Early in pregnancy, the implantation sites in rat endometrium contain 3.5-fold higher concentration regions. As pregnancy progresses, the myometrium starts to express CRH-R2α. In addition, at term, the myometrium expresses the CRH -R1c and -R1d subtypes, indicating a possible functional role for these receptor subtypes at the end of pregnancy (Grammatopoulos *et al.*, 1999). CRH-R1 maintains myometrial quiescence whereas CRH-R2 promotes smooth muscle contractility. It has been suggested that CRH of fetal and maternal origin regulates FasL production, thus affecting the invasion process through a local autocrine/paracrine regulatory loop of cytotrophoblast cells and regulating their own apoptosis. CRH decreases FasL expression in embryonic trophoblast and maternal deciduas and promotes apoptosis of activated T lymphocytes. Abnormalities of maternal immune tolerance to the fetal semiallograft, have been implicated in pathological conditions of pregnancy, such as recurrent early miscarriage, preeclampsia, and eclampsia. These conditions are characterized by inflammation in the fetal–maternal interface and/or systemic manifestations. More specifically, it has been proposed that inadequate, CRH-mediated, self-induction of FasL in extravillous trophoblasts might be involved in the pathophysiology of infertility and recurrent fetal resorption or miscarriage. Abortive deciduas contain leukocytes that are positive for FasL and EVTs, which show increased rates of apoptosis and increased expression of Fas, in contrast to normal pregnancies (Minas *et al.*, 2007). Although very little is known regarding regulation of expression of CRH-Rs in intrauterine tissues, it is possible that chronic exposure to elevated levels of placental CRH in preeclampsia or IUGR might downregulate its own receptors (Karteris *et al.*, 2005). In fetuses with fetal growth restriction umbilical cord CRH is also elevated (Madhappan *et al.*, 2003). Interestingly, the observed downregulation of CRH-R in the preeclamptic placenta is not an isolated finding: several hormonal signals that regulate NOS expression and activity have attenuated effects due to downregulation of their respective receptors, including CRH-R1 and -R2. This downregulation results in compromised responses and reduced relaxation in feto-placental vessels from preeclamptic placentas (Vatish *et al.*, 2006).

IL-6 and CRH are both secreted in a pulsatile function during the active phase of term human labor. The time-integrated concentrations of the two hormones are positively correlated, with IL-6 leading CRH secretion (Papatheodorou *et al.*, 2013). It appears, thus, that proinflammatory mediators may be direct and/or indirect promoters of placental CRH release. Furthermore, the secretion of IL-6, which is a myokine, seems to be associated positively with uterine contractility. Additional studies are needed to elucidate the combined effect of inflammation, placental CRH release and/or CRH-Rs in parturition (Papatheodorou *et al.*, 2013). Corticotropin-releasing hormone induces the production of chemokines and cytokines in myometrium at term and subsequently participates in the cascade of inflammation in uterus. The CRH-induced inflammation can lead to activation of the uterus (You *et al.*, 2014).

Pregnancy is known to be a state of transient hypercortisolemia (Mastorakos and Ilias, 2003). Increased levels of unbound placental CRH are responsible for the hypercortisolism of the second half of pregnancy. This hypercortisolism is followed by a transient suppression of hypothalamic CRH secretion in the postpartum period. This has been associated to the depressive states frequently observed in the postpartum period (Vitoratos *et al.*, 2006).

Perspectives

Pyrrolopyrimidine compounds have been developed as CRH receptor antagonists. Antalarmin has been used in investigations of the physiologic central and peripheral roles of CRH in the I/I response and reproductive function. The binding kinetics of antalarmin were determined in competitive displacement binding experiments with homogenates prepared for tissues differentially expressing CRH-R subtypes. In experiments in rats, the in vivo administration of antalarmin significantly antagonized both central and peripheral actions of CRH. In these experiments, the prior administration of antalarmin or neutralizing anti-CRH antibody blocked pituitary CRH receptors and the exogenous or endogenous CRH-induced ACTH release. Confirming the peripheral pro-inflammatory actions of CRH, antalarmin also suppressed the subcutaneous inflammation induced by carrageenan (Webster *et al.*, 1996). Leukocyte concentrations of subcutaneous exudates were reduced by antalarmin compared to vehicle controls. This effect was dose-dependent and was comparable to that of CRH antibody, where suppression of the leukocyte concentration was observed.

In some experiments, antalarmin was administered in rats from day 1 of pregnancy and for the following 10 days. A 50% reduction was observed in the number of implantation sites in animals that received the higher dose of antalarmin. Additionally,

female rats treated with antalarmin showed diminished endometrial FasL expression. Hence, implantation in rats was prevented by antalarmin, which blocked CRH-R1. Antalarmin reduced the inflammatory-like reaction of the endometrium to the invading blastocyst. Consequently, antalarmin and analogous compounds might represent a new class of nonsteroidal inhibitors of pregnancy at its very early stages.

In sheep, hypothalamic CRH stimulates the fetal production of ACTH, which in turn leads to a surge of fetal cortisol secretion that precipitates parturition. A 10-day intravenous infusion of antalarmin in sheep fetuses significantly prolonged gestation. Thus, CRH receptor antagonism in the fetus can also delay parturition.

Astressin B, a nonspecific CRH receptor antagonist is shown to have a different antagonist profile than antalarmin. Astressin B is unlikely to have access to the CNS following systemic administration in contrast to antalarmin which exerts its activity on the CNS. The differences between antalarmin and astressin B may be due either to non-CRH receptor-mediated effects of antalarmin or to a complex interaction of antalarmin effects at both central and peripheral CRH-Rs (Broadbear *et al.*, 2004). Another study demonstrated that antalarmin and astressin exert different effects on prostaglandin biosynthetic enzymes and thereby modulate the output of prostaglandins from placenta which would be important for controlling pregnancy and parturition (Gao *et al.*, 2008). Xiao *et al.*, showed that astressin B treatment accelerates the return to normal cyclicity, by restoring the normal neuroendocrine regulation of gonadotropin secretion. This effect of CRH receptor antagonist happens although astressin B does not blunt the peripheral HPA axis response to the stressor. The ability to restore normal luteal phase places astressin B or any other CRH antagonist in a very important position in the research of a potential therapeutic agent in stress-related endocrine dysfunction, including the functional hypothalamic chronic anovulation syndrome or the persistent inadequate luteal phase syndrome, and therefore in the treatment of infertility (Xiao *et al.*, 2007).

Given the ability of peripheral CRH to degranulate mast cells, CRH-R1 antagonists could be considered for the treatment of allergic conditions such as asthma, eczema, urticaria or even stress-induced brain inflammatory disorders that increase blood–brain-barrier permeability (Theoharides *et al.*, 1998; Esposito *et al.*, 2002). In the GI tract, these compounds open new therapeutic options in the treatment of lower GI inflammatory diseases associated to CRH, such as the chronic inflammatory bowel syndromes, irritable bowel disease and ulcerative colitis (Kawahito *et al.*, 1995; Gravanis and Margioris, 2005). In human endometrium, CRH-R1 antagonists may be used as antiimplantation agents interfering with the inflammatory phenomena taking place during implantation (Gravanis and Margioris, 2005). Administration of antalarmin to early pregnant rats (day 1 of pregnancy) results in a 70% reduction in implantation sites (Makrigiannakis *et al.*, 2001; Chan, 1998). These examples illustrate the potential therapeutic significance of the CRH in regulating inflammatory phenomena without affecting the rest of the immune system.

The therapeutic potential of pyrrolopyrimidine compounds in some forms of inflammation directly mediated by CRH-R1 is evident and hopefully will enhance the understanding of the multitude of roles that CRH plays in I/I reactions. Although the systemic toxicity of this class of compounds has not yet been fully determined, preliminary studies in rats and nonhuman primates have indicated that they are relatively safe.

Adrenal Insufficiency: Etiology and Diagnosis☆

Nicolas C Nicolaides and Evangelia Charmandari, National and Kapodistrian University of Athens Medical School, Athens, Greece and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Nomenclature

3β-HSD	3β-Hydroxysteroid dehydrogenase
ABCD1	ATP-binding cassette, subfamily D, member 1
ACTH	Adrenocorticotropic hormone
APS	Autoimmune polyendocrinopathy syndrome
CRH	Corticotropin-releasing hormone
CYP	Cytochrome P450
NNT	Nicotinamide nucleotide transhydrogenase
StAR	Steroidogenic acute regulatory protein
TRXR2	Thioredoxin reductase 2
SGPL1	Sphingosine-1-phosphate (S1P) lyase 1

Glossary

Cushing syndrome A condition caused by increased adrenocortical secretion of cortisol resulting from adrenocortical hyperplasia or tumor and characterized by central obesity, acne, amenorrhea, hypertension, abdominal pain, and weakness.

HIV infection Human immunodeficiency virus, the causative agent of AIDS.

Thrombosis The formation, development, or presence of a thrombus, or blood clot, in a blood vessel or the heart.

Introduction

Adrenal insufficiency is a life-threatening disorder characterized by impaired production or action of glucocorticoids, mineralocorticoids and/or adrenal androgens (Charmandari *et al.*, 2014). Adrenal insufficiency may result from diseases affecting the adrenal cortex (primary), the pituitary gland (secondary), or the hypothalamus (tertiary) (Arlt and Allolio, 2003). The clinical manifestations of this condition were first described by Thomas Addison in 1855, and include fatigue, weakness, abdominal pain, anorexia, weight loss, salt craving and orthostatic hypotension. In case of primary adrenal insufficiency, patients may also present with the characteristic hyperpigmentation of the skin (Addison, 1855; Løvås and Husebye, 2005). Although rare, the prevalence of primary adrenal insufficiency has been doubled since 1960s (Mason *et al.*, 1968). The most frequent cause of primary adrenal insufficiency in adults is autoimmune adrenalitis, whereas the most common form in children is congenital adrenal hyperplasia (Charmandari *et al.*, 2014). Interestingly, the ever-increasing application of next generation sequencing technologies has enabled us to have a deeper understanding of genetic defects causing adrenal insufficiency (Flück, 2017). This chapter provides a brief overview of the etiology and diagnosis of adrenal insufficiency.

Causes of Adrenal Insufficiency

Primary Adrenal Insufficiency (Table 1)

Autoimmune Adrenalitis

This condition is the most common cause of primary adrenal insufficiency in adults, and results from an autoimmune process that destroys the adrenal cortex. Both humoral and cell-mediated immune mechanisms directed at the adrenal cortex are involved. Antibodies against several steroidogenic enzymes as well as all three zones of the adrenal cortex are detected in 60%–75% of patients with autoimmune primary adrenal insufficiency but only rarely in patients with other causes of adrenal insufficiency or normal subjects (Husebye and Løvås, 2009a, b). Indeed, antibodies that react with 21-hydroxylase are found in approximately 90% of patients with primary adrenal insufficiency (Erichsen *et al.*, 2009). In addition, antibodies against 17α-hydroxylase and cholesterol side-chain cleavage enzyme have been detected in adults with autoimmune adrenalitis (Mitchell and Pearce, 2012). Approximately 50% of patients with autoimmune adrenal insufficiency have one or more other autoimmune endocrine disorders, as occurs in autoimmune polyendocrinopathy syndrome (APS) type 1 or APECED (autoimmune polyendocrinopathy, candidosis, ectodermal dystrophy) syndrome, which is characterized by adrenocortical insufficiency, hypoparathyroidism, chronic

☆*Change History*: December 2017. Nicolas C Nicolaides and Evangelia Charmandari added Abstract, Keywords, Nomenclature, Tables 1, 2 and 3, and updated the sections "Causes of Adrenal Insufficiency," "Diagnosis," and the reference section.

This chapter is an update of Evangelia Charmandari and George P. Chrousos, Adrenal Insufficiency, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 75–80.

Table 1 Causes of primary adrenal insufficiency

Disease	*Pathogenetic mechanism*
Autoimmune adrenalitis	
Isolated	Associations with HLA-DR3-DQ2, HLADR4-DQ8, MICA, CTLA-4, PTPN22, CIITA, CLEC16A, Vitamin D receptor
APS type 1 (APECED)	AIRE gene mutations
APS type 2	Associations with HLA-DR3, HLA-DR4, CTLA-4
APS type 4	Associations with HLA-DR3, CTLA-4
Infectious adrenalitis	
Tuberculous adrenalitis	Tuberculosis
AIDS	HIV-1, cytomegalovirus
Fungal adrenalitis	Histoplasmosis, cryptococcosis, coccidiodomycosis
Syphilis	Treponema pallidum
African trypanosomiasis	Trypanosoma brucei
Bilateral adrenal hemorrhage	Meningococcal sepsis (Waterhouse–Friderichsen syndrome), primary antiphospholipid syndrome
Bilateral adrenal metastases	Primarily lung, stomach, breast and colon cancer
Bilateral adrenal infiltration	Primary adrenal lymphoma, amyloidosis, haemochromatosis
Bilateral adrenalectomy	Unresolved Cushing syndrome, bilateral adrenal masses, bilateral pheochromocytoma
Drug-induced adrenal insufficiency	
Anticoagulants (heparin, warfarin), tyrosine kinase inhibitors (sunitinib)	Hemorrhage
Aminoglutethimide	Inhibition of P450 aromatase (CYP19A1)
Trilostane	Inhibition of 3β-hydroxysteroid dehydrogenase type 2 (HSD3B2)
Ketoconazole, fluconazole, etomidate	Inhibition of mitochondrial cytochrome P450-dependent enzymes (e.g., CYP11A1, CYP11B1)
Phenobarbital	Induction of P450-cytochrome enzymes (CYP2B1, CYP2B2), which enhance cortisol metabolism
Phenytoin, rifampin, troglitazone	Induction of P450-cytochrome enzymes (primarily CYP3A4), which enhance cortisol metabolism
Genetic disorders	
Adrenoleukodystrophy or adrenomyeloneuropathy	*ABCD1* and *ABCD2* gene mutations
Congenital adrenal hyperplasia	
21-Hydroxylase deficiency	*CYP21A2* gene mutations
11β-Hydroxylase deficiency	*CYP11B1* gene mutations
3β-Hydroxysteroid dehydrogenase type 2 deficiency	*HSD3B2* gene mutations
17α-Hydroxylase deficiency	*CYP17A1* gene mutations
P450 Oxidoreductase deficiency	*POR* gene mutations
P450 Side-chain cleavage deficiency	*CYP11A1* gene mutations
Congenital lipoid adrenal hyperplasia	*StAR* gene mutations
Smith–Lemli–Opitz syndrome	*DHCR7* gene mutations
Adrenal hypoplasia congenita	
X-linked	*NR0B1* gene mutations
Xp21 contiguous gene syndrome	Deletion of the Duchenne muscular dystrophy, glycerol kinase and NR0B1 genes
SF-1 linked	*NR5A1* gene mutations
IMAGe syndrome	*CDKN1C* gene mutations
Kearns–Sayre syndrome	Mitochondrial DNA deletions
Wolman disease	*LIPA* gene mutations
Sitosterolemia (also known as phytosterolemia)	*ABCG5* and *ABCG8* gene mutations
Familial glucocorticoid deficiency (*FGD, or ACTH insensitivity syndromes*)	
Type 1	*MC2R* gene mutations
Type 2	*MRAP* gene mutations
Variant of FGD	*MCM4* gene mutations
FGC—deficiency of mitochondrial ROS detoxification	*NNT*, *TXNRD2*, *GPX1*, *PRDX3* gene mutations
Primary generalized glucocorticoid resistance or Chrousos syndrome	*NR3C1* gene mutations
Triple A syndrome (Allgrove syndrome)	*AAAS* gene mutations
Sphingosine-1-phosphate lyase 1 deficiency	*SPGL1* gene mutations
Infantil Refsum disease	*PHYH*, *PEX7* gene mutations
Zellweger syndrome	*PEX1* and other *PEX* gene mutations

Modified from Charmandari, E., Nicolaides, N. C. and Chrousos, G. P. (2014). Adrenal insufficiency. Lancet 383, 2152–2167; Nicolaides, N.C., Chrousos, G.P. and Charmandari, E. (2017). Adrenal Insufficiency. In: De Groot L. J., Chrousos G., Dungan K., Feingold, K. R., Grossman A., Hershman, J. M., Koch, C., Korbonits, M., McLachlan, R., New, M., Purnell, J., Rebar, R., Singer, F., Vinik, A., eds. Endotext [Internet]. South Dartmouth (MA): MDText.com, Inc., 2000 Flück, C.E. (2017). Mechanisms in Endocrinology: Update on pathogenesis of primary adrenal insufficiency: Beyond steroid enzyme deficiency and autoimmune adrenal destruction. European Journal of Endocrinology 177, R99–R111.

mucocutaneous candidosis, hypoplasia of the dental enamel, and nail dystrophy (Akirav *et al.*, 2011; Michels and Gottlieb, 2010). In APS type 2, patients may present with autoimmune thyroid disease, adrenal insufficiency, with or without diabetes mellitus type 1 (Betterle *et al.*, 2002, 2004; Michels and Gottlieb, 2010). APS type 4 is characterized by autoimmune adrenal insufficiency in association with one or more autoimmune diseases, such as atrophic gastritis, coeliac disease, hypogonadism, vitiligo, pernicious anemia and alopecia, but without thyroid diseases, diabetes mellitus type 1 or other characteristics of APS type 1 or 2 (Betterle *et al.*, 2002, 2004; Michels and Gottlieb, 2010). On the other hand, patients with the more common autoimmune endocrine disorders, such as type 1 diabetes mellitus, chronic autoimmune thyroiditis, or Graves' disease, rarely develop adrenal insufficiency.

Infectious Adrenalitis

Many infectious agents may affect the adrenal gland and result in adrenal insufficiency, including tuberculosis, syphilis, African trypanosomiasis, disseminated fungal infections, HIV infection, and HIV-associated infections, including adrenalitis due to cytomegalovirus and mycobacterium avium complex (Bhatia *et al.*, 1998; Walker *et al.*, 1989; Norbiato *et al.*, 1994).

Hemorrhagic infarction

Bilateral adrenal infarction caused by hemorrhage or adrenal vein thrombosis may lead to adrenal insufficiency (Rao *et al.*, 1989; Rao, 1995). Adrenal hemorrhage has been mostly associated with coagulopathies and the heparin-induced thrombocytopenia syndrome, the primary antiphospholipid syndrome, as well as with meningococcemia (Waterhouse–Friderichsen syndrome) and Pseudomonas aeruginosa infection (Caron *et al.*, 1998).

Drugs

Drugs may cause adrenal insufficiency by inhibiting cortisol biosynthesis, particularly in individuals with limited pituitary and/or adrenal reserve (aminoglutethimide (antiepileptic), etomidate (anesthetic-sedative) (Wagner *et al.*, 1984; Jabre *et al.*, 2009), ketoconazole, fluconazole (antimycotic) (Sonino, 1987) and metyrapone (Schoneshofer and Claus, 1985)), or by accelerating the metabolism of cortisol and most synthetic glucocorticoids following induction of hepatic mixed function oxygenase enzymes (phenytoin, barbiturates, and rifampicin) (Elias and Gwinup, 1980). Moreover, many novel tyrosine kinase-targeting drugs, such as sunitinib, have been shown to cause adrenal dysfunction in animal models (Rock *et al.*, 2007).

Genetic disorders

Several genetic disorders have been identified to cause primary adrenal insufficiency (Reviewed in Flück, 2017). Adrenoleukodystrophy is an X-linked disorder caused by mutations in the ATP-binding cassette, subfamily D, member 1 (*ABCD1*) gene leading to impaired transport of very long-chain fatty acids into peroxisomes and disturbed β-oxidation (Kemp *et al.*, 2012). In patients with adrenoleukodystrophy, these fatty acids are accumulated in many organs, including the adrenal glands, causing dysfunction. In addition to adrenoleukodystrophy, congenital adrenal hyperplasia (CAH) also causes primary adrenal insufficiency due to mutations in genes encoding crucial enzymes for biosynthesis of cortisol in the adrenal cortex. The most frequent form of CAH is classic 21-hydroxylase deficiency, which is caused by *CYP21A2* gene mutations, and characterized by impaired production of glucocorticoids and mineralocorticoids, hyperandrogenism, and dysfunction of the adrenal medulla (Miller and Auchus, 2011; Merke *et al.*, 2000; Charmandari *et al.*, 2002). Other rare forms of CAH have been attributed to mutations in genes encoding 11β-hydroxylase, 3β-hydroxysteroid dehydrogenase, 17α-hydroxylase, 17,20-lyase or P450 oxidoreductase. On the other hand, adrenal hypoplasia congenita has also been demonstrated to cause primary adrenal insufficiency. There are three forms of this condition: (i) the X-linked form, which is caused by *NR0B1* gene mutations; (ii) the Xp21 contiguous gene syndrome, which is attributed to deletion of genes for Duchenne muscular dystrophy, glycerol kinase and *NR0B1*; and (iii) the SF-1 linked form due to *NR5A1* gene mutations (Charmandari *et al.*, 2014; Nicolaides *et al.*, 2017). Moreover, many other rare pathologic conditions listed in **Table 1** have been associated with primary adrenal insufficiency, including the Triple A syndrome (Allgrove syndrome), the IMAGe syndrome, the Kearns–Sayre syndrome, the Wolman's disease, and sitosterolemia (Charmandari *et al.*, 2014; Nicolaides *et al.*, 2017; Flück, 2017). Furthermore, familial glucocorticoid deficiency or corticotropin insensitivity syndromes have been listed as potential causes of primary adrenal insufficiency. Many of these cases have been associated with mutations in the *MC2R* gene (type 1), *MRAP* gene (type 2), and *MCM4* gene (variant of familial glucocorticoid deficiency) (Charmandari *et al.*, 2014; Nicolaides *et al.*, 2017; Flück, 2017). In patients with familial glucocorticoid deficiency syndrome, who do not have any mutations in the above-mentioned genes, the application of next generation sequencing methods revealed novel mutations in the nonclassic steroidogenic acute regulatory protein (*StAR*), *CYP11A1*, nicotinamide nucleotide transhydrogenase (*NNT*), and thioredoxin reductase 2 (*TRXR2*) genes (Reviewed in Flück, 2017). Interestingly, primary adrenal insufficiency was recently associated with steroid resistant nephrotic syndrome, and optionally ichthyosis, cryptorchidism, primary hypothyroidism, neurological anomalies and immunodeficiency. Patients with this syndrome harbored mutations in the gene encoding sphingosine-1-phosphate (S1P) lyase 1 (*SGPL1*) (Prasad *et al.*, 2017; Lovric *et al.*, 2017). Finally, a rare cause of primary adrenal insufficiency is primary generalized glucocorticoid resistance or Chrousos syndrome, which affects almost all tissues, and is characterized by partial insensitivity to glucocorticoids due to mutations in the gene for human glucocorticoid receptor (*NR3C1*) (Nicolaides and Charmandari, 2017).

Secondary and Tertiary Adrenal Insufficiency (Tables 2 and 3)

Secondary adrenal insufficiency may be caused by any disease process that affects the anterior pituitary and interferes with ACTH secretion. The ACTH deficiency may be isolated or occur in association with other pituitary hormone deficits (**Table 2**) (Charmandari *et al.*, 2014; Nicolaides *et al.*, 2017). On the other hand, tertiary adrenal insufficiency can be caused by any process that involves the hypothalamus and interferes with CRH secretion (**Table 3**) (Charmandari *et al.*, 2014; Nicolaides *et al.*, 2017). The most common causes of tertiary adrenal insufficiency are abrupt cessation of high-dose glucocorticoid therapy and treatment of Cushing syndrome; therefore slow withdrawal of glucocorticoids over 9-–12 months is highly recommended for complete recovery of the glucocorticoid-suppressed hypothalamic-pituitary-adrenal (HPA) axis.

Table 2 Causes of secondary adrenal insufficiency

Disease	*Pathogenetic mechanism*
Space occupying lesions or trauma	
Pituitary tumors (adenomas, cysts, craniopharyngiomas, ependymomas, meningiomas, rarely carcinomas) or trauma (pituitary stalk lesions)	Decreased ACTH secretion
Pituitary surgery or irradiation for pituitary tumors, tumors outside the HPA axis or leukemia	Decreased ACTH secretion
Infections or Infiltrative processes (lymphocytic hypophysitis, hemochromatosis, tuberculosis, meningitis, sarcoidosis, actinomycosis, histiocytosis X, Wegener's granulomatosis)	Decreased ACTH secretion
Pituitary apoplexy	Decreased ACTH secretion
Sheehan syndrome (peripartum pituitary apoplexy and necrosis)	Decreased ACTH secretion
Genetic disorders	
Transcription factors involved in pituitary development	
HESX homeobox 1	HESX1 gene mutations
Orthodentical homeobox 2	OTX2 gene mutations
LIM homeobox 4	LHX4 gene mutations
PROP paired-like homeobox 1	PROP1 gene mutations
SRY (sex-determining region Y) – box 3	SOX3 gene mutations
T-box 19	TBX19 gene mutations
Congentital Proopiomelanocortin (POMC) deficiency	POMC gene mutations
Prader–Willi Syndrome (PWS)	Deletion or silencing of genes in the imprinting center for PWS

Modified from Charmandari, E., Nicolaides, N. C. and Chrousos, G. P. (2014). Adrenal insufficiency. Lancet 383, 2152–2167; Nicolaides, N. C., Chrousos, G. P. and Charmandari, E. (2017). Adrenal insufficiency. In: De Groot, L. J., Chrousos, G., Dungan, K., Feingold, K. R., Grossman, A., Hershman, J. M., Koch, C., Korbonits, M., McLachlan, R., New, M., Purnell, J., Rebar, R., Singer, F., Vinik, A., editors. Endotext [Internet]. South Dartmouth (MA): MDText.com, Inc.; 2000.

Table 3 Causes of Tertiary Adrenal Insufficiency

Disease	*Pathogenetic mechanism*
Space occupying lesions or trauma	
Hypothalamic tumors (craniopharyngiomas or metastasis from lung, breast cancer)	Decreased CRH secretion
Hypothalamic surgery or irradiation for central nervous system or nasopharyngeal tumors	Decreased CRH secretion
Infections or Infiltrative processes (lymphocytic hypophysitis, hemochromatosis, tuberculosis, meningitis, sarcoidosis, actinomycosis, histiocytosis X, Wegener's granulomatosis)	Decreased CRH secretion
Trauma, injury (fracture of skull base)	Decreased CRH secretion
Drug-induced adrenal insufficiency	
Glucocorticoid therapy (systemic or topical) or endogenous glucocorticoid hypersecretion (Cushing syndrome)	Decreased CRH and ACTH secretion
Mifepristone	Tissue resistance to glucocorticoids through impairment of glucocorticoid signal transduction
Antipsychotics (chlorpromazine), antidepressants (imipramine)	Inhibition of glucocorticoid-induced gene transcription
Opioids	Decreased CRH and ACTH secretion
Protease inhibitors	Increased sensitivity to GC feedback

Modified from Charmandari, E., Nicolaides, N. C. and Chrousos, G. P. (2014). Adrenal insufficiency. Lancet 383, 2152–2167; Nicolaides, N. C., Chrousos, G. P. and Charmandari, E. (2017). Adrenal insufficiency. In: De Groot, L. J., Chrousos, G., Dungan, K., Feingold, K. R., Grossman, A., Hershman, J. M., Koch, C., Korbonits, M., McLachlan, R., New, M., Purnell, J., Rebar, R., Singer, F., Vinik, A., editors. Endotext [Internet]. South Dartmouth (MA): MDText.com, Inc.; 2000.

Clinical Manifestations of Adrenal Insufficiency

In most of cases, the onset of adrenal insufficiency is insidious and the diagnosis may be difficult until an illness or other stressors precipitate an adrenal crisis.

Adrenal Crisis

Adrenal crisis or acute adrenal insufficiency may be precipitated by a severe infection, bilateral adrenal infarction or hemorrhage or any stressors. Patients with adrenal crisis may present with shock or other nonspecific symptoms, including abdominal pain, nausea, vomiting, fatigue, weakness, confusion or coma. The main pathogenetic mechanism leading to hypotension in adrenal crisis is mineralocorticoid deficiency; however, glucocorticoid deficiency may also cause hypotension by decreasing the synthesis of renin substrate, reducing the responsiveness of blood vessels to vasoconstrictive hormones, and/or increasing the production and action of vasodilatory hormones (Charmandari *et al.*, 2014; Nicolaides *et al.*, 2017).

Chronic Primary Adrenal Insufficiency

The clinical manifestations of chronic primary adrenal insufficiency are fatigue, weakness, general malaise, weight loss, anorexia, abdominal pain, nausea, vomiting, diarrhea, which may alternate with constipation, hypotension, hyperpigmentation, decreased axillary and pubic hair, and loss of libido and amenorrhea in women. Electrolyte abnormalities include hyponatremia, hyperkalemia and metabolic acidosis (Charmandari *et al.*, 2014; Nicolaides *et al.*, 2017).

Secondary or Tertiary Adrenal Insufficiency

Patients with secondary or tertiary adrenal insufficiency may present with clinical manifestations similar to those of chronic primary adrenal insufficiency; however, hyperpigmentation of the skin is not present, because plasma ACTH concentrations are not increased. In addition, dehydration and hyperkalemia do not occur in cases of secondary or tertiary adrenal insufficiency, because the synthesis of mineralocorticoids is preserved; therefore hypotension is less prominent. On the other hand, hyponatremia in these patients may be caused by the "inappropriate" increase in vasopressin secretion. Hypoglycemia mostly occurs in secondary adrenal insufficiency because of the concomitant growth hormone insufficiency and in isolated ACTH deficiency. Clinical manifestations of other anterior pituitary hormone deficiency, headache or visual field defects may also occur in cases of pituitary or hypothalamic tumors (Charmandari *et al.*, 2014; Nicolaides *et al.*, 2017).

Diagnosis

The clinical diagnosis of adrenal insufficiency can be confirmed by demonstrating inappropriately low cortisol secretion, determining whether the cortisol deficiency is secondary or primary and, hence, dependent or independent of ACTH deficiency, and detecting the cause of the disorder (Arlt and Allolio, 2003; Neary and Nieman, 2010).

Cortisol Concentrations

The diagnosis of adrenal insufficiency depends on the demonstration of inappropriately low cortisol secretion. Serum cortisol concentrations are normally highest in the early morning hours (06:00 h–08:00 h) and range between 10 and 20 μg/dL (275–555 nmol/L). Serum cortisol concentrations of less than 3 μg/dL (80 nmoL/L) at 08:00 h are strongly suggestive of adrenal insufficiency, whereas values less than 10 μg/dL (275 nmol/L) make the diagnosis likely (Hägg *et al.*, 1987). Basal urinary cortisol and 17-hydroxycorticosteroid excretion is low in patients with severe adrenal insufficiency but may be low-normal in patients with partial adrenal insufficiency. Generally, baseline urinary measurements are not recommended for the diagnosis of adrenal insufficiency.

ACTH, Renin and Aldosterone Concentrations

Inappropriately low serum cortisol concentrations in association with increased plasma ACTH concentrations determined simultaneously are suggestive of primary adrenal insufficiency. The normal concentrations of plasma ACTH concentrations range between 20 and 52 pg/mL (4.5–12 pmol/L). Patients with primary adrenal insufficiency have increased plasma ACTH concentrations, increased concentration or activity of plasma renin, reduced aldosterone concentrations, hyponatremia and hyperkalemia (Oelkers *et al.*, 1992). On the other hand, inappropriately low baseline morning cortisol and ACTH concentrations indicate secondary or tertiary disease. In these cases, patients have normal concentrations of renin and aldosterone (Oelkers *et al.*, 1992). Given that plasma ACTH measurements depend on proper preparation of the sample and may not be readily available, confirmation of the diagnosis requires stimulation of the adrenal glands with exogenous ACTH.

Standard Dose ACTH Stimulation Test

A standard-dose ACTH stimulation test should be performed in all patients suspected to have adrenal insufficiency (Gleeson *et al.*, 2003; Agha *et al.*, 2006; Arlt, 2009; Chrousos *et al.*, 2009). It involves the intravenous administration of 250 mcg synthetic ACTH (1–24) (cosyntropin), which has the full biologic potency of native ACTH(1–39), and subsequent measurement of serum cortisol concentrations at 0, 30, and 60 min post stimulation. The test is normal if serum cortisol concentrations at 30 min are higher than 18–20 mcg/dL (500–550 nmol/L), making the diagnosis of primary adrenal insufficiency and most of the cases of secondary adrenal insufficiency unlikely. It is worth mentioning that with LCMS or more recent assays for cortisol, the normal values tend to be less than with previous immunoassay methods. This test should not be used in cases of recent onset of secondary adrenal insufficiency, because the adrenal glands will still have the ability to normally respond to ACTH stimulation, since they have not yet atrophied (Arlt, 2009; Chrousos *et al.*, 2009). In such cases, a low-dose ACTH stimulation test or an insulin-induced hypoglycemia test may be used to increase the sensitivity.

Low-Dose ACTH Stimulation Test

This test theoretically provides a more sensitive index of adrenocortical responsiveness because it results in physiologic plasma ACTH concentrations. It is performed by measuring serum cortisol concentrations immediately before and $+10$ min, $+15$ min, $+20$ min, $+25$ min, $+30$ min, $+35$ min, $+40$ min and $+45$ min after intravenous injection of cosyntropin in a dose of 1.0 μg (160 mIU) per 1.73 m^2 (Abdu *et al.*, 1999). In normal subjects, this dose leads to a peak plasma ACTH concentration approximately twice that of insulin-induced hypoglycemia (Nye *et al.*, 1999). A value of 18 μg/dL (500 nmoL/L) or more at any time during the test is indicative of normal adrenal function. The advantage of this test is that it can detect partial adrenal insufficiency that may be missed by the standard high-dose test (Rasmuson *et al.*, 1996; Thaler and Blevins, 1998; Kazlauskaite *et al.*, 2008). The low-dose test is also preferred for patients with secondary or tertiary adrenal insufficiency (Mushtaq *et al.*, 2008; Stewart and Clark, 2009).

Prolonged ACTH Stimulation Tests

Prolonged ACTH stimulation tests are rarely performed because the history and physical examination, the CRH test, and/or determination of cortisol and ACTH concentrations in association with the low-dose ACTH test may provide all necessary information. Prolonged stimulation with exogenous ACTH is used to differentiate between primary and secondary or tertiary adrenal insufficiency. In secondary or tertiary adrenal insufficiency, the adrenal glands display cortisol secretory capacity following prolonged stimulation with ACTH, whereas in primary adrenal insufficiency, the adrenal glands are partially or completely destroyed and do not respond to ACTH. During the test, 250 μg of ACTH is administered intravenously as an infusion over 8 h (8-h test) or over 24 h on two (or three) consecutive days (two-day test). Before and after the infusion, serum cortisol, 24-h urinary cortisol and 17-hydroxycorticoid (17-OHCS) concentrations are simultaneously measured (Rose *et al.*, 1970).

Insulin-Induced Hypoglycemia Test

The insulin tolerance test is another choice to confirm the diagnosis of secondary adrenal insufficiency, especially of recent origin. This test investigates the integrity of the HPA axis. For this purpose, insulin is administered at a dose of 0.1–0.15 U/kg to induce hypoglycemia. Serum cortisol concentrations are measured every 30 min for at least 2 h (Chrousos *et al.*, 2009; Grossman, 2010). Importantly, this test should not be performed in patients with cardiovascular disease or a history of seizures.

CRH Stimulation Test

This test is used to differentiate between secondary and tertiary adrenal insufficiency. In both conditions, cortisol concentrations are low at baseline and remain low after CRH. In this test, 1 mcg/kg CRH (up to a maximum of 100 mcg) is administered intravenously. Subsequently, serum cortisol and plasma ACTH concentrations are determined at 0, 15, 30, 45, 60, 90 and 120 min. In patients with secondary adrenal insufficiency, there is little or no ACTH response, whereas in patients with tertiary disease there is an exaggerated and prolonged response of ACTH to CRH stimulation, which is not followed by an appropriate cortisol response (Schulte *et al.*, 1984; Gold *et al.*, 1987).

Autoantibody Screen

More than 90% of patients with autoimmune adrenalitis of recent onset have autoantibodies to the adrenal cortex or against 21-hydroxylase. Moreover, autoantibodies that react against other enzymes involved in the steroidogenic pathway and antibodies to steroid-producing endocrine cells can be detected in some patients (Husebye and Løvås, 2009a, b; Betterle and Morlin, 2011).

Very Long Chain Fatty Acids

When adrenoleukodystrophy is suspected in cases of male patients with primary adrenal insufficiency without any autoantibodies, plasma concentrations of very long chain fatty acids should be determined (Kemp *et al.*, 2012).

Imaging

A computed tomography (CT) scan of the adrenal glands is highly recommended in patients with no associated autoimmune disease and negative autoantibodies. In patients with tuberculous adrenalitis, CT shows initially hyperplasia of the adrenal glands and spotty calcifications as the disease progresses in the late stages. CT also enables the detection of bilateral adrenal lymphoma, adrenal metastases or adrenal infiltration (amyloidosis, sarcoidosis, and hemochromatosis). If secondary or tertiary adrenal insufficiency is suspected, a magnetic resonance imaging (MRI) scan of the pituitary and hypothalamus should be performed to detect any potential disease, including pituitary adenomas, meningiomas, craniopharyngiomas, metastases and infiltration by Langerhans cell histiocytosis, sarcoidosis or other granulomatous diseases (Boland, 2011; Ouyang *et al.*, 2011). It is worth noting that imaging is not required if autoantibodies against the adrenal cortex have been detected.

Glossary

Hormone insensitivity Inability of the body to respond to the physiological action of a hormone.
Hypothalamic–pituitary–adrenal (HPA) axis The hormonal axis that regulates the production of adrenal steroid hormones, including glucocorticoids, mineralocorticoids and androgens.
Hypoplasia Lack of normal development of an organ or a tissue (atrophy).
Orphan receptor A receptor for which no endogenous ligand has been identified as yet.

Introduction

Steroid hormones, including glucocorticoids, mineralocorticoids, and androgens, are secreted by the cortex of the adrenal glands (Kyrou and Tsigos, 2005; Tsigos and Chrousos, 1994). Cortisol (the main glucocorticoid in humans) is secreted by the cells of the intermediate *zonae fasciculata*, under the tight regulatory control of an endocrine cascade involving corticotropin-releasing hormone (CRH), vasopressin (AVP), and the adrenocorticotropic hormone (ACTH), thus forming the hypothalamic–pituitary–adrenal (HPA) axis. Glucocorticoids constitute the final effectors of the HPA axis and are vital for the maintenance of metabolic, cardiovascular, and immune homeostasis. The mineralocorticoid aldosterone is produced by the outer adrenal *zona glomerulosa* and regulates water and electrolyte homeostasis. The adrenal secretion of aldosterone is under the principal control of the renin–angiotensin axis, while it is only weakly influenced by ACTH. Finally, adrenal androgens with 19 carbon atoms, such as dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEA-S), and androstenedione, are secreted by the inner *zona reticularis* and are under the control of ACTH.

A spectrum of genetic defects can disrupt the normal development of the adrenal glands and the HPA axis function, causing adrenal hypoplasia and various forms of adrenal insufficiency presenting in infancy or childhood (Charmandari *et al.*, 2014; Meimaridou *et al.*, 2013; Mazilu and McCabe, 2011; Ferraz-de-Souza and Achermann, 2008; Tsigos *et al.*, 1993). The genetic causes of primary/familial adrenal hypoplasia syndromes can be broadly categorized into:

(a) Familial adrenal hypoplasia caused by ACTH resistance syndromes (i.e., familial glucocorticoid deficiency and Triple A syndrome).
(b) Adrenal hypoplasia caused by primary defects in the development of the adrenal glands (i.e., X-linked adrenal hypoplasia congenital caused by DAX1 mutations, primary adrenal hypoplasia caused by steroidogenic factor-1 mutations, and the IMAGe syndrome caused by cyclin-dependent kinase inhibitor 1C gene mutations).

ACTH Resistance Syndromes Causing Familial Adrenal Hypoplasia

Familial Glucocorticoid Deficiency

Familial, isolated, glucocorticoid deficiency (FGD) is an autosomal-recessive disorder which is rare and potentially lethal, manifesting as primary adrenal insufficiency (usually without mineralocorticoid deficiency) (**Table 1**) (Meimaridou *et al.*, 2013; Clark *et al.*, 2009; Chan *et al.*, 2008; Tsiotra *et al.*, 2006; Penhoat *et al.*, 2002). FGD was first described in 1959 (Shepard *et al.*, 1959), and since then it was apparent that affected individuals suffer from a form of hereditary unresponsiveness to ACTH. Children with FGD commonly present within the first 2–3 years of life with hyperpigmentation, recurrent hypoglycemia which can cause convulsions or coma, chronic asthenia, and failure to thrive. In the long term, FGD can lead to neurological complications due to recurrent hypoglycemic episodes and even death, if left undiagnosed/untreated. Tall stature may also be observed in some cases of FGD caused by MC2R mutations (Elias *et al.*, 2000). Biochemically, the affected children exhibit deficient production of cortisol and adrenal androgens, in the presence of markedly elevated ACTH levels. Circulating cortisol levels are undetectable in the majority of these cases and fail to increase with short or prolonged stimulation with pharmacological doses of ACTH. Moreover, the aldosterone and adrenal androgen responses to ACTH are also lost in these patients, suggesting that the underlying unresponsiveness to

☆*Change History*: December 2017. Ioannis Kyrou and Constantine Tsigos updated the entire text and added two new tables.

This chapter is an update of Constantine Tsigos, Familial Adrenal Hypoplasia Syndromes, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 548-551.

Table 1 ACTH resistance syndromes

ACTH resistance syndrome	*Genetic defect*	*Clinical presentation*
FGD Type 1 (~25% of FGD cases)	MC2R gene mutations	Hyperpigmentation, episodes of recurrent hypoglycemia, lethargy, and muscle weakness, but normal blood pressure (intact renin–angiotensin axis). Tall stature may be observed
FGD Type 2 (~20% of FGD cases)	MRAP gene mutations	Hyperpigmentation, hypoglycemia, lethargy, and muscle weakness, but normal blood pressure (mostly normal production of mineralocorticoids)
FGD variant (5% of FGD cases)	StaR CYP11A1	CLAH with adrenal and gonadal steroid deficiencies (markedly under-androgenized external genitalia). A milder phenotype may be observed (without gonadal derangement) in partial loss of function mutations (non-classical CLAH)
FGD variant form (~5%–10% of FGD cases)	NNT gene mutations	NNT (antioxidant defense) gene defects associated with glucocorticoid deficiency. Extra-adrenal features have been speculated, but not described in humans so far
FGD variant form (DNA repair defect)	MCM4 gene mutations	Short stature, classical natural killer cell deficiency with susceptibility to viral infections. Progressive glucocorticoid deficiency, but with normal mineralocorticoid production. Increased risk of cancer and developmental defects
FGD variant form	TXNRD2 gene	Disrupted redox homeostasis causes primarily glucocorticoid deficiency. Extra-adrenal manifestations may be expected (? dilated cardiomyopathy)
Triple A syndrome (Allgrove syndrome)	AAAS gene mutations (coding the ALADIN protein)	Difficulty in swallowing due to achalasia of the esophagus (achalasia cardia), lack of tears (alacrima), deafness, hyperpigmentation, mental retardation, skin hyperkeratosis and progressive neurodegeneration. Glucocorticoid deficiency may be accompanied by a variable degree of mineralocorticoid deficiency

AAAS: Achalasia-addisonianism (adrenocortical insufficiency)-alacrimia syndrome; *ACTH*: adrenocorticotropic hormone; *ALADIN*: ALacrima-Achalasia-aDrenal Insufficiency-Neurologic disorder; *CLAH*: congenital lipoid adrenal hyperplasia; *FGD*: familial glucocorticoid deficiency; *MC2R*: melanocortin 2 receptor; *MCM4*: mini-chromosome maintenance deficient 4; *MRAP*: melanocortin-2 receptor accessory protein; *NNT*: nicotinamide nucleotide transhydrogenase; *TXNRD2*: thioredoxin reductase 2.

ACTH is generalized. Renin and aldosterone levels, however, are usually normal and exhibit appropriate responses to activation of the renin–angiotensin axis by orthostasis, salt restriction, or furosemide-induced diuresis. Imaging studies of the adrenal glands in affected patients (computed tomography (CT) and magnetic resonance imaging (MRI) scans) show bilateral adrenal hypoplasia with small in size adrenal glands. In addition, histological postmortem studies of the adrenals have revealed extreme atrophy of the inner ACTH-dependent *zonae fasciculata* and *reticularis* which are reduced to a narrow band of fibrous tissue. Contrary, the outer angiotensin II-dependent *zona glomerulosa* is relatively well preserved, indicating that the defect is limited to the ACTH-dependent *zonae* of the adrenal cortex. Treatment of hereditary isolated glucocorticoid deficiency consists of glucocorticoid replacement therapy, which allows the affected subjects to achieve normal growth and development and live an otherwise normal life.

Genetic defects

FGD is a genetically heterogeneous disease, involving primarily mutations in the ACTH receptor (also referred to as the melanocortin 2 receptor (MC2R); approximately 25% of FGD patients) and mutations in the MC2R accessory protein (MRAP; approximately 20% of FGD patients) (**Fig. 1** and **Table 1**) (Charmandari *et al.*, 2014; Meimaridou *et al.*, 2013; Mazilu and McCabe, 2011; Clark *et al.*, 2009; Chan *et al.*, 2008; Collares *et al.*, 2008; Tsigos *et al.*, 1993).

The cloning of the ACTH receptor gene in 1992 allowed to precisely study the implication of the ACTH receptor gene in FGD (Tsigos *et al.*, 1993; Clark *et al.*, 1993), as indeed hypothesized since the first description of the syndrome in the late 1950s (Shepard *et al.*, 1959). The ACTH receptor (ACTH/MC2-R) consists of 297 amino acids and is encoded by an intronless gene mapped to the distal end of chromosome 18 (Tsigos *et al.*, 1993; Clark *et al.*, 1993). ACTH/MC2-R belongs to the distinct melanocortin subfamily of the G protein-coupled receptors that couple to G_s and adenylyl cyclase to generate cyclic AMP as a second intracellular messenger. To date, multiple point mutations and frameshift mutations in the ACTH receptor gene (homozygote or compound heterozygote mutations) have been detected in different pedigrees with isolated glucocorticoid deficiency (Charmandari *et al.*, 2014; Meimaridou *et al.*, 2013). These mutations are scattered throughout the ACTH receptor molecule and have been shown to affect all aspects of the receptor function (e.g., ligand binding/affinity, signal transduction, trafficking, and cell surface expression) or cause receptor truncation and structural disruption (Charmandari *et al.*, 2014; Meimaridou *et al.*, 2013; Hirsch *et al.*, 2011; Chung *et al.*, 2008, 2010; Collares *et al.*, 2008; Tsigos *et al.*, 1993, 1995, 2000; Clark *et al.*, 1993). Interestingly, in one case, compound heterozygosity of a frameshift mutation in the coding region with a single base substitution in the promoter area of the ACTH receptor gene, seemed to have resulted in the clinical manifestation of ACTH resistance (Tsiotra *et al.*, 2006). Mutations in the ACTH receptor appear to account for approximately 25% of FGD patients (also referred to as FGD type 1; **Table 1**) (Charmandari *et al.*, 2014; Meimaridou *et al.*, 2013; Mazilu and McCabe, 2011; Clark *et al.*, 2009; Chan *et al.*, 2008; Collares *et al.*, 2008).

The involvement of the MRAP gene in FGD was described in 2005 (Metherell *et al.*, 2005). MRAP is a small single transmembrane accessory protein which is essential for the translocation/trafficking of the ACTH/MC2-R from the endoplasmic reticulum to the cell surface and, thus, for subsequent signaling in response to ACTH (Cerdá-Reverter *et al.*, 2013; Novoselova *et al.*, 2013; Webb and Clark, 2010; Metherell *et al.*, 2005). Mutations of the MRAP gene appear to account for approximately 20%

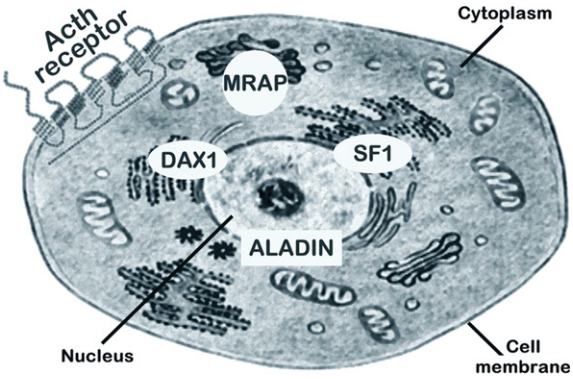

Fig. 1 Key proteins which can cause adrenal hypoplasia when mutated, depicted in an adrenocortical cell secreting glucocorticoids and/or mineralocorticoids. ACTH: adrenocorticotropic hormone; ALADIN: ALacrima-Achalasia-aDrenal Insufficiency-Neurologic disorder, nuclear envelope protein; DAX1: dosage-sensitive sex reversal-adrenal hypoplasia congenita-critical region on the X chromosome gene 1, nuclear receptor protein encoded by the NR0B1 gene; MRAP: melanocortin-2 receptor accessory protein; SF1: steroidogenic factor-1.

of FGD cases (also referred to as FGD type 2; **Table 1**) (Charmandari *et al.*, 2014; Meimaridou *et al.*, 2013; Mazilu and McCabe, 2011; Clark *et al.*, 2009; Chan *et al.*, 2008; Collares *et al.*, 2008).

Mutations in the steroidogenic acute regulatory protein (StAR protein; responsible for the transfer of cholesterol across the mitochondrial membrane, and, thus, for initiating the first step of steroidogenesis) and in CYP11A1 (cytochrome P450 monooxygenase; catalyzes the conversion of cholesterol to pregnenolone, the first and rate-limiting step in the synthesis of steroids) appear to account for approximately another 5% of FGD cases. Mutations in these two enzymes result in both adrenal and gonadal steroid deficiencies, a condition called Congenital Lipoid Adrenal Hyperplasia (CLAH or Lipoid Congenital Adrenal Hyperplasia, LCAH) (**Table 1**) (Meimaridou *et al.*, 2013; Novoselova *et al.*, 2015; Metherell *et al.*, 2009; Flück *et al.*, 2011). Milder phenotypes of adrenal deficiency (without gonadal involvement) have also been described in patients with certain partial loss-of-function mutations of these genes (non-classical CLAH) (Meimaridou *et al.*, 2013; Novoselova *et al.*, 2015; Metherell *et al.*, 2009; Flück *et al.*, 2011).

Another gene implicated in FGD is the nicotinamide nucleotide transhydrogenase gene (NNT: an antioxidant defense gene, encoding a redox-driven proton pump of the inner mitochondrial membrane; NNT mutations account for approximately 5%–10% of FGD cases; **Table 1**) (Meimaridou *et al.*, 2013; Novoselova *et al.*, 2015; Meimaridou *et al.*, 2012; Yamaguchi *et al.*, 2013). The adrenal cortex is very sensitive to reactive oxygen species (ROS), and both steroidogenesis and cell survival depend on adequate NADPH production by the NNT enzyme. Extra-adrenal features have been speculated, given the ubiquitous expression of NNT, but not described in humans so far. Interestingly, oxidative stress is implicated in other forms of primary adrenal failure, such as the Triple A syndrome and X-linked adrenoleukodystrophy (Prasad *et al.*, 2014a). Of note, a homozygous mutation in the thioredoxin reductase 2 (TXNRD2 gene: encoding one of the three thioredoxin reductases, which is mitochondria specific and contributes to the maintenance of redox homeostasis) was recently described in an extended consanguineous Kashmiri kindrend presenting with FGD (**Table 1**) (Prasad *et al.*, 2014b). Glucocorticoid production was primarily affected, as the final step of cortisol production in the mitochondria accounts for nearly 40% of the total electron flow for NAPDH. Extra-adrenal manifestations may also be expected. Indeed, novel mutations in TXNRD2 have been identified in patients with dilated cardiomyopathy (Prasad *et al.*, 2014b; Sibbing *et al.*, 2011), but unfortunately no information was available about their adrenal status.

Recently, mutations in another gene, namely the minichromosome maintenance-deficient 4 (MCM4) gene, have been identified in patients with growth retardation and classical natural killer cell deficiency (susceptibility to viral infections and complications of viral illnesses) (**Table 1**) (Charmandari *et al.*, 2014; Meimaridou *et al.*, 2013). Typically these patients have short stature and go on to progressively develop primary adrenal insufficiency characterized by ACTH resistance with isolated glucocorticoid deficiency. Notably, abnormalities in the MCM4 gene, which is important for DNA replication and genome integrity, result in genomic instability and increased incidence of cancer and developmental defects (Charmandari *et al.*, 2014; Meimaridou *et al.*, 2013). Finally, in approximately 40% of all FDG cases the underlying genetic defect remains unknown.

Triple A Syndrome

In addition to hypocortisolism (adrenal insufficiency), a subset of the patients with hereditary unresponsiveness to ACTH also develop alacrima (lack of tears) and achalasia of the esophagus (achalasia cardia; leading to difficulty in swallowing). This constellation of symptoms is known as the Triple A syndrome (alacrima-achalasia-adrenal insufficiency/Addison disease; **Table 1**), which was first described by Allgrove *et al.* (1978) (Allgrove Syndrome). Alacrima is attributed to autonomic dysregulation and structural abnormalities of the lacrimal glands and is probably the earliest and most consistent feature of this syndrome, although achalasia cardia and/or adrenal insufficiency are commonly the presenting manifestations at diagnosis. Low tear production is usually present from early infancy on and may be confirmed by the Schirmer's test. Esophageal dysmotility in affected patients can

be documented by barium swallow and/or endoscopic examination. Of note, in some cases the diagnosis of achalasia may precede the diagnosis of cortisol deficiency by several years. Moreover, affected patients may also develop a varying degree of mineralocorticoid deficiency. Finally, the Triple A syndrome is also frequently (approximately 60% of cases) associated with progressive and variable neurologic impairment, involving both central, peripheral, and autonomic neurons. Neurological defects may include autonomic and peripheral neuropathy, ataxia, mental retardation and cerebellar and neuro-ophthalmological signs, thus, potentially resulting in severely disabling disease (Sarathi and Shah, 2010). Moreover, a number of other features have been described in association with this syndrome, including short stature, skin hyperkeratosis, osteoporosis, xerostomia, pes cavus (a foot deformity that is manifested with a high arch of the foot which does not flatten with weight bearing), and microcephaly (Huebner *et al.*, 1999; Houlden *et al.*, 2002; Kimber *et al.*, 2003; Storr *et al.*, 2009).

Genetic defects

Triple A syndrome is a rare autosomal recessive disorder. Initially, it was proposed that the ACTH receptor may also be defective in the Triple A syndrome; however, there were no mutations found in the entire coding region of this gene in several affected families (Tsigos *et al.*, 1995; Clark and Weber, 1994). Contrary, homozygote or compound heterozygote mutations were found in the AAAS gene on chromosome 12q13 in families with the Triple A syndrome (**Table 1**) (Handschug *et al.*, 2001; Weber *et al.*, 1996). The AAAS gene codes for the WD repeat-containing protein ALADIN (ALacrima-Achalasia-aDrenal Insufficiency-Neurologic disorder; a nuclear pore complex protein located in the nuclear envelope and involved in nucleo-cytoplasmic transport/trafficking—**Fig. 1**) (Sarathi and Shah, 2010; Huebner *et al.*, 2004). More than 60 different mutations have already been described in this gene and appear to account for approximately 90% of the Triple A syndrome cases (Storr *et al.*, 2009). Most of these mutations produce a truncated protein, but missense and point mutations have also been reported. Some Triple-A syndrome patients lack identified mutations in the AAAS gene. Of note, the phenotype/genotype correlation of this syndrome is weak, even between affected siblings, indicating that additional factors may be implicated in its manifestations and progression (Storr *et al.*, 2009; Brooks *et al.*, 2005; Prpic *et al.*, 2003; Houlden *et al.*, 2002; Sandrini *et al.*, 2001).

Primary Adrenal Hypoplasia Syndromes

X-Linked Adrenal Hypoplasia Congenita

X-linked adrenal hypoplasia congenita (X-linked AHC) is a rare disorder which is characterized by primary adrenal insufficiency, usually during early infancy, and hypogonadotropic hypogonadism in adolescence (**Table 2**) (Achermann and Vilain, 2013; Tabarin, 2001; Achermann *et al.*, 1999, 2001; Peter *et al.*, 1998; Sikl, 1948). Most affected patients with X-linked AHC present with acute primary adrenal insufficiency in childhood and more frequently during early infancy (approximately 60% of X-linked AHC cases present at an average age of 3 weeks). However, it should be noted that, a few affected patients with partial forms of X-linked AHC present later in adulthood with delayed-onset adrenal failure or partial hypogonadism. Acute-onset adrenal insufficiency typically presents in male infants with a spectrum of symptoms, including vomiting, dehydration, feeding difficulty or even shock caused by a salt-wasting episode. Indeed, isolated salt loss or recurrent hypoglycemic episodes that can cause seizures may constitute the initial symptoms of X-linked AHC. Acute episodes of stress and/or superimposed illness (e.g., infections), injury or surgery can trigger the onset of adrenal failure in older affected children. In adolescence, affected males typically exhibit delayed or arrested puberty with hypogonadotropic hypogonadism and remain infertile, as administration of human chorionic gonadotropin only stimulates testosterone concentrations into the normal range in most patients, but not spermatogenesis. In these patients pubertal delay is considered related to defective production of hypothalamic gonadotropin-releasing hormone (GnRH) and

Table 2 Primary adrenal hypoplasia syndromes

Primary adrenal hypoplasia syndrome	*Genetic defect*	*Clinical presentation*
X-linked AHC	NR0B1 (DAX1) gene mutations	Acute adrenal insufficiency usually in male infants with salt loss and hypogonadotropic hypogonadism at puberty. Precocious puberty with impaired spermatogenesis has also been reported. Carrier females may occasionally exhibit symptoms of adrenal insufficiency and hypogonadotrophic hypogonadism
SF1 linked	NR5A1 (SF1) (autosomal)	In some cases early adrenal failure is combined with complete 46,XY sex reversal or gonadal dysgenesis. In most cases, milder gonadal phenotypes develop, with or without adrenal failure
IMAGe syndrome	CDKN1C (maternal transmission; imprinted mode of inheritance)	AHC and intrauterine growth restriction, metaphyseal dysplasia, hypercalcemia, and mild genitourinary abnormalities. Growth restriction constitutes the cardinal component of this syndrome

CDKN1C: Cyclin-dependent kinase inhibitor 1C (p57, Kip2); *DAX1*: dosage-sensitive sex reversal-adrenal hypoplasia congenita-critical region on the X chromosome gene 1, nuclear receptor protein encoded by the NR0B1 gene; *NR0B1*: nuclear receptor subfamily 0, group B, member 1; *NR5A1*: nuclear receptor subfamily 5 group A member 1; *SF1*: steroidogenic factor-1; *X-linked AHC*: X-linked adrenal hypoplasia congenita.

impaired responsiveness of pituitary gonadotropes to GnRH. In more than 10% of affected males, bilaterally undescended testes are noted at birth. However, in some cases early pubertal development with pubertal arrest has also been reported. Furthermore, in a few cases carrier females may also exhibit symptoms of adrenal insufficiency or hypogonadotropic hypogonadism (Achermann and Vilain, 2013; Jadhav *et al.*, 2011; Seminara *et al.*, 1999; Merke *et al.*, 1999).

Primary adrenal failure in a male infant in the presence of increased ACTH serum concentrations with low aldosterone and low or normal 17-hydroxyprogesterone serum concentrations is highly suggestive of X-linked AHC (Achermann and Vilain, 2013). Adrenal failure is typically manifested with hyperkalemia, hyponatremia, metabolic acidosis and hypoglycemia and can rapidly lead to death if left undiagnosed and/or untreated with glucocorticoids and mineralocorticoids. Circulating cortisol concentrations during the first weeks of life in these cases can range from very low to even high; however, the latter still remains inappropriately low for a severely sick child (Achermann and Vilain, 2013; Landau *et al.*, 2010). An ACTH test would detect cortisol deficiency in affected patients, while a GnRH test would likely reveal impaired gonadotropin responsiveness (Jadhav *et al.*, 2011).

Genetic defects

X-linked AHC is caused by mutations of the NR0B1 gene (NR0B1 for Nuclear Receptor subfamily 0, group B, member 1; historically known as DAX1 for Dosage-sensitive sex reversal-adrenal hypoplasia congenita-critical region on the X chromosome gene 1—**Fig. 1** and **Table 2**) (Achermann and Vilain, 2013; Lin *et al.*, 2006; Phelan and McCabe, 2001; Tabarin, 2001; Zanaria *et al.*, 1994). The NR0B1 gene is located on the short arm of the X chromosome (Xp21) and encodes a 470 amino-acid protein which has the structure of a transcription factor and is classified as a member of the nuclear receptor superfamily with an unknown ligand (orphan receptor). This orphan nuclear hormone receptor has a novel DNA-binding domain with a unique structure that does not resemble the classic zinc-finger DNA-binding domain of these receptors. Nuclear receptors are transcription factors and appear to play a functional role in the establishment and maintenance of steroidogenic tissues, regulating gene networks which are important for development, homeostasis and reproduction in response to various extracellular and intracellular signals. The DAX1 gene is expressed not only in the adrenal glands, but also in most of the reproductive tissues, including the hypothalamus, the anterior pituitary gonadotropic cells, and the gonads, thus playing a key role in the development and function of both the adrenals and the gonads. The exact molecular mechanisms and biological role of DAX1 have not been fully clarified yet (Achermann and Vilain, 2013; Phelan and McCabe, 2001; Tabarin, 2001).

Multiple different defects in the DAX1 gene have been reported in patients with X-linked AHC, including missense, nonsense, frameshift and splice site mutations, as well as large and small deletions and insertions (Achermann and Vilain, 2013; Lin *et al.*, 2006; Phelan and McCabe, 2001; Tabarin, 2001; Muscatelli *et al.*, 1994). Of note, gross deletions usually occur as a continuous gene deletion including the genes of glycerol kinase and Duchene muscular dystrophy. Finally, it is also noteworthy that a remarkable discrepancy characterizes the genotype/phenotype relationship of X-linked AHC, even within affected families (e.g., the same mutation resulted in two brothers with the complete syndrome, an unaffected grandfather, and a homozygote aunt with hypogonadotropic hypogonadism and normal adrenal function). This genotype/phenotype discrepancy indicates that the clinical presentation and manifestations of this syndrome may be affected by additional genetic or environmental factors (Achermann and Vilain, 2013; Jadhav *et al.*, 2011; Landau *et al.*, 2010; Phelan and McCabe, 2001; Tabarin, 2001).

Primary Adrenal Hypoplasia Caused by Steroidogenic Factor-1 Mutations

Steroidogenic factor-1 (SF1) is an orphan nuclear receptor (**Fig. 1**) which was initially identified as a key factor in the tissue-specific expression of cytochrome P450 steroid hydroxylases that are essential for the synthesis of steroid hormones (Lala *et al.*, 1992). Subsequently, SF1 was recognized as a crucial regulator of multiple genes involved in adrenal and gonadal development, steroidogenesis and reproduction (Parker *et al.*, 2002; Parker and Schimmer, 1997). Indeed, SF1 is encoded by the nuclear receptor subfamily 5 group A member 1 gene (NR5A1; located on chromosome 9q33) and is expressed in both the adrenals and the gonads, being essential for the development and function of these organs and for normal sexual differentiation (Achermann, 2005; Parker *et al.*, 2002; Ozisik *et al.*, 2002; Parker and Schimmer, 1997; Wong *et al.*, 1996). In the adrenals, SF1 not only regulates the levels of cytochrome P450 steroid hydroxylases, but also modulates the expression of the ACTH receptor, 3β-hydroxysteroid dehydrogenase, and steroidogenic acute regulatory protein (StAR). Furthermore, SF1 appears to play multiple roles in the central nervous system (CNS) and is expressed in the pituitary gland and the hypothalamus, contributing to the differentiation of pituitary primordial cells into gonadotropes (Büdefeld *et al.*, 2012; Ramayya *et al.*, 1997).

Genetic defects

SF1 mutations in humans were initially described in patients with 46,XY disorders of sex development (46,XY DSD), testicular dysgenesis and primary adrenal failure (**Table 2**) (Achermann *et al.*, 1999, 2002). The first mutation was reported in a 46,XY phenotypic female that had a de novo heterozygous loss of function missense mutation in exon 3 of one of the SF1 genes (Achermann *et al.*, 1999; Ito *et al.* 2000). This mutation causes substitution of glycine by glutamate at amino acid 35 in the "P" box region of the first zinc-finger of the DNA-binding domain of SF1, hence abolishing its DNA-binding activity and markedly affecting its function. This affected patient presented in the first 2 weeks of life with primary adrenal failure characterized by low circulating cortisol and aldosterone and high ACTH levels. At the age of 10 years, although pituitary gonadotropins responded to GnRH, testosterone did not respond to administration of human chorionic gonadotropin, indicating defective gonadal function. The

karyotype of the affected patient was 46,XY, however, normal Müllerian structures were found at laparotomy and streak-like gonads containing poorly differentiated seminiferous tubules and connective tissue were detected and removed. Treatment of this patient with estradiol gel and cyclical progestogen resulted in breast development, growth of the uterus and regular menstruation.

Furthermore, a second mutation was reported in a phenotypically female infant born to consanguineous parents that exhibited a recessively-inherited homozygous mutation (Achermann *et al.*, 2002). This mutation affected the "A" box of SF1, a region that functions as a secondary DNA-binding domain, hence, resulting in partial loss of function. Notably, three relatives (both parents and the sister) of the affected infant were phenotypically normal despite being heterozygous for the mutation. This infant presented with hyponatremia, hyperkalemia, progressive hypotonia, weight loss and hypoglycemic convulsions. Circulating 17-hydroxyprogesterone levels were low, although the fetal adrenal steroid DHEA-S was detectable. Abdominal CT scanning revealed left adrenal hypoplasia and right adrenal agenesis. Although the karyotype of the affected infant was 46,XY, a uterus was detected on pelvic ultrasound and by MRI.

Finally, a heterozygous SF1 mutation has also been described in a 46,XX female that presented at the age of 14 months with apparently normal ovarian development, primary adrenal failure and seizures after an otitis/tonsillitis episode 1 week earlier (Biason-Lauber and Schoenle, 2000). This genotypically and phenotypically normal girl had a heterozygote G > T transversion in exon 4 of the NR5A1 gene, leading to the missense p.R255L mutation in the SF1. This mutant SF1 protein fails to transactivate target genes potentially due to inability to bind canonical DNA sequences. This mutation in a genotypically female patient suggests that SF1 is not necessary for female gonadal development, despite playing a vital role in the formation of the adrenals in both genders.

More recent studies revealed that heterozygous missense, nonsense or frameshift mutations affecting the DNA-binding domain of the SF1 protein, can lead to 46,XY disorders of sex development (46,XY DSD; e.g., sex reversal, XY gonadal dysgenesis) (Lourenco *et al.*, 2009; Reuter *et al.*, 2007; Correa *et al.*, 2004; Hasegawa *et al.*, 2004; Mallet *et al.*, 2004) or other milder phenotypes, including partial androgen insensitivity (Coutant *et al.*, 2007), hypospadias (Köhler *et al.*, 2008; Lin *et al.*, 2007), bilateral anorchia (Philibert *et al.*, 2010) and primary ovarian insufficiency (Warman *et al.*, 2011; Lourenco *et al.*, 2009), without adrenal failure. Thus, it is evident that SF1 mutations may lead to a relatively wide spectrum of sex development phenotypes, which are only rarely related to primary adrenal insufficiency.

IMAGe Syndrome

An association between AHC and intrauterine growth restriction, metaphyseal dysplasia, and genitourinary abnormalities has been also described (IMAGe syndrome: intrauterine growth retardation—metaphyseal dysplasia—AHC—genital abnormalities), with growth restriction being the cardinal component of this syndrome (**Table 2**) (Achermann and Vilain, 2013; Arboleda *et al.*, 2012; Lin *et al.*, 2006; Vilain *et al.*, 1999). Adrenal crises may develop in the neonatal period, while radiologic identification of metaphyseal dysplasia or delayed endochondral ossification with osteopenia and hypercalcemia/hypercalciuria may help the diagnosis. Growth hormone deficiency represents another common finding in these patients and early replacement therapy could improve linear growth. Dysmorphic craniofacial features include prominent forehead, low-set ears, short nose, short arms and legs, whilst genital abnormalities of variable severity are confined to male patients and include micropenis, hypospadias, and undescended testes.

Genetic defects

The genetic cause of IMAGe syndrome has recently been shown to be mutations in the cyclin-dependent kinase inhibitor 1C (p57, Kip2) gene (CDKN1C gene: located on 11p15; encodes p57 (KIP2) which is a tight-binding inhibitor of several G1 cyclin/Cdk complexes and a negative regulator of cell proliferation; expressed in the brain, eye, heart, lung, skeletal muscle, kidney, pancreas, testis, placenta, and in the subcapsular or developing definitive zone of the adrenals) (**Table 2**) (Arboleda *et al.*, 2012). Of note, de novo mutations or an imprinted mode of inheritance have been revealed by familial analysis, with exclusive maternal transmission of the mutation. Missense mutations in the PCNA-binding domain in the carboxy-terminal region of the CDKN1C gene have been identified (Arboleda *et al.*, 2012; Tan *et al.*, 2006; Milani *et al.*, 2014). Interestingly, IMAGe-associated mutations have been shown to markedly increase the protein stability, suggesting that the reduced-growth phenotype of this syndrome probably derives from CDKN1C gain-of-function due to IMAGe-associated mutations causing increased protein stability (Hamajima *et al.*, 2013). Finally, a novel variant in the CDKN1C has been associated with intrauterine growth restriction, short stature, and early-adulthood-onset diabetes, but without adrenal insufficiency or metaphyseal dysplasia (Kerns *et al.*, 2014).

Impact of Glucocorticoid Receptor Polymorphisms on Glucocorticoid Action

Mesut Savas and Elisabeth FC van Rossum, Erasmus MC, University Medical Center Rotterdam, Rotterdam, The Netherlands

Glossary

Cortisol The most important and abundant glucocorticoid in humans.

Glucocorticoids Class of steroid hormones produced by the adrenal glands which can influence glucose homeostasis and various other processes throughout the body.

Glucocorticoid receptor (GR) Intracellular protein that belongs to the nuclear receptor family which regulates the genomic and nongenomic action of glucocorticoids.

Polymorphism A common genetic variation in the general population.

Introduction

The adrenal glands are responsible for producing several classes of steroid hormones. An important part of its end products comprises the glucocorticoids with cortisol being the major player within this class of hormones. Despite the name hinting on effects on the glucose metabolism, glucocorticoids are in fact responsible for various effects throughout the body. It is known that this class of hormones are involved in a wide range of metabolic, cardiovascular, inflammatory, cognitive, and reproductive processes, throughout the lifespan of humans and animals.

