear protein menin (Chandrasekharappa *et al.*, 1997). Through protein–protein interaction, and also epigenetic modifications, it participates in cell cycle control, oxidative stress regulation and DNA repair. For example, it suppresses the transcription of prolactin and induces cell cycle inhibitors including p27 (Agarwal *et al.*, 2004; Thakker, 2014; Scacheri *et al.*, 2006). Inactivating germline *MEN1* mutations are present in 80% of cases, among which 10% are de novo mutations. >700 mutations in *MEN1* have been described (Thakker, 2010). In 75% of cases, these mutations are nonsense inactivating mutations (23%), frameshift (41%) or with splice site alterations. In 1%–5% of the cases with normal sequencing, large genomic rearrangements can be found by multiple ligation-dependent probe amplification (MLPA) and can be seen in familial MEN1 cases. In >90% of MEN1 tumors, the second allele is inactivated, as demonstrated by loss of heterozygosity (LOH) at chromosome 11q13 (Thakker, 2010). There is no genotype–phenotype correlation, except for rare forms with a high prevalence of prolactinomas, described in families from the Burin peninsula in Newfoundland, Canada (MEN1-Burin) (Thakker, 2010; Wautot *et al.*, 2002; Olufemi *et al.*, 1998).

MEN1 guidelines recommend genetic screening in patients with two or more typical MEN1 manifestations and in first-degree relatives of proven mutation carriers. Regular clinical and biochemical screening for potential MEN1-associated tumor development is advised starting from a young age, due to the observation of MEN1 manifestations in pediatric patients (Thakker *et al.*, 2012). A MEN1-associated pituitary adenoma has been reported in a boy as young as 5 years of age (Stratakis *et al.*, 2000). Genetic testing for *MEN1* and *AIP* gene mutations should be considered in sporadic pediatric or young adult cases with pituitary adenomas, as *AIP* mutations are frequent and *MEN1* mutations are detected in 8% in those with a young age at onset of pituitary disease (Cuny *et al.*, 2013; Tichomirowa *et al.*, 2011; Stratakis *et al.*, 2010).

Multiple Endocrine Neoplasia Type 4 (MEN4)

Among patients that present with a MEN1 phenotype, up to 20% have no *MEN1* mutation; these are usually sporadic cases. One alternate genetic cause of a MEN1-like presentation is MEN4 syndrome caused by an inactivating germline mutation of the *CDKN1B* gene coding for a 196 amino-acid cyclin-dependent kinase inhibitor (p27Kip1). Initially, Pellegata and collaborators described this condition as MENX in a rat model with autosomal recessive transmission, characterized by mixed clinical manifestations between MEN1 and MEN2 (Fritz *et al.*, 2002; Pellegata *et al.*, 2006). They also reported a pathogenic mutation in the human *CDKN1B* gene in a family with acromegaly, PHPT, renal angio-myolipoma, and a testicular tumor, which was named MEN4 (Lee and Pellegata, 2013). Both sporadic and familial forms of MEN4 can occur. MEN4 is a rare and heterogeneous condition, most frequently occurring with PHTP, although several cases of pituitary adenomas of various phenotypes (including acromegaly) have also been reported in the context of this syndrome (Lee and Pellegata, 2013). Other MEN4 manifestations include gastroenteropancreatic NETs, adrenal and thyroid tumors, carcinoids and other non-endocrine abnormalities. Mutations of *CDKN1B* are reported in 2%–3% of MEN1-negative cases (Lee and Pellegata, 2013). However, MEN4 appears to explain very few cases of syndromic pituitary adenomas (Stratakis *et al.*, 2010), and *CDKN1B* mutations should be considered as a very rare genetic predisposition to pituitary adenomas.

Carney Complex (CNC)

A complex condition was defined by Carney in 1985 as an association of myxomas, point-like pigmented lesions of the skin and endocrine hyperactivity. It is a rare autosomal dominant syndrome (<1000 cases described) characterized by over-activity of the cAMP pathway and development of lentigines (70%), myxomas of various locations including the heart (30%), schwannomas, primary pigmented nodular adrenal disease (PPNAD) (~60%), testicular (60%), and ovarian (30%) tumors and pituitary hypersecretion (Boikos and Stratakis, 2007). In 70% of cases Carney complex is familial (Stratakis *et al.*, 2001). Given the potential severity of cardiac myxomas, very early family screening is recommended.

Multifocal somatomammotrope hyperplasia and/or GH-prolactin secreting pituitary adenomas can cause acromegaly in about 10% of CNC cases. However subclinical hypersecretion of GH/IGF1 and/or prolactin can occur frequently (75%). Acromegaly in

CNC has a mean age at diagnosis of 35 years, and usually has a mild course (Correa *et al.*, 2015). Mixed PAs other than GH/prolactin secreting (with positive staining for TSH, LH or alpha subunit) are also found in CNC (Pack *et al.*, 2000).

The main gene found to be responsible in 60%–65% of CNC is *PRKAR1A* on chromosome 17q24, encoding the 1A regulatory subunit of protein kinase A (PKA) (Bertherat *et al.*, 2009; Horvath *et al.*, 2010). While another potential locus (CNC2) exists at 2p16, alterations in individual genes have not been yet characterized (Casey *et al.*, 1998; Stratakis *et al.*, 1996). A case of CNC-like phenotype presenting with acromegaly due to a pituitary tumor in association with pigmented spots and myxomas was identified recently and was associated with a triplication on chromosome 1p31.1, including the *PRKACB* gene which encodes the catalytic subunit of PKA (Forlino *et al.*, 2014).

3P Association (3PAs)

Cases of pituitary adenoma coexisting with pheochromocytoma were described as early as 1952 (Iversen, 1952). This association of pituitary tumor and pheochromocytomas/paragangliomas (termed "3P Association" or 3PAs) has recently been demonstrated to occur in patients with mutations in genes encoding the subunits of succinate-dehydrogenase (SDH), which are known pheochromocytoma/paraganglioma risk genes (Xekouki *et al.*, 2012; Dwight *et al.*, 2013; Denes *et al.*, 2015). Familial and sporadic 3PAs cases were reported. In families, each affected person can have both pituitary adenomas and pheochromocytoma/paraganglioma or have each tumor separately. Inactivating mutations in *SDHx* genes are detected in 40% of 3PAs (Denes *et al.*, 2015). The most common SDHx mutation- associated PAs are somatotropinomas, followed by prolactinomas and NFPA. These pituitary tumors almost all are macroadenomas and appear to be aggressive (Denes *et al.*, 2015). LOH at the corresponding locus was found in some 3PAs- associated pituitary adenoma samples. These findings demonstrated the pathogenic role of *SDHx* gene mutations in pituitary tumorigenesis (Denes *et al.*, 2015; Xekouki *et al.*, 2012). However, *SDHx*-related pituitary adenomas are very rare, accounting for only 0.3% of all pituitary tumors (Gill *et al.*, 2014). Based on these data, the genetic screening for *SDHx* mutations is recommended only in patients with both pituitary adenomas and pheochromocytoma/paraganglioma and in kindreds corresponding to familial 3PAs. Alterations in other genes involved in the onset of pheochromocytomas/paragangliomas seem to have only an exceptionally rare association with pituitary adenomas (O'Toole *et al.*, 2015). For instance, intragenic deletions of one or more exons in the *MAX* gene have recently been shown to occur in patients with aggressive pheochromocytomas in association with pituitary adenomas (Daly *et al.*, 2018).

DICER1 Syndrome and Pituitary Blastoma

Pituitary blastomas are very rare pituitary tumors of embryonic origin (Scheithauer *et al.*, 2012). They usually occur in pediatric patients, as ACTH-dependent hypercortisolism and young onset Cushing's disease (de Kock *et al.*, 2014). This rare condition was found to be associated with germinal or somatic mutations of the *DICER1* gene, coding for a ribonuclease involved in the maturation of microRNAs. Classically, mutations in *DICER1* were reported in other pediatric tumors (nephromas, testicular Leydig or Sertoli cell tumors, and sarcomas). The identification of pathogenic *DICER1* mutations requires screening for other DICER1-related tumors in these patients, although mosaicism for mutations in *DICER1* can be present, leading to a diverse phenotypic presentation (de Kock *et al.*, 2014).

McCune–Albright Syndrome (MAS)

MAS is non-familial genetic syndrome due to a mosaicism for an activating mutation of the α-subunit of the stimulatory guanine binding (Gs) protein gene (*GNAS1*), which induces constitutive activation of the cAMP pathway (Weinstein *et al.*, 1991). The clinical phenotype therefore depends on the type of cells affected by the mutation. Clinically it presents as a specific triad: an association of hyperpigmented "café au lait" spots, polyostotic fibrous dysplasia and various endocrine gland hypersecretion. The latter can lead to precocious puberty, hyperthyroidism, Cushing syndrome and GH/IGF1 hypersecretion (Dumitrescu and Collins, 2008).

GH hypersecretion is often due to pituitary hyperplasia and is frequently accompanied by hyperprolactinemia (Salenave *et al.*, 2014). Interestingly, the pituitary abnormalities in MAS can present also as a somatotropinoma surrounded by diffuse pituitary hyperplasia (Vasilev *et al.*, 2014). Acromegaly affects 20%–30% of MAS cases, with a young age of onset. Early exposure to GH excess can lead to pituitary gigantism (Vasilev *et al.*, 2014). In addition to MAS, the presence of pituitary somatotrope hyperplasia and adenoma in young patients with overgrowth can also occur in association with *AIP* mutations, Carney complex or in the setting of X-LAG syndrome (germline Xq26.3 microduplications or mosaicism), so this finding on histopathology should stimulate genetic investigations (Villa *et al.*, 2011; Trivellin *et al.*, 2014; Daly *et al.*, 2016).

Considering the absence of familial cases of MAS reported in humans and the low rate of the *GNAS1* mutation detection in the leukocyte DNA (no higher than 45% even in the patients with the complete MAS triad), the recommendations for genetic screening are ambiguous. Some new techniques like digital droplet PCR (ddPCR) for *GNAS1* somatic mosaicism can help to

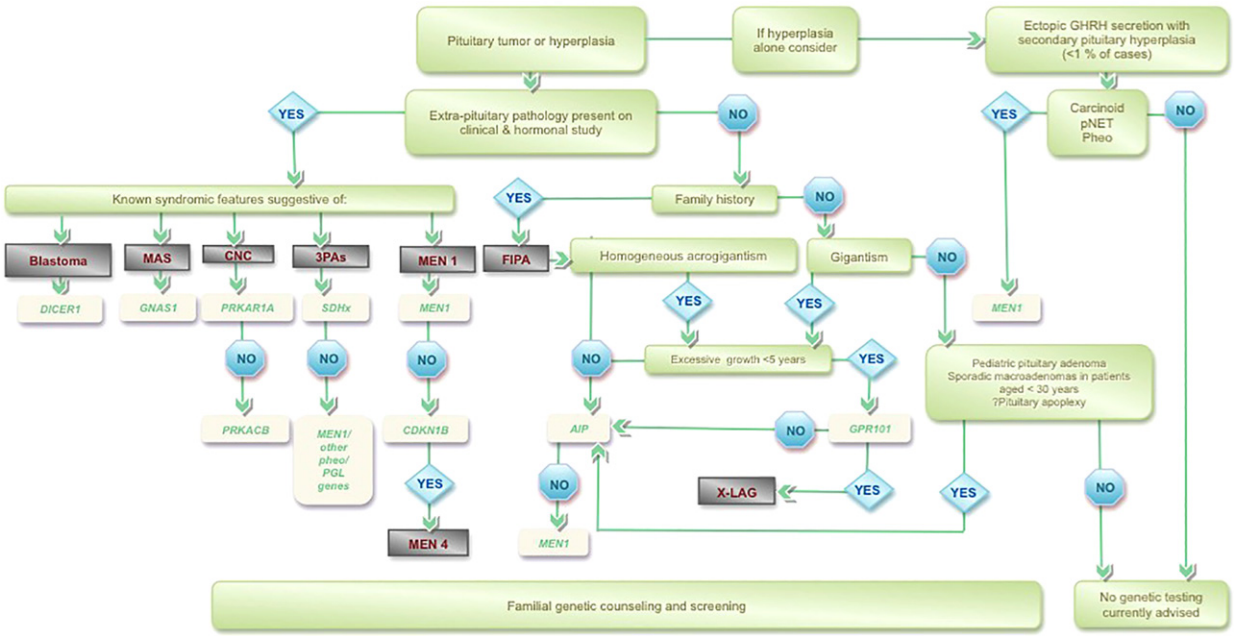

Fig. 1 Genetic screening algorithm in patients with pituitary adenomas. Adapted with permission by the authors from their own work in Rostomyan, L. and Beckers, A. (2016). Screening for genetic causes of growth hormone hypersecretion. *Growth Hormone & Igf Research*, **30–31**, 52–57.

increase the diagnostic yield (Vasilev *et al.*, 2014). Inheritance is not described in humans, although it has been established in transgenic mice (Saggio *et al.*, 2014).

Conclusions

Inherited and genetic forms of PAs can be present in association with various endocrine and non-endocrine abnormalities. Genetic alterations specific for each condition contribute to the clinical features of PA, as noted above. Most of PAs with a genetic predisposition have early onset and aggressive behavior, present frequently as large invasive tumors and some are resistant to conventional medical treatment options.

Genetic studies of the main genes of interest in inherited pituitary tumor syndromes, when informed by the clinical presentation can identify high-risk groups for the genetic predisposition to pituitary adenomas (**Fig. 1**). Consequently, adequate biochemical and clinical screening algorithms can lead to early detection of these tumors at an early stage.

Aging and Longevity of Human Populations☆

Diana van Heemst, Leiden University Medical Center, Leiden, The Netherlands

Glossary

Antioxidant A substance that chemically inhibits oxidation reactions.

Caloric restriction Eating fewer calories than *ad libitum* while achieving adequate or optimal nutrition. This has extended both mean and maximum life span in various animal models.

Cellular senescence A cell fate decision and stress response characterized by a permanent arrest of cell proliferation coupled to a complex secretory phenotype.

Mitochondria Any of various round or long cellular organelles of most eukaryotes that are found outside the nucleus, produce energy for the cell through oxidative processes, and are rich in fats, proteins, and enzymes.

Nuclear DNA DNA found within the nucleus of the cell.

Oxidative theory of aging The theory that declines in physiological function with age are due to damage accumulated from reactive oxygen species.

Superoxide disumutase (SOD) A potent intracellular antioxidant.

Telomere The natural end sequence of a eukaryotic chromosome.

Aging and longevity are fundamental characteristics of human populations. Over the last two centuries, human life expectancy has more than doubled, resulting in a significant increase in the number of older individuals worldwide. Aging typically means the loss with increased chronological age of the functional capability of different organs of the body resulting in an increased risk of disease and death. While aging has for long been regarded a nonmodifiable risk factor for major chronic diseases, such as cancer or cardiovascular diseases, discoveries in experimental model organisms have provided evidence that the rate of aging can be modulated by genetic and environmental interventions in a number of conserved mechanisms that seem to be the main drivers of aging. Often, aging has been defined at the cellular level, such as the replicative senescence of cells whose telomere reaches a critical length, or related to mitochondrial dysfunction in energy production due to the accumulated damage of reactive oxygen species. Longevity, the number of years lived, is generally viewed as being determined by senescent processes reaching their end stage. To capture the key biological mechanisms underlying aging and longevity and their complex interrelationships in a conceptual framework "the hallmarks of aging" have recently been proposed. In this conceptual framework, aging features that occur at different hierarchical levels are integrated, namely the subcellular or molecular level, the single cell level, and the tissue and whole-body level. Neuro-endocrine mechanisms have been identified as important regulators of aging and longevity by affecting several of the hallmarks of aging, in ways that are complex and always not well understood.

Cell-Based Senescence

Biological models of human aging and longevity have often focused on the senescence and death of the individual cell—the fundamental building block of the human organism. For example, one model of senescent-limited longevity is based on a model of genetic restrictions on the number of cell replications that can occur under the so-called Hayflick limit. The physical basis for this phenomenon called replicative senescence is believed to be the telomere, the end sequence of the chromosome that tends to decrease in length with each replication of the cell. These cell-based models tend to underplay the significance of endocrine and growth factors.

One problem with this perspective is that an experimental analysis of the decline in the number of replications that a cell can perform (often estimated at 50–60) per year of age in vitro was estimated to be 0.2/year in humans aged 30–80, implying that this mechanism limited the human life span to 250–300 years. The highest reliable age reported at death is currently that of Madame J. Calment, who died at age 122. A second problem is that although the Hayflick limit may explain longevity bounds, it does not explain loss of function with age.

Several studies observed that in healthy human subjects, and controlling for the biopsy site, there was no significant negative correlation between the cell's replicative capacity in a given tissue and subjects' age in vitro. As a consequence, questions are raised about the importance and exact role of the loss of cell replicative capacity as a limiting factor in human longevity. Additionally, studies have found the correlation of telomere length with replicative senescence to be complex because it varies across tissue types and because the telomere may have additional cellular functions, such as monitoring oxidative cell damage. Further complicating

☆*Change History*: February 2018. Diana van Heemst updated the text and references to this article.

This article is an update of Kenneth G. Manton, Aging and Longevity of Human Populations, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 116–121.

 doi:10.1016/B978-0-12-801238-3.95813-6

analysis of the mechanisms controlling longevity is the fact that most tissues, including the brain, are now thought to have a small proportion of stem cells from which new cells can generate.

While telomere shortening can induce replicative senescence, cellular senescence can be induced by different genomic, epigenomic, or metabolic stresses that put replication-competent cells at risk for neoplastic transformation. Cellular senescence is characterized by a permanent arrest of cell proliferation coupled to a complex pro-inflammatory senescence-associated secretory phenotype (SASP). The proliferative arrest is a potent anticancer mechanism, whereas the complex secretory response can promote wound healing and tissue repair by transiently providing the required proteases, cytokines and growth factors. With age, numbers of senescent cells increase in most mammalian tissues, and senescent cells are enriched at sites of age-related pathologies. It is unknown what causes senescent cells to accumulate with age, but age-related decreases in the efficiency of clearance by the immune system and via apoptosis are thought to contribute. When present in sufficiently high numbers, senescent cells can negatively influence tissue homeostasis. Their proliferative arrest can hamper tissue repair and regeneration by curtailing the proliferation of stem or progenitor cells. Likewise, the senescence-associated secretory phenotype can create a chronic inflammatory milieu that may drive or exacerbate several age-related diseases, including cancer. The development of therapies that pharmacologically target senescent cells may constitute a novel strategy for treatment of age-related diseases. In experimental animal models, removal of senescent cell by targeted induction of apoptosis has recently been shown to delay several age-related pathologies and increase healthy lifespan.

Oxidative Stress and Mitochondrial Influences on Aging

Another promising model of the cellular mechanisms limiting the human life span is the senescence of the human mitochondria. This is a specific form of the general theory of an oxidative basis for aging originally proposed by Harman. Mitochondrial DNA (mtDNA) has fewer error monitoring and correcting mechanisms than does nuclear DNA (nDNA). Furthermore, since the mitochondria is the primary center of energy production in cells, the organelle is thought to be especially vulnerable to the oxidative stress of reactive oxygen species (ROS), which are produced in the respiratory processes centered in the mitochondria.

Because the mutation rate of mtDNA is much greater (approximately 10-fold) than that of nDNA, in a variant of the oxidative theory of aging, "aging" of the mitochondria has been suggested to be the physiological process limiting human longevity to a maximum of 130 years.

Of interest is that the production of many mitochondrial proteins in humans has been taken over by nDNA, with 47 of 60 mitochondrial proteins produced in the nucleus, in which error monitoring and corrective mechanisms are more complete. An interesting corollary of this model is that as aging degrades the efficiency of energy production, the physical activity of the organism is degraded, inducing a correlation of functional loss and longevity. Cell-specific failure can be communicated systematically by cytokines such as interleukin-8, which is increased by stress due to ROS, and interleukin-6, which is a proinflammatory cytokine.

Exogenous Modulators of Mitochondrial Function

Problems arise with this model of longevity and senescence when one considers how "external" factors affect the process of mitochondrial senescence and functional degeneration. A common model for life-expectancy extension is caloric restriction. In this case, the lowering of caloric consumption without malnutrition is thought to decrease basal metabolism, reduce oxidative stress, and retard age-related degeneration. Since this involves energy production and metabolism, it is reasonable to consider the mitochondria as the focal point of these processes. Such an intervention has been shown to increase life expectancy in experimental models of rodents and other lower organisms. Recently, different studies have assessed the effects of caloric restriction in Rhesus monkeys. While a study by the University of Wisconsin study reported a positive impact of caloric restriction on survival, in a study by the National Institute on Aging study no significant survival effect was detected. While differences in study design, including differences in the age of onset of caloric restriction, the amount of food consumed by the control group and the composition of diet have likely contributed to the differences in the effect on survival between studies, both studies observed health benefits of caloric restriction in non-human primates. Additionally, several genetic mutations in *Caenorhabditis elegans* and *Drosophila* have shown that slowing metabolism, and reducing growth and reproduction, can significantly extend the life span. It is believed that longevity-extending mutations in these organisms either protect against ROS species (e.g., genes controlling SOD2 production) or alter insulin and insulin growth factor-1 pathways and signaling.

A significant counterexample to these experimental models is *Apis mellifera*, the common honeybee. Both bee workers and queens have identical genotypes. Their polyphenotypic differentiation occurs due to differences in larval nutrition whereby larva destined to become queens are fed royal jelly, which contains juvenile hormone that alters the developmental trajectory, increases body size and respiration/metabolic rate, increases life expectancy 15- to 30-fold over that of the worker bee, and increases the level of royal jelly produced in queens.

Juvenile hormone seems to affect basal metabolic rate by increasing the production of mitochondrial transcription factors and certain mitochondrial enzymes (Cox-1 and Cytc-C) involved in the respiratory process. Thus, juvenile hormone in bees appears to play roles similar to those of thyroid hormones in humans, which can also affect the developmental process as well as the

mitochondrial energy production function. Of interest is that the nuclear receptors for thyroid hormone T_3 also code for the type of mitochondrial translation proteins elevated in queen bees. One of the crucial findings of experimental studies of the queen bee was that the increases in respiration rate were due to enhanced mitochondrial function and not to increased numbers of mitochondrial organelles. The queen bee model raises the question of how thyroid hormones in humans might regulate senescence and affect longevity by controlling mitochondrial behavior and function (a process not extensively studied), especially regarding how nutritional and physical activity (energy expenditure) factors may affect mitochondrial function.

There is significant evidence that nutritional or dietary factors can alter mitochondrial function and, indeed, changes in mitochondrial functions with age in animal models. Improved mitochondrial efficiency would lead to the generation of less ROS and lower amounts of oxidative stress. It was recently observed that in humans, a two-year caloric restriction intervention reduced whole body oxidative stress based on measurement of urinary concentrations of F2-isoprostanes.

Tissue Interdependence and Hormonal Control in Longevity

Any model that attempts to explain human longevity and senescence solely at a cellular or molecular level is likely to fail as an oversimplified representation of the physiological and molecular mechanisms involved. The fact is that the molecular functioning of a cell is important not only for its internal maintenance but also for the functioning of the organism. Thus, part of the question of the relation of senescence and longevity concerns the biological complexity of the organism due to the functional differentiation of tissue and organs and the hormonal synchronization of the wide variety of heterogeneous physiological functions that need to be performed.

The hormone and signaling pathways studied most intensively for their effects on longevity and aging are insulin, insulin-like growth factor 1 (IGF-1), and growth hormone (GH) because of the experimental observation of increases in longevity conferred by single gene mutations affecting these hormonal pathways, as well as by nutritional interventions, such as caloric restriction. Among the experimental models most frequently used in such studies are *C. elegans*, *Drosophila melangocaster*, yeast, and rodents. IGF-1 and GH have been intensively studied because of the conceptual attractiveness of the oxidative theory of aging and because of the effects of caloric restriction on life span in experimental models (e.g., rodents), which are believed to be mediated, in part, by IGF-1, insulin, and/or GH. The logic of the relation is that caloric restriction slowed metabolism, the production of ROS, the accumulation of oxidative damage, and thus the aging rate. In laboratory mice, significant increases in longevity conferred by genetic mutations that result in GH resistance or deficiency are accompanied by increased production of antioxidants, such as catalase or SOD2, greater stress resistance, reduced inflammation and cellular senescence, in concert with shifts in mitochondrial function and metabolism, including enhanced insulin sensitivity and lower circulating levels of insulin. The ability of GH to activate nutrient sensing pathways, such as the mechanistic target of rapamycin (mTOR) signaling pathway has been put forward as an explanation for the negative correlation between GH signaling and longevity that is observed among laboratory mice. Activation of the mTOR pathway prevents cell death, promotes protein synthesis and growth and (over) stimulation of this pathway is thought to contribute to accumulation of unfolded proteins, increased ROS production, inhibition of autophagy and stimulation of cellular senescence.

It is unclear, however, whether the effect of such genetic mutations or nutritional interventions work in the same way in humans because of their greater histological (especially hormonal) complexity. Genetic mutations that altered GH resistance or deficiency, although associated in experimental models with increased longevity, have been associated in humans with a number of adverse conditions, such as obesity. However, despite increased obesity and lack of a consistent effect on longevity, GH resistance in the syndrome of Laron dwarfism has been observed to provide protection from cancer and diabetes.

An additional rationale for the focus on of research on associations of insulin, insulin-like growth factor 1 (IGF-1), and growth hormone (GH) and longevity, is reasoning based on evolutionary models that there is a trade-off of energy expended in growth and reproductive function and somatic maintenance. Periods of scarce food supplies causes metabolism in *C. elegans* to decrease and reduces the requirement for energy and may cause organisms to enter a quiescent, or dauer, state. This quiescent, low-energy consumption state is often associated with reduced oxidative stress and increased longevity but a lower rate of reproduction and less growth.

Hormonal control, however, is more complex in humans than in these experimental models. The IGF-1/insulin effect in the fly and the worm may favor localized hormonal actions. In worms and flies, there was a single receptor that favored local system actions of insulin and IGF peptides, permitting aging regulation to be dominated by a single tissue type (e.g., the neuroendocrine tissue of *C. elegans*). In tetrapods, in contrast, there are four candidate receptors—IGF-1, IGF-2, IR, and RR. This may have led to the developmental differentiation of insulin to control metabolic factors and IGF-1 to control mechanisms of growth in humans. As a consequence, in humans, caloric restriction may have become disassociated from factors controlling longevity, with factors linked to human longevity no longer simply associated with caloric restriction. Indeed, recent animal studies show that intermittent starvation, as opposed to caloric restriction, leads to preservation of growth while having even greater effects on insulin and insulin sensitivity and, consequently, on longevity. Another experiment in mice is also of interest. Mice were raised without a gene for the insulin receptor in adipose tissue. These mice were found to have greater longevity ($+18\%$) than control mice. In addition, the gene knockout mice were lighter and much leaner than the control mice, even though they consumed more food. This suggests that they had a higher rate of respiration along with their greater average and maximal longevity. Indeed, increasing the efficiency of mitochondrial function and energy expenditure appears to also be associated with increased longevity in rodents with profound

changes in thyroid hormone metabolism. Thus, both insulin regulation and thyroid function appear to be factors that can strongly regulate human longevity and perhaps senescence, suggesting systematic multiorgan regulation of longevity rather than simple, universal cellular "clocks."

Whereas insulin, IGF-1, and GH have been extensively studied, one endocrine system's effects on aging and longevity that has not been well studied is that of the thyroid. Thus, an interesting future focus of hormonal research on human longevity and aging is on the effects of thyroid hormone, T_3, on mitochondrial respiration. It is suggested that thyroid hormone has at least three effects. The first is up-regulation of mitochondrial respiration by altering their membrane structure and permeability. A second effect is the stimulation of mitochondrial biogenesis which increases mitochondrial respiratory capacity. A third effect is the promotion of mitochondrial uncoupling mechanisms to generate heat at the expense of ATP production, which is thought to result in a reduction of ROS production. Thus, there are fundamental interactions between mitochondrial performance and T_3 hormone. The action of T_3 also seems to be involved in stem cell function and differentiation so that there is a direct linkage of metabolic level and thyroid hormone availability and the energy demands of organism development. Tight local control of thyroid hormone action has been implicated in coordination of tissue development, growth, and maintenance and repair, with reduced thyroid hormone availability favoring cell proliferation and increased thyroid hormone availability favoring cell differentiation. It can be hypothesized that inappropriate local regulation of thyroid hormone action, either too much or too little, may exhaust the stem cell population precociously or contribute to pathological amplification. The relation of these factors in controlling human longevity and development/senescence needs extensive study.

Also significantly involved in senescence and longevity is the endocrine control of immune function during aging by the hypothalamic–pituitary–adrenal axis. Hormones play many roles in cytokine production, and cytokines perform a number of important tasks. It is thought that the level of interleukin-6 (IL-6) increases with age. IL-6 controls inflammatory processes in part by stimulating C-reactive protein production in the liver. However, this mechanism is controversial as a model of aging, disability, and longevity because IL-6 is not clearly elevated in centenarians. Possibly, successful aging into advanced ages is characterized by immunoremodeling that reflects adaptations to chronic immunological challenges and exposures.

A Conceptual Framework of Aging and Longevity

To capture the key biological mechanisms underlying aging and longevity and their complex interrelationships in a conceptual framework "the nine hallmarks of aging" have been proposed (in analogy with "the hallmarks of cancer"). In this conceptual framework, aging features that occur at different hierarchical levels are integrated, namely the subcellular or molecular level, the single cell level, and the tissue and whole-body level. Four primary hallmarks of aging (genomic instability, telomere attrition, epigenetic alterations, and loss of proteostasis) have been proposed as the main types of molecular damage that drive aging. Three antagonistic hallmarks (deregulated nutrient sensing, mitochondrial dysfunction, and cellular senescence) have been proposed as cellular stress responsive processes that confer beneficial and protective effects at low levels but become deleterious at high levels. Finally, two integrative hallmarks (stem cell exhaustion and altered intercellular communication) have been proposed as the ultimate causes of loss of physiological integrity that occur as a deleterious result of accumulated damage and stress responses. The interaction between endocrine functions and aging are many and complex. On the one hand, neuro-endocrine mechanisms have been identified as important regulators of aging and longevity by affecting several of the hallmarks of aging. On the other hand, with aging, changes occur in the levels and actions of several hormones. It is not always clear whether such changes are neutral, detrimental or adaptive, or possibly a combination of these. A well-known example is the decreased secretion of growth hormone with aging (known as the "somatopause"). While decreased secretion of growth hormone may negatively affect body composition and accelerate loss of muscle mass, it may at the same time represent an adaptive response aimed at directing available resources towards maintenance and repair so as to reduce risk of cancer.

Conclusion

As the biological complexity of organisms increases, hormonal factors increase in importance as determinants of the correlation of senescence and mortality. Since no single organ dominates survival, the coordination and communication between organ systems becomes more crucial to survival and successful functioning. Because of the increased biological complexity of humans, the linkage of GH, IGF-1, and insulin observed in many studies of simple organisms likely does not function in the same way in humans. The role of thyroid hormones, especially their roles in mitochondrial function and in tissue maintenance and repair, must be further studied as a fundamental factor in senescence and longevity. It is reasonable to assume hormonal factors significantly affect human longevity and related aging processes in a variety of complex ways, that these are altered by exogenous factors such as nutrition, physical activity, by genetic polymorphisms, and that, if understood, could indicate how to better control senescent loss of function and overall survival.

B Rogina, L Haynes, and GA Kuchel, University of Connecticut Health Center, Farmington, CT, USA

Glossary

DNA sequencing Technique used to determine the sequence of nucleotide bases present in a DNA molecule or fragment.
Epithelial Layers of cells forming the outer surface of the body and also lining its internal cavities.
Mutagenesis Causing a permanent heritable change in the nucleotide sequence of a chromosome.
Phenotype Observable characteristics of a cell or an organism.
Transgenesis The stable introduction of a cloned gene into a plant or an animal, allowing its transmission to future generations.

General Principles of Aging Research

As described by Weindruch, animal models have been used in different categories of aging studies. Many investigators have used cross-sectional and (less commonly) longitudinal study designs to examine the influence of normal aging on parameters that are thought to either cause aging or be the consequence of aging processes. One major pitfall of this type of study is attributing observed differences to normal aging without taking into account the presence of confounding disease processes. Other difficulties arise from an inappropriate choice of ages. For example, an investigator comparing very young (e.g., newborn) rats with older adult (e.g., middle-aged) rats may be studying maturational rather than aging processes, and a failure to include intermediate ages between young and old may cause the investigator to miss important changes that may herald the aging process. Interestingly, the absence of appropriate life tables for the determination of survival curves has been the limiting factor in the use of some potentially useful aging models.

Other, more comparative studies examine species with widely different longevity to identify factors associated with longevity and aging. Similarly, different strains within the same species (e.g., congenic mice) may possess major differences in longevity. Finally, animal models of accelerated aging (e.g., senescence accelerated mouse) and models of decelerated aging (e.g., Drosophila overexpressing catalase or superoxide dismutase) both have proved to be useful in aging studies.

The Laboratory Rat

NIA's decision to provide the Fischer 344 (F344) rat strain to the scientific community has played a major role in its great popularity for aging studies. Many investigators also welcomed this inbred strain because the commonly used outbred Sprague–Dawley strain tended to become grossly obese in old age and exhibited tremendous variability when purchased from different suppliers. Unfortunately, although inbred F344 rats have the advantage of being genetically identical, this also results in their frequent development of tumors (testicular interstitial cell and pituitary) as well as renal failure from nephropathy. Although these tumors are rarely metastatic or secretory, screening is important because both the tumors and renal failure could confound research data. Fortunately, the NIA also offers the inbred Brown Norway (BN) rat, as well as an F1 hybrid (F344/BN), through a contractual arrangement. Caloric restriction still remains the best validated and most robust means of extending longevity in rodents while also decreasing their burden of disease (including F344 nephropathy). Many investigators have argued for the use of rodents that have undergone modest caloric restriction because such animals tend to be healthier in old age, minimizing the confounding effect of illness and disability. Interestingly, some investigators have used the heterogeneity present in other outbred strains (e.g., Wistar, Long–Evans) to great advantage in aging studies. For example, Long–Evans rats remain relatively healthy into old age and exhibit great variability in their spatial memory performance on a Morris water maze test.

The rat is a popular model for examining endocrine and reproductive issues in old age. Although this has resulted in the availability of considerable information regarding this model, great caution must be exercised when extrapolating from these studies to human conditions. For example, unlike women whose ovaries cease to produce estrogens past menopause, rat ovaries appear to be

☆*Change History:* July 2014. E Lee, B Rogina, L Haynes and GA Kuchel includes authorship change with E Lee and L Haynes replacing Q Zhu and SH Clark who have retired; word "different" to replace "five" in the first sentence of "General Principles of Aging Research" section; Information was added on the Diversity Outbred and the Collaborative Cross added at the end of the section on "The Laboratory Mouse", a Section on "Other Rodents" added right after the section on "The Laboratory Mouse", a Discussion on "C Elegans" has been completely rewritten by a new co-author (E Lee) and a Discussion on "Drosophila Melanogaster" has been completely rewritten by a co-author (B Rogina).

This article is an update of George A. Kuchel, Qing Zhu, Blanka Rogina, Stephen H. Clark, Aging, Animal Models for, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 126–130.

capable of normal or near-normal function throughout their life span. In contrast to human menopause, reproductive senescence in rats is associated with the development of irregular cycles. This is followed by a period constant estrus in nearly one-half of the animals, which then proceed to a state of persistent diestrus, whereas the other half proceeds immediately to persistent diestrus. As a result, approximately one-half of 2-year-old rats will be in a state of constant estrus with a minimum of three consecutive epithelial vaginal smear cycles, whereas the other half will proceed to a state of persistent diestrus with a minimum of three leucocytic smears. Interestingly, estrogen levels are only slightly higher in the former group. As discussed previously, a high prevalence of pituitary and testicular tumors, particularly in aged F344 rats, also needs to be considered when using this strain in aging studies.

The Laboratory Mouse

Being smaller than rats, mice provide investigators with smaller amounts of tissue, and systemic physiological studies can sometimes be difficult. However, mouse genetics are extremely well known, and the ability to create genetically modified mice has become an important tool for studying aging and age-related processes. The presentation of a phenotype in any organism is a composite of the interactions between its genetic complement and the environment in which it is placed. Although the process of aging is a complex phenotype, it is no exception to this generally accepted biological principle. In contemporary biomedical research, the laboratory mouse has become a premier model organism to study processes important to human biology. This surge in mouse-related research has been driven largely by the ability to develop genetically engineered mice both by transgenesis via pronuclear injection and with gene targeting using embryonic stem (ES) cells. In addition, large mutagenesis programs have been initiated to isolate new mutations associated with a wide variety of biological processes. These activities have been complemented with other technological advances, including the initiation of a DNA sequencing effort to completely sequence the mouse genome and the development of microarray technology. Although the promise of these efforts in contributing to the genetic dissection of complex biological processes is extraordinary, having the appropriate model to which one can apply these emerging technologies is paramount to a successful and productive outcome.

Although the mouse has many advantages, it is not without its disadvantages. It must be recognized that not all discoveries or observations made with the mouse will have direct parallels in the human. Furthermore, with a life span of many months as compared with days in a species such as Drosophila, another powerful genetic model, data collection is inherently slower. Finally, housing costs and the operation of a barrier facility is a major consideration in the selection of this model.

The mouse model provides an opportunity for investigators to control both the nutrition and housing environments for their experiment animals. It has been well documented that caloric restriction can substantially lengthen the life span of laboratory mice. This principle seems to be true not only for mice and other rodents but also for insects, worms, and nonhuman primates, with possible implications for humans. Clearly, continued work with genetic models such as Drosophila and the mouse will ultimately reveal the genetic basis for this phenomenon. In the design of an aging study, the program for housing animals should be evaluated carefully. Caging style, light–dark cycle, ambient temperature, and the number of mice housed per cage all are obvious concerns. Other factors for consideration include extraneous noise and consistency in caretaker handling of the animals. Careful training of caretakers for uniformity in handling of the mice during cage-changing activities should not be underestimated.

Infectious diseases have long been known to have a potential impact on experimental analyses in mice. It is important to be able to determine whether the onset of a disease state is a function of the aging process or the result of a pathogen infection in the colony. In this context, the development and maintenance of specific pathogen-free (SPF) colonies for aging studies is essential. A researcher is also aided in this area by the existence of a large literature base on diseases in mice and on variations in susceptibility to diseases in specific lines or strains. The SPF status of study animals should be defined and maintained by careful husbandry practices. Frequently, an SPF barrier facility equipped with micro-isolator caging is employed to minimize the risk of an unwanted pathogen entering the colony. Access to such barriers is limited, and strict protocols for entry and animal-handling practices are mandated for staff working in such areas. A carefully designed sentinel program is essential for monitoring the health status of the colony and should be associated with a careful plan to respond if a break in the SPF status should occur.

Many inbred strains of mice have been developed and maintained by brother–sister matings for numerous generations. One major advantage of an inbred strain is genetic uniformity from one generation to the next. This feature permits an experiment to be repeated in both time and space with an identical or nearly identical genetic environment. In addition, a wealth of information on individual strain characteristics has been accumulated through years of research with these lines. Several inbred strains have been used in aging studies and can be obtained from a variety of sources. Inbred mice currently available through the NIA include BALB/cBy, CBA, C57BL/6, and DBA/2. Hybrids and calorically restricted mice will be increasingly available in future years. However, genetic uniformity of the inbred strain does not come without a price in that certain lines come with their own particular set of problems that can affect an aging study. In the selection of a particular strain for analysis, previous work with that strain, the nature of the aging question being addressed, and potential strain idiosyncrasies must be evaluated. Fortunately, databases that allow rapid electronic access to much of this information have been developed to assist investigators with strain selection.

One approach to reduce the potential problems associated with the use of inbred strains is the production of an F1 hybrid mouse that is created by mating individuals from two different inbred strains. These F1 animals have the virtue of being genetically identical as well as being potentially heterozygous at most loci (F1 mice will be homozygous only for loci that happened to be identical in their inbred parents), reducing the impact of certain idiosyncrasies found in their inbred parents.

The number of variants at individual genetic loci has grown precipitously as a function of genetic engineering and focused mutagenesis programs that have been initiated relatively recently. Because designer variants and many spontaneous mutations are often isolated on different or mixed genetic backgrounds, breeding programs are frequently conducted to place each variant in a defined genetic background. This is accomplished by a series of back-crosses of the variant locus to a selected inbred strain such as C57BL/6. Lines established in this fashion are referred to as congenic strains. To avoid the complications of studying a variant in an inbred setting, a second congenic line in a different inbred strain can be created. By crossing these two congenic strains, a particular variant can be analyzed in an F1 hybrid and compared with the phenotype in the inbred strain.

Although the inbred strains and F1 hybrids allow rigid control of the genetic environment in a set of experimental animals, not all researchers agree with this approach. Concerns about the lack of genetic variance in these experimental paradigms (inbred lines and F1 hybrid) has led some researchers to favor experimental systems that provide more genetic heterogeneity. One experimental paradigm involves F2 hybrids. In this model, experimental mice are obtained by mating two F1 mice of the same type (e.g., F1 mice produced by crossing C57BL/6 mice with C3H mice). Alternatively, F2 animals can be developed using the four-way breeding scheme. This breeding program involves the mating of two different F1 parents. In this type of mating system, the resulting F2 animals have four different grandparents, whereas they have only two different grandparents if the F1 parents are of the same type. In either system, the F2 mice are genetically heterogeneous, yet the genetic makeup of the population is defined and reproducible from laboratory to laboratory.