The importance of glucocorticoids additionally becomes clear giving the distribution of its receptor, the glucocorticoid receptor (GR), which is expressed in essentially all tissues (Dezso *et al.*, 2008). Moreover, genome-wide analysis revealed hundreds of genes which are in one way or another influenced by glucocorticoids with regard to their expression (Reddy *et al.*, 2009). This all together indicates the importance of glucocorticoids and explains why absence of cortisol, as seen in patients with severe untreated adrenal insufficiency, or GR mutations leading to total inactivation are not compatible with life.

Glucocorticoid Receptor

The first step in the cascade of glucocorticoid action starts with binding to the intracellular GR. The GR is part of the nuclear receptor family and hence has the capacity to regulate the expression of certain genes after binding to its ligand. The gene encoding GR, *NR3C1*, is located on the long arm of chromosome 5 and comprises one noncoding exon (exon 1) followed by eight coding exons (exons 2–9) as shown in **Fig. 1**. Alternative splicing of the last exon yields two isoforms, i.e., GRα and GRβ, with each distinct properties. Three functional domains of the receptor have been identified, which are the N-terminal transactivation domain, the DNA-binding domain, and the C-terminal ligand-binding domain (Gross and Cidlowski, 2008).

In unbound state, GR monomers are coupled to a complex of proteins, especially heat shock proteins, and remain inactive in the cytoplasm (Pratt *et al.*, 2006). Once bound to glucocorticoids, the GR gets released and subsequently translocates into the

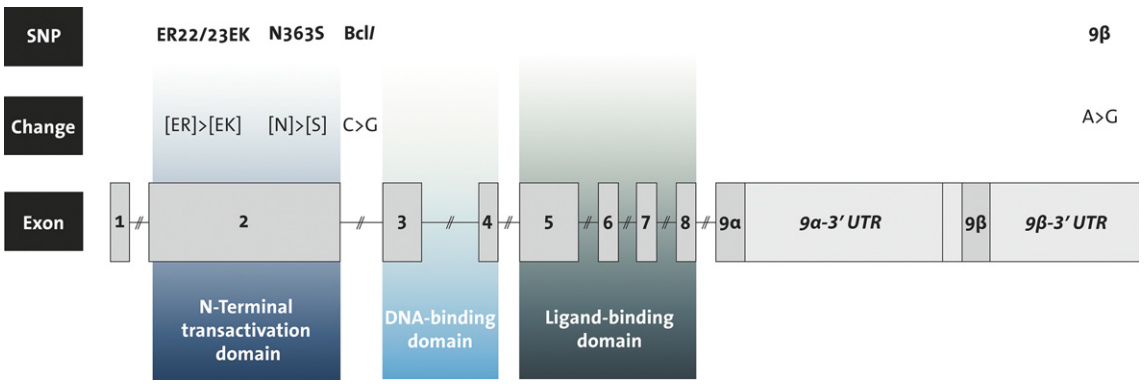

Fig. 1 Glucocorticoid receptor gene with four of its most studied polymorphisms. The letters inside brackets indicate an amino acid change. Abbreviations: *A*, nucleotide adenine; *C*, nucleotide cytosine; *E*, amino acid glutamic acid; *G*, nucleotide guanine; *K*, amino acid lysine; *N*, amino acid asparagine; *R*, amino acid arginine; *S*, amino acid serine; *SNP*, single nucleotide polymorphism; *UTR*, untranslated region.

nucleus. The mode of action on genomic level is carried out by functioning as a transcription factor leading to alterations in gene expression. By binding directly to specific glucocorticoid response elements (GRE), the glucocorticoid-GR complex can activate the transcription of certain genes (transactivating effect), whereas binding on other specific GREs can repress the transcription (transrepressing effect) of the corresponding target gene. In the same manner, transactivation and transrepression can also occur by interacting with other transcription factors, such as NFκB, AP-1, and STAT proteins, and thereby influencing their effect (Reichardt and Schutz, 1998; Necela and Cidlowski, 2004). Another mode of glucocorticoid action occurs outside the nucleus, hence called the nongenomic action, and is rather responsible for the quick response usually seen upon administration of exogenous glucocorticoids (Song and Buttgereit, 2006).

The transactivating effect is usually held accountable for inducing Cushingoid-like metabolic adverse events in glucocorticoid users, whereas the preferable immunosuppressive effects of glucocorticoids are attributed to its transrepressing effect (for example suppression of IL-2, GM-CSF, TNF-*a* transcription) (Barnes, 1998; Newton and Holden, 2007). So far, thousands of polymorphisms of the GR have been indexed (see website dbSNP) of which the majority have been identified in the intronal regions. Some of these lead to alterations in GR effect and have been associated with distinct differences in body composition, cognitive functioning, and effect of glucocorticoid treatment. Four of the most studied variants with their corresponding reference single nucleotide polymorphism (SNP) ID numbers include the Bcl*I* (rs41423247), N363S (rs6195), ER22/23EK (rs6189 and rs6190) and the 9*β* (rs6198) variants. These variants are broadly considered as either "glucocorticoid sensitive" (Bcl*I* and N363S) or as "glucocorticoid resistant" (9*β* and ER22/23EK) polymorphisms.

Bcl*I* (rs41423247) Polymorphism

The Bcl*I* variant is due to a single nucleotide change of C➔G in intron 2. Carriers of this variant have been shown to be more sensitive to glucocorticoids (van Rossum *et al.*, 2003), which is in line with clinical studies showing to varying degrees unfavorable anthropometric and metabolic features in homo- and heterozygous carriers. It is assumed to be the most common functional GR polymorphism with variations in prevalence across ethnicities (Fleury *et al.*, 2003).

N363S (rs6195) Polymorphism

The N363S variant covers an A➔G nucleotide substitution in codon 363 of exon 2 leading to an amino acid change from asparagine (N; codon AAT) to serine (S; codon AGT). In vivo studies suggest this variant to be associated with increased glucocorticoid sensitivity as, for example, carriers had increased cortisol suppression and insulin response after dexamethasone administration in comparison to wild-type subjects (Huizenga *et al.*, 1998). A previous in vitro study also showed the N363S polymorphism to be associated with increased transactivating capacity without alterations in the transrepression action (Russcher *et al.*, 2005a).

ER22/23EK (rs6189 and rs6190) Polymorphism

Another common polymorphism in exon 2 leading to alteration in GR function is the ER22/23EK variant. This variant actually consists of two linked G➔A substitutions in adjacent codons leading to an alteration of codons GAG AGG to GAA AAG. At protein level, there is no change in amino acid resulting from the first variation (codon 22; glutamic acid (E)), whereas the second SNP in codon 23 leads to a change from arginine (R) to lysine (K). Effects of this variant have been found to be in line with a relative glucocorticoid resistance in in vivo and in vitro studies. ER22/23EK carriers had for example a reduced suppression of cortisol levels after dexamethasone administration (van Rossum *et al.*, 2002), and decreased transactivating capacity in bioassays and transfection experiments (Russcher *et al.*, 2005a). Several mechanisms have been proposed regarding the underlying mechanisms including a switch in GR forms due to change in translation start sides, yielding receptors with relatively less transactivating activity (Russcher *et al.*, 2005b).

9*β* (rs6198) Polymorphism

Alternative splicing of the GR transcript yields several different isoforms among which the GR*β* splice variant. In contrast with the active GRα, which can induce transcriptional changes upon activation, the GR*β* variant does not bind glucocorticoids and instead has a dominant-negative inhibitory effect on GR action. The 9*β* variant results from an A➔G nucleotide substitution in exon 9*β* leading to a higher expression and a relatively more stable GR*β* isoform (Derijk *et al.*, 2001). This is thought to give rise to glucocorticoid resistance. Accordingly, expression assays with peripheral blood mononuclear cells of homozygous carriers revealed decreased repression of *IL-2* expression upon dexamethasone addition, whereas no effect was found concerning the transactivating effect (van den Akker *et al.*, 2006).

Body Composition and Cardiometabolic Traits

Excess glucocorticoid exposure and subsequent increased cellular action manifests itself in phenotypic and biochemical changes. Patients with Cushing syndrome who are endogenously secreting exuberant amount of cortisol usually gain weight (especially around the waist) and develop, among others, a moon-face, buffalo-hump, hypertension, glucose intolerance, and dyslipidemia (Nieman, 2015). Similar findings are also present in patients with iatrogenic Cushing syndrome due to glucocorticoid treatment with weight gain reported as the most common adverse event (Curtis *et al.*, 2006). The combination of (central) obesity with metabolic disturbances additionally increases the risk of metabolic syndrome and its sequela as for example diabetes mellitus and cardiovascular diseases. This emphasizes the importance of proper glucocorticoid action. Given the altered glucocorticoid sensitivity of the mentioned GR polymorphisms, previous studies have extensively focused on their associations with cortisol-related body compositional and cardiometabolic features.

Body Mass Index and (Central) Obesity

Most of the studies concerning GR polymorphisms and body composition have been performed for the variants associated with a relative increased glucocorticoid sensitivity. Regarding the Bcl*I* polymorphism, carriers were more likely to have higher abdominal obesity as measured as visceral fat area (Buemann *et al.*, 1997; Ukkola *et al.*, 2001), sagittal diameter (Rosmond *et al.*, 2000), and waist-to-hip ratio (Krishnamurthy *et al.*, 2008; Rosmond *et al.*, 2000; Srivastava *et al.*, 2011), which is in line with the expected central fat accumulation in case of high glucocorticoid action. The association with body mass index (BMI) has been found to be more inconsistent, with studies showing (a tendency towards) a higher BMI (Clement *et al.*, 1996; Rosmond *et al.*, 2000), or no relationship at all (Buemann *et al.*, 1997; Panarelli *et al.*, 1998; Weaver *et al.*, 1992). Several individual studies investigating the link between obesity and N363S found an association with higher BMI (Huizenga *et al.*, 1998; Roussel *et al.*, 2003) and (abdominal) obesity (Lin *et al.*, 2003a; Dobson *et al.*, 2001). Even within a group of patients with severe obesity, female N363S heterozygotes had significantly higher BMI as well as a higher food intake in comparison to women with the wild-type genotype (Di Blasio *et al.*, 2003). Interestingly, an allele-dosage effect was shown in two separate study populations by Lin *et al.* with the homozygous N363S carriers having the highest BMI (Lin *et al.*, 1999b). The previous findings concerning anthropometric measures in relation to the N363S variant were not observed in several other studies with only male participants (Echwald *et al.*, 2001; Rosmond *et al.*, 2001) nor in a meta-analysis (Marti *et al.*, 2006). However, in our recent study we showed an increased metabolic syndrome risk in low-educated subjects and young men with the N363S variant, indicating an interaction with environmental factors (Wester *et al.*, 2016).

With regard to the ER22/23EK polymorphism, we previously demonstrated sex-specific beneficial differences in favor of the carriers. Male adult carriers were shown to be taller, leaner, and have more muscle strength, whereas female carriers tended to have a smaller waist circumference in comparison to noncarriers (van Rossum *et al.*, 2004b). For the other relative glucocorticoid resistant polymorphism, Caucasian female carriers of the 9β variant were also more likely to have lower waist circumference and a lower waist-to-hip ratio (Syed *et al.*, 2006), which are in line with what one would expect in case of decreased glucocorticoid effect. This was not evaluated in another study with elderly subjects (van den Akker *et al.*, 2006), which could perhaps hint at a potential interaction with age. Neither of the studies regarding the 9β polymorphism could show any relation with BMI.

Glucose and Lipid Profile, and Blood Pressure

Disturbances in glucose homeostasis have been described in studies concerning the effect of the Bcl*I* polymorphism. Among obese women, carriers were more likely to have hyperinsulinemia and have a higher homeostatic model assessment (HOMA)-index compared to noncarriers with comparable BMI and waist-to-hip ratio (Weaver *et al.*, 1992). Unfavorable alterations in insulin and glucose were also shown in another obese study population by Srivastava *et al.* who showed higher levels for both measurements in Bcl*I* carriers (Srivastava *et al.*, 2011). Rather similar results were also found in Bcl*I* homozygous patients with Addison's disease, who had a higher HOMA-index, and higher glucose levels after oral glucose tolerance test in comparison to heterozygous carriers and noncarriers (Giordano *et al.*, 2012). The authors showed no differences in duration of the disease or dose of glucocorticoid treatment between the groups, however, the homozygous carriers were on average more centrally obese, which could (additionally) induce metabolic alterations. Moreover, the same carriers were also shown to have higher total cholesterol and triglyceride levels. These findings were nonetheless not observed in other studies without Addison patients (Kuningas *et al.*, 2006; Srivastava *et al.*, 2011). Di Blasio and colleagues had also found no differences in metabolic measures, however, subjects carrying *both* Bcl*I* and N363S polymorphisms did have significantly higher total and LDL-cholesterol levels (Di Blasio *et al.*, 2003). Some studies focusing on N363S found higher triglyceride and cholesterol levels among carriers (Kuningas *et al.*, 2006; Lin *et al.*, 2003b), which persisted after adjustments for important covariates as gender, BMI, and waist-to-hip ratio (Lin *et al.*, 2003b).

As expected, considering the decreased rather than increased glucocorticoid sensitivity, we had earlier found opposite associations in ER22/23EK carriers. This polymorphism was associated with a lower HOMA-index, lower fasting insulin, total, and LDL-cholesterol levels, and also with a relatively lower cortisol suppression after a 1.0 mg dexamethasone suppression test (van Rossum *et al.*, 2002). Moreover, in a follow-up study of elderly men, we also found a better survival in carriers compared to noncarriers (van Rossum *et al.*, 2004a). Other works involving elderly participants reported no differences in metabolic profile

(Mora *et al.*, 2012) or found, in persons aged 85 and older, higher HbA_{1c}-levels in carriers (Kuningas *et al.*, 2006). For the 9β polymorphism, beneficial lipid levels, with lower total cholesterol and higher HDL-cholesterol, have been described in Caucasian male carriers (Syed *et al.*, 2006).

Blood pressure seems to be relatively unaffected by the mentioned polymorphisms giving the fact that no differences were found between noncarriers and carriers of the Bcl*I* (Di Blasio *et al.*, 2003; Syed *et al.*, 2008), N363S (Huizenga *et al.*, 1998; Lin *et al.*, 1999a, 2003a), ER22/23EK (van Rossum *et al.*, 2002, 2004a), or 9β variant (Syed *et al.*, 2006). A higher blood pressure is however previously described in Bcl*I* carriers from Northern India (Srivastava *et al.*, 2011), and likewise in children with the homozygous 9β genotype who also appeared to have an increased heart rate and left ventricular mass (Geelhoed *et al.*, 2011).

Mental Health

Many psychological illnesses show a connection with disturbances in the hypothalamic-pituitary-adrenal (HPA) axis function. This usually reflects in elevated cortisol levels which are additionally resistant to suppression with dexamethasone (Keller *et al.*, 2006). Patients are also frequently found to have increased levels of the corticotropin-releasing hormone (CRH) (Claes, 2004), which stimulates the HPA axis and subsequently leads to the secretion of cortisol. High circulating cortisol levels are known to give rise to anatomical alterations as well as imbalances in neurotransmitter systems (Popoli *et al.*, 2011). Hence, smaller hippocampal volume, cerebral atrophy, and psychological comorbidities such as depression and anxiety disorders, are regularly being observed in patients with Cushing syndrome (Starkman *et al.*, 1992; Bourdeau *et al.*, 2002; Sonino and Fava, 2001). However, the impaired negative feedback regulation in combination with increased CRH levels have also put the focus on possible alterations at GR level in mental disorders (Pariante, 2009).

We previously assessed the association between the glucocorticoid sensitive Bcl*I* variant and major depression disorder (MDD) and found it to be more prevalent among patients with MDD in comparison to controls (van Rossum *et al.*, 2006). Similar findings were also described in other studies with the homozygous Bcl*I* variant being more common in depressed patients (Zobel *et al.*, 2008; Krishnamurthy *et al.*, 2008). With regard to treatment response, we did not find any treatment effect for the Bcl*I* polymorphism (van Rossum *et al.*, 2006). However, Brouwer and colleagues showed that Bcl*I* carriers tended to be more resistant to treatment with paroxetine in comparison to noncarriers (Brouwer *et al.*, 2006), whereas a more recent study showed carriers to have a better response to another SSRI (fluvoxamine) and no difference after treatment with the serotonin-norepinephrine reuptake inhibitor milnacipran (Takahashi *et al.*, 2014).

Regarding the relative glucocorticoid resistant ER22/23EK polymorphism, we previously reported this variant to be associated with beneficial cerebrovascular effects given the findings that elderly carriers had lower risk of dementia and white matter lesions (van Rossum *et al.*, 2008). Additionally, the carriers among depressed inpatients tended towards better results on the divided attention test in comparison to noncarriers (van Rossum *et al.*, 2006). With respect to mood disorders, the ER22/23EK has been linked to presence of MDD (van West *et al.*, 2006), recurrence of depressive disorders (Galecka *et al.*, 2013; van Rossum *et al.*, 2006), but also to a faster treatment response with antidepressants (van Rossum *et al.*, 2006). Interestingly, carriers of either the ER22/23EK or 9β polymorphism were more likely to develop depressive symptoms only in case of childhood adversity (Bet *et al.*, 2009).

Glucocorticoid Treatment Response and Adverse Events

The first synthetic glucocorticoids were produced halfway through the last century and have since then experienced a remarkable development resulting in a variety of glucocorticoid analogous. By modifying the chemical structure, newer variants became available which were more potent in regard to their anti-inflammatory action while the mineralocorticoid effects became less or (nearly) absent (Benedek, 2011). A high antiinflammatory potency warrants higher efficiency in suppression of the inflammatory process, but in general also increases the likelihood of developing glucocorticoid-related side effects such as abdominal obesity, glucose intolerance, and osteoporosis. Moreover, glucocorticoids with high mineralocorticoid potency are more likely to also induce disturbances as hypokalemia as well as edema and hypertension.

Glucocorticoids are nowadays available in a wide variety of local and systemic administration forms which makes it applicable to a wide range of illnesses. We recently showed in a large Dutch population-based cohort study that almost 11% of all participants were using any form of exogenous glucocorticoids (Savas *et al.*, 2017). Highest user rates were especially found for the local administration forms, in particular, the inhaled, nasal, and dermal glucocorticoids. Similar prevalence rates were found in the United States, with one in every seven patients in ambulatory care receiving adrenal corticosteroids (Raofi and Schappert, 2006). Since glucocorticoids are utilized on such a large scale, it becomes even more important to balance between maintaining proper therapeutic response on one hand, and preventing or minimizing undesired side effects on the other hand. GR polymorphisms leading to alterations in glucocorticoid action, either by affecting transactivating and/or transrepressing potency, could theoretically affect this balance.

The relationship between the mentioned GR polymorphisms and glucocorticoid treatment outcomes have been investigated for different medical conditions. An overview of these is given in **Table 1**. In acute lymphoblastic leukemia (ALL), glucocorticoids (especially predniso(lo)ne, and dexamethasone) play an important therapeutic role due to their antiproliferative and apoptotic effects in the leukemic cells (Pui and Evans, 2006). Several studies have assessed the difference in effect of glucocorticoid treatment in the background

Table 1 Overview of clinical studies investigating the relationship between glucocorticoid receptor polymorphisms and glucocorticoid treatment outcomes

Indication	*Reference*	*Study population*	*Type of glucocorticoid treatment*	*GR SNP (s)*[a]	*Relevant observations*
Acute lymphoblastic leukemia	Eipel *et al.* (2013)	346 pediatric ALL patients	Systemic (prednisolone, dexamethasone)	N363S	– Good responders to prednisone; – Better 5-year event-free survival; – Higher prevalence of treatment-related hepatotoxicity and abnormal glucose metabolism
	Felder-Puig *et al.* (2007)	37 pediatric ALL patients	Systemic (prednisolone, dexamethasone)	BclI/ N363S ER22/ 23EK	– No association between polymorphisms and adverse psychological reactions due to glucocorticoid treatment
	Fleury *et al.* (2004)	222 pediatric ALL patients	Systemic (prednisone, dexamethasone, hydrocortisone (IT))	BclI/ N363S ER22/ 23EK	– Decreased overall survival probability in homozygous BclI carriers; – No differences for other variants in regard to event-free, disease-free, and overall survival
	Kaymak Cihan *et al.* (2017)	49 pediatric ALL patients	Systemic (prednisolone, dexamethasone)	BclI/ N363S	– Higher prevalence of Cushingoid-like symptoms, dyspepsia, and depression symptoms during treatment in BclI carriers; – No N363S carriers (Turkish study population)
	Labuda *et al.* (2010)	310 pediatric ALL patients	Systemic (prednisone, dexamethasone, hydrocortisone (IT))	BclI/ 9β	– Lower event-free survival in both variants; – Lower overall survival in BclI homozygotes
	de Ruiter *et al.* (2014)	25 pediatric ALL patients	Systemic (prednisone)	BclI/ N363S ER22/ 23EK 9β	– Increased duration of adrenal insufficiency in homozygous BclI carriers, whereas decreased duration in ER22/23EK carriers
	Tissing *et al.* (2005)	57 pediatric ALL patients	Systemic (prednisone)	BclI/ N363S ER22/ 23EK	– No correlation with in vivo prednisone response, in vitro prednisolone sensitivity, and event-free survival
	Xue *et al.* (2015)	63 pediatric ALL patients	Systemic (prednisone)	BclI/ ER22/ 23EK 9β	– Good responders to prednisone with BclI variant; – No 9β and ER22/23EK carriers (Chinese study population)
Asthma	Keskin *et al.* (2016)	82 asthmatic children with moderate or severe exacerbations	Inhaled (fluticasone propionate)	BclI/	– Better response to inhaled glucocorticoids during asthma exacerbation in homozygous carriers
	Mohamed *et al.* (2015)	40 severe adult asthmatic patients	Systemic (prednisolone)	BclI/	– C allele carriers more frequent among glucocorticoid sensitive patients
	Panek *et al.* (2012)	234 asthmatic adults	Not mentioned	N363S	– Homo- and heterozygous carriers less likely to have uncontrolled asthma
	Tsartsali *et al.* (2012)	62 asthmatic children	Inhaled (budesonide, fluticasone)	BclI/	– Higher basal cortisol levels in heterozygous carriers; – Lower cortisol levels in homozygous carriers (in interaction model with other SNPs)
	Szczepankiewicz *et al.* (2008)	113 asthmatic children	Inhaled (budesonide, fluticasone)	BclI/ N363S ER22/ 23EK	– No association between variants with asthma severity and steroid demand
Duchenne muscular dystrophy	Bonifati *et al.* (2006)	48 pediatric Duchenne patients	Systemic (prednisone, deflazacort)	N363S	– Carriers tended to have a later age at loss of ambulation
Graves' orbitopathy	Vannucchi *et al.* (2014)	43 adult patients with moderate-severe Graves' orbitopathy	Systemic (methylprednisolone)	BclI/ N363S ER22/ 23EK	– No associations with glucocorticoid therapy response or occurrence of related adverse events

Table 1 Continued

Indication	*Reference*	*Study population*	*Type of glucocorticoid treatment*	*GR SNP (s)*[a]	*Relevant observations*
Immune thrombocytopenia	Xuan *et al.* (2014)	473 young and adult immune thrombocytopenic patients	Not mentioned	BclI/ N363S ER22/ 23EK	– No relation between BclI and steroid response; – No N363S and ER22/23EK carriers (Chinese study population)
Inflammatory bowel disease	De Iudicibus *et al.* (2007)	119 young IBD patients (64 CD/55 UC)	Systemic (prednisone)	BclI/ N363S ER22/ 23EK	– Better treatment response in carriers of BclI/ polymorphism; – No differences for other SNPs
	De Iudicibus *et al.* (2011)	154 young IBD patients (82 CD/72 UC)	Systemic (prednisone)	BclI/	– More common in responders and associated with good steroid response
	Krupoves *et al.* (2011)	296 pediatric CD patients	Systemic (prednisone, methylprednisolone, budesonide)	N363S ER22/ 23EK	– ER22/23EK (rs6190) associated with resistance to glucocorticoid treatment
	Maltese *et al.* (2012)	200 young and adult IBD patients (100 CD/100 UC)	Systemic (prednisone)	BclI/ N363S ER22/ 23EK	– No differences between glucocorticoid responders and resisters
	Mwinyi *et al.* (2010)	173 adult IBD patients (84 CD/89 UC)	Not mentioned	N363S ER22/ 22EK	– No association with glucocorticoid therapy outcome
Nephrotic syndrome	Teeninga *et al.* (2014)	113 pediatric NS patients	Systemic (prednisolone)	BclI/ N363S ER22/ 23EK 9β	– BclI carriers tended towards a better therapeutic outcome; – 9β polymorphism associated with steroid dependency and worse therapeutic outcome; – ER22/23EK and N363S not assessed due to low allele frequencies
	Zalewski *et al.* (2008)	118 pediatric NS patients	Systemic (prednisone)	BclI/	– Shorter time to proteinuria resolution in carriers of BclI variant in combination with rs33389 polymorphism (not in single BclI carriers)
Retinal diseases	Gerzenstein *et al.* (2008)	52 elderly patients	Intravitreal (triamcinolone acetonide)	BclI/ N363S ER22/ 23EK	– No association between BclI variant and degree of intraocular pressure change; – N363S and ER22/23EK not included in analyses
Rheumatoid arthritis	Quax *et al.* (2012)	147 female (pregnant) rheumatoid arthritis patients	Systemic (prednisone)	BclI/ N363S ER22/ 23EK 9β	– Glucocorticoid treatment in group of BclI and/or N363S carriers resulted in lower postpartum disease activity scores in comparison to treated group of 9β or 9β with ER22/23EK carriers
Photorefractive keratectomy	Szabo *et al.* (2007)	102 adult patients undergoing photorefractive keratectomy	Ocular (fluorometholone, prednisolone acetate)	BclI/ N363S ER22/ 23EK	– Increased intraocular pressure with prednisolone treatment in N363S carriers; – No effect found for other variants

[a]Only SNPs as discussed in this chapter are mentioned.

Abbreviations: *ALL*, acute lymphoblastic leukemia; *CD*, Crohn's disease; *GR*, glucocorticoid receptor; *IT*, intrathecal; *NS*, nephrotic syndrome; *SNP*, single nucleotide polymorphism; *UC*, ulcerative colitis.

of GR polymorphisms in pediatric ALL patients. A good prednisone response, based on a defined concentration of <1000 leukemic blasts/μL in peripheral blood after treatment, showed no association with the BclI, N363S, and ER22/23EK variants (Tissing *et al.*, 2005). However, another study performing a similar combined treatment of prednisone with methotrexate in Chinese ALL patients showed BclI carriers more likely to be good responders to prednisone (Xue *et al.*, 2015). In contrast, a larger Canadian study comprising more than 300 ALL patients treated with different treatment protocols showed lower event-free survival in BclI carriers, with homozygotes having also a reduced overall survival. The researchers also observed a lower event-free survival in 9β carriers (Labuda *et al.*, 2010). Fleury et al. additionally found homozygous BclI carriers to have a decreased overall survival probability (Fleury *et al.*, 2004). Concerning the N363S variant, carriers were more likely to be good responders to prednisone and have higher event-free survival, but

were also more susceptible to develop hepatotoxicity (31.3% vs. 11.2%) and abnormalities in glucose metabolism (18.8% vs. 3.7%) when compared to noncarriers (Eipel *et al.*, 2013). Kaymak Cihan and colleagues also evaluated steroid-induced side effects in ALL patients and found Bcl*I* carriers to be more prone for developing dyspepsia, depression symptoms, and Cushingoid-like changes (e.g., adiposity, striae, diabetes mellitus) (Kaymak Cihan *et al.*, 2017), which fits with our previously observed associations of a relative glucocorticoid hypersensitivity (van Rossum *et al.*, 2003). Moreover, adrenal insufficiency after treatment with prednisone was found to be of longer duration in homozygous Bcl*I* carriers, whereas the opposite was found in patients with the ER22/23EK polymorphism (de Ruiter *et al.*, 2014). For adverse psychological events due to glucocorticoid treatment, no associations were found with the Bcl*I*, N363S, and ER22/23EK variants (Felder-Puig *et al.*, 2007).

Bronchial asthma is one of the main indications for glucocorticoid treatment, which also becomes clear giving the high prevalence of inhaled glucocorticoid use in the general population (Savas *et al.*, 2017). In asthmatic patients, contrasting results have been described regarding the presence of Bcl*I* variant. Pietras *et al.* found patients with asthma to be more likely to have the Bcl*I* polymorphism (Pietras *et al.*, 2011), whereas another study showed the opposite in severe asthmatic patients (Mohamed *et al.*, 2015). Within the asthmatic group, the latter also found the wild-type genotype to be more common in patients with a relatively good FEV_1 improvement (i.e., $>30\%$) after a two-week prednisolone course. Another study in glucocorticoid-naïve (for at least 3 months) asthmatic children showed heterozygous Bcl*I* carriers to have higher basal cortisol levels both before and after treatment with inhaled glucocorticoids. However, SNP interaction analyses with polymorphisms of other HPA axis related genes (i.e., *CRHR1* and *MC2R*) showed homozygous Bcl*I* carriers to have diminished cortisol levels when compared to wild-type and heterozygous carriers (Tsartsali *et al.*, 2012). Homozygous Bcl*I* carriers have also been described to have a better improvement in FEV_1 (24.2% vs. 7.9%) after treatment for asthma exacerbation in children (Keskin *et al.*, 2016). Regarding the N363S variant, carriers of the G allele were less likely to have uncontrolled asthma which the authors also linked to a better anti-inflammatory steroid response (Panek *et al.*, 2012). However, this association was not observed in another study with asthmatic children (Szczepankiewicz *et al.*, 2008).

Glucocorticoids are also essential in the treatment of inflammatory bowel diseases (IBD). High doses of prednisone are usually given to patients with moderate-to-severe Crohn's disease and ulcerative colitis in order to induce a disease remission. The response to glucocorticoid treatment varies significantly between patients with some showing complete remission to others not responding at all (Faubion *et al.*, 2001). De Iudicibus *et al.* investigated the differences in Bcl*I* genotype between glucocorticoid-dependent and responsive IBD children and found that patients from the latter group, i.e., without need for glucocorticoids 1 year after initial treatment, were more likely to have the Bcl*I* variant (De Iudicibus *et al.*, 2007, 2011). Another Italian study also investigated differences in regard to the Bcl*I* variant between glucocorticoid responders and resisters and did not find any association (Maltese *et al.*, 2012). However, clinical response was only evaluated in the short term with responders defined as achieving remission within one to 2 months. For the N363S and ER22/23EK polymorphisms, no associations were found with clinical response to steroid therapy (De Iudicibus *et al.*, 2007; Maltese *et al.*, 2012; Mwinyi *et al.*, 2010). One study showed the polymorphism rs6190, leading to amino acid change in ER22/23EK carriers, to be associated with resistance to glucocorticoid treatment (Krupoves *et al.*, 2011). However, a meta-analysis on the ER22/23EK, Bcl*I*, and N363S variants could not establish an association between any of the three polymorphisms with glucocorticoid resistance in IBD patients (Chen and Li, 2012).

The steroid response in relationship to GR polymorphisms has also been investigated in childhood nephrotic syndrome patients. Haplotype analysis of three intronic single nucleotide polymorphisms, including the Bcl*I* variant, was performed in 118 steroid treated nephrotic syndrome children. Combination of the Bcl*I* variant with a certain other SNP (rs33389) in the GR gene was more prevalent in patients who reached remission within 7 days after treatment with prednisone in comparison to late responders. However, this was not the case anymore for the Bcl*I* carriers in absence of the rs33389 polymorphism (Zalewski *et al.*, 2008). In another study with Dutch nephrotic syndrome patients, a trend towards a better therapeutic outcome was observed in children with the Bcl*I* haplotype, whereas the 9β variant was related to steroid dependency (52% vs. 25% in noncarriers) and worse therapeutic outcome (Teeninga *et al.*, 2014).

Moreover, the difference in effect of glucocorticoid treatment between the carriers of the mentioned variants has been assessed in female rheumatoid patients before, during, and after pregnancy. Disease activity scores in the postpartum period were significantly lower in treated patients with the Bcl*I* and/or N363S variants when compared to the relatively glucocorticoid resistant polymorphisms (Quax *et al.*, 2012). In regard to Bcl*I*, carrying this variant was not related with response to glucocorticoid treatment in immune thrombocytopenic patients (Xuan *et al.*, 2014) nor in patients with active Graves' orbitopathy (Vannucchi *et al.*, 2014), and was also not associated with change in intraocular pressure after intravitreal injection (Gerzenstein *et al.*, 2008). The N363S polymorphism tended towards beneficial effect in children with Duchenne muscular dystrophy concerning the age at loss of ambulation (Bonifati *et al.*, 2006) and was associated with increased intraocular pressure due to prednisolone droplets after laser eye surgery (photorefractive keratectomy) (Szabo *et al.*, 2007).

In summary, glucocorticoid treatment effects and adverse events seem to be altered to a certain extent in carriers of the relatively glucocorticoid sensitive and resistant GR polymorphisms, depending on disease, duration, and dose of the steroid therapy.

Conclusion

The GR is essential in the pathway of glucocorticoid action. Numerous polymorphisms of the GR have been described, however, only some of these have been extensively investigated. These SNPs can roughly be divided in relatively glucocorticoid sensitive (Bcl*I* and N363S) and glucocorticoid resistant (ER22/23EK and 9β) variants. Both in vivo and in vitro studies have shown differences in carriers

matching expectations of an altered glucocorticoid sensitivity. Not all findings are observed consistently though, which may be attributed to differences in study design, demographic characteristics (e.g., ethnicity, age, sex), and other factors influencing glucocorticoid action. Nevertheless, evidence is mounting that GR polymorphisms may indeed alter the glucocorticoid sensitivity leading to modest changes in somatic and mental characteristics as well as in response to glucocorticoid treatment.

Glucocorticoid Resistance Syndromes and States☆

Nicolas C Nicolaides and George P Chrousos, National and Kapodistrian University of Athens Medical School, Athens, Greece and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Nomenclature

AF	Activation function domain
AP-1	Activator protein-1
DBD	DNA-binding domain
GR	Glucocorticoid receptor
GREs	Glucocorticoid-response elements
GRIP1	Glucocorticoid receptor-interacting protein 1
hGRα	Human glucocorticoid receptor alpha
hGRβ	Human glucocorticoid receptor beta
HPA axis	Hypothalamic–pituitary–adrenal axis
HSP	Heat shock protein
LBD	Ligand-binding domain
MAPK	Mitogen-activated protein kinase
NF-κB	Nuclear factor-κB
NRB	Nuclear receptor-binding domain
NTD	Amino-terminal domain
PI_3K	Phosphatidylinositol 3-kinase
STATs	Signal transducers and activators of transcription

Glossary

Glucocorticoids Steroid hormones, including cortisol, corticosterone, and cortisone, released by the cortex of the adrenal gland in a circadian fashion or during stress.

Receptor Protein molecules on the cell surface or inside the cell that recognizes a specific ligand or hormone.

Resistance Degree of nonresponsiveness to a particular hormone in the body. Also called insensitivity.

Introduction

Glucocorticoids are steroid hormones synthesized in the adrenal cortex and secreted into the circulation under the control of the hypothalamic–pituitary–adrenal (HPA) axis. These lipid molecules are major effectors of basal and stress-related homeostasis, influencing cardiovascular functions, intermediary metabolism, as well as the quantity, and quality of immune response (Nicolaides and Charmandari, 2017). All these fundamental biologic actions are mediated by specific intracellular receptor proteins, termed *glucocorticoid receptors* (GRs), which function as ligand-activated transcription factors (Nicolaides *et al.*, 2010).

Abnormalities of tissue glucocorticoid sensitivity can be divided into two major groups: resistance and hypersensitivity (Nicolaides *et al.*, 2016b). Complete glucocorticoid resistance is incompatible with life because of severe neonatal respiratory distress syndrome, as demonstrated in an in vivo study in which GR − / − knockout mice died within a few hours after birth. On the other hand, when partial glucocorticoid resistance occurs, the decreased tissue responsiveness to glucocorticoids causes compensatory activation of the HPA axis leading to hypersecretion of adrenocorticotropic hormone (ACTH) by the anterior lobe of pituitary gland (Nicolaides and Charmandari, 2015). The increased plasma ACTH concentrations result in adrenal cortex hypertrophy and increased secretion of cortisol (corticosterone in rodents) and cortisol precursors with mineralocorticoid activity [deoxycorticosterone (DOC) and corticosterone] and adrenal androgens (Nicolaides and Charmandari, 2015).

Primary familial or sporadic generalized glucocorticoid resistance or Chrousos syndrome has been described in 22 cases/kindreds and the molecular mechanisms of resistance in all of these patients have been elucidated using molecular and structural biology methods (reviewed in Nicolaides and Charmandari, 2017).

Molecular Actions of Glucocorticoids

At the cellular level, glucocorticoids carry out their actions through a ~94 kDa intracellular receptor protein, the GR (Nicolaides *et al.*, 2010). Since 1985, when the sequence of GR cDNA was first published, two alternative splicing products of the same gene located on chromosome five have been described: the GRα and the GRβ. The two receptors are highly homologous, differing in just the last 50 and 15 amino acids, respectively (Chrousos and Kino, 2005). Therefore, the first eight exons of the *NR3C1* gene containing the 5′ noncoding and coding sequences are common to both receptor isoform cDNAs, whereas exons 9α and 9β containing the coding and 3′ noncoding sequences are specific for GRα and GRβ, respectively. The GRα and β receptor isoforms

☆*Change History*: February 2018. GP Chrousos and NC Nicolaides updated the text and further reading to this entire chapter, added a new Table 1 and new figures.

This chapter is an update of Alexandra Vottero and George P. Chrousos, Glucocorticoid Resistance Syndromes and States, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 235–241.

have different properties in terms of ligand-binding ability, cellular localization and transcriptional activity (Chrousos and Kino, 2005). In addition to these two main isoforms, it was shown that the hGRα mRNA translation might be initiated from eight alternative sites giving rise to eight hGRα isoforms (hGRα-A, hGRα-B, hGRα-C1, hGRα-C2, hGRα-C3, hGRα-D1, hGRα-D2, and hGRα-D3) (Lu and Cidlowski, 2005). We hypothesize that similar molecular mechanisms might exist for the translation of hGR*β* mRNA into eight translational receptor isoforms.

In the absence of the ligand, the hGRα resides primarily in the cytoplasm of cells in a multiprotein complex consisting of the receptor polypeptide, heat shock proteins (HSPs), and immunophillins (**Fig. 1**) (Grad and Picard, 2007). The HSPs are thought to allow proper folding and stabilization of the receptor, maintaining the latter in a high-affinity, hormone-binding friendly state and preventing its interaction with proteins of the importin system, which are involved in the cytoplasm-to-nucleus translocation of many proteins (Pratt and Toft, 1997). Experimental evidence supports a model of constant bidirectional shuttling of the complex in the unliganded state between the cytoplasm and the nucleus. Once the hormone binds, the receptor dissociates from the multiprotein complex and homo- or hetero-dimerizes with another translational or alternative splicing isoform. This complex interacts with the importin system and translocates via the nuclear pore into the nucleus, where it binds to specific DNA sequences located in the promoter regions of glucocorticoid-responsive genes, termed *glucocorticoid response elements* (GREs), influencing the transcription rate of numerous genes in a positive or negative fashion (Chrousos and Kino, 2005; Nicolaides *et al.*, 2010; Nicolaides and Charmandari, 2017). Alternatively, the hGRα can modulate target gene transcription possibly as a monomer via protein–protein interactions with other transcription factors, such as activator protein-1 (AP-1), nuclear factor KB (NF-κB), and signal transducers and activators of transcription (STATs) (**Fig. 1**) (Barnes and Karin, 1997; Karin and Chang, 2001; Didonato *et al.*, 1996).

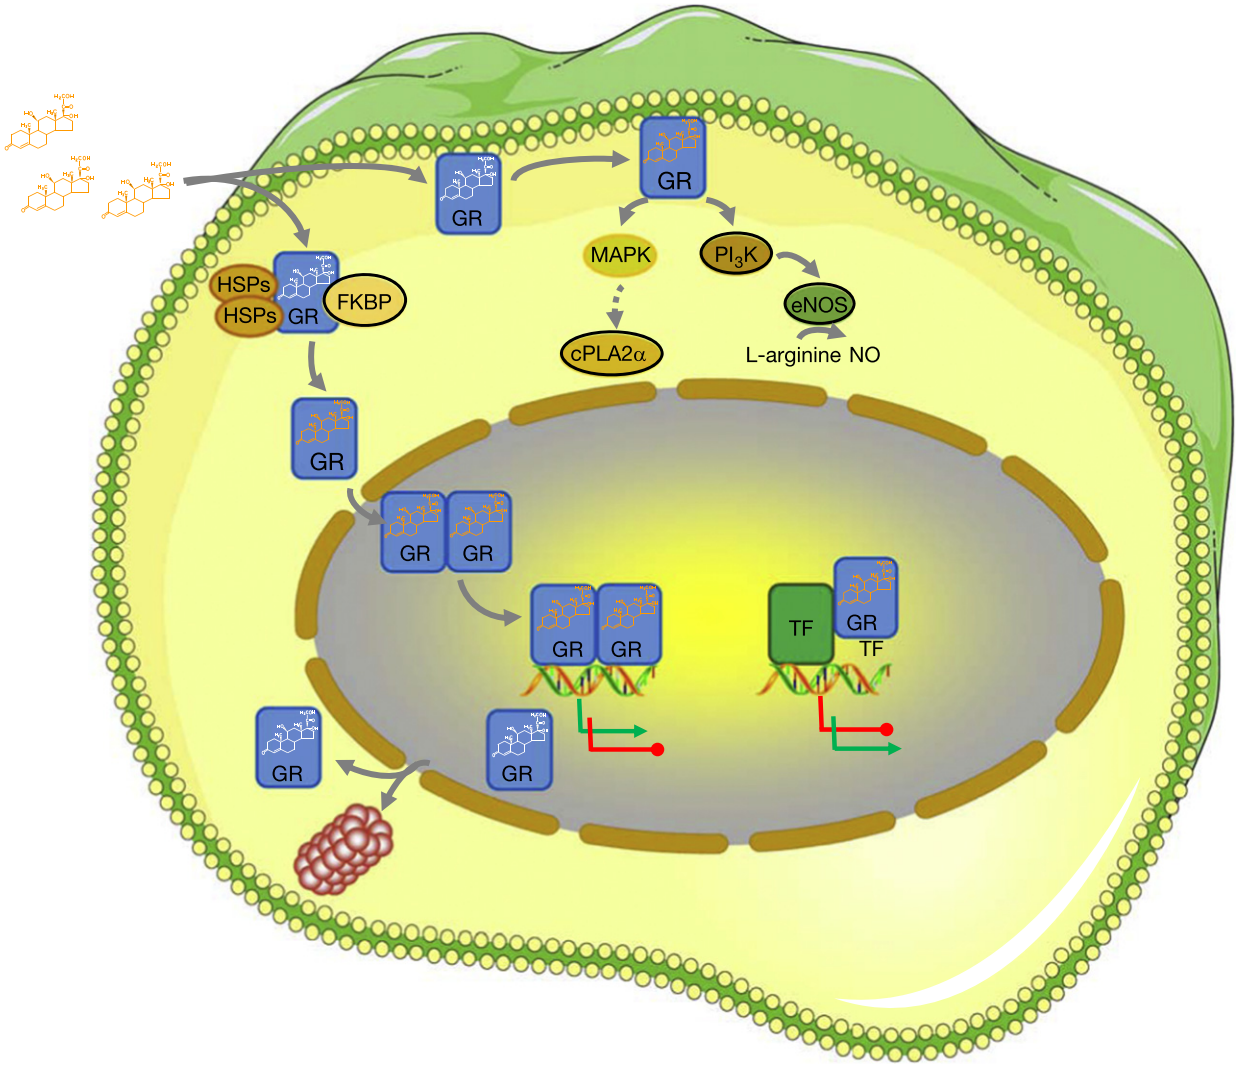

Fig. 1 Genomic and nongenomic actions of glucocorticoids. *cPLA2α*, Cytosolic phospholipase A2 alpha; *eNOS*, endothelial nitric oxide synthetase; *FKBP*, immunophillins; *GR*, glucocorticoid receptor; *HSPs*, heat shock proteins; *MAPK*, mitogen-activated protein kinases; *NO*, nitric oxide; *PI_3K*, phosphatidylinositol 3-kinase; *TF*, transcription factor.

In contrast to hGRα, the hGR*β* is localized in the nucleus of certain types of cells, such as endothelial cells, and functions as a dominant negative regulator of hGRα transcriptional activity (Bamberger *et al.*, 1995). Importantly, the hGR*β* was recently shown to have intrinsic transcriptional activity independently of hGRα (Kino *et al.*, 2009). Moreover, accumulating evidence suggests that this isoform plays an important role in insulin signaling, gluconeogenesis, glioma formation and bladder cancer cells migration (He *et al.*, 2015; Yin *et al.*, 2013; McBeth *et al.*, 2016).

In addition to genomic actions, growing evidence suggests that glucocorticoids can induce nongenomic effects through membrane-bound GRs, which upon ligand-binding, activate specific kinase signaling pathways, such as mitogen-activated protein kinases (MAPKs) or phosphatidylinositol 3-kinase (PI_3K) (**Fig. 1**) (Groeneweg *et al.*, 2012). Apart from their short time frame, these effects are pharmacologically resistant to transcriptional or translational inhibitors and can occur in nonnucleated cells, such as red blood cells (Stellato, 2004).

Molecular Mechanisms of Glucocorticoid Resistance

The molecular basis of glucocorticoid resistance has been ascribed to mutations in the *NR3C1* gene that impair one or more of the molecular mechanisms of GR function, thus altering tissue sensitivity to glucocorticoids (**Fig. 2**) (Chrousos, 2011; Charmandari, 2012; Charmandari *et al.*, 2013; Nicolaides *et al.*, 2014b). Inactivating mutations within the DNA- and ligand-binding domains, as well as a 4 bp mutation at the 3′ boundary of the *NR3C1* gene, have been identified and functionally characterized (**Table 1**).

In 1976, Vingerhoeds *et al.* described the first two patients, a father and a son, with long-term "hypercortisolism" not associated with clinical manifestations of Cushing syndrome (Vingerhoeds *et al.*, 1976). In 1982, Chrousos *et al.* demonstrated that these patients had abnormal glucocorticoid receptor properties and suggested that they suffered from glucocorticoid resistance (Chrousos *et al.* 1982). In 1991, the Chrousos group described the molecular mechanism underlying the disease in this family: the propositus was a homozygote for a single non-conservative point mutation, replacing aspartate at amino acid position 641 with valine, in the ligand-binding domain of the GR (Hurley *et al.*, 1991). This mutation reduced glucocorticoid receptor binding affinity for dexamethasone by threefold and caused loss of transactivation activity on the mouse mammary tumor virus (MMTV) promoter (Hurley *et al.*, 1991).

The second family was described in 1993 by the Chrousos group as well; the proposita of this family was a young woman with manifestations of hyperandrogenism (Karl *et al.*, 1993). Molecular analysis showed a 4 bp deletion at the 3′ boundary of exon 6, removing a donor splice site. This resulted in complete ablation of expression of one of the GR alleles associated with a 50% decrease in GR protein in the affected members of the family (Karl *et al.*, 1993).

The propositus of the third kindred, a boy with peripheral precocious puberty, had a single homozygotic point mutation at amino acid 729 (valine to isoleucine) in the ligand-binding domain, which reduced both the affinity and the transactivation activity of the GR (Malchoff *et al.*, 1993). Moreover, the hGRαV729I showed delayed nuclear translocation following dexamethasone binding, and impaired interaction with the glucocorticoid receptor-interacting protein (GRIP)1 coactivator (Malchoff *et al.*, 1993; Charmandari *et al.*, 2004).

In 1996, another interesting, sporadic case of a man with a history of infertility, hypertension, and 5- to 10-fold elevation of urinary free-cortisol levels was described by the Chrousos group (Karl *et al.*, 1996). This patient had a de novo, germ-line heterozygotic mutation at amino acid 559 (isoleucine to asparagine) in the ligand-binding domain, at the hinge region of the GR. This receptor had a two- to threefold more potent dominant negative activity than GR*β* on the wild-type receptor and was expressed at a 1:1 ratio with the normal GRα in the patient's cells. Interestingly, this mutant receptor prevented translocation of the normal receptor into the nucleus, an effect that would be overcome at very high dexamethasone concentrations (Karl *et al.*, 1996;

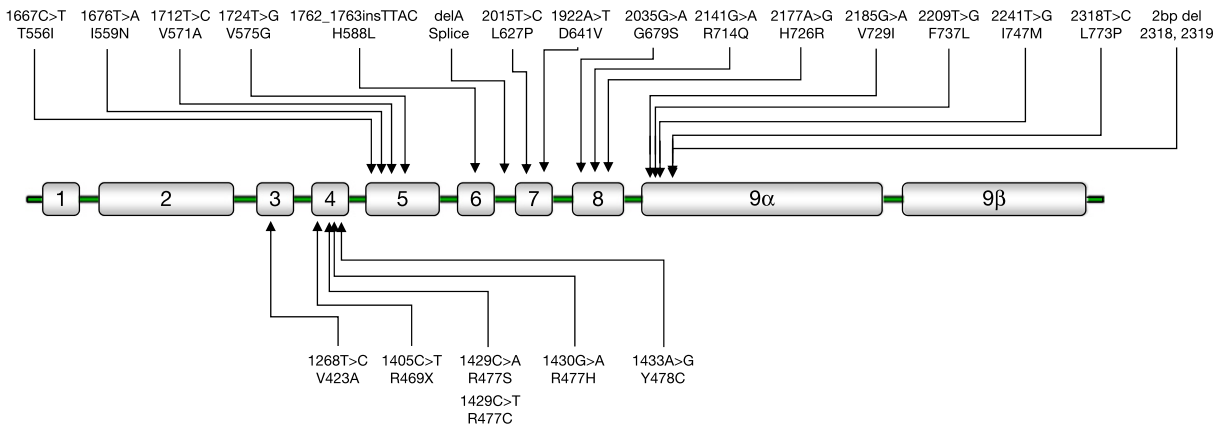

Fig. 2 Schematic representation of the known mutations of the *NR3C1* gene causing Chrousos syndrome. Mutations in the upper panel are located in the LBD of the receptor, while mutations in the lower panel are located in the DBD of the receptor.

Kino *et al.*, 2001; Charmandari *et al.*, 2004). Later this patient developed Cushing disease due to an ACTH-secreting pituitary adenoma.

Since then, a few novel cases of generalized glucocorticoid resistance have been attributed to inactivating point mutations in the *NR3C1* gene (**Table 1**). Our group recently identified three novel heterozygous *NR3C1* mutations and proceeded to the functional characterization of these gene defects (Roberts *et al.*, 2013; Nicolaides *et al.*, 2014a, 2015). The first patient, a 9-year old boy with a history of anxiety, fatigue and hypertension, harbored a mutation in the *NR3C1* gene, which resulted in substitution of valine (V) by alanine (A) at amino acid position 423 in the DNA-binding domain (DBD) of the receptor (Roberts *et al.*, 2013). Compared to the wild-type receptor, the hGRαV423A showed reduced transcriptional activity due to decreased ability to bind to the promoter regions of glucocorticoid-responsive genes, and required longer time to fully complete nuclear translocation following activation (Roberts *et al.*, 2013). Structural biology studies demonstrated that the substitution of the hydrophobic valine by alanine permits diffusion of water molecules into the ion-binding region of the mutant receptor, ultimately leading to reduced DNA-binding of the mutant receptor (Roberts *et al.*, 2013).

The second *NR3C1* mutation that was recently reported by our group was found in a 70-year-old man and his two daughters who had increased urinary free cortisol excretion without any symptoms or signs suggestive of Cushing syndrome (Nicolaides *et al.*, 2014a). All of them carried a point mutation in the *NR3C1* gene that caused a substitution of valine (V) by glycine (G) at amino acid 575 in the LBD of the receptor. The hGRαV575G displayed lower affinity for dexamethasone, demonstrated reduced transcriptional activity, had a 2.5-fold delay in nuclear translocation, and interacted with the GRIP1 coactivator mostly through its AF1 domain, since the substitution of valine by glycine at this amino acid position led to the loss of two noncovalent bonds formed between the valine of the wild-type receptor and the LXXLL motif of the GRIP1 coactivator (Nicolaides *et al.*, 2014a).

We lastly described a 30-year-old woman with a long-lasting history of hirsutism, acne, alopecia, anxiety, fatigue and irregular menstrual cycles, who harbored an inactivating *NR3C1* mutation that resulted in histidine (H) to arginine (R) substitution at amino acid position 726 in the LBD of the receptor (Nicolaides *et al.*, 2015). The mutant receptor hGRαH726R causes generalized glucocorticoid resistance through several molecular mechanisms, such as reduced transactivation, decreased affinity for the ligand, delayed nuclear translocation, and interaction with the GRIP1 coactivator through its AF1 domain (Nicolaides *et al.*, 2015).

Structural biology studies demonstrated that the H726R mutation resulted in a structural shift in the rigidity of helix 10 in the LBD of the receptor, leading to reduced flexibility and decreased affinity of the defective receptor for the ligand (Nicolaides *et al.*, 2015).

We also investigated the molecular mechanism of action of the mutant receptor hGRαT556I, which was identified in a 56-year old man with an adrenal incidentaloma (Zhu *et al.*, 2011; Nicolaides *et al.*, 2016a). We demonstrated that the hGRαT556I caused tissue resistance to glucocorticoids through decreased affinity for dexamethasone, delay in nuclear translocation following dexamethasone-induced activation, and impaired interaction with the GRIP1 coactivator, ultimately causing reduced ability to transactivate glucocorticoid-responsive genes (Nicolaides *et al.*, 2016a). The T556I mutation caused a disruption of the hydrogen bond between threonine with the =O group of P637 backbone, leading to decreased ligand binding of the mutant receptor and abnormal interaction with the GRIP1 coactivator (Nicolaides *et al.*, 2016a).

Velayos and collaborators identified recently two novel point mutations in the *NR3C1* gene in three patients (Velayos *et al.*, 2016). The first mutation was a cytosine to thymine substitution (1429C→T) in exon 4, causing an arginine to cysteine (R→C) substitution at amino acid position 477 in the DBD of the receptor (Velayos *et al.*, 2016). The second *NR3C1* genetic defect was an insertion of four bases between nucleotides 1762 and 1763, which caused a substitution of four amino acid residues at positions 588–591, leading to a truncated protein (Velayos *et al.*, 2016).

Vitellius *et al.* described three patients with adrenal incidentalomas and elevated glucocorticoid concentrations without any stigmata of Cushing syndrome (Vitellius *et al.*, 2016). The R477S and the Y478C mutations were located in the DBD, whereas the L672P was found in the LBD of the receptor. In vitro studies showed that the mutant receptors hGRαR477S and hGRαY478C displayed decreased ability to transactivate glucocorticoid target genes, reduced ability to bind to DNA and a significant delay in nuclear translocation following ligand-binding. In terms of structural biology, the hGRαR477S lost two hydrogen bonds with GREs, whereas the hGRαY478C displayed impaired interaction with neighboring amino acids (Vitellius *et al.*, 2016). The hGRαL672P was not able to influence glucocorticoid target genes, had reduced ligand binding and maintained exclusively its cytoplasmic localization. Structural biology assays showed that the hGRαL672P caused a conformational change of helix 8 leading to glucocorticoid resistance (Vitellius *et al.*, 2016).

The importance of GRβ under physiologic conditions is controversial, but it has been proposed that in pathologic situations, such as glucocorticoid resistance or hypersensitivity, it might play a pathophysiologic role. Taking into consideration the finding that increasing amounts of GRβ produce a dose-dependent decrease in wild-type GRα transcriptional activity, an imbalance in the expression of these two isoforms might determine an altered sensitivity to glucocorticoids. Supporting a possible role of GRβ in glucocorticoid sensitivity, a genetically determined imbalance in the expression of the glucocorticoid receptor isoforms was observed in cultured lymphocytes from a patient with congenital generalized glucocorticoid resistance and chronic leukemia (Shahidi *et al.*, 1999). In this patient, a low GRα to GRβ ratio was found compared to a group of normal controls, possibly explaining the glucocorticoid resistance, since no abnormalities in the sequence of the entire cDNA or in individual exons of this patient's gene were found (Shahidi *et al.*, 1999). In keeping with these findings, significantly higher hGRβ expression levels are associated with glucocorticoid resistance in numerous inflammatory disorders, including rheumatoid arthritis, systemic lupus erythematosus, asthma, and ulcerative colitis, as well as in several mood disorders, such as major depression, schizophrenia (Lewis-Tuffin and Cidlowski, 2006; Ramamoorthy and Cidlowski, 2016).

Animal models of systemic glucocorticoid resistance, such as New World primates, including squirrel monkeys, marmosets and owl monkeys, have been described (Chrousos *et al.*, 1983, 1986). These animals have total plasma cortisol levels that are 7–20 times higher than in humans or other Old World primates, whereas the concentration, affinity, and predicted amino acid sequence of their GRs are similar to those of the human receptor. Interestingly, these animals exhibit resistance to a variety of other steroid/sterol hormones, including estrogens, progesterone, androgens, aldosterone, and vitamin D (Chrousos *et al.*, 1983, 1986). Immunoreactivity of both isoforms of the GR has been found in Epstein-Barr virus-transformed B lymphocytes from marmosets, with the β-isoform being ~10 times overexpressed compared to the corresponding human cells. An altered splicing pattern of the GR pre-mRNA or differential rates of mRNA translation, mRNA degradation, and/or GR protein degradation might contribute to the steroid resistance of these animals. Alternatively, these animals may have decreased coactivator activity and/or increased corepressor activity, leading to their "pansteroid" resistance (Chrousos *et al.*, 1986).

Two sisters with manifestations of glucocorticoid resistance were described by New and collaborators (1999). Their evaluation revealed resistance not only to glucocorticoids, but also to mineralocorticoids and androgens; however, they displayed no resistance to vitamin D or thyroid hormones. The diagnosis of these patients was multiple, partial steroid resistance (New *et al.*, 1999). The New World primate physiologic and biochemical syndrome and the two pathologic human multiple steroid resistance syndrome cases are the first conditions in which a defective steroid receptor coregulator has been suggested to be responsible for an altered clinical and/or biochemical picture.

Clinical Manifestations of Glucocorticoid Resistance

Patients with the primary glucocorticoid resistance syndrome have compensatory elevations in circulating cortisol and ACTH concentrations, which maintain circadian rhythmicity and appropriate responsiveness to stressors, albeit at higher hormone concentrations (Charmandari, 2011, 2012; Charmandari *et al.*, 2013; Nicolaides and Charmandari, 2015; Nicolaides *et al.*, 2016b). They also have resistance of their HPA axis to dexamethasone suppression, but no clinical evidence of overt hypo- or

hypercortisolism. The excess of ACTH results in increased production of adrenal steroids with mineralocorticoid and/or androgenic activity (Charmandari, 2011, 2012; Charmandari, *et al.* 2013; Nicolaides and Charmandari, 2015; Nicolaides *et al.*, 2016b).

The clinical spectrum of this disease is quite broad, ranging from completely asymptomatic to mild to severe symptomatic conditions. A large number of subjects may be asymptomatic displaying biochemical alterations only. Clinical manifestations due to the excess of mineralocorticoids (including cortisol itself), acting on the intact mineralocorticoid receptor of the patients, are hypertension with or without hypokalemic alkalosis (Charmandari, 2011, 2012; Charmandari, *et al.* 2013; Nicolaides and Charmandari, 2015; Nicolaides *et al.*, 2016b). The increased amounts of androgens, on the other hand, lead to acne, hirsutism, male pattern baldness, menstrual irregularities (oligoamenorrhea), oligoanovulation, and infertility in women. In children, early and excessive prepubertal adrenal androgen secretion has been associated with ambiguous genitalia and peripheral precocious puberty. In adult men, oligospermia and infertility have been observed, possibly as the result of interference with follicle-stimulating hormone feedback regulation by the excessive adrenal androgens or by the ACTH-induced intratesticular growth of adrenal rests, which may occur as they do in classic and "late-onset" congenital adrenal hyperplasia. Because of the excessive secretion of adrenal androgens and decreased glucocorticoid effects, bone mass density is usually high-normal to elevated in patients with glucocorticoid resistance, in contrast to patients with Cushing syndrome, in whom osteoporosis is observed (Charmandari, 2011, 2012; Charmandari *et al.*, 2013; Nicolaides and Charmandari, 2015; Nicolaides *et al.*, 2016b).

Diagnostic Approach

The hallmark of the diagnostic evaluation of glucocorticoid resistance is increased 24-h serum cortisol concentrations and 24-h urinary free-cortisol (UFC) excretion without Cushing syndrome clinical stigmata (Charmandari, 2011, 2012; Charmandari *et al.*, 2013; Nicolaides and Charmandari, 2015; Nicolaides *et al.*, 2016b). Importantly, patients may have significant variations in the 24-h serum cortisol concentrations and UFC excretion because of variations in the impairment of glucocorticoid signal transduction. Serum cortisol concentrations may be up to sevenfold higher than the highest value of its normal range, while the 24-h UFC excretion may be up to 50-fold higher when compared with the upper normal range (Nicolaides and Charmandari, 2015). Despite cortisol excess, plasma ACTH concentration is normal or high. The circadian rhythm of cortisol and its responsiveness to stress are intact in patients with glucocorticoid resistance who are also resistant to single or multiple doses of dexamethasone.

The dexamethasone suppression test remains one of the most useful tools to evaluate the responsiveness of the HPA axis to exogenous glucocorticoids, as well as to determine the appropriate pharmacologic dose to be administered when treatment will be commenced. Therefore, dexamethasone at increasing concentrations (0.3, 0.6, 1.0, 1.5, 2.0, 2.5, 3.0 mg) are administered per os at midnight every other day, and serum cortisol and dexamethasone concentrations are determined at 08:00 h the following morning. To effectively suppress serum cortisol concentrations by 50%, dexamethasone should be administered at a dose up to 7.5-fold higher than that required to achieve the same degree of HPA axis suppression in normal subjects (Nicolaides and Charmandari, 2015).

Therapeutic Management

Asymptomatic, normotensive subjects with primary glucocorticoid resistance do not require any treatment. In contrast, patients with symptomatic generalized glucocorticoid resistance are treated with high, individualized doses of oral mineralocorticoid-sparing synthetic glucocorticoids, such as dexamethasone (1–3 mg given once daily at night) to effectively activate the mutant and/or wild-type hGRα, and suppress the endogenous secretion of ACTH (Charmandari, 2011, 2012; Charmandari *et al.*, 2013; Nicolaides and Charmandari, 2015; Nicolaides *et al.*, 2016b).

Hypertensive patients should receive the smallest dose that lowers the serum concentration of cortisol and other mineralocorticoids and corrects electrolyte abnormalities. Hirsute patients should be treated with doses able to reduce the androgen excess.

Untreated patients have no risk of adrenal insufficiency and do not need extra doses of dexamethasone in particularly stressful situations, such as surgery and illness. In contrast, patients undergoing chronic treatment should receive the appropriate glucocorticoid coverage.

X-Linked Adrenoleukodystrophy/Adrenomyeloneuropathy☆

William B Rizzo, University of Nebraska Medical Center, Omaha, NE, United States

Glossary

Leukodystrophy A heritable and progressive disorder of the cerebral white matter.

Peroxisome A membrane-enclosed organelle characterized by the presence of catalase and an enzyme system for fatty acid β-oxidation.

Very-long-chain fatty acid A fatty acid that is 22 or more carbons long.

Clinical Features

Patients with X-ALD are free of symptoms in infancy and early childhood. This is in contrast to neonatal adrenoleukodystrophy, which is a distinctly different disease that bears similarity to X-ALD in its name and some biochemical features. Neonatal adrenoleukodystrophy will not be discussed here.

Childhood Cerebral ALD

The most severe X-ALD phenotype, referred to as childhood cerebral ALD (CCALD), constitutes approximately one-third of the cases. CCALD is marked by prominent central nervous system demyelination that usually develops between 5 and 12 years of age. Affected boys initially present with subtle cognitive symptoms of inattentiveness, declining school performance, emotional lability, staring spells, or behavioral changes. The diagnosis is often delayed, however, until more overt neurologic symptoms appear, such as gait abnormalities, declining vision, deteriorating handwriting, or rarely a seizure. Patients show a rapidly progressive downhill course, leading to blindness, loss of speech, feeding problems, and a vegetative state within 2–5 years. From this point, time of survival time is variable. Magnetic resonance imaging (MRI) of the brain typically shows white matter disease involving the parieto-occipital lobes with a periventricular distribution (Fig. 1A). White matter disease can be seen on MRI prior to the onset of neurologic symptoms and it typically progresses in the early phase of the disease along with symptoms. The presence

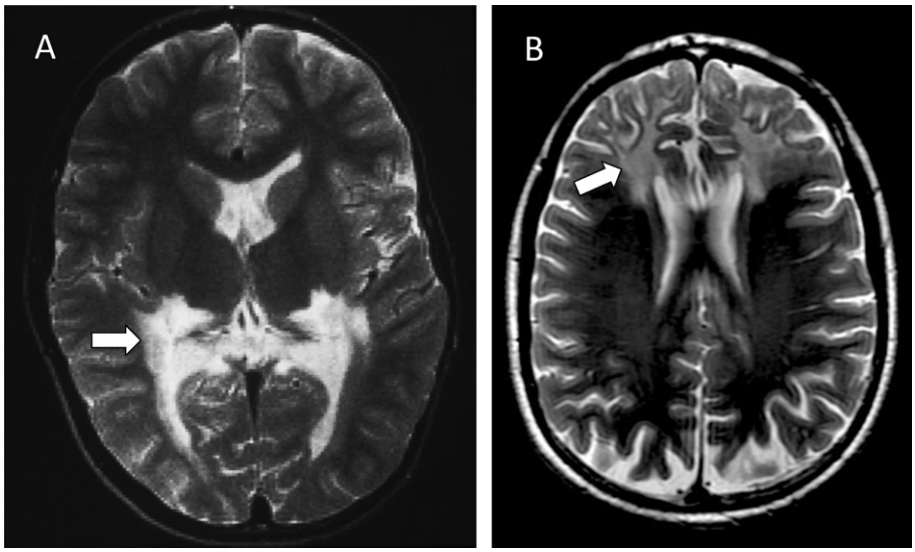

Fig. 1 Brain MRI of X-ALD patients with the typical parieto-occipital white matter disease (A) or a more frontal involvement (B). Arrows point to regions of white matter disease on T2-weighted images.

☆*Change History:* October 2015. WB Rizzo updated sections, figures and tables.
This article is an update of William B. Rizzo, X-Linked Adrenoleukodystrophy/Adrenomyeloneuropathy, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 689-693.

 doi:10.1016/B978-0-12-801238-3.99427-3

of gadolinium-enhancing lesions on MRI is a characteristic finding early in the disease. Patients with prominent hyperactivity and behavioral abnormalities may have a more frontal lobe involvement (Fig. 1B). Visual-evoked potentials and brainstem auditory-evoked responses (BAERs) are usually abnormal.

Adrenomyeloneuropathy

Adrenomyeloneuropathy (AMN) accounts for at least one-half of all X-ALD cases. It has its neurologic onset usually in the second to fifth decade of life and is dominated by a slowly progressive spinal cord involvement with spastic paraparesis and peripheral neuropathy. Neurologic symptoms are insidious at onset. Leg stiffness on awakening in the morning is a frequent early symptom of the spastic paraparesis that ultimately ensues. In time, patients develop a worsening gait, leg scissoring, urinary retention, and impotence as the neurologic disease progresses. Hyperreflexia in the lower extremities with a positive Babinski sign is elicited in all patients. Peripheral neuropathy is manifest in the lower extremities with relative sparing of the hands. Patients show an abnormal wear pattern to their shoes. In most cases, the brain MRI is normal at the time of initial diagnosis, but approximately 50% of AMN patients ultimately develop cerebral white matter involvement and carry a worse prognosis. MRI of the spine shows non-specific atrophy. Somatosensory-evoked potentials and BAERs are often abnormal and nerve conduction velocities in the lower extremities may be delayed. As the neurologic disease progresses over the course of 10–30 years, cerebral involvement becomes more apparent in many AMN patients and signs of subcortical dementia supervene. Unrelated to the neurologic or adrenal disease, AMN patients frequently develop premature thinning of their scalp hair.

Other Forms of X-ALD

In addition to CCALD and AMN, there are several less common ALD phenotypes. Some males have adolescent or adult-onset forms of cerebral X-ALD, with a rapid progression of neurologic disease similar to that seen in CCALD. A small number (5%) of X-ALD patients exhibit Addison's disease only and lack neurologic symptoms. By screening families of X-ALD probands, a significant proportion of asymptomatic males who carry the gene, but lack neurologic or adrenal symptoms have been identified. Most of the males who are beyond 12 years of age are destined to develop AMN or other neurologic variants as they get older.

Although males express the full spectrum of symptoms, as many as 65% of female heterozygotes ultimately develop mild spastic paraparesis, similar to AMN males, in the fourth to sixth decades of life. Most of these show subtle signs of neurologic disease, such as hyperreflexia and decreased vibratory sensation in the lower extremities. The neurologic involvement tends to progress very slowly over decades. Some females will develop spastic paraparesis as severe as that seen in affected men. However, female heterozygotes rarely develop adrenal insufficiency.

A perplexing observation is the lack of consistency in the X-ALD phenotypes within families. Approximately one-half of X-ALD kindreds have male patients affected with CCALD and AMN, even though these patients share the same ALD mutation. Furthermore, identical twins have been reported to show divergent phenotypes. This argues strongly for the presence of other genetic, epigenetic or environmental factors that modify the clinical expression of X-ALD. Genetic studies implicate the existence of one or more modifier genes, which have yet to be convincingly identified.

Adrenal Insufficiency and Testicular Dysfunction

Adrenal insufficiency is a characteristic finding of X-ALD that may develop years prior to onset of neurologic disease or afterwards. There is no apparent correlation between the neurologic disease and adrenal symptoms. At the time of diagnosis, approximately 30% of CCALD patients have a history of adrenal symptoms, such as multiple episodes of hyponatremia and dehydration, prolonged recovery from general anesthesia or other stress, or rarely hypoglycemia. At least 80% of patients will exhibit frank adrenal insufficiency or diminished adrenal reserve on provocative testing. Hyperpigmentation may be present, although it is often missing at the time CCALD is diagnosed.

Approximately 30–50% of AMN men have normal adrenal function at the time of diagnosis. In those with adrenal insufficiency, hyperpigmentation is a common sign and some patients relate a lifelong history of resistance to sunburn. The adrenal insufficiency may be heralded by psychiatric problems, electrolyte disturbances, or overt Addisonian crises.

In addition to the adrenal disease, AMN patients often show diminished testicular function with decreased testosterone levels in combination with elevated luteinizing hormone and follicle-stimulating hormone levels. Nevertheless, many AMN patients have fathered children prior to the onset of neurologic symptoms or early in its course.

Genetic Defect

X-ALD is inherited as an X-linked trait with variable expressivity. It is caused by mutations in the *ABCD1* gene on Xq28. The gene spans 26 kb and is composed of 10 exons that code for a 745-amino-acid protein (ALDP), which is localized to the peroxisomal membrane. ALDP is a member of the ATP-binding cassette (ABC) family of membrane transport proteins and shows homology to several other ABC proteins that are located within peroxisomal membranes, including ALDR and PMP70. ALDP is a half-

transporter that is active when it forms a dimer with itself, ALDR, or other ABC half-transporter proteins. The ALDP protein is necessary for transport of VLCFA-CoA esters into peroxisomes where they are broken down by β-oxidation.

Almost 700 mutations have been found in the ALD gene, including missense mutations, deletions, insertions, and splicing defects. Most of these mutations result in the absence or severe reduction of immunologically detectable ALDP. It is notable that there is no correlation between the type of mutation and the associated X-ALD phenotype or the severity of the VLCFA oxidative defect as measured in cultured skin fibroblasts. Approximately 4% of male probands represent new mutations.

ABCD1 is subject to X-inactivation and female heterozygous carriers for the mutant gene are functionally mosaic for cells that express either the mutant gene or the wild-type gene. Owing to the random nature of X-inactivation, the nervous tissues of ALD heterozygotes may be composed of a preponderance of functionally mutant cells, which is probably responsible for their neurologic symptoms.

Biochemical Abnormalities

Patients with X-ALD have abnormal VLCFA metabolism. Free VLCFAs are converted to metabolically active VLCFA-CoA esters by action of fatty acyl-CoA synthetase (FATP4), which is localized in peroxisomes, mitochondria and endoplasmic reticulum. VLCFA-CoAs are metabolic substrates for synthesis of various lipids in the endoplasmic reticulum. Degradation of VLCFA-CoA occurs in peroxisomes and requires ALDP for transport across the peroxisomal membrane where they are degraded by β-oxidation enzymes. Mutant ALDP prevents VLCFA-CoA esters from entering the peroxisome. As a consequence, VLCFA-CoAs are diverted into alternate pathways in the endoplasmic reticulum for biosynthesis of other lipids, including phospholipids, cholesterol esters, and sphingolipids.

In almost all tissues of X-ALD patients, fatty acid analyses of total lipids reveal abnormal elevations in saturated VLCFAs that are longer than 22 carbons. In the adrenal cortex and brain, saturated VLFAs (C24:0 and C26:0) may account for over 50% of the fatty acid composition of cholesterol esters, whereas VLCFA in cholesterol esters are almost undetectable in normal controls. VLCFA elevations are seen in other lipid fractions as well. In plasma from X-ALD patients, C26:0 levels in total lipids are increased up to sixfold, whereas X-ALD erythrocytes generally show a lesser twofold accumulation. In cultured skin fibroblasts grown from X-ALD patients, total C26:0 levels are elevated about sixfold over normal controls, which provides a diagnostically useful marker for this disease.

Lipid species of lyso-phosphatidylcholine (lyso-PC) comprised of saturated VLCFAs, such as C24:0 or C26:0, have recently been demonstrated to accumulate in X-ALD. Lyso-PCs containing VLCFAs are a minor component of total phospholipids in all tissues, but may be pathologically important in X-ALD due to their unique biological effects.

Pathogenesis of X-ALD

Neurologic Disease

The pathogenesis of endocrine and neurologic disease in X-ALD is complex and poorly understood. Pathologic mechanisms must account for the extraordinarily diverse clinical phenotypes and the intrafamilial variation in symptoms. Nevertheless, an excess of saturated VLCFAs is the cardinal biochemical feature of X-ALD that underlies all aspects of disease mechanisms (Fig. 2). Although the extent of lipid abnormality and the types of VLCFA-containing lipids vary from one tissue to another, the vulnerable organs in X-ALD are those that show the greatest accumulation of VLCFAs. In electron micrographs, these lipids are manifest as structurally observable lamellar lipid inclusions in adrenal cortical cells, Leydig cells, Schwann cells, and brain macrophages.

VLCFA-containing lipids are very hydrophobic and have a great propensity to partition into membranes. Free VLCFAs, especially saturated ones, are toxic when added to cultured cells including oligodendrocytes, astrocytes and neurons, whereas shorter chain fatty acids (i.e. C16:0) do not elicit this effect. Cells exposed to VLCFA develop mitochondrial depolarization and abnormal intracellular calcium homeostasis, but it is unclear whether these changes are a result of free VLCFAs, which are a minor component in X-ALD, or VLCFA-containing lipids.

The major neuropathologic differences between cerebral forms of X-ALD and pure AMN are the active cerebral inflammatory demyelination observed in the former and the prominent axonal degeneration observed in the latter. The brain in CCALD exhibits decreased myelinated axons and oligodendrocytes, reactive astrocytosis, sudanophilic lipid deposits in macrophages, and a striking perivascular lymphocytic infiltration. Both T and B cell lymphocytes are present. Inflammatory mediators, such as tumor necrosis factor-α and interleukin-1, are produced in regions of active demyelination, which is associated with localized endothelial damage and disruption of the blood–brain barrier.

Although VLCFA levels in plasma and cultured fibroblast are equivalent in patients with CCALD and AMN, there is evidence for a relatively greater amount of VLCFA in autopsied brain from CCALD than AMN. This same trend is seen in cultured oligodendrocytes derived from induced pluripotent stem cells grown from CCALD and AMN patients. Lipid analyses of select regions of autopsied CCALD brain show that the fatty acid abnormality precedes areas of demyelination, suggesting a link between VLCFA and inflammatory demyelination.

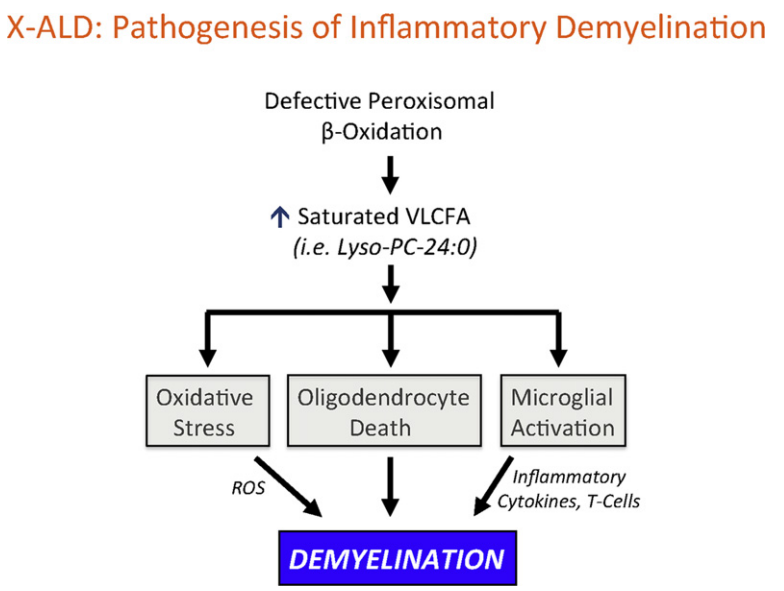

Fig. 2 Likely pathogenic mechanisms for cerebral demyelination in ALD.

The particular lipid species that contain VLCFA may be critical for the inflammatory reaction in CCALD brain. VLCFA accumulation seems to initiate in phosphatidylcholine and later spreads to other lipids as demyelination proceeds. Actively demyelinating lesions show the highest level of cholesterol esters containing VLCFAs, but these lipids are unlikely to elicit an antigenic or inflammatory response. In contrast, animal studies demonstrate that intracerebral injection of C24:0-lyso-PC into mouse brain leads to microglial activation and apoptosis, whereas C16:0-lyso-PC does not have a similar effect. This raises the possibility that VLCFA-lyso-PC lipids are critically involved in initiating cerebral inflammation (Fig. 2). In addition, certain myelin proteins in X-ALD, particularly proteolipid protein, have been shown to be acylated with VLCFAs, which could also contribute to the underlying myelin abnormalities. Irrespective of the mechanism, the inflammatory demyelinating lesions in the brain of X-ALD are not seen in other lipidoses associated with white matter disease, implicating VLCFA accumulation in this process.

In contrast to the cerebral forms of X-ALD, AMN seems to lack an immune component to the neurologic disease. In AMN, the spinal cord is mainly affected with loss of myelinated axons in the ascending and descending tracts. The peripheral nerve is also affected. This dying back axonopathy is characteristic of AMN, but the mechanism is still unclear. A mouse *Abcd1* knockout model for X-ALD develops an AMN phenotype after 18 months without evidence of cerebral inflammation and demyelination. Studies have revealed prominent mitochondrial dysfunction and depletion in the spinal cord, which leads to impaired energy formation and the release of toxic reactive oxygen species (ROS). Oxidative damage to the mouse spinal cord is seen many months prior to onset of a spastic gait. Treatment of the affected animals with antioxidant drugs dramatically reduces the oxidative damage and improves the gait symptoms. These animal studies implicate VLCFA-dependent mitochondrial damage as a causative factor resulting in oxidative stress in the pathogenesis of the myelopathy (Fig. 2).

Endocrine Disease

VLCFA accumulation in adrenocortical cells is thought to be solely responsible for the adrenal gland dysfunction, but more than one pathogenic mechanism may be in play. Addition of saturated VLCFAs to cultured adrenocortical cells has been shown to blunt adrenocorticotropic hormone (ACTH) receptor responsiveness, probably by increasing plasma membrane microviscosity. In addition, cholesterol esters containing VLCFAs, which accumulate in the adrenal gland, are poor substrates for hydrolyzing enzymes to generate free cholesterol precursors for steroidogenesis. In time, adrenocortical cells become ballooned and striated from lipid accumulation and then die. In contrast to autoimmune forms of Addison's disease, anti-adrenal antibodies are missing in X-ALD. Whether analogous pathogenic mechanisms occur in Leydig cells and are responsible for testicular dysfunction is not known.

Diagnosis

The diagnosis of X-ALD may be challenging because of its rare occurrence and striking clinical variation. Identification of X-ALD is often delayed until symptoms involving the nervous system and adrenal gland appear together, a condition that is lacking in a significant proportion of patients at the time of initial presentation. AMN males and symptomatic heterozygote females are therefore frequently misdiagnosed as having multiple sclerosis or familial spastic paraparesis. In boys with neurologic symptoms,

however, the diagnosis of CCALD is more readily suspected owing to the characteristic distribution of white matter disease on brain MRI.

Because neurologic symptoms can be missing or develop many years after the onset of adrenal disease, X-ALD should be suspected in any male with isolated primary adrenal insufficiency. In adults, adrenal insufficiency is often caused by other etiologies, but a significant proportion of boys who present with isolated Addison's disease in childhood have X-ALD. In those who initially present with neurologic symptoms, however, adrenal disease might be suspected only after a diagnostic work-up for leukodystrophy has been initiated. In these patients, a 60 min ACTH stimulation test will usually detect adrenal involvement. Measurement of a morning serum cortisol concentration alone is not an adequate screening test, because basal cortisol levels may be maintained in the face of diminished adrenal reserve. However, plasma ACTH is usually elevated before hypocortisolemia develops, so both cortisol and ACTH should be measured together.

Owning to its wide clinical variation, the diagnosis of X-ALD is critically dependent on laboratory confirmation. The most convenient diagnostic test is measurement of VLCFAs in plasma, which is noninvasive, relatively inexpensive, and detects abnormal elevations of VLCFAs in patients long before symptoms develop, even at the time of birth. Affected patients accumulate C26:0 and C24:0, but have normal C22:0. The C26:0/C22:0 and C24:0/C22:0 ratios are particularly useful for discriminating X-ALD patients from non-ALD controls. In males, there are very few conditions, such as a ketogenic diet, that give rise to false-positive results and false-negative results are uncommon. In circumstances where the plasma VLCFA results are equivocal, fatty acids can be measured in cultured skin fibroblasts grown from a patient. Female carriers for X-ALD tend to show intermediate elevations in plasma VLCFAs, but interpretation of a normal test result is problematic because plasma VLCFAs are elevated in only 85% of carriers. A normal result, therefore, does not completely eliminate the possibility that the female is carrying the X-ALD gene. DNA testing is more reliable for heterozygote detection if the mutation is known in the family. The lack of a common mutation in the X-ALD gene hampers the development of simple DNA screening tests for routine diagnosis.

Newborn screening for X-ALD has recently been initiated in the United States. By detecting elevated levels of C26:0-lyso-PC in a dried blood spot using liquid chromatography-tandem mass spectrometry, newborn infants with X-ALD can be readily discriminated from unaffected controls. The ability to identify all newborn infants with X-ALD will have major impact on diagnosis, disease surveillance and therapy in the future.

The diagnosis of X-ALD in a family has profound implications for genetic counseling, disease prevention and outcomes. Family studies indicate that only 4% of the X-ALD probands represent new mutations. It is therefore important to screen at-risk family members by measuring plasma VLCFA or by mutation analysis. This frequently leads to the identification of asymptomatic males who should be monitored for the appearance of symptoms even though it is not yet possible to predict which X-ALD phenotype a presymptomatic male may later develop.

Prenatal diagnosis affords the ability to prevent X-ALD in at-risk families. Affected fetuses can be identified by DNA analysis or by measuring VLCFA content of chorionic villi cells obtained at 8.5–10 weeks gestation and in amniocytes obtained during the second trimester.

Preimplantation genetic diagnosis of X-ALD has also been accomplished. After in vitro fertilization, DNA from a single blastomere is removed from an early embryo and amplified by PCR to detect unaffected embryos. Non-ALD embryos are transferred into the mother with subsequent delivery of unaffected infants.

Management

All X-ALD patients should be monitored for the onset of adrenal insufficiency. In presymptomatic X-ALD boys and those lacking adrenal insufficiency at the time of neurologic diagnosis, adrenal function should be tested at least yearly by measuring plasma ACTH in combination with a morning serum cortisol. The adrenal insufficiency in X-ALD is easily treated with hormone replacement, but it has no effect on the progression of neurologic disease. Hydrocortisone is typically used alone or in combination with fludrocortisone, depending on the severity of mineralocorticoid deficiency. The glucocorticoid dosage should be increased in response to stresses, such as febrile illnesses and general anesthesia. No therapy has been found to prevent or reverse the adrenal insufficiency.

Therapeutic options for the serious neurologic symptoms of X-ALD have thankfully emerged. Allogeneic hematopoietic stem cell transplantation (HSCT) has been shown to stabilize the neurologic disease in CCALD. To receive clinical benefit, however, patients need to be transplanted at the earliest sign of neurologic involvement when white matter changes first appear on brain MRI or only cognitive symptoms are predominant. With HSCT, it is assumed that the genetically normal transplanted stem cells migrate into the brain and alter the inflammatory demyelination by differentiating into microglial cells, which are metabolically normal and not activated to produce inflammatory molecules. The clinical response requires a period of 12–18 months during which the neurologic symptoms may still progress. Presymptomatic X-ALD boys should therefore receive brain MRI every 6–12 months to detect the onset of white matter disease at its earliest appearance. Given the known risks of HSCT, the procedure is not recommended for asymptomatic or AMN patients.

Gene therapy has recently been applied to several boys with early CCALD symptoms. Using an *ex vivo* gene therapy approach, bone marrow was harvested and the normal *ABCD1* gene was transferred into the patient's own hematopoietic stem cells using a Lentivirus vector, and subsequently infused back into the patient. In the initial small cohort of boys receiving gene therapy, the outcome appears to be similar to allogeneic HSCT without any graft-vs-host complications.

Other therapeutic approaches are either ineffective or less robust. Dietary restriction of saturated VLCFA has no effect on the disease, probably because endogenous fatty acid synthesis is the major source of VLCFA. In contrast, VLCFA restriction together with dietary supplementation with monounsaturated fatty acids (Lorenzo's oil) normalizes plasma C26:0 by inhibiting saturated VLCFA synthesis. This approach has no significant clinical impact once neurologic symptoms develop, probably because fatty acids in the brain are not readily altered. In presymptomatic boys, however, the Lorenzo's oil diet has been reported to delay the onset of neurologic disease and uncontrolled studies suggest that it may decrease the rate of neurologic deterioration in AMN men. Rigorous controlled investigations, however, are needed to confirm these conclusions. Attempts to modify the inflammatory reaction in the brain of CCALD boys with immunosuppressive drugs, gamma globulin or β-interferon have been unsuccessful. Furthermore, pharmacologic approaches to increase the peroxisomal VLCFA-oxidizing activity using 4-phenylbutyrate or statin drugs, which upregulate expression of ABC-half transporters and restore VLCFA oxidation in cultured cells, have not been clinically effective.

Background

Thomas Addison first described adrenal insufficiency (AI) in 1855. The condition was universally fatal until the 1930s, when adrenal glands extracts were recognized to reverse the features of AI. Cortisone was isolated in 1935 (Mason *et al.*, 1936) and in 1948 hydrocortisone, the pharmacological equivalent of cortisol, was synthesized for the first time (Benedek, 2011). Despite 70 years of experience in the treatment of AI, patients continue to experience an impaired quality of life and an excess of cardiovascular, metabolic, and bone related morbidity. The relative risk of death for AI patients is more than double that of the background population (Bensing *et al.*, 2008; Bergthorsdottir *et al.*, 2006; Erichsen *et al.*, 2009). Patients with non-functioning pituitary adenoma and adrenal insufficiency on doses greater than 20 mg hydrocortisone equivalent (HCeq) every day have a higher mortality when compared to similar patients on doses <20 mg day^{-1} (Hammarstrand *et al.*, 2017). It is likely that these poor outcomes in part reflect the difficulty in replicating physiological cortisol levels using current glucocorticoid medications (Porter *et al.*, 2017). Here we review the physiology of cortisol, current protocols for cortisol replacement, the treatment of adrenal crisis and new technologies in development.

The Hypothalamic–Pituitary–Adrenal Axis

Serum cortisol levels are regulated by the hypothalamus in response to various neuronal and humeral inputs, stimulated by changes in the internal and external environment. The hypothalamic–pituitary–adrenal (HPA) axis is an example of a classical feedback loop. Corticotrophin releasing hormone (CRH) and arginine vasopressin release from the paraventricular nucleus of the hypothalamus stimulate release of adrenocorticotrophic hormone (ACTH) from corticotrophs in the anterior lobe of the pituitary which, in turn, stimulate cortisol synthesis and rhythmic release from the zona fasciculata of the adrenal gland. Cortisol is secreted by diffusion into the peripheral circulation, and then exerts an inhibitory effect on CRH secretion from the hypothalamus and ACTH secretion from the pituitary. Studies of healthy adults and children report cortisol secretion rates of 6.3 mg m^{-2} body surface area (BSA)/day (range 5.1–9.3) in adults and 8.0 mg m^{-2} BSA/day (range 5.3–12.0) in children (Peters *et al.*, 2013). Cortisol secretion shows a circadian rhythm, regulated by the central pacemaker in the suprachiasmatic nucleus (SCN) of the hypothalamus. The SCN rhythm has an approximate period of 24.2 h, and requires a daily resetting via the daily light/dark photoperiod to maintain a 24 h rhythm (Dunlap, 1999). Cortisol concentrations peak shortly after waking and decline through the day. A nadir is reached at midnight, and cortisol concentrations start to rise again from 02.00 to 04.00 (Debono *et al.*, 2009; Peters *et al.*, 2013). The circadian rhythm of cortisol secretion can be observed from the age of 2 months (Porter *et al.*, 2017). Cortisol secretion is also stimulated in response to physical and psychological stress, with the magnitude of change in cortisol concentration being related to the nature, intensity, and duration of stress. This "stress response" is superimposed on the normal circadian profile.

Adrenal Insufficiency

The causes of AI are classified according to the point at which the HPA axis is disrupted: Disorders of the adrenal are described as "primary AI," those of the pituitary as "secondary AI" and those of the hypothalamus, "tertiary AI." Causes of AI are detailed in **Table 1**. In childhood, congenital adrenal hyperplasia (CAH) accounts for most causes of primary AI, while autoimmune disease is the commonest cause of acquired primary AI. In adults secondary AI is more common than primary AI and is most frequently due to benign pituitary adenomas. Tertiary AI due to exogenous steroid administration is increasingly recognized and may be much more common than both primary and secondary AI as glucocorticoids remain widely prescribed antiinflammatory agents (Fardet *et al.*, 2011).

 doi:10.1016/B978-0-12-801238-3.64307-6

Table 1 Causes of adrenal insufficiency

Primary adrenal insufficiency

Defects of steroid biosynthesis

- Congenital adrenal hyperplasia: 21 hydroxylase deficiency, 11B hydroxylase deficiency, 3B hydroxysteroid dehydrogenase deficiency, 17 hydroxylase deficiency, P450 oxidoreductase deficiency
- Congenital lipoid adrenal hyperplasia
- P450 side chain cleavage syndrome
- Aldosterone synthase deficiency
- Cortisone reductase deficiency
- Apparent cortisone reductase deficiency

Adrenal dysgenesis

- X linked adrenal hypoplasia congenital
- IMAGe syndrome
- Pallister–Hall syndrome
- Pseudotrisomy 13
- Galloway–Mowat syndrome

ACTH resistance

- Familial Glucocorticoid Deficiency
- DNA repair defect
- Triple A syndrome

Cholesterol synthesis disorders

- Wolman disease
- Smith–Lemli–Opitz disease
- A beta liporoteinaemia
- Familial hypercholesterolaemia

Metabolic disorders: peroxismal defects

- X Linked adrenoleukodystrophy
- Neonatal adrenoleukodystrophy
- Infantile Refsum disease
- Zellweger syndrome

Autoimmune disorders

- Isolated autoimmune adrenalitis
- Autoimmune Polyglandular syndromes type 1, 2, and 4

Acquired defects

- Haemorrhage
- Infections
- Surgery/trauma
- Infiltration
- Drugs

Secondary adrenal insufficiency

Congenital

- Pituitary aplasia/hypoplasia
- Pituitary stalk interruption syndrome
- Isolated ACTH deficiency
- Proprotein convertase 1

Acquired

- Steroid withdrawal after prolonged administration or endogenous overproduction
- Tumor, e.g., pituitary macroadenomas
- Radiation therapy
- Lymphocytic hypophysitis

Tertiary adrenal insufficiency

Congenital

- Septo-optic dysplasia
- CRH deficiency

Table 1 Continued

Acquired
• Steroid withdrawal after prolonged administration or endogenous overproduction
• Trauma
• Radiation therapy
• Surgery
• Tumors, e.g., craniopharyngioma
• Infiltrative disease
• Drugs such as opiates

Glucocorticoids

Glucocorticoids are steroid hormones with a common structure, incorporating the delta-4,3-keto-11-beta,17-alpha,21-trihydroxyl configuration, which is essential for glucocorticoid activity. Modification of this basic structure alters glucocorticoid activity and pharmacokinetics. Cortisol circulates bound to cortisol binding globulin (CBG) which has high affinity and low capacity and albumin that has low affinity and high capacity. Only 5% of circulating cortisol is unbound or "free" (Lewis *et al.*, 2005) and is able to interact with the glucocorticoid receptor (GCR). The degree of protein binding for other, synthetic glucocorticoids is variable, with most only binding weakly to albumin and others circulating as free hormones. Prednisolone has approximately 60% of the CBG binding affinity of cortisol, prednisone 5%, and dexamethasone only 1% (Migeon *et al.*, 1959; Pugeat *et al.*, 1981).

Two isoforms of the enzyme 11β-hydroxysteroid dehydrogenase (11βHSD) regulate glucocorticoid activity at the target tissue level. The inactive hormone, cortisone, and synthetic glucocorticoid prednisone, are converted to the active hormones, cortisol and prednisolone, by 11βHSD type 1. Polymorphisms for 11βHSD type 1 have been implicated to explain the higher tendency for certain individuals to develop metabolic complications from glucocorticoids (Molnar *et al.*, 2016). In tissues where the mineralocorticoid receptor is expressed, including salivary glands, the bowel, kidney and placenta, cortisol and prednisolone are inactivated by conversion to cortisone and prednisone by 11βHSD type 2. This process of inactivation protects the mineralocorticoid receptor from activation by glucocorticoids, which has equal affinity for cortisol and aldosterone. Synthetic glucocorticoids differ in their affinity for these two isoforms of 11βHSD. Dexamethasone, which is fluorinated at the 6-alpha or 9-alpha position, is protected from inactivation by 11βHSD type 2, while prednisolone, which has a double bond between positions 1 and 2, is inactivated more effectively than cortisol by 11βHSD type 2.

Glucocorticoids signal through the GCR which is expressed by nearly every cell in the body, while mineralocorticoid receptor (MCR) expression is restricted to the limbic-forebrain, where activation promotes attention, memory retrieval and appraisal and drives expression of fear and aggression, and tissues that influence Na^+/K^+ balance, including the distal renal tubule, parotid glands, colon, sweat glands and the nucleus tractus solitarii and circumventricular organs of the brain.

Activation of the GCR by glucocorticoid binding induces or suppresses the activation of target genes, which together comprise 10%–20% of the human genome (Oakley and Cidlowski, 2013). A wide range of physiological processes are regulated by glucocorticoids, including intermediate metabolism, growth, cognition, reproduction and immunity and glucocorticoids play an essential role in homeostasis. A single gene encodes the GCR, however a number of different GCR isoforms arise from alternative splicing and alternative translation, and various posttranslational modifications. Differential expression of GCR isoforms, in part, determines cellular responses to glucocorticoid binding (Oakley and Cidlowski, 2013). GCR polymorphisms are associated with increased weight gain and may influence the dose needed for replacement (Molnar *et al.*, 2016). The mechanism of action of glucocorticoids through binding the GCR are genomic through transactivation and transrepression of genes, nongenomic independent of gene transcription and at very high dose possibly through nonspecific interactions with cell membranes (Buttgereit *et al.*, 2004).

Glucocorticoids are metabolized primarily in the liver, through reduction, oxidation or hydroxylation and the products of these reactions are conjugated with sulfate or glucuronic acid to make them water soluble, ready for elimination in the urine. Hepatic metabolism of glucocorticoids is influenced by a number of factors, including concomitant medications. Drugs inhibiting CYP 3A4 increase glucocorticoid concentrations whilst enzyme inducers decrease glucocorticoid levels (**Table 2**). Glucocorticoid metabolism is also increased in patients with cystic fibrosis (Dove *et al.*, 1992) and hyperthyroidism (Frey *et al.*, 1988), and patients with these diagnoses may require higher or more frequent dosing.

Glucocorticoid Treatment of Adrenal Insufficiency

The goal of cortisol replacement therapy in patients with AI is to ameliorate the symptoms of cortisol deficiency, prevent adrenal crisis, restore normal quality of life, and avoid the adverse effects of glucocorticoid excess. In current practice, five medications are commonly used: Hydrocortisone, cortisone, prednisolone, prednisone, and dexamethasone. The choice of glucocorticoid medication, dose and frequency of administration is the focus of some considerable clinical research, driven by a desire to improve

Table 2 Medications that interact with glucocorticoid metabolism

Class of drug: examples	*Mechanism*	*Effect*
Anticonvulsants	Induction of CYP-3A	Accelerated clearance and reduced effect
• Carbamazepine • Phenobarbitone • Phenytoin • Primidone		
Antibiotics		
• Rifampicin • Rifabutin		
Antibiotics	Inhibition of CYP-3A	Reduced clearance, enhanced effect
• Erythromycin		
Antifungals		
• Itraconazole • Ketoconazole		
Anti-virals		
• Atazanavir		
Estrogens		
HIV treatment boosting agents:		
• Cobicistat • Ritonavir		
Immunsuppressives:		
• Cyclosporin • Tacrolimus • Everolimus		
Oral Antacids	Reduced absorption possible	Variable effects

clinical outcomes. Hydrocortisone as the native hormone is first choice in clinical guidelines (Bornstein *et al.*, 2016), but requires twice or thrice daily administration and doesn't replace the circadian cortisol rhythm. Prednisolone has its advocates because of price and only requiring twice daily administration (Amin *et al.*, 2014), and dexamethasone has the potential for once daily administration.

Metabolic syndrome and glucocorticoid choice: All glucocorticoid therapies given in excess will result in the features of Cushing syndrome that include the metabolic syndrome. In a cohort of nearly 200 adult patients with CAH, the prevalence of obesity was reported to be 40%, of hypercholesterolemia, 46%, and insulin resistance 29% (Arlt *et al.*, 2010; Han *et al.*, 2013a). This was felt primarily to relate to glucocorticoid therapy. Patients treated with prednisolone are reported to have a worse lipid profile than those treated with hydrocortisone (Han *et al.*, 2013b; Quinkler *et al.*, 2017), and insulin resistance occurred more commonly in those treated with dexamethasone (Han *et al.*, 2013a). Patients with secondary and tertiary AI may be more difficult to study; it can be difficult to distinguish the adverse effects of glucocorticoid replacement therapy from the effect of the primary pathology and related endocrinopathies, in particular untreated growth hormone deficiency. Patients with hypopituitarism are at increased risk of developing the metabolic syndrome, and hydrocortisone doses in excess of 20 mg day^{-1} are associated with an increased risk of dyslipidaemia (Filipsson *et al.*, 2006). Following preprandial administration of glucocorticoids, serum insulin and glucose are elevated, even in the presence of acceptable cortisol concentrations (al-Shoumer *et al.*, 1995). Higher doses of hydrocortisone are associated with higher systolic and diastolic blood pressures (Werumeus Buning *et al.*, 2016b) in patients with secondary AI.

Quality of Life (QoL) and glucocorticoid treatment regimen: QoL and glucocorticoid treatment regimen has been studied in a diverse population of 1250 patients, recruited through patient organizations from across the world (Forss *et al.*, 2012). In this cohort, 84% reported they had primary AI, 11% secondary and the remaining patients were uncertain. 74% of patients were treated with hydrocortisone, 11% with prednisolone and the remaining patients with cortisone. Health related QoL was reported to be adversely affected by AI in 87% of patients with secondary AI and 60% of patients with primary AI. The likelihood of reporting an impaired QoL was inversely related to the frequency of glucocorticoid doses, and patients treated with hydrocortisone were less likely to report impaired QoL than those treated with prednisolone, prednisone or cortisone. In patients with CAH, QoL is also reported to be poorer in patients treated with prednisolone or dexamethasone than in those treated with hydrocortisone (Han *et al.*, 2013b), and in obese patients and those with insulin resistance (Arlt *et al.*, 2010). In patients treated with hydrocortisone, QoL has been related to total daily dose, with those treated with higher doses having a poorer QoL than those in whom doses are

lower (Ragnarsson *et al.*, 2014). The challenge in interpreting these studies is that patients with a poor QoL may be the patients who have their dose increased or transfer to other glucocorticoids.

Bone mineral density (BMD): BMD in patients with AI, BMD is lower than the background population (Løvås *et al.*, 2009), and is inversely related to glucocorticoid dose (Zimmermann *et al.*, 2009). Nearly 50% of adult patients with CAH are reported to have osteopenia or osteoporosis (Han *et al.*, 2013b). Total glucocorticoid exposure during childhood and adolescence has been associated with the risk and severity of impaired BMD in adult life in previous cohorts (Paula *et al.*, 2008; Zimmermann *et al.*, 2009). Prednisolone treatment is associated with lower BMD than treatment with hydrocortisone, and normal BMD has been reported in patients with primary AI treated with hydrocortisone in doses of 15 mg m^{-2} day^{-1} for CAH and 12 mg m^{-2} day^{-1} for primary AI of other causes (Koetz *et al.*, 2012). Reductions in hydrocortisone doses in patients treated with higher doses have been associated with improvements in bone health (Schulz *et al.*, 2016). Treatment with dexamethasone has been associated with lower rates of bone turnover than hydrocortisone in biochemical studies of bone turnover markers (Suliman *et al.*, 2003).

Childhood: data describing long term outcomes in pediatric patients come from cohorts of patients with CAH, as other causes of AI in childhood are rare. These patients are at increased risk of obesity, insulin resistance, elevated leptin levels, dyslipidaemia, and impaired glucose metabolism (Völkl *et al.*, 2006). The severity of this adverse metabolic profile has been related to the total hydrocortisone dose and the duration of treatment (Zimmermann *et al.*, 2010). Working memory is poorer in children with CAH than in their unaffected relatives and quality of life is also reported to be reduced (Browne *et al.*, 2015). Boys and girls are equally affected suggesting that this is not simply related to androgen excess in girls and associated disorders of sex development. As noted above, the doses of hydrocortisone used in the treatment of CAH are higher than those used in other causes of AI in childhood, and long term outcomes in other groups of patients may be better.

Glucocorticoid Treatment Regimens

Hydrocortisone and cortisone are widely recommended as the glucocorticoids of first choice in clinical guidelines (Bornstein *et al.*, 2016), because they are of lower potency than the synthetic glucocorticoids and may be associated with fewer adverse effects. Doses can be titrated in smaller increments and adequacy of treatment assessed clinically. It is recommended that the use of the synthetic glucocorticoids prednisolone and prednisone is restricted to patients in whom symptoms of cortisol deficiency are not adequately controlled with hydrocortisone or cortisone, or where adherence to multiple daily dose regimens is poor (Bornstein *et al.*, 2016). The use of dexamethasone is discouraged because of the risk of excess glucocorticoid exposure. Data from the EU-AIR observational study suggest that these recommendations are adhered to in European clinical practice. In this cohort of nearly 1500 patients treated in the UK, Germany, the Netherlands, and Sweden, 92% of patients were treated with hydrocortisone or cortisone, while 5% were treated with prednisolone and only 0.1% were treated with dexamethasone (Murray *et al.*, 2017). In childhood, little work has been done to critically compare the effectiveness and side effects of treatment with different glucocorticoids. In a small pilot study of nine prepubertal children with CAH, ACTH, androstenedione and 17-hydroxyprogesterone (17-OHP) were lower during treatment with dexamethasone (0.3 mg m^{-2} day^{-1}), and higher during treatment with prednisone (3 mg m^{-2} day^{-1}), than during treatment with hydrocortisone (15 mg m^{-2} day^{-1}) (Nebesio *et al.*, 2016). In a study of children followed to final adult height, treatment with prednisolone was associated with a lower final adult height than treatment with hydrocortisone. Hydrocortisone treated patients receiving doses in excess of 20 mg m^{-2} day^{-1} at the start of puberty were significantly shorter than those treated with lower doses (Bonfig *et al.*, 2007). Prednisolone is generally accepted to be more potent than hydrocortisone. The conversion of prednisone to prednisolone in childhood is unreliable as 11β hydroxysteroid dehydrogenase type 1 activity is less predictable than during adult life (Wiegand *et al.*, 2007).

Hydrocortisone

The plasma half-life of hydrocortisone is only 90 min, requiring the administration of multiple doses to achieve adequate cortisol concentrations throughout the waking hours. Unless the patient wakes to take an early morning dose before rising in the morning, cortisol concentrations are subphysiological on waking, and overnight hypoglycaemia has been reported in patients with Addison's disease, treated with hydrocortisone (Meyer *et al.*, 2012; Petersen *et al.*, 2015). In a pharmacokinetic study of 13 different hydrocortisone regimes in 50 subjects with AI 50%–80% of patients were over- or undertreated at different times of the day (Simon *et al.*, 2010).

Current guidelines recommend hydrocortisone doses for adult patients are 15–25 mg day^{-1} and for cortisone, 20–35 mg (Bornstein *et al.*, 2016), given in two to three divided doses. These treatment guidelines are based on a number of studies that have estimated cortisol secretion rates, and investigated the effect of different dosing regimens on biochemical parameters, bone health and health related QoL (HRQoL). However, most of these studies are of small patient populations, and the observation periods are too brief to enable meaningful application of study findings to long term dosing regimens. It is also important to recognize that the pharmacokinetics of hydrocortisone show marked inter-individual variability (Simon *et al.*, 2010), even after intravenous administration (Jung *et al.*, 2014). Individual dosing regimens should be titrated according to symptoms whilst on treatment:

Lethargy, headache, nausea, poor concentration, weight loss and in children, inadequate weight gain etc., and cortisol excess: rapid weight gain, hypertension, peripheral oedema, and poor sleep. In CAH treatment should be adapted to patient requirements at the stage of life; essentially supraphysiological doses when regulation of hyperandrogenism is crucial and using physiological doses in adults and the elderly when symptomatic control is not vital but prevention of glucocorticoid side effects is a priority.

The bioavailability of hydrocortisone is nearly 100%, and cortisol concentrations rise rapidly from 30 min following an oral dose (Hindmarsh, 2014; Jung *et al.*, 2014; Werumeus Buning *et al.*, 2017). Cortisone requires activation to the active drug, hydrocortisone, and the onset of action is slightly slower. When plasma cortisol concentrations approach 550 nmol L^{-1}, the binding capacity of CBG is exceeded, free cortisol concentrations rise and then fall rapidly as free cortisol is filtered in the urine (Tunn *et al.*, 1992). At these levels cortisol clearance increases lowering the half-life of the steroid. As a consequence of this combination of rapid absorption followed by rapid elimination, patients may experience wide fluctuations in cortisol concentrations from supra-physiological levels shortly after a dose of hydrocortisone, followed by troughs when cortisol concentrations may be undetectable (Charmandari *et al.*, 2001a, b, Maguire *et al.*, 2007). In eight dexamethasone suppressed healthy volunteers, cortisol concentrations ranged from 943 to 1419 nmol L^{-1} 1 h following an oral dose of 20 mg (Jung *et al.*, 2014), well in excess of spontaneous cortisol peaks reported in healthy individuals (Debono *et al.*, 2009; Whitaker *et al.*, 2014).

Smaller doses of hydrocortisone, given more frequently, have the potential to give a more physiological cortisol profile than once or twice daily dosing. When cortisol profiles and wellbeing were studied in patients with adrenal insufficiency, treatment with three daily doses was superior, to twice daily doses, and was favored by most patients (Groves *et al.*, 1988). Improvements in cortisol and ACTH profiles were reported when cortisone was given thrice rather than twice daily (Laureti *et al.*, 2003). In a double blind, cross over, placebo controlled study, comparing two to four times daily dosing regimens, patients stated a preference for the four times daily dosing regimen (Ekman *et al.*, 2012). Nevertheless, it is also important to recognize that adherence to treatment for chronic disease is inversely related to the number of medication doses prescribed per day (Coleman *et al.*, 2012), and for some patients twice daily dosing is more practicable.

In patients in whom hydrocortisone is prescribed twice daily, two thirds of the dose is prescribed in the morning and one third in the afternoon. Three times daily dosing is distributed so that the largest dose of the day is given upon waking, the second dose after lunch and the final, smallest dose of the day in the early evening, not less than 4–6 h before bed as later dosing may have an adverse effect on sleep and insulin sensitivity (Plat *et al.*, 1999). Dose adjustment for body size may be beneficial in adult patients, as doses derived from either BSA or weight are more likely to result in cortisol concentrations within the normal range, than treatment with fixed 10 mg doses (Mah *et al.*, 2004). While patients are reported to favor weight based and more frequent dosing, improved clinical outcomes in the longer term have yet to be reported.

A variable dose dependent effect between glucocorticoid dose and HRQoL has also been reported. In a double-blind cross-over randomized controlled of weight based dosing regimens in patient with secondary AI, HRQoL was superior during higher, compared to lower, dose treatment (0.2–0.3 vs. 0.4–0.6 mg kg^{-1} body weight day^{-1}) (Werumeus Buning *et al.*, 2016a). In an observational study, authors reported poorer HRQoL in patients treated with more than 30 mg day^{-1} (Bleicken *et al.*, 2010). In a second observational study of patients with secondary AI, higher doses were also associated with a poorer HRQoL, and mortality almost doubled in patients treated with doses in excess of 20 mg (Hamarstrand et al., 2017), but did not differ from the background population in those treated with lower doses. A causative relationship between higher hydrocortisone dose and these adverse outcomes has not been demonstrated. In observational studies, it is possible that hydrocortisone doses are increased to treat symptoms of AI that arise from other causes. While recommendations can be made regarding hydrocortisone doses, it will always be important to consider how individual variability in glucocorticoid sensitivity and metabolism may require titration of doses against symptoms of cortisol deficiency and excess, and serum cortisol concentrations.

Despite these data, favoring lower compared to higher daily doses, the authors of a recent systematic review and metaanalysis found no evidence of benefit from low total daily doses of hydrocortisone (20 mg vs. 30 mg), or increased frequency of dosing (Al Nofal *et al.*, 2017). They did, however, report improved QoL in patients treated using subcutaneous hydrocortisone infusions and modified release hydrocortisone.

The use of stress hydrocortisone dosing in AI has been debated as cortisol levels naturally rise during stress such as exercise. During and after intense and moderate intensity exercise, blood glucose and adrenaline concentrations are lower in patients with AI than in healthy controls, and aerobic capacity and stamina is also reported to be significantly reduced (Green-Golan *et al.*, 2007; Simunkova *et al.*, 2016; Weise *et al.*, 2004). In a double blind, placebo controlled trial, a 10 mg dose of hydrocortisone taken 1 h before intensive exercise had no effect on exercise performance, metabolic or endocrine parameters or sense of well-being, although cortisol concentrations were double those recorded in healthy control subjects (Simunkova *et al.*, 2016). Similar data have been reported in patients with CAH during high and moderate intensity exercise (Weise *et al.*, 2004), and preexercise doses of hydrocortisone are not currently recommended.

Hydrocortisone therapy in childhood

In pediatric practice, hydrocortisone and cortisone doses are always derived from measurements of body size, generally body surface area. Cortisone can be used with caution, as 11βHSD type 1 concentrations are variable in childhood and estimates of dose equivalency for hydrocortisone quoted from the adult literature may be unreliable (Wiegand *et al.*, 2007).

In patients with AI due to causes other than CAH, hydrocortisone doses of 8 mg m^{-2} day^{-1}, given in three daily doses, are recommended. Doses are titrated against clinical features of adrenal insufficiency or glucocorticoid excess as in adult practice, and monitoring growth and weight gain provides additional, important information.

In children with CAH, higher doses of hydrocortisone are required to achieve adequate suppression of ACTH drive to the adrenal. Doses of 10–15 mg m^{-2} day^{-1} are usual, but doses as high as 25 mg m^{-2} day^{-1} may be required for some patients (Clayton *et al.*, 2002). In these patients, rapid growth is likely to result from increased androgen secretion in patients treated with hydrocortisone doses that are insufficient to suppress ACTH drive to the adrenal, while slow growth is likely to indicate treatment with doses that are excessively high. Final adult height in patients with CAH has been related to corticosteroid exposure during infancy and adolescence, with a loss in final adult height of 0.4 cm for every 1 mg m^{-2} day^{-1} increase in dose (Sarafoglou *et al.*, 2014). Doses not exceeding 20 mg m^{-2} day^{-1} in infancy and 17.5 mg m^{-2} day^{-1} in older children are recommended to minimize the adverse effect on growth (Silva *et al.*, 1997).

Prednisolone

Treatment with prednisolone is recommended for adult patients in whom the symptoms of adrenal insufficiency cannot be treated adequately with hydrocortisone, and those in whom adherence to the three times a day, hydrocortisone treatment regimen is difficult. Another use for prednisolone could be in those who are unable to take their hydrocortisone tablet for a long period such as during prolonged fasting. Prednisolone is absorbed rapidly following oral administration and concentrations peak within the first hour (English *et al.*, 1975). Like hydrocortisone, the plasma half-life of prednisolone is reported to show marked inter-individual variability, even after intravenous administration, and ranges from 120 to 360 min (English *et al.*, 1975; Al-Habet and Rogers, 1980). The longer half-life results in a smoother profile of glucocorticoid exposure, enabling once daily dosing. The problem with this is that there is a tendency to bind longer to the glucocorticoid receptor with slower dissociation, preventing the latter from exchanging rapidly with glucocorticoid response elements in DNA and slowing down gene cycling. This may alter body physiology and increase the risk of side effects. On the other hand the effect of hydrocortisone is faster with rapid redistribution of the receptor-response element on completing a glucocorticoid response (Stavreva *et al.*, 2009). Recommended doses are either as a daily dose of 4 or 5 mg at 07:00 h or as a twice daily dose of 3 mg and 2 mg or 3 mg and 1 mg at 07:00 h and 14:00 h, respectively (Husebye *et al.*, 2014). Doses up to 6 mg day^{-1} may be used in CAH. In some countries prednisone is used. This has a plasma half-life of 60 min and, similar to cortisone, is inactive. It must be reduced by 11βHSD Type 1 in the liver to the active prednisolone.

Studies of the effect of glucocorticoids on ACTH suppression, indicate that prednisolone has approximately four times the biological activity of hydrocortisone (Khalid *et al.*, 1982) despite having only 1.7-fold higher trans-activating activity of the GCR (Grossmann *et al.*, 2004). This discrepancy may be accounted for, in part, by the relatively higher concentrations of free hormone, as prednisolone has only 50% of the affinity for CBG as hydrocortisone, and a higher re-activation rate from the inactive form, prednisone (Diederich *et al.*, 2002). The growth suppressive effect has been reported to be 15-fold that of hydrocortisone (Punthakee *et al.*, 2003), while the immunosuppressive effects are reported to be approximately fourfold that of hydrocortisone (British National Formulary, 2017). The spectrum of potencies of prednisolone on systems regulated by glucocorticoids suggest the determinants of the synthetic glucocorticoid activity are not simply dose related, but are regulated by differential effects on glucocorticoid target genes.

Prednisolone is used rarely in childhood, as its high potency increases the risk of clinical features of glucocorticoid excess, in particular poor growth (Punthakee *et al.*, 2003). It may be helpful in some adolescent patients, nearing completion of growth in whom adherence to a three times daily dosing regimen required for hydrocortisone is particularly difficult. For patients with CAH, the recommended doses are 2–4 mg m^{-2} day^{-1}, given once daily (Clayton *et al.*, 2002) or twice daily, and in adolescents with adrenal insufficiency from other causes, lower doses are likely to be sufficient. Irrespective of being classified as an intermediate acting glucocorticoid the use of prednisolone in patients with CAH does not control morning androgen levels with hormonal escape occurring after 10 h (Debono *et al.*, 2015).

A modified release formulation of prednisolone with a delayed release mechanism, Lodotra, has been produced as an attempt to try and provide more physiological replacement. By administering this drug before sleeping at 22:00 h patients with adrenal insufficiency showed a better quality of life with less complaints and fatigue when compared to taking prednisolone on waking, highlighting the importance of early morning glucocorticoid exposure (Langenheim *et al.*, 2013). Randomized placebo controlled studies are necessary to confirm the benefits of this formulation in patients with adrenal insufficiency.

Dexamethasone

The use of dexamethasone as a cortisol replacement therapy is discouraged in both adult and pediatric practice. The plasma half-life is around 200 min and the biologic half-life varies between 36 and 54 h. The potency, estimated by antiinflammatory effect, is 30 times that of hydrocortisone though the antigrowth effect may be up to 80 times higher (Finkielstain *et al.*, 2012). Dose titration is difficult because of the potency of dexamethasone, and the risk of Cushingoid side effects is high (Clayton *et al.*, 2002; Husebye *et al.*, 2014). Adult replacement dose are 0.25–0.75 mg day^{-1} (Bornstein *et al.*, 2016), and for children doses of 0.25/0.375 mg m^{-2} day^{-1} have been used (Clayton *et al.*, 2002). Although better control of androgens is achievable with dexamethasone and so the drug may be useful for a short period to improve fertility in women and reduce testicular adrenal rest tumor size in males it is associated with a high risk of metabolic complications such as insulin resistance (Han *et al.*, 2013a). In addition in CAH androgens escape control after around 16 h (Debono *et al.*, 2015).

Subcutaneous Hydrocortisone Infusion

The use of insulin pumps to administer hydrocortisone subcutaneously, offers the opportunity to reproduce the physiological, diurnal profile of cortisol. Infusion sets and cannula need to be re-sited every 3 days, and patients need to learn how to increase hydrocortisone infusion rates during periods of ill health. Despite considerable advances in pump technology, technical problems still occur frequently, and site infections are not uncommon (Ross *et al.*, 2015, 2016). Improved QoL has been reported in open label pump studies or case reviews, together with a reduction in the frequency of hospital admissions (Björnsdottir *et al.*, 2015; Khanna *et al.*, 2015). Improved cortisol and nocturnal glucose profiles are described in adults with Addison's disease, without deterioration in insulin sensitivity (Björnsdottir *et al.*, 2015). However, the only blinded randomized controlled trial failed to demonstrate superior QoL during hydrocortisone infusion therapy compared to treatment with oral hydrocortisone in Addison's patients with preexisting good quality of life (Gagliardi *et al.*, 2014). In children and adults with CAH, androgen profiles have been reported to improve during subcutaneous hydrocortisone therapy (Bryan *et al.*, 2009; Nella *et al.*, 2016; Tuli *et al.*, 2011), and this may be particularly helpful during puberty, when altered hydrocortisone pharmacokinetics and poor adherence make treatment particularly challenging (Charmandari *et al.*, 2001a,b). They may also be useful in patients with gastric side effects or fast metabolizers. In patients with AI subcutaneous hydrocortisone infusions achieved ACTH and cortisol levels similar to normal circadian levels (Oakley and Cidlowski, 2013). While these studies demonstrate that hydrocortisone infusion therapy is safe, enables physiological cortisol profiles, improved biochemistry and possibly QoL, there is no evidence that these changes translate into improvements in the long term morbidity and mortality of AI, and the issue of health economics has yet to be considered.

Modified Release Hydrocortisone Formulations

Two modified release (MR) hydrocortisone formulations have been developed or are in development Plenadren and Chronocort. Plenadren (Shire Plc. Jersey) is a modified release hydrocortisone with an outer coating layer that provides an immediate release of the drug and an extended release core. Plenadren provides a more extended serum profile of cortisol compared to immediate release Hydrocortisone. In adults a single morning dose of Plenadren gives similar cortisol exposure to a thrice daily regime of immediate release hydrocortisone although Plenadren tends to provide higher levels of cortisol in the late morning and lower in the late evening than a conventional regime and overall has approximately 20% less bioavailability (Johannsson *et al.*, 2012). Studies in adult patients reported promising results, with improvements in metabolic profiles, weight, and blood pressure (Quinkler *et al.*, 2015). Beneficial effects are also reported for QoL (Bergthorsdottir *et al.*, 2015; Giordano *et al.*, 2016). For the treatment of CAH, Plenadren is unlikely to control excess androgens as the overnight rise in cortisol is not replicated, and nocturnal dosing of Plenadren would expose patients to high levels of cortisol throughout the night during the quiescent period of the cortisol circadian rhythm.

Chronocort (Diurnal Ltd. UK) a product under development is a modified release hydrocortisone, but differs from Plenadren in having a delayed and sustained absorption profile rather than an immediate and sustained release profile (Porter *et al.*, 2017). Chronocort aims to replace physiological cortisol levels by dosing at morning and night such that the night time dose provides release of hydrocortisone in the early hours of the morning providing a prewaking rise in cortisol levels and a cortisol profile similar to physiological cortisol levels (Whitaker *et al.*, 2014). In CAH patients, Chronocort given twice daily last thing at night and first thing in the morning gave superior control of androgens both at night and in the day compared with standard hydrocortisone given three times daily (Jones *et al.*, 2017; Mallappa *et al.*, 2015).

Management of Adrenal Crisis

Adrenal crisis is a life threatening condition which requires immediate treatment. In a large, prospective study, 8.3 episodes of adrenal crisis/100 patient years were reported, with an associated mortality rate of 0.5/100 patient years (Hahner *et al.*, 2015). Patients with CAH use sick day rules 171 times during their life and attend hospital for an adrenal crisis 11 times (Hummel *et al.*, 2016). Patient education regarding possible precipitants, the need to increase glucocorticoid doses during periods of stress and prompt recognition of the early features of adrenal crisis is essential. All patients are encouraged to wear or carry identification, alerting health care professionals of the diagnosis of AI to enable prompt treatment in an emergency setting.

Patients with primary adrenal insufficiency are most likely to be affected, but during periods of stress, particularly during vomiting or diarrheal illness when oral glucocorticoid absorption is unreliable and fluid and electrolyte losses may be high, patients with secondary or tertiary AI may also be affected. Other common precipitants include flu like illnesses, and in children, respiratory tract infections. The introduction of new medications that alter glucocorticoid clearance (**Table 2**) may also precipitate adrenal crisis.

The biochemical features of adrenal crisis include hyponatraemia and hyperkalaemia in patients with mineralocorticoid deficiency with a high urea. Patients with secondary and tertiary AI are likely to have normal mineralocorticoid activity, but hyponatraemia may be present due to vasopressin secretion. Hypoglycaemia is more common in children than in adults.

The treatment of adrenal crisis is based on expert opinion, and to date no clinical trials have been performed to determine the optimal glucocorticoid dosing regimen in either adults or children. In 2016, the Endocrine Society, in collaboration with the European Society of Endocrinology and the American Society for Clinical Chemistry published treatment recommendations

Table 3 Treatment of adrenal crisis

Hydrocortisone therapy	*Intravenous fluid*
Adults 100mg IV bolus *Followed by* 200 mg day^{-1} as a continuous infusion for 24 h *Followed by* 100 mg day^{-1} as a continuous infusion Children 50–100 mg m^{-2} IV bolus *Followed by* 50–100 mg m^{-2} day^{-1} as boluses given every 6 h	Adults 1000 mL isotonic saline or 5% dextrose in isotonic saline over first hour *Followed by* Continuous infusion of isotonic saline, adjusted according to patient need Children Rapid bolus of isotonic saline 20 mL kg^{-1}, to be repeated up to 60 mL kg^{-1} within first hour for shock Hypoglycaemia: 0.5–1.0 g dextrose or 2–4 mL kg^{-1} of 25% dextrose (maximum single dose 25 g) infused at a rate of 2–3 mL h or 5–10 mL kg^{-1} 10% dextrose for patients <12 years old.

detailed in **Table 3**. Hydrocortisone is always used for the emergency treatment of adrenal crisis as it has a mineralocorticoid effect at the high doses prescribed in this scenario, as 11βHSD type 2 is saturated at high cortisol concentrations.

Cortisol concentrations have been measured in eight healthy volunteers, following dexamethasone suppression of the HPA, after the administration of 50 mg hydrocortisone intravenously. In these subjects cortisol concentrations exceeded 2000 nmol L^{-1} 30 min after the dose had been given, and ranged from 400 to 900 nmol L^{-1} 5 h following a dose (Jung *et al.*, 2014), suggesting that it may be safe to use lower doses of hydrocortisone during acute illness.

Management of Intercurrent Illness and Surgical Stress

Early management of intercurrent illness and surgical stress should avoid progression to acute adrenal crisis in most patients. The cortisol response to stress reflects the intensity, duration and nature of the stressor, and hydrocortisone doses titrated against the severity of the stress are recommended.

While there is little doubt that severe stress requires additional glucocorticoid, the threshold at which doses should be increased is uncertain. An effect of general anesthesia on cortisol concentrations has been studied in children and adults. Approximately a quarter of children undergoing general anesthesia for elective imaging demonstrated a stress response (Hsu *et al.*, 2012; Rains *et al.*, 2009), although a reduction in cortisol concentrations was also reported in a third and was not associated with an increased risk of adverse events (Rains *et al.*, 2009). A study of adult patients undergoing thyroidectomy or parathyroidectomy, described a cortisol stress response during reversal of anesthesia, endotrachial extubation, and the early recovery period, but not during the surgical procedure (Udelsman *et al.*, 1987).

Studies of the cortisol response to minor surgery, for example, inguinal hernia repair in adults (Chernow *et al.*, 1987), and elective urological procedures in healthy children (Taylor and Auchus, 2013) report that, for these minimally invasive procedures, there is no significant cortisol response. Adult patients undergoing moderately (e.g., cholecystectomy) or highly (e.g., colectomy) stressful procedures mounted a stress response within an hour of surgery, which persisted in some for up to 24 h, with a return to baseline values in all patients within 5 days (Chernow *et al.*, 1987). During childhood febrile illnesses cortisol levels are reported to be three to five times higher than baseline levels, with the magnitude of change reflecting the severity of the illness (Nickels and Moore, 1989).

Glucocorticoid dosing regimens draw on data reported in studies measuring cortisol secretion rates during surgery. In a review article published in 1994, data from seven studies were integrated (Salem *et al.*, 1994). For minor surgery, cortisol secretion rates were estimated to be 25 mg day^{-1} hydrocortisone equivalent, for moderate surgery, 50–75 mg day^{-1} and for major surgical stress, 100–150 mg day^{-1}. Recommended doses are higher than these, recognizing that there are currently no data to demonstrate that these doses have an adverse effect, or that lower doses are safe. The recommendations of the Endocrine Society, in collaboration with the European Society of Endocrinology and the American Society for Clinical Chemistry (Bornstein *et al.*, 2016) are given in **Table 4**.

Conclusion

Patients with adrenal insufficiency have a higher mortality rate compared to the normal population and are at risk of multiple complications, including metabolic disturbances, a poor quality of life and adrenal crises. Conventional glucocorticoid replacement since development in mid-20th century has had a positive impact on the lives of these patients but remains inadequate. No

Table 4 Glucocorticoid management of intercurrent illness and surgical stress

Home management of pyrexial illness
Adult and pediatric patients
• Temperature $>38^{\circ}C$: hydrocortisone doses double • Temperature $>39^{\circ}C$: hydrocortisone doses tripled
Plus increased consumption of electrolyte containing fluids
Intercurrant Illness: oral hydrocortisone not tolerated Adult patients: 100 mg hydrocortisone S.C. or I.M. Pediatric patients: 50 mg m^{-2} I.M. *or* • Infants 25 mg • School age children 50 mg • Adolescents 100 mg
Minor to moderate surgery Adult patients: 25–75 mg day^{-1} hydrocortisone Pediatric: 50 mg m^{-2} I.M. or normal replacement doses doubled or tripled
Major surgery/trauma/delivery or critical care[a] Adult patients: 100 mg I.V. bolus followed by 200 mg day^{-1} for 24 h, followed by 100 mg day^{-1} Pediatric patients: 50 mg m^{-2} I.V. followed by 50–100 mg m^{-2} day^{-1} every 6 h *plus* weight appropriate fluids (5% dextrose and 0.2 or 0.45% NaCl)

[a]Illness requiring intensive care.
S.C., subcutaneous; I.M., intramuscular; I.V., intravascular.

specific biomarkers for glucocorticoids are available to aid management. Weight adjusted hydrocortisone dosing in adults or BSA based in children, administered three times daily, seem the best options resulting in least variability with potential for less side effects.

Oral modified release hydrocortisone formulations and subcutaneous hydrocortisone infusion pumps that mirror the physiological cortisol circadian rhythm are promising but long term studies assessing metabolic outcomes, quality of life and mortality are still awaited. Patient education to avoid adrenal crises remains fundamental and should be strengthened at each clinic visit. Identifying diagnostic and therapeutic strategies based on pharmacogenetics or biochemical markers to individualize patient treatment could in the future offer physicians novel tools to upgrade and modernize the management of adrenal insufficiency.

Management of Adult Patients With Congenital Adrenal Hyperplasia Due to 21-Hydroxylase Deficiency

Virginie Grouthier, Jérôme Dulon, Anne Bachelot, and Philippe Touraine, Sorbonne University, Paris, France

Nomenclature

21OHD	21-hydroxylase deficiency
BMI	Body mass index
BP	Blood pressure
CAH	Congenital adrenal hyperplasia
cIMT	Carotid intima-media thickness
CV risk	Cardiovascular risk
DEX	Dexamethasone
GC	Glucocorticoid
HC	Hydrocortisone
MC	Mineralocorticoid
SV	Simple-virilizing form
SW	Salt-wasting form
TART	Testicular adrenal rest tumor
UK	United Kingdom

Introduction

Congenital adrenal hyperplasia (CAH MIM 201910) corresponds to a group of inherited autosomal recessive disorders that arise from defective steroidogenesis and results from a deficiency in one or several of the enzymes of cortisol biosynthesis.

Deficiency of the 21-hydroxylase enzyme is the most common form of CAH, accounting for >95% of the cases and is one of the most common known autosomal recessive disorders. CAH due to 21-hydroxylase deficiency (21OHD) is the result of deletions or deleterious mutations in the active gene CYP21 (Auchus, 2015). There are many mutations of the CYP21 gene identified so far, which cause of varying degrees of impairment of 21-hydroxylase activity (New *et al.*, 2013). Most patients are compound heterozygotes. The clinical phenotype, related to the less severe mutated allele, is classified as classic for the severe form, or nonclassic. Classic CAH encompasses salt-wasting (SW) or simple-virilizing (SV) forms, depending on the degree of aldosterone deficiency. Hormonal treatment is based on cortisol and, when necessary, aldosterone substitution. Its role is to reduce the excessive ACTH production and consequently the increased androgen production by the adrenal gland, to ensure normal fertility, and to avoid the long-term consequences of GC use. The physiological circadian rhythm of cortisol cannot be mimicked with traditional oral GC, and the doses needed to suppress the androgens are usually higher than those needed for substitution (Auchus, 2015; New *et al.*, 2013; Han *et al.*, 2014).

In this article, we decided to focus on the new findings published on CAH over the last years. An exhaustive PubMed research has been performed with the terms "congenital adrenal hyperplasia," "21 hydroxylase deficiency." We excluded all the data that were dealing with nonclassic CAH and childhood outcomes of CAH, with female fertility and prenatal treatment, in order to focus on studies dealing with classic CAH in adults. We also chose to go further into four themes: cardiovascular risk and mortality, male fertility, bone mineral density and treatment management, since most of the recent publications concern those topics.

Metabolic and Cardiovascular (CV) Risk

Cohorts of adults with CAH due to 21OHD from Europe (Arlt *et al.*, 2010; Bachelot *et al.*, 2015; Falhammar *et al.*, 2015) and the United States (Finkielstain *et al.*, 2012) have been published in the recent years and have shown an increased risk for metabolic disorders (Han *et al.*, 2014; Falhammar *et al.*, 2011; Falhammar and Thorén, 2012). Overweight and obesity have been reported in adult patients with CAH. In the cross-sectional study conducted in the United Kingdom, BMI was found to be higher in CAH patients than in the general population (Arlt *et al.*, 2010). However, in the American cross-sectional study and in two French cohorts, prevalence of obesity was similar to that found in the general population (Bachelot *et al.*, 2015; Bouvattier *et al.*, 2015). More recently, repartition of adipose tissue was studied in CAH adolescents and young adults, and showed increased abdominal adiposity, with a higher proportion of proinflammatory visceral adipose tissue in CAH patients (Kim *et al.*, 2015). Metabolic syndrome was observed in nearly 20% of CAH adults in the NIH cohort (Finkielstain *et al.*, 2012). Blood pressure (BP) control in children and adult CAH patients has been investigated by several independent groups, with some studies reporting normal resting (Mooij *et al.*, 2010; Ubertini *et al.*, 2009; Sartorato *et al.*, 2007; Falhammar *et al.*, 2007) and 24 h BP profile (Marra *et al.*, 2015) and others reporting a slight increase systolic BP (Arlt *et al.*, 2010; Cutler and Laue, 1990; De Silva *et al.*, 2004; Völkl *et al.*, 2006; Nermoen *et al.*, 2012; Mooij *et al.*, 2011; Roche *et al.*, 2003). In a recent epidemiological Swedish registry study, increased frequency of hypertension in individuals with CAH has been shown, but when analyzing the different subgroups, only SV females had increased blood pressure (Falhammar *et al.*, 2015). This was in accordance with a recent study showing that adult males with classic CAH have a rather low BP compared with healthy men (Bouvattier *et al.*, 2015). Dyslipidemia in individuals with CAH has

been reported in some studies. In the epidemiological Swedish registry study, an increased rate of dyslipidemia was found, especially in males with null genotype (Falhammar *et al.*, 2015).

In this intricate scenario, it is reasonable to expect a high CV risk profile in CAH patients. However, cardiovascular morbidity and mortality are not easy to bring out in this population, as very few of the studied patients are older than 50. Carotid intima-media thickness (cIMT) is a marker of early, subclinical atherosclerotic change, that is correlated to the risk for coronary artery disease and stroke (Stein *et al.*, 2008). While increased cIMT has been shown in CAH adults in one study (Ubertini *et al.*, 2009), further studies in children or adolescent CAH patients showed normal cIMT compared to a body mass index (BMI)-matched cohort (Sartorato *et al.*, 2007; Falhammar *et al.*, 2007) or increased cIMT compared to controls, but linked to higher BMI and unfavorable metabolic parameters (Marra *et al.*, 2015; Cutler and Laue, 1990; De Silva *et al.*, 2004). Recently, we reported the complex interactions between gonadotropins and steroid hormones on the duration of ventricular repolarization. We found that CAH QT interval duration was shorter in women with CAH than in control women (Abehsira *et al.*, 2016). These findings and their clinical impact have to be further examined. The association between endothelial dysfunction, cIMT progression, hormonal imbalance, treatment of CAH, and CVD events, will be important to figure out in this at-risk cohort.

The rate of CV events among adults with CAH is beginning to be characterized (Falhammar *et al.*, 2015). The long-term outcomes in CAH patients were studied using the Swedish national CAH registry. The mean age of death was lower in CAH patients (41.2 $\pm$ 26.9 vs. 47.7 $\pm$ 27.7 years ($P < 0.001$)). The hazard ratio of death was 2.3 (1.2–4.3) in males and 3.5 (2.0–6.0) in females. The causes of death were adrenal crisis (42%), cardiovascular diseases (32%), cancer (16%), and suicide (10%) (Falhammar *et al.*, 2014). Interestingly, the same team analyzed CV and metabolic morbidity in CAH patients (Falhammar *et al.*, 2015). This study showed an increase in both CV and metabolic disorders (OR 3.9; 95% CI [3.1–5.0]), and CV disease (OR, 2.7; 95% CI [1.9–3.9]). Separate analyses of the individual diseases showed higher frequencies of hypertension, diabetes, obstructive sleep apnea, dyslipidemia and atrial fibrillation in CAH patients. Obesity was consistently increased in all subgroups. However, the nonobese patients with CAH were similarly affected as the entire CAH cohort. Increased frequency of venous thromboembolic events was also reported. This should be further studied to determine if, as reported in both Cushing syndrome and GC use, there is a higher risk of venous thromboembolism due to a state of hypercoagulability, which should lead to more frequent use of thrombosis prophylaxis in this population.

CAH is therefore associated with higher CV risk factors and probably with excess CV and metabolic morbidity. Some subgroups of patients seem to be more affected. Regular follow-up is needed, along with lifestyle interventions, to limit the onset of weight gain and obesity, to screen for diabetes, other metabolic disorders and CV risk factors. Close monitoring of GC doses is important. Further studies on larger cohorts are necessary to better clarify the mechanisms leading to metabolic and CV abnormalities, and to precise the respective roles of androgen and lifelong GC treatment.

Male Fertility

Male patients with CAH may present impaired gonadic function and infertility. It appears that adult males with CAH face a dual problem. Adrenal steroid overproduction, especially androgen and progesterone, might interfere with FSH and LH production, resulting in gonadotropic deficiency. In addition, testicular adrenal rest tumors (TARTs) may become hypertrophic under chronic ACTH stimulation and influence both endocrine and exocrine testicular functions (Reisch *et al.*, 2010).

TARTs are rare and benign testicular tumors, first defined in 1940 by L. Wilkins. They have usually been reported in classic CAH and, even if it is still controversial, presence of TART would be sometimes also detected in nonclassic CAH (Falhammar and Thorén, 2012). TARTs have been identified with a prevalence of 30%–95% depending on age and modality of diagnosis, that is, palpation or ultrasound (Bouvattier *et al.*, 2015; Pierre *et al.*, 2012). The prevalence of TARTs increases with age, after onset of puberty (Claahsen-van der Grinten *et al.*, 2014; Aycan *et al.*, 2013). TARTs volume and prevalence seem higher in patients with SW form compared with those in the SV form (Pierre *et al.*, 2012; Reisch *et al.*, 2009; Yu *et al.*, 2015). Because of their central localization in testis, TARTs are difficult to palpate especially if they measure <2 cm. Therefore, imaging plays an important role. Ultrasonography should be the method of first choice for detection and follow-up of these lesions, because it is the cheapest and quickest imaging technique (Stikkelbroeck *et al.*, 2003). Magnetic resonance imaging (MRI) has not been completely approved yet. But, in particular cases (like surgery treatment), MRI could be recommended because it details mapping and shows lesion margins optimally (Stikkelbroeck *et al.*, 2003; Ozisik *et al.*, 2017).

The pathogenesis of TARTs could result from proliferation of aberrant adrenal-like tissue. Its cells of origin may be adrenal cortical rest cells, hilar Leydig cells or pluripotential cells of the testes (Engels *et al.*, 2017). In CAH disease, the elevated ACTH level stimulates such remnant adrenal cells leading the development of this testicular adrenal rest tumors. However, some studies report the development of TARTs despite good hormonal control, suggesting that undertreatment is not the only cause for their growth (Chihaoui *et al.*, 2016; Reisch *et al.*, 2013). Indeed, a recent study about molecular characterization of TARTs has shown that these tumors have multiple steroidogenic properties, including the expression of adrenal cortex and typical Leydig cell markers (Smeets *et al.*, 2015).

TARTs are most often responsible for impaired spermatogenesis. In patients with and without TARTs, inhibin B levels differ significantly and there are higher total sperm counts and concentration in patients without TARTs (Bouvattier *et al.*, 2015). In a large cohort of 164 male CAH patients who underwent testicular assessment with ultrasound, 71 had a sperm analysis. Seventy percent of the patients had severe oligospermia or azoospermia when TARTs were found versus only 3.6% when they were not

(Bouvattier *et al.*, 2015). Because of their central localization near the rete testis, TARTs can lead to compression of the seminiferous tubules that may finally lead to obstructive azoospermia and irreversible damage of the surrounding testicular tissue (Reisch *et al.*, 2009). They also can destroy and replace healthy testicular tissue. A decreased tubular diameter and presence of peritubular fibrosis and tubular hyalinization were reported in testicular biopsies of man CAH patients with TARTs and infertility history (Claahsen-van der Grinten *et al.*, 2008). The profile of the gonadotropic–testicular axis in these patients will primarily show testicular failure and eventually reveal endocrine and exocrine testicular dysfunctions (Bry-Gauillard *et al.*, 2014).

Fertility preservation is a key management goal in TART. Treatment options for male patients with TARTs are still limited and mainly based on a good hormonal control with GC (Yu *et al.*, 2015). Intensified glucocorticoid treatment is recommended as a first step treatment. However, in some patients, treatment is poorly tolerated, and the medical response is disappointing. Sparing surgical approach can be proposed for important tumors and steroid unresponsive masses or in testicular pain situation but there are no data on fertility preservation. Recently, Bry-Gaillard *et al.* have shown that mitotane could restore fertility in CAH patients with TARTs (Bry-Gauillard *et al.*, 2014). After 8 months of treatment, gonadotropins levels, inhibin B and sperm counts have improved, and on the other hand, size of TARTs has shrunk.

Prevention has a real important place in the management of male CAH fertility. A systematic ultrasound evaluation is recommended at puberty to detect lesions at an early stage. A semen analysis should also be realized as soon as possible, and the question of systematic sperm cryopreservation seems fully justified (King *et al.*, 2016).