More recently, aging mice generated through the Diversity Outbred and the Collaborative Cross Inbred strains have offered powerful insights into novel genetic linkages to specific mouse phenotypes and outcomes [1]

Other Rodents

Although mice and rats represent by far the most commonly rodents, several other rodents have found a unique place in aging research. Most important among these is the naked mole rat which at 28.3 years is the longest lived rodent known. Moreover, the naked mole rat's slower rate of aging makes it a far more relevant as a model of human aging processes. In fact, it has been argued that given an adjustment for its body size, the naked mole rat may represent a model of successful human aging.

Invertebrate Model Systems in Aging

Saccharomyces cerevisiae (yeast), *Caenorhabditis elegans* (nematode), and *Drosophila melanogaster* (fruit fly) are the leading invertebrate model systems used in aging research. Their great advantages include ease of maintenance, short life spans, advanced molecular and genetic tools, and availability of their complete genomic sequences. Genetic screens have already identified a number of genes that appear to be involved in the aging process. Genetic and molecular characterization of these genes has provided valuable information about the physiological pathways that may be important in the aging process. Furthermore, the molecular conservation that has been so widely observed among yeast, *C. elegans*, *Drosophila*, and mammalian model systems such as mice and rats suggests that information obtained in these "simpler" systems is certain to facilitate our understanding of aging.

The budding yeast, *S. cerevisiae* (a single-cell organism), has been used in aging research since 1959, when Mortimer and Johnson described an increase in volume and number of scars as an aging phenotype. Aging of the yeast is measured as the average number of cell divisions that a mother cell can undergo or as the survival of nondividing cells during the stationary phase. The asymmetric cell divisions result in a larger mother cell and smaller daughter cells that can be easily separated, leaving behind the scar. Average cell divisions can range from 15 to 30 generations, depending on the strain. During the past decade, more than 16 longevity genes have been discovered in yeast, many of which are now being found to be important in the aging process of other invertebrates and mammals.

C.elegans research has contributed immensely to our current understanding of longevity and aging. As an experimentally tractable, multicellular eukaryotic organism, this invertebrate nematode will continue to be an impactful model organism in aging research. *C.elegans* as a model organism offers a number of experimental benefits for research and for aging research specifically. Experimentally, *C. elegans* is easily cultured and manipulable, offering many practical aspects of research benefit. In either liquid or solid agar based media, *C. elegans* is grown at 20 °C (*i.e.*, close to room temperature) from fertilized egg to adult within ~3 days (isolatable life stages include egg, L1, L2, L3, and L4 larval stages, adult, and egg-producing, fully reproductive adult stage); the average median lifespan of wild-type *C. elegans* ranges from ~10 to 30 days (Gems and Riddle, 2000; Johnson and Wood, 1982) with the longest lived strains and single worms living still less than ~4 months. *C. elegans* are hermaphrodites, and a single wild-type worm may produce up to 300–400 eggs over their fertile lifespan. This allows for culture of thousands of worms within just a few days and both single worms and lysates of masses of worms can be assayed. *C. elegans* may also reproduce sexually for a more genetically controllable method of reproduction. The food source for culture is most often a non-pathogenic OP50 *E. coli* strain, but diet can be altered according to experimental needs. Finally, mutant strains of countless genetic *C. elegans* models are available for purchase at merely $7 per strain and the worm community offers endless diversity in available mutants and genetic tools. Needless to say, *C. elegans* is an inexpensive, rapid, and easy model organism to work with. The power of this easy model is represented by some of the fundamental work that has led to 5 Nobel Prize researchers being awarded for work in *C. elegans*.

To complement its ease of use as an animal model, *C. elegans* possesses many features that make it ideal for a discovery model in diverse types of controlled experiments in aging. The *C. elegans* genome is highly conserved, fully sequenced, and extensively annotated. Both forward and reverse genetics are easily possible. Reverse genetics can be performed in this model by feeding, soaking, injection and requires only engineered *E. coli* strains producing dsRNA for a particular gene of interest. By feeding, *C. elegans* may ingest dsRNA producing *E. coli* and dsRNA is taken up by all somatic cells through the gut. By soaking, introduction of silencing dsRNA is taken up by cells directly from the bathing media, and by injection, dsRNA can be injected into target tissues or eggs. The effects of gene knockdown by RNA interference (RNAi) can be immediate, within the experimental worm, and can be removed by removal of the dsRNA stimulus, and re-introduced within the same lifespan of a single worm. Prolonged RNAi over many generations can be introduced by continuous exposure to dsRNA producing bacterial food sources. Over 20,000 different strains of *E. coli* producing dsRNA for almost every gene in the C. elegans genome are available for easy purchase from commercial libraries (Fraser *et al.*, 2000; Kamath and Ahringer, 2003; Kamath *et al.*, 2003). Furthermore, the most recent developments in using CRISPR-caspase methods of easily introducing more permanent gene mutations in the *C. elegans* genome to create novel mutants, is already well-developed in this animal model and moving forward rapidly (Chen *et al.*, 2013; Chiu *et al.*, 2013).

C. elegans genetic tractability has made it a powerful tool to perform genome-wide screens for genes that can be implicated in lifespan extension, shortening, or even more functionally important, preservation of healthy signs of aging. Dozens of genome-wide screens have been performed in *C. elegans* and each genome wide screen of the effects of any of the given ~20,000 RNAi clones can take as little as 3–4 months to complete (Solis and Petrascheck, 2011; Wang *et al.*, 2013). Many of the fundamental aging research has stemmed from genome-wide screens in *C. elegans* that have identified hormonal, metabolic, insulin-signaling, proteostasis, mitochondrial, antioxidant, and stress-related roles in lifespan extension and prolonged healthy aging (Bennett *et al.*, 2014; Gonidakis *et al.*, 2010; Hamilton *et al.*, 2005; Hansen *et al.*, 2007; Kenyon, 2011; Lin *et al.*, 2001; McCormick *et al.*, 2012; Samuelson *et al.*, 2007a,b). The effects of multiple gene knockdown via RNAi in concert with multiplexed mutations in single worm strains also adds power to genetics questions of aging that we can ask with *C. elegans*. In similar ways, we are now able to screen *C. elegans* strains and genome-wide variants for the effects of pharmacological agents, supplements, and diets on aging (Ye *et al.*, 2014). Contextualizing or applying genome-wide RNAi or pharmacological screens within or to specific models of aging diseases such as Parkinson's or Alzheimer's adds power to C. elegans utility as an aging research model (Bennett *et al.*, 2014; Brignull *et al.*, 2006; Labbadia and Morimoto, 2014).

Additional features of *C. elegans* that have served the aging research community well, are the physiological, behavioral, and microscopic assays that are available to scientists. *C. elegans* is a transparent invertebrate animal that at its largest is 1mm in length. Developmentally, the cell fate/lineage of each of the 959 somatic cells has been fully characterized from embryo to adult. The development of every stage post-fertilization is visually observable as every egg in the reproductive tract is sequentially and linearly organized according to stage of development. The simple body plan also has allowed full characterization of each of the 302 neurons for example; researchers focused on aging induced spontaneous protein aggregation inn neurons, have been able to use *C. elegans* to better understand conserved mechanisms of neurodegeneration (David *et al.*, 2010; Kraemer *et al.*, 2003). Approaching aging research using the powerful genetic, microscopy, and other biochemical tools available in *C. elegans*, in concert with functional behavioral and physiological assays has allowed researchers to deeply probe key pathways in lifespan regulation, including highly conserved pathways such as insulin signaling and proteostasis.

Drosophila Melanogaster

Drosophila melanogaster (fruit fly) is one of the leading invertebrate model systems used in aging research. *Drosophila* and closely related species have been used to study aging since 1915. *Drosophila* show an age-related functional decline as well as a decline in behavioral performance similarly to other species. For example, *Drosophila*'s learning abilities, heart function, sensory function, fecundity, and locomotor activity declines with age. There are numerous advantages of using *Drosophila* as a model system to study aging, such as the fact that fruit flies are not expensive to breed, are easy to maintain, and have a relatively short life span. *Drosophila* live about 2 months at 25 °C, much shorter than mice who live 4 years or nonhuman primates, such as *Macaca mulatta* who live 29 years. There are a number of environmental manipulations that can alter the life span of *Drosophila*, such as temperature of the environment, reproductive status, addition of drugs, as well as changing the caloric or dietary content of the food. Flies, who are poikilothermic organisms, live about 3 months at 18 °C and live only 1 month at 29 °C. Another manipulation that affects *Drosophila* longevity is a change in reproduction status. Reproduction has a strong negative effect on longevity in fruit flies. Both virgin female and male flies live significantly longer than do fully mated ones. The costs of reproduction in flies include energy allocation for courtship and mating, egg production and egg laying, and direct toxic effects of mating. Dietary restriction (DR) without malnutrition is the most efficient manipulation that extends longevity of a variety of species, including *Drosophila*. DR causes many changes in fly physiology that are similar to changes found in DR mammals. Such changes include decrease in weight, increased spontaneous locomotor activity, decreased resistance to starvation, decrease in fecundity, and lower levels of carbohydrates and triglycerides. All of those changes contribute to longer and healthier fly life. The use of flies to determine effects of different drugs on health and longevity has been an important part of longevity studies. These experiments have discovered that addition of resveratrol, rapamycin, metformin or other nutraceuticals in fly food can modulate aging by promoting many health benefits. Also of interest is that a majority of the cells of adult fruit flies are postmitotic, with exceptions of intestinal stem cells in the fly gut, malphigian tubules (fly kidneys), salivary glands, gonads and brain. Therefore, most of the

tissues in *Drosophila* age synchronously. Examination of the role of intestinal stem cell homeostasis in fly health and longevity has been of interest in recent years.

The genetic tools that have been developed over the past 100 years or so of *Drosophila* research have reached a point where researchers have great control over the molecular genetics of the fly. Through a combination of various available techniques, it is possible to increase or decrease the level of expression of any gene in a tissue specific manner at any time in life, from development to old age. Genetic screens have identified a number of genes that appear to be involved in the aging process. Genetic and molecular characterization of these genes has provided valuable information about the physiological pathways that may be important in the aging process. Among the first genes identified to be involved in fly longevity were *Methuselah*, *Indy* (*I'm not dead yet*) and members of the insulin/insulin like pathway. A number of stocks necessary to perform research are easily available from several Stock Centers (Bloomington *Drosophila* Stock Center, The Exelixis Collection at the Harvard medical School, Vienna *Drosophila* RNAi Center). In addition, the complete genomic sequences are now available for *Drosophila* and related species. The molecular conservation in sequences that has been so widely observed between *Drosophila* and mammalian model systems such as mice and rats suggests that information obtained in fly systems is certain to greatly contribute to our understanding of aging. This is illustrated by a number of important physiological pathways that have been implicated in fly longevity, which have been also implicated in longevity of other species. For instance, decreases in the insulin/insulin-like growth factor-1 (IGF-1) and the Target of Rapamycin (TOR) signaling pathway have been shown to affect life span in flies as well as in yeast, worms and mice.

Nonhuman Primates

The high cost and small availability of aged nonhuman primates have limited their use to selected research centers. Further compounding the difficulties in conducting research with these animals is their long life span and a lack of good survival data. At the same time, the phylogenetic proximity of these primates to humans makes these highly attractive, and in some cases even indispensable, models for the study of human aging and disease. For example, true menstruation occurs only among some primate species, making some nonhuman primates invaluable models for the study of female human menopause. Another area is brain structure, where only nonhuman primates represent adequate models for the study of many aspects of higher cortical structure and physiology.

Oxidative Stress and Aging☆

Arthur K Balin and RG Allen, The Sally Balin Medical Center, Media, PA, USA

Glossary

Antioxidants Proteins and non-protein molecules that remove or neutralize oxidants.

Environmental change Refers to organism-specific parameters rather than habitat and may include such things as the ability to adjust body temperature when the surroundings become either too hot or cold, increasing cardiac output during physical stress, or maintaining the capacity to heal injuries.

Free radical Atom, ion, or molecule that contains an unpaired electron.

Oxidant Substances that accept electrons.

Redox State The ratio of oxidizing to reducing equivalents; charge potential.

Reductant Substances that donate electrons.

Definition

Aging is a progressive, time-dependent deterioration in the capacity of an organism to respond adaptively to environmental change resulting in an increased vulnerability to death. Oxidative stress reflects the extent to which the concentration of oxidants in cells exceeds the cellular capacity to remove them. It can alter the cellular redox environment, damage cellular constituents, influence gene expression and cause cells to divert energy and other resources from growth to repair.

Introduction

Aging

The irreversible, time-dependent deterioration in the capacity of an organism to adapt to environmental changes and resulting in an increased vulnerability to death is generally referred to as aging. Although aging itself does not directly kill the organism, it results in a progressive increase in the probability of its death. The probability that certain diseases will occur increases with the passage of time; however, aging itself is distinct from any known disease pathology because it crosses virtually all species barriers and, unlike any known disease, aging affects all members of a species. The exact causes of aging are unknown, but there is much evidence to support a role for cellular oxidants as a primary causal factor in the phenomenon.

Oxidants and Oxidative Stress

There are many different types of cellular oxidants. In order to understand how they form it is important to recall that molecules must contain only paired electrons in order to be stable. Atoms and molecules that contained unpaired electrons quickly react with whatever surrounds them and share electrons to meet the paired electron stability rule imposed by nature. Most of the time molecules that contain unpaired electrons can be mass-produced only under very controlled laboratory conditions; they are almost always very unstable, meaning that they can exist only a few thousandths or millionths of a second after their creation. Molecules that contain unpaired electrons are referred to as free radicals. In organisms, enzyme molecules catalyze chemical reactions that sometimes pass through intermediate steps in which they contain unpaired electrons. During normal metabolism in mitochondria, dioxygen (O_2) molecules act as the terminal electron acceptor of oxidative phosphorylation. Each molecule of oxygen accepts four electrons to form water.

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$

Most of the oxygen consumed by cells is used in this way, but a small amount (12%) escapes from the electron transport chain after receiving only one electron rather than the usual four. When this happens, superoxide radicals ($O_2^{\bullet -}$) are created. Of course, superoxide like other free radicals is very short-lived; its half-life is about one millionth of a second (s). $O_2^{\bullet -}$ radicals can react with the surrounding cellular structures and cause damage; however, they often simply react with each other to form hydrogen peroxide (H_2O_2). H_2O_2 is also produced directly by some enzymes such as glucose or amino acid oxidases. H_2O_2 is not a radical because it

☆*Change History:* January 2015. AK Balin and RG Allen made minor grammatical changes to the following sections: B. Oxidants and Oxidative Stress, Oxidative Stress and Aging, and C. Oxidative Stress and Cancer and B. Oxidative stress and gene expression (New material was also discussed in this section). The 'For Further Reading' section was updated.

This article is an update of Arthur K. Balin, R.G. Allen, Oxidative Stress and Aging, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 470–474.

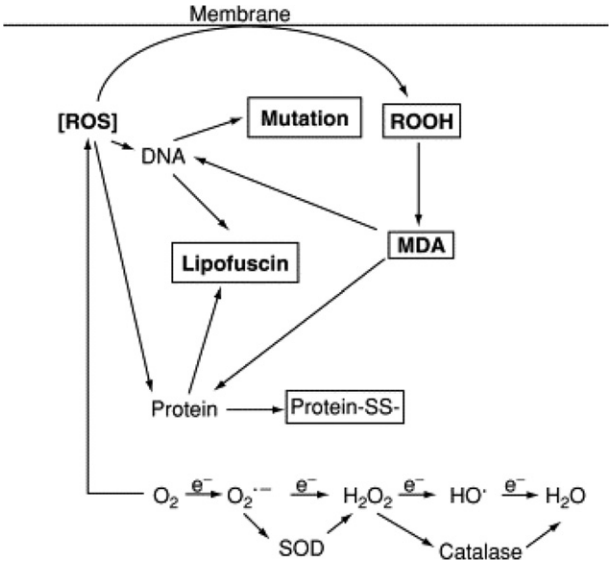

Fig. 1 Pathways of oxidant formation and reaction. ROS = reactive oxygen species; MDA = malondialdehyde; ROOH = organic peroxide; protein-SS- = protein disulfide. See text for discussion.

contains only paired electrons. It is therefore far more stable than free radicals and exhibits a half-life of many years in pure water. Nevertheless, H_2O_2 is still much more reactive than water particularly in the presence of metal ions and can damage many cellular components by reacting with them (see Fig. 1).

In some cases, H_2O_2 reacts with $O_2^{\bullet -}$ and forms the hydroxyl radical (HO•). This reaction is catalyzed by transition metals such as iron. HO• is much more reactive than either H_2O_2 or $O_2^{\bullet -}$; in fact, it can even break water molecules apart. Collectively these reactive forms of oxygen are called reactive oxygen species (ROS). There are other types of ROS. For example, ozone is composed of three oxygen atoms that share electrons. Oxygen molecules can also simply absorb energy to form reactive molecules that are not free radicals, but that are more reactive than ground state oxygen. These energized oxygen molecules are referred to as singlet oxygen. Normally, the production of oxidants by cells is in balance with oxidant removal (see next subsection). When the production of ROS exceeds the cellular capacity to remove them or when an external source of oxidation is added, the result is oxidative stress. The severity of the stress will depend on the relative rates of oxidant production/removal. Severe stress resulting from bombardment by uncontrolled oxidant generation is lethal. In addition to the oxygen centered radicals, nitrogen centered free radicals and reactive species also form in cells and may influence a number of biological processes.

Antioxidant Defenses

The production of ROS is fatal to unprotected cells; however, cells that use oxygen in their energy metabolism also contains proteins and other small molecules collectively referred to as antioxidant defenses that remove more reactive species and prevent cellular damage. These include superoxide dismutases (SOD) that remove $O_2^{\bullet -}$ and produce H_2O_2, and catalase and peroxidases that remove H_2O_2. Enzymic defenses that remove HO• radicals have never been identified, but non-enzymatic antioxidant defenses, such as tocopherol (Vitamin E), carotenoids (such as beta carotene), ascorbate (Vitamin C), uric acid, lipoic acid and glutathione (GSH), can remove free radicals including HO• by reacting directly with them. The non-enzyme antioxidants can also break chain oxidation reactions and dissipate the extra energy from the singlet oxygen. The equilibrium between oxidant generation and removal is ultimately manifested in the distribution of cellular charges. The ratio of oxidizing to reducing cellular components is often referred to as cellular redox state. Glutathione, a tripeptide consisting of glycine, cysteine and glutamic acid moieties, is the primary cellular component that affects redox state. It exists as both a reduced (GSH) and an oxidized form (GSSG). GSH contains more than 90% of the reducing equivalents present in most cells. Because of this, glutathione is often referred to as a cellular redox buffer.

Oxidative Stress and Aging

The idea that oxidative stress contributes to aging is relatively old although it has been repackaged in several different ways. The most encompassing theory that directly linked oxygen metabolism to aging was Denham Harman's Free Radical Theory of Aging.

Harman theorized that low levels of oxidants are produced in metabolic pathways resulting in an incessant bombardment of cellular components by ROS. Oxidation reactions resulted in accumulation of damage, cellular dysfunction and ultimately organ dysfunction. An implication of this theory is that free radicals would be expected to have an impact on all organisms that utilize

oxygen. Although the Free Radical Theory of Aging now enjoys great popularity, it was not immediately accepted. For more than a decade after it was proposed an intense controversy raged over whether free radicals were actually ever produced in living cells. Several studies demonstrated that various types of radicals existed in skin and in specific types of cells, but many scientists questioned whether these results were artifacts of the methods used to measure free radicals. Additionally, some enzymes such as xanthine oxidase were also observed to produce free radicals when added to a reaction mixture. However, it was unclear that radicals would be produced *in vivo*. It was not until 1969 when McCord and Fridovich identified superoxide dismutase as an enzyme that used superoxide radicals as a substrate that this issue was definitively resolved. Cell must produce free radicals if they contained enzymes to remove them.

Evidence Supporting Free Radicals and the Damage Hypothesis of Aging

Several studies have shown that the rate at which cells generate oxidants increases with aging. In most cases the antioxidant defenses remain unchanged or decline with increasing age. The net effect of these changes is that the cells of young individuals exhibit a level of oxidation (redox state) that differs from the one seen in older individuals. In general, the tissues of older individuals tend to become more oxidized.

Lipid peroxidation products accumulate with age

Some of the most compelling evidence supporting the Free Radical Theory of Aging is found in the fact that by-products of free radical reactions accumulate in animals as they age. For example, lipid peroxidation occurs in cells. This is the same process that causes fats to turn rancid. Once they form, lipid peroxides are either removed by defense enzymes or breakdown and rearrange to form malondialdehyde (MDA) an even more reactive chemical that can damage DNA and proteins. The reaction products of MDA and various cellular components are further rearranged to form a fluorescent pigment called lipofuscin (**Fig. 1**). It is essentially cellular trash that can be rearranged or processed no further.

Since cells have no mechanism to dump this by-product they simply accumulate it as more is formed. The pigment is observed mainly in postmitotic cells such as neurons and cardiac myocytes. Unlike its precursors, lipofuscin is stable. Although the concentration of lipid peroxide does not necessarily increase dramatically in older organisms, the more stable lipofuscin accumulates progressively with age in animals ranging in biological complexity from insects to humans.

Lipofuscin does not cause aging; however, older individuals typically have more of it than do young individuals. Because of this it has been used as a marker to predict remaining lifespan. For example, houseflies typically live 2 weeks. If placed in a small container that prevents them from flying (low activity) their lifespan is doubled to about 4 weeks. When lipofuscin is measured, it is found to accumulate more slowly in the longer-lived flies. The longest living flies in both control and low activity populations have accumulated the same amount of lipofuscin by the end of their life, but the longer-lived low activity group accumulates it at a proportionally slower rate.

Unfortunately, lipofuscin has not proven to be a reliable marker of physiological age, since factors that do not necessarily influence lifespan can markedly influence the accumulation of lipofuscin. For example, the ingestion of some dietary antioxidants can retard the formation of lipofuscin even when they fail to increase lifespan. Some oxidants, such as the herbicide paraquat, also impede lipofuscin formation, apparently by destroying precursors needed for its formation.

Some types of DNA Damage accumulate with age

In general, the sequence of genomic DNA (the DNA in the nucleus of the cell) is not greatly altered by age because repair mechanisms eliminate damage and more heavily damaged cells die. Nevertheless, DNA breaks accumulate during aging. Somatic mutations (mutations that occur in cells outside the reproductive system) also accumulate but at a slow rate. Longer-lived species exhibit greater DNA repair capacity than shorter-lived species. It has been proposed that accumulation of DNA damage contributes to the aging process; although, the existing evidence fails to directly support this hypothesis. Nevertheless, oxidatively modified DNA bases (8-OH dG) are excreted in urine and can be isolated from mitochondrial and nuclear DNA.

In contrast to the low rate of mutation seen in nuclei, the DNA found in cellular mitochondria rapidly accumulates damage with the passage of time. This is significant because most of the oxygen consumed by cells (and hence, many of the oxidants produced) is in mitochondria. Mitochondrial membranes also tend to become peroxidized more rapidly than cell membranes. Although damaged mitochondrial DNA cannot be repaired, there are many copies of the mitochondrial genome within each mitochondrion; this permits mitochondria to continue to replicate even if some copies of their DNA have been damaged. As compared to cells, which can live more than 90 years in humans, mitochondria have short lifespans of no more than a few weeks. Damaged mitochondria are usually replaced relatively quickly; however, the rate at which they are replaced declines with age. Thus, the cells of older individuals frequently exhibit greater numbers of dysfunctional mitochondria. Although most types of DNA damage are lethal to mitochondria, they are able to survive some types of deletions. Those that do survive can replicate, and may even become predominant in cells. The energy metabolism of those cells is compromised. The accumulation of defective mitochondria in cells has also been postulated to contribute to the aging process, but this hypothesis remains controversial because the number of defective mitochondria usually remains small and the number of cells in which defective mitochondria become predominant is also low. The central point here is that damage to mitochondrial DNA is much greater than damage to nuclear DNA, presumably because mitochondria are also the sites of oxidant generation.

Protein damage accumulates with age

It is important to note that the proteins made by older animals are exactly the same as those made by young animals. The cellular machinery that encodes and synthesizes proteins does not produce errors as a result of aging, albeit, the rate of synthesis may decline with age. After proteins have been synthesized, they are quickly removed (digested and the amino acids recycled into new proteins) from cells if they become damaged by oxidants. In older animals the rate of protein turnover decreases. As a result, the subpopulation of damaged protein molecules is greater than is observed in the cells of younger animals. It is noteworthy that cellular redox state tends to increase (become more oxidized) during aging. This promotes the formation of disulfide bridges between proteins, which also impairs or inactivates them completely. The effects of damaged protein accumulation can be significant. For example oxidative damage to lens proteins appears to contribute significantly to cataract formation.

Under certain conditions, antioxidants increase lifespan

A large number of studies have examined the effects of feeding various antioxidants to organisms. In many cases, the average lifespan of test organisms is increased by these treatments but the maximum lifespans reached by the oldest members of the population are usually unaffected. The reasons that maximum lifespans tend to be unaffected by antioxidant treatments appear to be many. The antioxidants used in these studies may not be distributed in cells evenly after they are ingested. In some cases, intestinal absorption of antioxidants decreases when larger amounts are ingested. Chemical antioxidants can have harmful side effects. Also, some of antioxidants become toxic after they react with oxidants.

For many years it was speculated that if antioxidant enzymes could be increased in cells, they would increase lifespan without the uncontrollable effects typically seen when treating with chemical antioxidants. Rats that overexpressed SOD were engineered, but showed no increase in lifespan. Similarly, insects that strongly overexpress SOD in all of their tissues failed to exhibit any increase in maximum lifespan. Flies that overexpressed SOD only in certain tissues (such as brain) or that only weakly over-expressed SOD in all their tissues exhibited some increases in lifespan. Conversely, it was shown that fruit flies that had only half the normal complement of SOD lived as long as normal controls. One reason for these apparent inconsistencies is that the product of SOD is H_2O_2, a toxic oxidant. Thus, increasing SOD also increases H_2O_2, which obviates any beneficial effect of superoxide radical removal. Similarly, increasing enzymes that remove H_2O_2 but not SOD fails to effect lifespan in insects or mammals.

Insects that over-expressed both SOD (to remove superoxide) and catalase (to remove H_2O_2) exhibit increased average and maximum lifespan. In fact, in some strains of flies the maximum lifespan is increased by as much as 50% with this dual treatment. It is also significant that amount of metabolic work (usually indicated by the total amount of oxygen consumed during life) was also increased by 50%. Many other treatments that increase maximum lifespan in cold-blooded animals tend to decrease the rate of metabolism and the total lifetime energy expenditure indicating that, although lifespan is longer, the quality of life is diminished. These results with dual overexpression of both SOD and catalase support the view that ROS contribute to the aging process and that removal of oxidants can retard aging in invertebrates.

Oxidative Stress and Gene Expression

The contribution of oxidants to the aging process has generally been inferred to stem from their propensity to inflict cellular damage. But is damage the only mechanism by which ROS influence the aging process? It has become apparent that ROS can stimulate changes in the expression of certain genes. Extremely large changes in oxidant production and in antioxidant defense levels are observed during embryonic development. These changes have been shown to promote differentiation of cells without inflicting large-scale cellular damage. This suggests that some of the genes critical to differentiation are sensitive to the changes in ROS. In fact, treatments that increase H_2O_2 or other ROS (including introduction of SOD into cells) stimulate differentiation in some types of cells, while treatment with chemical antioxidants can inhibit or slow some types of differentiation. It was recently demonstrated that the developmental fate of stem cells is influenced by experimental modulation of the level of oxidative stress.

ROS have been shown to play an important role in many cellular signaling pathways. For example, the addition of growth factors such as platelet-derived growth factor (PDGF) to cells causes them to produce small bursts of oxidants that activate signaling molecules in the cells. The activated signal transduction cascade stimulates genes associated with cell growth. At least some elements in each of the MAP kinase pathways are sensitive to changes in cellular redox balance. Stimulation of these pathways can lead to either activation or repression of genes, depending on the target.

The pathways that respond to redox changes during development remain sensitive to increases in ROS production in adult cells. The fact that aging is associated with a tendency for cells to become increasingly oxidized may ultimately be linked to some of the age-associated changes in gene expression. For example, if the cellular environment becomes more oxidized, it might be expected that pathways activated by oxidants would be less sensitive. This is not to say that the pathways will be inactive in older people; however, it does suggest that they may be less efficient. This type of change is consistent with the original Free Radical Theory of Aging although the target is different than the ones that were originally proposed.

In another type of study, it has been observed that inactivation of certain genes in fruit flies as well as in nematodes can increase lifespan. In depth analyses of these effects reveal that in most cases the increases in longevity are associated with either decreased rates of metabolism or increased mitochondrial density. These observations would suggest that changes in levels of oxidative stress plays a crucial role in the life lengthening effects of certain gene deletions.

Oxidative stress and cancer

The frequency of many types of cancer increases with age. Cellular accumulation of somatic mutations resulting from oxidative damage is almost certainly a decisive factor in the aging associated increase in malignancy. However, it should not be assumed that increased oxidation is always a factor in cancer formation. Paradoxically, antioxidation can also contribute to tumor formation. For example, basal cell carcinomas exhibit increased expression of the gene *Bcl-2*, which increases the enzyme antioxidant defenses. This increase in antioxidant defense tends to make the cells resistant to apoptosis. It has been observed that melatonin has antioxidant properties and can increase average lifespan when fed to rats; however, the treated group exhibits higher rates of cancer than the controls. Although the enzyme defenses are frequently maintained at low levels in tumor cells, GSH is often elevated in tumors. Of course, antioxidants are not a major cause of cancers, neither are they a panacea for all of the deleterious effects attributed to oxidants. Indeed, not all oxidation is bad. Increased cellular oxidation is an important step in killing defective (tumor) cells through apoptosis. A strict maintenance of cellular redox state and capacity to respond to stress appears to be far more important to the normal function of cells than complete elimination of oxidants.

Immunology and Aging☆

Victor Appay, INSERM Centre d'Immunologie et des Maladies Infectieuses (CIMI-Paris), Paris, France

Glossary

Antigen A substance that can elicit an immune response following recognition by T-cells or B-cells. Antigens can be of many sorts: proteins, carbohydrates, nucleic acids, lipids, hormones. The immune system usually responds only against foreign antigens (e.g. from pathogens), but can also react against modified self-antigens (in case of cancer) or self-antigens (in case of autoimmune diseases).

B-cells A population of white blood lymphocytes found in the bone marrow, lymph nodes and blood circulation. B-cells are generated and mature in the bone marrow; their role is to produce antibodies to bind and neutralize pathogens and toxins. Each antibody is strictly specific to only one antigen.

Cytokines Proteins synthesized by cells of the immune system. Cytokines include an extensive range of mediators (interleukins, interferons, chemokines and growth factors) with various functions (e.g. immunostimulatory or immunosuppressive).

Immunosenescence Deterioration of the immune system or its function with time.

T-cells A population of white blood lymphocytes found in the thymus, lymph nodes and blood circulation. T-cell precursors are generated in the bone marrow; following their maturation in the thymus, naive T-cells are exposed to foreign antigens, and produce effector T-cells, as well as memory T-cells, which are long-lived antigen-experienced cells that rapidly respond to a subsequent exposure with the same antigen. T-cells have many functions including the elimination of foreign pathogens, infected cells and tumor cells, and the regulation of the immune response by assisting or suppressing other cells of the immune system.

Introduction

The study of our native immunity began in the late 18th century, and has led to incredible discoveries regarding the role of our immune system and the mechanisms through which pathogens attempt to penetrate our defences. Immunogerontology is a relatively new field in comparison, which is gradually becoming more relevant as the older population is increasing at an unprecedented rate. Owing to the progress in medicine and public health, life expectancy in developed countries has nearly doubled over the last century. Nowadays, it is common to live beyond 70 years old, and this trend is likely to continue, with an important impact on human demographics. However, advanced age is accompanied by an increase in chronic diseases, resulting in a significant decline in quality of life. The aging of the human population represents therefore a considerable challenge to public health authorities, raising both healthcare related and socio-economic issues.

Old people usually present increased severity and susceptibility to infectious, malignant and autoimmune diseases. The development of these pathologies is thought to be directly linked to the decline of the immune system with age. It is indeed well established that the functional capacity of the immune system gradually declines with age, so that the immune system cannot respond as quickly and as efficiently to stimuli, in particular new antigens (Dorshkind *et al.*, 2009). This deterioration, also referred to as immunosenescence, is reflected by a deregulation of the immune system, characterized by changes in cellular phenotype and function, and alterations of whole organs. The study of the aging immune system, or immunogerontology, is therefore a public health priority with crucial implications to optimize care of elderly people, as well as to develop better therapies and vaccines for this population.

Immune Alterations Associated with Aging

The Hayflick Limit

In 1961, Hayflick and Moorhead showed that cultures of fetal human fibroblasts could reach an irreversible state of growth arrest, hence reporting the first evidence for replicative senescence. Accumulating evidence shows that the so-called Hayflick limit is not restricted to cultured human fibroblasts, but applies also to the cells of the immune system, which may have a limited replicative lifespan *in vivo* (Effros and Pawelec, 1997). Although the notion of immunosenescence is not limited to cellular senescence, the concept of limited replicative lifespan is important in the context of immune aging. The occurrence of replicative senescence is primarily related to the number of cell divisions, varying according to cell type and cellular environment. A commonly used

☆*Change History:* August 2014. V Appay updated all sections and the figure of the article in order to reflect the advances in knowledge on Immunology and Aging over the last 10 years.

This article is an update of Victor Appay, Aging, Immunology and, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 131–134.

 doi:10.1016/B978-0-12-801238-3.03854-X

marker of replicative history is the length of the telomeres (DNA repeats found at the end of the chromosomes) which is reduced after each cell division. Cells which have reached a state of replicative senescence have short telomeres.

Hematopoiesis

All the cells which constitute our immune system originate from hematopoietic stem cells (found in the bone marrow) which differentiate and commit themselves to one specific cellular lineage (e.g. myeloid or lymphoid) to continuously generate new immunocompetent cells of the innate (e.g., neutrophils and monocytes) or adaptive (e.g., naïve lymphocytes) arms of immunity. Increasing evidence indicates that hematopoietic stem cells are affected with aging, resulting in a deregulation of hematopoiesis. Hematopoietic stem cells exhibit a reduced capacity to generate new immunocompetent cells with old age. Their telomeres appear to be shorter in adults than in the cord blood of newborns. Neutrophils and naïve T-cells show a shortening in telomere length associated with age, suggesting that this applies also to hematopoietic stem cells (Rufer *et al.*, 1999). Moreover, there is a clear bias towards fewer hematopoietic progenitors with lymphoid, versus myeloid, precursor capacity in elderly individuals (Kuranda *et al.*, 2011). Hematopoietic stem cells thus appear to have a limited replicative potential and survival capacity so that their ability to replenish the cells of the immune system is not infinite (Wang *et al.*, 2011). In addition to intrinsic defaults of old hematopoietic stem cells, extrinsic causes of altered hematopoiesis may also be related to decreased production of growth hormone and loss of bone marrow stromal cells in the elderly. Although there is still debate regarding whether altered hematopoiesis has a real consequence on the immune function in aging, it implies that the renewal capacity of the immune system is not unlimited and can reach exhaustion over time.

Adaptive Immunity

The adaptive system involves mounting of highly specific immune responses, with the establishment of immunological memory. There are two types of adaptive immune responses: humoral (mediated by antibodies produced by B-lymphocytes) and cellular (mediated by T-lymphocytes). Over the years, strong evidence has accumulated to show that aging results in important alterations of the T- and B-cell numbers and functions.

Thymic involution and homeostatic T-cell proliferation

Mounting of primary immune response is highly dependent on T-cell priming, when, encountering a new antigen, naïve T-cells become activated and differentiate into antigen-experienced T-cells, which exhibit direct effector functions and can expand greatly to eliminate foreign antigens from the body. Naïve T-cells represent therefore the primary source to mount an immune response against pathogens or tumors. The thymus is the primary lymphoid organ where lymphoid precursors mature into naïve T-cells. However, with aging, the thymus undergoes a progressive shrinking, characterized by changes in its architecture and decreased mass of its functional tissues, referred to as thymic involution (Gruver *et al.*, 2007). Historically, it has been accepted that the young thymus sets the T-lymphocyte repertoire during early life, whereupon atrophy begins until the elderly thymus is a non-functional residual trace. Despite the dramatic decline in thymic output from puberty to old age, humans have a remarkable ability to maintain relatively constant lymphocyte numbers across many decades. This phenomenon, called homeostasis, is achieved by matching the production, self-renewal, death, and rates of phenotype transition across varied lymphocyte subpopulations. Increased naive T-cell proliferation has been reported in people over 70 years old. However, while increased homeostatic proliferation can partially compensate reduced thymic output, this does not appear to be sufficient to maintain a constant number of peripheral naïve T-cells in elderly adults (Sauce *et al.*, 2012). Thymus output decline is associated with the gradual reduction in naive $CD4^+$ and $CD8^+$ T-cell numbers with age, and its deterioration is thought to be directly linked of the reduction in immunosurveillance in the elderly (Linton and Dorshkind, 2004).

Reduced TCR repertoire and intrinsic alterations of naïve T-cells

A central facet of the naïve T-cell pool resides in the large diversity of its T-cell receptor (TCR) repertoire, which permits the response to an infinite array of antigens, and is key for effective immunity. However, a progressive loss of naïve TCR repertoire diversity, associated with their reduced production and frequency, has been reported in aging murine models. Mouse infection models showed that contraction of the naive T-cell repertoire can result in impaired T-cell response to immunodominant epitopes (Yager *et al.*, 2008). A lower precursor frequency is likely to affect negatively the properties and efficacy of T-cell responses. In humans, the diversity of the naïve T-cell TCR repertoire (shown for $CD4^+$ T-cells) experiences also a sudden and profound decline around age 70 (Naylor *et al.*, 2005). In addition to quantitative alterations, evidence of intrinsic defects of old naïve T-cell responsiveness has accumulated in aged mice. Altered gene expression profiles in old naïve $CD8^+$ and $CD4^+$ T-cells have been observed (Mirza *et al.*, 2011). Upon stimulation, naïve T-cells from old mice present defects in T-cell synapses and early TCR signaling events (Sadighi Akha and Miller, 2005), and are characterized by altered expression of inhibitory molecules and cytokine secretion capacity (Decman *et al.*, 2012; Valkenburg *et al.*, 2012). Alterations of naive T-cell activation and differentiation (shown for $CD4^+$ T-cells) also occur in old humans, with age-associated defect in TCR-induced extracellular signal-regulated kinase phosphorylation (Li *et al.*, 2012). Eventually, both quantitative and qualitative alterations in the naïve T-cell compartments with

advanced age may result in impaired induction of *de novo* T-cell responses, and a reduction of the elderly immune competence against cancer and pathogens (Appay and Sauce, 2014).

Changes in the pool of memory T-cells

Historically, a primary hallmark of immunosenescence in humans has been the increasing proportion of terminally differentiated memory T-cells (CD28 negative), often considered as cells approaching senescence (Pawelec *et al.*, 1999). Aging is actually associated with a variety of changes in the characteristics and function of antigen-experienced T-cells: (1) changes in T-cell receptor signal transduction and in the expression of cell surface receptors including the loss of co-stimulatory receptors (e.g., CD28, CD27) involved in activation; (2) changes in the profile of cytokine expression, for example decreased production of IL-2 (necessary for proliferation); (3) reduced capacity to expand upon stimulation, associated with shorter telomere length, and increased susceptibility to undergo activation induced cell death; (4) restricted T-cell repertoire, so that T-cells recognize a narrower range of antigens (Nikolich-Zugich, 2008). All these functional changes have been postulated as playing a role in the decrease of immunocompetence associated with age. Interestingly these characteristics may reflect a change in the T-cell subset distribution, with a shift towards more differentiated (with short telomeres) and more oligoclonal memory T-cell populations, so that the lymphocyte repertoire becomes increasingly skewed towards previously encountered antigens (see **Figure 1**).

Alterations of the B-cell compartment with age

Interestingly, quantitative and qualitative impairments of the B-cell compartment also occur with aging (Siegrist and Aspinall, 2009), similarly to the changes observed for the T-cell compartment. B-cell precursor (pre-B and pro-B) numbers are decreased in the bone marrow of aged mice, as well as their ability to mature into naÿve B-cells. This is associated with a reduced production of naïve B-cells and altered B-cell repertoire in the periphery. The quantity and the quality of the production of antibodies by B-cells are directly affected with old age. The elderly is characterized by lower antibody production and ability to switch (with more secretion of IgM). The affinity of the antibodies produced during a humoral immune response, and therefore their protective nature, are decreased. Eventually this is associated with a reduction of the quantity, diversity, and quality of serum antibodies specific for foreign antigens and reduced duration of an effective humoral response. Deregulated humoral immunity in elderly is also characterized by a shift of the specificity towards autologous antigens (with production of autoantibodies).