Reduced fertility in CAH men can also be secondary to hypogonadotropic hypogonadism due to poor hormonal control with increased adrenal androgens and progesterone, leading to an increase in estrogen levels by aromatization. A recent case report has demonstrated the restoration of fertility by gonadotropin replacement in a CAH man (Rohayem *et al.*, 2014). The patient had hypogonadotropic azoospermia and TARTs due to untreated SV form. A treatment with gonadotropin replacement permitted to obtain after 21 months a stable low sperm concentration with good sperm motility, enabling the couple to have a healthy girl.

Besides these somatic causes of impaired fertility in CAH males, there might be aspects of psychosocial adaptation and sexual well-being. Very few data have been reported on sexual satisfaction in CAH males. Two recent studies have shown that fewer CAH patients than controls had an active sexual life and that they had fewer lifetime partners (Falhammar and Thorén, 2012; Falhammar *et al.*, 2014). In a Swedish cohort of 30 CAH males, erectile dysfunction was found in about half of these patients (Falhammar *et al.*, 2014) as was described in the study from Dudzińska *et al.* A sexual well-being study of 20 CAH males has revealed impairments in sexual drive, erections and ejaculations (Dudzińska *et al.*, 2014). Poor control disease was associated with a reduced sexual drive. However, in the recent Swedish follow-up study described previously, although the reason is unknown, men were more often married than controls (OR 1.6 (1.0–2.5)) but, as the CAH women, they had less biological children than controls (OR 0.4 (0.2–0.6)) (Strandqvist *et al.*, 2014). Further studies are needed to properly assess these psychosocial outcomes, to improve the care given to the patients.

Bone Mineral Density

Bone mineral density alteration has been an understandable concern for adult patients with CAH and who receive chronically glucocorticoids (Ogilvie *et al.*, 2006). Corticosteroid therapy is known to inhibit osteoblastic activity, which potentially leads to decreased bone density (Guo *et al.*, 1996); similarly, markers of bone formation such as osteocalcin, are reported to be low in adult CAH. However, the potential impact of chronic GC therapy on BMD is difficult to precisely determine due to the young age of patients enrolled in some studies, leading therefore to conflicting results. Most reports fail to show decreased BMD in young patients, contrarily to studies enrolling older patients (Mora *et al.*, 1996; Cameron *et al.*, 1995; Bachelot *et al.*, 2007; Chakhtoura *et al.*, 2008). Although increased BMI might protect against low BMD, this has not been found in CAH patients. However, all these studies provide compelling evidence that the lowest possible GC dose should be used in the treatment of CAH, and lower-dose and short-acting GC may be sufficient in the middle-aged and elderly female when osteoporosis becomes, more than fertility, an important concern (Merke, 2008). Osteoporosis prophylaxis such as physical activity and calcium and Vitamin D supplementation should be implemented at a young age. Screening dual-energy x-ray absorptiometry (DXA) should be performed in CAH adults.

Treatment of Classic CAH in Adults

Treatment in classic 21OHD is necessary to compensate for GC and MC deficiencies but also to correct adrenal androgen excess. Ideally, the treatment should be monitored in order to avoid iatrogenic comorbidities and to enable a good quality of life (Reisch, 2015). However, this goal is not reached up to now, since increased comorbidities and mortality are reported in patients with CAH (Bachelot *et al.*, 2017).

GC substitution is available since the 1950s. Although this treatment has notably changed the prognosis of children with CAH, it has remained the only medical solution for the last decades and has failed to meet all of the needs for the patient. Indeed, contrarily to primary adrenal insufficiency, the aim of GC treatment is not only to compensate for the deficient hormone but also to blunt the nocturnal ACTH secretion, which is the major driver of adrenal androgen production. Since cortisol is secreted mainly in the morning and, reaches a peak between 6 and 8 am, most oral GC regimens are proposed with at least half or 2/3 of the global dose in the morning. Up until now, whatever regimen used, the dilemma has persisted between using the physiological HC, well

tolerated but with a poor control of androgen secretion or the long acting prednisone, prednisolone or dexamethasone (DEX), with a higher risk of side effects. Unfortunately, an adequate androgen secretion is difficult to achieve without a high dose of GC, therefore leading to side effects in relation to hypercorticism. Recently a new slow release HC formula (Plenadren) has become available and another one (Chronocort) is under current investigation. In addition, besides the GC approach, non-GC approaches are under current development, such as the use of molecules interfering with CRH function and nonselective adrenal steroidogenesis blockade (Turcu and Auchus, 2016) (**Fig. 1**).

New Glucocorticoid Approaches

The first molecule is a dual-release HC which was developed for once-daily morning administration in patients with primary adrenal insufficiency (Plenadren, ViroPharma-Shire) (Johannsson *et al.*, 2009). It is a modified-release HC with an outer coating layer that provides an immediate release of the drug and an extended-release core. It provides a more extended serum profile of cortisol compared with immediate-release HC. In adults, a single morning dose of Plenadren gives similar cortisol exposure to a thrice-daily regimen of immediate-release HC. Preliminary studies in patients with primary adrenal insufficiency and CAH have demonstrated that this new formula compared with HC regimen, improves body weight, systolic and diastolic blood pressure, and glucose metabolism (Johannsson *et al.*, 2012; Quinkler *et al.*, 2015). This molecule also provides a more circadian-based serum cortisol profile in patients with primary adrenal insufficiency. Unfortunately, there are no data currently available regarding hormonal control in patients with CAH. However, in the latter case, this molecule is unlikely to control excess androgens as the overnight rise in cortisol is not replicated, and evening administration of Plenadren would expose patients to high levels of cortisol during the night.

The second molecule, Chronocort, is under current development by Diurnal (United Kingdom) (Debono *et al.*, 2015). This molecule is a modified-release HC, but it differs from Plenadren by having a delayed and sustained absorption profile rather than an immediate- and sustained-release profile. Chronocort aims at replacing physiological cortisol concentrations by dosing at

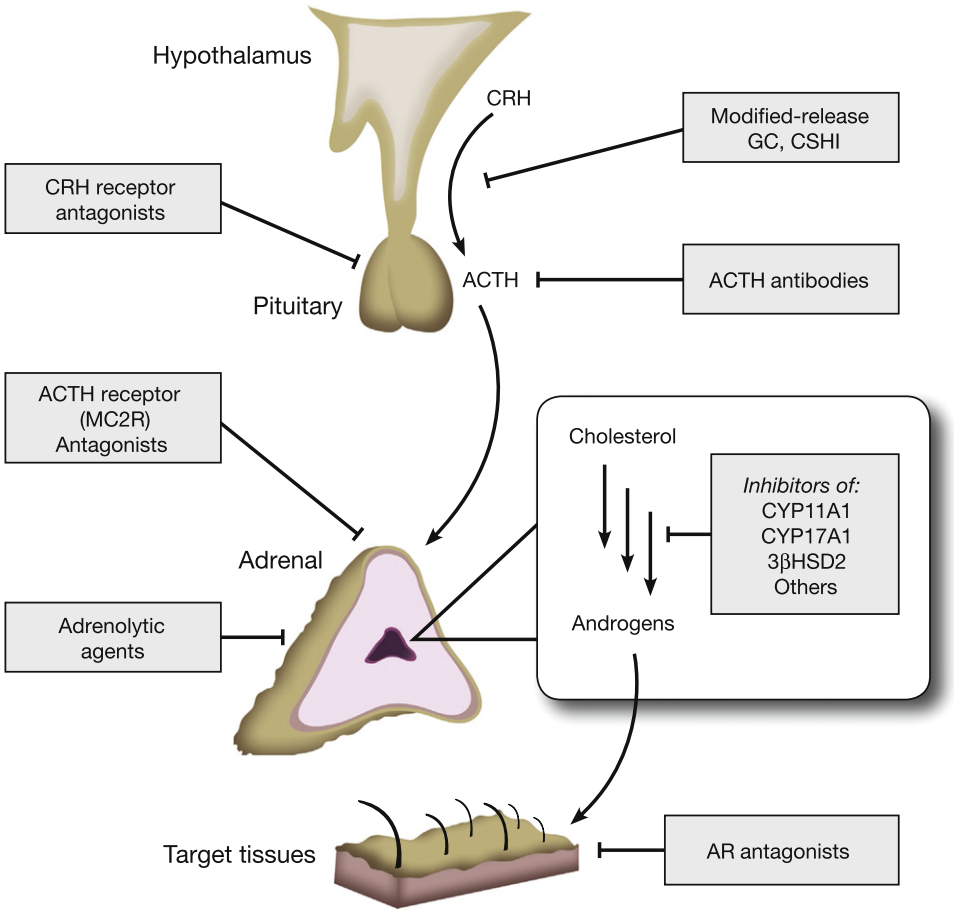

Fig. 1 Potential therapeutic targets in congenital adrenal hyperplasia. *3βHSD2*, 3β-hydroxysteroid dehydrogenase type 2; *ACTH*, adrenocorticotropin hormone; *AR*, androgen receptor; *CRH*, corticotropin-releasing hormone; *CSHI*, continuous subcutaneous hydrocortisone infusion; *CYP11A1*, cholesterol side chain cleavage enzyme; *CYP17A1*, 17α hydroxylase/17,20 lyase; *GC*, glucocorticoids.

morning and night such that the night dose provides release of HC in the early hours of the morning providing a prewaking rise in cortisol levels. In a first Phase II, open label study, Chronocort has shown its ability to decrease the 8 am 17OHP level; however, androgen levels rise in the afternoon with once-daily dosing, suggesting that an additional morning dose of GC is needed (Verma *et al.*, 2010). Another phase 2 study on 16 patients was designed to evaluate the efficiency of a double dose of Chronocort (10 mg at 7 am and 20 mg at 11 pm). It showed that after 6 months of treatment, the mean androstenedione and 17OHP levels were diminished compared with those observed under classical GC therapies (Mallappa *et al.*, 2015). More recently, Chronocort has been shown to reduce the 17OHP and alternative pathway metabolite excretion, also observed in CAH patients by gas chromatography–mass spectrometry, to near-normal levels, more consistently than other GC preparations (Jones *et al.*, 2017). All these preliminary data need to be confirmed also on clinical parameters and in larger populations.

Before the development of these new molecules, the use of parenteral GC infusion had been discussed. The reproduction of cortisol circadian rhythm permitted to bring 17OHP and ACTH levels closer to physiological values compared to conventional therapies (Merza *et al.*, 2006). More recently, a continuous subcutaneous HC infusion was found to be more efficient than conventional GC in a randomized trial on 33 patients with primary adrenal insufficiency. Doses of HC were adjusted depending on salivary cortisol. In this study, ACTH levels and cortisol profiles were respectively lower and more physiological than those observed under conventional oral GC therapy. However, the impact of this treatment on quality of life remains a matter of debate (Oksnes *et al.*, 2014; Gagliardi *et al.*, 2014). Another approach has been proposed to improve the dynamics of HC infusions. In healthy volunteers, intrinsic adrenal function was blocked by DEX, whereas HC was permanently infused subcutaneously (Russell *et al.*, 2014). Cortisol and ACTH were measured every 10 and 60 min, leading to the replication of the circadian rhythmicity. A recent phase 2 trial on the use of sub cutaneous hydrocortisone pump in eight CAH patients with poor control has been published (Nella *et al.*, 2016). In this study, subcutaneous hydrocortisone pump approximated physiologic cortisol secretion. Six months treatment resulted in improved adrenal steroid control and had positive effects on quality of life. All these studies may be considered as interesting or even more promising; however they also underline the difficulty in managing the patients daily (Russell *et al.*, 2014). The cost of these pumps, the potential dysfunction and local irritation, may also be considered as limiting factors. The long-term effect, tolerance and acceptation of this treatment will require further studies.

Nonglucocorticoid Approaches

The most radical treatment is the surgical removal of both adrenal glands. This approach must be carefully discussed since it can induce the development of TARTs in men and less frequently retroperitoneal adrenal rest tumors in women (Tiosano *et al.*, 2010; Crocker *et al.*, 2012). Chemical adrenalectomy may be obtained using Mitotane, an adrenolytic agent for which the mechanisms of action remain poorly understood. Recent evidences focus on apoptotic effects at adrenocortical level reducing activity of the respiratory chain complex and inducing mitochondrial fragmentation, leading to programmed cell death (Gentilin *et al.*, 2014; Hescot *et al.*, 2013). Mitotane also modulates the expression of several genes involved in steroid hormone biosynthesis (Hescot *et al.*, 2013). In addition, the lack of LH increase following the decrease in free testosterone suggests that Mitotane may have a toxic effect on the testes and also on the pituitary by reducing viability of gonadotroph cell lines through activated apoptosis (Gentilin *et al.*, 2014).

Two novel approaches are under current investigation: the development of androgen biosynthesis inhibitors and the development of ACTH and CRH receptor antagonists.

The development of androgen biosynthesis inhibitors is based on the necessity of decreasing secretion and action of androgens since, as previously mentioned, most of the GC treatments are unable to induce such blockade. Abiraterone is an inhibitor of CYP17A1, an enzyme necessary for androgen synthesis (**Fig. 1**). In men treated for prostate cancer, abiraterone acetate has proven its efficiency in decreasing testosterone levels (Ryan *et al.*, 2015). A recent phase I study in CAH women permitted to observe, after 6 days of treatment, a decrease by 2/3 of the androstenedione level when the administered dose was 100 mg/day. When the dose was increased up to 250 mg/day, the androstenedione level was completely normalized after 6 days of treatment. However, this approach does not compensate for the adrenal insufficiency, and therefore requires the adjunction of a GC, and in some patients MC treatment (Auchus *et al.*, 2014). This treatment cannot be used in male patients, as it blocks all androgen synthesis.

Since ACTH is a key factor in controlling adrenal function, the opportunity of interfering with the corticotrope axis has been proposed. ACTH is the only known naturally occurring agonist for its receptor. The high degree of ligand specificity suggests that antagonism of its receptor could provide a useful therapeutic approach and at least an investigational tool. Different experimental models, in animals, may provide new insights in this potential new approach (Clark *et al.*, 2016).

Besides ACTH, CRH is at the hypothalamic level, the key factor inducing, after a specific binding to CRH receptor type 1, ACTH secretion. Any antagonism to this receptor could be a potential therapeutic strategy. This approach has been recently explored with a selective CRH receptor type 1 antagonist NBI-77860. In a single blind, placebo-controlled study, eight patients with CAH have received a fixed dose of 300 or 600 mg, each period of treatment being separated by a 3 weeks washout time; treatment was prescribed at 10 pm and ACTH and 17OHP were measured sequentially during the day after drug administration. There was a reduction of ACTH by a mean of 43% and 41%, under 300 and 600 mg respectively compared with placebo, whereas 17OHP was reduced by a mean of 0.7% and 27% under the same treatments (Turcu *et al.*, 2016). These promising data provide a rationale for ongoing experimental studies using CRH receptor antagonist, without forgetting that this approach does not compensate for cortisol and aldosterone deficiencies.

Table 1 Management of adult patients with classic CAH

Monitoring of the efficacy of glucocorticoid replacement therapy
● Early-morning serum concentrations of 17-OHP, Δ4-androstenedione, total testosterone, 30 to 60 min after drug intake
● SHBG approximately every six to 12 months
● Diurnal 17OHP curve with dried blood spots if available
● Weight gain and clinical signs of cortisol and androgen excess
Monitoring of the efficacy of mineralocorticoid replacement
● Blood pressure
● Plasma electrolytes
● Early-morning plasma renin activity concentration
Periodic measurements and/or monitoring of the following:
● Weight
● Lipid profile
● Blood pressure
● Glycemia
● Bone mineral density
Assessment of male gonadic function and fertility
● Testicular adrenal rest by ultrasonography
● Sperm analysis
● Fertility preservation
● Hormonal measurements: total testosterone, LH, FSH
Genetic counseling
Psychological support

Conclusion

Recent years have brought new insights in the description of CAH comorbidities especially in the CV and fertility areas (**Table 1**). In both cases this description suggests the need for new therapeutic approaches. After decades of relatively stagnant progress, advances are now noted. Besides improved GC delivery systems, oral or parenteral, new GC approaches are under current elevation such as inhibitors of androgen biosynthetic enzymes or CRH receptor antagonists. All these approaches may have pros and cons. In all cases, larger trials to determine the outcomes and safety profiles are needed, in adults as well as in children.

Cushing Syndrome; Screening and Differential Diagnosis

André Lacroix, Centre hospitalier de l'Université de Montréal (CHUM), Montréal, QC, Canada
Lynnette K Nieman, National Institutes of Health (NIH), Bethesda, MD, United States

Abbreviations

ACTH	Adrenocorticotropic hormone or corticotropin
ARMC5	Armadillo Repeat Containing 5 gene
BMAH	Bilateral macronodular adrenal hyperplasia
cAMP	Cyclic adenosine monophosphate
CBG	Corticosteroid-binding globulin
CRH	Corticotropin releasing hormone
CS	Cushing syndrome
CT scan	Computed tomography scan
DST	Dexamethasone suppression test
FDG PET scan	Fluorodeoxyglucose-positron emission tomography scan
GNAS	Stimulatory G-protein alpha subunit
GPCR	G-protein coupled receptor
HDDST	High dose dexamethasone suppression tests
HPLC	High performance liquid chromatography
iMAD	Isolated micronodular adrenocortical disease
LC-MS/MS	Liquid chromatography tandem mass spectrometry
LNSC	Late night salivary cortisol
MC2R	Melanocortin 2 receptor (ACTH receptor)
MRI	Magnetic resonance imaging
PET	Positron emission tomography
PKA	Protein kinase A
PPNAD	Primary pigmented nodular adrenal dysplasia
PRKACA	Protein kinase A catalytic subunit α
SPECT	Single-photon emission tomography
UFC	Urinary free cortisol in 24 h collection

Glossary

ARMC5 Was recently identified as a gene whose germline and somatic mutations cause 25%–50% of BMAH; it is thought to be a tumor suppressor gene but its precise function is still unknown.

BMAH Primary bilateral macronodular adrenal hyperplasia is a rare cause of Cushing syndrome.

Cortisol secreting adrenal adenoma The most frequent cause of ACTH-independent Cushing syndrome, in which a unilateral adrenocortical tumor produces excess cortisol.

Cushing disease The most frequent etiology of Cushing syndrome, in which a pituitary corticotroph tumor produces excess ACTH.

PPNAD Primary pigmented nodular adrenal dysplasia is a rare cause of bilateral micronodular adrenal hyperplasia that can be familial and associated with other tumors of the Carney complex.

Introduction

Cushing syndrome (CS) patients often constitute a challenge for clinicians who suspect and wish to confirm hypercortisolism, identify its specific etiology and achieve optimal treatment, which generally involves removal of a causative tumor(s) (Pendleton *et al.*, 2010; Nieman *et al.*, 2008). The diagnosis of CS is considered to be one of the most difficult to establish in endocrinology. This rare and highly morbid condition often requires several months or years before proper diagnosis and effective therapy are achieved.

There is a wide range of severity of cortisol excess in endogenous CS from clinically almost silent, cyclical, mild to rapid onset severe variants (Arnaldi *et al.*, 2003; Biller *et al.*, 2008; Nieman *et al.*, 2008; Lacroix *et al.*, 2015). The variable biology of the different tumors responsible for CS explains the imperfect reliability of biochemical and radiological investigations, in particular in the initial phases or mild forms of the syndrome (Arnaldi *et al.*, 2003; Nieman *et al.*, 2008; Lacroix *et al.*, 2015). The numerous caveats to diagnosis of CS together with its rarity emphasize the need for the eventual referral to expert teams that have a solid experience in CS. We review here the recent progress on the initial screening and identification of the various etiologies of CS. Other chapters of this Encyclopedia review the molecular mechanisms, specific investigation and therapies of the various specific etiologies of CS.

Epidemiology and Etiologies

As CS is a rare condition, its precise incidence and prevalence has not been well established. Its incidence was 0.2–5.0/million/year and its prevalence between 39 and 79/million individuals in various studied populations (Etxabe and Vazquez, 1994; Lindholm *et al.*, 2001; Steffensen *et al.*, 2010; Bolland *et al.*, 2011; Valassi *et al.*, 2011). A Danish population studied during 11-years yielded

an incidence of CS (nonmalignant disease) of 2.3/million/year; the median age was 41.4 year (range, 3.6–77.7) with a female: male ratio of 3:1 (Lindholm *et al.*, 2001). Using a retrospective private health insurance claims database (16 million insured lives per year from all regions of the United States), CS incidence rates was estimated to be of 39.5–48.6 per million person-years, a much higher rate than reported for European populations (Broder *et al.*, 2015); ascertainment of diagnosis was not however as stringent as in the previous European studies. CS incidence was higher in women than men, with rates of 61.5–77.4 for women, compared to 15.6–17.2 for men (Broder *et al.*, 2015). Some studies identified higher, but variable prevalence of CS in patients with uncontrolled diabetes type II, hypertension or early onset osteoporosis (Taniguchi *et al.*, 2008; Murakami *et al.*, 2010; Chiodini *et al.*, 2007; Gagliardi *et al.*, 2010; Terzolo *et al.*, 2012; Krarup and Hagen, 2012).

Endogenous CS is caused by ACTH-dependent or ACTH-independent disorders (**Table 1**) (Lacroix *et al.*, 2015). The most frequent cause is excess secretion of ACTH either by a pituitary corticotroph adenoma (Cushing's disease (CD)), or less frequently from extra-pituitary (i.e., "ectopic") benign or malignant tumors, which are primarily neuroendocrine tumors (NET) (Lacroix *et al.*, 2015). Up to 20% of the ACTH-secreting ectopic tumors remain occult for many years (Ilias *et al.*, 2005; Isidori *et al.*, 2006). Rarely, the responsible tumor (medullary thyroid carcinoma or pheochromocytoma) secretes either corticotropin-releasing hormone (CRH) alone, which stimulates excess pituitary ACTH secretion, or both CRH and ACTH (Lacroix *et al.*, 2015).

The prevalence of the most frequent etiology, CD, was 39.1 per million inhabitants (incidence 1.2–2.4 newly diagnosed cases/million persons per year) in previous European studies (Lindholm *et al.*, 2001; Etxabe and Vazquez, 1994). The prevalence of CD was higher (62.1/million) in an Icelandic population, with a significant female predominance (52.8 vs. 9.3/million for men) (Agustsson *et al.*, 2015). In a recent Danish pediatric age population study, the annual incidence of CS was 0.89 cases/million population with a median age at the time of diagnosis of 13.8 years (interquartile range: 10.5–18.2 years), 58% were female and 70% had a corticotroph pituitary adenoma (Holst *et al.*, 2017). The average age at diagnosis in other pediatric CD series was similar at 13 years (symptom onset 10.6 years) (Kanter *et al.*, 2005; Lonser *et al.*, 2013). Symptom initiation to diagnosis averages 2–3 years in pediatric and adult cases (Zillio *et al.*, 2014). Before puberty, the ratio of female-to-male cases is similar (1:1) (Kanter *et al.*, 2005; Lonser *et al.*, 2013).

Cortisol excess from unilateral adrenocortical adenomas or carcinomas suppresses ACTH levels, leading to their characterization as "ACTH-independent." These tumors account for approximately 20% of CS cases (Arnaldi *et al.*, 2003; Biller *et al.*, 2008; Nieman *et al.*, 2008; Lacroix *et al.*, 2015). Infrequently, CS is caused by primary bilateral macronodular adrenal hyperplasia (BMAH), or primary pigmented nodular adrenocortical disease (PPNAD) and its nonpigmented variant, isolated micronodular adrenocortical disease (iMAD) (Lacroix, 2009; Stratakis, 2008; Doppman *et al.*, 1989). As 10%–15% of adrenal incidentalomas are bilateral, BMAH with modest cortisol secretion is more frequent, but its precise prevalence is unknown (Lacroix, 2009, BMAH chapter in this Encyclopedia). Similarly, 5%–30% of unilateral incidentalomas are associated with modest cortisol secretion that rarely progresses to overt clinical CS as the cases with overt Cushing syndrome frequently carry *PRKACA* mutations (Chiodini, 2011; Fassnacht *et al.*, 2016; Beuschlein *et al.*, 2014).

Clinical Symptoms and Initial Screening

The wide distribution of glucocorticoid receptors throughout the body explains the varied and multiple clinical manifestations of CS that include morphological changes (weight gain, central obesity, buffalo hump, etc.); neuropsychiatric (insomnia, cognitive impairment, depression and irritability) and dermatological (easy bruising, facial plethora, purple striae, acne, hirsutism) disorders; immunosuppression leading to vulnerability to infections; cardiovascular (hypertension, atherosclerosis), metabolic (hypokalemia, glucose intolerance, diabetes mellitus, and dyslipidemia), musculoskeletal (proximal muscle weakness, osteoporosis), and sexual/reproductive complications (hypogonadism, hirsutism) (Arnaldi *et al.*, 2003; Biller *et al.*, 2008; Nieman *et al.*, 2008; Lacroix *et al.*, 2015; Pivonello *et al.*, 2015, 2016). This heterogeneity makes the clinical diagnosis of CS challenging, considering that many features of this condition are nonspecific and highly prevalent among the general population, such as high blood pressure, abdominal obesity, diabetes, osteoporosis, and altered phenotypic characteristics (Nieman *et al.*, 2008; Pivonello *et al.*, 2016).

Screening is recommended in individuals in whom CS manifestations are most likely: patients with unusual age-related features (e.g., hypertension in young adults), with multiple and progressive manifestations, children with decreasing growth velocity and increasing weight, and patients with adrenal incidentaloma (Nieman *et al.*, 2008). Multiple and progressive features suggestive of CS might not be all be present, but some more specific ones, such as catabolic features and central obesity justify screening (Nieman *et al.*, 2008; Guignat and Bertherat, 2010); patients with unexplained severe features, such as resistant hypertension and osteoporosis, regardless of age, require screening. Proximal muscle weakness, wide purple striae, and in children, diminished growth, appear more specific to CS, but are usually found in cases with higher or longer lasting hypercortisolism (Nieman *et al.*, 2008; Pecori Giraldi *et al.*, 2003). The use of exogenous glucocorticoids should be excluded before biochemical screening. As CS is a rare condition, routine screening in patients with morbid obesity, type 2 diabetes or in those with hypertension is unwarranted unless progressive new symptoms have accumulated relatively recently (Nieman *et al.*, 2008).

Biochemical evaluation of CS exploits the cardinal features of the increased endogenous production of cortisol: abnormal feedback of cortisol excess on the pituitary–adrenal axis, and the loss of the normal cortisol circadian rhythm (Lacroix *et al.*, 2015; Lonser *et al.*, 2017).

Table 1 Causes of endogenous Cushing syndrome

	Proportion (%)	*Age (peak)*	*Female:male*	*Features*
ACTH-dependent	70–80	–	–	–
Cushing's disease	60–70	–	–	–
Corticotroph adenoma	60–70	3rd–4th decades	3–5:1	Roughly 50% nonvisible on MRI
Corticotroph hyperplasia	Very rare	–	–	–
Ectopic ACTH[a]	5–10	–	–	–
Malignant neuroendocrine tumors	About 4	5th–6th decades	0.6–1:1	Might have very high ACTH
Benign neuroendocrine tumors	About 6	3rd–4th decades	–	Might respond to dexamethasone, CRH, desmopressin
Occult neuroendocrine tumors	About 2	–	–	–
Ectopic CRH	Very rare	–	–	Causes pituitary corticotroph hyperplasia
ACTH-independent	20–30	–	–	–
Unilateral adrenal	–	–	–	–
Adenoma	10–22	4th–5th decades	4–8:1	Most pure cortisol secretion
Carcinoma	5–7	1st, 5th–6th decades	1.5–3:1	Mixed cortisol and androgen frequent
Bilateral adrenal	1–2	–	–	–
Bilateral macronodular adrenal hyperplasia[b]	<2	5th–6th decades	2–3:1	Modest cortisol secretion compared with size; raised steroid precursors; might have combined androgen and mineralocorticoid cosecretion
Aberrant G-protein-coupled receptors	–	–	–	–
Autocrine ACTH production	–	–	–	–
Sporadic or familial (ARMC5)	–	–	–	–
Bilateral micronodular adrenal hyperplasias	<2	–	–	Adrenal size often normal
Primary pigmented nodular adrenocortical disease	Rare	lst–3rd decades	0.5:1 <12 years 2:1 >12 years	Frequent paradoxical increase of urine free cortisol with Liddle's oral dexamethasone suppression test
Isolated or familial with Carney complex	Rare	lst–3rd decades	–	–
Isolated micronodular adrenocortical disease	Very rare	Infants	–	Nonpigmented adrenal micronodules
Primary bimorphic adrenocortical disease	Very rare	Infants	–	–
McCune–Albright syndrome	Rare	Infants (<6 months)	1:1	Internodular adrenal atrophy
Bilateral adenomas or carcinomas	Rare	4th–5th decades	2–4:1	–

[a]Most frequent sources of ectopic ACTH syndromes are small cell lung carcinoma and neuroendocrine tumors of lung, thymus, and pancreas. Less frequent causes include medullary thyroid carcinoma, gastrinoma, pheochromocytoma, prostate carcinoma, and several others.

[b]In bilateral macronodular adrenal hyperplasia tissues, autocrine and paracrine ACTH might be produced and contribute to cortisol secretion. If confirmed by in vivo studies, the ACTH-independent classification will need to be modified in the future.

ACTH, Adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

Reproduced with permission from Lacroix, A., Feelders, R.A., Stratakis, C.E. and Niemann, L.K. (2015). Cushing's syndrome. *Lancet* **386**, 913–927.

Three screening tests for the diagnosis of CS are recommended in the clinical practice guidelines of the Endocrine Society: late night salivary cortisol, 24-h urine free cortisol (UFC) and the 1 mg overnight (or 2-day 2 mg) dexamethasone suppression test (**Table 1**) (Nieman *et al.*, 2008; Lacroix *et al.*, 2015; Sharma *et al.*, 2015). To optimize sensitivity, despite decreased specificity, it is recommended to use the upper limit of the reference range as a cutoff for normal basal cortisol values; the assay sensitivity should allow for measurement of a serum cortisol below 50 nmol/L (1.8 μg/dL) the morning after 1 mg dexamethasone administration, which is the upper threshold for a normal response (Nieman *et al.*, 2008).

Other guidelines such as the French "National Diagnosis and Treatment Guideline (NDTG) for Cushing's syndrome" recommend screening for CS not only in those with unusual features based on age, but also if there are features with atypical severity, such as resistant hypertension, or unexplained osteoporosis (Guignat and Bertherat, 2010). The French NDTG does not consider the 2 mg 48-h DST as appropriate for first-line testing due to the difficulty in its implementation in the outpatient setting. It is therefore recommended as a potential second-line test, only following referral to an endocrinologist. Furthermore, the French disagree with the Endocrine Society guideline's suggestion that the desmopressin test be restricted to the research setting; the NDTG placed greater weight on emerging evidence from Europe that the desmopressin test may have better diagnostic accuracy than the Dex-corticotropin-releasing hormone (CRH), particularly in mild cases of hypercortisolism when the differential diagnosis includes only CD and pseudo-Cushing's states (Nieman *et al.*, 2008; Guignat and Bertherat, 2010).

CS diagnosis is highly probable in patients with a high pretest positive probability who have two abnormal screening tests (Nieman *et al.*, 2008). Patients that present cyclic hypercortisolism or nonconsistent screening tests responses may require additional testing. It is indicated to repeat tests, perform alternate tests, and/or await progression in patients with only mild features of CS (low pretest probability) and mildly abnormal test results (Nieman *et al.*, 2008; Lacroix *et al.*, 2015). Confirmation of hypercortisolism benefits from frequent midnight salivary cortisol and UFC measurements over a long period, sometimes over years (Atkinson and Mullan, 2011; Graham *et al.*, 2013). In a series of 152 patients with confirmed CD, the intrapatient coefficient of variation of UFC was 52% (95% CI: 48–56) between four basal values (Petersenn *et al.*, 2014).

Urinary Free Cortisol

UFC is an index of circulating free (biologically active) cortisol (de Castro and Moreira, 2007; Newell-Price *et al.*, 1998; Nieman *et al.*, 2008). Unlike plasma cortisol, which measures total cortisol (bound and unbound), factors that modulate corticosteroid-binding globulin (CBG) concentrations do not affect UFC results. When plasma cortisol exceeds the maximal binding capacity of CBG (approximately 690 nmol/L), plasma free cortisol and UFC increase more rapidly than cortisol production, and become sensitive indicators of hypercortisolism. UFC values greater than fourfold normal are rare except in CS (Nieman *et al.*, 2008; de Castro and Moreira, 2007; Newell-Price *et al.*, 1998). Lesser values are found either in CS or pseudo-CS. Up to 11% of patients with CS may have a normal UFC in one of four collections (Nieman *et al.*, 2008; Petersenn *et al.*, 2014; Ceccato *et al.*, 2015). When UFC is measured by immunoassays, the upper limit of normal in various assays ranges up to 220–330 nmol/day (80–120 μg/day) and often the antibodies will cross-react with various metabolites of cortisol and some exogenous glucocorticoids, which are measured as "cortisol." When separation of urinary glucocorticoids and cortisol metabolites is achieved by HPLC (or more recently by structure-based liquid chromatography tandem mass spectrometry (LC-MS/MS)), the normal range of UFC is usually $<$140–170 nmol/day. For the detection of CS, the sensitivity of UFC by HPLC is 95%–100% and its specificity is 94%–98% (Newell-Price *et al.*, 1998; Arnaldi *et al.*, 2003; Lacroix *et al.*, 2015) and by LCMS/MS of 97% and 91%, respectively (Ceccato *et al.*, 2015). Due to the variability of cortisol secretion from day to day, three 24-h urine specimens should be collected in order to increase the diagnostic yield. Urinary creatinine and volume also should be measured to verify the adequacy of the collection. If glomerular filtration rate is less than 30 mL/min, UFC is decreased, and may be normal despite the presence of CS (Nieman *et al.*, 2008).

Plasma Cortisol Variability and Midnight Plasma Cortisol

Several factors modify cortisol binding globulin (CBG) and consequently alter total cortisol concentrations. Predictably, oral estrogen administration (at higher doses in contraceptives) and pregnancy increase serum CBG and increase total cortisol values. The utility of plasma cortisol measurements for the diagnosis of CS rests on the loss or blunting of the normal circadian cortisol nadir. Healthy individuals who consistently sleep at the same time of day have a nadir cortisol that is tightly entrained to sleep onset (Krieger *et al.*, 1971). By contrast, although patients with CS often have awakening serum cortisol concentrations within or above the normal range, they lose the normal diurnal nadir, as the tumors secrete throughout the day even if in a pulsatile way. In hospitalized CS patients compared to healthy individuals, plasma cortisol was above 50 nmol/L, when sleeping at midnight, with sensitivity and a specificity of 100% (Newell-Price *et al.*, 1995). Midnight plasma cortisol was greater than 207 nmol/L (7.5 μg/dL) in awake patients with CS; this value had a sensitivity of 96% and a specificity of 100% in differentiating CS from pseudo-Cushing's states (Papanicolaou *et al.*, 1998). However serum cortisol measurements are not practical to obtain as most patients are not admitted to hospital for investigation.

Late Night Salivary Cortisol (LNSC)

Cortisol concentration in saliva correlates highly with free plasma cortisol, is independent of salivary flow rates, and is stable for up to 1 week in samples at room temperature (Raff, 2009). LNSC obtained at 23:00 can distinguish normal individuals from patients with CS (Raff, 2013). Diagnostic ranges vary between studies, due to the different assays and comparison groups used to set cutoff points (de Castro and Moreira, 2007). Salivary cortisol can be measured by immunoassay or liquid chromatography–tandem mass spectrometry (LC/MS-MS). Given the lower sensitivity of LC/MS-MS (as it may not measure cortisol metabolites/precursors), immunoassay remains a frequently utilized methodology for Cushing syndrome screening (Gafni *et al.*, 2000; Raff, 2013).

Education of the patient on optimal timing of specimen collection in relation to their normal sleep–wake cycle, as well as avoiding exciting or stressful experiences on the evening of the test, are important. False-positive results also can result from contamination of the saliva sample with blood from tooth brushing. Recent reports suggest that increased age and comorbidities of diabetes and hypertension are associated with increased values (Liu *et al.*, 2005; Raff *et al.*, 1999). However, overall, ease of collection, stability at room temperature, and a greater than 90% sensitivity and specificity make it a highly useful test, especially in outpatients, children, and in assessment of cyclic Cushing syndrome (de Castro and Moreira, 2007; Raff, 2013).

Low-Doses Dexamethasone Suppression Tests (DST)

The low dose DST is used to differentiate CS patients from those who do not have CS (**Fig. 1**); it is also the most sensitive screening test to identify modest cortisol secretion from adrenal incidentalomas (Nieman *et al.*, 2008; Fassnacht *et al.*, 2016). The overnight low dose DST (1 mg orally between 23:00–midnight) excludes with high probability the presence of CS when the 08:00–09:00 plasma cortisol on the following morning is below 50 nmol/L (1.8 μg/dL) and the patient does not have cyclical CS (Nieman *et al.*, 2008); rare patients with mild CS may suppress with 1-mg but not with 0.5-mg overnight DST (Liddle, 1960; Findling *et al.*, 2004). However, its specificity is limited, due to misclassification of patients with increased CBG, acute and chronic illness or pseudo-CS. If the next day 8:00 am serum cortisol is >275 nmol/L (10 μg/dL), the patient has a high probability of having CS. Between 50 and 275 nmol/L (1.8–10 μg/dL) the result is equivocal and further testing should be performed (Nieman *et al.*, 2008; Sharma *et al.*, 2015).

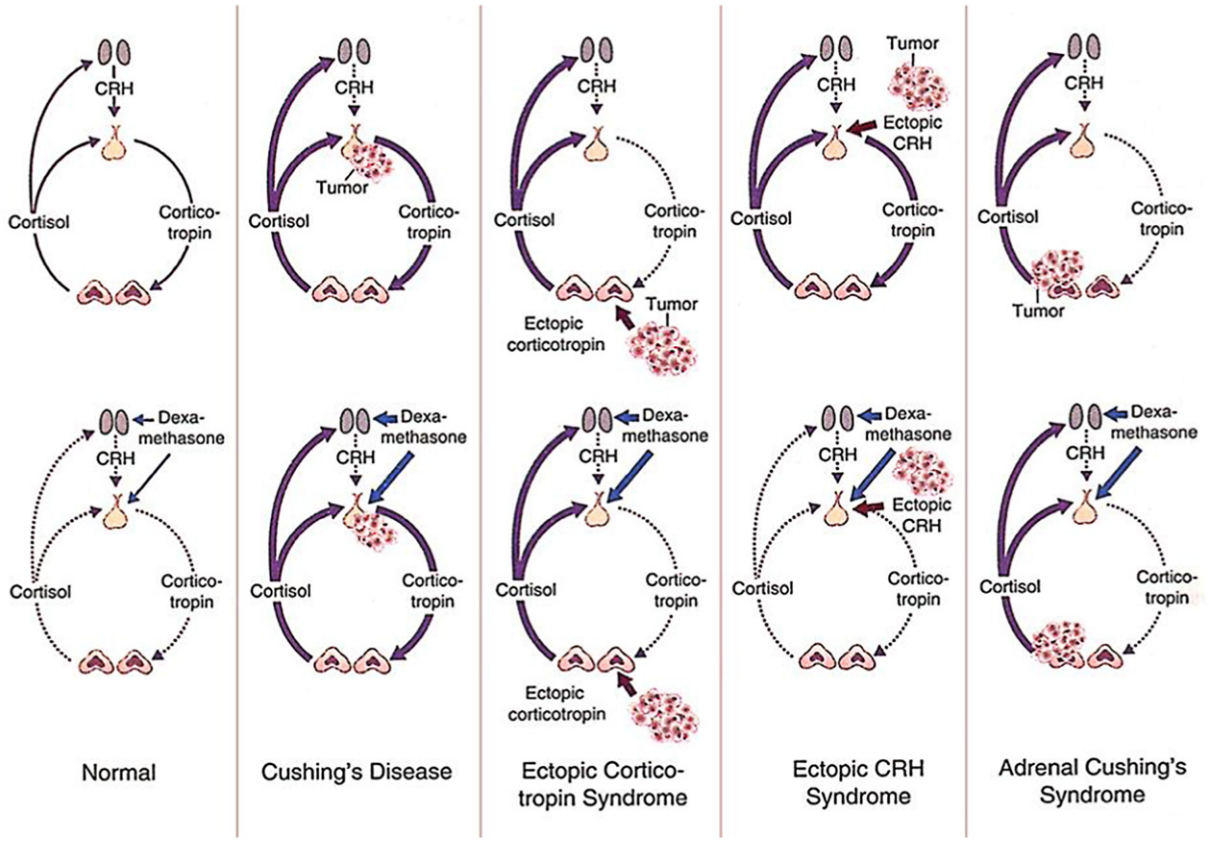

Fig. 1 Differential regulation of the hypothalamic–pituitary–adrenal axis in normal subjects and in the various etiologies of Cushing syndrome. In normal subjects, stimulation of the hypothalamus by central nervous system centers regulates the secretion of CRH which in turn increases ACTH secretion. ACTH stimulates adrenal secretion of cortisol which, as exogenous low dose dexamethasone (lower panel), inhibits the secretion of both CRH and ACTH. In Cushing's disease, excess ACTH originating from the corticotroph tumor is partially resistant to excess glucocorticoid and high dose dexamethasone suppression, while CRH and normal corticotropes are suppressed. Ectopic ACTH secretion from malignant tumors is usually autonomous from CRH and dexamethasone regulation, while ectopic ACTH originating from up to 50% of benign NET can be suppressed partially by high dose dexamethasone or respond to exogenous CRH or desmopressin similar to Cushing disease. In adrenal Cushing syndrome caused by unilateral adrenal tumors, ACTH is suppressed by excess cortisol and is not modified by CRH or high doses of dexamethasone. In bilateral macronodular adrenal hyperplasia, cortisol can be regulated by the ligands of various aberrant hormone receptors (GPCR) stimulating paracrine ACTH production by adrenal hyperplasia cells acting on the ACTH receptor (MC2R); however, circulating ACTH levels remain low. Normal hormone secretion is shown by lines, suppressed secretion by thinner or dotted lines, and hypersecretion by thick lines. Reproduced with permission from Lacroix, A., Feelders, R.A., Stratakis, C.E. and Niemann, L.K. (2015). Cushing's syndrome. *Lancet* **386**, 913–927.

In the 2-day low dose test, dexamethasone 0.5 mg is taken orally at 6-h intervals for eight doses. Urine is collected for UFC on two baseline days and during dexamethasone administration. A normal response consists of a urinary free cortisol <27 nmol (10 μg) per 24 h on the second day of dexamethasone administration (Nieman *et al.*, 1986); plasma cortisol should be <50 nmol/L (1.8 μg/dL) on the third morning.

Interfering conditions causing an apparent lack of suppression following dexamethasone include: decreased dexamethasone absorption, drugs enhancing CYP3A4 hepatic dexamethasone metabolism (barbiturates, phenytoin, carbamazepine, rifampin, meprobamate, methaqualone), increased concentration of CBG (estrogen treatment, pregnancy) and pseudo-CS. Plasma dexamethasone levels can be determined at the time of the cortisol blood-draw and should be between 20 and 51 nmol/L (Newell-Price *et al.*, 1998; Nieman *et al.*, 2008).

Dexamethasone-CRH Test

This test developed at NIH was shown to be particularly helpful in distinguishing CS from pseudo-CS (Yanovski *et al.*, 1993). The rationale was that patients with pseudo-CS have chronically elevated centrally stimulated CRH levels and do not respond to additional exogenous CRH administration, under dexamethasone suppression, as opposed to Cushing's disease patients who have suppressed endogenous CRH levels and fail to suppress normally to dexamethasone. Dexamethasone is taken orally starting at 12:00 (0.5 mg every 6 h) for 48 h and ovine CRH (1 μg/kg) is administered iv at 8:00 (2 h after the last dose of dexamethasone). The plasma cortisol value 15 min after CRH increased above 38 nmol/L (1.4 μg/dL) in patients with CS, but remained suppressed in normal individuals and in patients with pseudo-CS. This combined test yielded a sensitivity of 98%–100% and a specificity of 88%–100% (Yanovski *et al.*, 1993, 1998). Other groups reported that the addition of CRH test did not provide added information to the conduct of the 2 days low dose DST (Gatta *et al.*, 2007; Pecori Giraldi *et al.*, 2007a, b). Several drugs utilized by patients undergoing investigation for CS can alter interpretation of Dex-CRH test (Valassi *et al.*, 2009). In patients with anorexia nervosa, several patients did not suppress morning cortisol levels after 2 days low dose DST, but did not increase cortisol following CRH administration; this stresses the importance of examining cortisol levels not only at the 15 min time point following CRH administration (Duclos *et al.*, 1999). Desmopressin was also found to be able to distinguish between CD and pseudo-Cushing's states (Tirabassi *et al.*, 2010; Pecori Giraldi *et al.*, 2007a, b). However, the exact diagnostic accuracy of these tests and the optimal cutoffs for diagnosis need further evaluation (Nieman *et al.*, 2008). A prospective study of 73 patients in Netherlands with clinical features of CS and an abnormal DST or UFC result reported a positive predictive value of 100% and a negative predictive value of 90% for the Dex-CRH test (sensitivity 94%, specificity 100%) using a 15-min post-CRH cortisol cutoff of 3.2 μg/dL (87 nmol/L) (Alwani *et al.*, 2014).

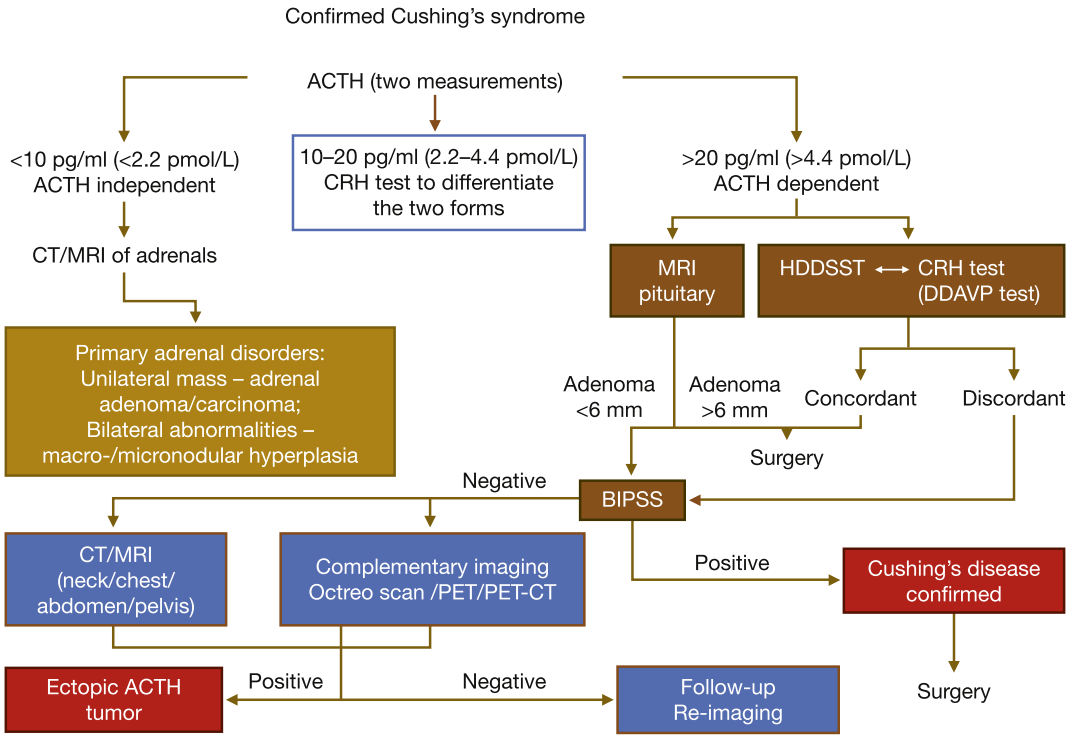

Fig. 2 Clinical decision making flow chart for the differential diagnosis of confirmed Cushing syndrome of different etiologies. Reproduced with permission from Lacroix, A., Feelders, R.A., Stratakis, C.E. and Niemann, L.K. (2015). Cushing's syndrome. *Lancet* **386**, 913–927.

Patients with minimal CS features, abnormal screening tests and no tumoral cause are referred as having "Pseudo-Cushing syndrome." Various conditions associated with mild hypercortisolism should be considered in the differential diagnosis. Generally, hypercortisolism resolves as these conditions are treated or remit (Findling and Raff, 2017).

Determining the Etiology of Confirmed CS

Once CS diagnosis is established, the cause must be determined to effect a specific treatment. Cortisol excess, apart from cyclic or minimal hypercortisolism, leads to CRH and ACTH suppression from normal cells (**Fig. 2**) (Lacroix *et al.*, 2015). Thus, the first step in the differential diagnosis of CS is measurement of plasma ACTH in the basal state, preferably on two different mornings (Arnaldi *et al.*, 2003; Lacroix *et al.*, 2015).

CS With Suppressed ACTH

A decreased plasma ACTH concentration (<5 pg/mL or 1.1 pmol/L) in a patient with overt endogenous hypercortisolism indicates an adrenal cause (Lacroix *et al.*, 2015) (**Figs. 1** and **2**). Intermediate ACTH values between 5 and 15 pg/mL (1.1–3.3 pmol/L) are less clear, but if CS is moderate to severe, it is probably ACTH-dependent. When cortisol secretion is modest or cyclic, ACTH suppression may be incomplete; a CRH stimulation test is recommended to evaluate ACTH responsiveness (Newell-Price *et al.*, 1998; Lacroix *et al.*, 2015). If ACTH is <1.1 pmol/L, thin-section CT images of the adrenal glands usually identifies its cause; unilateral adenoma is the most common (Arnaldi *et al.*, 2003; Lacroix *et al.*, 2015). If a suspicious lesion (by morphology or large size) is found, or if DHEAS levels are elevated, the possibility of adrenal carcinoma is high; FDG-PET scan and MRI may help to establish this diagnosis (Else *et al.*, 2014).

In bilateral micronodular hyperplasias, the adrenal size is not enlarged, but occupied by several bead-like small nodules on high resolution CT (Doppman *et al.*, 1989). In PPNAD, cortisol is usually poorly stimulated by exogenous ACTH and patients respond frequently with a paradoxical UFC increase during sequential low and high doses dexamethasone tests as a consequence of overexpression of glucocorticoid receptors in the micronodules (Stratakis *et al.*, 1999; Bourdeau *et al.*, 2003).

In BMAH, plasma 17-OH-progesterone or urinary 17-OH-corticosteroids are proportionally more elevated than urinary free cortisol as a result of reduced activity of several steroidogenic enzymes in the tumor cells with accumulation of steroid precursors (Antonini *et al.*, 2006; Hsiao *et al.*, 2009; Libe *et al.*, 2010). Screening for aberrant GPCR are helpful to confirm BMAH with overt or subclinical primary CS (Hsiao *et al.*, 2009; Libe *et al.*, 2010; Hofland *et al.*, 2013; El Ghorayeb *et al.*, 2015). A genetic cause of BMAH should be sought using analysis for germline *ARMC5* mutations (Drougat *et al.*, 2015; Espiard *et al.*, 2015; Fragoso *et al.*, 2015); if the index case does not carry an *ARMC5* mutation, family screening can be performed, searching for excess plasma morning cortisol following the 1 mg overnight DST; those with cortisol responses >50 nmol/L (1.8 μg/dL) should undergo adrenal imaging (Lacroix, 2009; Lacroix *et al.*, 2015).

ACTH-Dependent CS

Pituitary imaging

Pituitary imaging should be performed only after biochemical confirmation of ACTH-dependent CS (Fig. 3). T1-weighted SE MRI with Gadolinium contrast identifies pituitary tumors in $\sim$50% of patients with CD (Patronas *et al.*, 2003; Newell-Price *et al.*, 1998; Lacroix *et al.*, 2015). Approximately 10% of healthy individuals have incidental pituitary lesions up to 6 mm diameter on MRI (Hall *et al.*, 1994; Buurman and Saeger, 2006). As a result, the finding of a pituitary lesion $\leq$6 mm does not reliably indicate that CD is the cause of CS. Other MRI techniques may have better sensitivity: spoiled gradient recalled acquisition in the steady state technique (SPGR) had better sensitivity for detection of microadenomas than T1 SE imaging in adults (80% vs. 49%) and children (68% vs. 29%) (Patronas *et al.*, 2003; Leães *et al.*, 2009; Batista *et al.*, 2005; Kasaliwal *et al.*, 2013).

Noninvasive testing

In contrast to most ectopic ACTH tumors, most CD adenomas maintain sensitivity to CRH stimulation and suppression with high dose dexamethasone test (Newell-Price *et al.*, 1998; Arnaldi *et al.*, 2003; Nieman *et al.*, 2008). Results are heterogeneous using human versus ovine CRH, different ACTH assays and different criteria for ACTH and cortisol response (Tirabassi *et al.*, 2011). The two largest studies found for the ACTH response to CRH a sensitivity of 93% (oCRH) and 70% (hCRH), respectively, and a specificity of 100% (Nieman *et al.*, 1993; Newell-Price *et al.*, 2002). For the cortisol response, sensitivity was 91% and 85% and specificity 88% and 100% respectively to detect CD.

Intravenous administration of 10 μg desmopressin (a preferential V2-vasopressin receptor agonist) increases ACTH secretion in 80%–90% of corticotroph adenomas via activation of vasopressin (AVPR2, AVPR1B) receptors; normal subjects only rarely increase ACTH secretion after desmopressin (Arnaldi *et al.*, 2003; Tsagarakis *et al.*, 2002; Tirabassi *et al.*, 2011). However, about 20% of ectopic ACTH secreting tumors express those receptors and respond to desmopressin, so the test cannot distinguish the ACTH source (Tsagarakis *et al.*, 2002). An increase in serum cortisol of 33% or more or a plasma ACTH increase of 30% or more is

considered as a positive response. Desmopressin is less expensive than CRH and can be used in performing petrosal sinus sampling and in the postoperative assessment of these patients (Tsagarakis *et al.*, 2002).

Various protocols with oral or intravenous high dose dexamethasone suppression tests (HDDST) evaluate CS etiology (Newell-Price *et al.*, 1998; Lacroix, 2017) UTD; the most frequently used are the oral 2-day 8 mg HDDST and the 8 mg overnight test using a >50% suppression of cortisol levels as indicative of pituitary-dependent CS. The diagnostic performance of HDDST alone is poor because 20%–30% of patients with ectopic ACTH (mainly bronchial carcinoids) suppress cortisol <50% of baseline and up 20%–30% of patients with CD fail to suppress cortisol levels >50% (Ilias *et al.*, 2005; Isidori *et al.*, 2006; Aron *et al.*, 1997). Combining CRH and HDDST tests increases specificity so that a positive response to both tests indicates CD; however, discordant results of CRH test and HDDST, with only one test positive, are found in up to 65% of patients with CD (Isidori *et al.*, 2003; Nieman *et al.*, 1986).

Petrosal sinus sampling (BIPSS)

BIPSS is the "gold standard" test to identify a pituitary versus ectopic source of ACTH, with sensitivity and specificity of ~95% (Arnaldi *et al.*, 2003; Nieman *et al.*, 2008; Lacroix *et al.*, 2015). A pituitary source results in a central to peripheral gradient >2 before and >3 after CRH or desmopressin (Fig. 3). Falsely positive results can occur in ectopic ACTH patients with cyclic hypercortisolism or mild hypercortisolism with insufficient suppression of normal corticotropes. False negative sampling may result from abnormal venous drainage or inability to cannulate the veins (Doppman *et al.*, 1999). Measurement of prolactin (to normalize ACTH values) in cases without a gradient can confirm successful catheterization (Sharma *et al.*, 2011). In 396 patients, all 10 with falsely negative results (none with positive results) had peak petrosal sinus ACTH values of <400 pg/mL (Wind *et al.*, 2013). BIPSS has limited value in identifying tumor location within the pituitary; a side-to-side gradient of >1.4 correctly identified tumor side in 69% of lateral adenomas (Wind *et al.*, 2013).

Source of ectopic ACTH/CRH production

Thin-cut multislice CT and/or MRI of thorax and abdomen and scintigraphic studies localize tumors in 70%–90% of ectopic ACTH cases (Ilias *et al.*, 2005; Isidori *et al.*, 2006). NET express somatostatin receptors, and may be identified with ^{111}In-pentreotide scintigraphy (octreoscan), with a sensitivity ranging from 25% to 80% depending on dosing and use of single-photon emission tomography (SPECT) (Tsagarakis *et al.*, 2003). Hypercortisolism can suppress tumoral somatostatin subtype 2 receptor levels leading to false negative results; negative octreoscan can become positive after medical control of hypercortisolism (de Bruin *et al.*, 2012). ^{111}In-pentreotide SPECT/CT fusion imaging improves tumor localization (Wong *et al.*, 2010). 18-Fluorodeoxyglucose (FDG) positron emission tomography (PET) has limited diagnostic yield for low grade NET. [18*F*]l-3,4-dihydroxyphenylalanine (F-DOPA)-PET and 11C-5-hydroxy-tryptophan (11C-5-HTP)-PET have higher sensitivity to detect NET, but no large series have been published with ectopic ACTH (Wong *et al.*, 2010; Pacak *et al.*, 2004; Koopmans *et al.*, 2006; Zemskova *et al.*, 2010; Nikolaou *et al.*, 2010; Jagannathan *et al.*, 2009).

Pediatric CS

Approximately 10% of CS cases occur in children, with a pubertal female:male predominance; in very young children a male to female predominance may exist (Stratakis, 2012). Before age 7, adrenal causes of CS (adenoma, carcinoma or bilateral hyperplasia) are most common while CD accounts for approximately 75% of CS after that age (Savage *et al.*, 2007; Stratakis, 2012). Overall, primary adrenal etiologies account for ~15% of CS in childhood. Adrenocortical neoplasms represent 0.6% of all childhood tumors and CS is present in one third of pediatric adrenal cancers; most patients present under age 5 and there is a female: male predominance. Micronodular bilateral hyperplasias (PBAD, PPNAD and iMAD) are a more frequent cause of CS in children than in adults (Stratakis, 2012). Ectopic ACTH accounts for <1% of CS in adolescents; neuroblastomas and ganglioneuromatous tumors may exceptionally cause ectopic ACTH in young infants.

The most common symptom of pediatric CS is weight gain, but a unique feature is the effect on height gain: the combination of weight gain and decreased height velocity is pathognomonic for CS in children. Other manifestations include facial plethora, headaches, hypertension, hirsutism, virilization, amenorrhea or delayed sexual development. Acne, violaceous striae, bruising and acanthosis nigricans are also common. The investigation and treatment of adult and pediatric CS are similar (Savage *et al.*, 2007; Stratakis, 2012).

Cyclical CS

The evaluation of patients with cyclical Cushing syndrome can be a major diagnostic challenge, in part due to its frequency, which can reach 15% of cases (Alexandraki and Grossman, 2011; Atkinson and Mullan, 2011). Cyclical CS has been reported from all causes of the syndrome (Mullan *et al.*, 2007). Regardless of age, PPNAD and iMAD often present with cyclical CS (Stratakis, 2012). Confirmation of hypercortisolism benefits from frequent midnight salivary cortisol and UFC levels over a long period, sometimes over years (Atkinson and Mullan, 2011; Graham *et al.*, 2013). Recently, the utility of capillary (hair) cortisol has been evaluated with the goal of establishing a temporal characterization of the cortisol secretion in cyclic Cushing syndrome (Manenschijn *et al.*, 2012).

CS in Pregnancy

Pregnancy occurs rarely in CS, probably because hypercortisolism inhibits ovulation. When present, it increases risk of fetal abortion, perinatal death, premature birth, intrauterine growth retardation, hypertension, diabetes, and preeclampsia (Lindsay *et al.*, 2005; Lekarev and New, 2011; Bronstein *et al.*, 2015; Caimari *et al.*, 2017). Diagnosis is complicated by the overlap of UFC levels between CS patients and normal pregnant women. Additionally, the etiology of CS in women who become pregnant is most frequently adrenal in origin (50%–60% of the cases), while in nonpregnant population pituitary-dependent Cushing's disease (CD) is responsible for 70% of the cases (Lindsay *et al.*, 2005; Abdelmannan and Aron, 2011; Bronstein *et al.*, 2015). The reason for this difference is not known; however, it has been suggested that in CD there is hypersecretion of both cortisol and androgens, impairing fertility, while in CS of adrenal origin hypersecretion is almost exclusively of cortisol with minimal androgen production (Buescher *et al.*, 1992). In primary adrenal causes of CS during pregnancy, ACTH levels are not uniformly suppressed, as CRH and ACTH of placental origin are not regulated identically to the ACTH of pituitary origin (Lindsay *et al.*, 2005; Abdelmannan and Aron, 2011; Bronstein *et al.*, 2015). Exacerbation or transient CS during pregnancy can regress partially postpartum when aberrant LHCG receptors are expressed in unilateral adenomas or BMAH (Lacroix *et al.*, 1999; Lacroix *et al.*, 2010; Plöckinger *et al.*, 2017); as the placenta produces many hormones, regulation by other placental factors could explain adrenal CS etiologies during pregnancy. TSS or adrenalectomy are preferred treatment except perhaps late in the third trimester where metyrapone can be used cautiously; remission may not improve the fetal prognosis (Lindsay *et al.*, 2005; Lekarev and New, 2011; Bronstein *et al.*, 2015; Caimari *et al.*, 2017).

Conclusions

Patients with CS require complex and often repeated investigations by a multidisciplinary expert team to identify the cause of their syndrome. This is the essential initial step which will then require specific surgery or medical therapy to hopefully result in remission, with requirement of monitoring for possible recurrence, insure adequate hormonal replacement and to treat the psychological and multiorgan consequences of the previous exposure to excess glucocorticoids which have been reviewed recently elsewhere and in other chapters of this Encyclopedia (Nieman *et al.*, 2015; Pivonello *et al.*, 2015; Lacroix *et al.*, 2015).

Adriana Albani, Ludwig Maximilian University of Munich, Munich, Germany and University of Messina, Messina, Italy

Abbreviations

11β-HSD	11-β-Hydroxysteroid dehydrogenase
ACTH	Adrenocorticotropic hormone
ACTHR	Adrenocorticotropic hormone receptor
AIP	Aryl hydrocarbon receptor-interacting protein
AKT	v-akt murine thymoma viral oncogene homolog 1
BMP4	Bone morphogenetic protein 4
Brg1	Brahma-related gene 1
CABLES1	CDK5 and ABL1 enzyme substrate 1
CCND2	Cyclin D2
CCNE1	Cyclin E
CD	Cushing disease
CDH23	Cadherin-related 23
CDK	Cyclin-dependent kinase
CDK4	Cyclin-depentent kinase subunit 4
CDKN1B	Cyclin-dependent kinase inhibitor 1B
CDKN2A	Cyclin-dependent kinase inhibitor 2A
CNC	Carney complex
CRH	Corticotropin-releasing hormone
CRHR1	Corticotropin-releasing hormone receptor 1
DKC1	Dyskeratosis congenital
DRD2	Dopamine receptor 2
EGF	Epithelial growth factor
EGFR	Epithelial growth factor receptor
ERBB2	v-erb-b2 erytrhoblastic leukemia viral oncogene homolog 2
ERK	Extracellular signal-regulated protein kinase
FGF	Fibroblast-growth factor
FGFR	Fibroblast-growth factors receptor
FIPA	Familial isolated pituitary adenomas
GNAS	Guanine nucleotide binding protein, alpha stimulating
GPR101	Orphan G protein-coupled receptor
GR	Glucocorticoid receptor
Gs	Stimulatory G protein
HDAC2	Histone deacetylase
HSP90	90 kDa heat shock protein
IL-6	Interleukin-6
LGALS3	Lectin galactoside-binding soluble 3
LIF	Leukemia inhibitory factor
MAS	McCune–Albright syndrome
MEK	Mitogen activated protein kinase
MEN	Multiple endocrine neoplasia
MGMT	O6-methylguanine DNA methyltransferase
miRNAs	microRNAs
NR0B1	Nuclear receptor subfamily 0 group B member 1
NR3C1	Nuclear receptor subfamily 3 group C member 1
PI3K	Phosphoinositide 3-kinase
PKA	Protein kinase A
POMC	Proopiomelanocortin
PRKAR1A	Protein kinase c-AMP dependent type1 regulatory subunit α
PRKCD	Protein kinase C-δ
PTTG	Pituitary tumor transforming gene
RPS13	Ribosomal protein S13
SDH	Succinate dehydrogenase
SHH	Sonic hedgehog
SSTR	Somatostatin receptor
TIMP2	Metalloproteinase inhibitor 2
TR4	Testicular orphan receptor 4
TSC	Tuberous sclerosis complex
USP8	Ubiquitin-specific protease 8
V<n>R	Vasopressin receptor <n>
ZNF676	Zinc-finger 676

Introduction

Cushing disease (CD) is a severe condition caused by the chronic exposure to excessive endogenous glucocorticoids triggered by ACTH-secreting pituitary tumor (corticotropinoma). It is characterized by multiple complications resulting in increased morbidity and mortality and severe impairment of quality of life (Newell-Price *et al.*, 2006; Dekkers *et al.*, 2007). It is a rare disease, with an annual incidence of 1.2–1.7 cases per million (Lindholm *et al.*, 2001). Corticotropinomas are usually sporadic tumors and only rarely they occur as part of genetic familial syndromes. The molecular basis of Cushing disease was unclear until recently, when next generation sequencing revealed a single somatic mutational hotspot in the ubiquitin-specific protease 8 (*USP8*) gene in almost half of the corticotropinoma cases (Reincke *et al.*, 2015; Ma *et al.*, 2015).

The Pathophysiology of Corticotroph Tumor Cells

The corticotroph function is tightly regulated by stimulatory and inhibitory signals from the hypothalamus and the negative regulatory glucocorticoid feedback loop from the adrenal gland.

Hypothalamic Regulation

Corticotrophin-releasing hormone (CRH) is the main corticotroph trophic factor that stimulates *POMC* transcription and ACTH synthesis. Its receptors (CRHR1 and 2) are coupled to the Gs protein that triggers cAMP production and downstream cAMP/PKA signaling cascade. CRHR1 is overexpressed in corticotropinomas compared to silent corticotropinomas and nonfunctioning pituitary tumors (De Keyzer *et al.*, 1998; Tateno *et al.*, 2007).

Vasopressin is another hypothalamic factor which, synergistically with CRH, stimulates ACTH release. Vasopressin receptors also belong to the G protein couple receptor superfamily. The vasopressin receptor V3R is abundant in corticotroph tumors but no mutations were detected in the coding region of the gene (de Keyzer *et al.*, 1996; Dahia *et al.*, 1996). Corticotroph tumors also express high levels of vasopressin receptor subtype 1b (VPR1b) and respond to the synthetic VPR1 ligand desmopressin by increasing their proliferation in vitro (Luque *et al.*, 2013).

Hypothalamic peptides that exert inhibitory action on corticotroph function include dopamine and somatostatin. Dopamine receptor D2 (DRD2, also known as D2DR and D2R) is found in the majority of corticopinomas and treatment with dopamine agonists inhibit ACTH secretion in vitro and suppress cortisol levels in patients with Cushing disease (Pivonello *et al.*, 2004). Corticotropinomas also express somatostatin receptor (SSTR) 5 and -in lesser extent-2 and 3 (Miller *et al.*, 1995). Excessive glucocorticoid stimulation suppresses *SSTR2* transcription probably accounting for the reduced SSTR2 levels (de Bruin *et al.*, 2009); SSTR2 expression is recovered after restoring cortisol levels to physiological levels (van der Pas *et al.*, 2013). Glucocorticoids do not affect SSTR5 and DRD2 expression and more than half of cases co-express DRD2 and SSTR5 (Hofland *et al.*, 2005; de Bruin *et al.*, 2009). To date use of SSTR5 targeting somatostatin analogs alone or in combination with the DRD2 agonist cabergoline is the only approved tumor-targeted pharmacological therapy available for the management of patients with Cushing disease (Feelders *et al.*, 2010).

Glucocorticoid Resistance

One of the hallmarks of Cushing disease is the resistance to the negative glucocorticoid feedback (Nieman *et al.*, 2008). Mutations in the *NR3C1* gene that encodes for the glucocorticoid receptor are extremely rare in corticotroph tumors (Karl *et al.*, 1996a,b; Dahia *et al.*, 1997). One study suggested loss of heterozygosity at the GR gene locus may contribute to glucocorticoid resistance (Huizenga *et al.*, 1998).

The local glucocorticoid action is regulated by the 11-β-hydroxysteroid dehydrogenases: the isoenzyme type 1 (11β-HSD1) metabolizes cortisone to cortisol whereas the isoenzyme type 2 (11β-HSD2) inactivates cortisol to cortisone. Corticotropinomas express high levels of 11β-HSD2, suggesting that increased inactivation of cortisol to cortisone may represent another molecular mechanism of intratumor glucocorticoids resistance (Korbonits *et al.*, 2001).

The transcriptional repression of *POMC* depends on transcriptional co-regulators like Brahma-related gene 1 (Brg1) and histone deacetylase 2 (HDAC2) (Bilodeau *et al.*, 2006). Brg1 and HDAC2 levels are dramatically decreased in corticotropinomas, which may hinder the ability of glucocorticoids to repress *POMC* transcription, resulting in glucocorticoid resistance (Bilodeau *et al.*, 2006). In contrast corticotropinomas show overexpression of testicular receptor 4 (TR4 nuclear receptor subfamily 2, group C, member 2) that blocks the GR transcriptional repressor activity resulting in increased *POMC* transcription, ACTH secretion and tumor growth in vitro and in vivo (Du *et al.*, 2013; Zhang *et al.*, 2016b).

A recent study has highlighted the importance of the heat shock protein 90 (HSP90) in promoting glucocorticoid resistance in corticotropinomas (Riebold *et al.*, 2015). HSP90 is a chaperone protein that regulates GR function influencing the correct folding of the ligand-binding domain and controlling its translocation to the nucleus. HSP90 was found to be overexpressed in corticotropinomas and to impair the ability of glucocorticoids to repress *POMC* transcription. Inhibition of HSP90 specifically at the c-terminal with silibilin restored glucocorticoid sensitivity in ATt20 cells and displayed potent antiproliferative and antisecretory action, improving clinical features of CD, in a mouse corticotroph model (Riebold *et al.*, 2015).

Mechanisms of Tumorigenesis

Corticotroph tumors present with aberrant expression of proteins crucial in cell cycle control, proliferation, growth, and differentiation.

Cell Cycle

Cell cycle is strictly controlled and fine-tuned by the complex interaction between cyclins and cyclins depended kinases (CDKs), which promote cell cycle progression, and CDK inhibitors, which arrest cellular proliferation (Sherr and Roberts, 1999). Cell cycle pathways are deregulated in all pituitary tumor types and as we will see below some specifically in corticotropinomas.

Cyclin D—INK4 cell cycle regulatory module

Cyclin D1 is encoded by the *CCND1* gene. It binds to CDK4 that phosphorylates and inactivates retinoblastoma (Rb), thereby promoting G1/S cell cycle progression. Cyclin D1 overexpression is observed mainly in nonfunctioning and aggressive pituitary tumors and is not a frequent event in corticotropinomas (Jordan *et al.*, 2000).

The cyclin D/CDK4/6 action is inhibited by the INK4 family of CDK inhibitors (p16, p18, and p19). p16/INK4 is encoded by the cyclin-dependent kinase inhibitor 2A (*CDKN2A*) gene. It specifically binds to CDK4/6 and prevents it from phosphorylating Rb, arresting the cells at G1. Undetectable or lower levels of p16 were documented in all pituitary tumors, including corticotropinomas (Woloschak *et al.*, 1996; Seemann *et al.*, 2001).

Cyclin E—Cip/Kip cell cycle regulatory module

Cyclin E is encoded by the *CCNE1* gene. It associates with the CDK2 that hyperphosphorylates Rb at the late G1/S phase. Cyclin E overexpression is predominant in corticotroph tumors (Jordan *et al.*, 2000).

The cyclin E/CDK2 function is inhibited by the Cip/Kip family of CDK inhibitors (p21, p27, and p57). p27/Kip1 is encoded by the cyclin-dependent kinase inhibitor 1B (*CDKN1B*) gene. It binds to CDK2 causing cell cycle arrest at the late G1 phase. p27/kip1 protein is dramatically reduced specifically in corticotroph tumors (Lidhar *et al.*, 1999). No changes were described at mRNA level indicating a posttranscriptional deregulatory event. However factors that regulate p27 translation, such as dyskeratosis congenita (DKC1)/Dyskerin, ribosomal protein S13 (RPS13), miR221 and miR222, are not deregulated in corticotropinomas (Martins *et al.*, 2016).

Cyclin E overexpression and p27 protein loss are concomitantly observed in corticotroph tumors (Roussel-Gervais *et al.*, 2016). A feasible explanation is that the cyclin E-bound CDK2 phosphorylates and marks p27/Kip1 for proteasomal degradation. Cyclin E is transcriptionally suppressed by Brg1, therefore the decreased Brg1 expression observed in corticotroph tumors may allow for excessive cyclin E expression that leads to p27 degradation and protein loss and aberrant cell cycle progression. These observations provide with a common pathogenetic mechanism responsible for the glucocorticoid resistance and cell cycle deregulation observed in corticotroph tumors.

CABLES 1

CABLES1 (CDK5 and ABL1 enzyme substrate 1) is a tumor suppressor gene, which inactivates several CDK causing cell cycle arrest. In corticotroph cells it is activated in response to glucocorticoids, playing an important role in the physiological negative feedback. CABLES 1 immunoreactivity is absent/dramatically reduced in in more than half corticotropinoma cases (Roussel-Gervais *et al.*, 2016). CABLES1 stabilizes members of the Cip/Kip family of CDK inhibitors and its loss of expression has been correlated with p27/kip1 loss in corticotroph tumor cells.

Screening a cohort of 146 pediatric and 35 adult CD patients for *CABLES1* mutations revealed four germline missense variants in four female patients, but no loss-of-heterozygosity (Hernández-Ramírez *et al.*, 2017). All patients harboring mutations had large corticotropinomas with high Ki-67 proliferation index and a difficult to manage disease. In vitro studies demonstrated that corticotroph cells harboring CABLES1 mutations are not sensitive to glucocorticoid negative feedback.

PTTG

The pituitary tumor transforming gene (PTTG) encodes for securin that regulates sister chromatid separation during anaphase. In addition it stimulates the expression of growth factors such as fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF) and *CMYC* oncogene. PTTG is overexpressed in pituitary tumors including corticotropinomas (Zhang *et al.*, 1999). PTTG overexpression is accompanied by increased proliferation index Ki-67, and both are associated with tumor aggressiveness and increased risk of recurrence (Filippella *et al.*, 2006).

Growth Factors and Cytokines

The anterior pituitary gland is under the regulation of trophic and inhibitory growth factors, cytokines and developmental factors and their receptors that are intrinsically expressed and finetune hormone production and cell proliferation.

EGF

Epidermal growth factor (EGF) is a major mitogenic and differentiation factor that regulates pituitary hormone secretion and cell proliferation. The EGF–EGFR system is of particular importance in corticotroph pathophysiology. EGF is a trophic factor for corticotroph cells and stimulates ACTH synthesis to similar extent as CRH (Theodoropoulou *et al.*, 2015 and references therein). EGFR is highly expressed in corticotropinomas where it correlates negatively with p27/Kip1 immunoreactivity (Kontogeorgos *et al.*, 1996; Theodoropoulou *et al.*, 2004). Small molecule EGFR inhibitors effectively suppressed corticotroph tumor growth and ACTH synthesis and ameliorated Cushing disease in xenograft animal models (Theodoropoulou *et al.*, 2004; Fukuoka, 2015; Fukuoka *et al.*, 2011).

EGFR activates two major signaling pathways, the mitogenic MEK/ERK, and the survival PI3K/Akt. Enhanced Akt signaling has been documented in pituitary tumors including corticotropinomas (Muşat *et al.*, 2005). In contrast there is evidence for a special role of the MEK/ERK pathway in regulating ACTH synthesis downstream to EGFR in corticotropinoma cells (Reincke *et al.*, 2015). This is further highlighted by the observations of remarkable reduction in corticotroph tumor growth and ACTH secretion in vitro and in vivo after treatment with the specific MEK-162 small molecule inhibitor (Zhang *et al.*, 2016a).

FGF

Fibroblast-growth factors (FGFs) play an important role in several processes such as mitogenesis, differentiation, angiogenesis, and tumorigenesis. The normal anterior pituitary gland expresses FGFR1, FGFR2, FGFR3, and low levels of FGFR4. In contrast corticotropinomas overexpress FGFR4 (Brito *et al.*, 2010) and functional *FGFR4* polymorphisms were linked either to silent macrocorticotropinomas (R388) or to small hormonally active tumors (G388). The FGFR-G388 polymorphism has been associated to lower postoperative remission rate in patients with Cushing disease (Nakano-Tateno *et al.*, 2014).

Cytokines

Interleukin 2 (IL-2) and its receptor are expressed in corticotropinoma cells were they exert an autocrine–paracrine loop that regulates cell proliferation (Arzt *et al.*, 1992).

IL-6 is potent stimulator of POMC transcription and ACTH secretion from corticotroph tumor cell cultures (Pereda *et al.*, 2000).

Leukemia inhibitory factor (LIF) is a pleiotropic immune cytokine, which plays an important role in the hypothalamo–pituitary–adrenal response to inflammation. LIF enhances *POMC* transcription in vitro in synergy with CRH (Bousquet *et al.*, 1997; Ray *et al.*, 1996). LIF knockout mice show low *Pomc* transcript levels and reduced adrenal response to stress, that is reversed by administration of exogenous murine LIF (Chesnokova *et al.*, 1998). LIF overexpression in transgenic animals induces corticotroph hyperplasia, hypercortisolism, and Cushingoid features (Yano *et al.*, 1998). No mutations on the gene encoding for the LIF receptor were found in the seven corticotropinomas analyzed (Heutling *et al.*, 2004).

BMP4

Bone morphogenetic protein 4 (BMP4) is member of the transforming growth factor-beta superfamily. BMP4 inhibits *POMC* transcription and secretion. BMP4 expression is decreased in corticotropinomas and nude mice inoculated with corticotroph tumor cells transfected with a dominant-negative form of the BMP4 or with a BMP4 inhibitor present with increased tumorigenesis reinforcing its role as a corticotroph tumor suppressor (Giacomini *et al.*, 2006). BMP4 mediates the antiproliferative and antisecretory action of pharmaceuticals with potential for the treatment of Cushing disease such as retinoic acid and somatostatin analogs (Giacomini *et al.*, 2006; Tsukamoto *et al.*, 2010).

Sonic hedgehog

Sonic hedgehog (Shh) signaling is crucial for early pituitary differentiation, but in the adult pituitary its expression is restricted to the corticotroph cells where it crosstalks with CRH to regulate ACTH secretion (Vila *et al.*, 2005a) Shh restrains corticotroph cell proliferation and its expression is lost in corticotropinomas indicating that it may act as a tumor suppressor (Vila *et al.*, 2005b).

Results From Transcriptomics Studies

Transcriptomic analysis of 12 corticotropinomas showed that the invasive corticotropinomas displayed different expression profile compared to noninvasive ones. Highlighted genes include *CCND2* coding for cyclin D2, and Zinc-finger 676 (*ZNF676*) that are increased in invasive corticopinomas, whereas death-associated protein kinase 1 (*DAPK1*) and metalloproteinase inhibitor 2 (*TIMP2*) were decreased (de Araújo *et al.*, 2017).

MicroRNAs

MicroRNAs (miRNAs) are noncoding RNA transcripts that silence gene expression posttranslationally and are subsequently involved in several biological processes such as proliferation, differentiation, and apoptosis. miRNAS have been detected in normal pituitary tissue and in pituitary tumors. Corticotropinomas show downregulation of the miR-let7a, -15a, -16, -21, -141, -143, -145, and -150 compared to the normal pituitary tissues (Amaral *et al.*, 2009). In contrast, miR-26a, -30, -122 and, -493 are significantly upregulated, with the last two being increased in corticotroph carcinomas compared to nonmetastatic tumors (Bottoni *et al.*, 2007; Stilling *et al.*, 2010; Gentilin *et al.*, 2013).

miR-26a suppresses protein kinase C delta (PRKCD), a serine-threonine kinase that regulates cell cycle, cellular proliferation, differentiation, and apoptosis. Knocking down *PRKCD* in corticotroph cells increased *POMC* transcription and ACTH secretion as well as cell viability (Gentilin *et al.*, 2013).

miR-493 regulates, among others, the expression of lectin galactoside-binding soluble 3 (*LGALS3*) gene that encodes for the galectin 3 protein, which is overexpressed in corticotropinomas where it correlates with tumor aggressiveness (Riss *et al.*, 2003; Stilling *et al.*, 2010).

Genetic Syndromes Associated With Cushing Disease

Corticotropinomas are usually sporadic tumors and only rarely described in the context of familial and other genetic syndromes.

MEN1

Multiple endocrine neoplasia type 1 (MEN1) is caused by an inactivating mutation of the *MEN1* suppressor gene that encodes for menin, a transcriptional cofactor that regulates the expression of genes encoding for cell cycle proteins, such as p27/kip1 and CDK4. MEN 1 syndrome is typically characterized by primary hyperparathyroidism, neuroendocrine tumors, and pituitary tumors. Corticotropinomas are rarely found in MEN1 patients and can be macro- or microadenomas (Thakker *et al.*, 2012; Vergès *et al.*, 2002; Simonds *et al.*, 2012). Early onset Cushing disease was described in two siblings with MEN1 syndrome (Matsuzaki *et al.*, 2004). Nevertheless corticotropinomas are rare in pediatric MEN1 patients (Rix *et al.*, 2004; Stratakis *et al.*, 2010).

MEN2

Multiple endocrine neoplasia type 2 (MEN2) is an autosomal dominant syndrome caused by an activating mutation of the proto-oncogene RET (Hofstra *et al.*, 1994). MEN2a syndrome presents with parathyroid adenomas, medullary thyroid carcinomas and pheocromocytomas, while MEN2b with medullary thyroid cancer, pheochromocytoma, multiple mucosal neuromas, intestinal ganglioneuromas, and marfanoid habitus. Cushing disease is extremely rare with only two cases reported to date, one in a MEN2A and the other in a MEN2B patient, both due to microcorticotropinoma (Kasturi *et al.*, 2017; Naziat *et al.*, 2013).

MEN4

Multiple endocrine neoplasia type 4 (MEN4) is an extremely rare MEN1-like syndrome caused by germline loss-of-function mutations in the *CDKN1B* gene that encodes for the cell cycle inhibitor p27/Kip1 (Pellegata *et al.*, 2006). A germline *CDKN1B* mutation was found in a female patient presenting with primary hyperparathyroidism, cervical neuroendocrine carcinoma and Cushing disease due to a corticotropinoma (Georgitsi *et al.*, 2007b). Nevertheless, no mutations were found in the *CDKN1B* gene in neither adult nor pediatric Cushing disease patients (Dahia *et al.*, 1998; Igreja *et al.*, 2009; Stratakis *et al.*, 2010). In contrast, a p27 rs2066827 (V109G) polymorphism was found to associate with the incidence of corticotropinomas in a large cohort of 447 patients presenting with various endocrine tumors (Sekiya *et al.*, 2014).

McCune–Albright Syndrome

McCune–Albright syndrome (MAS) is caused by a mosaicism of activating somatic mutations in the *GNAS1* oncogene (guanine nucleotide binding protein, alpha stimulating) that encodes for the alpha subunit of the stimulatory Gs protein. Clinical characteristics include polyostotic fibrous dysplasia, *café-au-lait* skin pigmentation and hyperfunction of endocrine glands including the adrenals. Hypercortisolism might occur in these patients, mostly as adrenal Cushing syndrome due to adrenal hyperplasia or adenoma. A somatic mutation in the codon Q227 of the *GNAS1* gene was identified in two unrelated patients with Cushing disease (Williamson *et al.*, 1995). Similarly a pediatric patient with Cushing disease was found to carry a somatic mutation at *GNAS1* R201 (Riminucci *et al.*, 2002).

Carney Complex

Carney complex (CNC) is caused by inactivating mutations in the PRKAR1A gene encoding for the 1 alpha regulatory subunit of the c-AMP dependent protein kinase A (PKA) in 70% of the cases (Kirschner *et al.*, 2000). CNC is characterized by myxomas, spotty skin pigmentation, schwannomas, and endocrine tumors. Adrenal hyperplasia is the sole cause of hypercortisolism in CNC (Correa *et al.*, 2015). However, very recently, the first case of a CNC patient with ACTH-dependent hypercortisolism due to a corticotropinoma was reported; the patient had a de novo heterozygous germline mutation in exon 2 of the *PRKAR1A* gene and the wild-type allele was partially lost in the tumor indicative of loss of heterozygosity (Kiefer *et al.*, 2017).

FIPA

Non syndromic-familial isolated pituitary adenomas (FIPA) are pituitary tumors in family members. Genes potentially associated with FIPA include *AIP*, *CDKN1B*, *MEN1*, *PRKAR1A*, *SDHA*, *SDHB*, *SDHC*, and *SDHD*. Mutations in the aryl hydrocarbon receptor-interacting protein (*AIP*) gene are found in around 20% of FIPA families (Tichomirowa *et al.*, 2011). Cushing disease is very rarely encountered in FIPA (Georgitsi *et al.*, 2007a). A germline AIP mutation was found in a 50 years old patient with family history of pituitary disease presenting with an aggressive macrocorticotropinoma (Dinesen *et al.*, 2015). Screening of 44 sporadic corticotropinomas revealed germline AIP mutations in only three patients (Cazabat *et al.*, 2012). Similarly germline AIP mutation was found in only one pediatric Cushing disease patient (Stratakis *et al.*, 2010).

TSC

Tuberous sclerosis complex (TSC) is caused by germline mutations in the *TSC1* (hamartin) or *TSC2* (tuberin) tumor suppressor genes genes and is characterized by the development of multiple hamartomas in several organs. TSC1/2 dimers inhibit mTOR, a

major regulator of cell growth and metabolism. There are two documented cases of TSC patients presenting with Cushing disease to date, one adult and one pediatric (Nandagopal *et al.*, 2007; Tigas *et al.*, 2005).

DICER

DICER syndrome is caused by heterozygous germline mutations in the *DICER1* gene, which encodes for a cytoplasmic endoribonuclease type III that cleaves precursor microRNAs into short, mature miRNAs. It is a pleiotropic early-onset tumor syndrome that includes pleuropulmonary blastoma, cystic nephroma, ovarian Sertoli-Leydig cell tumors, sarcoma of the uterine cervix, ciliary body medulloepithelioma, pineo-blastoma, pituitary blastoma, and thyroid cancer. Pituitary blastoma is a very rare pituitary tumor that bears embryonic tissue characteristics and occurs in infants (Scheithauer *et al.*, 2008). The most common presentation of pituitary blastomas is severe Cushing disease that may turn lethal as observed in the few cases of infants with germline and somatic *DICER1* mutations (Scheithauer *et al.*, 2008, 2012; Wildi-Runge *et al.*, 2011; Sahakitrungruang *et al.*, 2014; De Kock *et al.*, 2014).

Other

Patients with congenital adrenal hyperplasia (CAH) secondary to mutations in the 21-hydroxylase enzyme (CYP21A2) show long-term impairment of glucocorticoid secretion secondary to 21-hydroxylase deficiency that could lead to the development of secondary and ultimately tertiary hypercortisolism by chronic stimulation of the hypothalamic–pituitary axis; however very few cases of Cushing disease were reported in CAH (Haase *et al.*, 2011).

A patient with X-linked congenital adrenal hypoplasia, a rare genetic disorder that is caused by mutation or deletion in the *NR0B1* gene encoding for the orphan nuclear receptor DAX1, presented with hyperpigmentation and elevated ACTH levels, which were not suppressed by steroid substitution, due to an invasive large ACTH-producing tumor (De Menis *et al.*, 2005). Histological examination of the pituitary tumor mass excluded the possibility of hyperplasia.

Duplications in the *GPR101* gene were found to be responsible of X-linked acrogigantism (X-LAG) (Trivellin *et al.*, 2014). *GPR101* encodes for an orphan G protein-coupled receptor that activates the cAMP cascade and is involved in the hypothalamic regulation of energy homeostasis and pituitary hormone secretion. Recently the possible role of *GPR101* in the development of corticotropinomas has been investigated in a cohort of pediatric Cushing disease, but neither mutations nor deregulations in transcript levels were found (Trivellin *et al.*, 2016).

Somatic Genetic Events

Proto-oncogenes and tumor suppressor genes that are frequently mutated in other cancers are very rarely reported in corticotropinomas. Mutations in the TP53 gene were found in a handful of ACTH-scecreting carcinomas and invasive corticotropinomas (Tanizaki *et al.*, 2007; Kawashima *et al.*, 2009).

USP8

Screening a limited set of corticotropinomas with whole exome sequencing led to the identification of a single somatic mutational hotspot in the gene encoding for ubiquitin-specific peptidase 8 (*USP8*) (Reincke *et al.*, 2015; Ma *et al.*, 2015). Subsequent studies showed that somatic USP8 mutations are found in 35%–60% of Cushing disease tumors (Perez-Rivas *et al.*, 2015; Hayashi *et al.*, 2016). Somatic *USP8* mutations were also found in 13 out of 42 pediatric Cushing disease cases (Faucz *et al.*, 2017). An independent whole genome sequencing effort identified *USP8* mutations exclusively in half corticotropinomas, but in no other pituitary tumor subtype (Song *et al.*, 2016). In contrast, no *USP8* mutations were found in ectopic ACTH-secreting neuroendocrine tumors (Perez-Rivas *et al.*, 2017).

The *USP8* gene encodes for a deubiquitinase that rescues tyrosine kinase receptors, such as EGFR, from proteasomal degradation and secures their activation (Mizuno *et al.*, 2005). The *Usp8* knockout is embryonic lethal and conditional knockout adult mice die because of liver failure; both cases present with dramatic reduction or absence of growth factor tyrosine kinase receptors (Niendorf *et al.*, 2007).

All *USP8* mutations identified so far in Cushing disease are somatic heterozygous single point mutations, while no germline mutations have been reported. The mutational hotspot is located in exon 14 and affects the USP8 protein region that binds to 14-3-3 proteins. Loss of 14-3-3 binding renders USP8 susceptible to proteolytic cleavage and allows the formation of a C-terminal fragment that possesses high catalytic capacity. Indeed the USP8 mutants displayed higher deubiquitinase activity and effectively deubiquitinated EGFR potentiating EGF-induced Erk1/2 signaling in vitro (Reincke *et al.*, 2015). Corticotroph tumor cells overexpressing USP8 mutants showed higher EGFR-induced *Pomc* transcription and ACTH synthesis. This effect was Erk1/2 dependent and concentrated on the AP1 binding site of the *Pomc* promoter (Reincke *et al.*, 2015). Studies in human Cushing tumors showed that those with somatic *USP8* mutations show higher *POMC* transcript levels compared to the wild type ones (Hayashi

et al., 2016). In contrast there is controversy regarding EGFR expression in *USP8* mutation positive Cushing disease tumors, with one study showing overexpression and the other finding no significant differences (Ma *et al.*, 2015; Hayashi *et al.*, 2016).

Patients with *USP8* mutation positive corticotropinomas are more frequently female (Perez-Rivas *et al.*, 2015). An interesting and with potential therapeutic implications observation is that *USP8* mutant corticotropinomas have higher levels of somatostatin receptor 5 (SSTR5) and O6-methylguanine DNA methyltransferase (MGMT), indicating that they may respond favorably to SSTR5-targeting somatostatin analogs and temozolomide (Hayashi *et al.*, 2016). Finally USP8 itself constitutes an attractive pharmaceutical target; a small molecule USP8 inhibitor displayed antisecretory and antiproliferation action in immortalized murine corticotroph tumor cells (Jian *et al.*, 2016).

Other

A somatic mutation in the *PIK3CA* gene encoding for the PI3K α subunit was reported in a noninvasive microcorticotropinoma (Murat *et al.*, 2012). *PIK3CA* mutations are rare in pituitary tumors and the few cases described were mostly aggressive tumors (Lin *et al.*, 2009).

Whole exome sequencing on familial and sporadic pituitary tumors revealed a germ-line missense mutation in the cadherin-related 23 (*CDH23*) gene that regulates cell–cell adhesion in all pituitary tumor subtypes, including sporadic corticotropinomas (4 out of 20) (Zhang *et al.*, 2017).

Conclusions

Corticotroph tumorigenesis is marked by posttranscriptional/translational deregulations in cell cycle proteins, growth factors, cytokines and their receptors as well as transcriptional co-regulators. The recent discovery of somatic driver mutations in the *USP8* gene represents an important progress to clarify genetic alterations underlying Cushing disease. The fact that so far *USP8* mutations have been detected exclusively in corticotropinomas underline a specificity to signaling cascades influenced by this deubiquitinase. The implications in clinical care and therapeutic management are subject of ongoing studies as is the search for driver mutations in the Cushing disease tumors with intact *USP8* gene.

Pituitary Surgery for Cushing Disease

Pamela Jones and Brooke Swearingen, Massachusetts General Hospital, Boston, MA, United States

Glossary

ACTH Adrenocorticotropic hormone.
CRH Corticotroph releasing hormone.
IPSS Inferior petrosal sinus sampling.

Introduction

Cushing Syndrome (CS) is caused by chronically elevated levels of systemic glucocorticoids. This leads to a constellation of symptoms including weight gain with centripetal fat distribution, hypertension, irritability, excess hair growth, irregular menses, decreased glucose tolerance, impaired immunity, osteoporosis, and increased risk of cardiac events (Boscaro and Arnaldi, 2009; Raff, 2015; Lonser *et al.*, 2017). While exogenous administration of steroids is the most common cause of CS overall, Cushing Disease (CD), or overproduction of adrenocorticotropic hormone (ACTH) by a pituitary adenoma, is the most common cause of endogenous CS, responsible for 70%–80% of cases. Other endogenous causes include an ectopic ACTH-producing tumor, often carcinoid, or overproduction of cortisol by an adrenal adenoma.

Diagnosis of Cushing Disease

Epidemiology

CS involves a spectrum of clinical sequelae from excess of corticosteroid exposure that was first defined by Harvey Cushing over a century ago. While CD is the most common noniatrogenic cause of CS, the disease itself is overall fairly rare, with an average incidence around 1.2–2.4 cases per million inhabitants per year (Daniel and Newell-Price, 2015; Hall *et al.*, 1994). The disease is typically diagnosed around 3 years after the onset of illness (Zilio *et al.*, 2014; Lonser *et al.*, 2013). The mean age at diagnosis is in the fourth decade of life. The disease is more common in women, with studies showing three to six times the prevalence compared to men (Lonser *et al.*, 2017; Zilio *et al.*, 2014).

Clinical Features

There are a number of characteristic features of patients who present for evaluation of possible CS/CD. The excess cortisol leads to central adiposity and fat deposits in face, supraclavicular, and posterior cervical spine regions, hyperglycemia, frequent ecchymosis, dark striae, excess sweating, proximal muscle weakness, edema, hypokalemia, thromboembolic events, psychiatric disorders like depression with cognitive impairment, and atypical infections. Of these symptoms, hypertension and abnormal glucose metabolism are the major predictors of morbidity and mortality in untreated disease. The overall mortality ratio for patients with CD compared to death rate in the general population is reported to be around 1.9–4.8, with the majority of deaths due to vascular disease (Yaneva *et al.*, 2013; Lonser *et al.*, 2017). The mortality rate is significantly greater in women aged 45–70 compared to men.

Cushing Disease Physiology

In addition to the clinical findings, evaluation of suspected CD also includes biochemical testing to confirm ACTH-dependent hypercortisolemia, followed by localization of the source (Daniel and Newell-Price, 2015). As discussed in other chapters, normal physiologic conditions of the hypothalamic–anterior pituitary–adrenal axis leads to a peak in cortisol levels in early morning and nadir late at night. Circulating cortisol provides physiological control of this endocrine axis by its negative feedback inhibition of corticotropin-releasing hormone (CRH) secretion by the hypothalamus and ACTH secretion by the pituitary. CS occurs when an excess of circulating cortisol disrupts the normal physiologic feedback mechanisms, either from an excess of ACTH (ACTH-dependent CS) or from an excess of cortisol secreted by the adrenal glands (ACTH-independent CS).

CD represents an ACTH-dependent elevation of cortisol caused by a pituitary adenoma that produces excess ACTH. As a result, the adrenal glands secrete an excess of cortisol, which then increases the negative feedback inhibition on CRH secretion by the hypothalamus. However, the ACTH-secreting adenoma is relatively resistant to excess cortisol and so biochemical testing reveals paradoxically elevated, or "nonsuppressed," levels of ACTH in addition to elevated levels of circulating cortisol.

Biochemical Testing for Diagnosis of Cushing Disease

CS is first determined by confirming excess of circulating cortisol, which can be done through various methods. Abnormal levels can be assessed by evaluating the amount of cortisol excreted in the urine over a 24-h period (urine free cortisol [UFC]), measurement of late-night (11 PM) salivary cortisol (LNSC), or low-dose dexamethasone suppression testing (DST) with overnight 1-mg DST or 48-h 2 mg DST. Established clinical guidelines recommend confirming excess endogenous cortisol by at least two of these screening tests (Nieman *et al.*, 2008).

Once CS is confirmed, additional testing is needed to identify the underlying cause. This first involves determining whether the hypercortisolemia is ACTH-dependent or ACTH-independent, and then whether the ACTH source is central or ectopic. Patients with ACTH-dependent CS most often have an underlying pituitary corticotroph adenoma (CD), but may sometimes have an ectopic tumor secreting either ACTH or, very rarely, CRH.

Once an ACTH-dependent hypercortisolemia is identified, the next step involves identification of the source of excess ACTH. This can be done biochemically, with a high-dose (8 mg) DST, or radiographically, with a pituitary-protocol MRI. With the high dose DST, cortisol secretion is suppressed in approximately 80% of CD patients, but cortisol levels in the majority of ectopic ACTH-secreting tumors typically do not suppress. This test has 81%–82% sensitivity and 67%–79% specificity for CD. A peripheral CRH stimulation test can be helpful in some patients, especially where intermediate levels of ACTH are identified, with the belief that corticotroph cells of the pituitary adenoma are more likely to respond to CRH stimulation than ectopic ACTH-secreting tumors. The CRH stimulation test has 70% to 93% sensitivity and 88% specificity for CD (Lonser *et al.*, 2017).

MRI

A pituitary MRI is sometimes diagnostic, but an adenoma is only visible in 40%–60% of CD cases (Jagannathan *et al.*, 2009; Ciric *et al.*, 2012; Hall *et al.*, 1994). When visible, the vast majority (90%) of pituitary corticotroph tumors are microadenomas. A high-resolution (1- to 1.5-mm slice thickness) MRI using a pituitary protocol enhances detection of ACTH-secreting pituitary tumors, with a sellar mass seen in 60%–70% of CD patients. It should be noted, however, that incidental sellar hypodensities of small size (<10 mm) are present in approximately 10% of individuals in the general population. Therefore, the presence of a pituitary abnormality on MRI is not always the source of ACTH excess.

Inferior Petrosal Sinus Sampling

When there is no obvious pituitary abnormality on MRI but clinical suspicion for CD is high, inferior petrosal sinus sampling (IPSS) is a useful technique for confirming a pituitary source before proceeding with transsphenoidal surgery. Tumors ≥ 6 mm have been associated with 96% specificity for CD, so the author's group typically pursues IPSS for tumors smaller than this (Yogi-Morren *et al.*, 2015). However, a study of 501 patients with surgically-confirmed ACTH-secreting adenomas showed that MRIs with obvious lesion ≥ 4 mm had a greater positive predictive value for laterality of lesion compared to IPSS (86% vs. 72%)(Wind *et al.*, 2013). Generally, IPSS is useful for predicting ACTH-secreting lesions for patients with MRI findings <7 mm, and MRI abnormalities ≥ 4 mm may help in guiding surgical approach for tumor localization.

The IPSS procedure involves inserting catheters in the inferior petrosal veins bilaterally and sampling ACTH levels before and after the administration of corticotropin-releasing hormone (CRH) or desmopressin (Deipolyi *et al.*, 2017; Giraldi *et al.*, 2015; Machado *et al.*, 2007). Central levels of ACTH are compared to peripheral venous levels of ACTH at the same time points, and, to confirm a central source of excess ACTH the ratio of central to peripheral ACTH should exceed 3:1 after CRH stimulation. Confirmation of hypercortisolemia at the time of the procedure is a prerequisite for accurate testing (Giraldi *et al.*, 2015). While this test is considered the gold standard for distinguishing between pituitary and ectopic sources, it requires considerable expertise to be performed safely and reliably. In rare cases it has been associated with thrombotic and neurologic complications. Anomalous venous drainage or incorrect sampling can limit the diagnostic performance of this test, thus, it is imperative that both the venous anatomy and accurate catheter positioning in the inferior petrosal sinuses be verified before and after specimen collection to ensure appropriate sampling. Measuring serum prolactin level in specimens may also help improve the diagnostic accuracy of this test, as elevated ratio of central to peripheral prolactin in cases of anomalous venous drainage can decrease the rate of false negative IPSS (Findling *et al.*, 2004; Sharma *et al.*, 2011).

Ectopic Sources

In cases where patients with ACTH-dependent CS are suspected of having an ectopic source, imaging studies of their chest, abdomen, and pelvis is recommended. Typically this involves a computed tomography (CT) study, although MRI, positron emission tomography (PET) in combination with CT, and/or whole-body scintigraphy using indium-111–labeled pentetreotide may also be useful. Ectopic sources of ACTH are typically small and may not be detected despite extensive imaging examinations in up to 19% of patients. There are additional laboratory tests that can be helpful in localizing an occult ectopic tumor, including tests for serum CRH, calcitonin, chromogranin A, fractionated plasma metanephrines, and 24-h urine 5-hydroxyindoleacetic acid (Lonser *et al.*, 2017).

Surgical Management of Cushing Disease

Surgery is considered first-line treatment option for CD, with the goal of adenomectomy to eradicate the ACTH-secreting lesion. Remission rates range from 65% to greater than 90%, with higher rates of remission achieved by more experienced neurosurgeons (Valassi *et al.*, 2010; Aranda *et al.*, 2015). Recurrence rates range from 10% to 35% (Hammer *et al.*, 2004; Swearingen *et al.*, 1999). Surgical options include microscopic approaches via either sublabial or endonasal exposure, as well as the endonasal endoscopic approach. The endonasal approach has become the more common of the microscopic approaches because of the decreased incisional morbidity, although some centers utilize the sublabial approach. Recurrences may be treated with repeat transsphenoidal surgery, as well as radiosurgery or radiation therapy with interim medical therapy until radiation therapy takes effect. There are now newer pharmacologic options as well. Refractory cases requiring urgent remission may be considered for bilateral adrenalectomy.

Microscopic

The microscopic, compared to the endoscopic approach, offers the advantage of a binocular stereoscopic view with superior optics. After induction of general anesthesia, the patient is positioned supine with the head on a gel headrest or in 3-point fixation. Navigation is provided by either fluoroscopy or CT- and/or MRI-guided stereotaxy.

In the endonasal approach, the posterior septal mucosa is infiltrated with local anesthetic containing epinephrine, and incised opposite the middle turbinate. The mucosa is lifted with a periosteal elevator, and the posterior septum fractured. A piece of the bony septum may be retained for later use. A self-retaining nasal speculum provides retraction as the anterior wall of the sphenoid sinus is drilled to provide sufficient room for later insertion and manipulation of appropriately sized curettes.

The sella is identified, and opened in the midline. A laser Doppler probe may be used to help identify the position of the cavernous carotid arteries, especially in cases of medially located cavernous sinuses. The dura is coagulated with a bipolar and sharply opened. The gland is hemisected and explored for adenoma. Tumor fragments are dissected free and delivered from the gland using an assortment of ring curettes. Because approximately 90% of tumors in CD are microadenomas, care should be taken to obtain sufficient specimen for histopathological analysis. The surface of the pituitary gland is closely inspected for residual fragments of adenoma. If no obvious tumor is visualized, a systematic exploration is undertaken. Serial frozen-section biopsies are often useful. If these remain negative, some advocate for hemi-hypophysectomy on the side predicted by the preoperative bilateral IPSS (Utz *et al.*, 2005).

Following resection, hemostasis is obtained. There are a number of techniques to reconstruct the sella. The authors employ fat harvested from a separate abdominal incision, which is then covered with a piece of previously harvested septal bone, titanium mesh, or other synthetic plug. If cerebrospinal fluid (CSF) leak is suspected, a layer of fibrin glue or other sealant may be applied. The nasal mucosal flap is reapproximated, and the nasal passage inspected before completion of the procedure.

Endoscopic

The endoscopic approach offers the advantage of a wider field of view and the capacity to inspect regions of the sella with angled fiber bundles. In this technique, a nasal speculum is not required. A 0 degree 4-mm endoscope is typically used during the sellar exposure. The ostia of the sphenoid sinuses are identified bilaterally. The sphenoid ostia are widened inferiorly and medially with care taken to preserve the posterior septal branch of the sphenopalatine artery, in case a nasoseptal flap is necessary for CSF leak repair. The goal of exposure is to achieve a sphenoidotomy that extends from floor to roof of the sphenoid sinus and laterally to bilateral superior turbinates. At this point, the approach to the pituitary gland and tumor resection is similar to the microscopic technique. During tumor dissection, the endoscope can be affixed to the operating table with an articulating arm or held by the assistant, allowing the surgeon to use conventional bimanual techniques. In the case of CSF leak, a nasoseptal flap may be harvested for a vascularized flap repair of the sella or a free mucosal graft may be harvested from nasal floor or middle turbinate.

Recent improvements in endoscope technology have provided much clearer high-definition visualization, including 4K resolution. Three-dimensional endoscopes are also growing in use and improving in quality. (Barkhoudarian *et al.*, 2013; Tabaee *et al.*, 2009) Several centers have reported remission rates similar to those of microscopic approaches, especially in cases of macroadenomas. (Wagenmakers *et al.*, 2013; Netea-Maier *et al.*, 2006)

Outcomes After Surgery

Predictors of Remission

Several factors have been linked to likelihood of successful surgical outcome, including size of tumor, invasiveness of tumor, and identification of tumor on pre-operative work-up and intraoperatively.

Tumor size

Most studies show an improved rate of remission with microadenomas (Swearingen *et al.*, 1999; Rollin *et al.*, 2007; Honegger *et al.*, 2012; Hofmann *et al.*, 2008; Fomekong *et al.*, 2009; Ammini *et al.*, 2011). Larger macroadenomas may have worse outcomes, perhaps because larger tumors are more likely to be invasive (Meij *et al.*, 2002; Cannavò *et al.*, 2003).

Tumor invasion

Patients with presence of tumor invasion are less likely to achieve remission after transsphenoidal surgery (Rees *et al.*, 2002; De Tommasi *et al.*, 2005). Invasion of the cavernous sinus and dura or suprasellar tumor extension results consistently in a higher incidence of persistent disease (Hammer *et al.*, 2004). Remission is unlikely even in cases where tumor seems to be removed from the cavernous sinus given the likelihood of dural involvement (Lonser *et al.*, 2012).

Tumor identification

Studies indicate that identification of adenoma on preoperative MRI and intraoperative histopathology have also been linked to improved chance of remission (Esposito *et al.*, 2006; Chee *et al.*, 2001; Fomekong *et al.*, 2009; Shimon *et al.*, 2002). Intraoperative identification of an adenoma is an important positive prognostic factor, and allows selective adenomectomy to be performed rather than a potentially more morbid procedure such as partial or total hypophysectomy (Hofmann *et al.*, 2008; Chee *et al.*, 2001; Nakane *et al.*, 1987; Prevedello *et al.*, 2008). The use of intraoperative frozen sections can be useful and, in one study, the use of preoperative MRI and bilateral IPSS for localization along with intraoperative frozen sections achieved 100% remission in 18 patients (Lim *et al.*, 2011). Systematic exploration of the gland can lead to identification of MRI-invisible adenomas (Oldfield and Vortmeyer, 2006). Intraoperative ultrasonography has been reported to increase intraoperative adenoma localization and yield higher remission rates (Watson *et al.*, 1998).

Tumor Pseudocapsule

Adenomas may sometimes create a "pseudocapsule" of surrounding fibrous tissue and compressed gland that, when present, may be an aide to tumor dissection and successful removal. This technique yields excellent results in experienced hands, with initial remission of 96.6%, increasing to 100% following early repeat surgery for initial treatment failures, with a recurrence of only 2.3% at a mean of 7 years (Jagannathan *et al.*, 2009; Oldfield and Vortmeyer, 2006; Lonser *et al.*, 2013).

Biochemical remission

Several biochemical parameters have been proposed to define remission, although a perfect predictor of long-term remission has not yet been identified. A number of parameters have been used to assess remission. Potential early predictors include low fasting serum cortisol (< 2 μg/dL), low 24 h urine free cortisol levels (below 20 μg/24 h), low serum ACTH (<5 pg/mL), or low midnight salivary cortisol within the first week after surgery (Lonser *et al.*, 2017; Carrasco *et al.*, 2008; Lindsay *et al.*, 2011; Lonser *et al.*, 2013). One study found 97% sustained remission in patients with serum cortisol less than 5 mg/dL within the first two postoperative days, although follow-up was brief at 33 months (Acebes *et al.*, 2007). More recent data suggests that morning serum cortisol level less than 1 μg/dL predicts remission with a positive predictive value (PPV) of 96% (Lonser *et al.*, 2017). Currently, based on this data, a consensus statement from clinicians experienced in management of CD recommends immediate reevaluation of patients with persistent serum cortisol levels greater than 5 μg/dL, and careful observation of those patients with cortisol levels between 2 and 5 μg/dL (Biller *et al.*, 2008).

Volume-outcome effect

While database studies indicate a volume-outcome effect, whereby surgeons that perform a higher volume of pituitary surgery have reduced morbidity and mortality rates, the contribution of surgical experience to surgical success in CD is difficult to document (Ciric *et al.*, 1997; Barker *et al.*, 2003). While many studies showing no changes in remission outcomes over a surgeon's career, several others reporting improvement with experience over time (Rees *et al.*, 2002; Yap *et al.*, 2002; Chee *et al.*, 2001; Hofmann *et al.*, 2008).

Predictors of Recurrence

Despite initial surgical cure of CD, many patients may develop recurrence of disease months or even years following initial surgery. Due to this variable timeframe of recurrence, the overall rate is difficult to determine because studies report differing lengths of follow-up. Overall, recurrent disease appears in 3%–22% of patients at a mean of 1.75–9.6 years (Pereira *et al.*, 2003; Prevedello *et al.*, 2008; Yap *et al.*, 2002; Rees *et al.*, 2002; Rollin *et al.*, 2007; Shimon *et al.*, 2002; Atkinson *et al.*, 2005; Wagenmakers *et al.*, 2013; Invitti *et al.*, 1999; Hammer *et al.*, 2004; Swearingen *et al.*, 1999). Recurrence continues to increase over time with long-term follow-up (Hammer *et al.*, 2004; Invitti *et al.*, 1999; Atkinson *et al.*, 2005; Prevedello *et al.*, 2008; Patil *et al.*, 2008a; Pereira *et al.*, 2003). For example, one study showed recurrence of 0.5%, 6.7%, 20.8%, and 25.5% at 1, 2, 3, and 5 years, respectively, and ultimate recurrence of 46% in patients followed for at least 5–13 years. Undetectable postoperative cortisol does not exclude the chance of future recurrence, and in one study where postoperative cortisol predicted remission at 6 months, it was not related to long-term remission (Atkinson *et al.*, 2005; Yap *et al.*, 2002; Pereira *et al.*, 2003). Other studies have also shown that elevated

postoperative ACTH as well as increased cortisol and ACTH levels following CRH stimulation have been related to recurrence (Sheth *et al.*, 2012; Lindsay *et al.*, 2011; Invitti *et al.*, 1999)

Recurrent tumors likely are caused by growth of residual microscopic tumor remnant from the initial surgery (Nakane *et al.*, 1987; Dickerman and Oldfield, 2002). Recurrence rates may be a function of tumor size, with macroadenomas recurring more frequently as a results of increased invasiveness (Swearingen *et al.*, 1999). However, a small study showed excellent long-term remission rates in patients with macroadenomas, and several studies have shown no difference in recurrence rates based on size (Yap *et al.*, 2002; Tritos *et al.*, 2011). Undetected dural invasion may contribute to unresected tumor tissue, and dural invasion increases with adenoma size, patient age, and male gender (Meij *et al.*, 2002; Dickerman and Oldfield, 2002).

The Role of Reoperation

Initial transsphenoidal surgery for CD has a higher likehood of successful remission compared to repeat surgery performed for treatment failure or recurrence, and subsequent surgeries may be associated with higher rate of complication. (Swearingen *et al.*, 1999; Patil *et al.*, 2008b; Hofmann *et al.*, 2008; Esposito *et al.*, 2006; Rollin *et al.*, 2007). Nonetheless, studies specifically examining the scenario of repeat surgery after initially unsuccessful procedures have found remission rates of 62%–87.5%. Repeat surgery should therefore be considered an option for refractory cases when initially remission was not achieved (Shimon *et al.*, 2002; Nakane *et al.*, 1987; Prevedello *et al.*, 2008).

Complications

Overall, the transsphenoidal procedure has a relatively low rates of mortality, with range of 0%–1.9%, and low rates of serious morbidity, ranging1.8%–15%. A nationwide study of inpatient data from transsphenoidal surgery for CD found in-hospital mortality of 0.7%, overall adverse outcomes, including death, of 2.9%, and morbidity of 42.1%*** (Patil *et al.*, 2007). Patients with CD who undergo transsphenoidal surgery may have higher immediate and delayed complication rates than patients with other pituitary tumors who undergo this operation, perhaps because of the higher incidence of medical comorbidities in the CD population and the effects of cortisol withdrawal (Aulinas *et al.*, 2012; Sheth *et al.*, 2012). Patients who are successfully surgically treated have improved long-term mortality risk, whereas those with persistent disease have increased mortality (Swearingen *et al.*, 1999; Hammer *et al.*, 2004).

Endocrine

Postoperative adrenal insufficiency is an anticipated sequela after a successful corticotroph adenomectomy. In CD, the normal corticotroph cells of the pituitary gland are inhibited by the hypersecretion of ACTH by the adenoma and the consequent increase in cortisol. If the tumor is successfully removed, patients will require glucocorticoid replacement for on average 6–18 months following surgery until their normal hypothalamic–pituitary–adrenal axis is restored. It is debated whether routine postoperative institution of steroid replacement is advisable; some centers withhold replacement until after inpatient testing is completed, while others begin low dose decadron (0.5 mg QD) immediately, so that outpatient testing can be safely performed without the risk of symptomatic adrenal insufficiency (Tritos *et al.*, 2011).

Deficiency of other pituitary hormones may also occur after transsphenoidal for CD, but this is highly dependent on the aggressiveness of surgery required. Deficiency of at least one pituitary hormone is reported in 8.6%–53% of patients, with lower rates in selective adenomectomy and increasing rates with extensive exploration, approaching 100% for subtotal or total hypophysectomy. The rate of hypopituitarism may increase with repeat surgeries (Friedman *et al.*, 1989; Rollin *et al.*, 2007).

Diabetes insipidus (DI) is a common postoperative endocrinopathy, and results from trauma to the posterior gland. It can occur transiently, lasting for days to weeks postoperatively, in 6%–75% of cases, whereas permanent DI is rare and occurs in 1%–15% of cases. Patients with DI require hormonal replacement with desmopressin (Semple and Laws, 1999; Ciric *et al.*, 1997; Swearingen *et al.*, 1999; Hammer *et al.*, 2004; Chee *et al.*, 2001; Fomekong *et al.*, 2009). Patients may also experience postoperative syndrome of inappropriate antidiuretic hormone (SIADH), usually within 7–14 days postop, and therefore all patients should be monitored for hyponatremia in the early postoperative period.

Neurologic

Neurologic complications are rare, but most often involve cranial nerve dysfunction. The most serious of these involves damage to the optic apparatus, which can cause vision loss. This is rare in surgery for CD, given that the vast majority of CD tumors are small and intrasellar. Other cranial nerve injuries typically arise from manipulation in cavernous sinus exploration. Cranial nerve palsies may be transient or permanent. The overall risk of carotid artery injury after transsphenoidal surgery has been reported to range from 0% to 2.5%; this is also rare for intrasellar microadenomas (Ciric *et al.*, 1997; De Tommasi *et al.*, 2005).

Cerebrospinal fluid rhinorrhea

Cerebrospinal fluid (CSF) may be encountered intra-operatively at a rate that ranges from 20% to 72%, and typically is repaired intraoperatively with fat graft packing, reconstruction of the sella with cartilage or titanium, dural sealant, or a vascularized or free

muscosal graft (Jakimovski *et al.*, 2014). CSF rhinorrhea discovered postoperatively requires prompt intervention, either though a lumbar drain with CSF diversion or by re-exploration for operative repair.

Infection

Recurrent and chronic sinus infection may occur in as many as 1.5%–8.5% of patients (Jagannathan *et al.*, 2009; Ciric *et al.*, 1997). Antibiotics are the first line of treatment, but many patients may require surgical drainage to achieve cure (Batra *et al.*, 2005). Meningitis is rare and is often associated with a persistent CSF leak. Incidence of postoperative meningitis is reported at 0.4%–7.9% (Hammer *et al.*, 2004; Ciric *et al.*, 1997).

Nasal/sinus

Postoperative epistaxis is an uncommon risk in the weeks following surgery. Occasionally, arterial bleeding from the septal branch of the spheno-palatine artery may be severe enough to require nasal packing, vessel cauterization, or endovascular vessel sacrifice. Severe epistaxis is rare, occurring in 0.4%–3.4% of patients (Swearingen *et al.*, 1999; Esposito *et al.*, 2006; Ciric *et al.*, 1997; Semple and Laws, 1999). Nasal morbidity also includes septal perforations and crusting.

Thromboembolic

Hypercortisolism is associated with a hypercoagulable state. There is a higher risk of venous thrombosis in patients with CD compared to patients undergoing transsphenoidal surgery without CD. It is important that patients receive appropriate deep vein thrombosis (DVT) prophylaxis, such as sequential compression devices and/or subcutaneous low molecular weight heparin. DVT or pulmonary embolism has been reported in 1%–6% of cases (Fomekong *et al.*, 2009; Rees *et al.*, 2002). Before treatment, patients with CD have an incidence of thromboembolic disease of 14.1 per 1000 person years. CD patients have a higher postoperative rate of thromboembolic events than patients undergoing pituitary surgery for nonfunctioning adenomas (van der Pas *et al.*, 2013; Stuijver *et al.*, 2011), and the advisability of routine postoperative anticoagulation has been debated. Although no evidence-based guidelines exist for thromboembolic prevention in the perioperative period he author's group, the author's group uses sequential compression devices during the immediate preoperative, intraoperative and postoperative periods. For mobile patients, early ambulation within hours of surgery is encouraged. For less mobile patients or those that will need extended postoperative recovery at a rehabilitation facility, chemoprophylaxis in the form of subcutaneous low molecular weight heparin may be used.

Conclusion

Given the significantly increased mortality and morbidity of untreated CD, it is imperative to diagnose the disease and treat expeditiously. Despite the advent of alternative medical therapy, surgery remains first line treatment. Overall, surgical management of CD yields high remission rates and low complication rates following either microscopic or endoscopic transsphenoidal surgery. Reoperation may be considered for recurrences of if the initial procedure is unsuccessful.

Evaluation and Follow-Up of Patients With Cushing Disease After Pituitary Surgery

Amandine Ferriere, Claire Cordroch, and Antoine Tabarin, University Hospital of Bordeaux, Bordeaux, France

Abbreviations

ACTH	Corticotrophin
CD	Cushing disease
CDDT	Combined dexamethasone-desmopressin test
CRH	Corticotrophin-releasing hormone
DST	Dexamethasone suppression testing
LNSC	Late-night salivary cortisol
UFC	Urinary free cortisol

Introduction

Cushing disease (CD) results from inappropriate ACTH secretion by a corticotroph pituitary tumor (almost always a benign adenoma), leading to a state of chronic hypercortisolism. CD is a severe condition responsible for numerous comorbidities and increased mortality (Feelders *et al.*, 2012).

The treatment goals in CD are to selectively remove the pituitary adenoma, thereby inducing long-term normalization of the hypothalamic–pituitary–adrenal (HPA) axis and, consequently, reversing the clinical features of Cushing syndrome while preserving normal pituitary function (Nieman *et al.*, 2015). Transsphenoidal surgery is the only therapeutic option that can achieve these goals and offer definitive cure with minor side effects. When performed rapidly after diagnosis, pituitary surgery has been shown to abrogate the increased mortality resulting from the chronic cortisol excess (Clayton *et al.*, 2016). Many factors influence the outcome of pituitary surgery, including gender, adenoma size, dural invasion, localization on preoperative imaging, intraoperative tumor visualization, and histological confirmation of a corticotroph adenoma (Pivonello *et al.*, 2015).

Pituitary surgery for CD is notoriously difficult, owing to the usually very small size of corticotroph adenomas and frequent bleeding in the operative field which can mask the pituitary gland. It is therefore highly recommended to address patients to an experienced neurosurgeon who treats a high volume of patients with CD. This helps to ensure successful resection of the corticotroph adenoma and reduces the potential complications of pituitary surgery (Nieman *et al.*, 2015; Petersenn *et al.*, 2015). However, even in the best conditions, the initial surgical cure rate for CD is only 65%–80% for patients with ACTH-secreting corticotroph microadenomas, and lower for patients with macroadenomas (see **Table 1**). Furthermore, pituitary surgery may be followed by a recurrence even after many years of apparent cure. It is therefore recommended to use the term postoperative remission, as a definitive cure can only be declared after the absence of recurrence several decades after initial surgery. Given the frequency of recurrences, life-long follow-up is recommended for patients operated on for CD (**Fig. 1**).

The following measures are crucial in the postoperative period:

- To precisely assess the status of the HPA axis, in order to diagnose surgical failure/remission and, ideally, to evaluate the individual risk of recurrence;
- To evaluate the rest of pituitary function and to compensate for any hormonal secretory deficits;
- To plan personalized patient follow-up.

The best criteria for defining remission versus ongoing disease in the postoperative period are controversial, and so are the most reliable prognostic factors for sustained remission. Given the rarity of CD, the natural history of recurrences following postoperative remission is poorly documented, and the best strategy for detecting early recurrences is also controversial (Nieman *et al.*, 2015). The following section discusses the modalities of postoperative evaluation and follow-up, in view of the current literature and the experience of our center. We limit this discussion to adult patients.

Initial Postoperative Evaluation

Establishing postoperative remission from CD is crucial but challenging. Several approaches have been used to evaluate postoperative HPA axis function.

It is generally accepted that the diagnosis of remission cannot rely solely on clinical findings. The time required for the symptoms of Cushing syndrome to subside may range from a few weeks to several years, even in case of a sustained cure (Sippel *et al.*, 2008). Furthermore, although biochemical remission is associated with clinical improvement, comorbidities such as obesity, metabolic syndrome, cognitive impairments and psychiatric disorders may not fully resolve (Ragnarsson and Johannsson, 2013).

Although it is well accepted that the diagnosis of remission requires biochemical criteria, the ideal protocol and criteria are controversial, for several reasons. Firstly, many biochemical tests, with various normal ranges, have been used to characterize remission (Petersenn *et al.*, 2015) (**Table 1**), and treatment statistics are obviously dependent on the criteria used to define outcome. Furthermore,

Table 1 Selection of surgical series of Cushing disease involving at least 60 operated patients per center with long-term follow-up

Author, year	*Mean follow-up (months, range)*	*Number of patients*	*Postoperative remission (%)*	*Biological criterion of early postoperative remission (≤ 6 months)*	*Recurrence (%)*	*Mean time to recurrence (months, range)*

Keskin *et al.* (2017)	90 (60–120)	82	72.3	Morning SC (≤ 2 μg/dL) OR normal LNSC, normal UFC, 1 mg DST (SC ≤ 1.8 μg/dL)	30.3	NA
Johnston *et al.* (2017)	52 (12–118)	101	83.0	Morning SC (≤ 3 μg/dL) or normal UFC, LNSC and LDSST	6.0	NA
Le Marc'hadour *et al.* (2015)	52 (18–180)	67	–	Hypocortisolism or normal circadian rhythm of SC, normal UFC, 1 mg DST (SC ≤ 1.8 μg/dL)	16.4	36 (3–100)
Lindsay *et al.* (2011)	126 (12–274)	331	–	Morning SC (≤ 5 μg/dL)/normal UFC (≤ 20 μg/day)	12	50.4 (12–156)
			Mean = 77.4 ± 7.2		Mean = 16.6 ± 7.8	Mean = 47.3 ± 22.8

LDDST: low dose dexamethasone suppression test, 1 mg DST: 1 mg dexamethasone suppression test; DST: suppression test with unknown dose of dexamethasone; SC: serum cortisol.

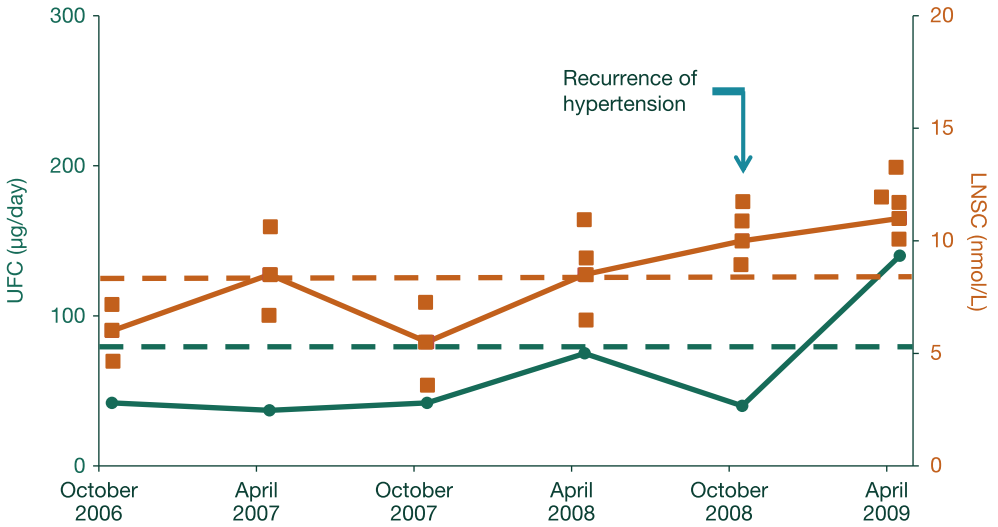

Fig. 1 A typical example of follow-up and postoperative recurrence in a patient with Cushing disease. Note that the increase in the mean value of LNSC values (*squares*) occurs before the increase in UFC measured at the same period. October 2006 correspond to the recovery of a normal HPA axis function following a 8 months period of postoperative corticotropic insufficiency (issued from Danet-Lamasou *et al.*, 2015). LNSC: late-night salivary cortisol; UFC: 24 h urinary free cortisol. Dashed lines represent the upper limit of normal range (ULN) for UFC (80 µg/day) and home assay of LNSC (8 mmol/L).

most published studies concern retrospective series comparing limited numbers of procedures. Follow-up is often short and the number of patients limited. As there is no agreement on the definition of remission or surgical failure, it is difficult to distinguish between recurrence following true remission versus progression in disease intensity following incomplete cure (e.g., persistence of milder disease) and to compare management strategies used in different clinical studies. This may explain the wide variations in reported remission rates, which ranged between 52% and 97% (mean 77%) and between 25% and 100% (mean 78%) in two recent meta-analyses (Petersenn *et al.*, 2015; Pivonello *et al.*, 2015) as well as our own analysis of the literature (**Table 1**).

From a pathophysiological perspective, CRH and normal corticotroph cells are suppressed by the chronic hypercortisolism in CD. It is therefore expected that the plasma cortisol concentration will be very low or undetectable after complete resection of the ACTH-producing tumor. Accordingly, measurement of morning plasma cortisol, alone or together with other clinical or biological parameters such as the plasma ACTH concentration, the 24 h urine free cortisol level (UFC) and cortisol suppression in response to dexamethasone administration (DST), has been the most widely used criterion. Remission is generally defined as a low morning serum cortisol concentration within 7–10 days following pituitary surgery. However, a variety of morning cortisol thresholds have been used, ranging from "undetectable" to "below the upper limit of the normal range of the assay" (**Table 1**). Evidently, less stringent cortisol thresholds lead to higher remission rates (Petersenn *et al.*, 2015). While some authors claim that a postoperative cortisol concentration below 50 nmol/L is associated with sustained remission with 100% specificity, the Endocrine Society considers remission to be associated with a cortisol concentration below 138 nmol/L (Nieman *et al.*, 2015). The use of additional tests such as the 24 h UFC and DST does not significantly influence the estimation of the remission rate in patients with low morning plasma cortisol concentrations (Petersenn *et al.*, 2015). More recently, a few studies have suggested that a low midnight or late-night salivary cortisol concentration (LNSC) has roughly equivalent performance for diagnosing remission as a combination of various biochemical tests including morning serum cortisol (Carrasco *et al.*, 2008; Amlashi *et al.*, 2015).

Although it is recommended to evaluate HPA axis function within 7–10 days following pituitary surgery, remission may occur later in a subset of patients. In a series of 56 patients cured by surgery, 6 patients with serum cortisol concentrations >138 nmol/L within 2 weeks after surgery had values below 50 nmol/L 3 months after surgery (Pereira *et al.*, 2003). Similarly, in a multicenter study involving 620 patients, 5.6% of those who had early elevated or normal UFC levels experience a delayed and persistent cortisol decline 38 $\pm$ 50 days after surgery (Valassi *et al.*, 2010). Delayed necrosis of residual corticotroph adenoma cells after the surgical insult is suspected, but the pathophysiology of these delayed responses is unknown. Be as it may, these observations suggest that the HPA axis should be reevaluated after several weeks following surgery before drawing definite conclusions, particularly in patients with eucortisolism. This attitude must be reconciled with recent data showing that the duration of exposure to excess cortisol is a determining factor for the postcure persistence of comorbidities associated with Cushing syndrome, suggesting that hypercortisolism should be corrected as rapidly as possible (Ragnarsson and Johannsson, 2013; Nieman *et al.*, 2015). It should be noted that delayed remission occurs in a minority of patients.

In accordance with the recommendations of the Endocrine Society (Nieman *et al.*, 2015), we classify patients' status during the immediate postoperative period as follows:

- patients with nonsuppressed morning plasma cortisol and who should have complementary investigations such as midnight salivary cortisol, 24 h UFC and 1 mg DST. These investigations will differentiate patients with persistent CD (surgical failure) who require further treatment from patients with eucortisolism who can be safely monitored without treatment and reevaluated at 3-month intervals.
- patients with hypocortisolism who are classified as being in remission. In these patients, hydrocortisone replacement therapy should be started, as well as education for treatment of adrenal insufficiency and prevention of acute adrenal crises. Although this topic is outside the scope of this article, patients should also be informed of the so-called "glucocorticoid withdrawal syndrome," which includes nonspecific disorders such as fatigue, anorexia, myalgias and arthralgias, and symptoms of depression, which undermine their quality of life. It usually persists for several months and is marginally improved by an increase in the hydrocortisone dosage.

The above-mentioned classification based on the morning plasma cortisol concentration assumes that normal corticotroph cells are suppressed by chronic hypercortisolism. This may no longer be the case when patients receive cortisol-lowering drugs preoperatively. Indeed, prolonged preoperative cortisol normalization may avoid early hypoadrenalism in cured patients and may therefore confound the interpretation of immediate postoperative findings. A small retrospective series of 16 patients in whom hypercortisolism was "controlled" by steroidogenesis inhibitors for a median of 139 days (21–161 days) suggests that preoperative cortisol-suppressive therapy does not necessarily reactivate dormant healthy corticotroph cells and that patients still may experience transient hypocortisolism following successful surgery (van den Bosch *et al.*, 2014). Complementary studies are needed to conclude on this point, as well as on the overall benefit of presurgical medical preparation of patients with CD. The same issue of absence of postoperative corticotropic insufficiency may arise in patients with cyclical Cushing disease. When the results of usual investigations may be misleading or ambiguous, the use of LNSC, a sensitive maker of hypercortisolism, is recommended (Nieman *et al.*, 2015).

The immediate postoperative period must also include an evaluation of the adverse consequences of pituitary surgery itself. Nonspecific adverse effects include hemorrhage, cerebral fluid leakage, meningitis, deep vein thrombosis and electrolyte disturbances. Serum sodium and fluid intake should be assessed several times during the first 2 weeks to detect hyponatremia and diabetes insipidus. Hyponatremia, which seems to be more frequent than after pituitary surgery for other pituitary tumors, may be secondary to inappropriate secretion of antidiuretic hormone (a probable consequence of SIADH), but also to the overhydration associated with adrenal insufficiency in patients not receiving glucocorticoid replacement therapy. Transient diabetes insipidus may occur in about one-quarter of patients but usually resolves over a 3- to 5-day period (Pivonello *et al.*, 2015). Deep vein thrombosis and pulmonary thromboembolism may be more frequent after pituitary surgery for Cushing disease, and anticoagulation with low-molecular-weight heparin during the postoperative period may be warranted (Stuijver *et al.*, 2011). Hypopituitarism, a common complication of pituitary surgery, is clearly correlated with the aggressiveness and extent of surgery. The typical small size of corticotroph adenomas, requiring extensive exploration/dissection of the pituitary gland and frequent hemihypophysectomy or subtotal hypophysectomy rather than selective adenomectomy, explains the higher frequency of hypopituitarism following surgery for Cushing disease than for other pituitary adenomas. Importantly, fewer complications are reported in centers with extensive experience (Petersenn *et al.*, 2015). In a recent meta-analysis, the mean frequency of hypopituitarism was 6.6%, 20.2% and 80.2% in patients who had undergone adenomectomy, hemi-hypophysectomy and total hypophysectomy, respectively (Pivonello *et al.*, 2015). Evaluation of pituitary secretion in the early postoperative period is complex, however, and the results may be difficult to interpret because chronic hypercortisolism itself inhibits the gonadotropic and thyrotropic axis as well as GH secretion. This suppressive action may take several weeks to resolve after remission of Cushing syndrome. Extensive clinical and biological evaluations should ideally be performed after 2–3 months, and the Endocrine Society recommends focusing on thyroid function during the early postoperative period, based on a comparison of free T4 concentrations obtained within 1 week after surgery with preoperative levels to identify hypothyroidism (Nieman *et al.*, 2015).

Pituitary MRI is often poorly contributive in the diagnostic work-up of CD and should not be used to diagnose remission. MRI is recommended within 2–3 months following surgery in order to serve as a new baseline in case of recurrence (Nieman *et al.*, 2015).

Recurrence of Cushing Disease

A major challenge in the treatment of Cushing disease is that, despite initial remission, CD recurs in a significant number of patients. In a recent meta-analysis of 17 studies using biochemical criteria, alone or combined with clinical endpoints, the mean recurrence rate was 15.2% but ranged from 5.0% to 47.4% (Petersenn *et al.*, 2015)! The mean time to recurrence was 50.8 months, with a range of 3–158 months. In our own analysis of 25 published studies (Sonino *et al.*, 1996; Blevins *et al.*, 1998; Barbetta *et al.*, 2001; Yap *et al.*, 2002; Chen *et al.*, 2003; Hammer *et al.*, 2004; Atkinson *et al.*, 2005; Carrasco *et al.*, 2008; Hofmann *et al.*, 2008; Patil *et al.*, 2008; Alwani *et al.*, 2010; Bou Khalil *et al.*, 2011; Lindsay *et al.*, 2011; Ciric *et al.*, 2012; Hassan-Smith *et al.*, 2012; Alexandraki *et al.*, 2013; Lambert *et al.*, 2013; Wagenmakers *et al.*, 2013; Costenaro *et al.*, 2014; Dimopoulou *et al.*, 2014; Amlashi *et al.*, 2015; Le Marc'hadour *et al.*, 2015; Chandler *et al.*, 2016; Johnston *et al.*, 2017; Keskin *et al.*, 2017) (**Table 1**), those including at least 60 patients operated on by the same team with lengthy follow-up (mean 78 months; range: 6–432) and using acceptable biological criteria for remission and recurrence reported roughly the same results: the mean recurrence rate was 18.5%

(range: 6%–44%) with a mean time to recurrence of 47.3 months (range: 3–345). The risk of recurrence increases with long-term follow-up (Pereira *et al.*, 2003; Patil *et al.*, 2008; Ciric *et al.*, 2012; Alexandraki *et al.*, 2013), some recurrences being observed even 20 years after surgery. However, most recurrences are seen during the 15 years following surgery. This points to variability in the aggressiveness of corticotroph adenomas: aggressive adenomas would recur early while less aggressive tumors would recur later. Interestingly, a recent meta-analysis of surgical series showed the highest recurrence rates in studies where 10 patients or fewer were operated on per year of study duration, while the lowest rates were seen when 31–40 patients were operated on per year (Petersenn *et al.*, 2015). These data form the basis of the Endocrine Society's recommendation that CD patients should be operated on by an expert surgeon and receive life-long follow-up after successful surgery (Nieman *et al.*, 2015).

Early Prediction of Recurrences of Cushing Disease

Bearing in mind that only a minority of patients will relapse, and that life-long follow-up is needed, a number of teams have tried to identify postoperative predictive factors of recurrence in patients experiencing remission, the ultimate goals being to stratify patients according to their ultimate risk of recurrence and to define groups at high and low risk for whom the necessary duration and frequency of follow-up examinations may differ.

Early postoperative corticotropic insufficiency is found to be a protective factor for recurrence in many but not all studies (Alexandraki *et al.*, 2013; Vassiliadi *et al.*, 2016). For example, in the large series reported by Patil *et al.* (2008), the actuarial recurrence rate at 5 years in patients who had postoperative serum cortisol >2 μg/dL was 28.5%, compared to 20.6% in patients who had serum cortisol ≤2 μg/dL. In the study by Chandler *et al.* (2016), 13% of patients with corticotropic insufficiency (morning plasma cortisol ≤3 μg/dL) recurred during follow-up, compared to 50% of eucortisolic patients (morning plasma cortisol and UFC within the normal range). Some authors have claimed that the probability of relapse correlates negatively with the morning cortisol concentration (e.g., low vs. very low concentrations) (Le Marc'hadour *et al.*, 2015) while others have not found this difference (Lindsay *et al.*, 2011). Obviously, although being a favorable prognostic factor, corticotropic insufficiency is not an absolute criterion for definitive cure. The reverse is also true for postoperative eucortisolism, that does not always identify patients with a residual tumor leading always to late recurrence (Bochicchio *et al.*, 1995). In addition, several groups have shown that the time to recurrence is longer in patients with postoperative corticotropic insufficiency (Bou Khalil *et al.*, 2011; Keskin *et al.*, 2017), a finding which suggests that a smaller number corticotroph adenomatous cells remain in these patients.

Late-night salivary cortisol (LNSC) has been shown to be useful tool for diagnosing mild Cushing disease, such as Cushing syndrome with normal UFC (Elias *et al.*, 2014; Raff, 2015). However, early postoperative LNSC (obtained within 3 months) was not found to predict the risk of recurrence.

The duration of corticotropic insufficiency and the need for hydrocortisone supplementation was the only significant predictor of recurrence in a recent UK study. Recovery within 6 months, 1 year and 2 years had a decreasing positive predictive value for recurrence of 64%, 61% and 59%, respectively (Alexandraki *et al.*, 2013) and no patients with corticotropic insufficiency lasting for >3 years experienced a recurrence. Although the duration of corticotropic insufficiency is probably related to the duration and intensity of Cushing syndrome, as well as to individual susceptibility to excess glucocorticoids, a similar prognostic value was found in a multicenter study (Bochicchio *et al.*, 1995).

Several groups have suggested that more accurate evaluation of the degree of postoperative hypocortisolism than that provided by a single measurement of morning plasma cortisol might be a better predictor of long-term remission. This was the rationale for evaluating pituitary and adrenal responses to the CRH stimulation test. In the largest prospective cohort published to date, with a median follow-up of 11 years, a plasma ACTH concentration ≥ 18 pg/mL in response to CRH during the 10 days following surgery was associated with a higher rate of recurrence in patients with low postoperative plasma cortisol concentrations (Lindsay *et al.*, 2011). However, there was such a large overlap with the response of patients who did not experience recurrence that CRH-stimulated cortisol and ACTH values had no added benefit for recurrence prediction over early basal cortisol testing.

The rationale underlying the use of the desmopressin test in the postsurgical evaluation of CD patients is based on evidence that ACTH and cortisol increments following desmopressin injection are secondary to the stimulation of V2 receptors, and that these receptors are expressed and upregulated only in adenomatous corticotroph cells, whereas normal corticotrophs only express V3 receptors, for which desmopressin is a weak agonist. A "paradoxical" response to desmopressin would therefore indicate the persistence of adenomatous corticotrophs aberrantly expressing V2 receptors that may induce late CD recurrence. A prerequisite and limitation of this test is that it would be informative only in patients with a positive response before surgery, which is the case of 70%–80% of patients with Cushing disease. Three studies have examined the prognostic value of desmopressin testing in the early postoperative period in selected patients exhibiting a positive response to desmopressin prior to surgery and who experienced postoperative remission (Romanholi *et al.*, 2008; Losa *et al.*, 2009; Vassiliadi *et al.*, 2016). Overall, the authors found that a positive response of ACTH or cortisol in the early postoperative period was associated with an increased risk of recurrence. However, the specificity and predictive value of the test were found to be low in two studies (Romanholi *et al.*, 2008; Losa *et al.*, 2009) while sensitivity for recurrence was 97% in one study (Vassiliadi *et al.*, 2016). The use of various criteria to define remission and the response to the desmopressin test may explain the discrepancies between these results. Further studies are thus needed to assess the usefulness of the desmopressin test in this setting.