Innate Immunity

The innate system consists of immunocompetent cells which are always present at the site of infection and have an immediate action against microbes. The main cellular components of the innate immune system are phagocytic leukocytes (i.e. neutrophils, macrophages and monocytes), dendritic cells (DCs) and natural killer (NK) cells. Several studies of the impact of age on innate immunity are ongoing, and increasing evidence highlight age related abnormalities. These concern qualitative, rather than

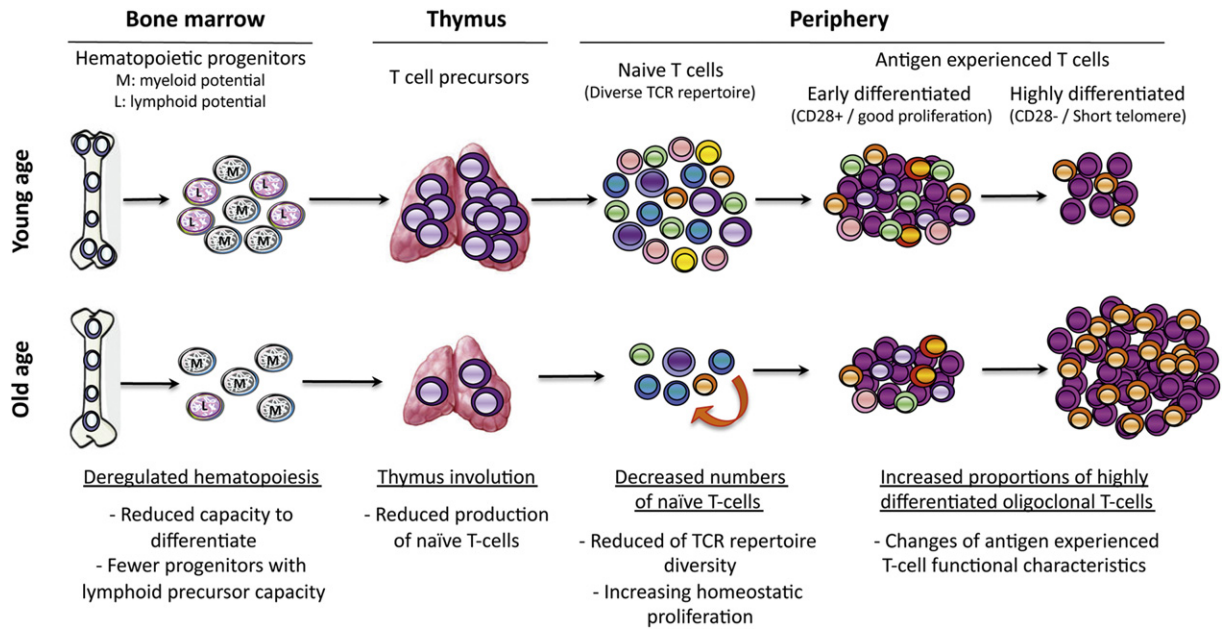

Fig. 1 Alterations of T-cell development associated with aging. Schematic representation of T-cell development from hematopoietic stem cells to highly differentiated memory T cells. The figure highlights the differences between young and old adults.

quantitative, attributes of innate immune cells. Migration and effector functions (e.g., phagocytosis, anti-bacterial activity, pro-inflammatory cytokine secretion) of neutrophils, monocytes, as well as NK cells appear to be altered with advanced age. Evidence suggests that aging compromises also the capacity of DCs to capture and process antigens, and that their response to stress molecules like ligands for toll like receptors and C-type lectin receptors is altered (Agrawal *et al.*, 2008). Since antigen presentation is at the heart of T- and B-cell response induction, impaired DC functions in the elderly is likely to have a significant impact on the mounting of effective adaptive immune responses.

Implications of Immunosenescence

The Causes of Immunosenescence

The precise mechanisms involved in the development of immunosenescence are still not completely understood, however the evidence accumulated so far converges towards the following hypothesis with regards to declining adaptive immunity. In adults, the ratio of naïve to antigen-experienced T- and B-cells is progressively reversed as naive cells are increasingly exposed to antigens. However with age, the naive lymphocyte pools are poorly replenished, a likely consequence of the gradual deterioration of the bone marrow and thymus capacity to produce mature T- and B-cells. The alteration of the hematopoietic stem cell compartment may play a role in the reduced production of naïve lymphocytes. Eventually highly differentiated oligoclonal antigen-experienced lymphocytes accumulate in the elderly, associated with a reduced T- and B-cell repertoire diversity. The very old individual can even become practically devoid of naïve T-cells. Immunosenescence may therefore be the result of the continuous challenge by a variety of antigens (e.g. derived from pathogens) to which the immune system is exposed throughout a life time. The maintenance of a protective immunity overtime may cause the eventual exhaustion of the finite renewal capacity of the adaptive immune system. Of note, chronic infections with persistent viruses, in particular cytomegalovirus (CMV), a prominent inducer of highly differentiated oligoclonal T-cell populations, have been shown to enhance the development of such 'immunosenescence profile' in humans (Koch *et al.*, 2006). In one study, the sum of certain parameters such as a high frequency of highly differentiated memory T-lymphocytes, a weak proliferative response of the T-lymphocyte pool and CMV seropositivity has even been associated to all cause early mortality in the elderly (Wikby *et al.*, 1998). The determinants of impaired innate immunity and inflammatory responses, and their link to the hyper-inflammatory status of the elderly remain to be clarified.

The Consequences of Immunosenescence

Overall, these manifestations are likely to affect the induction of effective cellular and humoral immune responses in the elderly. The age associated decline in immunocompetence results in an increase of the incidence and/or severity of many infectious diseases (e.g. influenza, pneumonia, meningitis, sepsis, varicella zoster virus, HIV, SARS …) in particular in developing countries where healthcare is not optimal. Similarly, this immune decline may also be related to the prevalence of cancers in the elderly. In addition deregulation of immune function may participate in the onset of non-infectious diseases such as autoimmune disorders (e.g. diabetes, multiple-sclerosis and even atherosclerosis) due to a decrease of the ability to discriminate between 'self' and 'non-self,' and possibly neurodegenerative disorders such as Alzheimer's disease. Interestingly, many of the immune characteristics associated with aging are also common to other conditions, independent of age, resulting also in a decline of immunocompetence (e.g., HIV infection and the genetic disorder ataxia telangectasia). These observations link the immunosenescence with the development of some degree of immunodeficiency. In the context of HIV infection, the virus is thought to cause elevated and chronic immune activation that may lead to a premature exhaustion or aging of the immune resources, which participates to the progression towards AIDS (Appay and Sauce, 2008).

Vaccination and Aging

It is also well-documented that the elderly do not respond to vaccination (and the adjuvants with which they are formulated) as well as young individuals. For example, the effectiveness of influenza vaccine is estimated to be twice lower in people greater than 65 years of age. In the elderly, T-cell and antibody responses to vaccines are slower and not as strong as in younger people (Weinberger *et al.*, 2008). Vaccines aim at inducing effective memory T- and B-cells from the pool of naive precursors present in vaccinees. Improving our knowledge of the exact causes and mechanisms underlying the decline in naïve T- and B-cell priming with age is necessary to improve vaccination efficacy for the elderly (Goronzy and Weyand, 2013). Although it is clear that detectable antigen-specific cells can be induced safely in humans by vaccination, the challenge is now to improve vaccine immunogenicity in the elderly populations. Several challenges must be faced to achieve this, including (i) the identification of the best vaccine formulation (e.g. antigen and adjuvant) to achieve priming of naive cell precursors in older individuals; and (ii) the development of personalized strategies that can be used to optimize vaccine procedures, knowing that variable responses will be due to a combined genetic difference and functional, age-related variance.

Premature Aging Syndromes☆

Fabio Coppedè, University of Pisa, Pisa, Italy

Introduction

Hutchinson–Gilford Progeria Syndrome (HGPS) and Werner syndrome (WS), also referred as to childhood- and adulthood-progeria respectively, represent two of the best-characterized premature aging disorders in humans. The identification of their genetic basis, paralleled by the creation of disease registers and databases, has allowed a better characterization of the phenotypes and a deeper understanding of associated symptoms, revealing the existence of a disease spectrum ranging from moderate and mild–severe to very aggressive forms, known as atypical progeroid syndromes.

Hutchinson–Gilford Progeria Syndrome

HGPS is an extremely rare genetic disorder named after the reports by doctors Hutchinson (1886) and Gilford (1904) who independently described the syndrome. The disease is a segmental progeroid syndrome involving multiple organs and tissues that mimic phenotypes associated with normal aging.

Epidemiology

HGPS has a reported birth prevalence of 1 in 8 million, but taking into consideration misdiagnosed or unreported cases, the estimated prevalence is of 1 in 4 million births. According to the Progeria Research Foundation database, which is the major online database of the disease (http://www.progeriaresearch.org), there is an estimate of between 350 and 400 children worldwide living with progeria, but only 132 of them have been identified as of October 1, 2015. The identified cases are from 46 different Countries, suggesting that the disease affects all ethnic groups and genders equally and there are no reported geographic clusters.

Clinical Manifestations

The affected children look normal and healthy at birth but the development of HGPS clinical features starts during the first year of their life. The author has recently reviewed the main HGPS clinical symptoms and their frequency (Coppedè, 2013) and an updated summary is provided below. The first signs in those infants are often a visible vein across the nasal bridge and skin lesions, followed by a profound failure to thrive resulting in the gain of only about ½ kg per year, and leading HGPS children to reach an average final weight of almost 14–15 kg. Most HGPS infants become bald by their second-third year of life due to progressive alopecia. Other symptoms that become apparent in the first years of life include a characteristic facies, loss of subcutaneous fat and abnormal tightness of the skin that with time becomes delicate, dry, translucent, and sometimes with hyperkeratosis. Stiffness of joints and bone changes also occur.

Facial abnormalities include a small face with a pinched nose and prominent eyes and scalp veins; a large cranium in relation to the facial size is seen in most of the patients, and other typical craniofacial anomalies are reported (Ullrich *et al.*, 2012). The subcutaneous fat in the face gradually disappears and the facial muscles decrease in size. HGPS infants also have a receding mandible, a high-pitched voice, protruding ears that lack lobules, and later develop low frequency conductive hearing loss. Dentition is delayed and crowded. HGPS children retain normal motor and mental development and have a normal social behaviour for their age. Also the cognitive functions are preserved, and there is no report of dementia or neurodegeneration (Ullrich and Gordon, 2015).

With time also the body shows a progressive loss of subcutaneous fat, musculoskeletal degeneration and joint protruding. At the bone level, small clavicles, coxa valga and acroosteolysis are seen in most of the patients. Other frequent skeletal abnormalities are hip dysplasia and thin ribs. Generalized osteopenia and other skeletal dysmorphisms are reported in less than 50% of the patients (Cleveland *et al.*, 2012).

HGPS individuals are not sexually mature and do not reproduce; with time their appearance becomes like that of an old person until death that usually occurs between ages 6 and 20 years. Cardiovascular and cerebrovascular complications culminate in mortality from myocardial infarction, stroke or congestive cardiac failure at an average age of 14.6 years. Autopsy data have shown widespread atherosclerosis in HGPS patients. Cerebrovascular arteriopathy, intracranial steno-occlusive arterial lesions, and early and clinically silent strokes have been also reported as a prevalent disease characteristic in HGPS (Silvera *et al.*, 2013).

Genetics

Progerin-producing LMNA mutations

In 2003 the *LMNA* gene was identified as the causative HGPS gene (De Sandre-Giovannoli *et al.*, 2003; Eriksson *et al.*, 2003). The commonest HGPS causative mutation is a de novo dominant point mutation in exon 11 of the gene (c.1824C>T, p.G608G) resulting in the activation of a cryptic donor splice site and leading to the production of a lamin A isoform containing an internal deletion of 50 amino acids, known as progerin (Eriksson *et al.*, 2003). It was however clear from the beginning that also less common *LMNA* gene mutations could cause the disease (Eriksson *et al.*, 2003). As of October 1, 2015, 104 out of the 132 living children with progeria identified by the Progeria Research Foundation have a progerin-producing mutation in the *LMNA* gene, and 28 have mutations in the lamin pathway but don't produce progerin. The heterozygous *LMNA* c.1824C>T mutation is found in about 85–90% of progerin-producing HGPS cases, referred as to classic HGPS. Other progerin-producing mutations found in 1–5% of the cases each, include heterozygous exon 11 c.1822G>A (p.G608S), c.1821G>A (p.V607V), and c.1868C>G (T623S) mutations, as well as heterozygous mutations at the intronic border of exon 11, such as c.1968+1G>A, c.1968+1G>C, c.1968+5G>C (http://www.progeriaresearch.org) and others (Gordon *et al.*, 2015). Despite that all those mutations result in the production of progerin, the resulting phenotype can be less or more aggressive depending on the nature of the mutation itself and the resultant final amount of progerin protein that is produced. For example both c.1968+1G>A and c.1821G>A mutations lead to a strong activation of the aberrant splice site, with subsequent increased progerin expression and a more severe phenotype compared to classic HGPS cases. By contrast, the c.1868C>G mutation results in the deletion of only 35 amino acids in the protein leading to a slowly progressing progeria compared to classic HGPS (Gordon *et al.*, 2015). A list of *LMNA* mutations causing classic HGPS or progerin-producing progeroid laminopathies can be found at the UMD-LMNA Mutations Database (http://www.umd.be/LMNA/).

Other LMNA mutations

Several atypical progeroid syndromes, also called nonclassical progeria, atypical HGPS, or atypical Werner syndrome, are not caused by progerin-producing *LMNA* mutations, but result from over 20 different heterozygous, homozygous, or compound heterozygous mutations in the *LMNA* gene. The clinical features of atypical progeroid syndromes include growth retardation and involve the same body systems as in classical HGPS, but the patients differ in age at onset and severity of the symptoms, which can be similar, more or less severe than in classic HGPS. A detailed review of those mutations and their models of inheritance can be found in Coppedè (2013). Additional data can be found at the UMD-LMNA Mutations Database (http://www.umd.be/LMNA/).

ZMPSTE24 mutations

Lamin A proteins are synthesized as prelamin A proteins, which undergo farnesylation and other posttranslational modifications to become mature proteins. The zinc metalloprotease ZMPSTE24 is required in prelamin A processing to yield mature lamin A. Recessive mutations in *ZMPSTE24* impair lamin A maturation causing three distinct premature aging disorders with increasing disease severity: (1) mandibuloacral dysplasia, which is a mild progeroid disorder characterized by postnatal growth retardation and craniofacial, skeletal, and skin abnormalities, (2) atypical HGPS, a severe non-classical form of HGPS, and (3) restrictive dermopathy, a fatal neonatal disorder representing an "extreme form" of progeria resulting from intrauterine growth delay. Also for *ZMPSTE24*, several different mutations have been identified in homozygosis or compound heterozygosis in the patients, and disease severity is inversely correlated with the residual protein activity conferred by those alleles, so that complete loss-of-function alleles lead to restrictive dermopathy, whereas alleles resulting in residual protein activity are associated with less severe phenotypes. An updated list of premature aging-related *ZMPSTE24* mutations can be found in Navarro *et al.* (2014).

Molecular Mechanisms

Lamins are the major components of the nuclear lamina and are essential not only for the formation and maintenance of a proper nuclear shape and structure, but also for the organization of the chromatin structure and of several nuclear processes such as transcription, DNA replication, DNA repair, epigenetic mechanisms and cell division and differentiation, all impaired in HGPS and likely contributing to the premature aging phenotype. Cells obtained from HGPS individuals accumulate defects in nuclear structure and architecture with cell passaging, such as lobulation, clustering of the nuclear pores and loss of peripheral heterochromatin (Goldman *et al.*, 2004). It is therefore believed that the accumulation of a non-mature and persistently farnesylated lamin A, either resulting from progerin-producing *LMNA* or from *ZMPSTE24* mutations, causes impaired structural and mechanical properties of the nuclear lamina because of the retain of the farnesyl group that renders progerin, or other farnesylated lamin A isoforms, permanently intercalated into the inner nuclear membrane. By contrast, non-progerin producing *LMNA* alleles lead to the production of lamin A isoforms with variable structure and function but all able to induce nuclear damages that overlap with those of progerin-producing alleles (Gordon *et al.*, 2015).

Diagnosis

The diagnosis of classic or atypical HGPS is made in individuals with common clinical features (listed above) or with features resembling classic HGPS, confirmed by the genetic test for *LMNA* mutations searching for the heterozygous c.1824C>T mutation

in exon 11 in classic HGPS or for less frequent *LMNA* mutations by sequencing of the coding and flanking regions in atypical HGPS forms.

Management and Experimental Therapies

Unfortunately there is actually no cure to halt the development of the premature aging phenotype in HGPS infants, so that drugs, dietary changes, exercise and hydrotherapy are recommended for HGPS individuals to counteract atherosclerosis risk, body fat reduction, and muscular atrophy. The extraction of primary teeth may help to avoid crowding, and sunscreens, hearing aids, eye care and shoe pads are also recommended when necessary. Low-dose aspirin and an adequate oral hydration are recommended for the prevention of cardiovascular and cerebrovascular complications (Gordon *et al.*, 2015).

There are actually three agents under investigation in human clinical trials for HGPS: lonafarnib, pravastatin, and zoledronate, all acting as inhibitors of the post-translational farnesylation of progerin (Gordon *et al.*, 2015). Available data on lonafarnib clinical trials revealed that the drug improved the rate of weight gain, vascular distensibility, bone structure, neurosensory hearing, and lifespan (Gordon *et al.*, 2015).

Werner Syndrome

WS is a rare genetic disease named after the doctoral thesis by Doctor Werner (1904) that first described it. It is a segmental progeroid syndrome and the most studied disease model of premature aging in adulthood.

Epidemiology

WS is an autosomal recessive disorder with an estimated sex ratio of 1:1. In the Japanese population, due to a founder effect, the disease frequency ranges from about 1 in 20.000 to 1 in 40.000. Another genetic cluster is found in Sardinia, with an estimated frequency of 1 in 50.000. WS prevalence in other populations is unknown, but far less frequent than in Japan and likely ranging from 1 to a few cases per 1 million individuals (Oshima *et al.*, 2014). Indeed, it was recently observed that almost 1.500 WS cases have been reported worldwide from 1904 to 2008, 75% of them in Japan (Goto *et al.*, 2013).

Clinical Manifestations

The author has recently reviewed the main WS clinical symptoms and their frequency (Coppedè, 2013) and an updated summary is provided below. WS individuals develop normally during the first decade of life, and the lack of a pubertal growth spurt during their early teen years, leading to a final short stature and low bodyweight, is the first clinical sign. In their 20s WS individuals begin to manifest greying or loss of hair and scleroderma-like skin lesions followed, in the 30s, by bilateral cataracts, type 2 diabetes mellitus, hypogonadism, skin ulcers, and osteoporosis. A prematurely aged face with beaked nose is found in most of the patients and fertility declines in both sexes soon after sexual maturity. WS subjects usually die at a mean age of 53–54 years from cancer or myocardial infarction.

An unusual spectrum of cancers has been reported in WS individuals, and the most common cancers are thyroid neoplasms, melanoma, meningioma, soft tissue sarcomas, hematologic/lymphoid cancers, and osteosarcomas (Lauper *et al.*, 2013).

Concerning vascular diseases and their complications, several forms of arteriosclerosis have been observed in WS individuals, with coronary artery atherosclerosis often leading to myocardial infarction and death. Less frequent are cerebrovascular disorders, observed in 2–5% of the cases (Oshima *et al.*, 2014; Takemoto *et al.*, 2013).

Concerning the involvement of the nervous system in WS only a few cases of dementia or peripheral neuropathy have been reported, but there is no evidence of increased risk for Alzheimer's disease (Coppedè, 2012).

Genetics

WRN mutations

Typical WS is caused by mutations of the *WRN* gene that codes for the WRN protein, a member of the RecQ DNA helicase family with multiple nuclear functions (Yu *et al.*, 1996). The *WRN* gene consists of 35 exons and over 70 different mutations have been identified in WS patients, including missense, nonsense, ins/del, and splice mutations. Founder mutations are reported in Japanese (c.3139-1G > C, resulting in skipping of exon 26) and Sardinian patients (c.2089-3024A > G, creating a novel exon between exons 18 and 19 and introducing a premature stop codon), and common or potential founder mutations are reported in other populations, such as the common mutation in Caucasians (c.1105C > T, p.R369X) creating a stop codon in exon 9, and potential founder mutations in Moroccan (c.2179dupT, p.C727fs), Dutch (c.3590delA, p.N1197fs), and Turkish (c.3460-2A > G, exon 30 deletion) populations (Friedrich *et al.*, 2010; Oshima and Hisama, 2014). Most of those mutations are null mutations, resulting in protein truncation with loss of the nuclear localization signal and/or in decay of the mutant mRNAs. Also missense mutations are

Table 1 Main characteristics of classic HGPS and typical WS

	Classic HGPS	*Typical WS*
Disease	Premature aging disease of childhood — segmental progeroid syndrome	Premature aging disease of adulthood — segmental progeroid syndrome
Prevalence	1 in 4–8 million births	1:20.000–40.000 in Japan 1:50.000 in Sardinia Less frequent elsewhere
Onset of symptoms	1st year of life	2nd-3rd decade of life
Mean life expentancy	14.6 years	53–54 years
Main cause of death	Myocardial infarction or stroke resulting from vascular diseases	Cancer or myocardial infarction, the latter resulting from vascular disease
Causative gene	*LMNA*	*WRN*
Mendelian inheritance	Autosomal dominant	Autosomal recessive
Sex ratio	1:1	1:1
Ethnic differences	Not reported	Frequent in Japan and Sardinia, due to a founder effect. Less frequent elsewhere
Main symptoms	Severe failure to thrive in infancy. Skin lesions. Progressive alopecia leading to total alopecia. Characteristic facies. Loss of subcutaneous fat. Bone changes. Skeletal anomalies. Musculoskeletal degeneration. Hearing loss. High-pitched voice. Delayed and crowded dentition. Atherosclerosis. Cerebrovascular disease	Lack of the pubertal growth spurt during early teen years. Greying or loss of hair. Scleroderma-like skin lesions. Bilateral cataracts. Type 2 diabetes mellitus. Hypogonadism. Skin ulcers. Osteoporosis. Characteristic facies. Arteriosclerosis
Cancer risk	Not reported	Elevated risk of thyroid neoplasms, melanoma, meningioma, soft tissue sarcomas, hematologic/lymphoid cancers, osteosarcomas, and other less frequent cancers
Nervous system disorders	Normal cognitive and motor functions. Signs of neurodegeneration are not reported	Only a few reported cases of dementia or peripheral neuropathy, but no clear evidence of increased risk for neurodegenerative disorders
Fertility	Sexually immature-do not reproduce	Reduced fertility-can reproduce
Diagnosis	Presence of disease symptoms confirmed by detection of the common *LMNA* c.1824C>T mutation	Presence of disease cardinal signs and molecular detection of biallelic *WRN* pathogenic variants
Treatments	Symptomatic	Symptomatic

mainly regarded as null mutations causing protein instability, or a significant decreased protein activity (Oshima and Hisama, 2014). A complete list of *WRN* mutations can be found at the Werner Syndrome Mutational Database (http://www.pathology.washington.edu/research/werner/database/).

LMNA mutations in atypical WS

Recessive *WRN* mutations account for most of WS cases denoted as typical WS. However, atypical forms of the disease (atypical WS) are reported, with patients showing no *WRN* mutations and often an early onset of the symptoms and an accelerated disease progression. Bilateral cataracts and diabetes are not common features in atypical WS. The International Registry of Werner Syndrome (Department of Pathology, University of Washington, Seattle, WA, USA) (www.wernersyndrome.org) contains data on 11 atypical WS individuals with mutations in the *LMNA* gene, including missense mutations and others at the intronic border of exon 11 leading to a weak activation of the same cryptic splice site as in HGPS (Oshima and Hisama, 2014). Interestingly, atypical WS cases that have neither *WRN* nor *LMNA* mutations are also reported (Oshima and Hisama, 2014).

Molecular Mechanisms

WRN is a nuclear protein with multiple functional domains involved in the maintenance of genome stability by means of DNA dependent ATPase, $3'\rightarrow5'$ helicase, $3'\rightarrow5'$ exonuclease, and DNA strand annealing activities involved in DNA replication, recombination, repair and transcription as well as in telomere maintenance and apoptosis. As such it is regarded as a "caretaker of the genome" (Muftuoglu *et al.*, 2008). As discussed above, most of the WRN mutations found in WS patients are null mutations leading to absence of a functional WRN protein in nuclei, and cells isolated from WS individuals display increased chromosomal aberrations, accelerated telomere shortening, DNA replication impairments, and premature senescence in culture (Melcher *et al.*, 2000).

Diagnosis

The clinical diagnosis of WS is based on the presence of four cardinal signs (bilateral cataracts, skin changes, short stature, and greying or loss of hair), which are all simultaneously observable in almost 91% of the patients, and supported by the presence of additional signs (bird-like face, osteoporosis, voice change, type 2 diabetes mellitus, atherosclerosis, and so on). The diagnosis is then molecularly confirmed by the detection of *WRN* pathogenic variants (Friedrich *et al.*, 2010; Oshima and Hisama, 2014).

Management and treatments

Treatments for WS are only symptomatic. Indeed, cholesterol-lowering drugs in case of abnormal lipid profile, treatment of skin ulcers, surgical treatment of cataracts, control of type 2 diabetes mellitus, and standard treatment of malignancies are among the available medicaments, accompanied by smoking avoidance and dietary/physical regimens to reduce atherosclerosis risk (Coppedè, 2013).

Summary and Comparison of the Main Characteristics Between Classic HGPS and Typical WS

Table 1 provides a summary of the text featuring the main characteristics of classic HGPS and typical WS.

Web Resources

HGPS

The Progeria Research Foundation database (http://www.progeriaresearch.org) is a major online source of HGPS by the numbers, containing updated information on HGPS, an updated database of identified cases, and disease management strategies.

The UMD-LMNA mutations database (http://www.umd.be/LMNA/) provides up-to-date information about mutations of the *LMNA* gene and related diseases, including HGPS and atypical progeroid syndromes.

WS

The International Registry of Werner Syndrome (www.wernersyndrome.org) is located in the Department of Pathology, University of Washington, Seattle, Washington and contains information on the disease and a registry of submitted cases.

The Werner Syndrome Mutational Database (http://www.pathology.washington.edu/research/werner/database/) contains up to date list of *WRN* causative mutations.

Hormonal Circadian Rhythms and Sleep in Aging

Georges Copinschi and Anne Caufriez, Free University of Brussels, Brussels, Belgium

Introduction

A prominent feature of endocrine secretion in man is its high degree of temporal organization. Hormonal variations may be observed in the ultradian range (i.e., once per 1–2 h), in the circadian range (i.e., approximately once per 24 h) and in the infradian range (i.e., periods longer than 24 h, for instance the menstrual cycle). This configuration provides the endocrine system with a high and complex degree of flexibility. The temporal regulation of hormonal secretions throughout the 24-h cycle results from the interaction, in the central nervous system, of two sophisticated time-keeping mechanisms: the so-called *sleep-wake homeostasis*, a mechanism linking the timing and the intensity of sleep to the duration of prior wakefulness, and the so-called *circadian pacemaker* (Copinschi and Challet, 2016).

The master circadian pacemaker—or circadian clock—is located in two bilaterally paired small nuclei in the anterior hypothalamus: the suprachiasmatic nucleus (SCN) (Rosenwasser and Turek, 2005). The generation and maintenance of circadian oscillations of the master circadian pacemaker involve a series of clock genes, which interact in complex feedback loops (Zhang and Kay, 2010; Partch *et al.*, 2014). Secondary circadian clocks are present in other brain areas (Abe *et al.*, 2002; Feillet *et al.*, 2008; Guilding *et al.*, 2009) and in almost all peripheral tissues, including endocrine glands (Yoo *et al.*, 2004; Balsalobre *et al.*, 1998; Oster *et al.*, 2006). These secondary circadian clocks are under the control of the SCN through the entrainment of the same circadian machinery at the local level. Together, the master and the secondary circadian clocks define a multioscillatory network generating circadian oscillations. The SCN controls and synchronizes peripheral endocrine clocks, either directly via neural signals transmitted through the autonomous nervous system, or indirectly via the sleep-wake cycle or the rhythm of feeding. In addition, circadian variations of corticosteroids and of melatonin release—two hormones tightly controlled by the SCN—probably contribute to the transmission of temporal signals throughout the body (Pevet and Challet, 2011; Balsalobre *et al.*, 2000; Segall *et al.*, 2006; Malek *et al.*, 2007). However, the endogenous circadian period is close to, but not exactly, 24 h. This implies that the circadian clock has to be entrained by external agents to avoid to fall out of synchrony with the environmental day. The primary synchronizing agent is the 24-h light-dark cycle (Meijer and Schwartz, 2003).

The SCN controls the timing of most circadian rhythms, including endocrine rhythms. In addition, SCN partly regulates the sleep-wake cycle. In turn, the sleep-wake cycle regulates the timing and the expression of many endocrine rhythms. Thus, the 24-h hormonal profiles frequently result from an interaction between the circadian pacemaker, the sleep-wake homeostasis, and an ultradian, or pulsatile, pattern of release, while the 24-h sleep-wake cycle is driven partly by the circadian clock and partly by the homeostatic regulation of sleep pressure.

Sleep and Aging

Sleep involves two distinct states of brain activity that are each generated in specific brain regions and are characterized by different patterns of cerebral and peripheral activity: the rapid eye movement (REM) stage and the non-REM stages. Throughout the sleep period, non-REM sleep and REM sleep occur in successive cycles lasting approximately 90 min. Each cycle is normally initiated by the lighter non-REM stages (stages 1 + 2), followed by a deeper non-REM stage (stage 3), then by REM sleep. During stage 3 sleep, the EEG is synchronized with low-frequency high-amplitude waveforms, referred to as slow-waves (SW). Therefore, stage 3 sleep is currently referred to as slow-wave sleep. The intensity of SW sleep, referred to as slow-wave activity (SWA), may be quantified by a spectral electroencephalogram (EEG) analysis. SW sleep is the most "restorative" sleep stage. During REM sleep, EEG is similar to that of active waking, muscle tone is inhibited and eye movements are present (Copinschi and Challet, 2016). Most dreams occur during REM sleep (Siegel, 2011).

In young healthy subjects (15–25 years), each night involves 4–6 successive sleep cycles. During the first cycle, the sequence normally includes an initial 10–20 min period of light non-REM sleep, followed by a nearly 60 min period of deeper non-REM sleep, then by a few minutes of REM sleep. As the night progresses, transient awakenings become longer and more frequent, non-REM sleep becomes shallower and the duration of REM sleep periods increases. In healthy young subjects, approximately 50% of a normal night is spent in light non-REM stages, 20% in SW sleep, 25% in REM sleep, and 5% in wake. A typical individual sleep pattern in a healthy young man is illustrated in **Fig. 1**.

During normal aging, this sleep-wake pattern undergoes major modifications, resulting in major alterations in sleep architecture. From early adulthood (16–25 years) to midlife (35–50 years), a spectacular decrease in SW sleep occurs, together with a compensatory increase in light non-REM sleep (stages 1 and 2), but there are no significant modifications in the duration of REM sleep, nor in the duration of transient nocturnal awakenings, and the total sleep time remains largely unchanged (Van Cauter *et al.*, 2000). From mid-life to old age (70–80 years), no additional decrease in SW sleep is observed, but both REM sleep and light non-

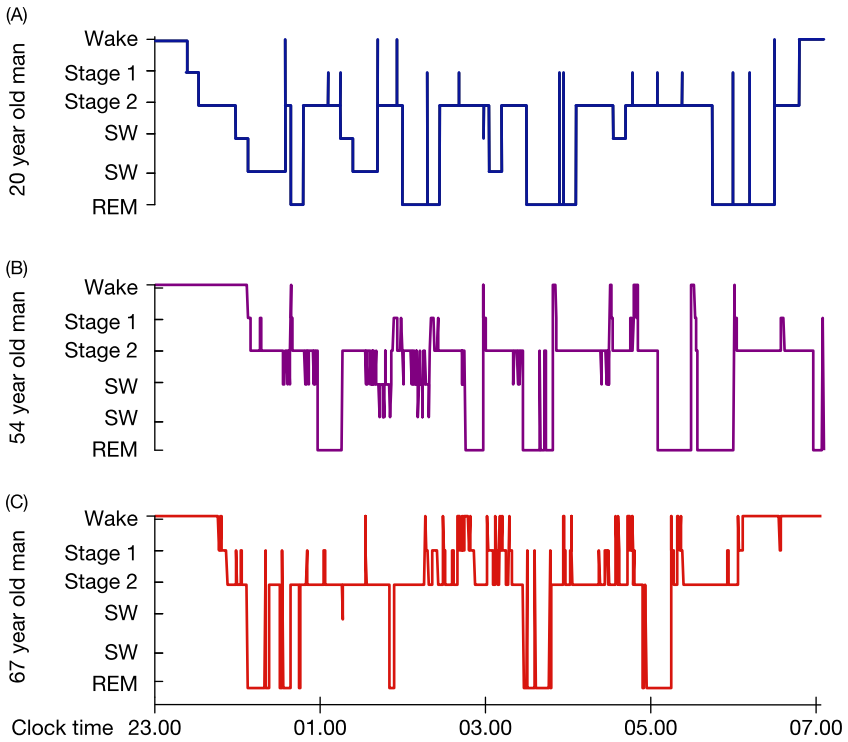

Fig. 1 Hypnograms recorded in healthy men aged 20 (A), 54 (B), and 67 (C) years. Unpublished data kindly provided by Rachel Leproult, Ph.D.

REM sleep progressively decline, associated with a mirror increase in wake time, resulting in sleep fragmentation and a decrease in total sleep time (Landolt *et al.*, 1996; Miles and Dement, 1980; Ohayon *et al.*, 2004; Van Cauter *et al.*, 2000). Moreover, there is a redistribution of REM stages across the sleep period, with a shift toward the initial part of the night. Typical individual sleep profiles in healthy 54- and 67-year old men are illustrated in **Fig. 1**. The time-course of age-related modifications of sleep architecture is illustrated in **Fig. 2**.

Those marked alterations in sleep architecture are frequently associated with major alterations in subjective sleep quality, which are more important and more frequent in older women than in older men (Groeger *et al.*, 2004; Middelkoop *et al.*, 1996; Vitiello *et al.*, 2004). During the night, healthy elderly subjects often complain of shallow sleep with frequent transient awakenings and an early final morning awakening, resulting in unwanted daytime naps (Prinz *et al.*, 1990; Bliwise, 1993; Prinz, 1995). Moreover, age-associated deficits in the quality of nocturnal sleep may be paralleled by decreased daytime alertness and performance, and attention and memory deficits (Ancoli-Israel, 2005).

Circadian System and Aging

Age-related alterations in hormonal circadian rhythms widely differ from one hormone to another. One of the most prominent alterations is a reduction in rhythm amplitude. Many hormonal circadian rhythms are also phase-advanced, so that phase-points of the rhythms occur earlier in the elderly than in young subjects (Copinschi and Challet, 2016). Those alterations are likely to result from both a reduction in the strength of the circadian signal and a reduction in the homeostatic drive to sleep (Dijk *et al.*, 1999). Reduced outdoor activity resulting in decreased exposure to bright light, reduced professional and social constraints and decreased mobility all also contribute to disruptions in circadian rhythmicity. Regular exposure to bright light and enhanced social activities may improve nighttime sleep and daytime alertness and reinforce circadian rhythms in the elderly (Copinschi and Challet, 2016).

The senescence process may be accelerated by conditions of circadian misalignment, such as occur in shift work or in jet lag, which induce a state of internal desynchrony between central and peripheral rhythms, with major disruptions of the internal temporal organization of a number of physiologic functions (Evans and Davidson, 2013; Leproult *et al.*, 2014; Scheer *et al.*, 2009). Not surprisingly, shift work is associated with increased risk for insomnia, infertility, weight gain, dyslipidemia, insulin resistance, diabetes, cardiovascular, and gastrointestinal disorders (Czeisler *et al.*, 1990; Knutsson *et al.*, 1986; Rosa, 1995; Van Amelsvoort *et al.*, 1999; Nagaya *et al.*, 2002; Pan *et al.*, 2011). In animals, prolonged circadian misalignment was found to reduce their lifetime (Penev *et al.*, 1998; Davidson *et al.*, 2006). Furthermore, a study performed in young grass rats has shown that circadian desynchronization triggers premature cellular aging (Grosbellet *et al.*, 2015).

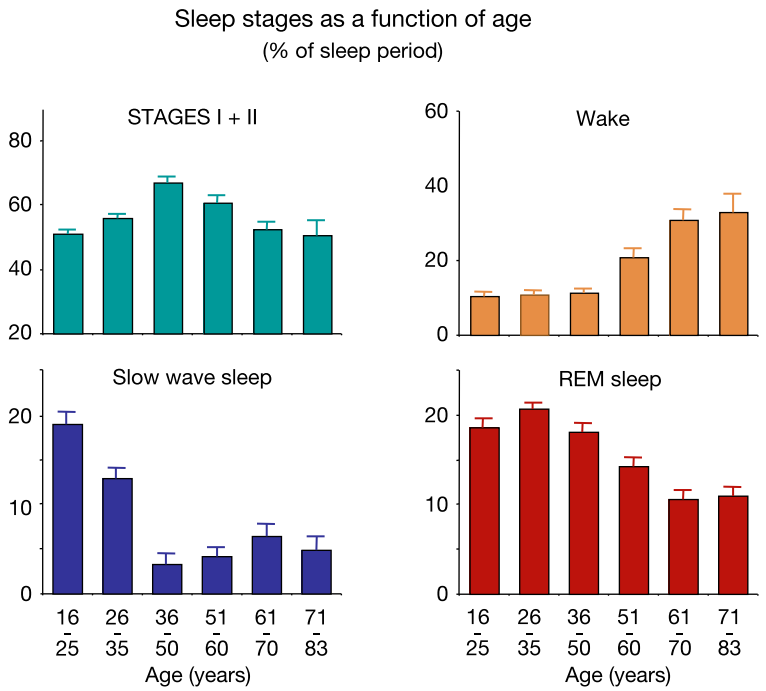

Fig. 2 Sleep stages as a function of age in 149 healthy men, aged 16–83 years. Values shown are mean (+SEM) for each age group. Data from Van Cauter, E., Leproult, R. and Plat, L. (2000). Age-related changes in slow wave sleep and REM sleep and relationship with growth hormone and cortisol levels in healthy men. *JAMA* **284**, 861–868.

The aging-related effects on melatonin, hormones of the hypothalamo–pituitary axis, glucose and insulin are reviewed in the following sections.

Melatonin

Melatonin rhythmicity is primarily dependent on the master circadian pacemaker (Rosenthal, 1991). In addition, a pineal molecular clockwork plays a stimulatory role on the amplitude of the major melatonin circadian rise, starting between 21.00 and 23.00 h, culminating around the middle of the night, followed by a progressive decline to return by 08.00 or 09.00 h to low levels that are maintained throughout daytime until the next evening circadian rise (Copinschi and Challet, 2016). Melatonin rhythmicity is highly sensitive to lighting conditions, as night exposure to light exerts an immediate dose-dependent inhibition of melatonin synthesis (Lewy *et al.*, 1980; Van Cauter et al., 1998a).

Daytime low melatonin levels are similar in young and old adults. But the evening circadian elevation is markedly dampened in most, but not all, older subjects (Van Coevorden *et al.*, 1991). This dampening may partly result from insufficient daytime environmental light since it may be reversed by midday exposure to bright light (Mishima *et al.*, 2001). In addition, the circadian rise is advanced by almost 1.5 h in the elderly, illustrating the advance of circadian phase (Van Coevorden *et al.*, 1991).

ACTH, Cortisol, Dehydroepiandrosterone

The circadian rhythms of hormones of the corticotropic axis are primarily controlled by central and adrenal circadian clocks, thanks to a flexible sophisticated machinery (Copinschi and Challet, 2016). Outputs from the SCN activate the circadian release of hypothalamic corticotropin-releasing hormone (CRH) that in turn stimulates circadian ACTH secretion. The 24-h profile of adrenocortical secretion primarily depends on ACTH diurnal pattern. In addition, neuronal signals generated by the SCN are also transmitted to the adrenal cortex by a multisynaptic neural pathway (Buijs *et al.*, 1999; Dickmeis *et al.*, 2013). The secondary adrenal circadian clock gates the adrenal response to ACTH, that is, modulates diurnal variations of the adrenal responsiveness to ACTH (Oster *et al.*, 2006).