A small proportion of individuals without Cushing disease (mostly obese subjects) may have a mild response to desmopressin, which might thus limit the specificity of the desmopressin stimulation test. It has therefore been suggested that 1 mg of

dexamethasone, administered at midnight prior to the injection of desmopressin at 0800 h (combined dexamethasone-desmopressin test or CDDT), may increase the specificity of the desmopressin test by suppressing normal corticotroph cell activity (Le Marc'hadour *et al.*, 2015). The performance of the CDDT test at 3–6 months after surgery has been compared to that of the desmopressin test and postsurgical morning plasma for the prediction of subsequent recurrence (Le Marc'hadour *et al.*, 2015). The CDDT had a negative predictive value of 93% (meaning that a lack of response may predict sustained remission), while its positive predictive value was only 50%. However, the study involved limited follow-up (3 years) and the patients were not tested preoperatively to exclude nonresponders, thus compromising the performance of the test for recurrence prediction. Overall, the results of this study were rather disappointing, as the CDDT test did not give more insights than the postoperative cortisol level.

In conclusion, there is currently no gold-standard predictor of long-term outcome after surgical treatment of CD that allows initial stratification according to a patient's risk of recurrence, or individualized follow-up in terms of duration and frequency. Life-long follow-up thus remains necessary (Nieman *et al.*, 2015). Although postoperative hypocortisolism does not eliminate the possibility of a recurrence, profound and prolonged postoperative corticotropic insufficiency is found to be a positive prognostic factor in the majority of studies, as well as the lack of recurrence during the 10 years following surgery. Follow-up might therefore be less rigorous for individuals who meet these conditions. Special attention should be paid to patients with postoperative eucortisolism, although this does not inevitably predict a recurrence. Further studies are needed to determine the utility of the desmopressin test.

Follow-Up and Early Diagnosis of Recurrences of Cushing Disease

Glucocorticoid replacement with hydrocortisone at 10–12 mg/m^2/day in two or three divided daily doses, with the first dose taken immediately after waking and the last not after 1700 h, is recommended for patients with postoperative corticotropic insufficiency. Hydrocortisone is preferred to other synthetic glucocorticoids with a longer half-life, as the latter may favor some degree of hypercortisolism, induce HPA axis suppression, and delay recovery of the HPA axis. There is no consensus protocol for assessing recovery of the HPA axis. According to the Endocrine Society (Nieman *et al.*, 2015), the morning plasma cortisol concentration should be measured before the morning intake of hydrocortisone, every 3 months, followed by a short synacthen ACTH stimulation test when the morning cortisol concentration is $\geq$200 nmol/L. A baseline or stimulated concentration of 450 nmol/L or higher in modern assays almost rules out the risk of acute adrenal insufficiency and authorizes the cessation of hydrocortisone replacement. A variety of hydrocortisone tapering and discontinuation strategies are used, including abrupt discontinuation when the function of the HPA axis has recovered, or tapering the dose at fixed intervals (Ragnarsson and Johannsson, 2013).

The cessation of corticotropic insufficiency raises the question as to whether the patient has achieved physiological recovery of the HPA axis or if the cortisol elevation is driven by tumoral corticotrophs indicating disease recurrence. In this perspective, our usual practice is to perform a complete evaluation of the HPA axis at the time of recovery, including at least two 24 h urinary UFC, two LNSC or midnight plasma cortisol, and a 1 mg DST to assess the precise status of the HPA axis and to serve as a new baseline in case of subsequent recurrence. The importance of this evaluation is illustrated in the study by Estrada *et al.* (2001). In a retrospective evaluation of a limited number of patients, these authors showed that patients exhibiting complete normalization of HPA axis function following a transient phase of hypocortisolism (including full suppression following the 1 mg DST, a normal diurnal cortisol rhythm (assessed by midnight plasma cortisol concentration), and a normal response to insulin-induced hypoglycemia) had a very low risk of recurrence as compared to patients with some abnormalities of these parameters (Estrada *et al.*, 2001). Importantly, the two groups of patients with different prognosis had similar morning plasma cortisol and UFC values at the time of the evaluation.

Many strategies have been proposed for the long-term surveillance pattern. However, the variety of test protocols and markers used, the limited number of patients involved in most studies, and the lack of prospective comparative protocols hamper attempts to define an optimal management strategy. It is important to inform the patient that life-long follow-up is necessary, including at least a yearly mandatory examination during the first 10–15 years.

Obviously, follow-up should rely on both clinical and biological investigations. Clinical follow-up is mandatory, as some comorbidities may persist despite biochemical remission or even cure (Ragnarsson and Johannsson, 2013). The clinician should be aware that some comorbidities may take several months or years to resolve (Sippel *et al.*, 2008). It is important to evaluate and treat the long-term sequelae of chronic hypercortisolism to reduce morbidity, improve QOL, and reduce the long-term excess mortality associated with CD (Dekkers *et al.*, 2007; Clayton *et al.*, 2016). The spontaneous clinical course of recurrences following transient remission is poorly documented in the literature. In this author's experience, despite extensive clinical experience in Cushing syndrome, regular monitoring usually identifies the recurrence of biochemical abnormalities before that of clinical symptoms (Danet-Lamasou *et al.*, 2015). Obviously, it is very important for the clinician to note his or her precise findings. Given the multiple clinical symptoms of Cushing syndrome, the development of a pertinent clinical score would be highly useful. Some patients who are exquisitely sensitive to glucocorticoids may experience early recurrence of a particular symptom such as hypertension or hyperglycemia. Elsewhere, some patients are intimately persuaded that their disease has recurred, based on psychological perception of their state during the phase of hypercortisolism. Further biochemical evaluation is warranted in such cases.

Classical biological follow-up relies on the tools used for the diagnosis of Cushing syndrome, such as 24 h UFC and overnight DST. However, several studies suggest that the increase in 24 h UFC is a late marker of CD recurrence and that LNSC, which has proven its usefulness in the diagnosis of mild Cushing syndrome, may be more sensitive for diagnosing recurrences at an early stage. We studied 36 patients in surgical remission of CD after a follow-up of 69.2 $\pm$ 10.6 months and who had successive

measurements of LNSC as well as an extensive biochemical evaluation within 3 months before or after saliva samples (24 h UFC, in-patient midnight plasma cortisol measurement, 1 mg DST, desmopressin test) (Danet-Lamasou *et al.*, 2015). Patients were considered to be in remission when all investigations were normal, and in early-stage recurrence when they had at least two abnormal results, no clinical evidence of recurrence, and a normal or mildly increased UFC (<2 ULN). Interestingly, UFC was normal in 61% of patients at the time of early-stage recurrence, and was mildly elevated ($<2 \times$ ULN) in only 39% of patients, a finding which illustrates that an unequivocal increase in UFC is a late marker of recurrence. In contrast, LNSC was as efficient for depicting early recurrences and correlated with the combined results of the multiple endocrine tests requiring hospitalization. However, owing to the large interindividual variability in LNSC at this period of the disease, three to four saliva samples and a revised threshold were necessary to ensure optimal diagnostic performance. Similarly, in the study by Bou Khalil *et al.* (2011), involving 21 patients with recurrence among a cohort of 101 patients, the increase in midnight cortisol occurred after a mean of 38.2 months, as compared to 50.6 months for the UFC elevation, and LNSC was abnormally elevated in all the patients while UFC was pathological in only 47% of these cases. Similarly, two studies (Carrasco *et al.*, 2008; Amlashi *et al.*, 2015), including a follow-up study in a large cohort of patients (Amlashi *et al.*, 2015), concluded that LNSC identified recurrences with a diagnostic accuracy superior to that of 24 h UFC. These results therefore favor the use of LNSC, a simple and noninvasive test, for the follow-up of patients in remission from CD. Unfortunately, no comparison with the results of the 1 mg DST alone was performed.

Stimulation testing has also been proposed to diagnose recurrences at an early stage. In a retrospective study (Bou Khalil *et al.*, 2011), the desmopressin and CRH tests were positive in respectively 85% and 93% of patients, and a positive response to either test preceded the increase in midnight cortisol or UFC in respectively 71% and 64% of patients. This suggests that a positive response to the desmopressin and/or CRH test occurs early during recurrence, being followed by an increase in midnight cortisol, while UFC elevation occurs at a later stage. Unfortunately, no comparison with the 1 mg DST was made in this series. Another limitation of this study is that the CRH and desmopressin tests were not performed in the group of patients with maintained remission (Bou Khalil *et al.*, 2011). This is important, as a positive CRH response may also be physiological and associated with normalization of HPA axis function. The desmopressin test and above-mentioned CDDT (see the section "Early Prediction of Recurrences of Cushing Disease") have also been evaluated by Castinetti *et al.* for earlier recurrence detection than with conventional hormonal tests (Le Marc'hadour *et al.*, 2015). The results were rather disappointing, however: the desmopressin and CDDT tests had positive predictive values of respectively 20% and 44% and negative predictive values of 72% and 100%. These results suggest that negative tests predict long-term remission more reliably than positive tests detect early recurrence. The limited number of patients studied and the relatively short follow-up hamper definitive conclusions on the usefulness of these investigations, which cannot currently be recommended for general use.

In summary, current knowledge supports life-long follow-up for patients in remission from CD. Individualized follow-up is still difficult to define, owing to problems in accurately stratifying patients at a low versus a high risk of recurrence. In the opinion of the author, surgery in an expert center, followed by a very low early postoperative cortisol level and prolonged corticotropic insufficiency would favor a less rigorous (albeit long-term) follow-up schedule with yearly examinations, while more stringent follow-up (every 6 months) would be preferable for other patients. Similarly, follow-up could be lightened (but not interrupted) after 10–15 years without recurrence. The predictive role of dynamic testing such as the desmopressin test deserves further prospective and comparative studies in large cohorts with lengthy follow-up. Recent publications favor clinical examination and repeated LNSC to diagnose recurrences at an early stage. The results of LNSC screening should be confirmed with accurate clinical examination and other biological investigations commonly used for the diagnosis of Cushing syndrome, although these may be pathological at a later stage. When LNSC is not available, the 1 mg DST test could be proposed for patients without interfering conditions, while 24 h UFC may detect later-stage recurrence. This raises questions as to the optimal treatment for patients experiencing early recurrence with a normal UFC. In a small retrospective "common practice in clinical care" study of 12 patients with mild recurrences diagnosed with the LNSC but a normal UFC (Carroll *et al.*, 2016), a significant clinical improvement was observed in 7 patients after various therapeutic approaches (repeat surgery, pharmacological treatment, or bilateral adrenalectomy). Systematic studies are needed to determine the optimal timing and modalities of therapeutic intervention for recurrent CD.

In conclusion, the best follow-up strategy for early diagnosis of CD recurrence after surgery, as well as well as the clinical effects and benefits/risks of treatment for mild hypercortisolism at the time of early recurrence, is listed in the *Future Directions and Recommended Research* of the 2015 clinical practice guidelines of the Endocrine Society for the treatment of Cushing syndrome (Nieman *et al.*, 2015).

Medical Therapy of Hypercortisolism

Richard A Feelders, Erasmus Medical Center, Rotterdam, The Netherlands

Introduction

Cushing syndrome (CS) is characterized by chronic overproduction of cortisol by the adrenal glands. This chronic state of hypercortisolism results in multisystem morbidity and an increased mortality (Dekkers *et al.*, 2007; Clayton *et al.*, 2011; Newell-Price, 2016). CS is traditionally divided into adrenocorticotropin (ACTH)-dependent CS and ACTH-independent CS (Lacroix *et al.*, 2015). ACTH-dependent CS which accounts for approximately 80% of cases, is most frequently caused by an ACTH-producing pituitary adenoma (≈70%) and, more rarely, by ectopic ACTH production (≈10%). ACTH-independent CS is caused by neoplasia of the adrenal gland. This involves most frequently a benign unilateral adrenal adenoma and more rarely bilateral micro- or macronodular adrenal hyperplasia or a cortisol producing adrenal carcinoma (Lacroix *et al.*, 2015).

The morbidity of CS includes major changes in body composition, alterations in other endocrine systems, important neuropsychiatric disturbances, clustering of cardiovascular risk factors and an increased thromboembolic risk (Lacroix *et al.*, 2015). Mortality is increased in untreated or suboptimally treated CS with cardiovascular disease as leading cause of death (Plotz *et al.*, 1952; Dekkers *et al.*, 2007; Clayton *et al.*, 2011; Newell-Price, 2016). In order to reverse morbidity and mortality in CS, treatment should aim to completely normalize cortisol production. The first-line treatment of all forms of CS is surgery. However, other treatment modalities including medical therapy, radiotherapy and bilateral adrenalectomy are necessary when surgery is not successful or not indicated in case of a high surgical risk or metastatic disease (Nieman *et al.*, 2015). This article will focus on medical therapy for CS with discussion of indications for medical therapy, the currently available drugs and recent developments in medical therapy. Because most studies on medical therapy have been performed in patients with Cushing disease (CD) the emphasis will be on drug therapy for corticotroph pituitary adenomas.

Indications for Medical Therapy in CS

There are subgroups of CS patients in whom medical therapy is (potentially) indicated: (1) in patients with CD medical therapy can be given after unsuccessful pituitary surgery, whether or not as bridging therapy during the period before radiotherapy becomes effective. In some CD patients primary medical therapy can be considered, for example, patients with a high surgical risk or patients with a nonvisible adenoma. Preoperative cortisol-lowering therapy is applied in some centers aiming to improve patient's condition and morbidity (e.g., diabetes, hypertension) and to prevent bleeding tendency during operation. However, to date there is no evidence yet that pretreatment reduces complications and improves surgical outcome; (2) patients with metastatic disease due to an ACTH producing neuroendocrine tumor or an cortisol producing adrenal carcinoma in whom surgery is not an option; (3) adrenal CS patients who are awaiting surgery or who have bilateral disease; and (4) patients with all forms of CS who present with acute complications of (severe) cortisol excess, for example. psychosis, severe hypertension and (opportunistic) infections (Feelders and Hofland, 2013).

Drug Categories for Medical Treatment of CS

Drugs for treatment of CS can be divided into three categories: (1) adrenal blocking drugs that suppress adrenal cortisol production via inhibition of steroidogenic enzymes; (2) pituitary-targeting drugs that inhibit ACTH production by the corticotroph adenoma; and (3) glucocorticoid receptor (GR) antagonists which block the GR and counteract the effects of cortisol at tissue level (Feelders and Hofland, 2013). The efficacy and side effects of the various drugs (**Table 1**.) as well as recently developed compounds within these drug categories will be discussed in the following sections.

Adrenal Blocking Drugs

Adrenal blocking drugs interfere with steroidogenic enzymes at different steps in the pathway of adrenal steroid hormone production. Ketoconazole and metyrapone are most widely used for this purpose (Daniel *et al.*, 2015). Ketoconazole suppresses many steroidogenic enzymes whereas metyrapone mainly inhibits the last step in cortisol synthesis by targeting 11-β-hydroxylase. The efficacy of both drugs in CS is comparable with normalization of cortisol production in approximately 50%–70% of patients, although efficacy data can only be obtained from retrospective studies (Castinetti *et al.*, 2014; Daniel *et al.*, 2015). Main side effects of ketoconazole are gastrointestinal complaints, hepatotoxicity and male hypogonadism, whereas metyrapone can cause gastro-

 doi:10.1016/B978-0-12-801238-3.64356-8

Table 1 Drugs for treatment of Cushing syndrome: dosage and side effects

Category	*Drug*	*Dosage*	*Main side-effects*
Adrenal blocking drugs	Ketoconazole	400–1600 mg/day	Hepatotoxicity, gynecomastia, gastrointestinal complaints, male hypogonadism
	Metyrapone	0.5–4.5 g/day	Dizziness, rash, gastrointestinal discomfort, worsening of hypertension, acne and hirsutism
	Mitotane	3–5 g/day	Gynecomastia, hepatotoxicity, hypercholesterolemia, prolonged bleeding time, gastrointestinal complaints, dizziness, ataxia, confusion, dysarthria, disturbed memory
	Etomidate	0.1–0.3 mg/kg/h	Nephrotoxicity
Pituitary targeting drugs	Cabergoline	0.5–7 mg/week	Headache, dizziness, gastrointestinal discomfort
	Pasireotide sc Pasireotide LAR	750–2400 μg/day 10–30 mg/month	Hyperglycemia, gastrointestinal complaints, cholelithiasis
Glucocorticoid receptor antagonists	Mifepristone	300–1200 mg/day	Hypokalemia, worsening of hypertension, clinical adrenal insufficiency, endometrial hyperplasia, gastrointestinal complaints

intestinal upset, and less frequently worsening of hirsutism and mineralocorticoid effects (hypertension, hypokalemia, and edema) (Daniel *et al.*, 2015).

Mitotane also inhibits multiple steroidogenic enzymes and has adrenolytic effects. For these properties it is mainly used for the treatment of adrenal carcinoma, aiming to suppress both steroid hormone production and cell growth (Baudry *et al.*, 2012). Considering the serious gastrointestinal, neurological and metabolic side effects it is not widely used for other forms of CS. Etomidate is an anesthetic drug that potently inhibits 11-β-hydroxylase and can only be administrated in an intensive care setting. It might, however, be useful in CS patients with life-threatening complications of severe hypercortisolism (Daniel *et al.*, 2015).

Two new adrenal blocking drugs are currently under investigation. Osilodrostat (LCI699) is a potent inhibitor of 11-β-hydroxylase and two pilot studies showed an efficacy, in terms of normalization of 24 h urinary cortisol excretion (UFC), between 79% and 92% (Bertagna *et al.*, 2014; Fleseriu *et al.*, 2016). Osilodrostat was generally well tolerated, main side effects were gastrointestinal complaints, hirsutism and hypocortisolism. Efficacy and safety of osilodrostat are currently evaluated in large multicenter trials. Ketoconazole is a racemic mixture of two enantiomers (2S,4R and 2R,4S). Levoketoconazole (COR-003) is the single 2S,4R enantiomer which may have two advantages over ketoconazole, that is, it may more potently inhibit steroidogenic enzymes and it seems to be less hepatotoxic (Rotstein *et al.*, 1992; Schwartz *et al.*, 2008; Thieroff-Ekerdt and Mould, 2016). Also levoketoconazole is studied in an ongoing large multicenter trial.

Adrenal blocking drugs can be effective in all forms of CS. All patients treated with these drugs should be carefully monitored, clinically and biochemically, for development of hypocortisolism.

Within the entity of adrenal CS the identification of G-protein coupled receptors (GPCR) and intra-adrenal ACTH production in bilateral macronodular adrenal hyperplasia (BMAH) offers new potential targets for medical treatment. BMAH often over-express eutopic or ectopic GPCR, for example, the receptors for luteinizing hormone, glucose-dependent insulinotropic peptide and vasopressin, with aberrant regulation of cortisol production by their ligands (El Ghorayeb *et al.*, 2015). Pharmacological treatment with blockade of these receptors or with inhibition of endogenous ligand production can successfully control cortisol production in selected patients (El Ghorayeb *et al.*, 2015). Recently it was shown that ACTH can be produced locally in BMAH tissue and can stimulate cortisol production in an autocrine or paracrine manner (Louiset *et al.*, 2013). ACTH receptor antagonists are in development (Halem *et al.*, 2016) and may be a medical treatment option for BMAH in the future.

Pituitary-Targeting Drugs

Pituitary-targeting drugs aim to inhibit ACTH production by the corticotroph adenoma. Somatostatin and dopamine receptors are both GPCR expressed by corticotroph tumors and in particular somatostatin receptor subtype 5 (SST5) and dopamine receptor subtype 2 (DA2) are important targets for medical therapy for CD (Feelders and Hofland, 2013).

Pasireotide is a somatostatin analog with a high affinity for SST5 and has been evaluated for treatment of CD in several clinical trials. In a randomized phase III clinical trial 162 patients with CD, were treated with subcutaneous (sc) pasireotide at a dose of 600 μg and 900 μg bid (Colao *et al.*, 2012). On average, UFC decreased by 48% after 6 months and UFC levels completely normalized in 15% and 26% of patients treated with lower and higher dose, respectively. Parallel with the decrease in UFC, clinical symptoms improved like body weight and blood pressure as well as quality of life. Interestingly, corticotroph tumor volume decreased in a subset of patients (Colao *et al.*, 2012). Most important side effect of pasireotide is induction or worsening of hyperglycemia via inhibition of incretin and insulin secretion (Henry *et al.*, 2013). A recent 12 months randomized trial evaluated the efficacy of long-acting pasireotide in 150 patients. With a monthly dose of both 10 and 30 mg pasireotide, normalization of

UFC was achieved in approximately 40% of patients after 7 months (Lacroix *et al.*, 2018). Pasireotide is officially approved for treatment of patients with CD for whom surgery is not an option.

Cabergoline is a potent DA2 agonist and several retrospective studies indicate that cabergoline can induce biochemical remission in approximately 30% of patients, although escapes do occur at the long term (Pivonello *et al.*, 2009; Godbout *et al.*, 2010; Ferriere *et al.*, 2017). Most important side effects of cabergoline include headache, nausea and postural hypotension.

Next to drugs targeting GPCR, the nuclear receptor ligand retinoic acid can inhibit ACTH secretion by corticotroph adenomas. Two small studies showed that retinoic acid can normalize UFC excretion in a subset of patients (Pecori Giraldi *et al.*, 2012; Vilar *et al.*, 2016).

An apart entity within CD includes aggressive corticotroph tumors that show invasive growth. The chemotherapeutic drug temozolomide can be useful in these patients to stabilize or reduce tumor size and to decrease ACTH secretion (Raverot *et al.*, 2012).

Several new potential targets in corticotroph tumor cells for medical treatment have been identified like the epidermal growth factor receptor (EGFR) (Fukuoka *et al.*, 2011), cyclin-dependent kinases (CDK) (Liu *et al.*, 2015) and heat shock protein 90 (HSP90) (Riebold *et al.*, 2015). Corticotroph tumor cells express the EGFR and ligand binding results in increased ACTH secretion in vitro (Fukuoka *et al.*, 2011). Recently it was shown that in approximately one third of corticotroph adenomas a mutation is present in the gene encoding for the deubiquitinase USP8 (Perez-Rivas *et al.*, 2015; Reincke *et al.*, 2015). Due to this mutation the activity of USP8 is enhanced leading to increased deubiquitination of the EGFR which prevents lysosomal degradation. As a result, EGFR signaling is increased in these corticotroph adenomas (Perez-Rivas *et al.*, 2015). The tyrosine kinase inhibitor gefitinib targets the EGFR and was demonstrated to inhibit ACTH secretion and tumor growth in vitro (Fukuoka *et al.*, 2011) and its efficacy in vivo is currently evaluated in a clinical study.

In corticotroph tumor cells CDK are involved in regulation of cell growth and expression of proopiomelanocortin (POMC). R-roscovitine is an CDK inhibitor and in experimental animal models this compound suppresses cell growth and POMC expression (Liu *et al.*, 2011, 2015). R-roscovitine is currently investigated in patients with CD.

Recently it was shown that HSP90 expression is increased in corticotroph tumor cells (Riebold *et al.*, 2015). HSP90 can capture the GR, preventing binding to its ligand. Because only the GR-glucocorticoid complex can exert transrepressive effects on gene (e.g., POMC) transcription, increased HSP expression is thought to cause glucocorticoid resistance. Inhibitors of HSP90 suppressed cortisol production and corticotroph cell proliferation in in vitro- and experimental animal models (Riebold *et al.*, 2015; Sugiyama *et al.*, 2015). To date, no clinical studies have been performed with HSP90 inhibitors in CD.

Glucocorticoid Receptor Antagonists

GR antagonists counteract the effects of cortisol at tissue level by blocking the GR. At present, mifepristone is the only GR antagonist available for clinical use. Mifepristone has a rapid onset of action and can be useful in patients who present with acute complications, for example, psychosis, of (severe) cortisol excess (Castinetti *et al.*, 2012). Mifepristone was demonstrated to improve blood pressure and glycemic regulation in patients with CS (Fleseriu *et al.*, 2012) and is approved in the US for treatment of CS patients with dysregulated diabetes mellitus who are no candidates for surgery. Currently no biochemical parameter is available to adjust the dose of mifepristone. Consequently, patients are at risk to develop clinical adrenal insufficiency in case of overtreatment. Furthermore, mifepristone interferes with negative feedback via the GR on the corticotroph adenoma which can result in increased ACTH and concomitantly increased cortisol production. Increased cortisol levels, in turn, can induce or worsen mineralocorticoid effects, that is, hypokalemia, hypertension and edema. Mifepristone not only antagonizes the GR but also the progesterone receptor. Therefore, during chronic treatment female patients should be monitored for development of endometrial hyperplasia (Castinetti *et al.*, 2012).

CORT125134 (relacorilant) is a new GR antagonist that selectively binds to the GR without anti-progesterone receptor effects (Hunt *et al.*, 2017). This new compound is currently evaluated in a phase II study (NCT02804750).

Combination Therapy

Patients with moderate to severe hypercortisolism usually need medical combination therapy to achieve complete biochemical remission. One study showed that a combination of ketoconazole, metyrapone and mitotane was effective in patients with severe, complicated CS and could prevent a rescue bilateral adrenalectomy (Kamenicky *et al.*, 2011). Combining drugs may also have synergistic effects. For instance, simultaneous targeting of SST5 and DA2 may result in enhanced signaling (Rocheville *et al.*, 2000). Two studies show that stepwise addition of cabergoline to pasireotide almost doubled the number of patients with controlled cortisol production (Feelders *et al.*, 2010, 2017). Combination of drugs may also allow for lower dosages of individual compounds with a potentially lower chance on developing side effects. For instance, combination of cabergoline and low dose ketoconazole was well tolerated and effective in a subset of patients (Vilar *et al.*, 2010; Barbot *et al.*, 2014).

Concluding Remarks

Medical therapy is an important treatment modality in patients with CS for whom surgery is not an option. Drugs to treat CS can be categorized into adrenal blocking drugs, pituitary targeting drugs and glucocorticoid receptor antagonists. In each patient medical therapy should be given in a tailor-made approach taking several factors into account including patient characteristics, severity of hypercortisolism, drug efficacy and (potential) side effects and drug availability and costs. It should be emphasized that treatment should completely normalize cortisol production in order to reverse morbidity and mortality. For this purpose medical combination therapy is often required.

Radiation Therapy in Patients With Cushing Disease

Nicholas A Tritos, Jay S Loeffler, and Beverly MK Biller, Massachusetts General and Harvard Medical School, Boston, MA, United States

Overview

Cushing disease (CD) is associated with substantial morbidity and mortality, which can be mitigated by achieving prompt control of hypercortisolism (Cushing, 1932, 1969; Nieman *et al.*, 2015). The initial treatment of choice in most patients with CD is transsphenoidal pituitary surgery (TSS), performed by an experienced pituitary neurosurgeon (Nieman *et al.*, 2015; Swearingen *et al.*, 1999). However, persistent or recurrent CD may occur in about 10%–20% and 20%–30% of patients, respectively, thus necessitating additional therapies (Swearingen *et al.*, 1999; Tritos *et al.*, 2011; Patil *et al.*, 2008). A second TSS can be an effective option in controlling cortisol excess in approximately 50%–60% of patients (Nieman *et al.*, 2015).

Radiation therapy to the sella is often recommended as adjunctive treatment in patients with CD who have active disease after TSS (Loeffler and Shih, 2011; Pashtan *et al.*, 2014). In rare cases, radiation therapy can be used as primary therapy in patients who are not surgical candidates. Radiation therapy is effective in preventing tumor growth and controlling hypercortisolism in the majority of treated patients, but requires time to take effect, generally ranging between several months to a few years (Loeffler and Shih, 2011; Pashtan *et al.*, 2014). In the interim, treated patients require medical therapy to control hypercortisolism (Tritos and Biller, 2014).

The aims of the present article are to review radiation therapy modalities used to treat CD and discuss patient outcomes with regards to efficacy and safety. To retrieve articles used in this review, computerized literature searches were conducted using the terms "Cushing disease" or "Cushing syndrome," "radiosurgery," "radiation therapy," "radiotherapy." Pertinent articles were retrieved and considered for inclusion in this article, based on authors' judgment.

Radiation Therapy Modalities and Techniques

Radiation therapy to the sella has been conventionally administered in fractions (typically 45–54 Gy in 25–30 sessions, delivering 1.8–2 Gy per fraction) (Loeffler and Shih, 2011). Using conventional techniques, dose fractionation is required to minimize radiation-induced injury to off-target structures, including the optic chiasm, other cranial nerves, the cochlea and the brain. Although effective, this approach is somewhat inconvenient to patients, as it necessitates daily (weekday) visits over a 5–6 week period.

Stereotactic radiation therapy techniques, also known as stereotactic radiosurgery (SRS), were developed to deliver a single, high dose of radiation (typically ranging between 12 and 35 Gy) to the tissue target in an extremely precise and accurate manner that minimizes radiation exposure to surrounding healthy tissues (Loeffler and Shih, 2011). Dose fractionation is also possible using stereotactic treatment modalities. Stereotactic techniques include the Gamma Knife™ (Elekta, Stockholm, Sweden) and linear accelerator-based treatment options (including the Cyberknife™ (Accuray, Sunnyvale, CA)), each of which deliver photon-based radiation therapy. Other stereotactic techniques employ proton beams or helium beams, which deliver positively charged particles.

Advanced methods in therapy planning and radiation beam shaping are required to achieve high tissue selectivity, which maximizes delivery of radiation to the intended target while minimizing exposure of healthy structures (Pashtan *et al.*, 2014). In addition, the physical properties of charged particle beams (made up of protons or helium nuclei) are instrumental in achieving selective delivery of radiation to target tissues. Charged particle beams deliver most of their energy at a predetermined tissue depth, known as the "Bragg peak," which can be designed to deposit almost the entire particle energy within the target area with essentially zero exit dose, thus minimizing radiation exposure to healthy tissues (Pashtan *et al.*, 2014).

The obvious advantage of SRS over conventional radiation therapy is greater convenience for patients, who typically receive this type of radiation therapy in a single treatment session. It also appears that endocrine remission may occur sooner after SRS in comparison with conventional radiation therapy (based on comparisons with historic data) (Sheehan *et al.*, 2005). Stereotactic techniques optimize radiation delivery to the tumor (target tissue) while sparing healthy, radiosensitive structures, including the optic chiasm, other cranial nerves, the cochlea or the brain. This selectivity would be predicted to translate into a more favorable long-term safety profile. However, large studies of long duration are needed to establish this conjecture with certainty.

Treatment Planning and Delivery

The choice between treatment modalities used to deliver radiation therapy obviously depends on local equipment availability. Proton beam facilities are very expensive to set up and maintain, which has limited the use of this technique to a relatively small

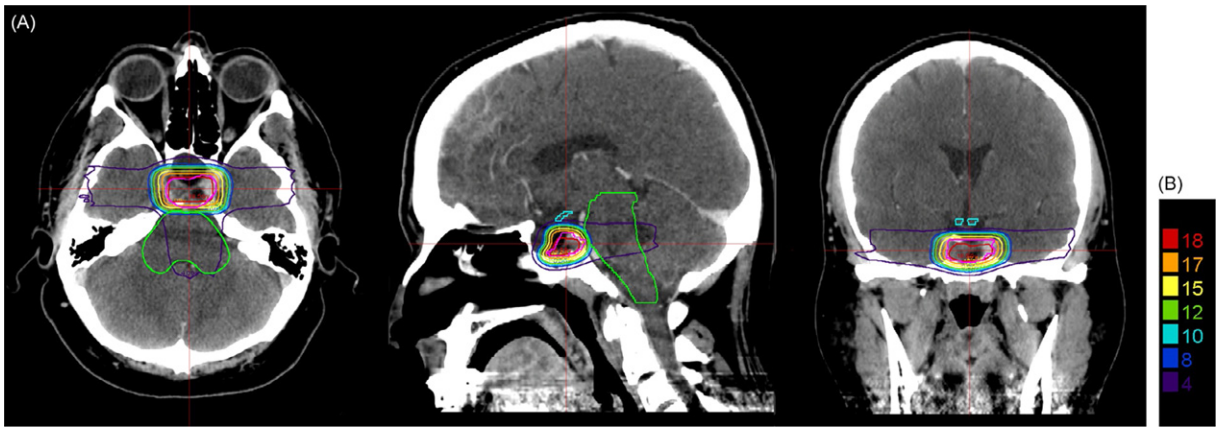

Fig. 1 Stereotactic proton beam radiation therapy plan in a patient with Cushing's disease (panel A). Color codes for isodose lines are shown in legend (panel B).

number of centers. Whenever possible, use of stereotactic techniques is advisable because of the potential advantages of these treatment modalities, as outlined above.

Using SRS, it is advisable to limit the radiation dose to the chiasm below 8–10 Gy, which is crucial in order to minimize the risk of optic neuropathy (Mayo *et al.*, 2010). However, administration of radiation therapy in a single fraction (SRS) is not always possible, depending on tumor size, geometry and its proximity to radiosensitive structures (such as the optic apparatus). In general, patients with pituitary adenomas larger than 3 cm or those that are closer than 3–5 mm to the optic chiasm are not good candidates for single dose therapy (i.e., SRS) because of increased risk of complications (Pashtan *et al.*, 2014). These patients may still be treated with fractionated therapy, which is considered to be safer and may also be delivered via stereotactic techniques. Use of a fraction size of 1.8–2 Gy per day is associated with a lower risk of optic neuropathy in comparison with a higher dose per fraction (Mayo *et al.*, 2010).

During treatment planning, high resolution, cross-sectional imaging data are used to identify the target and establish a treatment plan by means of dedicated software. An example of a treatment plan depicting isodose radiation curves in the case of a patient receiving proton beam radiation therapy to the sella is shown in **Fig. 1**.

Accurate patient positioning is critical in patients receiving SRS. A thermoplastic face mask is created to help position and immobilize the patient's head during conventional radiation therapy. A higher degree of precision in head positioning is required during SRS and is achieved with a variety of methods, including use of a positioning frame secured to the skull by means of implanted pins (fiducial markers), a custom-made bite piece and/or high-precision image guidance (Pashtan *et al.*, 2014).

In patients receiving SRS using Gamma Knife™, the head is immobilized in a metal helmet that bears >200 collimated bores that focus radiation emanating from cobalt 60 sources to the target (Loeffler and Shih, 2011; Pashtan *et al.*, 2014). Use of multiple non-coplanar radiation beams helps optimize target selectivity in patients receiving Gamma Knife™ or proton beam therapy. In patients treated with the Cyberknife™, the treatment gantry rotates around the patient's head to deliver radiation beams from different angles during the session.

Outcomes of Patients With Cushing Disease Who Received Radiation Therapy

As already noted, radiation therapy to the sella is generally recommended as adjunctive therapy in patients who have persistent or recurrent hypercortisolism after undergoing TSS and are not candidates for additional pituitary surgery (Loeffler and Shih, 2011; Nieman *et al.*, 2015; Pashtan *et al.*, 2014). Other candidates for radiation therapy include patients with CD who have residual or enlarging corticotroph tumors after TSS (Loeffler and Shih, 2011; Nieman *et al.*, 2015; Pashtan *et al.*, 2014). Patients who receive radiation therapy require medical therapy to control hypercortisolism until the salutary effects of radiation therapy occur (usually for a period ranging between several months to several years) (Tritos and Biller, 2014).

Several retrospective or prospective studies have reported on the outcomes of patients with CD who underwent radiation therapy (**Table 1**) (Littley *et al.*, 1990; Levy *et al.*, 1991; Murayama *et al.*, 1992; Tsang *et al.*, 1996; Estrada *et al.*, 1997; Witt *et al.*, 1998, Laws and Vance, 1999; Sheehan *et al.*, 2000; Kobayashi *et al.*, 2002; Jane *et al.*, 2003; Devin *et al.*, 2004; Colin *et al.*, 2005; Castinetti *et al.*, 2007; Jagannathan *et al.*, 2007; Minniti *et al.*, 2007; Petit *et al.*, 2008; Wan *et al.*, 2009; Sheehan *et al.*, 2013; Budyal *et al.*, 2014; Wilson *et al.*, 2014; Wattson *et al.*, 2014; Marek *et al.*, 2015; Cohen-Inbar *et al.*, 2016; Mehta *et al.*, 2017). These case series presented the outcomes of patients treated with a single treatment modality (either conventional radiation therapy or various SRS options) and did not include a patient control group. Tumor control, defined as either lesion stability or regression, was achieved in 83%–100% of patients after radiation therapy. Biochemical control of hypercortisolism, which was most often defined as normal 24 h urine free cortisol with or without normal plasma ACTH levels (in the absence of concurrent medical

[e]Tumor control was defined as lack of progression (that is, either stability or regression); NR: not reported.

therapy) or, less often, as normal cortisol response on 1 mg dexamethasone suppression testing, was variably reported in 22%–86% of patients after radiation therapy in different series. There are no published data on late night salivary cortisol levels in patients with CD who received radiation therapy. Based on historical comparisons, it appears that the interval between

administration of radiation therapy and achievement of control of cortisol excess may be shorter in patients who received SRS than those who were administered conventional fractionated radiation therapy (Sheehan *et al.*, 2005). However, published studies directly comparing two treatment modalities in a head to head manner are lacking.

Some data have suggested that endocrine remission is delayed or decreased in subgroups of patients with CD who have been receiving concurrent medical therapy at the time radiation therapy has been administered (Sheehan *et al.*, 2013; Castinetti *et al.*, 2007). These findings have raised the possibility that concomitant medical therapy may blunt the effects of radiation therapy to the sella. On the basis of these data, it has been suggested that medical therapy be withdrawn for several weeks before administration of radiation therapy to the sella. However, allocation to concurrent medical therapy was not random in these studies. It is possible that patients who received medical therapy at the time radiation therapy was administered had more severe hypercortisolism at baseline. Thus, confounding by indication is another possible explanation for these observations. As a corollary, additional research is needed to fully elucidate this issue.

Recurrence of hypercortisolism may occur in a minority of patients who achieved endocrine remission after the administration of radiation therapy. In one study of 96 patients who received SRS (Gamma knife™), remission occurred in 70% at a median time interval of 16.6 months. Subsequently, biochemical recurrence developed in 15 patients at a median time interval of 38 months (Sheehan *et al.*, 2013). In a recent multicenter study of 278 patients with CD, recurrence of hypercortisolism developed in 18% of patients who had initially achieved remission (Mehta *et al.*, 2017). Clearly, all patients with CD require lifelong follow-up in order to establish long-term outcomes.

Safety

Patients who have received radiation therapy to the sella are at long-term (likely lifelong) risk of anterior hypopituitarism (Pashtan *et al.*, 2014). In these patients, the normal pituitary gland is very close to the tumor target, thus imparting a substantial risk of radiation-induced damage to anterior pituitary function. The risk of anterior hypopituitarism appears to be comparable in patients who have received either conventional radiation therapy or SRS (Pashtan *et al.*, 2014). Between 20% and 60% of patients who received radiation therapy developed one or more anterior pituitary hormone deficits at 5 years after treatment in different series (Estrada *et al.*, 1997; Minniti *et al.*, 2007; Sheehan *et al.*, 2005). Up to 85% of patients developed evidence of anterior hypopituitarism at 15 years after radiation therapy (Minniti *et al.*, 2007).

Radiation-induced optic neuropathy or other cranial neuropathies may also occur in 1%–3% of patients (Brada *et al.*, 1993; Sheehan *et al.*, 2005; Mehta *et al.*, 2017). Proper treatment planning aimed at limiting radiation exposure to the radiosensitive chiasm and optic nerves can help minimize the risk of optic neuropathy. Specifically, maintaining a dose limit to the optic chiasm of $<$8–10 Gy during SRS or 45–55 Gy (administered in 1.8–2 Gy fractions) in patients receiving fractionated therapy helps minimize the risk to vision (Mayo *et al.*, 2010).

Conventional radiation therapy has been associated with a delayed risk of stroke, presumed to occur as a long-term consequence of irradiation of the major blood vessels in the circle of Willis and/or internal carotid arteries. Such cerebrovascular events have been reported in 4% of patients at 5 years after conventional fractionated radiation therapy, with cumulative risk rising further over time (Brada *et al.*, 1999). It is hoped that SRS and proton beam radiation therapy will prove to be associated with a lower risk of stroke; data regarding this endpoint are not yet available.

Other infrequent risks of radiation therapy include temporal lobe necrosis (rare) and secondary tumor formation (including meningiomas and sarcomas, reported in 1%–3% of patients at 20 years after radiation therapy) (Minniti *et al.*, 2005; Sheehan *et al.*, 2005). Thus far, these events have only been reported in patients who have received conventional fractionated radiation therapy but have not yet been described after SRS. With the advent of modern planning techniques, stereotactic approaches and proton beam radiation therapy, it is anticipated that the risks of these events will prove to be extremely low in the modern era. However, long-term studies of adequate size are needed in order to reliably estimate the risk of such delayed and infrequent potential adverse outcomes.

Summary

Radiation therapy is an effective treatment option in CD. It is generally recommended for patients who have persistent or recurrent hypercortisolism and/or residual or growing tumor after undergoing TSS, and are not considered candidates for additional pituitary surgery. Since there is a latency period after the administration of radiation therapy until hypercortisolism is controlled, medical treatment is required as a "bridge" intervention.

The advent of modern treatment planning techniques, SRS and proton therapy helps minimize untoward radiation exposure of the normal brain and other radiosensitive structures, including the optic apparatus. All patients who received radiation therapy to the sella are at lifelong risk of anterior hypopituitarism and possibly of neurologic sequelae, and require long-term follow-up.

Bilateral Adrenalectomy for Cushing Disease

Frederic Castinetti, Aix Marseille University, Marseille, France

Introduction

Cushing disease is a rare condition due to an adrenocorticotropin hormone (ACTH)-secreting pituitary adenoma, leading to hypercortisolism. A chronic or acute increase in the cortisol level leads to a high number of clinical signs, hypertension, diabetes, osteoporosis, and depression. This explains why an optimal management of this condition is mandatory. Bilateral adrenalectomy is now still considered as the ultimate therapeutic option in Cushing disease, probably because the "primum non nocere" paradigm is always considered by physicians who prefer to avoid adrenal insufficiency (Lacroix *et al.*, 2015). This is why the majority of endocrinologists now prefer to use long-term medical treatments aimed at controlling cortisol hypersecretion: such treatments, as we shall discuss later, have their own drawbacks. The aim of this review is to clarify the potential roles of bilateral adrenalectomy in the management of Cushing disease.

Since the first description of bilateral adrenalectomy in 1936 (Young, 1936), several technical advances have been done, the most important being laparoscopy about 25 years ago. Gagner *et al.* reported their experience of laparoscopic adrenalectomy in three patients, one with unilateral adrenal adenoma, one with a pheochromocytoma, and the last with failed transsphenoidal surgery leading to bilateral adrenalectomy. In this latter case, the operative time was 3.5 h for both adrenalectomies, and the patient could be discharged on the third postoperative day, receiving supplementation by hydrocortisone and fludrocortisone (Gagner *et al.*, 1992). The original approach was slightly modified by posterior retroperitoneoscopy or robot-assisted bilateral adrenalectomy (Lan *et al.*, 2015; Raffaelli *et al.*, 2014), but the major principles remained the same. The side effects are rarely severe with a mortality $<3\%$, and an overall morbidity of $<20\%$ (Reincke *et al.*, 2015; Ritzel *et al.*, 2013). The per-operative complications are more frequently due to the hypercortisolic state, when still present at the time of surgery, than the surgery per se.

Merits and Pitfalls of Bilateral Adrenalectomy in the Context of Insidious Cushing Disease

The Natural History and Management of Cushing Disease

Cushing disease is one of the most challenging diseases for endocrinologists. Most of the time, the diagnosis will be confirmed only after several years of general complaints, including weight gain, depression, fatigue, badly controlled hypertension, diabetes, etc. This progressively evolving hypercortisolic state will be named classical Cushing disease in this section, by opposition with rapidly evolving hypercortisolic states, named severe hypercortisolism in the following section.

In classical Cushing disease, transsphenoidal surgery is considered as the first-line treatment: in experienced hands, it can lead to remission in up to 80% cases (Nieman *et al.*, 2015). However, even in patients with reassuring postoperative predictive factors, recurrence can be observed in up to 30% of patients (Patil *et al.*, 2008). As Cushing disease is frequently due to micro or picoadenoma (and surgery can sometimes be performed in patients with negative pituitary MRI), it is expected that the majority of patients will present recurrence and negative magnetic resonance imaging (MRI), excluding the possibility to perform radiation techniques. At that stage, the pituitary staff usually have to decide between lifelong medical treatment, transient medical therapy while awaiting for radiological signs of tumor recurrence, or bilateral adrenalectomy. Medical treatment will not be detailed as it is not the aim of this article. Endocrinologists should, however, keep in mind the difficulties of ascertaining eucortisolism in patients treated with drugs lowering cortisol or ACTH: as there is currently no perfect biological marker of eucortisolism, it is indeed difficult to be sure that such patients will not present mild hyper or hypocortisolism on a long-term basis, leading to long-term comorbidities (Petersenn *et al.*, 2014). Such treatments can also present more or less severe side effects (liver enzymes increase, worsening of hypertension or hypokalemia, diabetes, etc.) that require a close follow-up. The treatments cannot cure the patient, and escape after initial control can be observed in up to 10%–20% of cases. Altogether, these treatments usually allow control of hypersecretion in roughly 50% of cases. This rate has to be compared with the efficacy of bilateral adrenalectomy, and the expected side effect of the surgical procedure, that is, adrenal insufficiency.

Control of Hypercortisolism by Bilateral Adrenalectomy and the Risk of Recurrence

While one should expect 100% cure after bilateral adrenalectomy for Cushing disease, the overall efficacy is probably a little lower, as few cases of recurrence have been reported in four different studies. However, it is difficult to determine whether these "recurrences" were true clinical recurrences, or only slightly higher than expected levels of cortisol. Nagesser *et al.* reported that 27% of 44 patients treated by bilateral adrenalectomy had early morning cortisol levels >50 nmol/L, in favor of persistent adrenal tissue; however, only 4.5% presented significant clinical recurrence (Nagesser *et al.*, 2000). These numbers were close to the ones reported by three other studies, in which the risk of recurrence was close to 2% (Chalmers *et al.*, 1981; Chow *et al.*, 2008; Kemink *et al.*, 1992). Most of the time, the recurrence will be due to incomplete first surgery, with recurrence happening a few years after

Table 1 Recurrence of adrenal remnants after bilateral adrenalectomy reported in the literature

First author, year	*Patients*	*Persistent adrenal tissue*	*Significant clinical recurrence*	*Time to recurrence*	*Subsequent treatment*
Chow *et al.* (2008)	68	NA	2 (2.9%)	Not cured immediately after surgery	Follow-up without treatment
Nagesser *et al.* (2000)	44	12 (27.3%)	2 (4.5%)	Early relapse	Additional surgery allowing cure ($n = 1$), follow-up without treatment ($n = 1$)
Kemink *et al.* (1992)	50	9 (18%)	1 (2%)	9 years	Transsphenoidal surgery
Chalmers *et al.* (1981)	5[a]	5	4	1, 2, 3, and 7 years after the surgery	Recurrence of Cushing's disease, pituitary radiotherapy, 5 months and 5 years later ($n = 2$); pituitary radiotherapy ($n = 2$); still in remission 4 years after glucocorticoid withdrawal ($n = 1$)
Pooled data (95% confidence interval)	162	23% (15–32%)	3.8% (1.4–7.3%)	—	—

[a]Five isolated case reports from five different centers (from Guerin *et al.*, 2016).

the procedure, because of the persistent stimulation of the adrenal tissue by ACTH. In rare cases, recurrence (or failed surgery) will be due to ectopic adrenal tissue. From a practical viewpoint, recurrence should be looked for in a patient presenting with persistent signs of cortisol overexposure, despite progressively lowering the dose of hydrocortisone, especially if postsurgical cortisol level is superior to 50 nmol/L. The main studies reporting this risk of recurrence are summarized in **Table 1** (from Guerin *et al.*, 2016).

The Risk of Nelson Syndrome After Bilateral Adrenalectomy

Nelson syndrome was first reported in 1958: skin hyperpigmentation, increased ACTH, and pituitary tumor were shown in a woman who had been treated by bilateral adrenalectomy a few years earlier. These three symptoms now represent the definition of Nelson syndrome, which might be due to either the loss of negative feedback of cortisol on the production of corticotropin releasing hormone (CRH) and ACTH, or independent tumor progression (Azad *et al.*, 2015). The possibility of developing Nelson syndrome has long been considered the major restraint for treating patients with bilateral adrenalectomy. This is likely because prior to introduction of MRI, pituitary imaging was not truly effective (cranial X-ray); the diagnosis of Nelson syndrome was made when the situation was already critic. This also led to prophylactic pituitary radiotherapy in patients treated with bilateral adrenalectomy. Novel imaging modalities with pituitary MRI allowed a close follow-up of patients after bilateral adrenalectomy, making unnecessary systematic pituitary radiotherapy (Assie *et al.*, 2007). Nelson syndrome prevalence is thought to be between 10% and 50% of patients treated by bilateral adrenalectomy for Cushing disease. The risk increases when an adenoma remnant is visualized before bilateral adrenalectomy, and when ACTH levels increase considerably during the first year after bilateral adrenalectomy. When Nelson syndrome is diagnosed, several therapeutic options can be used: transsphenoidal surgery, radiation techniques, cabergoline, or Pasireotide. Temozolomide has also been used successfully in a rapidly progressive pituitary remnant (Azad *et al.*, 2015). As previously mentioned, performing regular imaging allows the identification and rapid treatment of a progression in size of the remnant. As no large series has ever been reported showing the superiority of these different therapeutic options, the decision will have to be taken by expert pituitary staff.

The Adrenal Insufficiency

While the mortality due to adrenal insufficiency is now very low, it can still be an issue despite the education of patients. An overall mortality rate of 1% was found in the patients followed in a German center, where they received a minimal education for dose change in stress situations; the risk of adrenal crises was evaluated at 8–9 per 100 patients per year (Hahner *et al.*, 2015). This emphasizes the need for a clear and repeated education of patients after bilateral adrenalectomy. Other than mortality, the lack of physiological replacement of cortisol nycthemeral rhythm by hydrocortisone intake is also an issue: as stated by the specific AddiQoL, patients with adrenal insufficiency have complaints due to chronic over- or under-dose and the lack of biological parameters to allow an optimal dose planning during the various periods of a day (Husebye *et al.*, 2014).

Is Eucortisolism Necessary Before Bilateral Adrenalectomy?

The per-operative improvement of patients operated on while in eucortisolism rather than hypercortisolism is still a matter of controversy. Only one study tried to determine whether a pre-surgical medical treatment (4 months with steroidogenesis

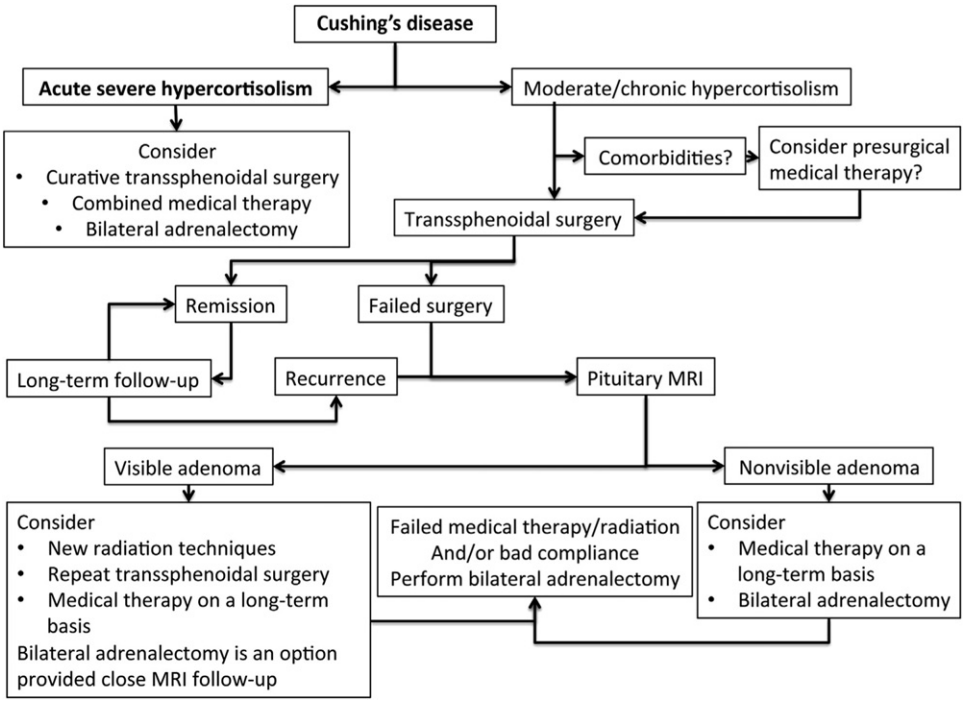

Fig. 1 Suggested therapeutic algorithm in Cushing disease. From Guerin, C., Taieb, D., Treglia, G., Brue, T., Lacroix, A., Sebag, F. and Castinetti, F. (2016). Bilateral adrenalectomy in the 21st century: When to use it for hypercortisolism? *Endocrine-Related Cancer*, **23**, R131–R142.

inhibitors before transsphenoidal surgery) allowed improvement of the general condition of the patients: the results were unclear, with seemingly a long-term improvement of hypertension and a decreased risk of thrombo-embolic events in patients with pretreatment (Valassi *et al.*, 2012). For this latter point, the number of events in the study was very low, and large-scale studies will be necessary to ascertain this conclusion. In a review by Ritzel *et al.*, the mortality and morbidity after bilateral adrenalectomy were comparable whether the patients were pretreated or not (1% vs. 2% mortality, 19% vs. 21% morbidity) (Ritzel *et al.*, 2013). In patients with classical Cushing disease, trying to obtain eucortisolism will not worsen the general condition of the patient: it thus can be tried, but should not delay the surgical procedure too much.

Current Roles of Bilateral Adrenalectomy in the Therapeutic Algorithm of Classic Cushing Disease

The first-line treatment of Cushing disease is transsphenoidal surgery. It is usually recommended even in patients with a negative pituitary MRI. However, the risks of recurrence remain very high (up to 15%–30%), even in patients with the best predictive factors (such as immediate postsurgical corticotroph deficiency). Usually, at the time of recurrence, transsphenoidal surgery is performed only in patients with an obvious adenoma remnant. In that case, if surgery is contra-indicated or technically impossible, radiation techniques can also be performed, as they will lead to cure in roughly 50% of cases. For these patients, the delay to remission can be prolonged, requiring a medical treatment to control hypercortisolism while waiting for the maximal efficacy of radiation techniques.

Bilateral adrenalectomy should thus be considered in any situation when transsphenoidal surgery is contra-indicated or when the pharmacological treatment is not effective (including the patients waiting for the efficacy of radiation techniques, but for whom medical treatment cannot control hypercortisolism). It should be noted that some patients might prefer a radical treatment rather that a lifelong intake of medical treatments, and this is also a point to consider, provided the patient is aware of the need for a prolonged substitutive treatment.

When a bilateral adrenalectomy is performed, one should keep in mind the risk of Nelson's syndrome: the ACTH level should be closely monitored, and a pituitary MRI be performed during the first year after bilateral adrenalectomy (though the frequency to perform pituitary MRI remains to be determined, particularly in patients with negative MRI despite biological recurrence). Prolonged clinical, biological, and imaging surveillance is required for these patients. Current management of Cushing disease is summarized in **Fig. 1** (from Guerin *et al.*, 2016).

The Specific Case of Bilateral Adrenalectomy in Severe Cushing Disease

Severe hypercortisolism is rarely due to Cushing disease: it is most frequently due to ectopic ACTH secretion or adrenal carcinoma. However, severe hypercortisolism is a life-threatening condition for which bilateral adrenalectomy is always considered. The aim is

Table 2 Results of fast-acting pharmacological treatments in severe hypercortisolism

Author, year	*Patients*	*Treatment*	*Theoretical onset of action*	*Dose*	*Short-term antisecretory efficacy*	*Adrenal insufficiency*	*Short-term side effects*
Corcuff *et al.* (2015)	14 EAS	Ke + Me	2–7 days	400–1200 mg/d (Ke) + 0.5–4 g/d (Me)	73% normal UFC	14%	Nausea and vomiting Hypokalemia Increased liver enzymes

Castinetti *et al.* (2009)	8 ACTH dependent	Mifepristone	48 h				400–2000 mg/d
		Improvement of clinical signs in all the patient, no biological follow-up available	14% (no biological evidence available)	Hypertension Hypokalemia			
Preda *et al.* (2012)	12 case reports	Etomidate	12–24 h	0.03–0.3 mg/kg/h	83% normal UFC	Depending on the dose/sedation level	Hemolysis, thrombophlebitis, pain at the injection site, nephrotoxicity

to decrease rapidly the levels of cortisol to avoid severe comorbidities (such as severe depression, pulmonary embolism, acute respiratory distress, uncontrolled hypertension or diabetes, and severe hypokalemia) or even death. Over the last few years, several studies showed interesting results on the association of steroidogenesis inhibitors, and this led to the questioning of the remaining roles of bilateral adrenalectomy in such patients. It should be noted that all these studies were retrospective, and were not aimed at comparing one approach (medical treatments) with the other (bilateral adrenalectomy). The main association reported up to now was based on ketoconazole and metyrapone, two highly effective adrenal steroidogenesis inhibitors. A large retrospective series as a single treatment reported an antisecretory efficacy in 50%–80% cases (Castinetti *et al.*, 2014; Daniel *et al.*, 2015). It was thus expected that the association of both would allow a rapid control of hypercortisolism in the majority of cases. In one of these two studies, mitotane was given at the same time, with the aim of allowing a long-term medical control (after withdrawal of ketoconazole and metyrapone, as mitotane is a slow-acting drug). While 24 patients were reported in these 2 studies, only 3 were presenting with Cushing disease. Ketoconazole and metyrapone were given at high doses. Roughly 70% of the patients were finally controlled: what was impressive was the decline of cortisol levels, with a dramatic decrease of urinary free cortisol in the first few days. Tolerance was good, provided a close monitoring of liver enzymes, potassium, and blood pressure was performed. Adrenal insufficiency was reported in 25% of the patients (Corcuff *et al.*, 2015; Kamenicky *et al.*, 2011).

Other drugs are also known to decrease rapidly the effects of hypercortisolism. Mifepristone is a glucocorticoid receptor antagonist. We reported about 10 years ago its rapid efficacy in patients with severe psychosis induced by hypercortisolism (Castinetti *et al.*, 2009). The drug is now marketed in the United States in the management of hypercortisolism, and it could be considered in these critical situations. One should keep in mind, however, that the blockade of glucocorticoid receptors is also present in the pituitary, thus leading to increased ACTH and cortisol levels, making it impossible to monitor the biochemical control of the efficacy of the drug. Moreover, increased cortisol levels can also lead to a pseudo-hyperaldosteronism, with a worsening of hypokalemia and hypertension. The use of mifepristone should thus be reserved to highly experienced teams (Fleseriu *et al.*, 2012).

Finally, etomidate, a rapidly effective adrenal steroidogenesis inhibitor, has also been used as a treatment of severe hypercortisolism. It is a drug that is difficult to use as it has to be administered in an intensive care unit (where it can also be used to induce anesthesia). Literature data showed a good efficacy in 12 patients with severe hypercortisolism and inability to take medications orally (Preda *et al.*, 2012).

To summarize, given the high efficacy of the drugs, the good tolerance, and the state of high frailty in which these patients can be at the time of initial diagnosis, one should thus always consider a trial with medical treatments in the aim of improving the general condition of the patient before surgery (whatever the surgery would be). The use of these treatments in these critical conditions should be reserved to highly experienced teams.

Main studies reporting the outcome of patients treated by adrenal steroidogenesis inhibitors for severe hypercortisolism are summarized in **Table 2** (from Guerin *et al.*, 2016).

Conclusions and Perspectives

Bilateral adrenalectomy is a rapidly acting treatment for Cushing disease. It leads to another disease, adrenal insufficiency, that needs proper management and follow-up. However, it is not yet clear whether other approaches always lead to eucortisolism: new radiation techniques lead to hypopituitarism in 20%–30% of cases; medical treatment improves hypercortisolism, but there is still a gap between normal urinary free cortisol (UFC) and real eucortisolism. Future studies should be aimed at defining whether metabolic parameters and quality of life are different in patients on a long-term medical treatment, and patients with a permanent adrenal insufficiency. In the second case, it is also likely that quality of life should be improved by new formulations of hydrocortisone. The final conclusion is that one should never consider that bilateral adrenalectomy is an obsolete treatment of Cushing disease; it might even become more important in the therapeutic algorithms in the future.

Cushing Syndrome—Unilateral Adrenal Adenoma

Guido Di Dalmazi, Alma Mater Studiorum University of Bologna, Bologna, Italy

Introduction

Cushing syndrome is characterized by signs and symptoms caused by chronic glucocorticoid hypersecretion. Despite the major advances that have been made during the last years, the diagnosis and the treatment of Cushing syndrome still represent a major challenge among physicians. Cushing syndrome is a life-threatening disease, if left untreated. An early diagnosis and a prompt appropriate treatment are therefore mandatory. Cushing syndrome may be either ACTH-dependent (the most frequent form) or ACTH-independent. This article is focused on the most common pathological condition among ACTH-independent causes of Cushing syndrome, the unilateral adrenocortical adenomas.

Epidemiology and Clinical Presentation

Cushing syndrome due to unilateral adrenocortical adenomas is a rare clinical condition. Among the ACTH-independent forms of hypercortisolism, which represents 15% of cases of endogenous Cushing syndrome, it is the most frequent pathological condition, followed by adrenocortical carcinomas and bilateral micro- and macronodular hyperplasia. The highest reported prevalence is 18.7% in a large series of patients with Cushing syndrome (Invitti *et al.*, 1999). The incidence of endogenous Cushing syndrome has been estimated between 0.7 and 2.4/million/year (Sharma *et al.*, 2015). The incidence of the disease peaks between the third and the fifth decades of life (Bertagna and Orth, 1981) and a strong preponderance of female sex has been reported in unilateral adenomas associated with Cushing syndrome (Pikkarainen *et al.*, 1999). Although this pathological condition has been considered rare in population-based studies, the exact prevalence and incidence is difficult to be estimated and may be higher than previously thought. Studies investigating cohorts of patients with uncontrolled diabetes have shown a prevalence of Cushing syndrome between 2% and 3% (Leibowitz *et al.*, 1996; Catargi *et al.*, 2003), even though not confirmed in other studies (Mullan *et al.*, 2010; Reimondo *et al.*, 2007; Newsome *et al.*, 2008; Gagliardu *et al.*, 2010). However, a systematic screening for Cushing syndrome in all patients with diabetes is not currently recommended.

The clinical presentation of Cushing syndrome is characterized by typical signs and symptoms related to prolonged cortisol exposure. The recognition of Cushing syndrome may be extremely difficult, because some features of the syndrome are unspecific and may be common in a large number of individuals. Sarcopenic obesity, hypertension, alteration of the bone mineral density, altered glucose metabolism, or depression, in isolation, do not necessarily characterize the clinical picture of Cushing syndrome. However, the simultaneous presence of those features or other comorbidities potentially associated with hypercortisolism raises the suspicion of Cushing syndrome. According to the results of a recent study, the ability of the physicians in distinguishing the clinical picture of Cushing syndrome from that of the so-called pseudo-Cushing syndrome have changed during the last 20 years, mainly because of the increasing knowledge of the clinical phenotype of hypercortisolism, leading to an early recognition of the disease (Schneider *et al.*, 2012). The typical clinical picture of Cushing syndrome is characterized by severe comorbidities and adverse events, due to the direct effects of hypercortisolism. The glucocorticoid receptor is expressed among almost all tissues of the human body and the effects of cortisol hypersecretion involve many organ systems. Classic signs and symptoms include easy bruising, facial plethora, proximal muscle weakness, and striae rubrae (Nieman *et al.*, 2008). Hypertension is diagnosed in up to 80% of the patients, with loss of nocturnal dipping. Drug-resistant hypertension is encountered in 17% of the cases (Magiakou *et al.*, 2006; Arnaldi *et al.*, 2004; Zacharieva *et al.*, 2004). Alterations of glucose and lipid metabolism are also common findings in patients with Cushing syndrome and diabetes is diagnosed in 22%–47% of the cases. Other clinical manifestations include centripetal obesity, due to increased visceral fat accumulation, oligo/amenorrhea, osteoporosis, mood disorders (e.g., depression or psychosis in severe hypercortisolism), hypercoagulable state, and recurrent infections. The clinical picture of patients affected by Cushing syndrome due to unilateral adrenocortical adenomas is characterized by elevated cortisol levels without increase in androgen secretion, as shown by reduction in DHEA-sulfate levels. The reduced androgen secretion is caused by alteration of the electron transport system due to decreased activity of P450 oxidoreductase and its cofactor cytochrome *b*5, leading to reduced 17,20 lyase activity of the enzyme P450c17 (Sakai *et al.*, 1994). Additionally, the suppression of ACTH secretion observed in patient with Cushing syndrome due to adrenocortical adenomas results in a reduced stimulation of adjacent and contralateral adrenal cortex, eventually leading to reduced androgen production. This specific pattern of androgen reduction is in sharp contrast with the one observed in patients with adrenocortical carcinomas associated with Cushing syndrome, who show often hirsutism and hyperandrogenemia.

Those comorbidities cause a severe impairment of the cardiovascular profile of patients with Cushing syndrome, with an increased incidence of cardiovascular events and mortality, if left untreated (Trementino *et al.*, 2010; Lindholm *et al.*, 2001). Moreover, there is an increased rate of severe infectious complications, increased incidence of osteoporotic fractures, and psychiatric disorders (Arnaldi *et al.*, 2012; Colao *et al.*, 2012).

Highlights on Diagnosis

Patients presenting the typical clinical features described above should be screened by hormonal testing to rule out Cushing syndrome. Moreover, patients with unusual findings for their age, such as osteoporosis or hypertension in young adults, or severe comorbidities potentially associated with hypercortisolism should undergo a hormonal screening. After exclusion of iatrogenic Cushing syndrome by an accurate anamnesis, patients should undergo one of the three first-line screening tests: overnight 1 mg dexamethasone suppression test (DST), late-night salivary cortisol, or 24-h urinary free cortisol (UFC) (Nieman *et al.*, 2008). Cushing syndrome is diagnosed in the presence of at least two different clearly altered tests. Cortisol levels after 1 mg DST <50 nmol L^{-1} (1.8 mcg dL^{-1}) are considered adequately suppressed and exclude Cushing syndrome. UFC levels should be clearly elevated (e.g., threefold above the upper limit of normal) to have a reliable diagnostic power in identifying Cushing syndrome. Once Cushing syndrome is diagnosed, hormonal tests and imaging should be performed to investigate the cause of hypercortisolism. Plasma morning ACTH concentration <1.1 pmol L^{-1} (5 pg mL^{-1}) provides evidence of ACTH-independent hypercortisolism and requires thin-section computed tomography (CT) scan of the abdomen, to investigate the morphology of the adrenal gland. Adrenocortical adenomas are identified in the presence of regular margins, maximum diameter usually <4 cm, and homogeneity of the lesion. The majority of adrenocortical adenomas (70%) contains significant amount of intracellular lipids (Boland *et al.*, 2008; Garrett *et al.*, 2016). Attenuation values ≤ 10 Hounsfield units (HU) on unenhanced CT identify lipid-rich adenomas with 98% specificity and 71% sensitivity (Boland *et al.*, 1998). Unenhanced images followed by venous and delayed phases (70–80 s and 15 min after iodine contrast administration, respectively) provide a better discriminant power in distinguish adenomas from nonadenomatous adrenal lesions (Boland *et al.*, 2008; Korobkin *et al.*, 1998; Caoili *et al.*, 2000). This technique is also useful for the identification of lipid-poor adrenal adenomas, which are typically characterized by high attenuation values at unenhanced CT scan (>10 HU). Adrenocortical adenomas have a faster contrast washout at 15 min than other types of adrenal lesions, including malignant tumors, which usually show poor contrast washout due to capillary leakage (Pena *et al.*, 2000). FDG-PET or FDG-PET/CT scan may be useful in difficult cases, as an aid in distinguishing adrenal adenomas from small adrenocortical carcinomas, with 97% sensitivity and 91% specificity (Boland *et al.*, 2011).

Pathophysiology

Genetic and Molecular Background

The genetic and molecular background of Cushing syndrome due to adrenocortical tumors has remained largely unknown until recently. Lately, several studies have thoroughly investigated the pathogenetic mechanisms of those tumor entities, thanks to the application of next-generation sequencing techniques. Therefore, it has been possible to unravel the molecular mechanisms underlying tumor progression and cortisol production in more than half of the cases. One of the major intracellular pathways involved in the pathogenesis of adrenocortical tumors associated with hypercortisolism is the cAMP/PKA pathway. However, several other intracellular signaling pathways seem to play a role in a nonnegligible proportion of tumors.

The cAMP/PKA pathway in adrenocortical cells

The cyclic AMP (cAMP) signaling pathway is a pivotal regulator of metabolism, cell proliferation, differentiation, and apoptosis in endocrine tissues. The discovery of this intracellular signaling pathway has been a milestone in cell biology, as highlighted by the assignment of Nobel prizes to Earl Sutherland for the discovery of cAMP (1971), Edmond Fischer and Edwin Krebs for the discovery of PKA (1992) and Alfred Gilman and Martin Rodbell for the discovery of G proteins (1994) (Chin *et al.*, 2002). One of the major effectors of cAMP is protein kinase A (PKA), which phosphorylates several cytosolic and nuclear substrates, including transcription factors of the CREB/ATF family (Rosenberg *et al.*, 2002). cAMP levels are tightly balanced in production and degradation by adenylyl cyclases and phosphodiesterases (PDEs), respectively (Hannah-Shmouni *et al.*, 2016). The second messengers cAMP and PKA are key regulators of almost all cellular functions and mediate the effects of several hormones and neurotransmitters via G protein-coupled receptors (GPCRs).

Under normal conditions, ACTH controls activity and proliferation of adrenocortical cells through the melanocortin 2 receptor (MC2R), a GPCR highly expressed on the surface of those cells. Upon binding to the MC2R, the stimulatory Gs protein leads to the activation of the adenylyl cyclase, which, in turn, increases the intracellular concentration of cAMP. The resulting stimulation of PKA ultimately leads to increased glucocorticoid production. PKA is a serine/threonine kinase and a typical model of allosteric regulation (Taylor *et al.*, 2012). In its inactive form, the PKA holoenzyme forms a tetramer made by a dimer of two regulatory (R) and two catalytic (C) subunits (Taylor *et al.*, 2012). PKA has two isoforms (I and II) depending on which type of R subunits bind the C subunits (16, 17 Weigand Sci Rep). There are three isoforms of C subunits (Cα, Cβ, Cγ) and four of R subunits (RIα, RIβ, RIIα, RIIβ), each coded by different genes (Taylor *et al.*, 2012). Additionally, the human protein kinase X (PrKX) can associate with the R subunits of PKA (Diskar *et al.*, 2010). The R subunits form homo- or heterodimers through docking and dimerization domains (Taylor *et al.*, 2012; Taskén *et al.*, 1993), which are also involved in binding the A Kinase-Anchoring Proteins, tethering different PKA isoforms to specific subcellular structures (Taylor *et al.*, 2012). In the inactive state, an inhibitory sequence of the R subunit occupies the active site cleft of the corresponding C subunit, impeding the access of PKA substrates by acting as a tethered substrate or pseudo-substrate. The binding of two cAMP molecules to each R subunit generates a conformational change that

allows the release of the C subunit, which, in turn, is able to phosphorylate cytosolic and nuclear targets (Kim *et al.*, 2005). The C subunit activation in adrenocortical cells activates the glucocorticoid synthesis machinery regulating the fast as well as the slow long-term steroid production, by inducing transcription of steroidogenic enzymes and genes involved in cell replication (Gallo-Payet and Payet, 2003).

Several genetic alterations in components of the cAMP/PKA pathway point toward the pivotal role of this intracellular signaling in inducing tumor progression and cortisol hypersecretion in several familial cases of adrenocortical hyperplasia, as well as in sporadic adrenocortical tumors (Calebiro *et al.*, 2015).

Genetic alterations in adrenal Cushing syndrome

PRKACA *somatic mutations*

Whole exome sequencing studies performed in sporadic cortisol-producing adrenocortical adenomas have highlighted several somatic mutations in *PRKACA*, the gene encoding the Cα subunit of PKA (Beuschlein *et al.*, 2014; Cao *et al.*, 2014; Goh *et al.*, 2014; Sato *et al.*, 2014). Replication studies using Sanger sequencing have confirmed the results of the exome sequencing (Di Dalmazi et al., 2014a; Nakajima *et al.*, 2014; Thiel *et al.*, 2015; Li *et al.*, 2016). The prevalence of *PRKACA* somatic mutations identified in studies published up to now are summarized in **Fig. 1**. Somatic mutations in *PRKACA* are found in 23%–66% of patients with Cushing syndrome due to sporadic adrenocortical tumors, with a mean pooled prevalence of 47% in all series published up to now (Di Dalmazi and Beuschlein, 2017). The studies reporting results of the genetic analysis of sporadic adrenocortical tumors and the list of the specific mutations are shown in **Table 1**. *PRKACA* somatic mutations have been identified selectively in adrenocortical unilateral adenomas associated with clinically-manifest Cushing syndrome, whereas they have been identified only in a small proportion of patients with subclinical hypercortisolism (0%–12%, mean pooled prevalence 5%). All somatic mutations are clustered in a hot-spot region of the coding sequence of *PRKACA*. The most common alteration is a missense mutation leading to the substitution of a leucine residue at position 206 with an arginine in Cα subunit (p.L206R). Additional somatic alterations identified in sporadic adrenocortical tumors associated with Cushing syndrome include mutations leading to the insertion of a valine between the amino acids 200 and 201 (p.C200_G201insV), the insertion of a tryptophan between the amino acids 199 and 200 (p.L199_C200insW), and the substitution of the serine in position 213 with an arginine, in addition to a large amino acid insertion (p.S213R + p.L212_K214insI-I-L-R).

Mechanism of PKA activation by PRKACA somatic mutations

All the amino acid changes caused by *PRKACA* somatic mutations are located on the surface of the Cα subunit, at the interface with the R subunit of PKA. The solved X-ray crystal structure of the mouse RIIβ–Cα-holoenzyme (Kim *et al.*, 2005) showed that somatic *PRKACA* mutations may interfere with the association between Cα subunit and R subunit, resulting in a constitutive activation of the former (Beuschlein *et al.*, 2014; Di Dalmazi et al., 2014a; Calebiro *et al.*, 2014). The in silico 3D reconstruction of the crystal structure of the mouse RIIβ–Cα-holoenzyme in wild type and mutants is depicted in **Fig. 2**.

L206 is part of the active site cleft of the Cα subunit of PKA. It takes part in the formation of a hydrophobic pocket that is responsible for substrate recognition, binding, and interaction with the inhibitory sequence of the R subunit. The substitution of L206 with a bulky and positively charged amino acid like arginine leads to steric hindrance between the side chain of R206 and residues V115 and Y228 of the R subunit (Beuschlein *et al.*, 2014; Calebiro *et al.*, 2014).

L199 and C200 are close to T198, which is part of the so-called activation loop. This region is parallel to the inhibitory sequence of the R subunit and is phosphorylated during the synthesis of the Cα subunit (Taylor *et al.*, 2012). Residues G201 and L199 are involved in main-chain hydrogen bonding with residues V115 and A117 of the R subunit. The insertion of an amino acid in this region interferes with the interaction between the R and Cα subunits (Beuschlein *et al.*, 2014; Calebiro *et al.*, 2014).

3D in silico reconstruction of p.S213R + p.L212_K214insI-I-L-R predicted a functional role also for this variant. Even though this region is not part of any direct contact site between Cα and R subunits, this mutation may interfere with the formation of a stable PKA holoenzyme. L212 is located on the surface of the Cα subunit in a "tip"-like structure that protrudes to the R subunit. The insertion of several amino acids in this region leads to an enlargement of this tip, impairing the association between Cα and R subunits (Di Dalmazi et al., 2014a).

Functional analyses have been performed for the most frequent mutation, the p.L206R, and for the variant p.C200_G201insV. In vitro experiments performed by coimmunoprecipitation assays, chromatography, and real-time fluorescence resonance energy

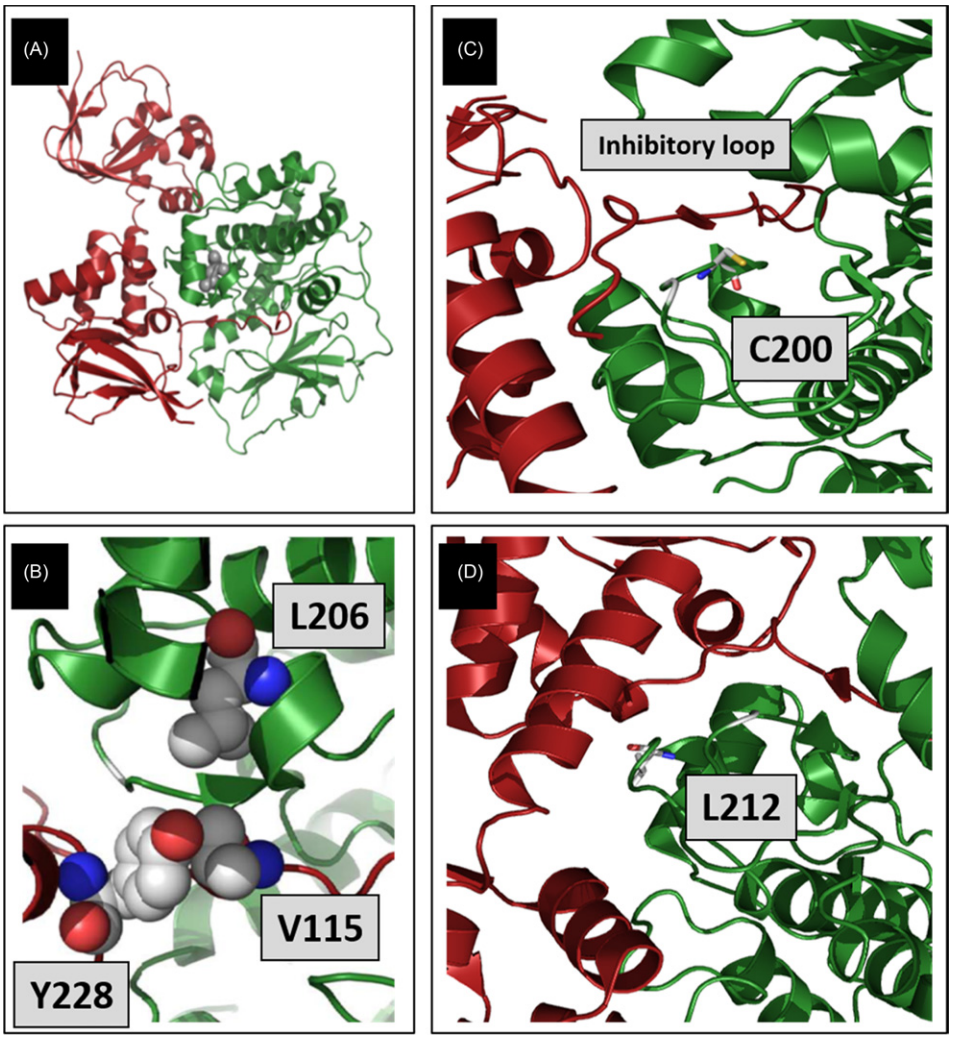

Fig. 2 3D–in silico reconstruction of the mouse RIIβ–Cα-holoenzyme with analysis of the amino acid changes in the catalytic subunit of PKA. transfer (FRET) measurements showed that both mutations abolished the association between Cα mutants and the R subunits. When compared to wild-type Cα subunit, mutant cells showed higher PKA activity, which was independent of the cAMP concentration. The maximal PKA activity of both mutants was also not different from that of the wild-type Cα subunit. According to the results of FRET experiments in living cells, both mutations impaired the formation of a stable PKA holoenzyme, causing a loss of regulation by cAMP (Calebiro *et al.*, 2014). All these experiments provide an explanation for the constitutive activation of PKA caused by *PRKACA* somatic mutations in adrenocortical tumors associated with Cushing syndrome.

Other somatic mutations

Several studies have identified different somatic alterations in components of the cAMP/PKA pathway, supporting the primary role of this intracellular signaling in cortisol hypersecretion and tumor progression (Lodish and Stratakis, 2016).

One of the first genetic aberrations was found in patients affected by adrenal hyperplasia in McCune–Albright syndrome, which is characterized by bone fibrous dysplasia, café au-lait spots on the skin, and involvement of several endocrine glands. Some patients also develop Cushing syndrome due to adrenal hyperplasia. Genetic analysis revealed mosaic, activating mutations of *GNAS*, the gene encoding the Gαs protein (Weinstein *et al.*, 1991). Additional genetic defects were found in patients with primary pigmented nodular adrenocortical disease in the context of Carney complex, characterized by cutaneous and neuronal tumors, cardiac myxomas, and pigmented lesions of skin and mucosae. Mutations in the gene encoding the RIα subunit of PKA (*PRKAR1A*) have been considered as a causative factor of the syndrome, by reducing the expression of the RIα subunits or impairing its association with Cα subunits (Kirschner *et al.*, 2000). Inactivating mutations in the two genes encoding phosphodiesterases 8 and 11A (*PDE8* and *PDE11A*) have been found in patients with adrenal hyperplasia (Horvath *et al.*, 2006; Rothenbuhler *et al.*, 2012).

The analysis of sporadic adenomas associated with Cushing syndrome has also revealed somatic mutations of *GNAS* (Cao *et al.*, 2014; Goh *et al.*, 2014; Sato *et al.*, 2014; Ronchi *et al.*, 2016, Fragoso *et al.*, 2003), *PDE8B*, and *PDE11A* (Rothenbuhler *et al.*, 2012; Hannah-Shmouni *et al.*, 2016). Somatic loss of 17q22–24 have been found in 23% of adrenocortical adenomas (Bertherat *et al.*, 2003) and inactivating mutations of the *PRKAR1A* gene were identified in a few number of sporadic tumors (49 Calebiro EJE). *PRKAR1A* mutations were predicted to cause a prematurely terminated R1α subunit and were considered as pathogenetic.

Apart from all alterations of the cAMP/PKA pathway described in sporadic adrenocortical tumors so far, with somatic mutations of *PRKACA* as the most frequent event, several different intracellular pathways have been identified as potentially pathogenetic for tumor progression and cortisol hypersecretion. Alterations of components of the Wnt/β-catenin pathway have been described in one fourth of the patients with adrenocortical adenomas. The most common alterations are somatic mutations of *CTNNB1*, the gene encoding β-catenin (Tissier *et al.*, 2005; Thiel *et al.*, 2015; Ronchi *et al.*, 2016). A specific analysis performed by exome sequencing revealed a prevalence of 18% of *CTNNB1* somatic mutations in adrenocortical adenomas associated with Cushing syndrome (Ronchi *et al.*, 2016). Most of *CTNNB1* mutations occur in a hot spot region, leading to amino acid substitutions in the serine in position 45 with a proline or a phenylalanine residue (p.S45P and p.S45F). These amino acid changes cause a constitutive activation of the Wnt/β-catenin pathway, a well-known intracellular signaling involved in cell proliferation in benign and malignant adrenocortical tumors. Besides the cAMP/PKA pathway and the Wnt/β-catenin pathway, the genetic background of sporadic adrenocortical tumors associated with Cushing syndrome is highly heterogeneous. The analysis of *PRKACA* wild-type tumors performed by exome sequencing revealed several somatic "private" mutations in different genes, without recurrent events (Ronchi *et al.*, 2016). However, the cluster analysis performed by combining mutational status and gene expression data revealed that mutations of components of the intracellular Ca^{2+}-signaling might play a role in adrenocortical tumorigenesis and cortisol hypersecretion. However, functional data proving the pathogenetic consequences of these variants are still lacking.

Aberrant receptors in adrenal Cushing syndrome

Hypercortisolism in adrenocortical adenomas may be caused by aberrant receptors in a nonnegligible proportion of patients. Aberrant receptors, usually GPCR, may be ectopic receptors that are not significantly expressed in the normal zona fasciculata or eutopic receptors that are highly expressed in adrenocortical tumors. Ectopic receptors include those for glucose-dependent insulinotropic polypeptide (or gastric inhibitory polypeptide; GIP), vasopressin (V_2–V_3 vasopressin receptors), serotonin, glucagon, and β-adrenergic receptors, whereas V1-vasopressin receptor and LH/HCG receptor are listed among eutopic receptors associated with hypercortisolism (El Ghorayeb *et al.*, 2015). Aberrant receptors have been found in up to 50% of the patients with unilateral adrenocortical adenomas associated with hypercortisolism, even though the prevalence of this disorder is higher in patients with subclinical hypercortisolism. Recent findings have shown that the increased GIP receptor expression in adrenocortical adenomas associated with food-dependent Cushing syndrome is driven by monoallelic overexpression of the *GIPR* gene, caused by chromosome rearrangements and other genetic alterations of the *GIPR* regulatory regions (Lecoq *et al.*, 2017).

Genotype–Phenotype Correlation

Keeping into account the deleterious effects of *PRKACA* somatic mutations on Cα subunit, which is constitutively active, the phenotype of patients carrying the mutations is expected to be more severe than that of subjects without mutations. Patients carrying somatic *PRKACA* mutations have a severe hypercortisolism, as demonstrated by the higher cortisol levels after DST than in wild-type patients. Moreover, 24-h free cortisol and midnight serum and salivary cortisol are higher in *PRKACA*-mutated patients (Beuschlein *et al.*, 2014, Sato *et al.*, 2014, Di Dalmazi et al., 2014a, Thiel *et al.*, 2015, Li *et al.*, 2016). PKA activity has been shown to play a role also in cell proliferation. Interestingly, although patients carrying *PRKACA* mutations have a higher cortisol secretion rate, the tumor size is smaller than their wild-type counterpart. The increased PKA activity associated with a smaller tumor size has been also observed in patients carrying *PRKAR1A* inactivating mutations (Bertherat *et al.*, 2003). The association between increased PKA activity and lower cell proliferation rate is still unexplained. Early studies have shown that the imbalance of RI/RII ratio in adrenocortical cells regulates apoptosis and stimulates, when increased, or inhibit, when decreased, cell proliferation (Mantovani *et al.*, 2008). This mechanism might explain the lower proliferation rate observed in *PRKAR1A* inactivating mutations. A recent study has also demonstrated that tumors carrying *PRKACA* mutations have reduced expression of the RIIβ subunit (Weigand *et al.*, 2017). Nevertheless, although this mechanism may provide a pathogenetic explanation for the reduced cell proliferation in cAMP/PKA altered tumors, the smaller size of tumors carrying *PRKACA* mutations might also be explained by the severity of the hormonal phenotype in patients with the mutations, who come earlier to medical attention, leading to timely clinical recognition and tumor removal. The younger age of patients with somatic *PRKACA* mutations strengthens this hypothesis. The prevalence of *PRKACA* mutations has shown some variability according to the different cohorts of patients (**Fig. 1**). Data from cohort of patients in Europe and United States highlight a mean pooled prevalence of 35%, consistent among all studies. The prevalence of *PRKACA* somatic mutations in patients form Asian regions is higher, being $>50\%$ in all but one study, with a mean pooled prevalence of 59% (Di Dalmazi and Beuschlein, 2017). The reason for this discrepancy is currently unknown and there is no evidence of genetic, environmental, or other factors that could explain the higher rate of *PRKACA* somatic mutations in Asian cohorts of patients. However, the possibility of a referral or enrollment bias among different cohorts of patients has not been investigated. Somatic

mutations in *PRKACA* are more frequent in females than in males. The reason for this specific gender distribution is not completely understood, and no studies have addressed this issue so far.

According to the results of the aforementioned studies, patients with somatic *PRKACA* mutations are mostly females, at young age, with severe hypercortisolism and full-blown Cushing syndrome, with relatively small adrenocortical tumors. This specific clinical picture seems to be common to all patients bearing mutations of components of the cAMP/PKA pathway. On the contrary, the phenotype of patients carrying somatic mutations of components of the Wnt/β-catenin pathway, mainly *CTNNB1*, is in strong opposition and it is characterized by large tumors, in older patients affected by Cushing syndrome with low clinical expression. The clinical phenotype of patients with genetic alterations involving pathways other than cAMP/PKA or Wnt/β-catenin (notably, alterations of Ca^{2+} signaling) is not associated with any specific characteristic (Ronchi *et al.*, 2016).

In summary, the clinical spectrum of Cushing syndrome due to adrenocortical adenomas is highly variable among patients. However, some phenotypic characteristics are associated with specific genetic and molecular background.

Treatment

Surgical Approach

The treatment of Cushing syndrome due to unilateral adrenal adenomas is surgical. The removal of the adenoma is virtually curative in all patients, considering that those tumors are monoclonal and that specific molecular events occurring at a somatic level have been identified as a causative factor for tumor proliferation and cortisol hypersecretion.

Firstly introduced in the early 1990s, laparoscopic surgery has become the recommended approach, thanks to lower rate of complications, shorter hospital stay, faster return to normal activity, and reduced postoperative pain than traditional open adrenalectomy (Shen *et al.*, 2005). Laparoscopic adrenalectomy may be performed through either a trans-peritoneal or a retro-peritoneal approach, depending on the experience of the surgeon. Robot-assisted laparoscopic adrenalectomy was firstly described in the late 1990s. Since then, this technique has shown safety and efficacy similar to laparoscopic adrenalectomy and it has slowly gained in popularity, thanks to the potential advantage of shorter length of hospitalization and less blood loss during surgical intervention (Brandao *et al.*, 2014). However, the higher cost represents the main limitation to the application of this technique. Stress-dose glucocorticoid supplementation (e.g. 100 mg hydrocortisone intravenously every 8 h) should be given in the perio-perative period and tapered postoperatively.

Post-Operative Adrenal Insufficiency

Adrenalectomy in unilateral adrenocortical adenomas associated with Cushing syndrome invariably results in adrenocortical insufficiency, requiring glucocorticoid replacement therapy. The adrenal insufficiency is caused by the suppression of CRH-producing cells in the hypothalamus, the inhibition of the secretion of stored ACTH, and the reduced transcription of the POMC gene, as a consequence of the chronic glucocorticoid excess.

In all studies published since 1981, the mean pooled prevalence of adrenal insufficiency after adrenalectomy is 99.7% (100% in all but one study that reported a prevalence of 80%) (Di Dalmazi et al., 2014b). The recommended dose of glucocorticoids as a replacement therapy is 10–12 $mg^{-1}\ m^{-2}\ day^{-1}$ of hydrocortisone given twice or thrice daily (Nieman *et al.*, 2015). The first dose should be given as soon as the patient wakes up. Other synthetic glucocorticoids may be given at the lowest replacement dose when hydrocortisone is not available. Glucocorticoid replacement therapy should be tapered according to the results of hormonal testing and the clinical judgment until hypothalamus–pituitary–adrenal (HPA) axis recovers its normal activity.

The mean prevalence of recovery of the HPA axis in patients with adrenal Cushing syndrome reported in the main series published up to now is 92%. Seven studies reported a total mean prevalence of 8% of patients who did not recover eucortisolism in a period of 69–103 months (Di Dalmazi et al., 2014b). There is no standardized definition of recovery of HPA axis after adrenalectomy, leading to high heterogeneity among studies. Most of the studies did not perform any hormonal test to define recovery, relying on clinical evaluation of the patients, whereas one-fourth of the studies performed short Synacthen test (250 mcg), with cut-off for normal response of cortisol after 60 min at 500 or 550 nmol L^{-1}, or morning cortisol >165 nmol L^{-1}. The most recent guidelines suggest to investigate the HPA axis by assessing morning cortisol level every 3 months, followed by an ACTH stimulation test when cortisol level is $\geq 7.4\ \mu g^{-1}\ dL^{-1}$ (200 nmol L^{-1}). Recovery can be considered when baseline or stimulated cortisol levels are $\geq 18\ \mu g^{-1}\ dL^{-1}$ (500 nmol L^{-1}).

The mean time to recovery a normal HPA axis function after adrenalectomy for Cushing syndrome in patients with unilateral adrenocortical adenomas is 18 months (range 1–30 months in the main series published up to now) (Di Dalmazi et al., 2014b; Berr *et al.*, 2015). In a study comparing different subtypes of hypercortisolism, patients with adrenal Cushing syndrome showed the longer time of HPA axis recovery, followed by patients with Cushing disease and those with ectopic Cushing syndrome, the latter showing the fastest return to eucortisolism despite similar dose of glucocorticoid replacement therapy (Berr *et al.*, 2015).

The recovery of HPA axis function is a stepwise process that involves the hypothalamus and the pituitary in the very early postsurgical period and adrenocortical cells in a later time. The phases of recovery of adrenocortical function in patients under-going adrenalectomy for Cushing syndrome due to unilateral adenomas can be summarized in an early phase of hypothalamic and adrenal insufficiency, followed by the recovery of the ACTH secretion, which rises to supernormal levels, and the subsequent

restoration of normal glucocorticoid secretion (Graber *et al.*, 1965; Bertagna and Orth, 1981; Gordon *et al.*, 1987; Klose *et al.*, 2004). This specific pattern of recovery seems to be independent of the cause of hypercortisolism and it was also observed in patients with iatrogenic Cushing syndrome after withdrawal of glucocorticoid treatment. The low expression of ACTH-receptor mRNA observed in peritumoral adrenocortical cells of patients operated for Cushing syndrome might be involved in the process of HPA axis recovery (Imai *et al.*, 2001).

Several patients suffer from glucocorticoid withdrawal syndrome, despite glucocorticoid replacement therapy. The clinical picture of the syndrome is characterized by symptoms like anorexia, nausea, weight loss, fatigue, myalgias, and psychiatric disorders (Dorn *et al.*, 1997) that can improve after a temporary increase in the dosage of glucocorticoid replacement therapy. However, no evidence has proven that supra-physiological doses of glucocorticoids in the early postoperative period might limit the onset of glucocorticoid withdrawal syndrome.

Patients undergoing unilateral adrenalectomy for sporadic adrenal adenomas associated with Cushing syndrome should be considered as cured by surgery, once the diagnosis has been confirmed by pathological examination.

Conclusion

Unilateral adrenocortical adenomas are the most frequent pathological condition among ACTH-independent forms of Cushing syndrome. During the last years, the pathogenesis of sporadic adrenocortical tumors associated with the syndrome has been clarified for most of the cases. Thanks to the application of next generation sequencing techniques, *PRKACA* somatic mutations could have been identified as the most common pathogenetic cause, occurring in more than half of the patients with Cushing syndrome. The discovery of the molecular events leading to tumors formations and cortisol hypersecretion has broadened the understanding of the pathogenesis of the disease, with future implications for diagnosis and treatment strategies. Laparoscopic adrenalectomy represents the best treatment option for patients affected by Cushing syndrome due to unilateral adrenocortical adenomas. The surgical treatment is invariably followed by adrenal insufficiency, which requires glucocorticoid replacement therapy for a variable period. Postoperative hormonal assessment should be performed at regular intervals to assess HPA axis function and avoid unnecessary glucocorticoid treatment. Once the diagnosis of unilateral adrenocortical adenoma is confirmed by histology, the patients should be considered as cured and no hormonal reassessment is required.

Somatic β-Catenin Gene Mutations and WNT Signaling in Adrenal Tumors

Isabelle Bourdeau, Centre hospitalier de l'Université de Montréal (CHUM), Montréal, QC, Canada

Abbreviations

ACC Adrenocortical cancer
AA Adrenocortical adenoma
APA Aldosterone producing adenoma
APC Adenomatous polyposis coli
ARMC5 Armadillo repeat containing 5 (*ARMC5*)
CK1α Casein kinase1α
CTNNB1 Catenin beta 1 or beta-catenin gene
Dvl Disheveled
FAP Familial adenomatous polyposis
GnRH Gonadotropin-releasing hormone
GSK3 *β* Glycogen synthase kinase3*β*
LDL Low-density lipoprotein
LEF Lymphoid enhancer-binding factor
LHCG Luteinizing hormone chorionic gonadotropin
NGS Next-generation sequencing
PKA Protein kinase A
PPNAD Primary pigmented nodular adrenal disease
TCF T-cell specific factor
TLE-1 Transducin likeenhancer-1
TP53 Tumor protein 53
WNT Wingless

Dysregulation of canonical Wnt/beta-catenin signaling has been associated with various diseases and cancers (Zhan *et al.*, 2017). Wnt/beta-catenin pathway plays a role on both embryonic development of the adrenal cortex and in maintenance of the adult normal adrenal glands (Kim *et al.*, 2008). Moreover, in the last decade Wnt/beta-catenin signaling was recognized as one of the major key player in adrenocortical tumorigenesis (Mazzuco *et al.*, 2012) which is the focus of this article.

Wnt Signaling Pathway

Wnt signaling is characterized by two distinct cascades: the noncanonical and the canonical pathways. The canonical Wnt pathway named Wnt/beta-catenin operates via beta-catenin protein. The two other noncanonical pathways include the planar cell polarity pathway and the Wnt/calcium pathway and both do not require beta-catenin protein. This article focuses on the involvement of the canonical Wnt/beta-catenin signaling in adrenocortical tumorigenesis.

In the absence of a Wnt signal, cytoplasmic beta-catenin is associated with a destruction complex composed of APC, axin, and 2 serine/threonine kinases: the casein kinase1 (CK1) and the glycogen synthase kinase3*β* (GSK3 *β*) (MacDonald *et al.*, 2009). CK1 and GSK3*β* phosphorylate the N-terminal of beta-catenin. First, CK1 phosphorylates Ser45 which allow the GSK3 *β*-sequential phosphorylation of Thr41, Ser37, and Ser 33 (Liu *et al.*, 2002). Phosphorylated beta-catenin is recognized by the E3 ubiquitin ligase beta-TrCP which lead to its ubiquitination and proteasomal degradation maintaining low cytoplasmic level of beta-catenin (Kimelman and Xu, 2006).

However, the pathway is activated when the secreted Wnt ligands bind to their receptor complex including the frizzled receptor and its coreceptor the low-density lipoprotein (LDL) receptor LRP5/6. This binding leads to phosphorylation of disheveled (Dvl) which in turn recruit Axin and GSK3 adjacent to the plasma membrane, thus preventing the formation of the destruction complex. The membrane sequestration of the destruction complex prevents phosphorylation and degradation of beta-catenin allowing beta-catenin to dissociate and accumulate in the cytoplasm and translocate to the nucleus.

In the nucleus, beta-catenin will bind to T-cell specific factor/lymphoid enhancer-binding factor (TCF/LEF) transcription factors to activate transcription of WNT target genes. In the absence of nuclear beta-catenin, TCF/LEF interact with the transcriptional corepressor transducin likeenhancer-1 (TLE-1), thus preventing beta-catenin target gene expression (**Fig. 1**) (Brantjes *et al.*, 2001).

Beta-catenin is composed of three distinct domains: the N-terminal domain, the C-terminal domain and the central armadillo domain repeats which bind various partners including Axin, APC and transcriptions factors. The C-terminal domain serves as a binding factor for several complexes promoting beta-catenin-mediated transcription while phosphorylation of the N-terminal domain leads to degradation of beta-catenin. Most mutations affecting the *CTNNB1* gene in adrenocortical tumors and in other nonadrenal cancers are localized in the exon 3 of the gene corresponding to beta-catenin N-terminal which harbors the phosphorylation sites for CK1 and GSK-3b. Thus *CTNNB1*mutations lead to disruption of the beta-catenin destruction complex allowing beta-catenin accumulation and Wnt activation (Dar *et al.*, 2017).

Beta-Catenin Mutations in Adrenocortical Adenomas and Carcinomas

One of the first evidence that Wnt/beta-catenin signaling was involved in the development of adrenal tumors was the identification of mutations in the beta-catenin gene itself. In 2005, we and others described for the first time the presence of beta-catenin

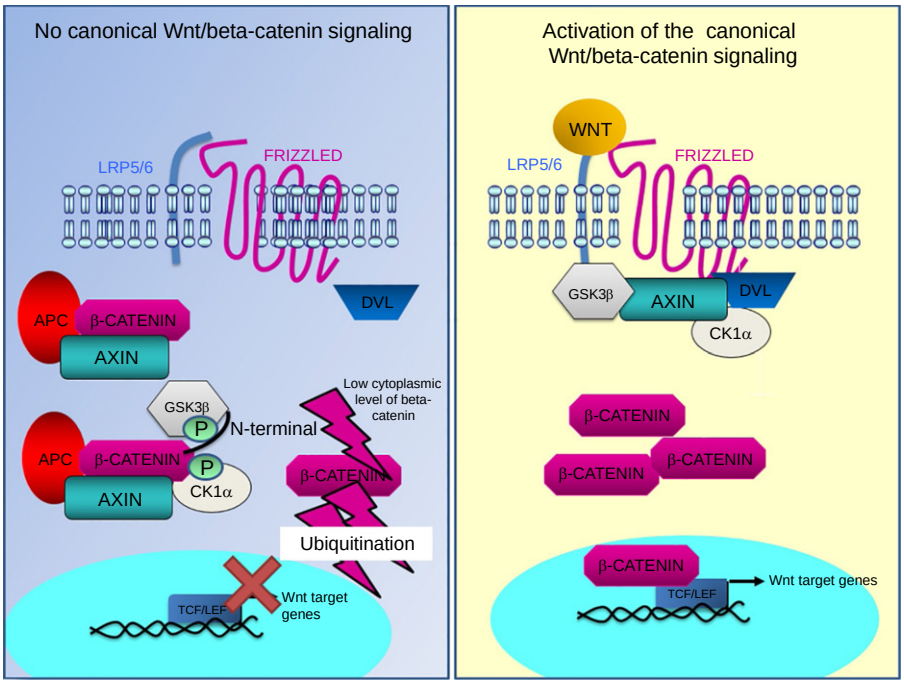

Fig. 1 Schematic representative of the canonical Wnt/beta-catenin signaling pathway. *Left panel*: *In the absence of a Wnt signal*, beta-catenin is associated with a destruction complex composed of APC, axin and two kinases; Casein Kinase1α (CK1α) and glycogen synthase kinase3β (GSK3 β). The kinases phosphorylate beta-catenin making it available for ubiquitination and maintaining its level low in the cytoplasm. *Right panel*: *The pathway is activated* when a Wnt ligand binds its frizzled receptor and its coreceptor LRP5/6. This complex associates with the disheveled protein that will prevent the formation of the destruction complex, avoiding beta-catenin phosphorylation and allowing beta-catenin to dissociate and accumulate in the cytoplasm and translocate to the nucleus. In the nucleus, beta-catenin will bind the T-cell factor (TCF)/Lymphoid enhancer factor LEF) transcription factors to activate Wnt target genes.

mutations in adrenocortical adenomas (AA) and adrenocortical carcinomas (ACC) (Tadjine *et al.*, 2005; Tissier *et al.*, 2005; Tadjine *et al.*, 2008a). Mutations of serine/theronine amino acids avoid beta-catenin degradation and leads to its cytoplasmic and nuclear accumulation and ultimately to upregulation of Wnt activity.

Since 2005, 7 large cohorts of patients with adrenocortical adenomas and/or carcinomas were screened for the presence of somatic *CTNNB1* mutations using direct sequencing (Tadjine *et al.*, 2005; Tadjine *et al.*, 2008a; Tissier *et al.*, 2005; Masi *et al.*, 2009; Gaujoux *et al.*, 2011; Bonnet *et al.*, 2011; Thiel *et al.*, 2015; Rubin *et al.*, 2016). Overall the prevalence of somatic *CTNNB1* mutations is of 25% in AA and ACC which is a high prevalence compared to other cancers such as colon cancer or breast cancer where the prevalence of *CTNNB1* mutations is of 4,7% and 0,2% respectively (Zhan *et al.*, 2017). Please note that these studies on adrenocortical tumors included mainly nonsecreting or cortisol-secreting tumors. **Table 1** summarizes the results of these seven studies.

Mutations in Other Components of the Wnt Signaling Pathway in Adrenocortical Tumors

An important observation is that beta-catenin protein accumulation is more frequent than *CTNNB1* mutations in adrenocortical adenomas and even more in adrenocortical carcinomas. For example, two studies found a prevalence of *CTNNB1* mutations of 27% (Tissier *et al.*, 2005) and 36% (Bonnet *et al.*, 2011) in adrenocortical adenomas, while beta-catenin protein accumulation was present with a prevalence of 39% and 59% respectively (Tissier *et al.*, 2005; Bonnet *et al.*, 2011). Similarly, *CTNNB1* mutations were found in 30,7% (Tissier *et al.*, 2005) and 18,4% (Gaujoux *et al.*, 2011) of ACC but beta-catenin accumulation was observed more frequently with a prevalence of 84,6% (Tissier *et al.*, 2005) and 44,8% (Gaujoux *et al.*, 2011). This suggests that defects in other components of the Wnt signaling pathway may lead to Wnt/beta-catenin pathway activation in adrenocortical tumorigenesis.

APC (adenomatous polyposis coli) which is part of the beta-catenin destruction complex was a candidate gene of the pathway. Inherited mutations of the *APC* gene are found in familial adenomatous polyposis (FAP). FAP is an autosomal dominant disease in which hundreds of colorectal adenomas develop early in life and may lead to colorectal cancer. Inactivation of the second allele of the *APC* gene conducts to stabilization of beta-catenin constitutively by impairing activity of the destruction complex. The incidence of adrenocortical tumors is increased in patients with FAP being two to four times more prevalent than in the general population (Marchesa *et al.*, 1997; Smith *et al.*, 2000). In addition, a germline *APC* mutation was found in a patient with BMAH (Hsiao *et al.*, 2009). Based on this data it was logical to exclude *APC* mutations in adrenocortical tumors. However, so far only

Table 1 Summary of larger cohorts of patients that were screened using direct sequencing for the presence of somatic *CTNNB1* mutations

	AA	*ACC*
Tissier et al. (2005)[a]	26,9% (7/26)	30,8% (4/13)
Tadjine et al. (2008a)	15% (5/33)	0% (0/4)
Masi et al. (2009)	19,5% (8/41)	20% (3/15)
Gaujoux et al. (2011)	NA	18,4% (9/49)
Bonnet et al. (2011)[a]	36% (36/100)	NA
Thiel et al. (2015)[a]	23,1% (12/52)	NA
Rubin et al. (2016)	18,3% (13/71)	20,1% (5/24)

[a]Excluding aldosterone-producing adenomas.
AA, Adrenocortical adenoma; ACC, Adrenocortical carcinoma.

silent *APC* mutations and polymorphisms were found in sporadic adrenocortical tumors (Gaujoux *et al.*, 2010). One other candidate was the Wnt signaling inhibitor *AXIN2* gene. AXIN2 inactivation leads to Wnt activation. The *AXIN2* in-frame heterozygous 12 bp deletion c2013_2024del12 was found in two adrenocortical adenomas and two carcinomas in two different studies (Chapman *et al.*, 2011; Guimier *et al.*, 2013). However, the significance of this variant remains to be determined.

Wnt Signaling in Adrenocortical Hyperplasia

In addition to adenomas and carcinomas, we described previously *CTNNB1* mutations in 2 out of 18 patients with primary pigmented nodular adrenal disease (PPNAD) (Tadjine *et al.*, 2008b) a form of bilateral micronodular adrenal hyperplasia. In both cases the mutations occurred in large adenomas that had formed in the background of PPNAD. Immunohistochemistry showed nuclear accumulation of beta-catenin in cells of the adenoma tissue whereas no nuclear immunoreactivity was detected in adjacent PPNAD nodular cells (Tadjine *et al.*, 2008b). Similarly, Gaujoux *et al.*, demonstrated beta-catenin accumulation in nine cases of PPNAD (Gaujoux *et al.*, 2008). Moreover, *CTNNB1* somatic activating mutations were found in the macronodule of two of the five macronodular PPNADs studied in this report (Gaujoux *et al.*, 2008).

Using microarray analysis, we found that Wnt signaling related genes were aberrantly expressed in bilateral macronodular adrenal hyperplasia (BMAH) however no *CTNNB1* mutations were described so far in BMAH (Bourdeau *et al.*, 2004). Recently, germline mutations in the Armadillo Repeat Containing 5 (*ARMC5*) gene were identified in sporadic and familial cases of BMAH (Assie *et al.*, 2013; Alencar *et al.*, 2014; Bourdeau *et al.*, 2016). In most cases an additional somatic *ARMC5* mutations were found in the BMAH adrenal tissue supporting the tumor suppressor role of *ARMC5*. Interestingly, ARMC5 contains an amino acid tandemly repeated sequence motif as in the mammalian armadillo homolog beta-catenin protein. Very recently, mouse models of ARMC5 deficiency were generated (Berthon *et al.*, 2017; Hu *et al.*, 2017) and lead to hypercorticosteroniemia at older age. Adrenocortical tissue analysis of the older ARMC5 deficient mice showed abnormal activation of the Wnt/beta-catenin signaling pathway in a subset of zona fasciculate cells (Berthon *et al.*, 2017).

Phenotype of Patients With Adrenal Tumors and Wnt Activation

In addition, to provide a better understanding on the molecular events leading to the development of adrenal tumors, Wnt signaling was described as associated to a more aggressive phenotype in patients with ACC (Gaujoux *et al.*, 2011). The presence of beta-catenin nuclear staining by immunohistochemistry and *CTNNB1* mutations were both significantly associated with decreased survival and disease free survival (Gaujoux *et al.*, 2011). These results were verified in two independent cohorts of ACC patients; the Cohin-COMETE cohort and the German-ENSAT cohort.

Regarding adrenocortical producing adenomas, in 2011, Bonnet *et al.*, studied a cohort of 100 tumors (Bonnet *et al.*, 2011). They found that tumors with *CTNNB1* mutations were predominantly nonsecreting and had larger size and weight compared to wild-type tumors suggesting less tumoral differentiation (Bonnet *et al.*, 2011).

This data was confirmed more recently in a study performed by the ENSAT study group where the genetic landscape of 99 adrenocortical cortisol-secreting or nonsecreting adenomas without the recurrent activating L206R mutation in the catalytic subunit of the cAMP-dependent protein kinase A (PKA) was determined using next generation whole exome sequencing (Ronchi *et al.*, 2016). In this study, the most frequent alterations were *CTNNB1* missense mutations localized at the amino acid 45 in the gene with a prevalence of 18% in patients with Cushing syndrome, 54% in patients with subclinical Cushing syndrome and 52% in patients with endocrine inactive tumors supporting Bonnet's data (Bonnet *et al.*, 2011). Thus *CTNNB1* mutations are more frequent in tumors with less differentiation. Moreover, this last study showed that mutations in the catalytic subunit of Protein kinase A (PKA) occur mutually exclusive to *CTNNB1* mutation (Ronchi *et al.*, 2016).

Beta-Catenin Mutations in Aldosterone-Producing Adenomas

Although most earlier studies on beta-catenin mutations focused on cortisol-secreting and nonsecreting tumors, few cases of aldosterone-producing tumors were reported in initial cohorts that were studied. In 2008, we described a 69-year old woman with primary aldosteronism where a somatic *CTNNB1* mutation was found in her aldosterone-producing adenoma (Tadjine *et al.*, 2008a). In 2009, Masi *et al.*, described two patients with aldosterone-producing adenomas and one patient with aldosterone-producing ACC with somatic *CTNNB1* mutations in their tumors (Masi *et al.*, 2009). In 2014, very important data was reported by a French team who found that constitutive activation of WNT/beta-catenin signaling was present in 70% of a cohort of 47 aldosterone-producing adenomas (APA) using immunohistochemistry (Berthon *et al.*, 2014). Although, no *CTNNB1* mutations were found in this study of 26 aldosterone-producing adenomas they demonstrated that decreased expression of the Wnt inhibitor SFRP2 may contribute to deregulation of Wnt signaling and APA development (Berthon *et al.*, 2014). In 2015, Teo *et al.*, reported the cases of three women with primary aldosteronism harboring *CTNNB1* mutations in their adenomas (Teo *et al.*, 2015). Two patients developed primary aldosteronism during pregnancy and one after menopause. In this study, the authors concluded to an association between somatic *CTNNB1* mutations in their adenomas and pregnancy or menopause due to high expression of LHCG receptors and GnRH receptors compared to other aldosterone-producing adenomas (Teo *et al.*, 2015). However, more recently, two large cohorts of patients with primary aldosteronism that were screened for the presence of *CTNNB1* mutations showed that the *CTNNB1* mutations may be found not only in females but in males as well. Although, no somatic *CTNNB1* mutations were found in initial studies (Boulkroun *et al.*, 2011; Berthon *et al.*, 2014), more recently somatic *CTNNB1* mutations were found in 2 out of 99 (prevalence of 2,1%) (Scholl *et al.*, 2015), 10 out of 198 (5, 1%) (Akerstrom *et al.*, 2016) and, 8 out 219 (3,7%) patients with primary aldosteronism (Wu *et al.*, 2017). All the patients reported so far in the literature with primary aldosteronism and somatic *CTNNB1* mutations are described in **Table 2**.

In Vitro Studies of Wnt-Signaling in Adrenocortical Cancer Cell Lines and In Vivo Mouse Models

The first evidence of a causal role of beta-catenin in the development of adrenal tumors was demonstrated by Lalli's group (Doghman *et al.*, 2008). They showed that the inhibitor of the T cell factor-beta-catenin complex PKF115–584 dose-dependently inhibits the human adrenocortical cancer cell line H295R proliferation (by decreasing the percentage of H295R cells and

Table 2 Summary of all cases of primary aldosteronism with somatic beta-catenin mutations described so far which include 19 females and 7 males with a mean age of 51-year old

	Sex	*Age (yo)*	CTNNB1 *mutations*

M: Male, F: Female, yo: year old, *CTNNB1*: beta-catenin gene.

increasing the % of apoptotic cells) (Doghman *et al.*, 2008). Furthermore, In 2010, Berthon *et al.*, showed that constitutive activation of beta-catenin in the adrenal cortex of transgenic mice leads to hyperplasia of the adrenal glands at 5 and 10 months with increase of adrenal size at 10 months. At 17 months, the mice developed primary hyperaldosteronism and their adrenal glands had malignant characteristics in 30% of cases (Berthon *et al.*, 2010).

Using microarray analysis we compared the gene expression profile of AA harboring *CTNNB1* mutations and wild-type AA (Durand *et al.*, 2011). We demonstrated up-regulation of *ISM1* (isthmin1, zebrafish homolog), *RALBP1* (RalAbinding protein 1), and *PDE2A* (phosphodiesterase 2A,cGMP-stimulated) in adrenocortical tumors with *CTNNB1* mutations compared with either WT adenomas or normal adrenal glands (Durand *et al.*, 2011). While *PHYHIP* (phytanoyl-CoA2-hydroxylase-interacting protein) was under expressed in tumors with *CTNNB1* mutations compared with normal adrenal tissue. mRNA expression and protein levels of *RALBP1*, *PDE2A*, and *ENC1* were decreased in a dose-dependent manner in the human adrenocortical cell line H295R which harbor a *CTNNB1* mutation after treatment with both antagonists of TCF/beta-catenin complex PKF115–584 and PNU74654 (Durand *et al.*, 2011).

Next-Generation Sequencing of Adrenal Tumors and Wnt/Beta-Catenin Signaling

In the last 3 years, the use of next generation sequencing including exome sequencing allowed to confirm the prevalence of *CTNNB1* mutations but also to identify new players of the Wnt/beta catenin signaling pathway. Genomic characterization of 122 ACC by Assié *et al.*, revealed that the most altered pathway in ACC was the Wnt/beta-catenin pathway with *CTNNB1* mutations being present in 16% of cases, and *APC* mutations in 2% of cases (Assie *et al.*, 2014). Moreover, homozygous deletions of the *ZNRF3* gene was found in 21% of tumors. *ZNRF3* encodes a cell surface transmembrane E3 ubiquitin ligase that acts as a negative feedback regulator of Wnt/beta-catenin signaling by promoting the degradation of the LRP and Frizzled receptors. *ZNRF3* mutations lead to loss of its negative feedback and activation of Wnt/beta-catenin signaling such as *CTNNB1* gene mutations but at a lesser degree. In other recent studies of ACC using NGS/exome sequencing, *CTNNB1* mutations were found in 9,8% (Juhlin *et al.*, 2015) and 16% (Zheng *et al.*, 2016) of ACC cases and *ZNRF3* mutations in 11,1% (Goh *et al.*, 2014), 9,8% (Juhlin *et al.*, 2015), and 16% (Zheng *et al.*, 2016) of ACCs. Similarly, a study combining exome sequencing and sanger sequencing approaches of 71 pediatric adrenocortical tumors demonstrated the presence of beta-catenin mutations in 13 out of 71 tumors with a prevalence of 18% but no *ZNRF3* mutations were reported in this pediatric series (Pinto *et al.*, 2015). *CTNNB1* mutations ($n = 13$) were detected only in tumors with wild-type germline *TP53* and not in those with constitutional *TP53* mutations (Pinto *et al.*, 2015).

Inhibition of Wnt Signaling Pathway as Potential Therapy

Taking into account the major role of Wnt signaling in adrenocortical tumors, Wnt components targets are of great interest for new treatments of ACC. Inactivation of Wnt signaling pathway could be achieved by various ways including (1) targeting extracellular signaling molecules with monoclonal antibodies for example, (2) preventing the FZD/Dvl interaction (3) stabilizing the destruction complex (4) increasing beta-catenin proteasomal degradation or (5) preventing the interaction between beta-catenin and its cofactors in the nucleus (Pez *et al.*, 2013). A wide variety of drugs inhibiting the Wnt pathway are currently used in preclinical studies or clinical trials for various cancers such as colon, breast or pancreatic cancers but none in in the treatment of ACC yet (Katoh and Katoh, 2017). Further studies are needed to explore the potential efficiency of these inhibitors for the treatment of patients with ACC for whom the actual options of treatment are limited and the overall survival remains poor.

Introduction

Heterotrimeric G-proteins are molecular switches that activate intracellular signaling cascades in response to the activation of G-protein-coupled receptors (GPCRs) by extracellular stimuli (Oldham and Hamm, 2008). These proteins are composed of α, β, and γ subunits, and their function depends on the ability of the G-protein α subunit (Gα) to cycle between an inactive conformation (GDP-bound) primed for interaction with an activated receptor and an active conformation (GTP-bound) that can modulate the activity of downstream effector proteins. The α subunit is a GTPase, which can be stimulated by the receptor to release GDP, bind GTP, and create an active state. Several α subunit types act directly on effector molecules to modulate their activity in specific manner: αs activates adenylate cyclases, αi inhibits adenylate cyclases, and αq activates phospholipase C isozymes (Hamm, 1998). (See **Table 1**.)

The GNAS gene encodes the α subunit of stimulatory G-proteins (GNAS, OMIM 139320) and is located on chromosome 20q13.32 (Weinstein *et al.*, 2004). Somatic gene point mutations are also termed *gsp* mutations and determine the loss of intrinsic α subunit GTPase activity, leading to subsequent constitutive activation of adenylate cyclase (Antonini *et al.*, 2004; Brown *et al.*, 2010).

gsp mutations are involved in the pathogenesis of McCune–Albright syndrome (MAS), which is classically defined by the clinical triad of bone fibrous dysplasia, *café au lait* skin macules, and gonadotropin-independent precocious puberty, in addition to other endocrine disorders. MAS is the first disease that has been linked to cAMP pathway signaling and Cushing syndrome due to excess cortisol production from the fetal adrenal gland, which primarily effects children in their first years of life (Dumitrescu and Collins, 2008).

Patients with MAS have the *gsp* mutation in a mosaic pattern with varying degrees of tissue involvement, ranging from a single site to a widespread distribution (Happle, 1986).

Naturally occurring mutations in codons 201 and 227, which alter GTPase activity in the *GNAS* gene, have been described in autonomous hormone-producing tumors. Mutations involving the substitution of arginine for cysteine; histidine; and, rarely, serine at codon 201 or arginine for glutamine at codon 227 were first described in GH-producing pituitary tumors (Landis *et al.*, 1989).

cAMP/PKA Signaling in Adrenocortical Cells

Metabolism, cell proliferation, steroidogenesis, and cortisol biosynthesis in the adrenal cortex are regulated predominantly by the cAMP/protein kinase A (PKA) signaling pathway (Almeida *et al.*, 2012; Bimpaki *et al.*, 2009; Bourdeau *et al.*, 2006). PKA exerts its functions via its effector, cAMP, by phosphorylating transcription factors of the cyclic AMP response element-binding (CREB) protein family. In normal adrenal cells, this pathway is activated through the binding of adrenocorticotropic hormone (ACTH) to the melanocortin 2 receptor (MC2R), a G-protein-coupled receptor (GPCR) that is highly expressed in adrenocortical cells, leading to increased levels of intracellular cAMP and subsequent activation of PKA (Bertherat *et al.*, 2003; Lefebvre *et al.*, 2015).

PKA is composed of four subunits, two catalytic and two regulatory, that are bound together when the pathway is not stimulated. As a result of pathway activation by hormones or neurotransmitter agonists of GPCRs, cAMP binds to the regulatory subunits of PKA. This binding induces the release of the catalytic subunits, which translocate to the nucleus in order to phosphorylate transcription factors. In the adrenal cortex, this process induces the transcription of steroidogenic enzymes and cortisol biosynthesis (Almeida and Stratakis, 2011; Bourdeau *et al.*, 2006).

Genetic alterations in the cAMP/PKA pathway have been reported in adrenocortical cells that lead to constitutive activation of this pathway and adrenal gland overstimulation, leading to tumor development and excessive hormone secretion (Louiset *et al.*, 2017).

Several genetic defects in cAMP/PKA that maintain pathway activation have been associated with adrenal disorders: ectopic expression of G-protein-coupled receptors (Lacroix *et al.*, 2001; Assie *et al.*, 2010), activating mutations in the gene encoding the $G\alpha_s$ protein (*GNAS*) (Landis *et al.*, 1989; Levine *et al.*, 1986; Weinstein *et al.*, 2004), activating mutations in *MC2R* (Almeida *et al.*, 2014), inactivating mutations in the gene encoding the RIα subunit of PKA (*PRKAR1A*) (Almeida *et al.*, 2012; Bimpaki *et al.*, 2009; Bourdeau *et al.*, 2006), inactivating mutations in the genes encoding two phosphodiesterases (PDE8 and PDE11A) (Horvath *et al.*, 2006; Horvath *et al.*, 2008), and activating mutations in the gene encoding the Cα subunit of PKA (PRKACA) (Calebiro *et al.*, 2014).

Thyroid cancer	~10	Suarez *et al.* (1991)

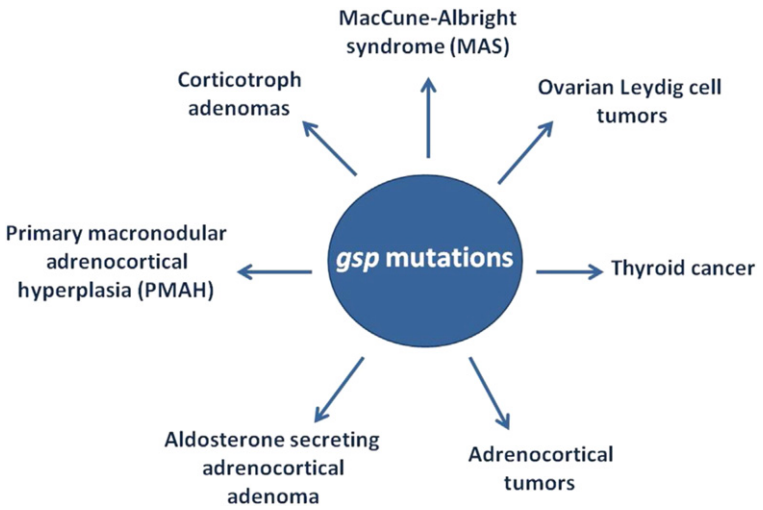

Fig. 1 *gsp* mutations associated with a variety of endocrine disorders.

Nevertheless, the molecular events described earlier are unable to explain all cases of adrenocortical disorders and the molecular pathogenesis of Cushing syndrome, as understanding the pathophysiology of adrenal tumors remains a challenge for the scientific community.

gsp Mutations in Adrenocortical Tumors

Although the pathogenesis of adrenocortical adenomas has not been completely elucidated, the genetic understanding of sporadic adrenocortical tumors has become clearer in the previous decades. Somatic mutations of genes encoding components of the cAMP/PKA pathway (*GNAS*, *PRKAR1A*, and *PDE8B*) and β-catenin (*CTNNB1*) have been reported in a small subset of cortisol-secreting adrenocortical tumors (Durand *et al.*, 2011).

gsp mutations have also been described in several tumors, such as corticotroph adenomas, thyroid cancer, ovarian and Leydig cell tumors, primary macronodular adrenocortical hyperplasia (PMAH) (Antonini *et al.*, 2004; Fragoso *et al.*, 2003; Hsiao *et al.*, 2009), and in rare cases cortisol- and aldosterone-secreting adrenocortical adenomas (**Fig. 1**). All of these described cases were outside of the classical context of McCune–Albright syndrome.

The first description of the involvement of *gsp* mutations in adrenal tumors was made by Yoshimoto *et al.* in 1993. This study systemically screened Gsα mutations in 197 human endocrine tumors, including pituitary, thyroid, parathyroid, endocrine pancreatic, and (cortex and medulla) adrenal tumors. The authors identified a unique female patient who was 29 years old and had primary aldosteronism associated with a somatic *gsp* mutation in an aldosterone-secreting adrenocortical adenoma, suggesting that when the renin–aldosterone system is suppressed, aldosteronomas become more sensitive to corticotropin stimulation. Accordingly, corticotrophins could be stimulated by Gsα-mediated cAMP production. The study hypothesized that *gsp* mutations may constitutively stimulate aldosterone synthesis via the zona glomerulosa by transmitting a constitutive signal through Gs-mediated cAMP production, which could play an important role in the tumorigenesis of aldosterone-secreting adenomas (Yoshimoto *et al.*, 1993).

Following the study by Yoshimoto *et al.*, several studies have detected the presence of *gsp* mutations in adrenal tumors, but none could explain their presence alongside the mechanism that leads to tumor formation and hormone hypersecretion. In 2000, Bugalho *et al.* described the presence of a mutation in codon 201 (CGT to TGT) in a patient with Cushing syndrome due to a

functioning adrenal adenoma that also expressed aberrant LH receptor (Bugalho *et al.*, 2000), Another patient with concomitant aberrant LH receptor expression and low-level autonomous cortisol secretion, formerly called "subclinical" Cushing syndrome, was found to have a heterozygous single-nucleotide substitution in the adrenocortical adenoma tissue, which altered codon 227 (Q227H) of the *GNAS* gene (Kobayashi *et al.*, 2000).

In 2004, *gsp* mutation was identified in one patient with ACTH-independent Cushing syndrome (Dall'Asta *et al.*, 2004). In 2013, the presence of genetic alterations was investigated in a series of 10 ACTH-independent Cushing syndrome cases due to adrenocortical cortisol-secreting adenomas. A *gsp* mutation was identified in only one case (Libé and Bertherat, 2005).

The first study to suggest that an activating mutation of *GNAS* associated with epigenetic alterations could lead to tumorigenesis was published by Sidhu *et al.* in 2013 (Sidhu *et al.*, 2013). This study demonstrated the presence of the *GNAS*-activating mutation (p.R201C) in a pediatric adrenocortical tumor. The tumor showed the following morphological features: areas of necrosis, microcytic degeneration, and venous and capsular microinvasion. The tumor tissue also presented an abnormal allele-specific hypomethylation of the *KCNQ1OT1* gene involved in Beckwith–Wiedemann syndrome (Sidhu *et al.*, 2013). It is known that somatic mutations in these genes may constitutively activate the cAMP/PKA signaling pathway, leading to cellular hyperproliferation that may result in genomic instability and epigenetic alterations to provide favorable conditions for the genesis of ACTs. The authors postulated that this activating mutation of the *GNAS* gene was the inciting event leading to hypomethylation of *KCNQ1OT1* (Sidhu *et al.*, 2013), which was already associated with tumorigenesis in other contexts (Sidhu *et al.*, 2013; Libé *et al.*, 2005; Sato *et al.*, 2014).

More recently, somatic mutations of *PRKACA* (encoding the catalytic subunit of protein kinase A) have been identified in more than one-third of the patients with Cushing syndrome due to sporadic adrenocortical adenomas. However, the molecular pathogenesis of the majority of sporadic adrenocortical tumors remained unclear (Bourdeau *et al.*, 2006; Libé *et al.*, 2005).

In a cohort of 65 adrenocortical tumors and matched normal specimens, a whole-exome sequencing study demonstrated that *PRKACA* was mutated in more than 50% of the tumor samples ($n = 34$; 28 confirmed as somatic), resulting in an identical c.T617G mutation predicted to cause the replacement of a leucine with an arginine at amino acid position 206 (p.L206R). This modification prevents binding to the inhibitory R subunits and leads to constitutive cAMP-independent activation of PKA. Furthermore, *GNAS* mutations (p.R201C) were found in 11 cases (6 confirmed as somatic). Mutations in *PRKAR1A*, *PDE11A*, *PDE8B*, and *ARMC5* were also investigated, but none were identified. Apparently, *PRKACA* and *GNAS* mutations in adrenocortical cells play an important role in the overt production of cortisol, as together they accounted for as many as 70% of the patient cohort in that study, almost exclusively in patients with clinical Cushing syndrome. Furthermore, *PRKACA*-mutated adenomas presented higher cortisol levels in the 1 mg overnight dexamethasone test and a smaller size when compared with wild type. Altogether, these results strengthen the hypothesis that mutations in these genes are related to the clinical features of these patients (Sato *et al.*, 2014).

Previous studies have demonstrated that mutations in *GNAS* and *PRKACA* are mutually exclusive and appear to be associated with small tumors, younger age at presentation, and overt Cushing syndrome (Sato *et al.*, 2014; Goh *et al.*, 2014).

In opposition to what has been observed in humans and mice, *GNAS* mutations in dogs seem more prevalent than *PRKACA*, as they were observed in 14 out of 44 cortisol-secreting adrenocortical tumors, whereas no functional mutations were found in *PRKACA*. This result, supported by the fact that *PRKACA* mutations have never been observed in dogs, suggests a difference in the molecular origin of the cAMP–PKA activation between these species (Kool *et al.*, 2013).

Recently, studies using next-generation sequencing have reported mutations in GNAS in an extensive variety of tumors, including parathyroid cancer, hepatocellular carcinoma, colon cancer, and pancreatic tumors. Next-generation whole-exome sequencing was performed by Ronchi *et al.*, in 2016, to detect the presence of *gsp* mutations in 11% of analyzed cortisol-producing adrenocortical adenomas (Ronchi *et al.*, 2016). *GSP* mutations have been identified in around 4.0% of the 9486 tumor sequences deposited in the COSMIC database of 185 somatic mutations in human cancer, making it one of the most frequently mutated G-proteins in cancers (Nakajima *et al.*, 2016; Fragoso *et al.*, 2003; Yoshimoto *et al.*, 1993).

De Martino *et al.* used hot spot gene sequencing and Sanger sequencing to identify a GNAS mutation in one adrenocortical carcinoma (ACC) case from a cohort of 40 ACC patients. This mutation was found in a patient presenting with isolated Cushing syndrome (stage III ACC (ENSAT), Weiss score = 6) and no clinical evidence of fibrous dysplasia (De Martino *et al.*, 2013). Juhlin *et al.* used whole-exome sequencing to detect 966 nonsynonymous somatic mutations in an ACC cohort, including 40 tumors with a mean of 16 mutations per sample and 1 tumor with more than 100 mutations. They also identified one sample with a mutation in *GNAS* (Arg201His) (Juhlin *et al.*, 2015).

Nakajima *et al.* recently detected *gsp* mutations in aldosterone-producing adenomas (APAs) with autonomous cortisol secretion. Interestingly, these mutations may induce the secretion of either cortisol and aldosterone or cortisol alone. The authors were the first to identify the *GNAS* mutation p.R201C in 2 out of 33 APAs, both of which presented with mild autonomous cortisol secretion as detected by nonsuppressed levels of cortisol after a 1 mg overnight dexamethasone test. In addition, they observed that in APAs harboring *KCNJ5* mutations, the presence of *GNAS* mutations was mutually exclusive (Nakajima *et al.*, 2016).

In summary, the presence of *gsp* mutations could affect both zonas fasciculata and glomerulosa, leading to either tumors that cosecrete aldosterone and cortisol or tumors that secrete cortisol alone. However, further studies are required to establish the mechanism by which *GNAS* mutations in these tumors cause hormone overproduction and cell proliferation.

Conclusion

Genetic analyses and a better understanding of the molecular pathogenesis of sporadic cortisol-secreting adenomas confirm that the cAMP/PKA signaling pathway plays an essential role in adrenocortical physiology and pathophysiology. Constitutive activating mutations of *GNAS* may cause cortisol-/aldosterone-secreting adenomas through the stimulation of both adrenocortical cell function and proliferation. Studies in this field have provided insight into the development of adrenal hormonal autonomy and may provide the basis for novel advances in the diagnosis and the treatment of Cushing syndrome due to adrenal disorders.

PPNAD, Carney Complex, and Other Micronodular Adrenal Hyperplasia

Stéphanie Espiard, Claude Huriez Hospital, Lille University Hospital, Lille, France
Jérôme Bertherat, Reference Center for Rare Adrenal Diseases, Cochin Hospital, Assistance Publique - Hopitaux de Paris, Paris, France

Nomenclature

cAMP	Cyclic adenosine monophosphate
CS	Cushing syndrome
CNC	Carney complex
iMAD	Isolated micronodular adrenocortical disease
MRI	Magnetic resonance imagery
PDE	Phosphodiesterases
PKA	Protein Kinase A
PPNAD	Primary pigmented nodular adrenal disease
PRKACA	Protein kinase cAMP-dependant catalytic subunit alpha
PRKAR1A	Protein kinase cAMP-dependant regulatory subunit type 1 alpha
US	Ultrasound

Introduction

The Carney complex (CNC) was first described in Carney *et al.* (1985). J. Aidain Carney and co. identified at the Mayo Clinic four cases of a quite unusual form of adrenal hyperplasia with micronodules and pigmentation leading to adrenal Cushing syndrome (CS) that he has named the primary pigmented nodular adrenal disease (PPNAD). After studying the history of these patients and additional patients presenting with PPNAD, he described the association of "myxomas, spotty pigmentation, and endocrine overactivity" named later Carney complex. Other syndromes previously described as the LAMB (lentigineses, atrial myxoma, mucocutaneous myxoma, blue naevi) (Rhodes *et al.*, 1984) or the NAME (naevi, atrial, myxoma, myxoid neurofibroma, ephelide) (Atherton *et al.*, 1980) are part of the CNC.

The PPNAD is the most frequent endocrine manifestations of the CNC. In the majority of cases, CNC is due to a germline mutation in the gene *PRKAR1A* encoding for the regulatory subunit type I alpha of the protein kinase A (PKA). Mutations of the gene can lead also to isolated PPNAD, that is, without other manifestations of the CNC (Espiard and Bertherat, 2013). Apart from this context, an isolated micronodular adrenocortical disease (iMAD) has been described in few cases related to mutations in the genes encoding for the phosphodiesterases (PDEs) *PDE11A* and *PDE8B* and to duplication of the gene *PRKACA* encoding for the catalytic subunit C-alpha of the PKA. The term of iMAD is preferred to PPNAD since a pigmentation of the micronodules is not constant in these cases (Almeida and Stratakis, 2010). To date, other cases of CNC or iMAD remain unexplained.

Carney Complex

Epidemiology and Clinical Presentations

The CNC is a rare disease. Its prevalence is also unknown (Lodish and Stratakis, 2016). The biggest published cohort included 353 patients from the National Institute Health (Bethesda, United States), the Mayo Clinic (Rochester, United States), and Cochin Hospital (Paris, France) (Bertherat *et al.*, 2009). Female are more often affected than male (Bertherat *et al.*, 2009; Stratakis *et al.*, 2001). There is no ethnic predisposition. Average age at diagnosis is 20-years-old (Stratakis *et al.*, 2001).

The CNC could be considered as an endocrine and nonendocrine multiple neoplasia syndrome (Stratakis *et al.*, 1998). The spectrum of manifestations, their severity and the age at diagnosis differ between the patients, even inside a same family. PPNAD can be the single manifestation of the disease, named in these cases isolated PPNAD. Isolated lentigines and isolated cardiac myxomas have been also described (Bertherat *et al.*, 2009). Diagnostic criteria have been established in 2001 (Stratakis *et al.*, 2001) (**Table 1**).

Cardiac Myxoma

Primary cardiac tumors are rare and cardiac myxomas are the most common of them. They are nonmalignant tumors, but with potential severe cardiovascular complications. Only 3%–10% of the cardiac myxomas are observed as familial cases. The majority of these familial cases occur as a component of CNC. The clinical presentation is variable: patients can be asymptomatic or presenting cardiovascular symptoms including heart failure, dyspnea, palpitations, and angina. Nonspecific constitutional symptoms as fever, asthenia, malaise, arthralgia have been also described. Embolization of tumor fragments or surface thrombi leads to the most dramatic complications: the stroke attack or the systemic infraction (Jain *et al.*, 2015). CNC patients are affected by cardiac myxomas in 32%–53% of cases (Bertherat *et al.*, 2009; Stratakis *et al.*, 2001). The usual locations are the left atrium

Table 1 Diagnostic criteria (established in Stratakis *et al.*, 2001) and their frequency among CNC patients

Major diagnostic criteria for CNC	*Frequency*[a] *(%)*
1. Spotty skin pigmentation (lentiginosis) with typical distribution (lips, conjunctiva and inner or outer canthi, vaginal mucosa)	70–77
2. Myxoma (cutaneous and mucosa)[b]	20–32
3. Cardiac myxoma[b]	32–53
4. Breast myxomatosis[b] or fat-suppressed magnetic resonance imaging findings suggestive of this diagnosis	20
5. Primary pigmented adrenocortical disease[b] or paradoxical positive response of urinary glucocorticosteroid excretion to dexamethasone administration during Liddle's test	26–60
6. Acromegaly due to GH-producing adenoma[b]	10–12
7. Large-cell calcifying Sertoli cell tumor[b] or characteristic calcification on testicular ultrasound	33–41
8. Thyroid carcinoma[b] or multiple, hypoechoic nodules on thyroid ultrasound in a young patient	5–25
9. Psammomatous melanotic schwannomas[b]	8–10
10. Blue nevus, epithelioid blue nevus[b]	50
11. Breast ductal adenoma[b]	20
12. Osteochondromyxoma[b]	2
Supplementary criteria	
1. Affected first degree relative	
2. Inactivating mutation of the *PRKAR1A* gene	

[a]According to (Stratakis *et al.*, 2001) and (Bertherat *et al.*, 2009).
[b]After histological confirmation.
Diagnosis of CNC is made if the patient exhibits two of the major manifestations or one of these and one of the supplemental criteria (Stratakis *et al.*, 2001).

followed by the right atrium, but in CNC, by contrast with sporadic myxomas, they can be located in any chambers and can be multiple (Bertherat *et al.*, 2009; Jain *et al.*, 2015). The median age at the detection of the first myxoma varies between 35 and 50-years-old depending on the series (Bandettini *et al.*, 2016; Bertherat *et al.*, 2009). Indeed, there is a large range in the age at diagnosis and tumor can be diagnosed in pediatric patients as early as 3-years-old. Risk of recurrence is higher in CNC than for sporadic cases. The growth of the tumor can be very fast and appearance of new myxomas can be observed in less than 1 year of time (Bertherat *et al.*, 2009; Jain *et al.*, 2015). Recently, it has been suggested that patients with growth hormone (GH) excess are more prompt to develop cardiac myxomas (Bandettini *et al.*, 2016).

Transthoracic echocardiography is the primary imaging for screening and follow-up of the cardiac myxomas. The tumor appears as an isoechogenic mass compared to cardiac wall (**Fig. 1**A). Transesophageal echocardiography and cardiac magnetic resonance imagery (MRI) are useful complement to better characterize multiple tumors and tumor shape and density. On MRI, the myxoma is heterogeneous, hyperintense in T2 weighted lesion (**Fig. 1**B) (Courcoutsakis *et al.*, 2013; Jain *et al.*, 2015).

The only definitive treatment is surgery. Progress made in this area the last decade improved the morbi-mortality of CNC patients. Historically, these tumors were the main cause of death because of their own complications but also the surgical complications (Espiard and Bertherat, 2013). Diagnosis must be also early and annual follow-up after 4-years-old is suggested (Stratakis *et al.*, 2001).

Skin Manifestations

The most frequent lesions are the spotty skin pigmentation component named lentigines observed in about 70% of patients (Bertherat *et al.*, 2009; Mateus *et al.*, 2008; Stratakis *et al.*, 2001). They are hamartomatous melanocytic lesions appearing typically as brownish to black macules located on the lips, the eyelids, the genital area in female or the fingers (**Fig. 2**A and B). The spots appear during the two first decades of life but can be detectable at birth. Color is more intense after puberty and can fade over time. The distinction with solar pigmented spots becomes also difficult (Espiard and Bertherat, 2013; Mateus *et al.*, 2008). Other pigmented lesions (blue, Spitz, and typical naevi, café-au-lait spots) are present in about 50% of patients. Blue naevi are the second most frequent dermatologic lesions in CNC patients (**Fig. 2**C) (Bertherat *et al.*, 2009; Mateus *et al.*, 2008).