In young adults, the 24-h profiles of ACTH and cortisol normally show an early morning peak, a progressive decrease toward minimal levels centered around midnight (referred to as the quiescent period), followed during the second part of the night by a sharp increase (referred to as the circadian rise) toward the early morning peak (**Fig. 3**). The diurnal pattern of cortisol secretion reflects a succession of secretory pulses, the magnitude of which is modulated by the circadian rhythm, without any evidence of tonic secretion (Van Cauter *et al.*, 1990). This pattern is largely unaffected by alterations of the usual sleep schedule, illustrating the

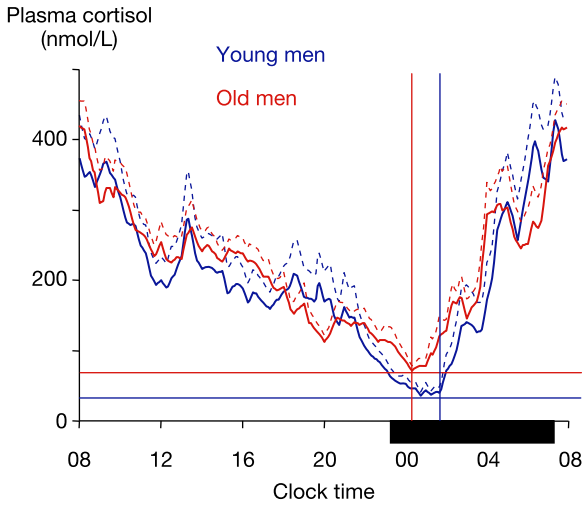

Fig. 3 Mean (+SEM) 24-h plasma cortisol profiles in eight healthy young men aged 17–24 years and in eight healthy old men aged 70–83 years matched for BMI. Dashed lines indicate SEM. The *black* bar represents the mean sleep period. *Horizontal* lines indicate the nocturnal minimum cortisol level in each group. *Vertical* lines indicate the timing of the circadian cortisol rise in each group. Note that in the older group, evening cortisol levels are increased and the timing of the circadian rise is advanced. Data from Van Cauter, E., Leproult, R. and Plat, L. (2000). Age-related changes in slow wave sleep and REM sleep and relationship with growth hormone and cortisol levels in healthy men. *JAMA* **284**, 861–868.

strength of the circadian control. Diurnal variations parallel to those of cortisol have been evidenced for other adrenal steroids, such as dehydroepiandrosterone (DHEA) (Copinschi and Challet, 2016).

However, cortisol release is also modulated by the sleep-wake homeostasis. Sleep onset (and more precisely SW sleep) is consistently associated with an immediate drop in circulating cortisol levels (Weitzman *et al.*, 1983; Van Cauter *et al.*, 1991; Weibel *et al.*, 1995; Caufriez *et al.*, 2002). This drop may be undetectable in early morning, when sleep onset coincides with a peak of corticotropic activity. Conversely, all awakenings at the end of the sleep period, as well as transient awakenings during this period, consistently trigger cortisol secretory pulses (Caufriez *et al.*, 2002; Follenius *et al.*, 1992; Spath-Schwalbe *et al.*, 1991; Van Cauter et al., 1990, 1991). In an analysis of nocturnal cortisol profiles performed in healthy young men and women, all transient awakenings that interrupted sleep during 10 min or longer were followed within 20 min by significant cortisol secretory pulses (Caufriez *et al.*, 2002). In normal sleepers, 24-h cortisol levels were found to be positively associated with the duration of nocturnal awakenings (Vgontzas *et al.*, 2003). Chronic insomnia (resulting in a reduction of total sleep time) was found to be associated with elevated nocturnal cortisol levels (Vgontzas et al., 2001a).

Furthermore, in rabbits and rats, intracerebral injections of CRH inhibit SW sleep (Ehlers *et al.*, 1986; Opp *et al.*, 1989), while blockade of CRH receptors reduce wakefulness (Chang and Opp, 1998). In humans, intravenous CRH injections may reduce sleep efficiency and SW sleep (Holsboer *et al.*, 1988; Tsuchiyama *et al.*, 1995; Vgontzas et al., 2001b), while cortisol administration may enhance SW sleep (Born *et al.*, 1991; Friess *et al.*, 1994; Bohlhalter *et al.*, 1997), presumably via a negative feedback on endogenous CRH secretion.

In healthy subjects, the circadian rhythm of cortisol persists throughout the aging process and is even present in the very elderly (Van Coevorden *et al.*, 1991; Van Cauter *et al.*, 1996), but, from 50 years of age onwards, evening cortisol levels progressively increase, the relative amplitude of the diurnal rhythmicity is dampened and the timing of the circadian rise is advanced (Van Cauter *et al.*, 1996), as illustrated in **Fig. 3**. After 70 years of age, late evening levels are markedly higher than in young adults (Van Cauter *et al.*, 1996). This elevation probably reflects a reduced resiliency of the corticotropic axis, resulting from age-associated alterations of hippocampal neurons (McEwen, 1998b). In older subjects, the quiescent period is markedly shortened, as it starts later, ends earlier and is fragmented. These alterations are more pronounced in women than in men: between 25 and 65 years of age, the quiescent period shortening averages approximately 4.5 h in women but less than 3 h in men (Van Cauter *et al.*, 1996). Not surprisingly, the circadian rhythm of dehydroepiandrosterone, though still present, is dampened in the elderly (Al-Turk and Al-Dujaili, 2016).

As illustrated in **Fig. 4**, the age-related elevation of evening cortisol levels and the age-related decrease of REM sleep occur in mirror image (Van Cauter *et al.*, 2000), suggesting that in the elderly, alterations of sleep quality could contribute to alterations of the corticotropic axis. This hypothesis is supported by a number of interventional studies. In young subjects, acute total or partial (4 h in bed) sleep deprivation results on the following day in significant elevations of cortisol levels in late afternoon and evening (Leproult *et al.*, 1997). Similar alterations occur if partial sleep restriction (4 h in bed per night) is enforced during six consecutive days (Spiegel *et al.*, 1999). These alterations are strikingly similar to those observed in healthy elderly with normal sleep schedules (**Fig. 5**). Furthermore, in a 4-year longitudinal study performed in 157 older adults, sleep duration was found to buffer long-term elevations of diurnal cortisol secretion, suggesting that long sleep protects to aging-associated increases in diurnal cortisol secretion

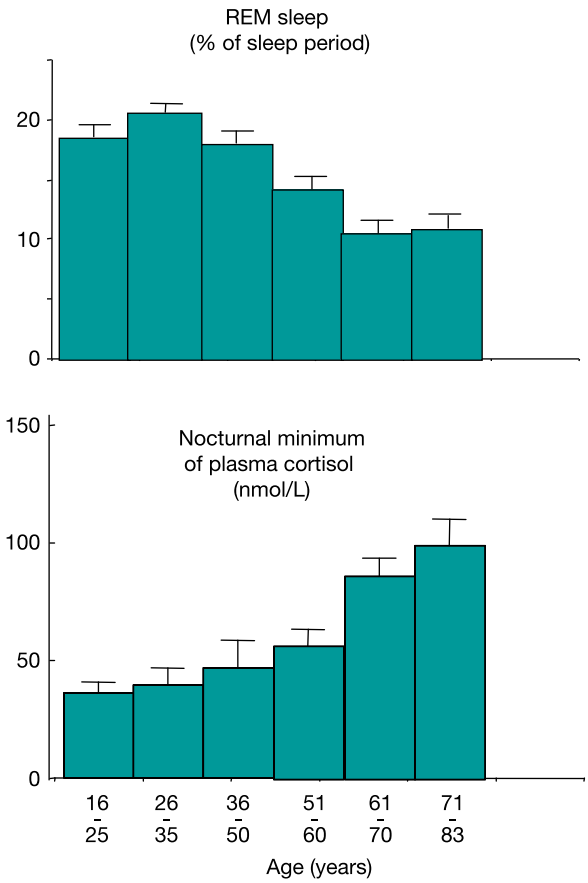

Fig. 4 REM sleep and nocturnal minimum of plasma cortisol levels as a function of age in 149 healthy men, aged 16–83 years. Values shown are mean (+SEM) for each age group. Note the similarity between the effects of sleep restriction and the effects of aging.

(Rueggeberg *et al.*, 2012). Thus, recurrent sleep curtailment is very likely to accelerate the senescence process of the corticotropic axis. Glucocorticoid excess, especially in the evening when cortisol levels are normally low, could favor the development of central and peripheral disturbances such as insulin resistance, osteoporosis and impaired cognitive function (Dallman *et al.*, 1993; Dennison *et al.*, 1999; McEwen, 1998a; McEwen and Stellar, 1993; Plat *et al.*, 1999; Johar *et al.*, 2015). Moreover, offspring of nonagenarian siblings are marked by a lower activity of the corticotropic axis, as assessed by lower diurnal salivary cortisol levels (Noordam *et al.*, 2012).

TSH and Thyroid Hormones

In healthy young adults, TSH levels during daytime are low and fairly stable. As illustrated in **Fig. 6**, they begin to rise in late afternoon or early evening, well before sleep onset. Maximal levels are reached around sleep onset. Thereafter, TSH levels progressively decrease to return to daytime low levels shortly after final morning awakening (Brabant *et al.*, 1990). The evening elevation, referred to as the circadian rise, appears to be controlled by the circadian clock, while the subsequent decline throughout the sleep period reflects an inhibitory action of sleep on TSH secretion, as the nocturnal TSH decline is associated with SW sleep (Goichot *et al.*, 1992; Gronfier *et al.*, 1995). Conversely, transient nocturnal awakenings are frequently associated with TSH elevations (Hirschfeld *et al.*, 1996). The 24-h TSH profile is generated by amplitude and frequency modulation of TRH-driven TSH secretory pulses (Veldhuis *et al.*, 1990). Free triiodothyronine (fT3) shows low amplitude diurnal variations that parallel TSH variations (Russell *et al.*, 2008). It is of interest to note that in healthy subjects with normal and regular sleep schedules, elevated TSH levels may occasionally be observed in blood samples collected in early morning.

As illustrated in **Fig. 6**, aging is associated with an advance shifting of the timing of the circadian rise (Van Coevorden *et al.*, 1991; Roelfsema *et al.*, 2014) and with a progressive decrease of TSH secretion, in particular during the night, resulting in a dampening of the amplitude of the circadian elevation (Van Coevorden *et al.*, 1991; Barreca *et al.*, 1985). After 60 years of age, TSH levels in healthy subjects are lower than in young adults throughout the 24-h span (Van Coevorden *et al.*, 1991). This decrease might result from a diminished capacity of the hypothalamus to synthesize thyrotropin-releasing hormone (TRH) (Mariotti *et al.*, 1995). In the elderly, thyroid hormone secretion is reduced, but circulating thyroxin levels may remain fairly unchanged since its renal clearance is also altered (Mariotti *et al.*, 1995).

Prolactin

In healthy young subjects, minimal prolactin levels are observed around noon, followed by a modest increase in the afternoon, then by a major nocturnal elevation starting shortly after sleep onset (**Fig. 7**). Maximal levels are reached around mid-sleep, with an average elevation of 200% above minimum day levels (Spiegel *et al.*, 1994; Waldstreicher *et al.*, 1996). The 24-h prolactin profile is generated by diurnal variations both in tonic secretion and in amplitude of secretory pulses (Veldhuis *et al.*, 1990). Prolactin levels are higher in cycling women than in young men or in postmenopausal women (Katznelson *et al.*, 1998). Sleep onset (and more precisely SW sleep) is constantly associated with a rise in prolactin levels, irrespective of the time of the day, and prolonged transient awakenings during the sleep period are associated with drops in prolactin levels (Spiegel *et al.*, 1995). Moreover, shifts in the sleep-wake cycle are immediately followed by parallel shifts in the diurnal profile (Van Cauter et al., 1998b).

Therefore, diurnal prolactin variations appear to be primarily dependent on the sleep-wake homeostasis. However, the amplitude of diurnal prolactin elevations may be dampened when associated with shifted daytime sleep as compared with nocturnal sleep (Van Cauter and Refetoff, 1985), and modest prolactin rises may occur during waking periods around the usual time of sleep onset, particularly in women (Waldstreicher *et al.*, 1996). Thus, diurnal variations of prolactin secretion also appear

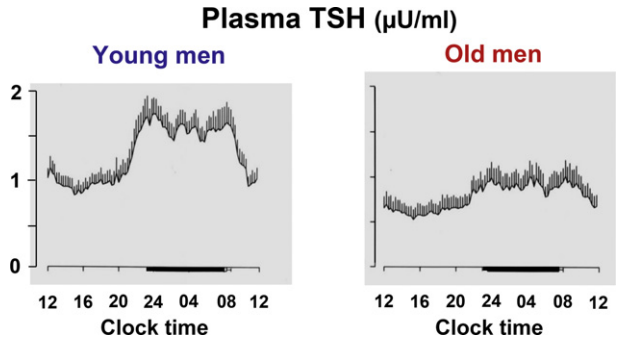

Fig. 6 Mean (+SEM) 24-h TSH profiles in eight young (20–27 years) and eight old (67–84 years) healthy men. Black bars represent the mean sleep periods. Note that in the older group, the onset of the circadian rise is advanced and its amplitude is reduced. Data from Van Coevorden, A., Mockel, J., Laurent, E., et al. (1991). Fig. 7 Mean (+SEM) 24-h plasma prolactin profiles in 10 healthy cycling young women (21–36 years) at early-mid follicular phase and in eight healthy postmenopausal women (48–74 years). The black bar represents the mean sleep period. In both groups, the onset of the nocturnal rise is concomitant with the onset of the sleep period. Note the dampening of the nocturnal rise in the older group. Data from Caufriez, A., Leproult, R., L'Hermite-Baleriaux, M., Moreno-Reyes, R. and Copinschi, G. (2009). A potential role of endogenous progesterone in modulation of GH, prolactin and thyrotrophin secretion during normal menstrual cycle. *Clinical Endocrinology* **71**, 535–542; Caufriez, A., Leproult, R., L'Hermite-Baleriaux, M., Kerkhofs, M. and Copinschi, G. (2011). Progesterone prevents sleep disturbances and modulates GH, TSH, and melatonin secretion in postmenopausal women. *The Journal of Clinical Endocrinology and Metabolism* **96**, E614–E623.

to be partly modulated by circadian rhythmicity. Maximal diurnal elevations occur when the effects of sleep and of circadian rhythmicity are superimposed, that is at the usual bedtime (Spiegel *et al.*, 1994; Waldstreicher *et al.*, 1996; Désir *et al.*, 1982).

Shallow and fragmented sleep is usually associated with a dampening of the nocturnal prolactin elevation. This is indeed observed in the elderly who may have a nearly 50% dampening of the nocturnal prolactin elevation usually observed in young healthy individuals (Greenspan *et al.*, 1990; Van Coevorden *et al.*, 1991). As illustrated in **Fig. 7**, there is no advance shifting of the nocturnal elevation, reflecting the fact that this elevation is associated with sleep onset and is not dependent on the circadian clock.

Growth Hormone (GH)

Pituitary GH secretion is stimulated by hypothalamic GH-releasing hormone (GHRH) and by the acylated form of ghrelin (a peptide mainly produced by the stomach), and inhibited by somatostatin (Copinschi and Challet, 2016). In healthy young adults, the 24-h GH profile exhibits stable low levels abruptly interrupted by secretory pulses (**Fig. 8**). In baseline conditions, the most reproducible pulse occurs shortly after sleep onset, in temporal association with the first phase of SW sleep (Van Cauter et al., 1998b), but other secretory episodes may be observed in later sleep and during wakefulness. In young men, this sleep-onset GH pulse is consistently the largest secretory episode over the 24-h span (Van Cauter et al., 1998b), while in normally cycling women, larger daytime pulses are frequently observed, resulting in higher 24-h GH levels than in age-matched men (Ho *et al.*, 1987). Daytime GH secretion was found to be higher during the luteal phase than during the follicular phase in normally cycling women (Caufriez *et al.*, 2009).

Sleep onset is closely associated, temporally and quantitatively, with a GH secretory episode, even when sleep is delayed, advanced, interrupted or fragmented (Holl *et al.*, 1991; Van Cauter *et al.*, 1992; Gronfier *et al.*, 1996). Conversely, GH secretion is inhibited by transient awakenings (Holl *et al.*, 1991; Van Cauter *et al.*, 1992; Gronfier *et al.*, 1996). Thus, shifts of the sleep-wake cycle are immediately followed by concomitant shifts of the GH secretory profile (Van Cauter et al., 1998b).

The mechanisms underlying relationships between GH release and SW sleep probably involve synchronous activity of two or more different populations of GHRH neurons in the hypothalamus (Obal and Krueger, 2003). In animals, inhibition of endogenous GHRH secretion inhibits both sleep and GH secretion (Obal et al., 1988, 1996). In rodents, GHRH injections stimulate both GH secretion and non-REM sleep in intact as well as in hypophysectomized animals (Obal et al., 1988, 1996). In healthy young adults, GHRH injections during the sleep periods may stimulate both GH release and SW sleep (Kerkhofs *et al.*, 1993; Marshall *et al.*, 1996), while octreotide, a somatostatin analog, inhibits both GH release and SW sleep (Ziegenbein *et al.*, 2004). Furthermore, stimulation of SW sleep by oral administration of low doses of gamma-hydroxybutyrate (a natural metabolite of GABA used in the treatment of narcolepsy) or of ritanserin (a selective 5HT2 antagonist) results in concomitant and correlated elevations of nocturnal GH secretion (Gronfier *et al.*, 1996; Van Cauter *et al.*, 1997) and SW sleep.

Thus, the temporal organization of GH secretion is clearly primarily dependent on the sleep-wake cycle. However, there is also some evidence for a circadian modulation of the occurrence and the amplitude of GH secretory pulses. The amplitude of the sleep-onset GH pulse is maximal when the surge of hypothalamic GHRH is concomitant with a period of decreased somatostatin inhibitory activity, in the evening and during the night (Van Cauter et al., 1998b; Ocampo-Lim *et al.*, 1996).

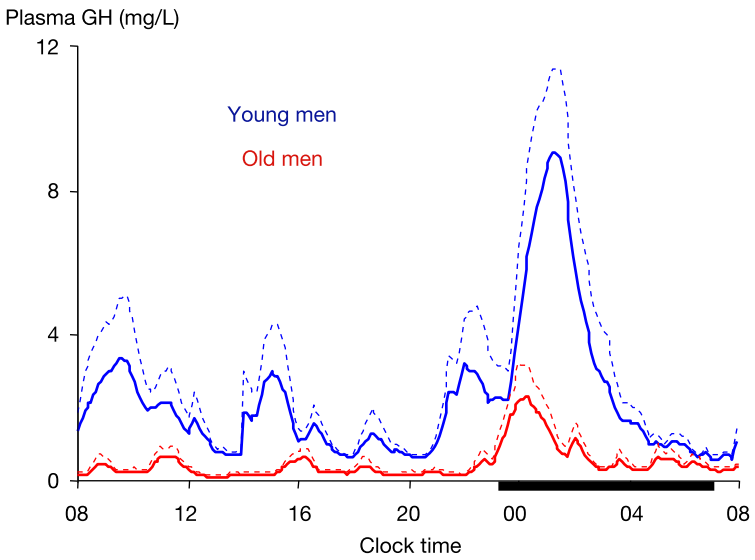

Fig. 8 Mean (+SEM) 24-h plasma GH profiles in eight healthy young men aged 17–24 years and in eight healthy old men aged 70–83 years matched for BMI. *Dashed lines* indicate SEM. The black bar represents the mean sleep period. Data from Van Cauter, E., Leproult, R. and Plat, L. (2000). Age-related changes in slow wave sleep and REM sleep and relationship with growth hormone and cortisol levels in healthy men. *JAMA* **284**, 861–868.

GH secretion is maximal during the pubertal spurt. Thereafter, a dramatic drop of GH production occurs in an exponential fashion between young adulthood and mid-age (Van Cauter *et al.*, 2000; Ho *et al.*, 1987). This decrease results from a reduction in amplitude, rather than in frequency, of secretory pulses (Van Coevorden *et al.*, 1991; Veldhuis *et al.*, 1995; Vermeulen, 1987). At mid-age (30–35 years), plasma GH levels fall to values below half the levels recorded in young adults despite the persistence of high levels of sex steroids. Twenty-four-hour plasma GH profiles in young and old healthy men are illustrated in **Fig. 8**. The age-related decline of GH secretion follows the same chronology as the decline of SW sleep (**Fig. 9**), and appears to be associated with these sleep alterations. Indeed, in a cross-sectional study performed to investigate the variance of sleep-associated GH secretion in relation to age and to SW sleep, it was shown that SW sleep and the interaction between age and SW sleep accounted for the largest part of the variance, while the effects of age per se were not significant (Van Cauter *et al.*, 2000). From midlife to old age, smaller progressive decrements of GH secretion occur (Van Cauter *et al.*, 2000), as shown in **Fig. 9**. In the elderly, 24-h GH profiles are largely similar in women and in men. IGF-I levels exhibit a progressive linear decrease from young adults to old age (Landin-Wilhelmsen and Wilhelmsen, 1994).

Gonadotropins and Sex Steroids

Men

Rhythms in the gonadotropic axis embrace a very wide range of frequencies, from ultradian pulsatile release to menstrual cycle. Interactions of these rhythms contribute to provide a sophisticated temporal system to organize the development of the reproductive axis and its operation at the different stages of maturation.

In young men, LH secretory pulses mainly reflect gonadotropin-releasing hormone (GnRH) pulsatility, and exhibit an important interindividual variability. During sleep, LH pulses appear to start preferentially during non-REM stages and to decrease during REM stages (Fehm *et al.*, 1991). Diurnal variations of LH levels over the 24-h span are of low amplitude or even undetectable. FSH profiles show occasional secretory pulses without any detectable diurnal variation. In contrast, a clear diurnal rhythm of testosterone levels is observed in healthy young men, with peaks in the early morning and troughs in late evening (Lejeune-Lenain *et al.*, 1987). Those diurnal testosterone variations are primarily dependent on the sleep-wake cycle, since daytime sleep, as well as nighttime sleep, is associated with significant elevations of circulating testosterone levels (Axelsson *et al.*, 2005). However, though dampened as compared with nocturnal sleep, a progressive increase in testosterone circulating levels persists during nocturnal wakefulness (Axelsson *et al.*, 2005), indicating the existence of a weak circadian component.

Aging is associated with a progressive decrease in circulating testosterone levels, by 1%–2% per year from 30 years of age onwards (Harman *et al.*, 2001; Kaufman and Vermeulen, 2005). This decline contrasts with a simultaneous increase in sex hormone binding globulin, so that the fall in bioavailable testosterone is more marked than the fall in total testosterone (Feldman *et al.*, 2002; Lejeune *et al.*, 2003; Yeap *et al.*, 2007; Lapauw *et al.*, 2008).

This decline in testosterone levels has a mixed etiology. On the one hand, primary functional alterations of testicular Leydig cells. On the other hand, altered neuroendocrine regulation of pituitary LH secretion (Kaufman and Vermeulen, 2005). In

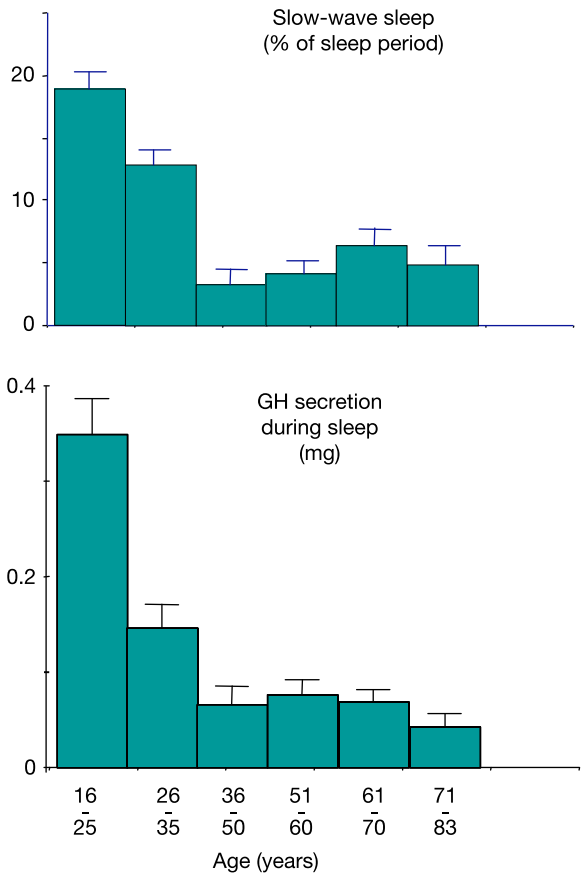

Fig. 9 SW sleep and GH secretion during sleep as a function of age in 149 healthy men, aged 16–83 years. Values shown are mean (+SEM) for each age group. Note the temporal concomitance between the decline in SW sleep and the decrease in GH secretion. Data from Van Cauter, E., Leproult, R. and Plat, L. (2000). Age-related changes in slow wave sleep and REM sleep and relationship with growth hormone and cortisol levels in healthy men. *JAMA* **284**, 861–868.

addition, the testosterone decline may also be modulated by age-related sleep disturbances. In older men, the duration of nocturnal sleep was found to be an independent predictor of morning free and total testosterone (Penev, 2007). Consistent with this finding, sleep restriction (5 h in bed per night for 1 week) was associated in young healthy men with significant decreases in daytime testosterone levels (Leproult and Van Cauter, 2011).

Animal studies indicate that the circadian rhythm of the Leydig cells endocrine function is attenuated in aged rats (Baburski *et al.*, 2016). Though dampened, the diurnal variation of circulating testosterone levels persists in older men (Bremner *et al.*, 1983; Tenover *et al.*, 1988), but LH diurnal variations are no longer detectable (Tenover *et al.*, 1988).

Women

In healthy adult menstruating women, no circadian rhythm of FSH and LH can be evidenced in constant routine conditions, indicating that the circadian pacemaker plays no role in their diurnal variations (Klingman *et al.*, 2011). Circulating FSH, LH, estradiol, and progesterone profiles show episodic pulses throughout the 24-h span (Backstrom *et al.*, 1982). Frequency and amplitude of gonadotropin pulses are modulated by estrogen levels and therefore vary markedly throughout the menstrual cycle (Filicori *et al.*, 1986; Caufriez *et al.*, 2011). In addition, they are also modulated by sleep. In early follicular phase, LH pulse frequency is diminished during nocturnal sleep as well as during daytime sleep, but not during nighttime wakefulness (Filicori *et al.*, 1986; Caufriez *et al.*, 2011; Hall *et al.*, 2005). During the sleep period, LH pulses preferentially occur in association with transient awakenings (Hall *et al.*, 2005). Therefore, sleep alterations (fragmentation and shortening of the sleep period) commonly observed in night and shift workers are likely to favor alterations of the menstrual function. Conversely, potential effects of the menstrual cycle on sleep architecture have also been evidenced. Awakenings are less frequent in the early luteal phase, when both estrogen and progesterone levels are increasing, and more frequent in late luteal phase when both hormones levels are decreasing.

Ovarian steroid secretions fall markedly at menopause. In postmenopausal women, estradiol, progesterone and testosterone circulating levels are very low, resulting in major gonadotropin elevations, principally of FSH. Gonadotropin levels and LH pulse frequency are already higher in normally cycling women beyond 40 years of age than in younger women (Reame *et al.*, 1996).

At the same time, postmenopausal women frequently complain of sleep problems, especially of more nocturnal transient awakenings. Awakenings may occur independently of vasomotor symptoms (hot flushes), but nocturnal flushes are consistently associated with concomitant awakenings (Freedman, 1998; Manber and Armitage, 1999; Moe, 2004). Hot flushes and concomitant sleep disruptions mostly occur around 04.00–05.00 h, that is, in temporal association with enhanced cortisol secretion, suggesting a possible involvement of the corticotropic axis. Both hot flushes and low inhibin B levels were found to be independent predictors of poor sleep quality (Pien *et al.*, 2008). Vasomotor symptoms were reported to be associated with increased cardiovascular risk (Gerber *et al.*, 2007; Gast *et al.*, 2008; Thurston et al., 2008, 2010, 2011; Bechlioulis *et al.*, 2010).

Studies in postmenopausal women concerning possible effects of hormonal replacement therapy on sleep quality have yielded inconsistent results, most likely because the protocol design varied widely from one study to another. In view of the fact that progesterone is also an active neurosteroid (Baulieu and Schumacher, 2000), it is of interest to note that oral administration of progesterone was found to restore normal sleep in postmenopausal women when sleep was disturbed by environmental conditions, improving both sleep duration and sleep quality with an increase in SW sleep (Caufriez *et al.*, 2011).

Glucose and Insulin

Glucose homeostasis is primarily dependent on the balance between glucose production by the liver and glucose consumption by insulin dependent tissues (such as muscle, adipose tissue) and noninsulin dependent tissues (such as brain). But in healthy subjects, glucose utilization varies throughout the 24-h span. In normal young subjects, fasting during daytime wakefulness is associated with a clear fall in circulating glucose levels. Conversely, during nocturnal sleep, glucose levels remain stable or decline only minimally despite relatively prolonged fasting. On the other hand, in case of prolonged fasting during nighttime wakefulness, glucose levels decrease, while they remain stable during daytime sleep, indicating that sleep associated mechanisms are operative to prevent inappropriate hypoglycemia (Van Cauter *et al.*, 1991).

Experimental investigations involving constant intravenous glucose infusion or constant enteral nutrition have shown that glucose tolerance deteriorates during the first part of nighttime sleep to reach a minimum around the middle of the night, and improves thereafter to progressively return to morning levels (Van Cauter *et al.*, 1991; Simon *et al.*, 1998; Scheen *et al.*, 1996). This sleep-associated decline in glucose tolerance results from a reduction in both peripheral and cerebral glucose utilization (Boyle *et al.*, 1994). Positron emission tomography studies have evidenced that during SW sleep (a dominant stage during the first half of the normal sleep period), cerebral glucose utilization is markedly lower than during REM sleep or during wake (Maquet, 1997, 2000). This is physiologically important since cerebral glucose utilization is estimated to represent at least 20% of total body glucose utilization (Defronzo, 2004; Magistretti, 2006). In addition, glucose uptake by insulin-dependent tissues is probably inhibited by the sleep-onset associated GH release (Moller *et al.*, 1990). It appears therefore that sleep-wake homeostasis exerts significant modulatory effects on glucose regulation.

Aging is associated with a decrease in both insulin secretion and insulin activity, resulting in a decrease in glucose tolerance (Chen *et al.*, 1985). Interestingly, following an intravenous glucose tolerance test (IVGTT), the magnitude of the reduction of glucose clearance rate in healthy older subjects beyond 65 years as compared with young controls, is fairly similar to the reduction

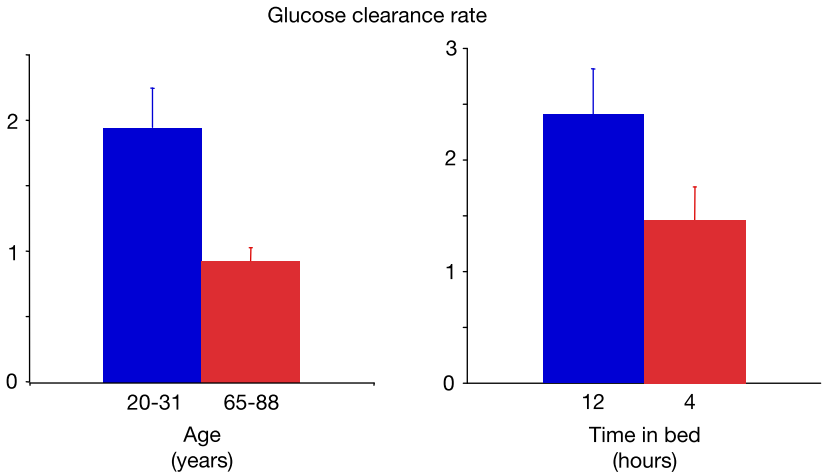

Fig. 10 *Left panel*: Glucose clearance rate following intravenous glucose injection (IVGTT) in 11 healthy old subjects (65–88 years) as compared to 11 healthy young subjects (20–31 years) (data from Palmer, J.P. and Ensinck, J.W. (1975). Acute-phase insulin secretion and glucose tolerance in young and aged normal men and diabetic patients. *The Journal of Clinical Endocrinology and Metabolism* **41**, 498–503); *right panel*: glucose clearance rate following intravenous glucose injection (IVGTT) in 11 healthy young subjects (18–27 years) in a sleep-debt condition as compared to fully rested condition (data from Spiegel, K., Leproult, R. and Van Cauter, E. (1999). Impact of sleep debt on metabolic and endocrine function. *Lancet* **354**, 1435–1439). Values shown are mean (+SEM). Note the similarity between the effects of aging and the effects of sleep restriction.

observed in healthy young subjects submitted to partial sleep restriction as compared to a fully rested condition (Spiegel *et al.*, 1999; Garcia *et al.*, 1997; Palmer and Ensinck, 1975), as illustrated in **Fig. 10**. Indeed, well-controlled laboratory studies have consistently shown that partial sleep deprivation for 1–7 days may result in increased insulin resistance (Spiegel et al., 1999, 2004, 2005; Buxton *et al.*, 2010). Prolonged (at least 6 months) voluntary sleep restriction was also shown to be associated with the development of insulin resistance (Mander *et al.*, 2001). Even alterations in sleep quality (all-night selective suppression of SW sleep), without reduction in total sleep duration, were found to induce a reduction in glucose tolerance (Tasali *et al.*, 2008). Moreover, these observations are consistent with data recorded in numerous epidemiologic studies showing that short sleep duration is significantly associated with an increased risk of developing diabetes (Knutson and Van Cauter, 2008). This bunch of data strongly suggests that sleep curtailment might accelerate age-associated alterations of glucose metabolism.

Conclusions

Though the respective roles of sleep and of the circadian clock in the regulation of endocrine function widely differ from one hormone to another, age-related sleep and endocrine-metabolic alterations frequently interact with each other. Most prominent age-related alterations of hormonal circadian rhythms are a phase-advance and a reduction in diurnal amplitude, which are likely to result from both a reduction in the strength of the circadian signal and a reduction in the homeostatic drive to sleep.

For a number of hormones, age-related alterations are strikingly similar to those observed in young healthy subjects submitted to sleep restriction. Thus, voluntary or not, recurrent sleep curtailment, currently experienced by an increasing number of children and adults, is likely to accelerate the senescence of endocrine and metabolic function.

Circadian Clock, Epigenetic Regulators (Sirtuins), and Metabolism

Mirella L Meyer-Ficca and Ralph G Meyer, Utah State University, Logan, UT, United States

Glossary

Amplitude Defines the magnitude of oscillation in a rhythmic process, which is often measured as differences between peak and trough values.

Chronobiology Research at the intersection of time and biology

Circadian entrainment Resetting process of biological rhythms to synchronize them to daily environmental cycles by external factors called zeitgebers (see below).

Circadian rhythm Rhythm of approximately 24 h in length (from Latin "circa" = about and "dies = day)

Free-running Endogenous period length that circadian rhythms assume in the absence of all zeitgebers.

Period length The time that passes between the same occurrences in a rhythmic process. For instance, if a patient's body temperature is lowest every day at 4:00 am, and highest every evening at 6:00 pm, then the period length is about 24 h.

Phase In a rhythm the phase is defined by timing of the recurrence of peak, trough (nadir), or onset of production (such as, e.g., melatonin).

Phase-shifting A change in timing of the circadian clock, which takes typically several days to complete, through entrainment by zeitgebers, such as during travel between time zones or when working night shifts.

Rhythm Biological measures or events that repeat themselves on a regular basis.

Zeitgeber: From German "time giver" Agents that provide circadian entrainment, such as daylight, feeding, physical activity or social cues.

Introduction

Probably based on the rotation of Earth, most lifeforms on our planet have developed daily rhythms that control many aspects of their lives. The "diurnal cycles" of the planet provide varying environmental conditions of light or temperature that may have led to the evolution of endogenous rhythms in cyanobacteria, plants and animals, probably as an adaptive advantage, that are called "circadian rhythms." These endogenous circadian rhythms are self-sustained and allow the animal to synchronize their daily routines to environmental cues such as a light/dark cycle of about 24 h. True circadian rhythms are formally defined by their endogenous nature, which makes them a special case among the other 24 h oscillations that occur in the lives of animals and plants and that are more dependent on environmental cues. Circadian rhythms therefore occur in an oscillating manner even in the absence of external stimuli, like an internal clockwork, but they are generally also adjustable. Environmental cues that occur repetitively, including, for example, light or temperature are called "zeitgeber(s)," which means "time giver" in German, because they are able to adjust ("entrain") circadian rhythms. The phenomenon can be appreciated when traveling between time zones and "jet lag" occurs until the personal "inner clock" is reset.

Much of our understanding of circadian clocks stems from research in Drosophila as a model organism. Because of the profound impact of circadian rhythms on human health, Drs. Michael W. Young, Jeffrey C. Hall and Michael Rosbash received the 2017 Nobel Prize in physiology or medicine for their groundbreaking discoveries in molecular chronobiology using fruit flies (Callaway and Ledford, 2017; Dibner and Schibler, 2017).

In mammals, the central circadian clock, which shares many similarities with the one in fruit flies at the molecular level, is located in the brain, where neurons of the hypothalamic suprachiasmatic nucleus (SCN) show synchronized oscillating transcription patterns that control behavior, as well as hormone levels and other central endocrine functions (Moore and Eichler, 1972; reviewed in Rusak and Zucker, 1979). Notably, many peripheral tissues such as the liver, kidney, and even individual cultured stem cells (Stringari *et al.*, 2015), also exhibit endogenous circadian rhythms that can continue entirely autonomously under isolated conditions. An important aspect of mammalian rhythmicity is that the central circadian clock in the SCN is able to entrain these peripheral clocks by providing endocrine cues, for example, in response to light/dark cycles that the SCN senses directly through the retinal-hypothalamic tract. Peripheral circadian clocks are also modulated by tissue-specific and environmental cues, like food intake, which may put them out of synchrony with the central circadian clock. Abnormal circadian rhythms in humans are known as "circadian rhythm disorders" (Bass, 2012; Vitaterna *et al.*, 2001), which will be discussed in the last section of this article.

Molecular Structure of the Core Mammalian Circadian Clock

At the molecular level, the clock machinery is present in almost all cell types where it regulates expression of at least 10% of all transcribed genes (Rosbash *et al.*, 2007). The central mechanism of the Circadian Clock system consists of positive and negative

 doi:10.1016/B978-0-12-801238-3.65831-2

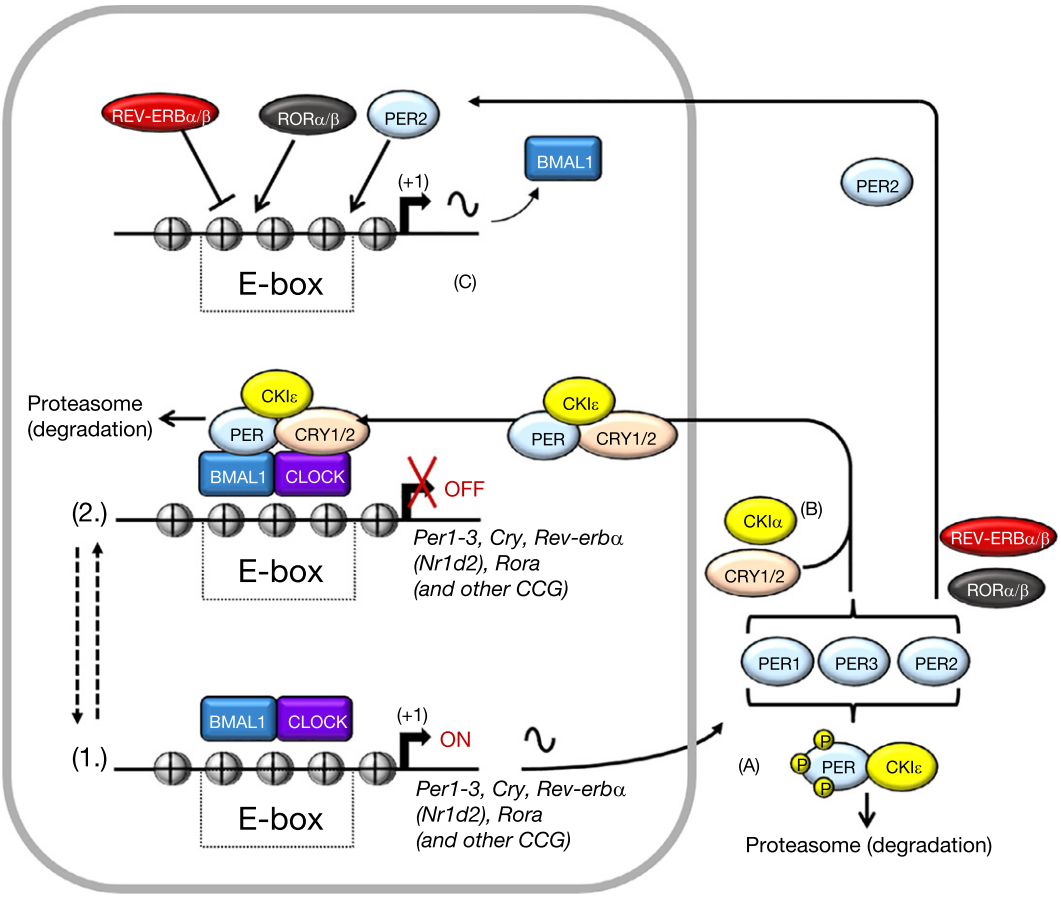

Fig. 1 Molecular architecture of the core circadian clock. Step 1. CLOCK and BMAL1 form a complex that binds to an *E*-box motif in a target gene, which activates it. Transcription and translation of the newly expressed proteins PER1–3 and CRY1/2 places them in the cytoplasm, where they are immediately phosphorylated by CKIε, which marks them for proteasomal degradation (A). Once their concentration becomes high enough, PER and CRY proteins form stable heterodimers, and enter the nucleus in a complex with CKIε (B). When PER/CRY complexes bind to BMAL1/CLOCK, the gene activating activity of BMAL1/CLOCK is inhibited (2.). Parallel pathways exist in the form of REV-ERBα/*β*-, PER2- and RORα/*γ*-dependent regulation of BMAL1 expression (C), which provides additional stability to the rhythmicity of this oscillating negative/positive transcriptional feedback cycle. Steps (1.) and (2.) together occur with a slightly longer interval of approximately 24 h. Note that in addition to these protein components of the core circadian clock listed in the figure many other genes, including many that are involved in metabolism, are (co-) regulated by these transcriptional oscillations due to the presence of E-box motives in their promoter regions.

transcriptional–translational feedback loops that are conserved across mammals (**Fig. 1**, reviewed in Song and Rogulja, 2017). The binding of two transcription factors, BMAL1 (brain and muscle ARNT-like protein 1, also known as ARNTL, aryl hydrocarbon receptor nuclear translocator like) and CLOCK (Circadian Locomotor Output Cycles Kaput), positively regulate expression of a large number of "circadian clock genes (CCG)" by binding to *E*-box elements in promoters of certain genes. Among the products of the CCG genes are repressor proteins that in turn suppress expression initiated by BMAL1 and CLOCK, thereby providing a negative feedback loop. These negative regulators include two cryptochromes (CRY1, CRY2) and three period proteins (PER1–3) in mammals. PER and CRY proteins form stable homo- and heterodimers in the cytoplasm in a concentration-dependent manner. If the concentration of PER protein is too low to form heterodimers with CRY, PERs are phosphorylated by the casein kinase CKI epsilon (CK1ε) (Eide *et al.*, 2005; Lowrey *et al.*, 2000), which triggers proteasomal degradation of PER. Once PER protein expression reaches sufficient levels and stable PER/CRY heterodimers can be formed, they enter the nucleus in a complex with CK1ε and bind to BMAL1 and CLOCK, which inhibits their gene activating function. By blocking their own expression, the concentration of the negative factor proteins declines over time due to their continuously ongoing degradation because no new copies of the proteins are expressed. This depletes PER and CRY levels to a point where BMAL1 and CLOCK are no longer inhibited (Rosbash and Hall, 1989). The degradation of PER and CRY proteins therefore sets the time interval until their transcription will commence again. The quintessential result is that PER and CRY protein levels oscillate in a circadian fashion, along with numerous other CCG output genes. In contrast to PER and CRY proteins, CLOCK levels are relatively constant. BMAL1 expression on the other hands oscillates as well because its expression is negatively regulated by REV-ERBα and REV-ERB*β* (Cho *et al.*, 2012; Preitner *et al.*, 2002) but positively regulated by PER2, RORα and ROR*γ* (RAR related orphan receptors *α*, *γ*). All of those are CCG products expressed under the control of CLOCK and BMAL1, which results in an overall oscillation of BMAL1 expression. RORα/*γ* bind to a

specific response element termed RORE that is present in many promoters that also have *E*-boxes (Sato *et al.*, 2004). REV-ERBα and REV-ERBβ also bind to RORE to antagonize RORα/γ-dependent gene activation. This results in a negative feedback loop that works in parallel with the PER/CRY negative feedback loop to regulate a large number of circadian clock genes along with regulating BMAL1 expression (Cho *et al.*, 2012; Stratmann and Schibler, 2012).

Molecular Mechanisms Linking Metabolism With the Circadian Clock (Food Entrainment)

The discovery that individual cultured fibroblasts exhibit serum-induced, self-sustaining circadian oscillations consistent with a circadian clock demonstrated that peripheral clocks can function autonomously (Balsalobre *et al.*, 1998). That begged the question to what extent the activities of the clocks in the brain and the peripheral tissues are coordinated and how much they are independent of each other. The central circadian clock located in the brain is regulated by light and controls the rhythmic neuroendocrine release of circulating factors known to be important general regulators of body functions, such as thyroid stimulating hormone (TSH), triiodothyronine (T3), thyroxine (T4) (Allan and Czeisler, 1994; Amir and Robinson, 2006), or glucocorticoids (Balsalobre *et al.*, 2000; Dickmeis *et al.*, 2013). While these and other secretory factors are important for entraining circadian rhythms in many peripheral clockworks, for many peripheral organs feeding-fasting rhythms are the dominant zeitgebers (Damiola *et al.*, 2000; Stokkan *et al.*, 2001). Available evidence now shows that peripheral circadian oscillators like those of the liver may be coupled to the master circadian clock in the brain primarily through rhythmic behavior, such as feeding (Stokkan *et al.*, 2001). It is not yet completely understood how feeding cycles can entrain the liver and other peripheral organs independently of the master clock in the SCN and the light cycle. Several emerging mechanisms have been identified as discussed below.

Genetic Regulation of Metabolism by Circadian Clock-Controlled Genes

The repression of BMAL1 expression by the PER/CRY negative feedback loop is counteracted by RORα/γ and another nuclear receptor protein, PPARα (peroxisome proliferator-activated receptor alpha). Genome-wide analyses of RORα/γ, PPARα and REV-ERBα/β binding sites showed that these transcription factors cooperate to regulate many CCG, including many metabolic genes (Canaple *et al.*, 2006; Lemberger *et al.*, 1996; Sato *et al.*, 2004). Similarly, analyses of the binding activity of core clock components BMAL1, CLOCK, PER1/2, and CRY1/2 showed that these transcription factors are enriched in the promoters of genes involved in metabolism, which further supports the view that metabolism is in part directly controlled by the circadian clock (Bugge *et al.*, 2012; Cho *et al.*, 2012; Koike *et al.*, 2012; Rey *et al.*, 2011). In addition, the transcriptional coactivator PGC1α, a major metabolic regulator, stimulates transcription of BMAL1 and of the proteins REV-ERBα and β by promoting the activity of RORα/γ (Liu *et al.*, 2007). Another example is the regulation of cholesterol biosynthesis by the genetic regulation of the rate-limiting enzyme HMGCoA reductase (HMGCR) by BMAL1 and REV-ERBα, in concert with other transcription factors that are also involved in cellular sterol sensing (Cho *et al.*, 2012; Koike *et al.*, 2012; Sancar and Brunner, 2014). Expression of HMGCR follows a strict circadian rhythm and peaks at night (Edwards *et al.*, 1972).

Similar to cholesterol synthesis, gluconeogenesis follows a circadian rhythm through the clock-mediated regulation of behaviors like feeding and fasting (Kida *et al.*, 1980). During fasting, enhanced gluconeogenesis ensures the maintenance of blood glucose levels. Low food intake stimulates release of the hormone glucagon, which in turn activates a heterotrimeric G protein to increase cellular cAMP synthesis by adenylyl cyclase in target tissues. The elevated cAMP levels activate PKA (protein kinase A) to phosphorylate, and hence activate, the transcription factor CREB (cAMP regulatory element binding transcription factor). CREB positively regulates expression of genes that code key enzymes in gluconeogenesis, like PCK1 and others. CREB activity during fasting is modulated by CRY1 and CRY2, which are rhythmically expressed in the liver. Elevated CRY1 expression during the night–day transition reduced fasting gluconeogenic gene expression by blocking glucagon-mediated increases in intracellular cAMP concentrations and in the protein kinase A-mediated phosphorylation of CREB (Zhang *et al.*, 2010; reviewed in Jitrapakdee, 2012). In mice, a liver-specific variant, CREBH regulates circadian expression of the key genes involved in hepatic triglyceride (TG) and fatty acid (FA) metabolism and is required to maintain circadian amplitudes of blood TG and FA (Zheng *et al.*, 2016). In addition, CRY proteins interact with the glucocorticoid receptor and thus inhibit its transcriptional activation of target genes involved in gluconeogenesis during the day when CRY1/2 levels are high. Specifically, CRY1/2 inhibit the glucocorticoid-stimulated expression of PCK1, the rate-limiting enzyme of gluconeogenesis, which therefore results in the circadian oscillation of blood glucose levels (Kalsbeek *et al.*, 2014; Lamia *et al.*, 2011). In summary, there is substantial evidence that metabolic genes are at least in part controlled by oscillations of circadian clock genes. As an example supporting the theory that peripheral circadian clocks may also be involved in cell differentiation, studies in mice have shown that the peripheral circadian clock in adipose tissue regulates the differentiation of adipocyte precursor cells. The deletion of *Per3* promotes adipogenesis in vivo in which PER3 and BMAL1 directly regulate expression of the master transcription factor Krüppel-like factor 15 (KLF15), a developmentally relevant regulator of adipogenesis (Aggarwal *et al.*, 2017).

Food Entrainment: Epigenetic Regulation of Metabolic Genes Controlled by the Circadian Clock

The circadian oscillation of REV-ERBα expression, which in rats leads to high levels of REV-ERBα protein when the animals rest during the day, is coupled to the expression of genes involved in lipogenesis. When REV-ERBα levels are high, it recruits NCoR1 (nuclear receptor corepressor 1), which strongly interacts with the histone deacetylase HDAC3, to RORE to form a repressive protein complex that shuts down lipogenic gene expression by removing gene activating histone acetylation marks (Feng *et al.*, 2011). When the levels of REV-ERBα decline and the animals enter their daily phase of physical activity at night, the repressive NCOR1/HDAC3/REV-ERBα complex is no longer present and new histone acetylation activates transcription of genes needed for lipogenesis (Feng *et al.*, 2011).

AMP/ATP ratio

The nutrient-responsive adenosine monophosphate-activated protein kinase (AMPK) phosphorylates and destabilizes CRY1/2 proteins, which provides another mechanism how metabolic cycles in the liver interact with the circadian clock (Lamia *et al.*, 2009; Suter and Schibler, 2009). AMPK acts as a cellular energy sensor that is conserved in eukaryotic cells. Its kinase activity is activated by stimuli that increase the cellular AMP/ATP ratio. AMPK-mediated phosphorylation of CRY1 and CRY2 stimulates their interaction with the protein FBXL3 (F-Box and Leucine Rich Repeat Protein 3). FBXL3 targets Skp-Cullin-F-box (SCF) E3 ligases to them, which mediate the degradation of phosphorylated proteins, in this case phosphorylated CRY1 and CRY2 (Ho *et al.*, 2006; Jordan and Lamia, 2013; Lamia *et al.*, 2009). AMPK can also phosphorylate CK1ε, which enhances the activity of the casein kinase I to phosphorylate CRY1/2 proteins, which in turns triggers their degradation (Um *et al.*, 2007).

NAD^+/NADH

Nicotinamide adenine dinucleotide (NAD) could act as a signal of nutrition intake because humans depend on vitamin B3 as a source for NAD synthesis. The vitamin B3 group ("niacin") includes nicotinic acid, nicotinamide and nicotinamide riboside, which all serve as dietary precursors for NAD synthesis via the Preiss–Handler pathway (Meyer-Ficca and Kirkland, 2016). NAD^+ and the reduced form NADH are essential coenzymes for redox reactions in central metabolic processes, including the Krebs cycle, glycolysis, fatty acid oxidation, gluconeogenesis, and fat and steroid synthesis. In addition, NAD^+ also serves as substrate for various enzymes, including sirtuins and ADP-ribose transferases. Sirtuins are class III NAD-dependent histone deacetylases regulating metabolic function, longevity and aging (for recent reviews, see, e.g., Imai and Guarente, 2016; O'Callaghan and Vassilopoulos, 2017).

Cellular NAD levels oscillate in a circadian rhythm in the liver and body-wide, which is at least in part food intake dependent. NAD levels are also determined in part by the rhythmic expression of nicotinamide phosphoribosyltransferase (NAMPT) under control of the circadian clock (Ramsey *et al.*, 2009) (**Fig. 2**). NAMPT is the rate-limiting enzyme that converts nicotinamide to nicotinamide mononucleotide in the NAD biosynthetic pathway from nicotinamide in mammals (Revollo *et al.*, 2004, 2007). How exactly NAD provides cues to entrain the circadian system is still not clear. However, a number of molecular mechanisms have been identified that demonstrate a strong regulatory role of NAD in circadian clock-controlled expression of metabolic genes (Nakahata *et al.*, 2008; Tahara and Shibata, 2013).

First clues to this were provided by the discovery that CLOCK has histone acetyl transferase properties (Doi *et al.*, 2006). CLOCK directs acetylation of histone H3 and of its dimerization partner BMAL1 at Lys537, an event essential for circadian function (Nakahata *et al.*, 2008), as well as acetylating PER proteins (Asher *et al.*, 2008) (**Fig. 2**). These acetylation marks are removed by the histone deacetylase (HDAC) activity of the NAD^+-dependent SIRT1 enzyme in a circadian manner, resulting in a rhythmic acetylation and deacetylation of BMAL1 and H3 (at H3K9 and H3K14 lysine residues) at circadian promoters. SIRT1 binds in a timed fashion to the CLOCK/BMAL1 chromatin complex at circadian promoters where it deacetylates BMAL1 and PER, which leads to targeting of PER for proteasomal degradation (Asher *et al.*, 2008). Acetylated H3 provides an open chromatin conformation conducive to active transcription from a promoter site. Additional and concurrent methylation of H3K4 by the histone methyltransferase MLL1 enhances the open chromatin state, attracts binding of the CLOCK/BMAL1 complex and provides a submissive epigenetic state of circadian gene promoters (Aguilar-Arnal *et al.*, 2015; Katada and Sassone-Corsi, 2010). To reverse the periodic activation of clock promoters, SIRT1, and likely SIRT6 (Masri *et al.*, 2014) deacetylate MLL1, which needs to be acetylated by CLOCK in positions K1130 and K1133 to be active. SIRT1 and SIRT6 deacetylation of H3 also promotes a closed chromatin conformation and silencing of the promoters. According to this model, high concentrations of NAD therefore activate SIRT1 when energy (i.e., NAD) levels are high to shut down metabolic genes that are involved in the generation of energy. On the same note, increasing concentrations of nicotinamide, which is one of the two products of the NAD-dependent SIRT1 reaction and the substrate of NAMPT, is an indicator of low cellular energy status and a specific inhibitor of SIRT1. Taken together, the available data show that SIRT1 functions as an enzymatic rheostat of circadian function by transducing signals that originate from cellular metabolites to the circadian clock (Nakahata *et al.*, 2008).

Poly(ADP-ribosyl)ation by PARP1

Chromatin modulation by histone acetylation and methylation by CLOCK, SIRT1 and MLL1 obviously provides an important epigenetic mechanism of circadian clock transcriptional control. Similar to SIRT1, poly(ADP-ribose) polymerase (PARP) enzymes are another group of epigenetic modulators whose activity depends on cellular levels of NAD^+. PARPs cleave NAD^+ into nicotinamide, which is recycled through the NAD salvage pathway via NAMPT, and ADP-ribose, which is polymerized to poly

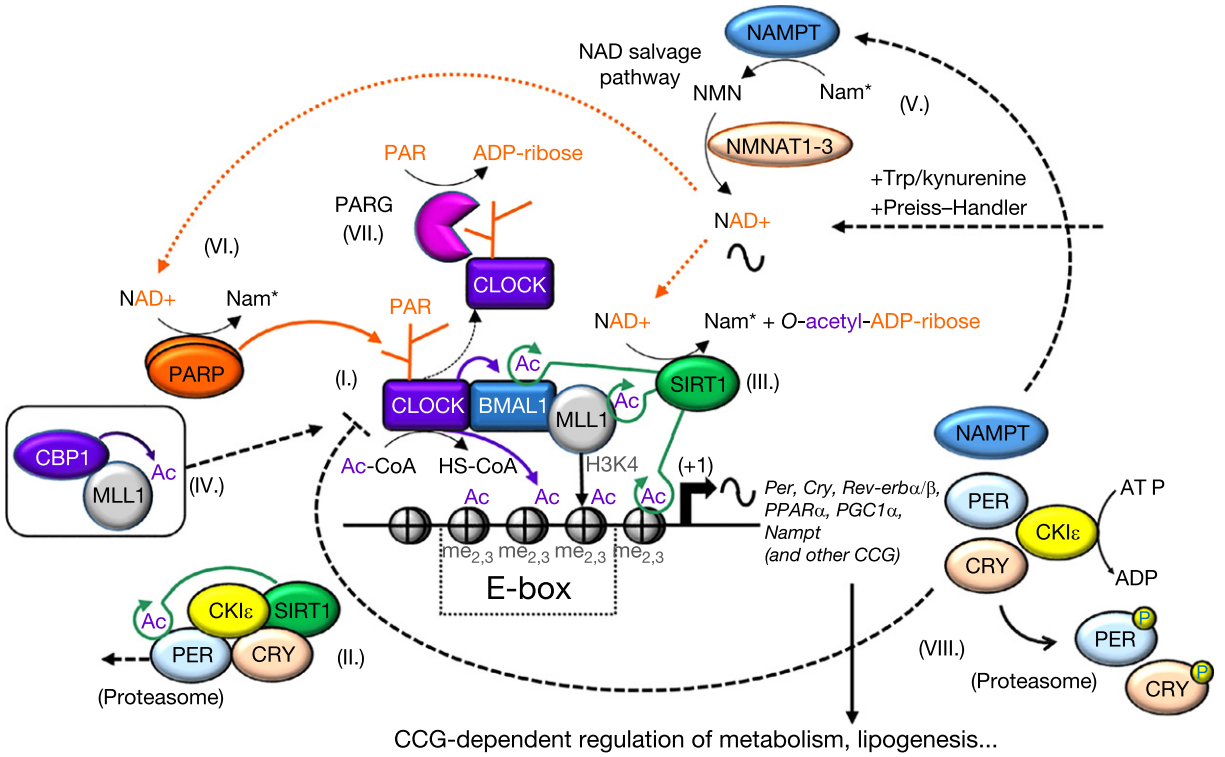

Fig. 2 NAD-dependent regulation and/or entrainment of SIRT1- and PARP1/2-mediated regulation of circadian genes involved in energy metabolism. (I.) CLOCK and BMAL1 bind to an E-box motif and CLOCK acetylates H3K9/K14 in the promoter region to activate transcription of target genes including Nampt, which encodes nicotinamide phosphotransferase (increases NAD synthesis). CLOCK also acetylates BMAL1, which later recruits PER and CRY proteins to form a repressive complex to inhibit promoter activity (see also **Fig. 1**), where PER proteins are stabilized by acetylation (II.). The NAD-dependent SIRT1 then deacetylates H3 (III.), which leads to deactivation of the promoter. SIRT1 also deacetylates BMAL1 and PER proteins (III.). This leads to degradation of PER proteins (II.). The promoter remains inactive until CLOCK/BMAL1 bind to the promoter and activate it again. The box to the left (IV.) shows MLL1 acetylation by CBP1, which activates the H3K4 di- and tri-methylating property of MLL1. H3K4me2/3 is a gene activating epigenetic mark. Collectively, if NAD concentrations are high due to feeding, NAMPT expression and resulting increased NAD levels (V.), SIRT1 activation leads to deacetylation and inactivation of MLL1, BMAL1 and H3K9/K14 (III.), which contributes collectively to silencing of the metabolic gene(s) in response to peaking cellular energy (i.e., NAD) levels. High NAD levels also activate PARP1 and PARP2 (VI.) to poly(ADP-ribosyl)ate (PAR) CLOCK, which in turn reduces its affinity to DNA and physically removes CLOCK from the promoter, stopping gene activation by the BMAL1/CLOCK complex. Poly(ADP-ribose) glycohydrolase (PARG) removes poly(ADP-ribose) from CLOCK, allowing the transcription factor to bind to the E-box motif again (VII.). The depicted CKIε-dependent phosphorylation of PER and CRY proteins (VIII.), which targets these proteins for degradation until a sufficient amount of PER and CRY proteins has been accumulated to enter the nucleus and inactivate the BMAL1/CLOCK complex, is ATP-dependent, potentially providing an additional link of circadian gene expression with cellular energy status.

(ADP-ribose) (PAR) and attached to target proteins as a large posttranslational modification ("PARylation," for reviews see Gupte *et al.*, 2017; Meyer-Ficca *et al.*, 2005). PAR carries a strong electronegative charge, which reduces the interaction of proteins with other peptides, DNA or RNA. PARylation of histones, particularly histone H1, results in an immediate and transient opening of chromatin (decondensation), which is an important requirement for DNA repair, DNA replication and transcription. PARP1 and PARP2, the two major nuclear PARP enzymes, are therefore important NAD-dependent enzymes with widespread functions in chromatin remodeling processes. PARP1/2 are enzymatically inactive until they become activated by either binding to DNA strand breaks, for example, during base excision repair, or by their posttranslational modification. PARP enzymes are, for example, phosphorylated, acetylated, methylated and ADP-ribosylated in accord with their diverse functions, which are mediated by several biochemical pathways (reviewed in Piao *et al.*, 2018). As seen for SIRT1, nicotinamide inhibits PARP enzymes and PARP activity is dependent on the availability of NAD^+. The finding that liver PARP1 activity oscillates with a circadian rhythm and is regulated by feeding suggested a role of the enzyme in regulating the circadian clock.

PARP1 binds to CLOCK-BMAL1 heterodimers and poly(ADP-ribosyl)ates CLOCK in a daily manner. Poly(ADP-ribosyl)ation of CLOCK modulates the DNA-binding activity of CLOCK/BMAL1 and its interaction with components of the negative limb, the PER and CRY proteins, which in turn alters circadian gene expression. PARylated CLOCK leaves the complex and no longer binds to the *E*-box sequence in promoters until a PAR glycohydrolase (PARG) degrades CLOCK's PAR modification to free ADP-ribose monomers. Free monomeric ADP-ribose is subsequently hydrolyzed by ADP-ribases, which are pyrophosphatase-type enzymes, to AMP and ribose-5-phosphate, which enters into sugar metabolism. Removal of PAR from CLOCK therefore quickly restores

CLOCK functions. Remarkably, the entrainment of liver clocks to inverted feeding, that is, feeding at a time when mice would normally be resting instead of feeding, is significantly delayed in the absence of PARP1 in PARP1 KO mice (Asher *et al.*, 2010) (see **Fig. 2**). The resetting of the circadian phase of the liver clock induced by restricted feeding is also delayed in PARP1 KO mice (Asher *et al.*, 2010). Hence, PARP1 might be involved in food entrainment of peripheral organs by transmitting the feeding signal to the circadian clock. Poly(ADP-ribose) modifications synthesized by PARPs are degraded by poly(ADP-ribose) glycohydrolases (PARG). In the plant *Arabidopsis thaliana*, a mutation in the tej gene encoding a poly(ADP-ribose) glycohydrolase lengthens the period of the circadian clock (Panda *et al.*, 2002). The long-period phenotype can be rescued by a PARP inhibitor, suggesting a role of the PARylation in the plant circadian clock although target protein(s) have not yet been identified.

In summary, PARP1-mediated modulation of the circadian clock is dependent on feeding and NAD^+ levels, thereby providing a circadian integration of metabolism and energetics (Bass and Takahashi, 2010; Nakahata and Bessho, 2016).

Pathologies Associated With CLOCK Desynchrony

Circadian rhythms have evolved to orchestrate metabolism with the energy requirements of animals, including humans, throughout the day when feeding and fasting cycles alternate during the daily routine. Circadian organization of metabolism likely offers the evolutionary advantage of being able to separate catabolic and anabolic processes in synchrony with activity and resting periods to optimize metabolic efficiency and maximize fitness (Gerhart-Hines and Lazar, 2015; Panda, 2016; Poggiogalle *et al.*, 2017). The underlying clockwork regulates thousands of genes, which makes it the largest regulatory network in normal physiology (Poggiogalle *et al.*, 2017). The central clock regulates circadian feeding and resting behavior in synchrony with light/dark cycles, but data from laboratory animal research have provided overwhelming evidence that the peripheral clocks are entrained by feeding and other cues to harmonize metabolism with the daily routine provided by the central master clock (reviewed in Tahara and Shibata, 2017). Of clinical interest is what happens when the balance of each clock is perturbed or when the central clock is not in synchrony with the peripheral ones.

When traveling between different time zones, one may experience the profound impact the central circadian clock has on human physiology in the form of "jet lag." The problem persists until our circadian clock has been reset to the local 24 h light/dark cycle, which speaks to the ability of all circadian clocks to be entrained by external stimuli. Unfortunately, modern human life is not necessarily still well suited for natural entrainment of circadian clocks to stay synchronized, as was the case when the fine-balanced system of circadian oscillations developed. There are artificial light, heating and cooling that keep environmental conditions constant, shift work, prevalence of a sedentary life style, as well as cheap, calorie-dense food that is available around the clock. Regular entrainment clues by the environment are upset or missing, which may have been contributing to the dramatic increase in "civilization diseases" we are currently experiencing.

The number of proteins and metabolites that are dependent on circadian rhythms is vast, and so is the number of pathological effects that can result from circadian misalignment. Forced desynchrony experimentation in rodents and humans has revealed cardiometabolic, immunological and neuronal dysfunction and other clinically potentially highly relevant effects, because physiological function, disease phenotypes and clinical pharmacokinetics and pharmacodynamics all vary by the time of day. The multitude of measurements and biochemical observations has recently led to the initiation of comprehensive approaches. These approaches intend to capture genetic and epigenetic effects of circadian clock misalignment on proteomics, metabolomics and cardiovascular physiology as well as other body functions in an attempt to characterize the human "chronobiome" (Castro *et al.*, 2015; Curtis *et al.*, 2007; Dallmann *et al.*, 2012; Feng and Lazar, 2012; Lowrey and Takahashi, 2004; Mauvoisin *et al.*, 2014; Skarke *et al.*, 2017).

Because circadian rhythms regulate so many rate-limiting steps in fatty acid and cholesterol synthesis (Feng *et al.*, 2011; Sitaula *et al.*, 2017) and hepatic gluconeogenesis (Zhang *et al.*, 2010), an array of metabolic processes – including insulin sensitivity, insulin secretion, cholesterol synthesis, fat oxidation, and energy expenditure – all follow a rhythm across the 24-h day (Li *et al.*, 2012). Data therefore increasingly suggest that disruption of the circadian system increases the risk of metabolic diseases (Baron and Reid, 2014; Gerhart-Hines and Lazar, 2015). In summary, when the external rhythms are out-of-sync with endogenous circadian rhythms, such as through exposure to bright light at night, sleeping during the daytime, or eating at night, several aspects of normal metabolism are expected to be impaired (Poggiogalle *et al.*, 2017).

The following section is intended to provide a nonexhaustive overview of the most robustly observed pathological effects of such circadian clock misalignments or defects. Current research continues to identify additional health risks of desynchronized circadian rhythms that are too numerous and preliminary to be discussed in detail here.

Obesity and Metabolic Syndrome

Time-of-day-dependent variations in the hormonal and metabolic responses to food are well established (Morgan *et al.*, 1998). Shift workers are at a higher risk of cardiovascular disease and of becoming obese and are more likely to present with other signs of metabolic syndrome, probably due to inappropriate timing of food consumption (reviewed in Guerrero-Vargas *et al.*, 2018). Studies of nighttime food consumption by simulated night-shift workers showed a postprandial persistence of relative lipid intolerance throughout the night (Al-Naimi *et al.*, 2004). Similarly, only four consecutive days of simulated shift work were sufficient to reduce insulin sensitivity and glucose metabolism in healthy subjects, which would be expected to increase the risk of

type 2 diabetes (Bescos *et al.*, 2018). These results and other available data provide consistent evidence that the consumption of food during the circadian evening and/or night, independent of more traditional risk factors such as amount or content of food intake and activity level, plays an important role in body composition (Albrecht, 2017; Engin, 2017; Hutchison *et al.*, 2017; McHill *et al.*, 2017; Plano *et al.*, 2017). Restriction of dietary food intake throughout the night may therefore be beneficial in night-shift workers who are not adapted to nighttime working (Al-Naimi *et al.*, 2004; Bescos *et al.*, 2018). A possible strategy to prevent the adverse health effects of night work may also include bright light phototherapy to facilitate rapid resetting of the peripheral clocks (Cuesta *et al.*, 2017; Danilenko *et al.*, 2013). In a similar vein, childhood obesity may be caused by social jetlag, that is, the discrepancy between an individual's circadian clock and social rhythms, and is measured as the difference in hours between the midpoint of sleep during work/school days and on free (weekend) days (Stoner *et al.*, 2018). Obesity is also a symptom of the night eating syndrome (NES), which is characterized by evening hyperphagia and frequent awakenings accompanied by food intake. Patients with NES display a delayed circadian pattern of food intake but retain a normal sleep–wake cycle. Phototherapy has also been suggested for the treatment of NES (Goel *et al.*, 2009).

Obesity and the metabolic syndrome entail numerous forms of detrimental impact on the cardiovascular system that are secondary to the misalignment of circadian clocks. In addition, the kidney, brain, nervous system, vasculature, and heart have all been identified through the study of mouse models and through clinical trials as peripheral clock regulators of blood pressure. The dysregulation of this circadian pattern of blood pressure, with or without hypertension, is associated with increased risk for cardiovascular disease (Douma and Gumz, 2017) and misalignment with the external light environment has been shown to potentially drive cardiac dysfunction (West *et al.*, 2017).

Sleep Disorders

Melatonin is a pineal hormone that is synthesized from serotonin and that is released in a circadian rhythm in response to the 24 h daylight rhythm. During the day, melatonin levels are negligible but at the onset of night, around 10:00 pm in normal individuals, melatonin is released and serves as a time cue to various organs. This includes the SCN itself and in the absence of light melatonin release may entrain the sleep–wake and neuroendocrine systems to the 24 h cycle (Zisapel, 2018). Melatonin levels peak between 2:00 am and 4:00 am before they return to very low daytime levels around 5:00 am. Melatonin levels in saliva and melatonin metabolites in urine have traditionally been used to monitor melatonin release in circadian rhythm research (reviewed in Pevet *et al.*, 2017). This daily synchronization process generally poses no problems for sighted individuals except when jetlag or working night shifts cause conditions of circadian desynchrony. The role of chronobiology in sleep disorders has long been known in this context (Monk and Welsh, 2003). In contrast, totally blind subjects with no light perception are more susceptible to periodical circadian desynchrony. These patients experience periodic or cyclical episodes of poor sleep and daytime dysfunction, which is a free-running disorder, also known as "Non-24 Sleep-Wake Rhythm Disorder" that can be confirmed clinically by measurements of circadian biomarkers such as urinary melatonin to demonstrate a circadian period outside the normal range. Management approaches include behavioral modification and pharmacological treatment using hypnotics, or alternatively, timed melatonin administration, which has shown promising results (Quera Salva *et al.*, 2017). There is a well-documented negative impact of light exposure during the night, even when the light was dim, on human circadian rhythm (reviewed in Monk and Welsh, 2003), which again emphasizes the power of environmental light as a zeitgeber. Along the same line, timed daytime exposure to bright light was found to help with realigning circadian peripheral clocks and to improve circadian melatonin release in individuals with sleep disorders and personnel working at Arctic and Antarctic latitudes (Mishima *et al.*, 2001; Park and Tokura, 1999; Takasu *et al.*, 2006; Arendt, 2012; Fukushige *et al.*, 2014; Albreiki *et al.*, 2017).

Cancer

There is overwhelming evidence that disruption of the circadian rhythm is associated with a 50%–100% higher risk of breast cancer in female night time workers such as nurses (reviewed in Touitou *et al.*, 2017). The precise mechanisms are unclear but the inhibited night time secretion of melatonin, which was shown to suppress breast cancer development, likely has an important role (Tamarkin *et al.*, 1981). In addition to its role for maintaining the 24-h circadian rhythms, melatonin also is a powerful antioxidant as a result of its ability to scavenge free radicals and to activate antioxidative enzymes such as glutathione peroxidase, glutathione reductase, superoxide dismutase, and catalase, explaining its cancer suppressing properties (for review, see, e.g., Mediavilla *et al.*, 2010; Zhou *et al.*, 2015). Other functions of melatonin in the prevention of breast cancer may include its interactions with the estrogen signaling pathways. These include (a) an indirect neuroendocrine mechanism where melatonin downregulates the hypothalamic–pituitary reproductive axis and consequently reduces levels of circulating gonadal estrogens and (b) direct melatonin actions at a tumor cell level where it directly interferes with the activation of the estrogen receptor (Cos *et al.*, 2006).

Links between other forms of cancer, including prostate cancer with desynchronization of circadian rhythms have been suggested (Lamia, 2017) but, although the concept is intriguing, available evidence is currently still too scarce to determine whether or not causal links exists (Touitou *et al.*, 2017; Wendeu-Foyet and Menegaux, 2017).

Somatotropic Axis in Human Aging

Sabrina Chiloiro, Antonio Bianchi, Antonella Giampietro, and Laura De Marinis, Pituitary Unit, Catholic University of Sacred Heart, Rome, Italy

The Physiology of Somatotropic Axis in Human Aging

The Somatotropic Axis

Growth hormone (GH), insulin-like growth factor I (IGF-I), insulin and their receptors interacts with a major impact on aging and longevity (Bartke *et al.*, 2013). GH is secreted by the anterior pituitary gland and positively regulated by growth hormone releasing hormone (RHGH), ghrelin, and some proteins. Instead GH secretion is negative regulated by IGF-I (though a negative feedback), somatostatin and other neuroendocrine hormones, as insulin (Ceda *et al.*, 1985) (**Fig. 1**). At least, GH and insulin enhances hepatic IGF-I synthesis, expression and secretion (Ceda *et al.*, 1985).

The Aging

The average length of human life is currently from 75 to 78 years and may increase to 85 years during the following 10 years (Fries, 1980). Most data indicate a modest gain in the number of healthy years lived but, a far greater increase in years of compromised physical, mental and social function (Campion, 1994). In fact, throughout the adult life, all physiological function start to gradually decline (Rudman and Rao, 1992). According to a progressive reduced capacity for cellular protein synthesis, several

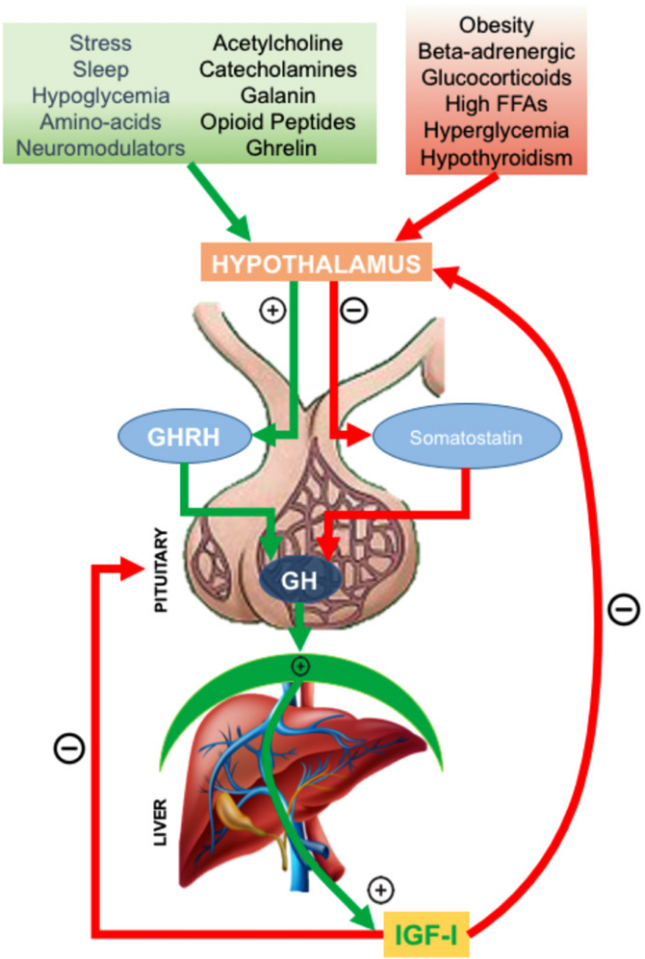

Fig. 1 Physiological mechanisms of GH secretion: positive and negative factors in the regulation of GH/IGF-I axis.

 doi:10.1016/B978-0-12-801238-3.66167-6

mechanisms occurred as decline of the immune function, increase of the fat mass, loss of mass and strength of the muscle, decrease of the bone mineral density (BMD) (Rudman and Rao, 1992). In fact, age-related disability, also called "physical frailty," is characterized by generalized weakness, impaired mobility and balance and poor endurance. Clinical correlates of physical frailty include falls, fractures, impairment in activities of daily living and loss of independence. Part of the aging process involving body composition (as loss of muscle strength and reduction of bone mineral density and increase of fat mass) might also be related to changes in endocrine system.

Changes of Somatotropic Axis in Human Aging

Although the most important clinical changes, in endocrine activity, during aging, involve pancreas, thyroid and gonadal glands, also the axis GH/IGF-I gradually declines its activity (Rudman and Rao, 1992; Corpas *et al.*, 1992), in term of reduction of GH mean pulse amplitude and duration, without any change in pulse frequency. GH secretion declines around 14% per decade in normal individuals (Toogood *et al.*, 1996, 1998). In parallel, a progressive drop of circulating IGF-I levels occurred in both sexes (Corpas *et al.*, 1992; Blackman, 1987). In fact, serum IGF-I levels are from 20% to 80% lower in healthy elderly individuals as compared to healthy young individuals (Borst *et al.*, 1994). This physiological process, called *somatopause*, seem due to hypothalamic mechanisms, rather than pituitary or peripheral factors.

The effect of GH and IGF-I age-related decline on the health in humans is complex and remains not completely resolved. The physiological attenuation of GH/IGF-I signaling, during aging, may also play a protective role from age-related disease (Milman *et al.*, 2016). This evidence is more robust for site specific cancers but remains equivocal for cardiovascular disease (CVD), mellitus diabetes type II (T2DM), osteoporosis and neurodegenerative disease.

Epidemiological studies demonstrated an increased risk of cancer in humans in cases of elevated circulating IGF-I levels (Renehan *et al.*, 2004), as in acromegaly (Boguszewski and Ayuk, 2016), particularly at hormone sensitive organs as breast, prostate, thyroid, and colon (Cao *et al.*, 2015; Key *et al.*, 2010; Rinaldi *et al.*, 2010).

The somatotropic axis is intrinsically linked to insulin pathway and glucose homeostasis (Milman *et al.*, 2016): IGF-I and insulin in fact can each bind the IGF-I and insulin receptors (respectively IGF-IR and InsR), although with a different affinity (Novosyadlyy and Leroith, 2012). Consequently, IGF-I acts biologically as insulin both in the periphery and in the brain, for regulating glucose homeostasis. However, metabolic changes in the elderly are extremely complex and influenced by several factors (Barzilai *et al.*, 2012), as concomitant hypogonadism and hypothyroidism and secretion of adipokines, leptin, and other inflammatory markers (PAI-1, TNF-alpha, and IL-6), secreted also by visceral fat. Moreover, the concomitant age-dependent decline of GH and IGF-1 serum levels may promote the loss of muscle mass and strength, inducing a condition of sarcopenia, and the increased of visceral fat mass. Actually, data on GH and insulin in elderly remain controversial.

Similarly, several studies conducted on older population (Janssen *et al.*, 1998; Langlois *et al.*, 1998; Ohlsson *et al.*, 2011; van Varsseveld *et al.*, 2015; Yamaguchi *et al.*, 2006), have documented a positive correlation between IGF-I levels and BMD and increased risk of vertebral fractures, as it is well known that both GH and IGF-I acts on osteoblasts, though paracrine and endocrine effect. However, data on bone metabolism and GH8IGF-I axis in elderly are actually not-conclusive.

Instead, data regarding IGF-I concentration, cognitive function remain controversial. In a study, conducted on older individuals, higher circulating IGF-I levels seem positively correlated with cognitive function, only in females (Al-Delaimy *et al.*, 2009). However, as suggested by animal models, neurological effects of GH and IGF-I should be due to a paracrine effect of locally produced GH and IGF-I.

Growth Hormone Deficit in Elderly

As the attenuation of GH/IGF-I signaling, during aging, is a physiological process, growth hormone deficit (GHD) is widely recognized as a distinct pathological clinical syndrome with an increased morbidity and mortality, that consequently has to be distinguished, diagnosed, and properly managed. Body changes occurred in health elderly and in elderly GHD individuals are summarized in **Table 1**.

Epidemiology and Clinical Implication of GHD in Elderly

GHD in elderly may be of either adult or childhood onset (Doga *et al.*, 2006). In elderly, GHD usually results from damage to the pituitary gland or hypothalamus: in around 70% of cases due the presence or history of previous not-functioning or secreting pituitary adenomas (Elgzyri *et al.*, 2004). Although rarer, GHD in elderly can occur also in patients carried cystic pituitary lesions, craniopharyngiomas, primary or secondary empty sella syndrome, Sheehan syndrome (Elgzyri *et al.*, 2004; Clayton *et al.*, 2007; De Marinis *et al.*, 2005; Chiloiro *et al.*, 2016, 2017). GHD in elderly is a clinical syndrome, characterized by a wide array of symptoms, as decrease of lean body mass, exercise capacity, mass and strength of muscle, cardiac performance and BMD, increase of weight and body fat mass, poor sleep and impaired sense of well-being (Drake *et al.*, 2001).

Inherently, in elderly GHD patients, GHD is associated to multiple pituitary hormone deficits (Clayton *et al.*, 2007).

Table 1 Difference of changes in body composition in health elderly individual, elderly GHD and acromegaly patients

	Physiological aging	*Elderly GHD*	*Elderly acromegaly*
Lean body mass muscle strength	Reduced	Reduced	Increased
Aerobic capacity	Reduced	Reduced	Increased
Percentage of body fat	Increased	Several increased	Reduced
Total and LDL cholesterol	Increased	Increased	Increased
Insulin sensitivity	Reduced	Reduced	Reduced
Serum IGF-I value	Within normal Range adjusted for age and gender	Within or lower of normal range adjusted for age and gender	Higher of normal ranges adjusted for age and gender
GH Peak after stimulation test	Normal	Reduced	NA

NA, Not applicable.

All these conditions can implicate several and important chronic complications, such as cardiovascular disease, increased risk of fracture rates, which may be responsible for an increased mortality. Although similarities have been observed between the changes associated with physiological aging in the healthy individuals and the symptoms of GHD, as increased fat mass and decreased muscle mass, Toogood (2003) demonstrated that fat mass and waist: hip ratio were significantly increased in elderly GHD patients, as compared to elderly healthy subjects, with a prevalent fat mass distribution in the trunk, arms and legs. Hypopituitary elderly GHD patients have been shown to have an increased number of atheromatous plaques in carotid and femoral arteries, compared with control individuals. Markers of atheromatosis found in GHD patients include a greater intima-media thickness, which is recognized as an independent predictor of acute myocardial infarction in men, increased stiffness of carotid arteries and reduced aortic distensibility (Markussis *et al.*, 1992). Evidence proven from KIMS Database (Feldt-Rasmussen *et al.*, 2004) have suggested that waist/hip ratio, waist circumference, prevalence of diabetes mellitus, coronary heart disease, stroke, and hypertension are higher in elderly (higher than 65 years old) GHD patients and compared to younger ones. Similarly, quality of life was lower in older GHD patients as compared to younger ones, suggesting that older patients perceived a worse quality of life.

Data on BMD in elderly GHD patients are not conclusive, as some authors identified superimposable BMD at different sites in elderly GHD patients as compared to healthy age and sex-matched subjects (Fernholm *et al.*, 2000; Toogood, 2003). Although it is widely demonstrated that adult GHD patients suffer from secondary osteoporosis and skeletal fragility (Wuster *et al.*, 2001; Mazziotti *et al.*, 2006; Holmer *et al.*, 2007; Mormando *et al.*, 2016), a positive correlation between age and BMD value at lumbar spine, femoral neck and total hip was proved in GHD affected patients: young adults GHD were observed to have reduced bone mass, whereas the elderly GHD patients had normal *Z* scores (Murray *et al.*, 2004). These discrepancies may be justified by interferences demonstrated in BMD evaluation that can be influenced by several factors, such as gender, presence of concomitant hypogonadism, age-related abnormalities of bone structure. In fact, degenerative joint alterations (characterized by osteophyte formation and facet-joint hypertrophy) may lead to an overestimation of BMD measured at lumbar spine (Romijn, 2013). However, evaluation of markers of bone formation and resorption demonstrated a significantly reduction in the elderly GHD patients compared with elderly healthy subjects (Toogood, 2003).

The clinical implication of GHD in elderly patients is moreover indirectly underlines by the real benefits of rhGH replacement treatment in these patients (Clayton *et al.*, 2007): in ederly GHD patients, GH replacement therapy achieve beneficial effects equivalent to those seen in younger patients with lower doses of rhGH (Monson and Jönsson, 2003; Feldt-Rasmussen *et al.*, 2004; Fernholm *et al.*, 2000).

Improvements of serum lipoproteins (Elgzyri *et al.*, 2004), of body composition (Toogood and Shalet, 1999; Monson and Jönsson, 2003) and of systolic and diastolic arterial pressure (Monson and Jönsson, 2003) were documented in elderly patients on rhGH treatment. In fact, several knowledges of the relationship between GH, IGF-I and obesity derive from researches conducted on Laron syndrome (Bartke *et al.*, 2013; Laron *et al.*, 1968), showing that in these patients, long-term IGF-I replacement therapy improved subcutaneous and visceral adiposity and nonalcoholic fatty liver (Laron and Klinger, 1993) and suggesting, consequently, a direct action of IGF-I on adipose tissue storage, according to the typical GH receptor resistance condition.

Date on effects of rhGH therapy on bone metabolism in elderly patients are, still actually, controversial: as rhGH seem not to prove significant change on BMD (Kokshoorn *et al.*, 2011), several studies documented significant variation of markers for bone formation (bone-specific alkaline phosphatase activity, osteocalcin, and procollagen I carboxyl-terminal peptide in serum) and bone resorption (pyridinoline in urine) (Fernholm *et al.*, 2000; Franco *et al.*, 2006). These finding, in fact, suggest that, also in elderly, rhGH replacement treatment acts on bone remodeling with its well-known typically "biphasic model," inducing in the first 6 months of treatment an increment of bone resorption and in the following 12 months an increment of bone formation (Ohlsson *et al.*, 1998). Consequently, as in younger GHD patients, also in older ones, long-term study on elderly patients on rhGH are required to better understand this mechanism.

On large interest, are evidence regarding quality of life in older GHD patients treated with rhGH. Indeed, quality-of-life data from KIMS showed that older patients with hypopituitarism experienced a significant improvement of quality of life (similarly to younger patients), during rhGH replacement treatment, particularly in term of restored of asthenia and fatigue (Clayton *et al.*,

2007), that in GHD condition seem related to impaired aerobic capacity (e.g., oxygen consumption and ventilation threshold) rather than to physical changes in the performance of skeletal muscle fibers (Woodhouse *et al.*, 2006). Benefits were observed for total quality of life, as well as for specific domains such as memory, self-confidence, tiredness (i.e., items relating to fatigue and energy levels), tenseness, and socializing. GH role in the control of cognitive function remain not completely known. Actually, have been provided growing evidences that GH can cross the blood-brain barrier. In fact, an increased concentration of GH in the cerebrospinal fluid during rhGH replacement treatment in GHD affected patients has been described (Johansson *et al.*, 1995). Moreover, several studies suggested that GH can influence mood and cognitive, as well as learning and memory formation (Sonntag *et al.*, 2005) and that reduction of circulating IGF-I levels is associated to brain deterioration (Piriz *et al.*, 2011). Conversely, restored IGF-I levels was associated to an enhance of neurogenesis and amelioration of age-related cognitive malfunction in aged brain (Sonntag *et al.*, 1998).

Diagnosis of GHD in Elderly

The diagnosis of GHD requires particular consideration in elderly individuals, according to the identification of the correct clinical context of GHD, the potential fragility of the elderly patients and the lower sensitivity of the most commonly used diagnostic tests.

Particularly, GHD should be investigated only after replaced and balanced all other pituitary tropin deficit.

As GH is secreted in a pulsatile manner, the assessment of random serum GH concentrations is worthless for diagnosis (Giustina *et al.*, 2008). Similarly, IGF-I measurements are rarely of value in isolation (Mukherjee *et al.*, 2003). About one-third of patients with GHD (diagnosed by GH stimulation tests) has IGF-I levels in the normal sex and age-adjusted range (Giustina *et al.*, 2008). Particularly, IGF-I sensitivity as marker of GHD declines with age, despite adjustment according to age-specific IGF-I reference ranges (Thomas and Monson, 2009). Toogood *et al.* found that only 21% of elderly GHD patients had a serum IGF-I concentration lower than age-matched controls (Toogood *et al.*, 1996). Moreover, in elderly low IGF-I value can be also due to intercurrent illness, as poor nutritional status, hepatic disease, renal disease, hypothyroidis, and diabetes mellitus (Fusco *et al.*, 2012; Baum *et al.*, 1996).

In elderly, GHD diagnosis must be established biochemically by provocative test of GH secretory reserve (Giustina *et al.*, 2008), as during aging the hypothalamic stimulation signaling for pituitary secretion of GH declines, instead the releasable reserve of GH in the pituitary gland is not affected (Toogood, 2003). In fact, IGF-I values can decline in health elderly subject and in elderly GHD, but provocative test can distinguish between the elderly functional reduction of IGF-I value and the "true" elderly GHD affected subjects.

Although insulin tolerance test (ITT) has been considered the gold standard for GHD diagnosis by the most important scientific societies (Giustina *et al.*, 2008), it is associated with important disadvantages when used to diagnose GHD, particularly, in the elderly, resulting contraindicated in patients with epilepsy, ischemic heart disease or cerebrovascular disease (Clayton *et al.*, 2007). In fact, as the likelihood of cardiovascular or seizure-related contraindications to ITT increases with age, alternative tests of GH reserve have been applied and, particularly, GHRH plus arginine have been proposed as valuable alternative to ITT (Thomas and Monson, 2009). In fact, in the hypopituitary control and complications study (HypoCCS), it was demonstrated, between 1996 and 2005, a shift in clinical practice from isolated arginine, clonidine and L-dopa testing, towards an increased use of the GHRH–arginine test (Webb *et al.*, 2009). In fact, as the usefulness of isolated arginine is limited by marked variation in response according to body mass index (BMI) (Clayton *et al.*, 2007) and the usefulness of isolated GHRH is limited by marked variation in response according to individual age (Ghigo *et al.*, 1990), recent studies have proven that GHRH with arginine stimulates GH secretion more in elderly patients as in younger adults or children, showing a high degree of sensitivity of this test, for the diagnosis of GHD in older patients (Ghigo *et al.*, 1998). In fact, GHD elderly patients showed a lower mean GH pak after GHRH plus arginine stimulation, as compared to younger GHD patients (De Marinis *et al.*, 2002).

rhGH Treatment, Dosage, and Adverse Events

The rationale for GH replacement therapy in elderly GHD patients is rafforced by the beneficial effects on some clinical end-points. Over the recent years, guidelines on the use of rhGH as a substitution treatment in adult hypopituitarism have been issued by international (Growth hormone research society-GRS, Endocrine Society) and relevant national (National Institute of Clinical Excellence-UK, NICE) institutions. rhGH replacement therapy should be considered in elderly patients with severe GHD (GH peak after stimulation with RHGH plus arginin lower than 9 ng/mL), in the adequate clinical context: all comorbidities, with particularly interest in the screening of oncological disease, have to been checked and, moreover, all pituitary tropin deficits have to be corrected and balanced, before starting rhGH replacement treatment.

In the first clinical trials and studies, conducted on adult GHD patients, initial rhGH replacement doses were based on body weight or surface area, resulting in several side effects due to fluid retention, as carpel tunnel syndrome and arthralgia (Thomas and Monson, 2009; Fernholm *et al.*, 2000). Interestly, in these studies, frequency of reported adverse events was superimposable between elderly and young GHD patients, although youngers were more frequently affected by fluid retention-related adverse events (as headache, oedema, and arthralgias) and elderly patients by increased occurrence of disorders of glucose metabolism, cerebrovascular events and neoplasms (Feldt-Rasmussen *et al.*, 2004).

Moreover, over the time, according to the current clinical practice, rhGH treatment is started at low dosage (0.1–0.2 mg daily) and titrated on an individual basis, with the aim to reach and maintaining IGF-I levels within the normal age- and sex-related range or clinical improvements, also according to quality of life. Consequently, rhGH dosage results significantly lower in elderly GHD patients as compared youngers, without difference in absolute change in IGF-I levels (Clayton *et al.*, 2007; Monson and Jönsson, 2003).

This procedure results in good efficacy and excellent tolerability (Clayton *et al.*, 2005), avoiding overtreatment and related adverse events (Thomas and Monson, 2009).

Acromegaly in Elderly

Acromegaly is a rare condition characterized by an excess of autonomous GH secretion, in most of cases due to the presence of a pituitary GH secreting adenoma. Although biochemically active acromegaly disease is characterized by an increased mortality as compared to general population (Rajasoorya *et al.*, 1994), most recent evidences have proved that life expectancy is now close to that of the general population, in cured or biochemically controlled disease, probably for the better management of the GH/IGF-I excess and related comorbidities (Maione *et al.*, 2017; Capatina and Wass, 2015). However, until now, in acromegaly, prevalent cause of death is neoplastic disease, reported in around 10% of patients, with a standardized incidence ratio of 1.34 (95% CI: 0.94–1.87) in men and 1.24 (0.77–1.73) in women (Maione *et al.*, 2017).

Epidemiology, Clinical, and Diagnosis of Acromegaly in Elderly

Around 3% of acromegaly patients are considered elderly (Kazunori *et al.*, 2008). It is widely proposed that in younger patients, acromegaly is characterized a more aggressive biological behavior (Fusco *et al.*, 2008; Bianchi *et al.*, 2013), similarly as occurred in all types of pituitary adenomas (Chiloiro *et al.*, 2015).

Elderly acromegaly patients typically present headache as onset symptom (Puchner *et al.*, 1995): in fact in these patients, typical acromegaly clinical features may be milder than in younger patients (Turner and Wass, 1997), also according to the lower GH/IGF-I value reported in elderly acromegaly as compared to youngers (Dupuy *et al.*, 2009). Instead, systemic complications, as diabetes mellitus, hypertension and impaired cognitive functions are more frequent in older acromegaly patients (Puchner *et al.*, 1995; Minniti *et al.*, 2005; Hatipoglu *et al.*, 2015).

Diagnosis of acromegaly in elderly patients can represent a challenge: age-corrected insulin-like growth factor I (IGF-I) ranges must be considered because of the physiological decline of IGF-I secretion (Minniti *et al.*, 2005). Since overt diabetes mellitus may limit the feasibility or reliability of the oral glucose-tolerance test for GH suppression, alternative testing may be indicated.

Moreover, an accurate morphological evaluation, trough contrasted magnetic resonance, of the pituitary region and the pituitary adenoma is mandatory, in cases of biochemically diagnosis of acromegaly.

Treatment of Acromegaly in the Elderly

Neurosurgery

Neurosurgery is considered by most authors as the first therapeutic choice in acromegaly, as biochemical remission of acromegaly can be reached in around 50%–60% of patients (Giustina *et al.*, 2000).

Also, in elderly patients transsphenoidal pituitary neurosurgery (TSS) is considered safe and can be proposed, after a careful evaluation of anaesthesiological risk.

According to the high incidence of hypertension, left ventricular hypertrophy and glucose metabolism abnormalities, anaesthesiological risk in elderly acromegaly patients resulted increased in more than 70% of patients (Minniti *et al.*, 2005). Moreover, no mortality or major complications were observed in recent series of elderly patients operated on by TSS (Minniti *et al.*, 2005), suggesting that in a medical center devoted to pituitary disease, the adequate presurgery evaluation and management of elderly acromegaly comorbidities and the surgeon's experience can allow to achieve a high percentage of cured acromegaly, without major complications (Barker *et al.*, 2003). Actually, GH/IGF-I normalization was achieved in 68% of patients underwent pituitary neurosurgery (Minniti *et al.*, 2005), with a superimposable percentage of controlled disease 1 year after treatment (Dupuy *et al.*, 2009). Moreover, successful TSS was accompanied by a significant improvement in cardiovascular and metabolic abnormalities (Minniti *et al.*, 2005). Consequently, current data on TSS in elderly acromegalics are encouraging.

Medical therapy for acromegaly

Elderly acromegaly patients show an especially sensitive to somatostatin analogues treatments (SSA) (van der Lely *et al.*, 1992), that might be due to the less aggressive biochemical characteristics of GH-secreting adenomas in this age group. SSA are able to normalize GH/IGF-I levels in 60%–70% of acromegalic patients with acceptable side effects and a significant improvement in disease-related cardiovascular abnormalities (Freda, 2003). Moreover, pharmacological treatment with SSA can be proposed in different ways. Although preoperative SSA treatment has not show to improve significantly surgical outcome, it can reduce pneumological and anesthetic complications (Ben-Shlomo and Melmed, 2003), particularly in elderly.

Other medical options in acromegaly are the dopamine-agonist (bromocriptine or cabergoline), the GH receptor antagonist (pegvisomant) and the pan-ligands for the somatostatin receptor (pasireotide).

Dopamine agonist treatment achieves normalization of GH/IGF-I level in only 30% of patients (Freda, 2003) and it is proposed particularly in cases of GH-/PRL-secreting adenomas. It is proposed particularly in cases of GH-/PRL-secreting adenomas, although with dosage higher than those commonly employed for prolactinomas. Consequently, in elderly patients, according to the potential valvulopathy risk, a careful cardiological with echocardiography should be scheduled at least annually.

To our knowledge, there are no age-related peculiarities in the use of pegvisomant and pasireotide, which are currently reserved for otherwise uncontrolled acromegaly.

At least, in elderly patients, the efficacy of conventional radiotherapy is hampered by the interval required to achieve biochemical remission: GH/IGF-I levels reach normal values in about 50% of acromegalics over a period of 10–15 years (Barrande *et al.*, 2000). Thus, radiotherapy remains an important option in elderly patients unresponsive to medical treatment.

Conclusion

During the human aging, GH/IGF-I axis gradually and physiologically declines its activity, according to the reduction of hypothalamic signaling. This mechanism, also called somatopause, plays a protective role for age-related disease, particularly cardiovascular, metabolic, and neoplastic. Symptoms of body change during aging overlap with the symptoms of the elderly GHD, that has to be investigated in the correct clinical context. Also, elderly patients affected by GHD may benefit clinically for replacement treatment with rhGH, that has to be prescribed in medical center with a large experience on pituitary disease and that required a careful management at prescription and during follow-up. Similarly to GHD, also GH excess condition, as acromegaly, is associated with an increased morbidity and mortality, requiring a proper diagnosis and management.

Abnormalities in Water Homeostasis in the Elderly☆

Laura E Cowen and Joseph G Verbalis, Georgetown University Medical Center, Washington, DC, United States

Introduction

Findley first proposed the presence of age-related dysfunction of the hypothalamic–neurohypophyseal–renal axis >50 years ago (Findley, 1949). Physiologic processes that occur with aging are associated with changes in both water metabolism and sodium balance, leading to alterations in plasma osmolality and body fluid compartment volumes (**Table 1**). As a result of these changes, the elderly have increased frequency and severity of hypo- and hyperosmolality, manifested by hypo- and hypernatremia, as well as hypo- and hypervolemia. These abnormalities have clinically significant implications with regard to cognition, gait instability, osteoporosis, bone fractures, and overall morbidity and mortality.

Clinical Overview of Hyponatremia

Hyponatremia is the most common electrolyte disorder encountered in clinical practice (Janicic and Verbalis, 2003). This hyponatremia becomes clinically significant when accompanied by plasma hypoosmolality. When hyponatremia is defined as a serum [Na^+] of <135 mmol/L, the inpatient incidence is reported to be between 15% and 22%. Studies that define hyponatremia as a serum [Na^+] < 130 mmol/L demonstrate a lower, but still significant, incidence of 1%–4% (Verbalis, 2001). Several excellent observational studies examining this issue have been published, but the literature has lacked a uniform threshold for defining hyponatremia. One such study suggests that the incidence of hyponatremia in elderly populations has been reported to vary widely between 0.2% and 29.8%, depending on the criteria used to define both "hyponatremia" and "elderly" (Hawkins, 2003). While the true incidence of hyponatremia in the elderly is difficult to define given differing diagnostic criteria across studies, it is clear that the problem is not uncommon.

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is a common cause of hyponatremia in elderly populations. SIADH was first described by Bartter and Schwartz in 1957 (Schwartz *et al.*, 2001). The defining criteria presented in this landmark publication remain valid and clinically relevant today (Verbalis, 2001). SIADH can be caused by many types of diseases and injuries common in the elderly, including central nervous system injury and degeneration, pulmonary diseases, paraneoplastic malignancy, nausea, and pain. An idiopathic form of SIADH associated with aging is also quite common. Several studies have demonstrated that SIADH accounts for approximately half (50%–58.7%) of the hyponatremia observed in some elderly populations (Miller *et al.*, 1996; Anpalahan, 2001; Hirshberg and Ben-Yehuda, 1997), and one-quarter to one-half (26%–60%) of elderly patients with SIADH appear to have the idiopathic form of this disorder (Miller et al., 1996; Anpalahan, 2001; Hirshberg and Ben-Yehuda, 1997).

Clinical Implications of Hyponatremia

Recent data has confirmed that hyponatremia in the elderly population has multiple clinically significant outcomes with regard to neurocognitive effects and falls (Munsch *et al.*, 2003), hospital readmission and need for long-term care (Wald *et al.*, 2010),

Table 1 Summary of the multiple factors that impair maintenance of normal body fluid homeostasis with aging

1. Effects due to altered body composition
   a. Reduced plasma volume
   b. Increased osmolal "flux"
2. Effects due to altered kidney function
   a. Impaired renal free water excretion
   b. Decreased urine concentrating ability
3. Effects due to altered brain function
   a. Decreased thirst perception
   b. Increased AVP secretion

 doi:10.1016/B978-0-12-801238-3.66141-X

incidence of bone fractures (Gankam *et al.*, 2008), and osteoporosis (Verbalis *et al.*, 2010). Hyponatremia is a strong independent predictor of mortality, reported to be as high as 60% in some series (Fried and Palevsky, 1997; Terzian *et al.*, 1994).

Terzian *et al.*, studied the occurrence of admission hyponatremia and its association with in-hospital mortality in a geriatric patient cohort over age 65 admitted to a community teaching hospital (Terzian *et al.*, 1994). Serum $[Na^+] < 130$ mmol/L within 24 h of admission was the cutoff for inclusion. The relative risk of in-hospital mortality associated with admission hyponatremia was significantly increased at 2.0. There was evidence of a linear association of in-hospital mortality with sodium level, with mortality increasing as sodium levels decreased. This study therefore suggested that the degree of hyponatremia may be an important prognostic indicator in older individuals (Terzian *et al.*, 1994).

In addition to an increase in inpatient mortality, studies have demonstrated an increase in outpatient mortality associated with hyponatremia as well. Hoorn *et al.*, examined the effect of hyponatremia on all-cause mortality within the framework of the Rotterdam Study, an ongoing prospective cohort study among outpatients older than 55 living in the Netherlands (Hoorn *et al.*, 2011a). All-cause mortality was higher in subjects with hyponatremia than those without hyponatremia (51.6% vs. 32.6%, $P < 0.001$) (Hoorn *et al.*, 2011a). Consequently, it should be clear that hyponatremia should no longer be considered a benign condition, particularly in the elderly population.

Renneboog *et al.*, conducted a case–control study to determine the functional significance of so-called "asymptomatic" mild chronic hyponatremia on falls and cognitive impairment (Renneboog *et al.*, 2006). In this study, 122 Belgian patients with $[Na^+]$ between 115 and 132 mmol/L, all judged to be asymptomatic at the time of emergency room presentation were compared with 244 age-, sex-, and disease-matched controls presenting during the same time period. Twenty-one percent of the hyponatremic patients presented because of a recent fall as compared to only 5% of controls, resulting in an adjusted odds ratio of 67 for hyponatremia. This study clearly demonstrated an increased incidence of falls in hyponatremic patients.

Renneboog *et al.*, also evaluated the clinical implications of asymptomatic hyponatremia on gait instability and attention deficits (Renneboog *et al.*, 2006). A subset of 12 patients with hyponatremia secondary to SIADH with $[Na^+]$ in the range of 124–130 mmol/L demonstrated significant gait instability that normalized with correction of hyponatremia. The patients were asked to walk a tandem gait on a computerized platform that measured the center of gravity on the ball of their foot. Deviation from the straight line was measured as "Total Traveled Way" (TTW). The hyponatremic patients wandered markedly off the tandem gait line in terms of their center of balance, but corrected significantly once their hyponatremia was corrected (**Fig. 1**). When performing a series of attention tests, patients in the hyponatremic subset (mean $[Na^+] = 128$ mmol/L) had prolonged response latencies compared with a group of patients after acute alcohol intake (blood alcohol concentration 0.6 g/L). These impairments suggested a global decrease of attentional capabilities that is more pronounced in hyponatremic patients (Renneboog *et al.*, 2006), which may contribute to gait instability and falls in the elderly.

Several international studies have demonstrated increased fracture rates in hyponatremic patients (Hoorn *et al.*, 2011b). The work by Kengne *et al.* investigated the association between bone fracture, falls, and clinically asymptomatic hyponatremia in an ambulatory elderly population older than 65 compared with controls (Gankam *et al.*, 2008). The prevalence of hyponatremia ($[Na^+] < 135$ mmol/L) was 13.06% and 3.9% in patients with bone fractures and control patients respectively. The adjusted odds ratio for bone fracture associated with hyponatremia was 4.16. The risk of bone fracture attributable to hyponatremia was 9.2% in all patients with bone fractures and attributable to the hyponatremia alone is up to 72.5% of cases.

Verbalis *et al.* explored the effect of hyponatremia and bone quality and demonstrated a link between chronic hyponatremia and metabolic bone loss (Verbalis *et al.*, 2010). In this study, Verbalis *et al.* used a rat model of SIADH to study the effects of hyponatremia on bone at the level of resorption and mineralization. Dual-energy X-ray absorptiometry (DXA) analysis of excised femurs established that hyponatremia for 3 months significantly reduced bone mineral density by approximately 30% compared with normonatremic control rats. The most striking histologic finding was an increase in the number of osteoclast numbers per bone area and osteoclast surface per bone surface in the hyponatremic rats. This study demonstrated that chronic hyponatremia causes a significant reduction of bone mass at the cellular level. Subsequent epidemiological analysis of 2.9 million patient records showed that chronic hyponatremia was associated with odds ratios of 3.99 for osteoporosis and 3.05 for fractures, thus confirming the translational significant of the animal studies (Usala *et al.*, 2015). Hyponatremia-induced bone resorption and osteoporosis are unique in that they represent attempts of the body to preserve sodium homeostasis at the expense of bone structural integrity (Barsony *et al.*, 2012).

Clinical Overview of Hypernatremia

Hypernatremia necessarily reflects an increase in plasma osmolality. Cross-sectional studies of both hospitalized elderly patients and elderly residents of long-term care facilities show incidences of hypernatremia that vary between 0.3% and 8.9% (Hawkins, 2003; Fried and Palevsky, 1997). While hypernatremia is a common presenting diagnosis in the elderly, 60%–80% of hypernatremia in elderly populations occurs after hospital admission (Fried and Palevsky, 1997). Similarly, up to 30% of elderly nursing home patients experience hypernatremia following hospital admission (Beck, 1998).

The clinical implications of hypernatremia in hospitalized elderly are significant. In a retrospective study, Snyder reviewed outcomes in 162 hypernatremic elderly patients, representing 1.1% of all elderly patients admitted for acute hospital care to a community teaching hospital (Snyder *et al.*, 1987). All patients were at least 60 years of age with a serum $[Na^+] > 148$ mmol/L. All-cause mortality in the hypernatremic elderly patients was 42%, which was seven times greater than age-matched

normonatremic patients. Furthermore, 38% of the hypernatremic patients who survived to discharge had a significantly decreased ability to provide self-care (Snyder *et al.*, 1987).

As hypernatremia develops, normal physiologic responses preserve water homeostasis through osmotically stimulated secretion of AVP to promote renal water conservation along with accompanying potent stimulation of thirst to restore body water deficits (Wong and Verbalis, 2002). Although renal water conservation can forestall the development of severe hyperosmolality, only appropriate stimulation of thirst with subsequent increase in water ingestion can replace body fluid deficits thereby reversing hyperosmolality (Palevsky, 1998). This entire physiologic response is impaired with aging: elderly patients have a decreased thirst perception (Phillips *et al.*, 1985), and blunted ability to maximally concentrate their urine in response to please AVP (Beck, 1998). Thus, the elderly have a greatly increased susceptibility to a variety of situations that can induce hypernatremia and hyperosmolality, with the attendant increases in morbidity and mortality that accompany this disorder (Snyder *et al.*, 1987; Beck, 2000).

Mechanisms Involved With Disturbances of Water Metabolism in the Elderly

Aging causes distinct changes that impact normal water homeostasis at several discreet locations along the neuro-renal axis responsible for maintaining normal water balance. The net result of these changes is that the elderly experience a loss of homeostatic reserve, and increased susceptibility to pathologic and iatrogenic causes of disturbed water homeostasis.

The sensation of thirst and the appropriate drinking response to thirst is compromised with aging. It is likely, as Phillips *et al.*, have suggested, that part of this defect is through loss of normal neural pathways that convey sensory input to the higher cortical

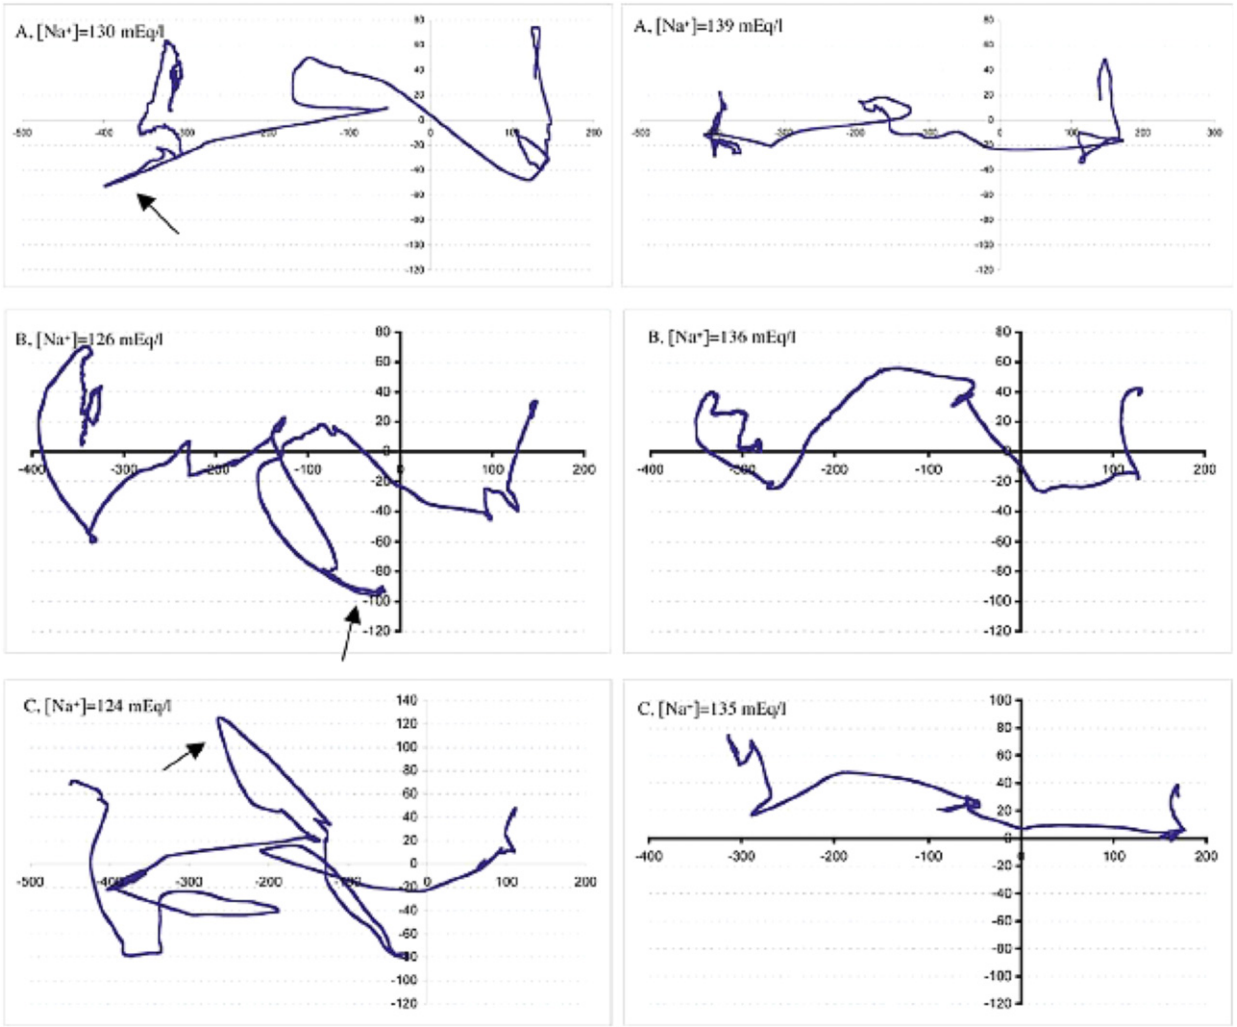

Fig. 1 Evolution of the "total traveled way" (TTW) by the center of pressure in the dynamic test to walk on the platform 3 stereotyped steps "in tandem," eyes open, in three patients (A, B, C) with mild asymptomatic hyponatremia and after correction. Patients are walking from right to left. Irregular paths of the center of pressure observed in the hyponatremia condition (*arrows*). From Renneboog, B., Musch, W., Vandemergel, X., Manto, M.U., and Decaux, G. (2006). Mild chronic hyponatremia is associated with falls, unsteadiness, and attention deficits. *The American Journal of Medicine* **119**(1), 71.

centers where thirst is perceived, and from which the thirst-activated drinking response emanates (Phillips *et al.*, 1993). Other studies have demonstrated that there is a change in baroreceptor-mediated control of thirst in the elderly. Stachenfeld's studies have clearly demonstrated that plasma volume expansion in elderly subjects does not generate the normal suppression of thirst found in the young (Stachenfeld *et al.*, 1997). A clear age-related deficit in the thirst response appears to arise from decreased sensitivity to osmolar stimulation. Studies by Mack *et al.*, suggest that this defect is due to a higher osmotic set point leading to a blunted thirst response in the elderly (Mack *et al.*, 1994). Most importantly, the loss of an appropriate thirst response compromises the critical compensatory mechanisms responsible for the drive to replace lost body fluid, and the only true physiologic means of correcting a hyperosmolar state.

Impaired GFR and resultant loss of maximal urinary concentrating ability appear a common, if not certain, consequence of aging (Lindeman, 1993; Lindeman *et al.*, 1985). The consequence of such a defect is clear: decreased GFR causes an inability to maximally conserve free water and favors development of inappropriate body water deficits. This can lead to clinically relevant hyperosmolality, and is also a likely cause of the observed increase in the frequency of hypernatremia in the elderly.

Paradoxically, a decrement in maximal water excretion also occurs in the elderly (Faull *et al.*, 1993; Clark *et al.*, 1994). The elderly are at a higher risk of developing diseases such as congestive heart failure that are associated with volume overload. So too, are the elderly at risk for inadvertent iatrogenic overhydration from intravenous and enteral hydration therapy. The inability to appropriately excrete an excessive fluid load would predispose to hypoosmolality in elderly individuals.

The secretion and end organ effects of AVP account for two of the most interesting, and perhaps least well understood aspects of water regulation in the elderly. Although a few exceptions exist, most agree that basal AVP secretion is at least maintained, and more likely increased, with normal aging (Wong and Verbalis, 2002). Further, the AVP secretory response, that is, the osmoreceptor sensitivity to osmolar stimuli, is also increased in normal aging (Davies *et al.*, 1995). Thus, AVP secretion represents one of the few endocrine stimulatory responses that increases rather than decreases with age. It is likely that enhanced secretion of AVP in the elderly and inability to appropriately suppress AVP secretion during fluid intake (Phillips *et al.*, 1993), combined with an intrinsic inability to maximally excrete free water (Faull *et al.*, 1993; Clark *et al.*, 1994), increase the likelihood that idiopathic SIADH will occur in this group of patients.

In conclusion, much has been learned in six decades since Findley's original reflections about the effects of aging on water homeostasis. Since then, clearly demonstrated deficits in renal function, thirst and responses to osmotic and volume stimulation have been repeatedly demonstrated in this population. The lessons learned serve to emphasize the fragile nature of water balance characteristic of aging. The elderly are at increased risk for disturbances of water homeostasis due to both intrinsic disease and iatrogenic causes. Recent studies have shown that these disturbances have real-life clinical implications in terms of neurocognitive effects, falls, hospital readmission and need for long-term care, and incidence of osteoporosis and bone fractures. It is therefore incumbent upon all those who care for the elderly to realize the more limited nature of the compensatory and regulatory mechanisms that occur with aging and to incorporate this understanding into the diagnoses and clinical interventions that are made in the care of this vulnerable group of patients.

Body Weight, Body Composition, and Aging☆

Odessa R Addison and Alice S. Ryan, University of Maryland School of Medicine, Baltimore, MD, United States

Glossary

Body Mass Index (BMI) A practical measure of an individual's weight in relation to height, and is used to define overweight and obesity.

Fat-free Mass (FFM) Encompasses all of the body's nonfat tissues including the skeleton, water, muscle, connective tissue, and organ tissues.

Intramuscular Fat (IMAT) A fat depot found beneath the fascia and within the muscle.

Osteoporosis A condition characterized by low bone mass (density) and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture.

Sarcopenia A condition characterized by an involuntary age-related decline in lean body mass, primarily due to the loss of skeletal muscle, that affects functional capacity and strength of older adults.

Visceral fat (intra-abdominal fat) A portion of the internal fat in the abdominal cavity lining the intestinal tract

Introduction

One of the fastest growing segments of the population is individuals >65 years of age. This age group which currently accounts for $\sim$15% of the population is expected to grow to account for more than 20% of the population by 2030. Increased and changing distributions of body fat and loss of bone mineral density (BMD) and muscle mass are defining characteristics of the aging process. These changes in body composition occur as a result of normal aging, have a detrimental impact on health status, and substantial economic consequences on the health care system. Obesity is associated with an increased prevalence of co-morbidities including cardiovascular disease, type 2 diabetes mellitus, hypertension, dyslipidemia, and other metabolic diseases. The decline in skeletal muscle mass is associated with weakness, functional disability, frailty and morbidity, whereas the decrease in BMD increases the risk of bone fractures and ultimately results in high rates of disability, morbidity and mortality in the elderly. This chapter focuses first on the classification and prevalence of overweight and obesity. This is followed by a discussion of the changes that occur during the aging process with specific emphasis on body weight, fat mass and fat-free mass and its constituents of skeletal muscle mass, total body water and bone, and intramuscular fat (IMAT). These changes in body composition are also described in context with metabolic disease states.

Classification of Overweight and Obesity

Body Mass Index (BMI), a practical measure of an individual's weight in relation to height, is used to define overweight and obesity. A BMI between 25 and 29 kg m^{-2} defines overweight in adults, whereas obesity is defined as a BMI$\geq$30 kg m^{-2}. Obesity can be further classified into Class 1 (30.0–34.9 kg m^{-2}), Class 2 (35.0–39.9 kg m^{-2}), and Class 3 ($>$40 kg m^{-2}). These criteria for defining overweight and obesity are based on epidemiologic evidence that shows a strong association between BMI$>$25 kg m^{-2} and an increased incidence of cardiovascular disease, type 2 diabetes mellitus, hypertension, and dyslipidemia that affect mortality and morbidity. Although the determination of BMI is a simple index of obesity to obtain, it does not differentiate between fat mass and lean muscle mass. Therefore, it can overestimate body fat in persons who are very muscular and underestimate body fat in persons who have excess fat and reduced muscle mass but normal body weight. Thus, other methods such as dual-energy X-ray absorptiometry and bioelectric impedance are necessary to more accurately determine body composition and are frequently used in research settings.

Prevalence of Overweight and Obesity

The National Center for Health Statistics has examined the prevalence and trends of overweight U.S. adults from 1960 to 2000 via the National Health Examination Survey (NHES I) and National Health and Nutrition Examination Surveys (NHANES I, II, III, continuous). The prevalence of overweight and obesity increased significantly over the 40-year period from 43% in 1960–62 to 68.5% in 2011–12. Most of this increase is attributable to a dramatic rise in the prevalence of obesity (BMI$>$30 kg m^{-2}) that

☆*Change History:* November 2015. O Addison and AS Ryan has made changes throughout the text, added new figure 2, second graph in figure 1 and table 1. This article is an update of Lyndon J.O. Joseph, Alice S. Ryan, Body Weight, Body Composition, and Aging, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 373-377.

Table 1 Estimated data based on measured height and weight of a sample of the civilian noninstitutionalized population

[a]No data included because estimates are unreliable.

Percent of population for each age and BMI category presented. Percents do not sum to 100 because the percentage of persons with BMI less than 18.5 is not shown. Obesity is a subset of the percentage with overweight.

Chart adapted from: National Center for Health Statistics. Health, United States, 2014: With Special Feature on Adults Aged 55–64. Hyattsville, MD. 2015.

remained stable at ~15% for the first three survey periods (1960–80), and then rose dramatically to 30.5% in 1999–2000. The increased prevalence of overweight and obesity in adults during this time period was evident in both genders, across all races and ethnicities, and across all age groups [Table 1]. The most recent survey (2011–12) estimates that 34.9% of the population is obese with even higher rates among Black (47.8%) and Latino (42.5%) adults.

Change in Body Weight and Fat Mass with Aging

In healthy people, body weight increases gradually from early adulthood until the fifth to sixth decade of life and then remains stable until age 65–70 years. During the period of weight gain, body weight increase occurs at a rate of 0.39–0.45 kg year^{-1} for women and 0.36–0.41 kg year^{-1} for men, irrespective of race. The slightly higher rate in women compared to men suggests that the transition from pre- to postmenopausal status affects the amount of weight gain. After age 60 years, body weight decreases slowly at a rate between 0.05 and 0.36 kg year^{-1} depending on race and gender. The rate of decrease is usually higher in women compared to men, regardless of ethnicity. Moreover, the rate of body weight decrease is highest in African-American women and lowest in African-American men. The variation in body weight regulation suggests that a nonlinear pattern of weight change occurs through the aging process.

The pattern of weight gain is generally consistent between cross-sectional and longitudinal studies and is characterized by a greater increase of fat than lean mass accounting for the increase in body weight. The relationship between age and body fat is curvilinear, with the greatest increase in body fat occurring in middle-aged persons and smaller increases in both the young and the elderly. That is, there is a pattern of increasing fat mass with age until 50–69 years, followed by a slow decline in fat mass in older age groups (>70 years). However, irrespective of the age group, 7–31% of the variation in the increase in fat mass (absolute or relative) in the adult population is accounted for by age.

The increase in weight with age is accompanied by an age-related redistribution of fat away from the subcutaneous fat depot beneath the skin, towards other more harmful locations such as in and around the abdominal organs and underneath the muscles fascia in and between muscle fibers. Sedentary women in their fifth decade of life have an average 1.5- to 3-fold higher visceral and subcutaneous abdominal fat area compared to their younger counterparts and athletes of similar age [Fig. 1]. Similarly, older women athletes in the fifth and sixth decade of life have a two- to threefold higher visceral fat area compared to younger athletes despite similar BMI and percent body fat [Fig. 1]. Therefore, there is an accumulation of fat in the abdominal region during the aging process irrespective of physical activity status. However, maintaining an active lifestyle partially negates the consequences of aging by dramatically reducing the amount of abdominal fat deposition. The ability to alter the accumulation of fat in the abdominal region is of clinical significance when one considers that intra-abdominal fat areas >100–110 cm^2 increase the risk for developing cardiovascular disease and other metabolic diseases. The age associated increase in visceral adiposity may contribute to the increase in triglyceride and total cholesterol concentrations, and glucose intolerance with age.

An increase in the infiltration of fat around and within skeletal muscle (IMAT) also occurs with aging. Similar to visceral adipose tissue it has been implied that IMAT increases with aging with estimates of increases in whole body IMAT ranging from 9 to 70 gyear^{-1}. In women aged ~18–70 years with a wide range of body fat and fitness, intramuscular fat increased with age and mid-thigh muscle area declined [Fig. 2]. Increases in IMAT adversely influences glucose and lipoprotein metabolism as well as muscle strength. CT-scans document a twofold increase in mid-thigh subcutaneous fat between pre- and postmenopausal sedentary women. Moreover, there is also a twofold increase in low-density lean tissue, a marker of intra-muscular fat. Approximately 27–33% of the variation in the increase in mid-thigh subcutaneous fat and low-density lean tissue areas in the mid-thigh region is accounted for by age. A 5 year longitudinal study of older adults age 70–79 found an increase in IMAT even after accounting for race, weight changes, and activity levels. However, some more recent work suggests that the increase in IMAT with

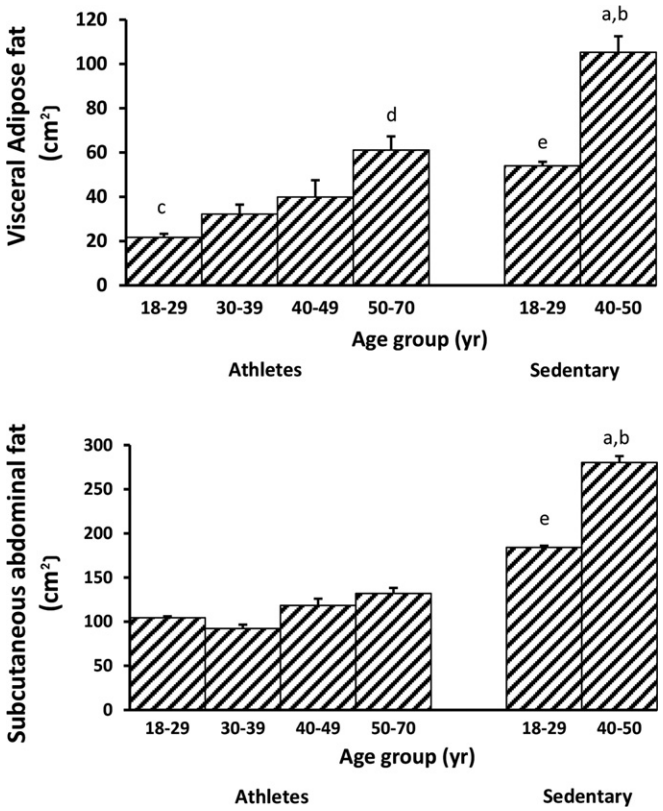

Fig. 1 Values of the visceral abdominal fat and subcutaneous abdominal fat are means ±SE of nos. of athletes and controls. It was determined by computed tomography. Significant differences ($P < 0.05$): [a] Sedentary Group 40–50 vs. Athletes Group 40–49; [b] Sedentary Group 40–50 vs. Sedentary Group 18–29; [c] Athletes Group 18–29 vs. Athletes Group 30–39; [d] Athletes Group 50–70 vs. Athletes Group 18–29; [e] Sedentary Group 18–29 vs. Athletes Group18–29.

aging may be at least partially due to increased inactivity often associated with aging. Longitudinal identical twin studies demonstrate that after 32 years of differing activity habits, IMAT was 54% higher in the inactive twin.

Higher amounts of IMAT may contribute to decreased muscle strength and metabolic dysfunction with aging. Multiple studies have reported a relationship between increased amounts of IMAT and decreased strength in the thigh and calf muscles of older adults. IMAT also appears to be a predictor of metabolic impairments. High levels of IMAT are strong predictors of fasting glucose and insulin impairments even when accounting for BMI. The contribution of intra-muscular fat to the metabolic dysfunction associated with the insulin resistance syndrome may help explain racial difference in glucose metabolism.

Change in FFM and It's Constituents with Aging

Even as body weight and fat mass increase with age, a decrease in skeletal muscle mass occurs even in healthy and active older adults. While lean mass accounts for 50% of the total body weight in young adults, by the age of 75, it accounts for less than 25% of total body weight. The loss of muscle mass may begin as soon as the fourth decade of life and by the age of 70 may occur at a rate of 1% per year in healthy individuals. This rate of loss may be even greater in chronically ill or inactive older adults. The loss of muscle mass with aging is not limited to just skeletal muscle mass but also occurs in total fat-free mass (FFM) and its constituents (all lipid-free chemicals and tissues including water, muscle, bone connective tissue and internal organs). In adults between 18–94 years, the overall change in FFM is 1.5 kg per decade lower in men and 0.8 kg per decade lower in women with greater losses in >60 year olds (men: 1.7 kg per decade and women: 1.1 kg per decade) suggesting that losses in FFM are higher as adults reach a certain older age. In adults over the age of 70 years, the ~5-year decline in body mass is -0.34 kg year^{-1} in men and -0.45 kg year^{-1} in women with the loss of FFM reported as -0.48 and -0.14 kg year^{-1} in men and women, respectively. In an examination of vastus lateralis muscle, muscle size begins to decrease at approximately age 30, decreasing 10% by age 50. Thereafter, muscle area declines more precipitously, largely from decreased total number of muscle fibers. Physical activity levels may attenuate the decline in body mass and changes in body composition with aging. Although energy expenditure from physical activity is associated with greater FFM, this does not change the rate of loss of FFM in older adults. Moreover, adults approximately 70 years of age who lose appendicular and leg FFM over a 5-year period are over twofold more likely to report increased disability.

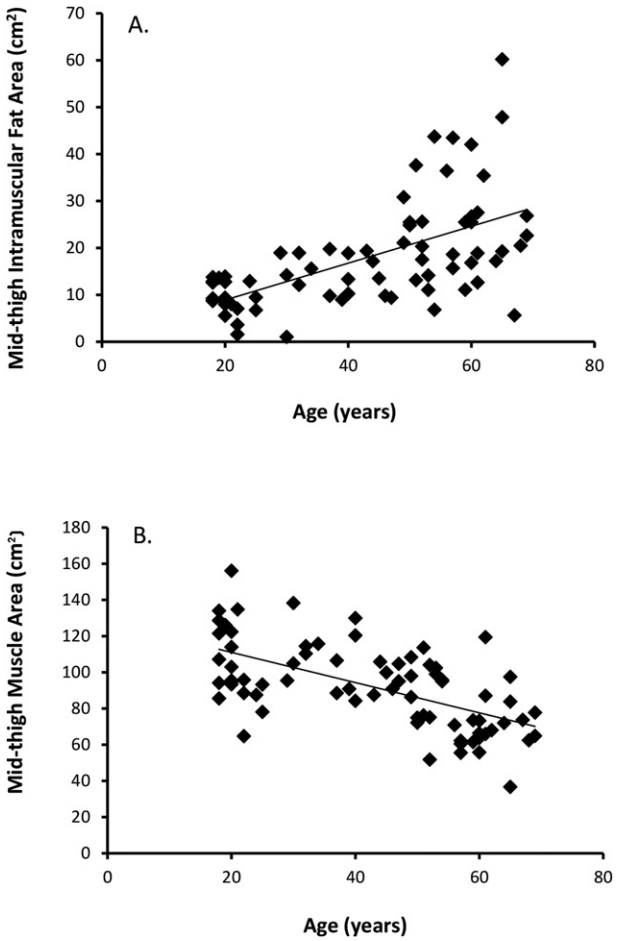

Fig. 2 Relationship between age and intramuscular fat area ($r=0.58$, $P<0.0001$) and muscle area ($r=-0.59$, $P<0.0001$).

The involuntary age-related decline in FFM and strength, primarily due to the loss of skeletal muscle, is termed "sarcopenia" and affects both the function and mobility of older adults. The prevalence of sarcopenia is estimated to be up to 33% of community dwelling elders. Sarcopenia is associated with a three- to fourfold increase in functional impairment, disabilities, and falls in the elderly and also increases the risk for hospital admissions, need for long term care, and death.

The loss of skeletal muscle mass is strongly associated with a loss of body water, because a large proportion of skeletal muscle (~75–80%) is water. Total body water accounts for approximately 80% of FFM at birth. In young adults, TBW comprises approximately 72% of FFM. Thus, a loss of body water occurs until maturity but remains relatively constant throughout adulthood and middle age. Total body water on average is lower in females than males. Losses of body water occur after age 70 in females and somewhat earlier in males with a nadir at this age (70–80 years). It is unclear whether the loss in TBW is due to a decrease in intracellular water, extracellular water, or a combination of the two, but most studies agree that TBW is decreased in elderly subjects and even more so in the very old. The decline in TBW suggests a change in the hydration of the fat-free compartment (increased with normal aging), although definitive conclusions are lacking.

In addition to the losses of FFM, skeletal muscle mass and TBW with age, the loss of bone mass is consistently documented. Peak bone mineral mass is reached at age 20–30 years followed by a progressive decline. Worldwide one out of three women and one out of five men will experience a fracture related to low bone mineral mass in their lifetime. By age 70, spinal and femoral neck bone mineral density (BMD) is diminished by approximately 20% and 25%, respectively. Furthermore, the rate of bone loss varies with site and may be greater in areas with more trabecular bone than those areas of predominantly compact bone. Total body mineral may decline at a slower rate than the decline observed in specific sites. In women, a more dramatic loss of bone mass occurs during menopause. The rate of BMD loss is greater among perimenopausal women compared to pre- and postmenopausal women and is site specific. Longitudinal studies estimate the rate of premenopausal BMD loss at 0.7–1.3% per year at the lumbar spine and 0.2–0.3% per year at the femoral neck. In contrast, the rate of BMD loss for perimenopausal women is 2–3% per year at the lumbar spine and 0.6–1% per year at the femoral neck. The estimated loss of BMD loss at the lumbar spine and the femoral neck is 1.3–1.5% per year and 1–1.4% per year in postmenopausal women, with the fastest rate of bone loss occurring immediately after menopause. The bone loss associated with menopause means women suffer a greater amount of bone loss at a younger age compared to men. Post-menopausal women experience a 2–5 time greater loss of bone resulting in a twofold decrease

in bone strength compared to men of the same age. Men experience a loss of BMD at two-thirds the rate of women in the spine, and one-half the rate of women in the femoral neck. The slower rate of bone loss result in a lower prevalence of osteoporosis in men (~4–6%) compared to women (~20%). The differences in bone loss and bone strength contribute to the increased risk of osteoporotic fracture risk in women compared to men. Overall women experience 61% of all osteoporotic fractures that occur. While women do experience a higher percentage of osteoporotic fractures, an age related increase in osteoporotic fractures is also evident in men who have an estimated 27% lifetime risk of experience a fracture related to low BMD.

Summary

The changes in body weight and composition associated with aging have major public health implications. The increase in total and abdominal obesity as well as increased IMAT within the muscle is associated with increased risk for developing cardiovascular disease, type 2 diabetes, hypertension, dyslipidemia and other metabolic diseases at an estimated cost of over $147 billion per year to the health care system. More importantly, approximately 112000 deaths a year may be attributable to obesity. Osteoporotic fractures generate substantial cost due to acute hospitalization and subsequent rehabilitation at an estimated cost of $17 billion per year with a projected increase to $22 billion per year as the population ages, and like obesity increase morbidity and mortality (e.g. 20% mortality rate during the first year after a hip fracture). However, structured programs that emphasize lifestyle behavior changes such as proper nutrition, increased regular physical activity, and intentional weight loss reduce the risk for developing metabolic and cardiovascular diseases. Moreover, caloric restriction to induce weight loss of 5–10%, aerobic exercise alone, and weight loss in combination with an aerobic exercise training program reduces the incidence of developing type 2 diabetes and improves the cardiovascular risk profiles in obese individuals. Aerobic and resistive exercise training programs >6 months duration maintain or increase muscle and bone mass and in effect may prevent the progression to sarcopenia and osteoporosis. With epidemiologic studies documenting the fastest growing segment of the population is individuals >65 years and an increase in the average life-span, structured behavioral programs that include nutrition and exercise should be recommended to alter the adverse body composition changes observed with aging.

Lipid Disorders in the Elderly☆

Wilbert S. Aronow, New York Medical College, Valhalla, NY, USA

Glossary

Atherosclerotic cardiovascular disease A disorder affecting medium and large arteries in which subintimal deposits of lipids and connective tissue cause a decrease or an obstruction of blood flow through the arteries; includes coronary artery disease, peripheral arterial disease, carotid arterial disease, cerebrovascular disease, and abdominal aortic aneurysm

Coronary artery disease a disorder in which one or more coronary arteries are narrowed by atherosclerotic plaques or vascular spasm; includes stable and unstable angina pectoris, myocardial infarction, and sudden cardiac death

Dyslipidemia a lipid disorder consisting of hypercholesterolemia, increased serum low-density lipoprotein (LDL) cholesterol, decreased serum high-density lipoprotein (HDL) cholesterol, hypertriglyceridemia, or combinations there of. The incidence of atherosclerotic cardiovascular disease (ASCVD) is much higher in older men and women than in younger men and women, suggesting that an elevated serum low-density lipoprotein (LDL) cholesterol may contribute more to the burden of atherosclerotic vascular disease in the elderly than in the young.

Introduction

Cholesterol, cholesteryl esters, and triglycerides are fats or lipids. To circulate in blood, these lipids are combined with phospholipids and protein in particles called lipoproteins. Only three classes of lipoproteins–LDL, high-density liporotein (HDL), and very low-density lipoprotein (VLDL) –are found in the serum of fasting persons.

Following ingestion of a fat-containing meal, cholesterol and triglyceride are absorbed from the intestine and transported in chylomicrons via intestinal lacteals and the thoracic duct to the plasma compartment to produce the alimentary lipemia that can give rise to lactesence in postprandial plasma. Cholesterol and triglyceride of endogenous origin also enter the plasma compartment from the liver as VLDL. Both chylomicrons and VLDL are converted to somewhat smaller, denser, relatively cholesterol-enriched remnant lipoproteins following the selective extraction of triglyceride by the enzyme lipoprotein lipase. The remnant lipoproteins are removed from the plasma by hepatic chylomicron receptors that recognize surface apolipoprotein E and/or the structural apolipoprotein B100 or are further metabolized by hepatic triglyceride lipase to LDL and then removed by LDL receptors. HDL is composed principallyof apolipoproteins A-I and A-II and cholesterol and phospholipid. HDL is synthesized in both the intestine and the liver, and it acquires cholesterol by exchange from triglyceride-rich lipoproteins and in the process of facilitating reverse transport of cholesterol from the periphery to the liver, where it is excreted in the bile unchanged or after conversion to bile acids.

LDL is the major cholesterol-containing lipoprotein implicated in the development of atherosclerosis and is the primary target of therapeutic hypolipidemic interventions. LDL cholesterol may be elevated to undesirable levels because of excessive intake of dietary cholesterol and saturated fat (especially the latter), obesity (and increased hepatic synthesis), and/or genetic disorders that increase synthesis or impair LDL removal (e.g., LDL receptor deficiency in familiar hypercholesterolemia) or because of secondary causes such as hypothyroidism, nephrotic syndrome, renal failure, and biliary cirrhosis. LDL levels may be decreased in certain genetic disorders associated with hypocholesterolemia (e.g., familial hypobetalipoproteinemia, a so-called longevity syndrome) but are also seen in inflammatory syndromes commonly seen in frail persons, especially prevalent in elderly persons in hospitals or long-term care settings.

HDL is synthesized in both the liver and the intestine, and it exerts a protective effect on the development of atherosclerotic vascular disease. In addition to reducing arterial tissue cholesterol levels that contribute to such atherosclerosis by facilitating reverse cholesterol transport, HDL inhibits oxidation and aggregation of LDL in the arterial wall. Lower HDL cholesterol may be associated with genetic disorders, nutritional habits (high carbohydrate intake), obesity, hypertriglyceridemia, cigarette smoking, and lack of exercise, whereas HDL levels are increased with alcohol ingestion and estrogens or in familial hyperalphalipoproteinemia, another longevity syndrome.

☆*Change History:* WS Aronow August 2014. Abstract and keywords added. Further reading includes 9 references, 8 of which are new. The 2013 American College of Cardiology (ACC)/American Heart Association (AHA) lipid guidelines state that ASCVD includes CAD, stroke, transient ischemic attack, and PAD which includes carotid arterial disease and abdominal aortic aneurysm as well as PAD of the lower extremities. These guidelines use a Pooled Heart Equation to estimate the 10-year risk of developing ASCVD. This equation includes sex, age, race, total cholesterol, HDL cholesterol, systolic blood pressure, treatment for hypertension, diabetes mellitus, and smoking. High-dose statins and moderate-dose statins are discussed. New clinical trial data on use of statins for secondary prevention and for primary prevention are discussed. The 2013 American College of Cardiology/American Heart Association lipid guidelines are discussed extensively.

This article is an update of Wilbert S. Aronow, Lipid Disorders in the Elderly, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 178-181.

VLDL is a triglyceride-rich lipoprotein synthesized and secreted by the liver. Hypertriglyceridemia is associated with genetic disorders, obesity, diabetes mellitus, renal failure, heavy alcohol intake, and drugs such as estrogens.

The measurement of fasting levels of LDL cholesterol, HDL cholesterol, and triglycerides in the serum is obtained as part of comprehensive assessment of the risk of ASCVD that is commonly estimated according to the following formula: total cholesterol = LDL cholesterol + HDL cholesterol + triglycerides/5. Dyslipidemia includes hypercholesterolemia, an increased LDL cholesterol, a decreased HDL cholesterol, and hypertriglyceridemia. Hypercholesterolemia is diagnosed if the serum total cholesterol is 200 mg dl^{-1} (5.2 mmol l^{-1}) or higher. A low serum HDL cholesterol is less than 40 mg dl^{-1} (1.04 mmol l^{-1}) in men and less than 50 mg dl^{-1} (1.2 mmol l^{-1}) in women. Hypertriglyceridemia is a triglycerides level of 150 mg dl^{-1} (3.9 mmol l^{-1}) or higher. Patients with atherosclerotic vascular disease should have their LDL cholesterol reduced to less than 70 mg dl^{-1} (1.82 mmol l^{-1}). Increased LDL cholesterol and decreased HDL cholesterol are risk factors for coronary artery disease (CAD), peripheral arterial disease (PAD), ischemic stroke, transient ischemic attack, carotid arterial disease, heart failure, abdominal aortic aneurysm, valvular aortic stenosis, and mitral annular calcium in elderly persons.

The 2013 American College of Cardiology (ACC)/American Heart Association (AHA) lipid guidelines state that ASCVD includes CAD, stroke, transient ischemic attack, and PAD which includes carotid arterial disease and abdominal aortic aneurysm as well as PAD of the lower extremities. These guidelines use a Pooled Heart Equation to estimate the 10-year risk of developing ASCVD. This equation includes sex, age, race, total cholesterol, HDL cholesterol, systolic blood pressure, treatment for hypertension, diabetes mellitus, and smoking.

Lifestyle Measures

Persons with hypercholesterolemia with and without ASCVD should be treated with a Step II AHA diet. They should achieve and maintain an ideal body weight. Cholesterol intake should be less than 200 mg/day. Less than 30% of total caloric intake should be fatty acids. Saturated fatty acids should comprise less than 7% of total calories, polyunsaturated fatty acids should account for up to 10% of total calories, and monounsaturated fatty acids should comprise 10–15% of total calories. Protein intake should account for 10%–20% of total calories. Carbohydrates should comprise 50%–60% of total calories. In addition to loss of weight in obese persons, daily aerobic exercise, and dietary treatment of hypercholesterolemia, cigarette smoking should be stopped, hypertension should be treated, and diabetes mellitus controlled with the hemoglobin A1c level reduced to less than 7.0%.

The 2011 ACC/AHA guidelines on treatment of hypertension in the elderly recommend reducing the blood pressure to less than 140/90 mm Hg in elderly persons younger than age 80 years. In persons aged 80 years and older, these guidelines recommend reducing the systolic blood pressure to 140–145 mmHg if tolerated. The 2013 ACC/AHA guidelines on treatment of hypercholesterolemia state that lifestyle modification must be used both prior to cholesterol-lowering drug therapy and together with use of cholesterol-lowering drug therapy.

Metabolic Syndrome

The clustering of high serum triglycerides, small dense LDL particles, low serum HDL cholesterol levels, hypertension, insulin resistance (with or without glucose intolerance), and a prothrombotic state is diagnosed as the metabolic syndrome. This constellation is extremely common in persons with type 2 diabetes mellitus and is thought to be a precursor to diabetes mellitus in persons at increased risk for developing diabetes mellitus with aging. The metabolic syndrome should be treated with lifestyle modification and with statin therapy to treat the atherogenic dyslipidemia of the metabolic syndrome.

Statins

The most effective lipid-lowering drugs in reducing cardiovascular events and mortality in elderly and younger persons are the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors or statin drugs. Statins reduce serum total cholesterol, LDL cholesterol, and triglycerides, and they increase serum HDL cholesterol. They also cause many pleiotropic effects which contribute to a reduction in cardiovascular events and mortality. The statin drugs include rosuvastatin, atorvastatin, simvastatin, pravastatin, lovastatin, fluvastatin, and pitavastatin. Statin drugs suppress cholesterrol biosynthesis by competitively inhibiting HMG-CoA reductase, the enzyme that catalyzes the conversion of HMG-CoA to mevalonate, a precursor of sterols (including cholesterol). This action induces upregulation of LDL receptors in the liver and increased clearance of LDL receptors in the liver and increased clearance of LDL from the plasma, thereby reducing plasma cholesterol levels.

High-dose statins (rosuvastatin 20–40 mg daily and atorvastatin (40–80 mg daily) reduce LDL cholesterol 50% or more. Moderate-dose statins (rosuvastatin 5–10 mg daily, atorvastatin 10–20 mg daily, simvastatin 20–40 mg daily, pravastatin 40–80 mg daily, lovastatin 40 mg daily, fluvastatin XL 80 mg daily, fluvastatin 40 mg twice daily, and pitavastatin 2–4 mg daily) reduce LDL cholesterol 30%–49%. Low-dose statins reduce LDL cholesterol less than 30%.

Numerous double-blind, randomized, placebo-controlled trials have shown that elderly persons with and without ASCVD or diabetes mellitus treated with statins have a reduction in cardiovascular events and in mortality. The lower the serum LDL

cholesterol reduced by statins, the greater the reduction in cardiovascular events and mortality. In the Heart Protection Study, where 5,806 of the 20,536 men and women at increased risk for cardiovascular events randomized to simvastatin or to double-blind placebo were 70–80 years of age at study entry and were 75–85 years of age at follow-up, 5 years of simvastatin therapy prevented myocardial infarction, stroke, and revascularization in 70–100 persons per 1,000 treated persons regardless of age, gender, or initial levels of serum lipids. In this study, reduction of serum LDL cholesterol in persons with a baseline serum LDL cholesterol of less than 100 mg dl^{-1} (2.6 mmol l^{-1}) was as effective in reducing cardiovascular events and mortality as reducing serum LDL cholesterol in persons with higher serum LDL cholesterol levels.

At 5-year follow-up, compared to placebo, simvastatin significantly decreased all-cause mortality by 13%, any cardiovascular death by 17%, major coronary events by 27%, any stroke by 25%, coronary or noncoronary revascularization by 24%, and any major cardiovascular event by 24%.

In the Study Assessing Goals in the Elderly (SAGE), 893 ambulatory CAD patients aged 65–85 years with at least 1 episode of myocardial ischemia lasting at least 3 min during 48-hour ambulatory electrocardiographic screening were randomized to atorvastatin 80 mg daily or to pravastatin 40 mg daily and followed for 12 months. Total duration of myocardial ischemia detected by 48-hour ambulatory electrocardiograms at month 3 and at month 12 after randomization was significantly reduced by both atorvastatin and pravastatin with no significant difference between the 2 treatment groups. Compared with pravastatin, atorvastatin significantly reduced serum LDL cholesterol levels, insignificantly reduced major acute cardiovascular events by 22%, and significantly reduced all-cause mortality by 67%.

In the Justification for the Use of Statins in Prevention: an Intervention Trial evaluating Rosuvastatin (JUPITER), 17,082 apparently healthy persons, median age 66 years, with a serum LDL cholesterol of less than 130 mg dl^{-1} (3.36 mmol l^{-1}) and high-sensitivity C-reactive protein levels of 2.0 mg l^{-1} or higher were randomized to rosuvastatin 20 mg daily or placebo [42]. At 1.9-year median follow-up, rosuvastatin significantly reduced serum LDL cholesterol levels by 50%, high-sensitivity C-reactive protein levels by 37%, and the primary end point of myocardial infarction, stroke, arterial revascularization, hospitalization for unstable angina pectoris, or death from cardiovascular causes by 44%.

A meta-analysis was performed in 9 randomized trials of statins for secondary prevention in 19, 569 patients aged 65–82 years Over 5 years, statins reduced all-cause mortality 22% (95% CI, 11–35%), CAD mortality 30% (95% CI, 17%–47%), nonfatal myocardial infarction 26% (95% CI, 11%–40%), need for revascularization 30% (95% CI, 17%–47%), and stroke 25% (95% CI, 6%–44%). The estimated number needed to treat to save 1 life was 28.

2013 ACC/AHA Lipid Guidelines

The 2013 ACC/AHA lipid guidelines recommend the use of high-dose statins to adults aged 75 years and younger with ASCVD unless contraindicated with a class I indication. Moderate-dose or high-dose statins are reasonable to administer to persons with ASCVD older than 75 years with a class IIa indication. Persons aged 21 years and older with a serum LDL cholesterol of 190 mg dl^{-1} (4.94 mmol l^{-1}) or higher should be treated with high-dose statins with a class I indication. For primary prevention in diabetics aged 40–75 years and a serum LDL cholesterol between 70 and 189 mg dl^{-1} (1.82–4.91 mmol l^{-1}), moderate-dose statins should be administered with a class I indication. For primary prevention in diabetics aged 40–75 years, a serum LDL cholesterol between 70 and 189 mg dl^{-1} (1.82–4.91 mmol l^{-1}), and a 10-year risk of ASCVD of 7.5% or higher calculated from the Pooled Heart Equation, high-dose statins should be administered with a class IIa indication. For primary prevention in diabetics aged 21–39 years or older than 75 years and a serum LDL cholesterol between 70 and 189 mg dl^{-1} (1.82–4.91 mmol l^{-1}), moderate-dose statins or high-dose statins should be administered with a class IIa indication. Adults aged 40–75 years of age without diabetes mellitus or ASCVD with a serum LDL cholesterol between 70 and 189 mg dl^{-1} (1.82–4.91 mmol l^{-1}) and a 10-year risk of ASCVD of 7.5% or higher calculated from the Pooled Heart Equation should be treated with high-dose statins or moderate-dose statins with a class I indication. Adults aged 40–75 years of age without diabetes mellitus or ASCVD with a serum LDL cholesterol between 70 and 189 mg dl^{-1} (1.82–4.91 mmol l^{-1}) and a 10-year risk of ASCVD of 5%–7.4% calculated from the Pooled Heart Equation should be treated with moderate-dose statins with a class IIa indication.

Besides the use of statins in these groups, other factors may be considered for use of statins. These factors include a primary serum LDL cholesterol of 160 mg dl^{-1} (4.16 mmol l^{-1}) or higher or other evidence of genetic hyperlipidemia, a family history of premature ASCVD with onset before age 55 years in a first-degree male relative, onset before age 55 years in a first-degree male relative or onset before age 65 years in a first-degree female relative, high-sensitivity C-reactive protein 2 mg l^{-1} and higher, a coronary calcium score of 300 Agaston units or higher or 75% and higher for age, sex, and ethnicity, an ankle-brachial index below 0.90, or an increased lifetime risk of ASCVD.

These guidelines also state that there is no additional ASCVD reduction from adding nonstatin therapy to further lower non-HDL cholesterol once an LDL cholesterol goal has been reached. Clinical trials have demonstrated no reduction in cardiovascular events or mortality in persons treated with statins by addition of nicotinic acid, fibric acid derivatives, ezetemibe, or drugs that raise HDL cholesterol.

Serum triglycerides 500 mg dl^{-1} (13.0 mmol l^{-1}) or higher should be treated to reduce the risk of pancreatitis. Gemfibrozil should not be given to patients on statins. Fenofibrate may be considered with low-dose or moderate dose statins with a class IIb indication, should not be used if the estimated glomerular filtration rate is less than 30 ml min/1.73 m^2, and should not exceed a dose of 54 mg daily if the estimated glomerular filtration rate is 30–59 ml min/1.73 m^2. If omega-3 fatty acids are used to treat

serum triglycerides 500 mg dl^{-1} (13.0 mmol l^{-1}) or higher, it is reasonable to evaluate the patient for gastrointestinal disturbances, skin changes, and bleeding.

In 18 randomized clinical trials (19 cohorts) for primary prevention of ASCVD by statins which included 56, 934 patients between 28 and 97 years of age, compared with placebo, statins significantly reduced LDL cholesterol 39 mg dl^{-1} (1.01 mmol l^{-1}), all-cause mortality 14%,fatal and nonfatal cardiovascular disease 25%, fatal and nonfatal CAD 27%, fatal and nonfatal stroke 22%, and coronary revascularization 38%. The incidence of cancers, myalgia, rhabdomyolysis, liver enzyme elevation, renal dysfunction, or arthritis did not differ between statins and placebo. The rates of adverse events (17%) and of stopping treatment (12%) did not differ between statins and placebo. One of 2 trials reported an increased risk of diabetes mellitus caused by statins (number needed to treat = 198 persons).

Gonadotropins and Testicular Function in Aging

Fiona Yuen, Peter Y Liu, Ronald Swerdloff, and Christina Wang*, Clinical and Translation Science Institute, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, CA, United States

Glossary

Late Onset or "Functional" Hypogonadism A decline in testicular function with aging, resulting in decreased testosterone production that may manifest with clinical presentations, including sexual dysfunction, mood changes, decreased energy, frailty, and decreased bone and muscle mass.

Feedback control Process in which the target organ (testis) secretes substances (testosterone, inhibin) to regulate the secretion of hormones (gonadotropin-releasing hormone, follicle-stimulating hormone, and luteinizing hormone) by the regulating organs (hypothalamus and pituitary) operating at molecular, cellular, and glandular levels.

Introduction

The hypothalamic–pituitary–testicular (HPT) axis controls the levels of testosterone (T) minute by minute via signaling interactions among gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), and T. GnRH neurons in the arcuate/infundibular nucleus of the hypothalamus, influenced by excitatory and inhibitory neuromodulators from the kisspeptin/neurokinin B/dynorphin (KNDy) neurons among others, secretes GnRH in pulses. GnRH stimulates the secretion of both FSH and LH from the anterior pituitary. LH is released in pulses, and stimulates Leydig cells to secrete T (Pinilla *et al.*, 2012). Unlike the menopause in women where there is more abrupt cessation of ovarian function, in men there is no distinct time point at which T production changes (Araujo and Wittert, 2011; Wu *et al.*, 2010). As men age, they have a gradual decline in circulating T levels which may be related with many co-morbidities occurring in aging men (Yeap, 2009; Yeap *et al.*, 2012; Wu *et al.*, 2010; Travison *et al.*, 2007a; Tajar *et al.*, 2012). However, this decline occurs even in men without co-morbidities and is also associated with multiple regulatory changes in the HPT axis which are present even in healthy men without known diseases. This suggests that some of these changes are age-related, rather than related to pathological processes that accumulate with age. Aging-related mechanisms that contribute to the decline in testosterone include (1) decreased hypothalamic GnRH outflow, (2) diminished effect of negative feedback by testosterone on the HPT axis, (3) impaired Leydig cell steroidogenesis in response to LH, and (4) increase in sex hormone binding globulin with age and decrease with obesity affecting both total and free T estimations.

Evidence Supporting Age-Related Testosterone Decline Men

In aging men, decreased T secretion from Leydig cell dysfunction should elevate LH and FSH due to the negative feedback mechanism, as seen in men with primary hypogonadism. However, serum FSH and LH levels are frequently not as elevated as would be expected given their serum levels of T. In older men, the increase in serum LH observed in longitudinal studies is approximately 0.9% per year, and the increase in serum FSH is approximately 3.1% per year (Wu *et al.*, 2008; Tajar *et al.*, 2010). LH concentrations may be normal when T concentrations are below the lower limit of normal. The Massachusetts Male Aging Study in community-dwelling men corroborated this decline in T with age, and noted that the existence of comorbidities increased the likelihood of hypogonadism. However, even healthy men had a decline in T at age 70 compared to age 40 (Travison *et al.*, 2007b; Araujo *et al.*, 2004a,b; Feldman *et al.*, 2002). Most available data show that the decline in T is due to both decline in Leydig cell function and in HPT axis dysfunction. There is also evidence that sex hormone binding globulin (SHBG) increases with age, independent of obesity, and free T declines more steeply than total T (Liu *et al.*, 2007). Recent studies of middle age and older men indicate that aging causes Leydig cell dysfunction manifested by low T and elevated LH, where abnormalities of the HPT axis is associated with comorbidities such as obesity (Wu *et al.*, 2008).

Decreased GnRH Release With Preservation of Pituitary Response to GnRH

There is indirect evidence that hypothalamic secretion of GnRH is reduced in older men. In rodent studies, there was diminished GnRH release by hypothalamic tissue (Gruenewald *et al.*, 1994) and decreased density of GnRH neuronal synapses (Witkin, 1987). Transplantation of fetal hypothalamic neurons to impotent aged male rats restored their reproductive function and improved LH

*Corresponding author.

and T levels (Huang *et al.*, 1987). Studies have also demonstrated that pituitary response to GnRH appears to be preserved. In rodent studies, LH response to exogenous GnRH was preserved (Gruenewald *et al.*, 2000). In humans, in comparisons of aged and young men, the aged men had the same mean serum LH concentrations as the young men, but their LH pulse frequency was significantly higher, and there was loss of high-amplitude LH secretory pulses (Mulligan *et al.*, 1995). However, when aged and young men were both treated with GnRH for 14 days, the 24 h serum LH concentrations were indistinguishable by cluster analysis to determine pulse frequency and amplitude and the orderliness was identical by approximate entropy (Mulligan *et al.*, 1999). This implies that the pituitary's ability to respond to GnRH is preserved.

Diminished Pituitary Negative Feedback From Androgens

How or whether androgen feedback is altered in older men is controversial. As seen in the European Male Aging Study (Wu *et al.*, 2008), the negative feedback mechanism of the HPT axis appears to be diminished in elderly men. LH levels may be normal despite lower levels of T. This impaired negative feedback mechanism has also been demonstrated in animal studies. In elderly rats, castration did not increase LH as much as it did in younger rats (Shaar *et al.*, 1975). Another study demonstrated reduced androgen receptor (AR) expression in the hypothalamus and pituitary, and also confirmed a decreased LH response to gonadectomy (Haji *et al.*, 1981). Altogether, these results suggest diminished responsiveness to negative feedback from androgens. In humans, several studies reported that suppression of LH concentrations in aged men after administration of high dose.

T was reduced (Gentili *et al.*, 2002), but could be increased with lower dose androgen therapy (Gentili *et al.*, 2002; Winters *et al.*, 1984; Winters and Atkinson, 1997). In studies using the antiestrogen clomiphene citrate, the increases in LH and FSH in aged men were less, compared to that of young men (Tenover *et al.*, 1987). These seemingly contradictory findings could be explained by differences in negative feedback at the hypothalamus compared with the pituitary. Mathematical constructs using graded competitive GnRH receptor antagonism and a calibrating mid-physiological dose of exogenous GnRH suggest that although negative feedback at the pituitary may be diminished by age, feedback suppression of androgens on hypothalamic GnRH drive may actually be augmented by age (Keenan *et al.*, 2011).

Impairment of LH Secretion

The result of these changes in the HPT axis is impairment of LH secretion. In elderly men, LH pulse amplitude decreases, pulse frequency increases, and the secretion patterns become more irregular/disorderly. Several studies have demonstrated this change in LH secretion (Mulligan *et al.*, 1999). The mean basal levels of LH remain the same. Deconvolution analysis of LH pulses predicts frequent and small LH secretory bursts with diminished T pulses (**Fig. 1**).

Testicular Function Declines With Aging

The decrease in serum T is partially due to defective Leydig cell steroidogenic capacity as well as decreased responsiveness of the Leydig cells to endogenous LH. Studies in our laboratory demonstrated that in aging male rats (Brown Norway rat), the lower serum T when compared to younger animals are due to both defective HPT axis (Bonavera *et al.*, 1997, 1998) and testicular dysfunction that may arise from inadequate blood flow, increased inflammation and chronic testicular stress resulting in increased reactive oxygen species (Wang *et al.*, 1999, 2002). In addition to low T levels, there was aged related reduction in Leydig cell volume per testis; the total number of Sertoli cell per testis; tubule diameter, length of tubules, and volume of tubules and their lumens. The testicular sperm concentration and total sperm production were significantly reduced in the 22- and 30-month-old rats (Wang *et al.*, 1993). Furthermore extensive studies of the Leydig cells in the same rat model demonstrated decreased steroidogenic capacity of Leydig cells both in vitro and in vivo in response to LH which is related to reduced cAMP production. Treatment of aged cells with dibutyryl cAMP or placing them in a younger rat testis environment resulted in restoration of LH stimulated Leydig cell steroidogenic capacity (Chen *et al.*, 1996, 2009; Beattie *et al.*, 2013).

In older men, there was less T secreted per LH burst (Mulligan *et al.*, 1995). Furthermore, pulsatile recombinant human LH administered under ganirelix blockade of endogenous LH secretion to mimic that typically observed in young men, results in lower mean T concentrations, reduced pulsatile secretion and reduced LH-T feedforward synchrony when applied to older, compared with younger, men (Liu *et al.*, 2005). Studies using this paradigm in 92 healthy men aged 18–75 years confirm these relationships (Veldhuis *et al.*, 2012). These data strongly implicate impaired Leydig cell responsiveness to LH stimulation with aging in men in the human.

Aging is associated with a progressive decline in serum total T as well as bioavailable and free T. In earlier studies serum total T levels decline by 1.6% and bioavailable T declines by 2.3% per year, while sex hormone binding globulin (SHBG) increases by 1.3% per year (Feldman *et al.*, 2002; Harman *et al.*, 2001). There is also a concomitant decline in androstenedione, dehydroepiandrosterone (DHEA), DHEA sulfate, and estrogen (Labrie *et al.*, 1997). Serum dihydrotestosterone (DHT) increases in

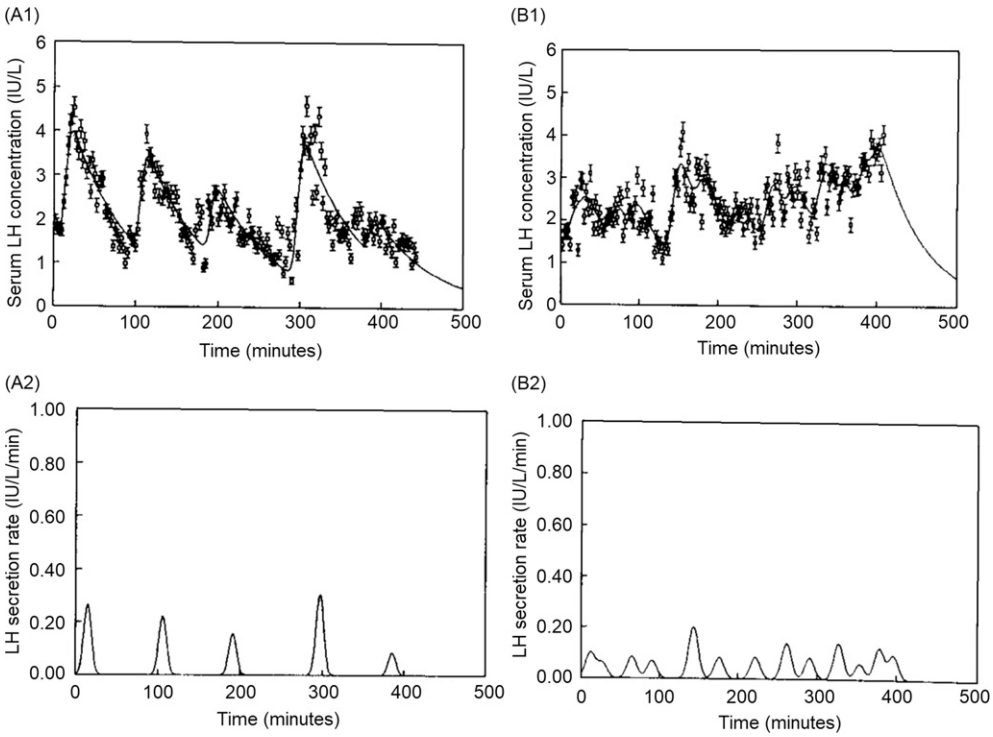

Fig. 1 Serum LH concentrations and LH secretion rate in a young man (A) and old man (B). The continuous lines are generated by deconvolution analysis. There is loss of high-amplitude LH and testosterone secretory pulses in older men with preservation of basal secretion rates. Entropy analyses showed irregularity of release of LH and testosterone in the older men. Reproduced from Mulligan, T., Iranmanesh, A., Gheorghiu, S., et al. (1995). Amplified nocturnal luteinizing hormone (LH) secretory burst frequency with selective attenuation of pulsatile (but not basal) testosterone secretion in healthy aged men: possible Leydig cell desensitization to endogenous LH signaling—A clinical research center study. *The Journal of Clinical Endocrinology and Metabolism* 80, 3025–3031 with permission from The Endocrine Society.

older men, possibly due to increased 5α-reductase activity in the liver, skin, or prostate. However, the levels of intraprostatic DHT remain stable (Geller *et al.*, 1976). In the European Male Aging study (EMAS, 3200 community dwelling men aged from 40 to 79 years in eight countries), serum T decrease was less than free T and serum LH and SHBG increased with aging. In addition to aging, higher body mass index was associated with lower T and free T and presence of comorbidities is also associated with lower total T without compensatory increases in LH levels (Wu *et al.*, 2008) (**Fig. 2**) The prevalence of symptomatic hypogonadism, that is, low T and specific symptoms, increases in age, from 0.1% for men 40–49 years old to 5.1% for men 70–79 years old (Wu *et al.*, 2010). The prevalence of hypogonadism increases with an increase in comorbidities (Wu *et al.*, 2010; Yeap *et al.*, 2012). Decrease in serum T was observed in men with decreased sexual desire, erectile dysfunction and decreased morning erection and ability to perform vigorous physical activity. This association of symptoms with decline in serum T does not appear to be linear; decrease in ability to perform vigorous activity appear to require a higher serum T threshold than sexual desire and erectile dysfunction (Zitzmann *et al.*, 2006; Wu *et al.*, 2010). Furthermore, men with low T and high LH (primary hypogonadism) are usually older and remained hypogonadal at 4 years follow up. Those with lower LH and low T are more obese (secondary hypogonadism) and 42% of them became eugonadal on follow up. The recovery from hypogonadism was predicted by nonobesity, weight loss, lower waist circumference and young age suggesting that the development of secondary hypogonadism can be reversed with weight loss (Tajar *et al.*, 2010; Rastrelli *et al.*, 2015).

The germinal epithelium continues to produce spermatozoa in elderly healthy men, despite the decline in T (Nieschlag *et al.*, 1982). In a larger study of over 1000 men aged 45–80 (mean 53) showed decline in sperm concentration, motility and morphology and only 46% of these men had semen quality that are considered within the adult male range (Hellstrom *et al.*, 2006). There are studies that showed the spermatozoa of older men may have more DNA fragmentation (Das *et al.*, 2013; Schmid *et al.*, 2013). Studies show that circulating inhibin B, a marker of Sertoli cell function, is maintained with age, though FSH rises and the inhibin B:FSH ratio decreases, indicating deficient Sertoli cell function (Mahmoud *et al.*, 2003). Aging is associated with decreased testis volume and testicular metabolism due to decreased volume of the seminiferous tubules (Yang *et al.*, 2011). On histology, there is a range of different seminiferous tubule abnormalities, with some tubules that appear normal, though with reduced spermatogenesis, to completely sclerosed tubules. Because the loss of germ cells is patchy, it is likely that other factors such as vascular ischemia, increased cytokines, reactive oxygen species, and other paracrine factors may play important roles in addition to decreased T production by Leydig cells (Sasano and Ichijo, 1969; Paniagua *et al.*, 1991).

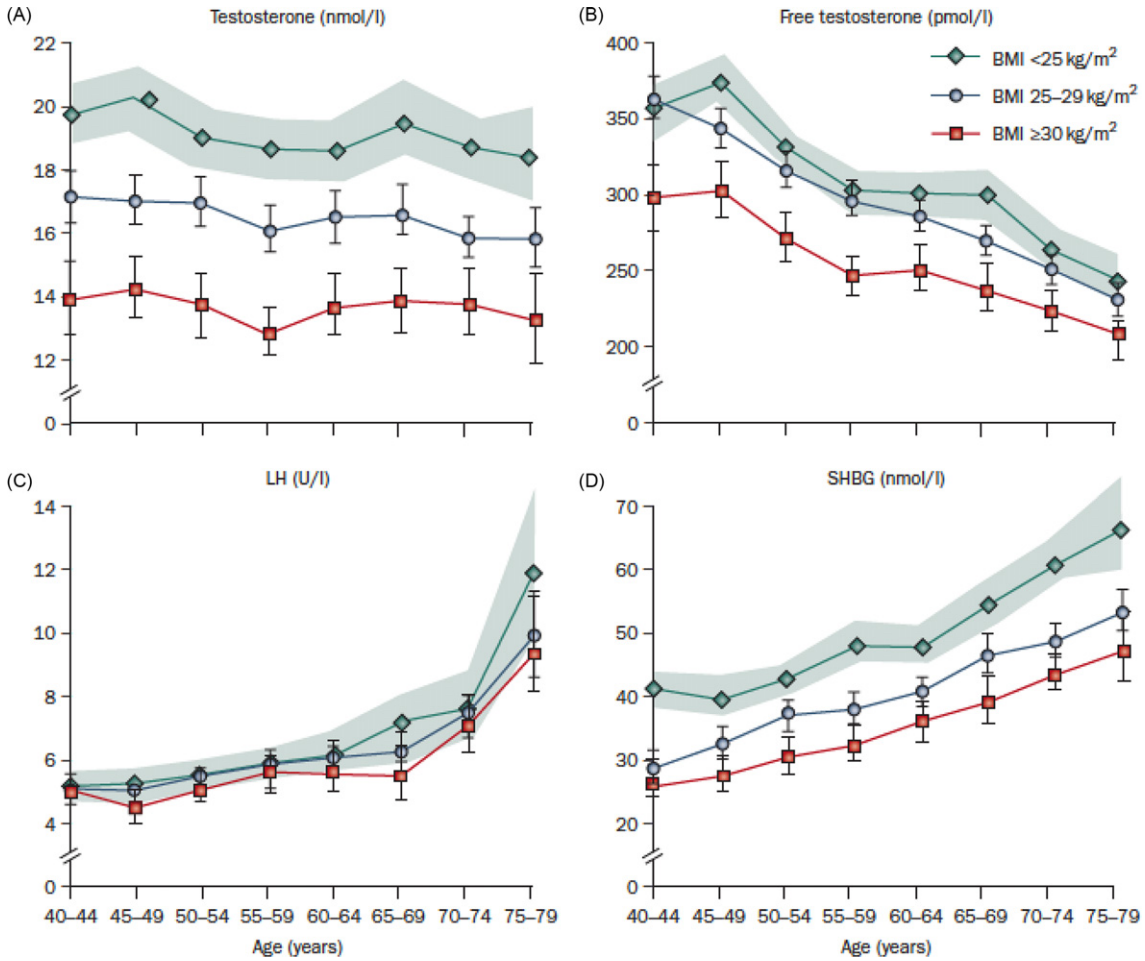

Fig. 2 Relationship between age, BMI, and hormones. The cohort was stratified according to BMI into three groups: nonobese (BMI <25 kg/m^2), overweight (BMI 25–30 kg/m^2), and obese (BMI >30 kg/m^2). Mean (95% CI in shaded area and vertical lines) total and free T (A, B) and SHBG (D) were significantly lower in the overweight and obese at all ages, compared with nonobese. The total T and SHBG age trends in the three BMI categories were similar, indicating no interaction between BMI and age. The free T age trend in the obese group was less steep than in the other two groups, indicating an interaction between BMI and age. Mean LH (C) was not significantly different among the three groups at the median age of 60 year. LH was higher in the older than 70 years nonobese group, compared with the overweight and obese groups, due to a negative BMI-age interaction. Reproduced from Wu, F. C., Tajar, A., Pye, S. R., et al. (2008). Hypothalamic–pituitary–testicular axis disruptions in older men are differentially linked to age and modifiable risk factors: The European Male Aging Study. *Journal of Clinical Endocrinology Metabolism* **93**, 2737–2745 with permission from The Endocrine Society.

Conclusion

In summary, evidence from animal models and men showed that aging is associated with dysfunction of the Leydig cells as well as the hypothalamic-pituitary-gonadal axis. Complex interactions exist within the HPT axis. Men with HPT axis abnormalities are more obese and may recover with lifestyle changes, whereas men with primary Leydig cell dysfunction are older and tend to remain hypogonadal.

Hypogonadism and Testosterone Therapy in Elderly Men

Bu B Yeap, University of Western Australia, Perth, WA, Australia and Fiona Stanley Hospital, Perth, WA, Australia

Introduction

Male ageing is characterized by a decline in circulating testosterone concentrations and the accumulation of medical comorbidities (Harman *et al.*, 2001; Feldman *et al.*, 2002). Cause and effect are debated as to whether age per se drives the decline in circulating androgens, or whether this is a reflection or consequence of increasing ill-health. Nevertheless in epidemiological studies lower testosterone concentrations consistently predict poorer health outcomes in older men extending across multiple health domains (Yeap *et al.*, 2012a). Prominent amongst these are medical comorbidities that become more prevalent during aging, namely frailty, osteoporosis, and cardiovascular disease.

Of note, androgen deficiency due to diseases of the hypothalamus, pituitary or testes can present in elderly men and this needs to be identified and treated appropriately taking age and any coexisting medical comorbidities into account (Yeap *et al.*, 2016a, b). However the broader role of testosterone as a pharmacological intervention in elderly men without hypothalamic, pituitary or testicular disease who have low testosterone concentrations when compared to younger men continues to be debated. In this context, improvements in sexual function, anemia and bone density can be expected, but not in walking ability, vitality or cognition (Snyder *et al.*, 2016, 2017; Roy *et al.*, 2017; Resnick *et al.*, 2017). Whether or not testosterone therapy precipitates cardiovascular adverse effects in frail elderly men remains controversial (Basaria *et al.*, 2010; Budoff *et al.*, 2017). Therefore the balance of benefits and risks of testosterone therapy in elderly men in the absence of pathological hypogonadism, particularly over extended periods of treatment, remain unclear.

In this review, the longitudinal trajectories of circulating testosterone during male aging will be explored, as will the epidemiological associations of low testosterone with age-related ill-health particularly frailty, osteoporosis and cardiovascular disease in older men. The diagnosis of hypogonadism in elderly men will be discussed together with indications for treatment and treatment-related considerations. The role of testosterone in elderly men who do not have hypothalamic, pituitary or testicular disease and the potential for cardiovascular adverse events will be considered. Finally, priorities for future research will be discussed.

Testosterone in Aging Men

Several longitudinal studies in men have demonstrated a consistent decline in circulating testosterone with increasing age (Harman *et al.*, 2001; Feldman *et al.*, 2002; Camacho *et al.*, 2013; Shi *et al.*, 2013; Hsu *et al.*, 2016). In studies using mass spectrometry for measurement of testosterone concentrations, the annual rate of decline is in the order of 1%–2% per annum: slightly less in middle-aged men and slightly more in older men (Camacho *et al.*, 2013; Shi *et al.*, 2013; Hsu *et al.*, 2016). Part of this decline may relate to presence of central adiposity or to the presence of medical comorbidities resulting in a reduction in function of the hypothalamic-pituitary-testicular axis and a low circulating testosterone with a low or normal luteinising hormone (LH) concentration (Shi *et al.*, 2013; Camacho *et al.*, 2013; Rastrelli *et al.*, 2015). Nevertheless, even very healthy older men aged 70–89 years have lower circulating testosterone compared with reproductively normal men aged 21–35 years (Yeap *et al.*, 2012b; Sikaris *et al.*, 2005). Therefore there is likely to be a contribution of advancing age to the decline in circulating testosterone in men. Conversely, observational analyses have correlated higher circulating concentrations of testosterone's bioactive metabolites, dihydrotestosterone and estradiol, with longer leucocyte telomere lengths in men, thus associating sex hormones with slower biological ageing (Yeap *et al.*, 2016c). Therefore advancing age, declining circulating testosterone and the accumulation of age-associated morbidities are interrelated factors impacting on men's health.

The entity of "late onset hypogonadism" (LOH) has been proposed to describe older men with lower circulating testosterone concentrations and associated sexual symptoms such as low sexual desire and poor erectile function (Wu *et al.*, 2010). Decreased libido is a presenting symptom of androgen deficiency, but erectile dysfunction tends to have a multifactorial basis and is a less common presenting feature of androgen deficiency and then only at very low testosterone concentrations (Yeap *et al.*, 2016a). In a study of men aged 40–70 years with erectile dysfunction and baseline testosterone concentrations <11.5 nmol/L of free testosterone <173 pmol/L, sildenafil dose was optimized following which men were randomized to testosterone or placebo (Spitzer *et al.*, 2012). Sildenafil alone increased erectile function and subsequent addition of testosterone did not further improve erectile dysfunction scores.

When using a board definition of sexual activity appropriate for epidemiological studies in elderly men, about a third will report being sexually active (Hyde *et al.*, 2010a). The proportion falls from $\sim$40% at age 75–79, to $\sim$10% at age 90–95 years. Low testosterone concentrations do predict reduced sexual activity in elderly men (Hyde *et al.*, 2010a); and causality is supported by the result of the T-Trials in which testosterone therapy in men aged ≥ 65 years with baseline testosterone <9.5 nmol/L improved sexual function (Snyder *et al.*, 2016). However multiple other factors are associated with reduced sexual activity in older men including advanced age, not cohabiting with a partner, cohabiting with a disinterested partner or a partner with physical

limitations, and the presence of medical comorbidities (Hyde *et al.*, 2010a). Thus while the concept of LOH can be utilized informatively for epidemiological studies, its clinical utility remains to be determined. A logical approach to men classified as having LOH on the basis of lower testosterone concentrations and three or more sexual symptoms (reduced sexual thoughts, weaker morning erections, and erectile dysfunction) would comprise lifestyle modification, reduction of excess weight, and good treatment of comorbid diseases, with evidence currently lacking for the benefits of testosterone treatment in this setting (Huhtaniemi, 2014).

Low testosterone with an elevated LH is an indicator of primary hypogonadism (Wu *et al.*, 2010; Yeap *et al.*, 2016a). Cross-sectional studies have reported higher LH concentrations in older men (e.g., Baker *et al.*, 1976). In a longitudinal study of 1,025 men who had a median age of 75.1 years at baseline followed for 8.6 years, the longitudinal decline in dihydrotestosterone which was −7.2%/year was more marked than the decline in testosterone of −2.0%/year (Yeap *et al.*, 2018). Declines in both dihydrotestosterone and testosterone were correlated with increases in LH. Of note, annualized increases in LH of 7.5%/year and sex hormone-binding globulin (SHBG) of 5.6%.year were present in these men (Yeap *et al.*, 2018). The proportion of men with an elevated LH (>16 IU/L) increased from 2.4% at baseline to 17.4% at follow-up. Therefore, there is some evidence to support the concept of longitudinal impairment of testicular endocrine function occurring in men transitioning from the eighth to ninth decades of life (Yeap *et al.*, 2018). The clinical implications of this observation require further clarification.

Low Testosterone and Frailty

Frailty can be characterized as a decline in multiple organ systems leading to loss of function, diminished physiological reserve and hence ability to cope with stressors, with an increased risk of disability and death (Fried *et al.*, 2001; Ahmed *et al.*, 2007). Frailty is increasingly prevalent in elderly adults and contributes to the poorer health outcomes (Ahmed *et al.*, 2007). A feature of frailty is unintentional weight loss, in particular of lean or muscle mass, with accompanying reductions in physical performance (Fried *et al.*, 2001). Thus there is an overlap between frailty and sarcopenia or loss of muscle mass or strength, leading to loss of mobility and function, and to falls and mortality (Morley *et al.*, 2014). Reduced muscle mass and strength is a recognized presenting feature of androgen deficiency (Yeap *et al.*, 2016a). In epidemiological studies in middle-aged and older men, lower circulating testosterone concentrations have been associated with frailty both cross-sectionally and longitudinally (Cawthon *et al.*, 2009; Hyde *et al.*, 2010b; Travison *et al.*, 2011). This is consistent with the actions of testosterone in older men to promote gain of lean or muscle mass and strength (Bhasin *et al.*, 2005; Page *et al.*, 2005; Sattler *et al.*, 2009). Therefore in elderly men, lower circulating testosterone, sarcopenia and frailty are interrelated conditions with implications for health.

In a randomized clinical trial (RCT) in men aged ≥65 years with low–normal baseline testosterone concentrations and mobility limitations, testosterone therapy over a 6 month intervention period improved measures of physical performance (Travison *et al.*, 2011). However, that trial was discontinued prematurely due to excess adverse events in the testosterone arm (Basaria *et al.*, 2010). Of note, a similar RCT in men aged ≥65 years with baseline testosterone ≤12 nmol/L who were intermediate-frail or frail fond that testosterone therapy over a 6 month duration improved lower limb muscle strength, with an improvement in physical function in a subgroup of older and more frail men (Srinivas-Shankar *et al.*, 2010). No signal for excess cardiovascular adverse events was seen in that study, but the benefits of testosterone therapy were not sustained at 6 months posttreatment (O'Connell *et al.*, 2011). In a secondary analysis of a 3 year RCT in healthy older men, testosterone treatment in men aged ≥60 years with baseline testosterone 3.5–13.9 nmol/L or free testosterone <174 pmol/L resulted in increased muscle strength compared with placebo (Storer *et al.*, 2017). However, in that study muscle strength peaked at 6 months, and declined toward baseline levels by month 36 despite continuation of treatment. In the Physical Function Trial of the T-Trials, there was no significant increase in the proportion of men who increased their walking distance by ≥50 m in the 6 min walk test in the testosterone arm compared with placebo (Snyder *et al.*, 2016). There was an increase in walking distance at 12 months when the entire T-Trials cohort was analyzed. Therefore while testosterone therapy in elderly men can be expected to have beneficial anabolic actions on muscle, the magnitude and durability of such effects and their functional benefits remain unclear. Thus further RCTs are needed to define the role of testosterone in elderly men with or at risk of frailty with regards to optimal timing and durability of therapy.

Low Testosterone and Osteoporosis

Osteoporosis is an important cause of morbidity in adult men and as with women its prevalence increases with age (Ebeling, 2008). Osteopenia, osteoporosis and fracture, or loss of height, are presenting clinical features of androgen deficiency (Yeap *et al.*, 2016a). In an epidemiological study of men aged >60 years, low circulating testosterone was associated with increased risk of low-trauma fracture (Meier *et al.*, 2008). In a study of men with an average age of 75 years, low serum estradiol and high SHBG concentrations were associated with increased risk of fractures (Mellstrom *et al.*, 2008). However other studies in older men have implicated higher concentrations of SHBG but not circulating sex hormones with increased risk of vertebral fracture (Cawthon *et al.*, 2016; Vandenput *et al.*, 2016). While the association of low estradiol and higher SHBG with fracture risk has been confirmed in a recent study, measurement of sex hormones did not add substantially to clinical fracture risk prediction as afforded by clinical

parameters such as age, body mass index and femoral neck bone mineral density, or tools such as the Fracture Risk Assessment Tool (FRAX) with measurement of bone mineral density (Orwoll *et al.*, 2017).

RCTs of testosterone therapy in men aged >65 years with reasonable baseline testosterone concentrations in the range of 12–14 nmol/L have not shown consistent increases in bone mineral density (Snyder *et al.*, 1999; Kenny *et al.*, 2001; Christmas *et al.*, 2002). Other studies in men aged 60 years or more with lower baseline testosterone concentrations in the range of 9–10 nmol/L have reported increases in primarily lumbar spine bone mineral density (Amory *et al.*, 2004; Basurto *et al.*, 2008). A meta-analysis of 29 testosterone RCTs, most of which were not designed with bone mineral density as the primary outcome, showed an improvement in lumbar spine but not femoral neck bone mineral density (Isidori *et al.*, 2005). In the T-Trials which recruited men aged ≥65 years with baseline testosterone <9.5 nmol/L, the Bone substudy demonstrated increases in volumetric bone mineral density and estimated bone strength and both spine and hip sites following 12 months of treatment with testosterone (Snyder *et al.*, 2017). Increases at the spine were consistently greater than those seen at the hip. However, it is important to recognize that testosterone has not been proven in RCTs to reduce incidence of fracture in older men. Until such RCT evidence is available to clarify the effect of testosterone on incidence of osteoporotic fracture, men at high risk of fracture should be treated with osteoporosis therapies proven to reduce incidence of fracture (Watts *et al.*, 2012). However, an improvement in bone mineral density could be considered as an additional benefit in men receiving testosterone therapy for treatment of androgen deficiency due to underlying hypothalamic, pituitary or testicular disease.

Low Testosterone and Cardiovascular Disease

Advanced age is a powerful predictor for incidence of cardiovascular disease encompassing cardiac events such as myocardial infarction and cerebrovascular events such as stroke (Roger *et al.*, 2011). Epidemiological studies have associated lower circulating testosterone concentrations with increased incidence of cardiovascular events (for review, see Yeap, 2015). For example, in a longitudinal analysis of 2416 men aged 69–81 years, men with higher testosterone concentrations had a lower incidence of cardiovascular events during follow-up compared to men with lower testosterone concentrations (Ohlsson *et al.*, 2011). No corresponding association was found in an analysis of predominantly middle-aged men (Chan *et al.*, 2016), suggesting that the relationship is more apparent in older men. There may be possible differences according to the vascular territory of interest. In a longitudinal analysis of 3690 men aged 70–89 years, lower circulating testosterone concentrations were independently associated with increased risk of stroke (Yeap *et al.*, 2009, 2014a). There was a parallel association of lower dihydrotestosterone with higher risk of stroke (Yeap *et al.*, 2014a). By contrast, a longitudinal analysis of 1032 men aged 76 years reported a U-shaped association of dihydrotestosterone with stroke (Shores *et al.*, 2014a). Similarly, epidemiological studies have demonstrated associations of lower circulating testosterone with deaths from cardiovascular disease (Tivesten *et al.*, 2009), and lower circulating dihydrotestosterone with deaths from cardiovascular disease (Shores *et al.*, 2014b) or ischemic heart disease (Yeap *et al.*, 2014b).

While the epidemiological data are suggestive of a protective effect of endogenous androgens in older men against the incidence of cardiovascular events particularly stroke, no RCT has been undertaken with the prespecified primary outcome of incident cardiovascular events. In light of this evidence gap, analyses have been undertaken of insurance databases of men prescribed testosterone and testosterone RCTs in which cardiovascular adverse events have been reported. Retrospective analyses comparing men who were prescribed testosterone with men who were not have reported conflicting results: suggesting an increased risk of cardiovascular adverse events (Vigen *et al.*, 2013; Finkle *et al.*, 2014), neutral or reduced risk of myocardial infarction (Baillargeon *et al.*, 2014; Sharma *et al.*, 2015), or a reduced risk of major cardiovascular events (Anderson *et al.*, 2016; Wallis *et al.*, 2016; Cheetham *et al.*, 2017). Several studies have associated testosterone prescription with lower mortality (Sharma *et al.*, 2015; Shores *et al.*, 2012; Muraleedharan *et al.*, 2013; Wallis *et al.*, 2016). However, retrospective analyses of this type have recognized limitations particularly the absence of randomization and multiple potential sources of bias and confounding.

One RCT of testosterone in older men with mobility limitations was stopped due to an excess of adverse events in the testosterone arm (Basaria *et al.*, 2010), another in a similar population of older men who were frail or intermediate frail did not show any signal for excess cardiovascular adverse events (Srinivas-Shankar *et al.*, 2010). The T-Trials Cardiovascular substudy reported an increase in noncalcified coronary atheromatous plaque in men in the testosterone group (Budoff *et al.*, 2017). However that finding is difficult to interpret because the groups were unbalanced: men in the placebo group had more plaque at baseline and at the end of the trial, compared with men in the testosterone group (Budoff *et al.*, 2017). By contrast, in a 3 year RCT testosterone treatment did not alter carotid intima-media thickness (Basaria *et al.*, 2015). In the T-Trials itself with 790 men allocated to either testosterone or placebo for 12 months, there were 7 major cardiovascular adverse events in each arm of the study (Snyder *et al.*, 2016), a low overall rate of events with no signal for any excess risk in the testosterone arm of the trial. Analyses of testosterone RCTs which have reported cardiovascular adverse events have generally not shown any increase in cardiovascular events associated with testosterone therapy (Albert and Morley, 2016; Onasanya *et al.*, 2016; Alexander *et al.*, 2017). However, in one analysis there was a possible signal for adverse events in the first 12 months of treatment predominantly in men aged ≥65 years (Albert and Morley, 2016).

Therefore, at present it is not possible to draw any definitive conclusion as to whether testosterone treatment would have a beneficial, neutral or adverse effect on the incidence of cardiovascular disease in older men. Epidemiological data suggest an association of endogenous testosterone with reduced cardiovascular risk, but a RCT with cardiovascular events as the prespecified primary endpoint is needed to provide clarity. Pending such an RCT it would be prudent to counsel older men particularly those

with preexisting cardiovascular disease that there is an evidence gap and there may be a possibility of precipitating adverse events with treatment, and to ensure that cardiovascular risk factors and disease are optimally managed irrespective of whether testosterone therapy is being considered.

Diagnosis of Hypogonadism in Elderly Men

The diagnosis of hypogonadism in elderly men should be made following a careful clinical assessment to determine whether symptoms and signs of androgen deficiency are present (Yeap *et al.*, 2016a). A comprehensive medical history including details of any systemic illnesses, pituitary conditions or testicular surgery or injury, use of medications including glucocorticoids and opioids, and a full physical examination are essential elements. In the context of an aging population there will be increasing proportions of elderly men with existing medical comorbidities contributing to reduced health and well-being (Vos, 2015). Thus several nonspecific symptoms of androgen deficiency such as lethargy, fatigue, low mood, impaired short term memory and sleepiness may overlap with symptoms often found in elderly men even in the absence of disease affecting the gonadal axis (see **Table 1**). Organ-specific symptoms need to be interpreted with care: osteoporosis and sarcopenia are common in elderly men and whilst their presence should prompt evaluation for androgen deficiency, they may be due to other causes (Johnell and Kanis, 2005; Ebeling, 2008; Rolland *et al.*, 2008). The symptom of decreased libido should also be interpreted in the context of aging: sexual activity remains an important consideration for many men in their early seventies, but less so for men in their late 80s and early 90s (Hyde *et al.*, 2010a). The time course over which symptoms have evolved and additional information from partners can be informative. A thorough physical examination should be conducted which includes assessment of lean and fat mass, presence of gynaecomastia, and testicular volumes.

In men with symptoms and signs indicative of androgen deficiency, confirmatory biochemical testing is indicated. Collection of an early morning blood sample for assay of testosterone together with LH and follicle-stimulating hormone (FSH) concentrations is recommended (Yeap *et al.*, 2016a). An accurate and reliable testosterone assay is important: automated immunoassays can exhibit nonspecificity and method dependent bias and mass spectrometry is preferred where available (Taieb *et al.*, 2003). Elderly men as a group will have lower testosterone concentrations compared with middle-aged or younger men (Handelsman *et al.*, 2015, 2016). Therefore an age-appropriate reference range for circulating testosterone should be utilized. Bearing in mind that each result needs to be interpreted with reference to the individual patient and that reference ranges are not necessarily 100% sensitive and specific, lower cut-offs for serum testosterone concentrations are reported as 10.4 nmol/L in reproductively normal men aged 21–35 years and 6.4 nmol/L in very healthy men aged 70–89 years (Sikaris *et al.*, 2005; Yeap *et al.*, 2012b). For men between the ages of 35 and 70 years interpolation would provide a cut-off at 8 nmol/L, which is concordant with previous cohort studies (Travison *et al.*, 2017). Confirmatory testing should be performed also with an early morning sample and fasting if practicable. In the setting of a low circulating testosterone, elevated LH, and FSH are indicative of primary testicular disease. The role of age-appropriate cut-offs for elevated LH is unclear: conventional immunoassays typically cite an upper cut-off of 8 IU/L whereas a value of 9.4 IU/L has been reported from a reference group of 40–44 year old men (Wu *et al.*, 2010) and one of 16 IU/L from a reference group of 71–87 year old men (Yeap *et al.*, 2018).

Testosterone circulates bound to SHBG and also to albumin with a small fraction unbound or free with ongoing controversy over the clinical utility of free testosterone concentrations for the evaluation of hypogonadism (Goldman *et al.*, 2017; Handelsman, 2017). Free testosterone concentration has been proposed as a potentially informative marker of androgen status in men with total testosterone concentrations near the lower limit of normal with alterations in SHBG concentrations (Bhasin *et al.*, 2010; Goldman *et al.*, 2017). In an epidemiological study of men aged 40–79 years, calculated free testosterone was associated with sexual symptoms even in the presence of normal (total) testosterone (Antonio *et al.*, 2016). However there are two major limitations of using free testosterone concentrations for clinical diagnostic purposes. Firstly, to measure free testosterone using equilibrium dialysis is labor-intensive (and expensive) therefore most laboratories calculate free testosterone from total testosterone and SHBG with results that can be variable and not wholly accurate (Sartorius *et al.*, 2009; Ly *et al.*, 2010). Secondly, validated reference ranges for calculated free testosterone are lacking, and such reference ranges would need to specify and utilize

Table 1 Presenting clinical features of androgen deficiency (postpubertal onset)

Nonspecific symptoms	*Organ specific symptoms*
Lethargy, fatigue	Bone: osteopenia, osteoporosis, fracture/loss of height
Decreased energy and/or endurance	Muscle: reduced muscle mass and strength (sarcopenia)
Low mood, irritability, poor concentration, impaired short-term memory, sleepiness	Adipose: increased fat mass
Deteriorating work performance	Gynecomastia
Hot flushes	Sexual/reproductive:
	Decreased libido
	Erectile dysfunction (uncommon as a presenting feature of androgen deficiency, and then only at very low serum testosterone)

both accurate measurement of total testosterone and accurate calculation of free testosterone. An alternative approach is to interpret the (total) testosterone result in the light of SHBG concentrations. SHBG concentrations can be markedly elevated by hyperthyroidism, liver disease and antiepileptic medications, or suppressed in the setting of obesity, insulin resistance and exposure to exogenous androgens (Yeap *et al.*, 2016a). In the first scenario, (total) testosterone concentrations may be high without androgen excess being present, in the second scenario (total) testosterone concentrations may be low without necessarily being indicative of androgen deficiency.

Testosterone Therapy in Elderly Men—Indications

Testosterone therapy should be considered in elderly men who have the clinical syndrome of androgen deficiency due to underlying hypothalamic, pituitary or testicular disease (see **Table 2**). In such men the indication for testosterone therapy would be to improve the symptoms and signs of androgen deficiency (Yeap *et al.*, 2016a). Acquired causes of androgen deficiency are more likely to present in older age. Of note, hypogonadism may present with both reduced fertility due to impaired spermatogenesis as well as with androgen deficiency from inadequate testosterone production: in such situations management of fertility precedes consideration of testosterone replacement therapy (Yeap *et al.*, 2016a). In elderly men, fertility is unlikely to be a presenting complaint, whereas the age of children fathered implies a timeframe for when gonadal function was previously adequate.

Age per se should not be regarded as a barrier to testosterone treatment in elderly men with androgen deficiency from hypothalamic, pituitary or testicular disease. However, age and the presence of a circulating testosterone that is low when compared to younger men, is not an indication for testosterone therapy in the absence of pathological hypogonadism (**Table 2**). Similarly the presence of sexual dysfunction or nonspecific symptoms in the absence of proven androgen deficiency is not an indication for testosterone therapy. Elderly men with LOH, or those with low testosterone in the setting of obesity or medical comorbidities, should be encouraged to adopt healthy lifestyle behaviors and have existing comorbidities optimally managed with more evidence needed to determine whether testosterone therapy would be efficacious and safe in that setting (Huhtaniemi, 2014; Grossmann and Matsumoto, 2017). Treatment with glucocorticoids or opioids is associated with reduction in function of the endogenous hypothalamic-pituitary-gonadal axis (Morrison *et al.*, 1994; Fraser *et al.*, 2009; Vuong *et al.*, 2010). Where ongoing treatment with glucocorticoids or opioids at substantive doses is medically indicated and symptoms or signs suggestive of androgen deficiency are present, specialist endocrine review to provide individualized assessment and care may be recommended.

The T-Trials enrolled men aged ≥ 65 years with baseline testosterone < 9.5 nmol/L who had symptoms consistent with, but not diagnostic of, hypogonadism (Snyder *et al.*, 2016). Those men did not have apparent hypothalamic, pituitary or testicular disease. Testosterone treatment in the T-Trials resulted in a modest improvement in sexual function although the difference between testosterone and placebo groups was diminishing at 12 months (Snyder *et al.*, 2016). Improvements in anemia and bone density were seen, with negative primary outcomes for the physical function, vitality, and cognition trials (Snyder *et al.*, 2016, 2017; Roy *et al.*, 2017; Resnick *et al.*, 2017). These findings provide important information on the effects of testosterone therapy, but in isolation are insufficient to constitute a new indication for testosterone therapy in the general population of elderly men. The T-Trials were conducted in response to the recommendation from the Institute of Medicine for efficacy trials to establish whether testosterone therapy would benefit this group of men (Liverman and Blazer, 2004). The second part of the Institute of Medicine's recommendation was for a larger trial to determine possible risks only if benefits were found. It is this second, larger trial that is now awaited before the benefits and risks of treating elderly men with testosterone in the absence of hypothalamic, pituitary or testicular disease can be fully defined.

Table 2 Use and misuse of androgens

Use: physiological treatment with testosterone replacement for androgen deficiency in men with pathological hypogonadism	*Subject of ongoing research: use in these conditions remains to be fully evaluated for safety and efficacy in randomized placebo-controlled clinical trials*	*Misuse: use without a valid medical indication*
Primary testicular failure • Klinefelter syndrome • Testicular trauma, torsion, removal • Testicular infection • Testis atrophy of any cause Hypogonadotrophic hypogonadism (Secondary testicular failure) • Congenital: Kallmann's, variants without anosmia • Acquired: pituitary tumor[a], surgery, radiotherapy	• Middle aged and older men • Androgen deficiency secondary to chronic disease and ill-health • Hormonal male contraception	• Male infertility • Sexual dysfunction/impotence (in the absence of proven androgen deficiency) • "Male menopause," "andropause," "low T," "late onset hypogonadism" • Nonspecific symptoms (lethargy, tiredness, low energy)

[a]In the case of prolactinoma, dopamine agonist therapy may normalize testosterone concentrations without requirement for testosterone therapy.

Testosterone Therapy in Elderly Men—Expected Benefits

In men who are hypogonadal due to underlying hypothalamic, pituitary or testicular disease, the expected benefit of testosterone therapy is to improve the symptoms and signs of androgen deficiency (**Table 1**). Many of these beneficial effects will extend across the spectrum of middle-aged to elderly men. With regard to sexual symptoms such as loss of libido, in the T-Trials there was an improvement in sexual function spanning a range of sexual behaviors in testosterone-treated men (Cunningham *et al.*, 2016). Clearly cohabitation with a willing partner is a potentially vital modulator of this effect (Hyde *et al.*, 2010a). With regard to reduced muscle mass and strength, older men are as responsive as younger men to the anabolic action of testosterone (Bhasin *et al.*, 2005; Page *et al.*, 2005). With respect to bone mineral density, older men with low–normal testosterone concentrations exhibit increases in bone mineral density in response to testosterone (Amory *et al.*, 2004; Basurto *et al.*, 2008). Frankly hypogonadal men show a similar improvement with the effects of testosterone more prominent in trabecular bone (Benito *et al.*, 2005). Therefore elderly men with pathological hypogonadism should expect improvement in the clinical features of androgen deficiency with appropriate testosterone replacement therapy.

Of note, nonspecific symptoms and even organ-specific symptoms which are due not to androgen deficiency but to other medical conditions, should not be expected to respond comprehensively to testosterone therapy (**Table 1**). Symptoms such as lethargy, fatigue, reduced energy and decreased endurance are symptoms of many medical illnesses which are common in elderly men. Clearly such underlying medical conditions need to be identified and appropriately treated in men whether or not testosterone therapy is being considered. The T-Trials vitality substudy reported a negative primary outcome (Snyder *et al.*, 2016), which may reflect the fact that multiple comorbidities contribute to symptoms such as fatigue. Of note, despite there being an association between low circulating testosterone and poorer performance on tests of cognitive function in aging men (for review, see Yeap, 2014), the T-Trials cognition substudy did not demonstrate any benefit of testosterone therapy in men classified as having age-associated memory impairment (Resnick *et al.*, 2017). This is concordant with two other recent RCTs in older men which found no benefit of testosterone therapy on cognition (Emmelot-Vonk *et al.*, 2008; Huang *et al.*, 2016). Therefore, while it is possible that men who are overtly hypogonadal with very low circulating testosterone concentrations might show improvement in symptoms relating to concentration or short-term memory when testosterone treatment is instituted, RCTs in men without overt pathological hypogonadism do not support a beneficial role for testosterone in that setting.

As noted earlier, sarcopenia and osteoporosis are manifestations of androgen deficiency but are also common in elderly men for a range of reasons even when there overt gonadal pathology is absent (Ahmed *et al.*, 2007; Ebeling, 2008). Factors such as poor nutrition, lack of physical activity, presence of systemic illnesses or other medical conditions such as thyrotoxicosis may contribute to weight loss and osteoporosis (Rolland *et al.*, 2008; Ebeling, 2008). Therefore, the presence of sarcopenia, or osteopenia or osteoporosis in elderly men should prompt clinical evaluation for possible underlying causes, with androgen deficiency being an important cause not to be overlooked. An improvement in muscle mass and in bone mineral density would be an expected benefit of testosterone therapy in elderly men with androgen deficiency, particularly when other contributing factors are absent or appropriately managed.

Contraindications, Precautions, and Potential Adverse Effects

The presence of hormone-sensitive malignancy such as prostate or breast cancer is a recognized contraindication to testosterone therapy in men (**Table 3**). Prostate cancer is more prevalent in elderly men compared to younger or middle-aged men (Heinzer and Steuber, 2009). Therefore it is advisable to screen elderly men for the presence of prostate cancer using digital rectal examination and measurement of prostate specific antigen (PSA) prior to commencing testosterone therapy (Yeap *et al.*, 2016b). In systematic reviews and meta-analyses of testosterone RCTs in men across a range of ages with duration up to 3 years, testosterone therapy was not associated with increased incidence of prostate cancer (Fernandez-Balsells *et al.*, 2010; Cui *et al.*, 2014). A similar result was

Table 3 Contraindications and precautions to testosterone treatment

Contraindications	*Precautions*
Advanced, metastatic or incurable prostate cancer Breast cancer	Undiagnosed palpable prostate abnormalities, with or without elevated serum PSA[a] Severe lower urinary tract symptoms (International Prostate Symptom Score >19) Untreated polycythemia Untreated severe obstructive sleep apnoea[b] Unstable or inadequately treated cardiac disease (e.g., poorly controlled cardiac failure or ischemia, recent cardiovascular events) When fertility is desired When subject to occupational drug testing

[a]Urological evaluation may be required. Testosterone treatment may be acceptable in men with screen-detected organ-specific prostate cancer after definitive or clinically adequate prostate treatment.

[b]Testosterone treatment only transiently worsens severity of obstructive sleep apnoea: this is not an absolute contraindication.

reported from a registry study of newly-diagnosed hypogonadal men comparing men treated with testosterone with those who did not receive treatment over a period of 3 years (Debruyne *et al.*, 2017). Benign prostatic hyperplasia is also more common in elderly men (Berry *et al.*, 1984). Thus the presence of severe lower urinary tract symptoms which might relate to impediment of urinary outflow due to benign prostatic hyperplasia is a precaution to be considered (**Table 3**). Urological review may be required where undiagnosed palpable prostate abnormalities are present or an elevated PSA is found.