Cutaneous myxomas are benign lesions detected in 20%–33% of patients but frequency is probably underestimated by lack of specialized screening. It is the most specific sign of the disease but differential diagnosis with other lesions as papilloma or cutaneous fibroma can be difficult at clinical examination. Skin biopsy is therefore usually needed to confirm the diagnosis. Appearance varies from small pink papules to large sessile lesions (**Fig. 2**D). Typical locations are the eyelids, the external ear canal and the trunk (Bertherat *et al.*, 2009; Mateus *et al.*, 2008; Stratakis *et al.*, 2001).

No malignant transformation of these lesions have been described and CNC does not seem to predispose to skin carcinomas (Espiard and Bertherat, 2013; Mateus *et al.*, 2008). The identification of the dermatologic lesions is important because they are among the earliest manifestations of the disease and patients with multiple skin manifestations seems to present larger number of others manifestations (Mateus *et al.*, 2008).

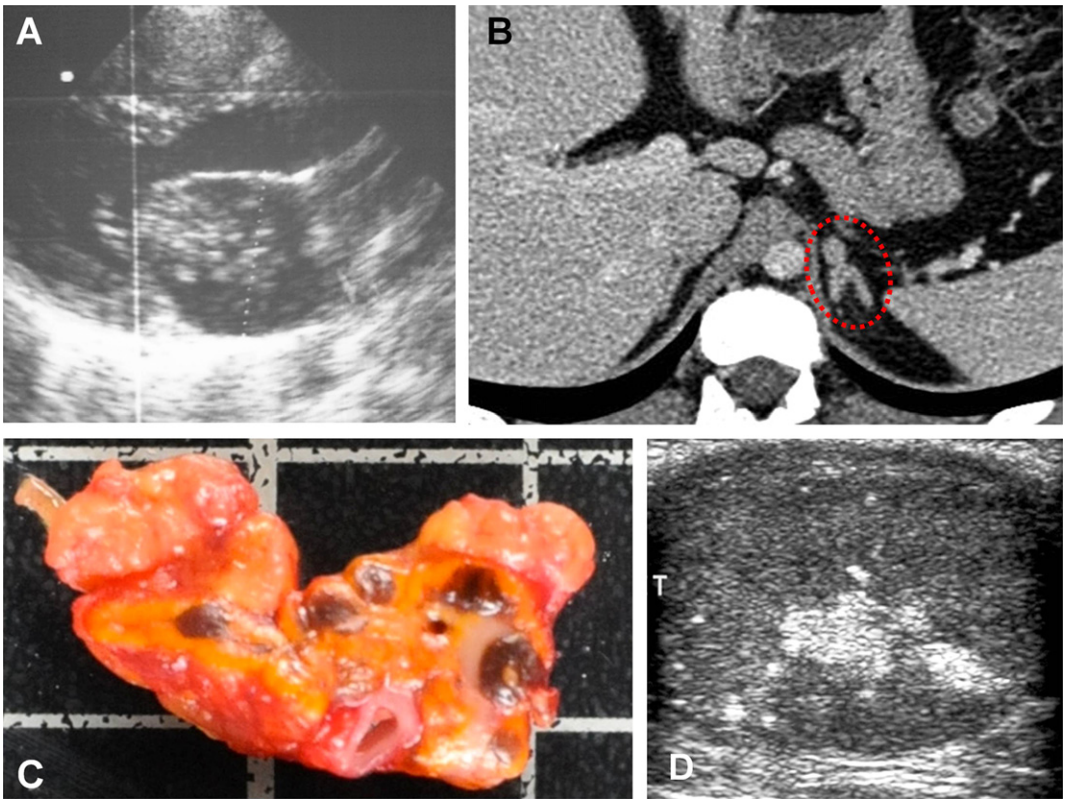

Fig. 1 Radiological and pathological findings in CNC. (A) Typical presentation of a left atrial cardiac myxoma on transthoracic echocardiography. (B) PPNAD appearance on CT-scan: left adrenal hyperplasia with micronodules of the body of the adrenal (*red circle*). (C) Macroscopic presentation of PPNAD: normal size adrenal with multiple pigmented nodules. (D) Multiple microcalcifications typical of LCCST on testicular US.

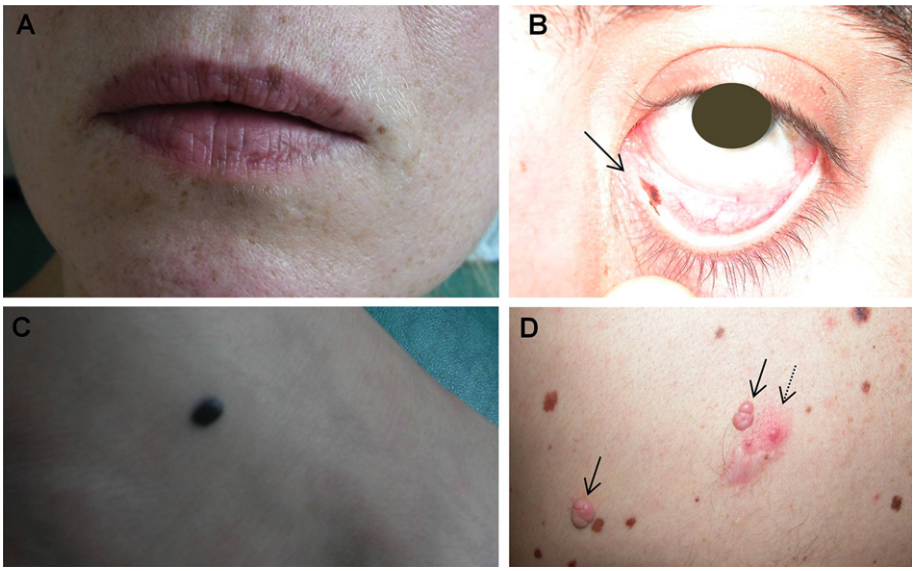

Fig. 2 Skin manifestations of CNC. (A) The perioral lentigines appears as pigmented spots. The presence of several lentigines and the confluency of some of them realize a typical lentiginosis. (B) Periocular lentigines with a typical lentigines of the inferior eyelid (*arrow*). (C) Bleu naevi: *dark blue* nodular lesion. (D) Cutaneous myxomas appearing as sessile nodular lesions (*continue arrows*) or papule (*discontinued arrow*).

PPNAD (Primary Pigmented Nodular Adrenocortical Disease)

PPNAD is the most frequent endocrine manifestations of the CNC reported in 26%–60% of patients (Bertherat *et al.*, 2009; Stratakis *et al.*, 2001). It is isolated for 12% of patients (Bertherat *et al.*, 2009). Some patients developed PPNAD during the first

years of life but the majority are diagnosed during the second and third decade (Stratakis *et al.*, 2001) with a median age evaluated at 35-years-old. After puberty, a female predominance is observed (Bertherat *et al.*, 2009).

The clinical presentation is variable: clinical CS (observed for about half of the patients), subclinical CS or no clinical signs (Lowe *et al.*, 2017). The appearance of the CS can be brutal, insidious or cyclic (Gunther *et al.*, 2004; Lowe *et al.*, 2017). The abnormal laboratory findings vary from an overt ACTH-independent CS to an isolated loss of cortisol suppression after dexamethasone test (Lowe *et al.*, 2017). These biological abnormalities could vary overtime. A paradoxical elevation of urinary free cortisol after Liddle's dexamethasone suppression test (increase of 50% of the basal UFC after administration of 0.5 mg/6 h for 2 days followed by 2 mg/6 h for 2 days) has been reported in 69% of patients with PPNAD (Stratakis *et al.*, 1999). This paradoxical response has been also observed in cortisol-producing adrenocortical adenoma due to somatic mutation of *PRKAR1A* (Bertherat *et al.*, 2003). This paradoxical response has been related to a stimulation of PKA subunits by dexamethasone through a glucocorticoid receptor (GR)-mediated mechanism (Bourdeau *et al.*, 2003; Louiset *et al.*, 2009).

There is no specific computed tomography feature of PPNAD. Imaging most often reveals micronodules or an abnormal contour of the glands but normal imaging or the presence of macronodules are frequent (Groussin *et al.*, 2002a; Vezzosi *et al.*, 2015). The realization of high resolution computed tomography with 3 mm-slice thickness and injection of contrast media is important to detect micronodules which appeared as hypodense spots (Courcoutsakis *et al.*, 2013). Noriodocholesterol scintigraphy shows a bilateral adrenal uptake in accordance to the bilateral nature of the disease, but asymmetrical scintigraphic uptake can be observed in patients with macronodules (Vezzosi *et al.*, 2015).

Pathologically, the glands have a normal size and weight or are slightly enlarged and the adrenal cortex harbors multiple small (<10 mm) yellow to black pigmented nodules around an atrophic cortex (**Fig. 1**C) (Carney *et al.*, 1985; Shenoy *et al.*, 1984; Stratakis *et al.*, 1999). Systematic autopsy shows adrenal lesions in every patient, even those who were asymptomatic (Stratakis *et al.*, 1999).

Recently, two cases of adrenocortical carcinomas were described in patients affected by CNC. In both cases, were observed a cosecretion of androgens and cortisol and rapid occurrence of metastasis and local recurrence (Anselmo *et al.*, 2012; Bertherat, 2012; Morin *et al.*, 2012). One case of androgen secreting benign adenoma has been described (Hofland *et al.*, 2013). It is not clear if these very rare manifestations could be considered as part of the syndrome.

The usual treatment for patients harboring CS is the bilateral adrenalectomy (Powell *et al.*, 2008; Sarkar *et al.*, 1990). Anticortisolic drugs as ketoconazole or Op'DDD have been more rarely used because they are less appropriated for a long-term treatment even if case reports have been described (Campo *et al.*, 2015). Usual follow-up for mutated patients who remain asymptomatic is annual measurement of the UFC (Stratakis *et al.*, 2001) but overnight 1 mg DXM suppression test could be considered now.

Acromegaly and Other Pituitary Manifestations

GH-producing tumor has been described in 10%–12% of patients (Bertherat *et al.*, 2009; Stratakis *et al.*, 2001). Clinical acromegaly is not frequent and does not become often apparent after treatment of CS if associated. On MRI, micro or macroadenomas, unique or multiple can be observed (Kirschner, 2010; Lonser *et al.*, 2017). Beyond these patients, biological dysregulation of the somatotroph axis without anomaly of the pituitary MRI is a frequent feature of CNC patients, especially an absence of suppression of GH after oral glucose tolerance test or a paradoxical increase of GH after TRH stimulation (Courcoutsakis *et al.*, 2013; Pack *et al.*, 2000; Raff *et al.*, 2000; Watson *et al.*, 2000). Mild elevation of PRL may be frequent (Raff *et al.*, 2000) but the occurrence of prolactinoma is rarely described (Kirschner, 2010). Pathological examination after surgery usually shows hyperplasia of the somatotroph compartment plus possibly the lactotroph one (Pack *et al.*, 2000). The adenoma, if present, stains for GH as well as frequently PRL, sometimes alpha subunit and rarely TSH and LH (Kirschner, 2010; Pack *et al.*, 2000). Management of patients with GH-producing tumors has no specificity comparing to non-CNC patients, even if partial or complete hypophysectomy may be required to achieve biochemical remission by surgery. Also, medical treatment as somatostatin analogue or GH antagonist are frequently used (Espiard and Bertherat, 2013; Lonser *et al.*, 2017; Watson *et al.*, 2000).

Thyroid Tumors

The occurrence of multiple thyroid nodules at young age has been described as part of CNC. Prevalence of nodules has been evaluated from 5% to 25% of CNC patients (Bertherat *et al.*, 2009; Stratakis *et al.*, 1997, 2001) but systematic thyroid ultrasound screening can reveal multiple, small, hypoechoic lesions in up to 64% of patients. The thyroid function is usually normal (Stratakis *et al.*, 1997). In case of benign nodules, pathological examination shows follicular adenomas (Stratakis *et al.*, 1997, 2001). CNC is associated with an increased risk to develop thyroid cancer. The prevalence of papillary of vesicular thyroid tumors has been evaluated from 2.5% to 3.8% of patients (Bertherat *et al.*, 2009; Stratakis *et al.*, 1997, 2001). It is therefore suggested to realize a thyroid US at the diagnosis (Stratakis *et al.*, 2001). Follow-up may be as recommended for the general population in function of the initial observation.

Testicular Lesions

Male patients can develop testicular lesions, especially large cell calcifying Sertoli tumors (LCCST) and rarely Leydig tumor or adrenocortical rests (Carney *et al.*, 1985; Stratakis *et al.*, 2001).

LCCST are a particular form of sex cord stromal tumors that is usually bilateral and multifocal (Gourgari *et al.*, 2012; Washecka *et al.*, 2002). Frequency is estimated to 33% to 41% of male (Bertherat *et al.*, 2009; Stratakis *et al.*, 2001). Mean age at diagnosis is in the third decade, but tumors have been observed as early as 4-years-old (Gourgari *et al.*, 2012; Washecka *et al.*, 2002). Most of the time, the lesions are not detectable by physical examination and are asymptomatic. Rarely, macrocalcifications and testis enlargement can be palpated. Because these tumors express aromatase, conversion of androstenedione to estrone in prepubertal males can cause growth acceleration and gynecomastia while conversion of testosterone to estradiol in postpubertal male can cause gynecomastia. Rare malignant forms with occurrence of metastasis have been described (Washecka *et al.*, 2002). Progressive expansion of the tumors can block the seminiferous tubes and participate to a reduction of the fertility. However, an independent decrease of the quality and the quantity of the sperm has been described in CNC male patients (Burton *et al.*, 2006). This might explain in part that in families, the disease tends to be more frequently transmitted by the mother (Stratakis *et al.*, 2001). Testicular US can show bilateral enlargement in testicular volume with or without microcalcifications (Gourgari *et al.*, 2012) (**Fig. 1**D). Medical treatment by antiaromatase or surgical treatment can be proposed (Brown *et al.*, 2007; Crocker *et al.*, 2014). Surgical treatment is only proposed for symptomatic disease (enucleation of tumors or partial orchidectomy) (Washecka *et al.*, 2002).

Leydig tumors or adrenal rest are observed in less than 1% of patients (Stratakis *et al.*, 2001). Cases of recurrence of the CS after bilateral adrenalectomy due to the gonadic rest have been described (Carney *et al.*, 1985).

Ovarian Lesions

Ovarian lesions have been diagnosed in 14% of female patients in a large restrospective study (Bertherat *et al.*, 2009). These are mainly surface-derived epithelial tumor. Systematic pelvic ultrasound show cystic lesions in more than half of the patients (Stratakis *et al.*, 2000). When surgery is needed, serous cystadenomas have been diagnosed but occurrence of ovary carcinoma has been described (Stratakis *et al.*, 2000).

Rarely, benign cystic teratoma (germinal tumor) (Carney *et al.*, 1985; Stratakis *et al.*, 2000) and granulosa tumor (stromal tumor) have been described, the latter causing virilization by testosterone production (Carney and Stratakis, 2011).

Schwannomas

Schwannomas has been observed in 8%–10% of patients (Bertherat *et al.*, 2009; Stratakis *et al.*, 2001). Specific pathological features have been described in CNC patients: pigmentation by melanin, frequent calcifications, and psammomatous body. Because of these characteristics they are named melanocytic psammomatous schwannomas. Usually these are multifocal, mainly located at the paraspinal sympathetic chain but also at the gastrointestinal tract, in bone or skin (Carney and Stratakis, 1998). Paraspinal and bone locations can cause neurological complications and pain respectively (Carney and Stratakis, 1998; Stratakis *et al.*, 2001). Malignancy has been observed (up to 10% of these schwannomas could probably be malignant) with occurrence of lung, liver or brain metastasis. MRI presentation depends of the size and the localization. Most often, they appear as a soft tissue tumor with calcifications and possibly bone osteolysis and osteosclerosis (Courcoutsakis *et al.*, 2013). Surgical treatment can be proposed but could be challenging for some localization and regarding the risk of surgical complications. In case of malignancy and metastasis, medical treatment or radiotherapy are alternative (Mees *et al.*, 2008).

Breast Lesions

Breast lesions are observed in about 20% of female patients (Bertherat *et al.*, 2009; Carney and Toorkey, 1991). However this percentage is likely to represent an underestimation of the true incidence of these lesions because breast imaging (MRI, ultrasound or mammography) was performed in only a small number of the patients of these series. The lesions are possibly palpable and most of the time asymptomatic (Courcoutsakis *et al.*, 1997, 2013).

Breast myxomas are characterized by an accumulation of myxoid material in single lobules, small groups of lobules or large aggregates of lobules resulting in the formation of myxoid fibroadema. Usually, lesions are multiple and bilateral. Male can also been affected (Carney and Toorkey, 1991; Stratakis *et al.*, 2001). Mammography shows opaque well-limited noncalcified lesions. These lesions are usually numerous and referred also as "breast myxomatosis." Chest MRI with inversion recovery sequence shows all the lesions which appeared hyperintense (Courcoutsakis *et al.*, 1997).

Breast ductal adenoma are detected in about 3% of patients (Carney and Toorkey, 1991; Stratakis *et al.*, 2001) and present usually as an unique palpable nodule. Mammography shows a well-limited calcified soft tissue tumor (Courcoutsakis *et al.*, 1997, 2013).

About 1% of female in the series reported in 2001 developed a breast carcinoma. Also a needle aspiration of every suspicious nodules, as the calcified ones, should be realized (Stratakis *et al.*, 2001).

Osteochondromyxomas

The osteochondromyxomas are rare bone lesions corresponding to benign chondrogenic tumors (Carney *et al.*, 2001). Frequency in CNC is estimated to 2% of patients (Stratakis *et al.*, 2001). These tumors have been mainly described in pediatric patients as early as few month of life suggesting that they could be congenital (Carney *et al.*, 2001). The most frequent location is the diaphysis of long bones or the sinus and nasal bones (Golden and Siordia, 2016). These tumors are painless. They are often diagnosed if they cause edema or mass effects as nasal obstruction for ethmoid tumor. There are no uniform radiological features and osteochondromyxomas can appear as lytic or as expansile bone lesions. On spinal MRI, it has been suggested that the vertebral lesions slightly hyperintense on T2 weightening with postcontrast enhancement observed in some CNC patients could correspond to spinal osteochondromyxoma (Courcoutsakis *et al.*, 2013). The pathological diagnosis is difficult: the tumors appeared as a mix bony and cartilaginous, myxoid, and hyalinous osteolytic lesion involving the adjacent soft tissue (Carney *et al.*, 2001; Golden and Siordia, 2016).

Other Lesions

Pancreatic tumors have been described in about 2% of CNC patients and are responsible for 4%–20% cause of death (Bertherat *et al.*, 2009; Carney and Toorkey, 1991). These tumors are mainly pancreatic cystic neoplasms, especially intraductal papillary mucinous neoplasms (IPMN) or pancreatic acinar cell carcinomas (Bertherat *et al.*, 2009; Gaujoux *et al.*, 2011).

Other rare tumors have been reported as malignant colonic or gastric tumors, hepatocellular adenomas or and carcinomas, and one case of retro-peritoneal fibrosing hystocytioma (Stratakis *et al.*, 2001).

Molecular Genetics and Pathophysiology

The cAMP/PKA-Signaling Pathway

The second messenger cAMP plays a major in development, maintenance and secretory activity of several endocrine glands. For instance, stimulation of the cAMP pathway by adrenocorticotropin (ACTH) is essential for adrenal cortex growth, maintenance and glucocorticoid and adrenal androgens production. ACTH stimulates the cAMP pathway after binding to the melanocortin 2 receptor, a 7-transmembrane receptor coupled to Gs protein. The activated Gs protein stimulated the enzyme adenyl cyclase (AC) which assures the synthesis of cAMP. PKA is a heterotetramer formed by two regulatory subunits and two catalytic subunits. In human, four different regulatory subunits (RIalpha, RIbeta, RIIalpha, RIIbeta), and four catalytic subunits (Calpha, Cbeta, Cgamma and PRKX) have been identified. When cAMP binds to the regulatory subunits of PKA, this results in the dissociation from the catalytic subunits. The free catalytic subunits can phosphorylate many cytoplasmic and nuclear targets such as the transcription factor cAMP response binding protein (CREB) involved in steroidogenesis. The cAMP is degraded by the phosphodiesterases which regulate the pathway (**Fig. 3**A).

Identifications of the CNC Gene Locus

Genetic linkage analysis identified two independent loci for CNC: CNC1 located on chromosome 17q22–24 and CNC2 on the 2p16 (Casey *et al.*, 1998; Stratakis *et al.*, 1996). In OMIM (Online Mendelian Inheritance in Man) database, the disease is referred as MIM160980 for CNC1, MIN605244 for CNC2 and MIM610489 for the isolated PPNAD.

The gene located at 17q has been identified in 2000 as *PRKAR1A* (Casey *et al.*, 2000; Kirschner *et al.*, 2000). The haploinsufficiency or the defective protein leads to an overactivation of the PKA signaling pathway by the lost of its inhibitory effect on the catalytic subunit (**Fig. 3**B).

Currently no candidate gene has been found on the CNC2 locus. Chromosomal alterations as an amplification of this loci has been described in different tumors from patients wild-type or mutated for *PRKAR1A* (Matyakhina *et al.*, 2003).

PRKAR1A Defects

The *PRKAR1A* gene contains 10 coding exons. In 2010, 117 different mutations had been reported in 284 unrelated families of various ethnic origins (Horvath *et al.*, 2010) and new mutations continue to be reported. In more than 60% of CNC index cases a *PRKAR1A* defect can be detected, including 80% of CNC familial cases and 37% of CNC sporadic cases (namely without a family history suggestive of CNC). The majority of the mutations in sporadic cases are also de novo (Bertherat *et al.*, 2009). Molecular alterations are point mutations or small deletions involving up to 15 bp (Bertherat *et al.*, 2009; Horvath *et al.*, 2010) although larger gene deletions have been described in rare cases (Horvath *et al.*, 2008a). *PRKAR1A* is a suppressor gene according the Knudson theory: one allele is inactivated by a germline mutation and the second allele is inactivated in the tumor (**Fig. 4**A). Mutations are spread along the exons and their adjacent intronic sequences. Exons 2, 3, 5, 7, and 8 are more frequently involved.

Mutations have been categorized in groups according to their molecular consequences. The first group including 80% of the mutations (nonsense, frame shift or splice variants) leads to a premature stop codon causing degradation of the messenger RNA (mRNA) by a mechanism of Nonsense Mediated mRNA Decay (NMD). In this case no mutant protein is produced. In the tumor,

(B) Inactivating mutations of the regulatory subunit I alpha of the PKA (*PRKAR1A*) lead to the dissociation of the catalytic subunits in the absence of cAMP. (C) Inactivation of phosphodiesterase by mutation leads to an accumulation of cAMP and overactivation of the pathway. (D) Duplication of *PRKACA* gene leads to an overexpression of catalytic subunits alpha and increase of its effect on target genes. *ACTH*, Adrenocorticotropic hormone; *AC*, adenylate cyclase; *PKA*, protein kinase A; *PDE*, phosphodiesterase; *R*, regulatory subunits of protein kinase A; *C*, catalytic subunits of protein kinase A; *CREB*, cAMP response binding protein. Adapted from Espiard, S. and Bertherat, J. (2015). The genetics of adrenocortical tumors. *Endocrinology and Metabolism Clinics of North America* **44**, 311–334.

the loss of the other allele is frequently observed. The second group of mutations escapes the NMD and leads to a defective mutant protein with an altered sequence for missense mutations. Alternatively, the protein is either shorter for premature stop codon in the 3′end or large deletion, either longer for frameshift mutation located in the last coding exons. Because these mutant proteins can exert a dominant negative effect over the wild type protein, the somatic allelic loss of the wild type allele is not always required with this group of mutations (Groussin *et al.*, 2002b; Horvath *et al.*, 2010). More recently, for some frameshift mutations located in the last coding exon of the gene, a mechanism of proteasomal degradation of the mutant protein leading to an haploinsufficiency has been described (Patronas *et al.*, 2012) (**Fig. 4**A and B).

Three mutations have been found in more than three pedigrees and are considered as hot spot: c.82C>T (exon 2), c.491_492del (exon 5) and c.709(-7-2)del (intron 7). The two latter were observed in 11 and 14 families respectively (Bertherat *et al.*, 2009). The other mutations are considered as "private," identified in only one or few families.

The overall penetrance of *PRKAR1A* mutations has been evaluated around 95% by the age of 50 years. Only two mutations (c.709(-7-2)del6 and c.1A>G) have an incomplete penetrance (Horvath *et al.*, 2010). Some genotype/phenotype correlations have been established (Bertherat *et al.*, 2009):

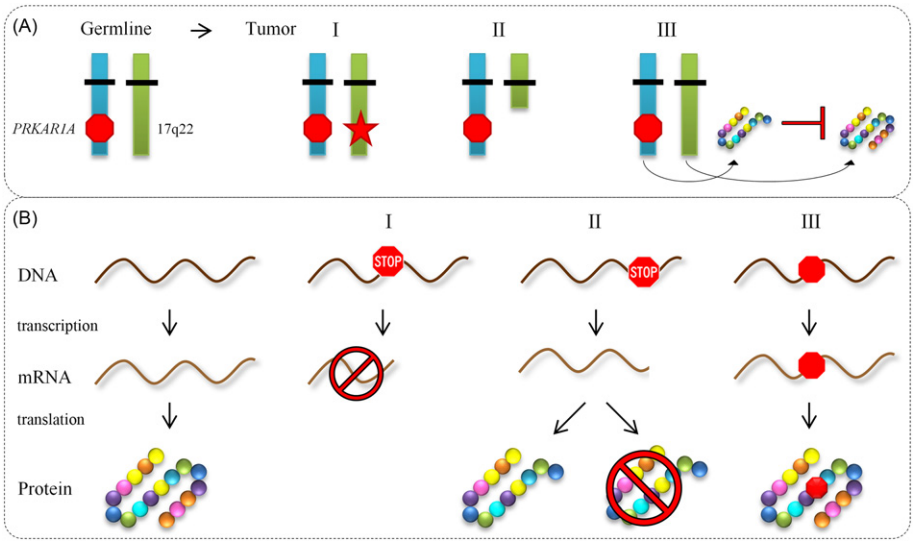

Fig. 4 Mechanism of inactivation of *PRKAR1A*. (A) One mutation (*red octagon*) inactivates one allele at the germline level. In the tumor, either the second allele is inactivated by another mutation (*red star*) (I), either the second allele is lost (II), either the mutant protein inhibits the normal function of the wild-type protein (dominant negative effect) (III). (B) The premature stop codon leads to the degradation of the mRNA (Nonsense mediated decay) (I). A mutation located at the end of the gene can lead to the translation of a defective protein (example a shorter protein for a stop codon) which can be quickly degraded by proteosome. A missense mutation leads to the translation of a defective protein (III) which can also exert a dominant negative effect on the wild-type protein.

- Intronic mutations lead to a less severe phenotype, especially the c.709(-7-2)del6 and c.1A>G mutations that are associated with isolated PPNAD.
- Exonic mutations are more often associated with acromegaly, cardiac myxomas, lentigines, and schwannomas.
- Mutations that escape NMD and lead to the translation of a mutant protein are associated with a higher number of CNC manifestations.
- The hot spot c.491–492delTG is most often associated with cardiac myxomas, lentigines and thyroid tumors.
- Patients without *RKAR1A* mutations have less myxomas at any locations and manifestations appeared latter.
- Recently, it has been suggested that the patients harboring large deletion of the gene may have a severe phenotype (Bataille *et al.*, 2014; Stelmachowska-Banas *et al.*, 2017).

Others Genetic Defects

Phosphodiesterases genes

The phosphodiesterases (PDE) hydrolyze cAMP and/or cGMP to decrease their cellular level. Inactivating germline mutations of *PDE11A* have been found in children with iMAD (Horvath *et al.*, 2006a). In addition, rare single nucleotide polymorphisms leading to a slight decrease of activity of the enzyme predispose Carney patients with *PRKAR1A* mutation to developed a PPNAD and/or a LCCST (Libé *et al.*, 2011). A mutation of the *PDE8B* gene has been described in a patient who developed PPNAD at 2-years-old (**Fig. 3**C) (Horvath *et al.*, 2008b; Rothenbuhler *et al.*, 2012).

PRKACA

Germline duplication of the locus at chromosome 19p containing the *PRKACA* have been described in patients presenting iMAD or isolated PPNAD responsible of an early and severe CS (**Fig. 3**D) (Beuschlein *et al.*, 2014; Lodish *et al.*, 2015).

Mice Models of CNC and Adrenal Hyperplasia

Various transgenic mice models have been developed to study the consequences of the inactivation of *PRKAR1A* on tumors development. *Prkar1a* homozygous knock-out mice died during embryonic development (Amieux *et al.*, 2002). To bypass the embryonic lethality, transgenic mice carrying inducible antisense transgene were established. These mice develop different tumors including thyroid hyperplasia and adenomas, adrenocortical hyperplasia, lymphomas, hepatocellular carcinomas, sarcomas, and others mesenchymal tumors (Amieux *et al.*, 2002). Heterozygous mice survive and develop only schwannomas, thyroid tumors and fibro-osseous bone lesions (Kirschner *et al.*, 2005) meaning that a complete loss a *prkar1a* is necessary for the development of the majority of tumors. Mice with a tissue-specific inactivation of *prkar1a* develop tumors of the targeted tissue, especially pituitary (Yin *et al.*, 2008a), heart (Yin *et al.*, 2008b), thyroid (Pringle *et al.*, 2012), neural crest (Jones *et al.*, 2008), and pancreatic tumors

Table 2 Summary of the murine models of carney complex (inactivation of *PRKAR1A*)

Mouse models	*Phenotype*	*References*
General knock out/down		
Prkar1a–/–	Death at E9.5 No functional heart tube development	Amieux *et al.* (2002)
Prkar1a + / –	Non pigmented schwannomas Fibro-osseous bone lesions Thyroid tumors Liver tumors Reduced fertility for male (sperm abnormality)	Kirschner *et al.* (2005) and Burton *et al.* (2006)
Prkar1a X2AS – / – (*tTA/X2AS* line)	Thyroid follicular hyperplasia and adenomas Adrenocortical hyperplasia Lymphomas Other mesenchymal tumors	Griffin *et al.* (2004)
Tissue-specific knock out		
Adrenal cortex (*Akr1b7*- CRE)	Cushing syndrome Adrenal tumors	Sahut-Barnola *et al.* (2010)
Cardiac (*αMHC*- CRE)	Death at E11.5 to 12.5 Thin-walled, dilated hearts Cardiac myxomatous degeneration	Yin *et al.* (2008b)
Pituitary (*GHRHR*- CRE)	Alterations of the GH axis Pituitary tumors with GH, prolactin, or TSH immunostaining	Yin *et al.* (2008a)
Neural crest precursor (*TEC3KO*)	Schwannomas	Jones *et al.* (2008)
Thyroid (*Tpo*- CRE)	Hyperthyroidism Benign and malignant follicular thyroid neoplasms	Pringle *et al.* (2012)
Pancreas (*Pdx1*-CRE)	Nonfunctioning endocrine or mixed endocrine/acinar cell carcinomas	Saloustros *et al.* (2017)

Adapted from Espiard, S. and Bertherat, J. (2013). Carney complex. *Frontiers of Hormone Research* **41**, 50–62.

(Saloustros *et al.*, 2017) (**Table 2**). Inactivation of *prkar1a* in the adrenal cortex lead to corticosteroids overproduction and a bilateral corticoadrenal hyperplasia caused by improper maintenance and proliferation of fetal adrenal cells (Yu *et al.*, 2012). Transgenic mice with inactivation of *Pde8b* and *Pde11* do not develop adrenal hyperplasia (Szarek and Stratakis, 2014).

Others Signaling Pathway

PRKAR1A haploinsufficiency is a general tumorigenic signal and may need additive effects of other oncogene, inactivation of other tumor suppressors and/or tissue-specific factors. Involvement of other signaling pathways has been also shown in CNC tumors as the activation of the Wnt/β-catenin signaling pathway in PPNAD (Almeida *et al.*, 2012; Horvath *et al.*, 2006b; Tadjine *et al.*, 2008). A cross-talk with the MAPK (mitogen activated protein kinase) signaling pathway (Robinson-White *et al.*, 2006) and the mTOR (mammalian target of rapamycin) pathway (de Joussineau *et al.*, 2014) contributes to the development of the adrenal micronodular hyperplasia. Interestingly, the activation of the mTOR pathway causes autophagic deficiency in *prkar1a* – / – mouse embryonic fibroblasts. Hyperpigmentation in PPNAD nodules is due to an accumulation of lipofuscin and may be a consequence of autophagic deficiency (Mavrakis *et al.*, 2006).

Conclusion

The PPNAD and the iMAD are rare causes of CS in children and young adults. Most of the PPNAD are part of the CNC. The CNC is a rare genetic neoplasia syndrome leading to a large spectrum of endocrine and nonendocrine tumors which has been well described. However, diagnostic difficulties persist. The identification of early manifestations, especially dermatologic lesions, is essential for the diagnosis and the follow-up since there are associated with more severe disease. After identification of a *PRKAR1A* defect in an index case, familial screening can be offered. Screening of all manifestations at the diagnosis of the disease or from 4-years-old in relative harboring *PRKAR1A* defect may prevent complications of life threatening manifestations as cardiac myxomas or malignant tumors. There are no clear recommendations about the follow-up of patients yet. Also, multidisciplinary management and follow-up in reference centers of these patients are important.

Genetics of Familial Forms of Cortisol-Secreting Adrenal Tumors and Hyperplasias

Ludivine Drougat and Constantine A Stratakis, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, United States

Abbreviations

ACA	Benign unilateral adenomas
ACC	Adrenocortical carcinomas
ACT	Adrenocortical tumors
ACTH	Adrenocorticotropic hormone
AIMAH	ACTH-independent macronodular adrenal hyperplasia
AIMBAD	ACTH-independent massive bilateral adrenal disease
AMAH	Autonomous macronodular adrenal hyperplasia
APC	Adenomatous polyposis coli
ARMC5	Armadillo repeat containing 5
BAH	Bilateral adrenocortical hyperplasia
BWS	Beckwith–Wiedemann syndrome
cAMP	Cyclic adenosine monophosphate
cAMP/PKA	Cyclic AMP/protein kinase A
CDKN1C	Cyclin-dependent kinase inhibitor 1C
CNC	Carney complex
cPPNAD	CNC-associated PPNAD
DMR	Differentially methylated region
FAP	Familial adenomatous polyposis
GIP/GIPR	Gastric inhibitory polypeptide/gastric inhibitory polypeptide receptor; also known as "glucose-dependent insulinotropic polypeptide" and "glucose-dependent insulinotropic polypeptide receptor", respectively
GNAS	Guanine nucleotide binding protein, alpha stimulating
HNPCC	Hereditary nonpolyposis colorectal cancer syndrome
IC	Imprinting center
IGF2	Insulin-like growth factor 2
iMAD	Isolated micronodular adrenocortical disease
iPPNAD	Isolated PPNAD
LFL	Li–Fraumeni-like syndrome
LFS	Li–Fraumeni syndrome
LH/hCG	Luteinizing hormone/human chorionic gonadotropin
LOH	Loss of heterozygosity
LS	Lynch syndrome
MAS	McCune–Albright syndrome
MEN 1	Multiple endocrine neoplasia type 1
MMAD	Massive macronodular adrenocortical disease
MMR	Mismatch repair
MSI	Microsatellite instability
NLS	Nuclear localization signal
PA	Primary aldosteronism
PBAD	Primary bimorphic adrenocortical disease
PBMAH	Primary bilateral macronodular hyperplasia
PDE	Phosphodiesterase
PKA	Protein kinase A
PPNAD	Primary pigmented nodular adrenocortical disease
PRKAR1A	Protein kinase A regulatory subunit 1A
UDP	Uniparental disomy

Introduction

Cortisol-producing adrenocortical tumors (ACT) collectively characterize a wide variety of neoplasms affecting the adrenal cortex. They may be divided into three major categories: benign unilateral adenomas (ACA), bilateral adrenocortical hyperplasias (BAH), and adrenocortical carcinomas (ACC), representing 75%–90%, 10%, $<5\%$ of all adrenocortical neoplasms, respectively (Lodish, 2017). Despite shared signaling pathways, each one of these entities has specific pathophysiologic, secretory, and genetic profiles. For example, the degree of cortisol oversecretion is very variable within these adrenocortical tumors leading to different degrees of severity of Cushing syndrome. Most ACTs occur sporadically; less than 10% of ACTs are due to hereditary conditions, mostly familial tumor syndromes, such as multiple endocrine neoplasia type 1 (MEN 1), Beckwith–Wiedemann syndrome (BWS), familial adenomatous polyposis (FAP), Li–Fraumeni syndrome (LFS), and Lynch syndrome (LS), considered among the 10 most penetrant syndromes (Nagy *et al.*, 2004). Each one of these inherited tumor syndrome is caused by genes (*MEN1*, *APC*, *MMR*, *TP53*, *IGF2*, and *CDKN1C*) that represent different biological pathways (**Table 1**). BAHs, on the other hand, and about half of all ACAs are linked to alterations of the cAMP/PKA pathway (**Table 2**). The discovery of causative genes in the inherited tumor syndromes has led to the identification of molecular defects associated with sporadic ACTs (Libé and Bertherat, 2005). The most recent wider availability of advanced sequencing technologies has greatly enhanced the molecular elucidation of all ACTs. In addition, genetics assisted in the discovery of new entities and, hence, a new classification of BAHs was proposed which incorporated histological and genetic data (Stratakis and Boikos, 2007). The most recent description of *ARMC5* mutations in primary bilateral macronodular adrenocortical hyperplasia (PBMAH) further enhanced our understanding of BAH and changed dramatically the management of these patients (Assié *et al.*, 2013). This article covers these new developments.

Table 1 Genetics of familial tumor syndrome and adrenal lesions associated

Syndrome	*Associated gene*	*Chromosomal location*	*Protein function*	*Prevalence of ACT*	*Type of ACT*	*Cortisol-secreting adrenal tumors (%)*
MEN1	*MEN1*	11q13.1	Transcriptional regulator	Between 9% and 73%	– Adenomas – Nonactive bilateral adrenal (most of them) – PBMAH – ACC	<5%
BWS	– *IGF2* – *DMR1* – *H19* – *CDKN1C* – *DMR2* – *KCNQ1OT1*	IC1 IC2	11p15.5 – Regulate cell growth and differentiation – Growth and development regulatory ncRNAs – Cell cycle – Chromatin regulatory ncRNAs	Up to 20%	– Benign including cysts and adrenals hyperplasia – ACC (1% of cases of BWS children)	Variable level of cortisol
FAS	*APC*	5q21	Wnt/βcatenin pathway	~ 7% and up to 13% in patients with family history	– PBMAH – Nonfunctional cortisol producing adenoma	Five cases reported as presenting an excessive secretion of cortisol
LS	– *MLH1* – *MSH2* – *MSH6* – *PMS2*	– 3p22.2 – 2p21–p16.3 – 2p16.3 – 7p22.1	DNA mismatch repair	Rare (the prevalence of LS in ACC patients is ~3%)	ACC	Variable level of cortisol
LFS	*TP53*	17p13	Maintaining the integrity of the genome "guardian of the genome"	Up to 11.56%	ACC	Variable level of cortisol

MEN1, Multiple endocrine neoplasia type 1; *BWS*, Beckwith–Wiedemann syndrome; *FAS*, familial adenomatous polyposism; *LS*, Lynch syndrome; *LFS*, Li–Fraumeni syndrome; *PBMAH*, primary bilateral macronodular hyperplasia; *ACC*, adrenocortical carcinomas; *IC*, imprinting center.

Table 2 Genetics of familial bilateral adrenal hyperplasia

Adrenal lesions	*Age patients*	*Associated gene*	*Chromosomal location*	*Protein function*	*Cortisol-secreting adrenal tumors (%)*
PPNAD	~10–40 years old	– *PRKAR1A* – Locus 2p16 – *PDE11A* – *PDE8B*	– 17q22–24 – 2q31.2 – 5q13	cAMP/PKA pathway	Variable level of cortisol
PBMAH	~50–60 years old	– *MEN1* – *APC* – *FH* – *PDE11A* – *ARMC5* – *PRKACA*	– 11q13.1 – 5q21 – 1q43 – 2q31.2 – 16p11.2 – 19q13	– Transcriptional regulator – Wnt/b-catenin pathway – Krebs cycle – cAMP/PKA pathway – Indirect or direct role in steroidogenesis, cell cycle, T-cell function, fetal development and cAMP/PKA pathway – cAMP/PKA pathway	2% of overt Cushing syndrome Unknown % of bilateral modest cortisol-secreting incidentalomas

PBMAH, Primary bilateral macronodular hyperplasia; *PPNAD*, primary pigmented nodular adrenocortical disease.

Multiple Endocrine Neoplasia Type 1

Multiple endocrine neoplasia type 1 (MEN 1) or Werner syndrome is caused by germline mutations in the *MEN1* gene. The human *MEN1* gene, which maps to chromosome 11q13.1, encodes for the *menin* protein (a molecule of 610 amino acids with a molecular weight of 68 kDa). The primary structure of menin reveals several domains involved in interaction with its partners and

a nuclear localization signal (NLS) domain influencing its cellular location. The nuclear scaffold protein menin modulates multiple processes related directly or indirectly to gene expression. Menin behaves as a tumor suppressor in endocrine cells, following the well-known Knudson's two hit mechanism. The MEN 1 syndrome is most often familial (approximately 90% of cases have inherited a mutation); very few cases are documented de novo defects. More than 70% of the patients diagnosed with MEN 1 syndrome are carriers of a germline mutation in the *MEN1* gene (Falchetti, 2010; Marini *et al.*, 2009); approximately 10% or more may harbor *MEN1* gene and/or chromosomal deletions that are not detected by simple sequencing. MEN 1 patients have a very high risk of developing multiple tumors involving several endocrine tissues: the parathyroid glands (up to 95% of cases), pancreas (50%–70% of cases), and the pituitary (20%–40% of cases) (Angelousi *et al.*, 2016; Falchetti, 2010; Lodish, 2017). Other tumors include adrenocortical hyperplasia and/or adenomas, and other ACTs, thyroid neoplasms, and lesions in nonendocrine tissues, such as facial angiofibromas, lipomas, meningiomas, and collagenomas. ACTs are found in as many as half of the patients with MEN 1 (a prevalence of 9%–73% has been reported) depending on the age of the patients and screening approaches (Gatta-Cherifi *et al.*, 2012; Goudet *et al.*, 2015; Langer *et al.*, 2002; Schaefer *et al.*, 2008; Skogseid *et al.*, 1995; Waldmann *et al.*, 2007). ACTs in MEN 1 develop either unilaterally or bilaterally and may be adenomas, macronodular hyperplasia, or even carcinoma; however, most adrenal lesions in MEN 1 are bilateral and functionally nonactive adenomas (20%–40%). Less than 5% of adrenal lesions in MEN 1 are cortisol-producing (Gatta-Cherifi *et al.*, 2012; Langer *et al.*, 2002; Schaefer *et al.*, 2008; Skogseid *et al.*, 1995; Waldmann *et al.*, 2007). Interestingly, Thevenon and collaborators reported, from a large cohort constituted of 797 patients from 265 families, that ACTs in patients carrying *MEN1* mutations affecting the JunD-interacting domain have a high heritability (approximately 65%). They established a reversed correlation between the adrenal tumor and the degree of relatedness; meaning that the familial correlation coefficient trends to be reduced between first- and second-degree relatives (0.16 vs. 0.14) and more dramatically for the third-degree relatives (0.04) (Thevenon *et al.*, 2015). This study supports the idea that the adrenal lesions are a common manifestation of MEN1 syndrome but more importantly that their growth depends on an inherited predisposition. Based on recent data from a MEN1 cohort including young patients diagnosed before the age of 21 years, Goudet and collaborators showed that ACC represents 1% of all lesions described. The authors mentioned that first analysis was undertaken in the late 1990s with different testing over the years and, thus, may represent an underestimate (Goudet *et al.*, 2015). Others found no ACTs among patients aged from 6 to 31 (Vannucci *et al.*, 2017); it is possible that ACTs develop later in patients with MEN 1 but when they do develop earlier they are more likely to be malignant (Goudet *et al.*, 2015). In summary, patients with MEN 1 develop ACTs and they may be screened for these; however, aggressive treatments and invasive approaches (i.e., adrenal surgery) should be individualized and reserved for the most likely to be functional and/or malignant.

Beckwith–Wiedemann Syndrome

Beckwith–Wiedemann syndrome (BWS) was first described by Wiedemann in 1964 (Wiedemann, 1964) and Beckwith in 1969. BWS is the most common overgrowth syndrome in infancy, with an incidence similar for female and male estimated of approximately 1 in 13,700 (Angelousi *et al.*, 2016; Pettenati *et al.*, 1986; Thorburn *et al.*, 1970; Weksberg *et al.*, 1993). BWS is characterized by a broad spectrum of symptoms including macrosomia, hemihyperplasia, macroglossia, abdominal wall defects (umbilical hernia, omphalocele, diastasis recti), neonatal hypoglycemia, ear creases, visceromegaly, renal malformations, facial nevus flammeus (Mazzuco *et al.*, 2012; Shuman *et al.*, 1993; Weksberg *et al.*, 1993). BWS results in genetic and epigenetic dysregulations of several growth regulatory genes mapped on chromosome 11p15.5. These genes are under control of imprinting center (IC), leading to a predominant or exclusive expression from either maternal or paternal alleles. Among them, the paternally expressed genes *IGF2* (insulin-like growth factor 2) and *H19* clustered in the IC1 and the maternally expressed genes *CDKN1C* (cyclin-dependent kinase inhibitor 1C or $p57^{KIP2}$) and *KCNQ1OT1* in IC2 are clearly links to BWS. Both IC contain a differentially methylated region DMR1 and DMR2, respectively (Choufani *et al.*, 2010; Weksberg *et al.*, 2003). Genetic alterations in BWS include loss of methylation of the IC2 on the maternal chromosome leading to an increased activity of the *KCNQ1OT1* gene (50%), paternal uniparental disomy (UPD) of 11p15.5 (20%), gain of methylation of the IC1 on the maternal chromosome (5%), mutation of the maternal CDKN1C allele (5%), and duplication, inversion or translocation of the chromosome 11p15.5. In approximately 15% of cases the cause remains unknown (Choufani *et al.*, 2010; Weksberg *et al.*, 2003, 2005). Children with BWS are predisposed to tumor development with an estimated overall risk of 7.5% (range between 4% and 21%), manifesting in the first decade of the life (Rump *et al.*, 2005; Shuman *et al.*, 1993; Weksberg *et al.*, 2010). The more frequent tumors are Wilms tumor, hepatoblastoma, neuroblastoma, rhabdomyosarcoma, and ACTs or rhabdomyosarcoma (Else *et al.*, 2014; MacFarland *et al.*, 2017; Mussa *et al.*, 2016). Most ACTs are benign including cysts and adrenal hyperplasia; they occur in up to 20% of all BWS cases; ACCs are described in 1% of children with BWS (Else, 2012; Lapunzina, 2005). A recent meta-analysis combining BWS cases studied in the last 15 years confirmed the high frequency of ACTs, present in 9.4% of 1370 patients (Mussa *et al.*, 2016). Few of these tumors are cortisol- and/or androgen-producing (Cardinalli *et al.*, 2012; Carney *et al.*, 2012; Hertel *et al.*, 2003; Schofield *et al.*, 1995).

On the other hand, one of the hallmarks of sporadic ACC is the aberrant expression of IGF2, a cell survival factor stimulating cell proliferation but unable to drive the tumorigenesis on its own (Drelon *et al.*, 2012; Guillaud-Bataille *et al.*, 2014). Elevated expression of IGF2 is also the most common molecular change seen in adrenal tumors associated with BWS, resulting from gain of methylation in IC1, duplication of the paternal allele, or some alterations in epigenetic imprinting at 11p15. Recently, aberrant expression of IGF2 were reported in 78% of patients with ACT, confirming the frequent changes in the IGF2 expression related to ACC in BWS (MacFarland *et al.*, 2017). In most cases, occurrence of BWS is sporadic (80%–85%) rather than familial (10%–15%)

(Weksberg *et al.*, 2010). A pathogenic variant is reported in *CDKN1C* gene in 40% of familial cases (Riccio *et al.*, 2009; Shuman *et al.*, 1993). Despite of low expression of CDKN1C regularly reported in ACC, mutations of this gene are not commonly found (Barzon *et al.*, 2001; MacFarland *et al.*, 2017). Interestingly, patients with dysregulation of imprinting center IC1 (IGF2/H19) present fewer mutations in *CDKN1C* gene, which do not seem to influence *IGF2* expression (Brioude *et al.*, 2015). Other familial BWS cases were explained by microdeletions at IC1 and more rarely microduplication at IC2 (De Crescenzo *et al.*, 2011; Shuman *et al.*, 1993). It is unclear what is the percentage of BWS cases that have excessive steroid hormone secretion. However, patients with BWS need to be carefully followed up for lesions of the adrenal in general, ACC development in particular, and the possible link to excessive steroid hormone secretion (Brioude *et al.*, 2013; MacFarland *et al.*, 2017).

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) represents approximately 1% of all colorectal cancer cases, making it the second multiple colorectal most frequent cause of inherited colorectal cancer (Lv, 2017). A germline mutation and then somatic loss of heterozygosity (LOH) of the *APC* (adenomatous polyposis coli) gene on chromosome 5q21 lead to the development of colorectal cancer in patients with FAP with a nearly 100% penetrance (Waller *et al.*, 2016). APC is a negative regulator of the Wnt/β-catenin signaling pathway, belonging to the β-catenin destruction complex which is composed by axin, CK1, GSK3β. The turnover of the β-catenin is controlled by phosphorylation-dependent proteasome degradation via this destruction complex; Wnt stimulation results in the inactivation of the complex degradation, leading to the accumulation and nuclear translocation of β-catenin. Nuclear β-catenin protein may then carry out its oncogenic transcriptional activity inducing the expression of a number of target genes (Berthon and Stratakis, 2014; Eshghifar *et al.*, 2017).

Patients with FAP develop, at an early age, multiple polyps in the lower gastrointestinal tract which may then lead to colorectal cancer, following the classically described adenoma–carcinoma sequence. These patients are also subject to the formation of other types of cancers such as adrenocortical tumors. More than a century ago, the first case of adrenal tumor associated with FAP was published in 1912 by Devic and Bussy; subsequent cases were mainly discovered at autopsies (Naylor and Gardner, 1981; Robinson *et al.*, 1972). Today, with imaging surveillance of FAP patients we know that the prevalence of adrenal masses is approximately 7% (Marchesa *et al.*, 1997) to 13% (Smith *et al.*, 2000), which is significantly higher than that in the general population (at approximately 3%) (Herrera *et al.*, 1991). Only few genetic defects were identified in *APC* gene in ADTs, in codons 2016–2017, 1542, 1577, 1981, 1061 (Beuschlein *et al.*, 2000; Hosogi *et al.*, 2009; Kartheuser *et al.*, 1999; Rekik *et al.*, 2010; Wakatsuki *et al.*, 1998). Interestingly, codon 1061 is known as frequently mutated in patients with FAP (8%) (González *et al.*, 2005). Nuclear localization of β-catenin is frequently seen in ACTs (Gaujoux *et al.*, 2010). Most patients with FAP have bilateral macronodular adrenal hyperplasia (Hsiao *et al.*, 2009; Kartheuser *et al.*, 1999; Yamakita *et al.*, 1997); few have been described with nonfunctioning ACAs and, rarely, ACC (Beuschlein *et al.*, 2000; Chelaïfa *et al.*, 2003; Naylor and Gardner, 1981; Painter and Jagelman, 1985; Pinés Corrales *et al.*, 2006; Wakatsuki *et al.*, 1998). To our knowledge, only four cases have been reported as presenting with Cushing syndrome due to a cortisol-producing ACA (Beuschlein *et al.*, 2000; Marchesa *et al.*, 1997; Rekik *et al.*, 2010); one patient with FAP presented with an ACA and hyperaldosteronism (Pinés Corrales *et al.*, 2006). In summary, even though ACTs are a rare manifestation of FAP, patients with this condition should be clinically followed for the development of both functioning and nonfunctioning ACTs, as well as the occasional ACC.

Lynch Syndrome

Lynch syndrome (LS), also known as hereditary nonpolyposis colorectal cancer syndrome (HNPCC), represents approximately 3% of all colorectal cancer cases, making it the most frequent cause of inherited colorectal cancer (approximately 15% of all colorectal cancer cases) (Rustgi, 2007; Shawki and Kalady, 2016). LS is an autosomal dominant genetic disorder caused by mutations in *MLH1*, *MSH2*, *MSH6*, and *PMS2* genes, belonging to the Mut-related family of DNA mismatch repair (MMR) genes (Kastrinos and Syngal, 2012). Ninety percent of mutations occurs in the *MLH1* and *MSH2* genes (Peltomäki, 2001). Germline mutations in any one of four genes leads to either microsatellite instability (MSI) or at the loss of expression of the related protein. Patients with LS are predisposed to colorectal cancer development with an estimated overall risk up to 80%, with peak age of incidence between 44 and 61 years (Bhattacharya and McHugh, 2017). Moreover, LS patients have a high risk of developing a carcinoma of endometrium (up to 60% of females), ovary, gastric, small bowel, hepatobiliary system, pancreas, central nervous system, lung adenocarcinoma, sarcoma, and ACC (Bhattacharya and McHugh, 2017; Raymond *et al.*, 2013). Even if ACC is not the most frequent cancer in LS, the prevalence of LS in ACC patients (3%) is equivalent to those from patients with colorectal and endometrial cancer (2%–5%) (Liu *et al.*, 2014; Raymond *et al.*, 2013).

MSH2, *MSH6*, and *MLH1* genes were reported mutated in LS patients with ACC, leading to a loss of expression of one or several MMR proteins analyzed by IHC, similar to other LS-associated-cancer (Berends *et al.*, 2000; Challis *et al.*, 2016; Else *et al.*, 2014; Zheng *et al.*, 2016). In combining studies describing mutations in MMR genes found in LS patients with ACC, MSH2 gene seems more frequently affected by mutations in these patients having a positive family history. It should be noted that ACCs do not demonstrate microsatellite instability unlike colorectal cancer (Berends *et al.*, 2000; Broaddus *et al.*, 2004; Challis *et al.*, 2016; Karamurzin *et al.*, 2012; Medina-Arana *et al.*, 2011). Several reports have linked ACC to Lynch syndrome, and this is further

supported by a more recent study (Challis *et al.*, 2016). Patients with LS should therefore be regularly surveilled clinically for the possible development of ACC (Challis *et al.*, 2016; Medina-Arana *et al.*, 2011).

Li–Fraumeni Syndrome

Li–Fraumeni syndrome or Li–Fraumeni-like syndrome (LFS, LFL) is a rare autosomal dominant syndrome, first described by Li and Fraumeni in 1969. The gene found responsible for Li–Fraumeni syndrome is *TP53*, located on chromosome 17p13. Germline mutations in the *TP53* tumor suppressor gene are harbored by up to 80% of LFS cases, with a high penetrance estimated of at least 80% by age 50 years (Angelousi *et al.*, 2016; Hwang *et al.*, 2003; Nagy *et al.*, 2004). Penetrance was not influenced by genre although the females are a greater risk to be diagnosed with cancer and at a younger age (Hwang *et al.*, 2003). Mutations in the *BRCA2* and *CHEK2* genes have also been reported in LFS; however, patients with these mutations do not seem to develop ACTs (Bachinski *et al.*, 2005; Bell *et al.*, 1999; Evans *et al.*, 2008; Mazzuco *et al.*, 2012).

Most LFS-related tumors are brain and soft tissue sarcomas and osteosarcomas, breast cancer, leukemia, whereas ACC is relatively less frequent (Hisada *et al.*, 1998; Li *et al.*, 1988; Malkin *et al.*, 1990): up to 11.56% of patient with LFS develop ACC, which is, thus, the fourth most common cancer among patients with LFS, according to the p53 database (www-p53.iarc.fr). Other studies show a prevalence of ACC between 6.9% and 9.9% of patients with LFS (Gonzalez *et al.*, 2009; Olivier *et al.*, 2003). ACC in patients with LFS usually presents either early (before the age of 10 years) or later, in the 6th decade of life (Kleihues *et al.*, 1997; Olivier *et al.*, 2003; Wajchenberg *et al.*, 2000; Wasserman *et al.*, 2015); the former is the case with 92% of the patients with ACC and LFS, whereas the latter is true for only about 8% of them (Wasserman *et al.*, 2012). In contrast to Cushing syndrome which appears to be the most frequently presenting manifestation in adults, ACCs in children with LFS usually present with virilization (Michalkiewicz *et al.*, 2004; Sandrini *et al.*, 1997).

In southern Brazil, children exhibit an increased risk for ACC that is 10–15-fold higher than children worldwide (Garritano *et al.*, 2010; Sandrini *et al.*, 1997). This is apparently due to the R337H *TP53* mutation described in more than 90% of these patients (Borges and Ayres, 2015; Ribeiro *et al.*, 2001), a defect that is present within the oligomerization domain of the gene. Most other *TP53* mutations causing ACC are located in the DNA-binding domain of the molecule (Wasserman *et al.*, 2012). Whereas the 175, 245, 248, 249, 273, and 282 codon hotspots predominate in *TP53*-related tumors (Petitjean *et al.*, 2007), Olivier and colleagues also showed hotspots that are specific for ACC at residues 151, 152, 219, and 220 (Olivier *et al.*, 2003; Wasserman *et al.*, 2015). Thus, certain codon mutations seem to be more specific for ACC development (Heinze *et al.*, 2014). Interestingly, Petitjean and colleagues showed that the mean age of disease onset for patients with ACC carrying nonfunctional mutants is earlier, compared to partially or fully functional missense mutants (Petitjean *et al.*, 2007).

Bilateral Adrenocortical Hyperplasia

Bilateral ACTs are further divided into two types: macronodular or micronodular, defined by the size of the associated nodules in each adrenal gland, larger or smaller than 1 cm, respectively. Patients with bilateral tumors represent up to 10% of all patients with adrenal-dependent Cushing syndrome and can occur in sporadic or familial form. To date, no less than six types of bilateral adrenal hyperplasias (BAH) were described, which are distinguished from their histologic and genetic characteristics (Stratakis and Boikos, 2007) (**Table 2**).

Micronodular Bilateral Adrenocortical Hyperplasia

Micronodular BAH may be further distinguished by the presence or absence of pigment in the associated nodules: primary pigmented nodular adrenocortical disease (PPNAD) is associated with pigmentation, whereas idiopathic micronodular adrenocortical disease (iMAD) is not. Most cases of PPNAD are associated with Carney complex (CNC) (cPPNAD, ~90% of PPNAD cases), whereas few are sporadic and isolated (iPPNAD); in addition, familial isolated PPNAD has also been reported very rarely (Bertherat *et al.*, 2009; Pandey *et al.*, 2013; Stratakis and Boikos, 2007). Patients with PPNAD and CNC may present with a variety of other tumors before they present with Cushing syndrome which typically develops in late childhood or young adulthood and is more frequent in females (Groussin *et al.*, 2006; Horvath and Stratakis, 2008). Atypical or cyclical forms of Cushing syndrome are also frequent in these patients (Hofland *et al.*, 2013; Stratakis *et al.*, 1999). CNC patients may also develop cardiac myxomas, thyroid tumors, and schwanomas which can complicate the treatment of Cushing syndrome in these patients (Almeida and Stratakis, 2010; Angelousi *et al.*, 2016). CNC is transmitted in an autosomal dominant manner, involving at least two loci mapped to chromosomes 17q22–24 (CNC1) and 2p16 (CNC2). The causal gene for CNC2 remains unknown; CNC1 is caused by defects inactivating the gene coding for PRKAR1A, the regulatory subunit type 1α (R1a) of PKA (Kirschner *et al.*, 2000; Stratakis, 2002). To date, the *PRKAR1A* mutation database contains approximately 135 mutations; defects in exons 2, 3, and 7 of the gene account for more than half of all (https://prkar1a.nichd.nih.gov/hmdb/prkar1a.html). Approximately 43% of those defects cause frameshift, 25% are nonsense and 11% missense mutations, and 4% are deletions. Functionally, all defects lead to partial (~50%) or complete deficiency of the PRKAR1A mutant protein. Most defects also cause nonsense-mediated decay (NMD) of the mutant

PRKAR1A mRNA (Almeida and Stratakis, 2010; Kirschner *et al.*, 2000; Robinson-White *et al.*, 2003). More than 70% of patients with CNC, and more than 80% of patients with PPNAD have *PRKAR1A* defects, which also have high penetrance that is estimated to be near 98% by age 40 years (Almeida and Stratakis, 2010; Stratakis *et al.*, 2001).

The *PDE11A* gene, mapped on 2q31–35, was found altered in patients with PPNAD or iMAD who did not have *PRKAR1A* or *GNAS* mutations (Horvath *et al.*, 2006a). Deficiency of the protein encoded by the *PDE11A* gene is caused by truncating mutations (2 frameshift and 1 nonsense) or missense substitutions affecting conserved regions of the gene. Although the *PDE11A* gene is highly polymorphic, some inactivating mutations with low-penetrance are related to an inherited predisposition to ACTs (Carney *et al.*, 2010; Horvath *et al.*, 2006b). Interestingly, *PDE11A* variants are also frequent in patients with PPNAD who are carriers of *PRKAR1A* mutations (Libé *et al.*, 2011) suggesting that in at least some patients with PPNAD the development of Cushing syndrome may be due to the coexistence of *PRKAR1A* and *PDE11A* defects. The PDE11A protein is highly present in the adrenal cortex and other tissues, such as the gonads and the prostate. Thus, *PDE11A* genetic variants have been reported in association with testicular germ cell tumors (TGCTs) (Horvath *et al.*, 2009). To date, the contribution of the *PDE11A* gene in the development of sporadic ACTs is not fully understood; *PDE11A* defects appear to act as modifiers cooperating with other genes in predisposition to adrenocortical and other tumors, such as TGCTs (Hannah-Shmouni *et al.*, 2016).

The *PDE8B* gene on chromosome 5q13, another member of the PDE family, was also linked to iMAD and PPNAD (Horvath *et al.*, 2006a; Rothenbuhler *et al.*, 2012). First, a missense substitution (H305P) found in a young girl with Cushing syndrome due to PPNAD, without any symptoms of CNC (Horvath *et al.*, 2006a). Then, several *PDE8B* germline variants were described in association with ACTs including PBMAH, PPNAD, and ACAs (Rothenbuhler *et al.*, 2012). Rothenbuhler *et al.* described two novel damaging variants of the *PDE8B* gene, H391A and P660L, in two patients with PBMAH and a nonsecreting adrenal tumor, respectively. PDE8B expression is positively correlated with higher cortisol production in sporadic cortisol-producing ACAs (Wilmot Roussel *et al.*, 2013). In conclusion, *PDE8B* defects are rare, but like *PDE11A*, they appear to contribute to predisposition to a variety of ACTs.

Primary Bilateral Macronodular Hyperplasia

Genetics of PBMAH between 1964 and 2013

More than 50 years ago, Kirschner *et al.*, described PBMAH (primary bilateral macronodular hyperplasia) for the first time (Kirschner *et al.*, 1964). Previously called autonomous macronodular adrenal hyperplasia (AMAH), ACTH-independent massive bilateral adrenal disease (AIMBAD), giant or huge macronodular disease, AIMAH (ACTH-independent macronodular adrenal hyperplasia) or also MMAD (massive macronodular adrenocortical disease), PBMAH is now the most recently preferred name. This new term eliminates ACTH-independence from the disease's name, since Louiset *et al.* showed ACTH produced by PBMAH cells stimulating local cortisol hypersecretion (Louiset *et al.*, 2013). PBMAH is a benign entity that is seen in less than 2% of endogenous Cushing syndrome cases. It is characterized by multiple nodules in both adrenal glands leading to increased adrenal volume. Its incidence peaks between 50 and 60 years of age (Drougat *et al.*, 2015; Lodish and Stratakis, 2016).

In PBMAH, the cAMP/PKA pathway is activated by the aberrant expression of receptors like those for luteinizing hormone/human chorionic gonadotropin (LH/hCG), vasopressin (V1, V2) or the 5-HT4 serotoninergic and β-adrenergic ones. Likewise, food-dependent Cushing syndrome is due to GIPR overexpression in this variant of PBMAH. These abnormalities are seen in both sporadic and familial cases (Christopoulos *et al.*, 2005; El Ghorayeb *et al.*, 2015; Lacroix *et al.*, 2010; Libé *et al.*, 2010). Familial cases were thought to be infrequent until recently (Hsiao *et al.*, 2009). A major genetic defect causing PBMAH was identified in 2013 (Assié *et al.*, 2013)—see below. The few genes that were identified to predispose to the development of PBMAH prior to 2013, were those affecting cAMP/PKA signaling, such as *GNAS*1 (which increases cAMP); the phosphodiesterases (PDEs), PDE8B and PDE11A that are involved in the regulation of cAMP levels; the ACTH receptor gene (MC2R, melanocortin-2 receptor), as well as others involved in a variety of pathways. These include *MEN1* coding for menin (see above in this article), fumarate hydratase (FH) (De Venanzi *et al.*, 2014), and adenomatosis polyposis coli (APC) (see also above in this article) (Hsiao *et al.*, 2009).

Genetics of PBMAH after 2013

Assié *et al.* identified inactivating mutations of the *ARMC5 (Armadillo repeat containing 5)* gene (Assié *et al.*, 2013) in approximately half of all patients with PBMAH that he studied. The protein encoded by the gene *ARMC5*, located on chromosome 16p11.2, is mostly composed by two domains involved in mediating protein–protein interactions, armadillo and BTB/POZ domain and is involved in numerous cellular mechanism (steroidogenesis, immune system, proliferation, and apoptosis) (Berthon *et al.*, 2017a, b; Cavalcante *et al.*, 2017; Hu *et al.*, 2017). To date, more than 100 mutations affecting *ARMC5* have been identified in many studies from several cohorts composed by people of different origins (French, American, French–Canadian, Australian, Africo-American, Portuguese, Brazilian, Italian, Japanese, Chinese). No hotspot was described among these mutations in this gene and in PBMAH. Indeed, the mutations are uniformly distributed along the gene *ARMC5* without affecting preferentially a specific domain or part of the gene, even if some mutations can be recurrent. More than 40 novel germline and somatic mutations in the *ARMC5* gene were identified in the last 2 years representing a total of 54 germline and 48 somatic exonic mutations, combining all studies published to date (Albiger *et al.*, 2017; Alencar *et al.*, 2014; Assié *et al.*, 2013; Bourdeau *et al.*, 2016; Cavalcante *et al.*, 2017; Correa *et al.*, 2015; Elbelt *et al.*, 2014; Emms *et al.*, 2016; Espiard *et al.*, 2015; Faucz *et al.*, 2014; Gagliardi *et al.*, 2014; Mulatero *et al.*, 2016;

Rego *et al.*, 2017; Suzuki *et al.*, 2015; Yu *et al.*, 2018; Zilbermint *et al.*, 2015). Three additional mutations were identified in tumor DNA but the germline or somatic origin was not determined (Else, 2012; Espiard *et al.*, 2015). Forty-two percentage of these defects are missense mutations, 36% frameshift, 18% nonsense, and 4% deletions. Interestingly, there are differences between germline and somatic mutations. Half of the somatic mutations are frameshift, the remaining equally divided between missense (21.9%) and nonsense ones (21.9%) with only 2% being deletions. Most of germline defects are missense (58%), followed by frameshift (27.6%), nonsense defects (14%), and deletions (4%). These data are from a total of seven studies, representing 58% of all mutations identified to date (Drougat *et al.*, 2015). Patients operated for PBMAH harboring *ARMC5* mutations present with more severe Cushing syndrome than those without *ARMC5* defects (Albiger *et al.*, 2017; Espiard *et al.*, 2015); however many *ARMC5* mutation carriers have only mild cortisol excess or only unilateral lesions when identified (Alencar *et al.*, 2014). ARMC5 defect may also predispose to meningioma and primary aldosteronism (PA) (Gagliardi *et al.*, 2014). Two different cohorts of 56 and 39 patients, respectively, reported PA among *ARMC5* mutation carriers (Mulatero *et al.*, 2016; Zilbermint *et al.*, 2015). Two studies showed *ARMC5* defects predisposing to meningioma within kindreds with PBMAH (Elbelt *et al.*, 2014; Alencar *et al.*, 2014). However, ARMC5 mutations underlie only 25% of all cases of PBMAH; germline amplification of the *PRKACA* gene may be associated with PBMAH in a few cases (Beuschlein *et al.*, 2014; Lodish *et al.*, 2015).

McCune–Albright syndrome and ACTs

MAS is associated with infantile Cushing syndrome (Angelousi *et al.*, 2015). *GNAS1* defects cause PBMAH without necessarily an MAS phenotype in older adults (Fragoso *et al.*, 2003). Cushing syndrome in children with MAS may vary from very severe and often lethal to mild and atypical that eventually burns out; the histology of these lesions is also interesting from simply hyperplasia of fetal adrenal-looking cells to distinct adenomas like in PBMAH (Carney *et al.*, 2011).

Conclusions

Our understanding of the genetics of ACTs has remarkably expanded over the last decade and is constantly evolving. New diseases and previously unknown genetic defects have been described that may lead to new medical treatments for these patients. It is essential that clinicians understand the connections between ACTs and inherited predisposition to other tumors in the context of genetic syndromes that have recently been molecularly elucidated.

Primary Bilateral Macronodular Adrenal Hyperplasia

André Lacroix, Centre hospitalier de l'Université de Montréal (CHUM), Montreal, QC, Canada

Nomenclature

ACTH Adrenocorticotropic hormone or corticotropin
AIMAH ACTH-independent bilateral macronodular adrenal hyperplasia
APC Adenomatous polyposis coli
ARMC5 Armadillo repeat containing 5 gene
BMAH Bilateral macronodular adrenal hyperplasia
cAMP Cyclic adenosine monophosphate
CRH Corticotropin releasing hormone
CS Cushing syndrome
CT scan Computed tomography scan
FDG-PET scan Fluorodeoxyglucose-positron emission tomography scan
GIP Glucose-dependent insulinotropic peptide or gastric inhibitory peptide
GNAS Stimulatory G-protein alpha subunit
GnRH Gonadotropin-releasing hormone
GPCR G-protein coupled receptor
HLRCC Hereditary leiomyomatosis and renal cell cancer
MC2R Melanocortin 2 receptor (ACTH receptor)
MRAP Melanocortin receptor associated protein
MRI Magnetic resonance imaging
NCCAH Nonclassic congenital adrenal hyperplasia
PBMAH Primary BMAH
PDE11A Phosphodiesterase isoform 11A
PKA Protein kinase A
PPNAD Primary pigmented nodular adrenal dysplasia
PRKACA Protein kinase A catalytic subunit α
SNP Single nucleotide polymorphisms
UFC Urinary free cortisol in 24-h collection
WNT Wingless-related integration site

Glossary

ARMC5 ARMC5 was recently identified as a gene in which germline and somatic mutations are causative in 25%–50% of BMAH; it is thought to be a tumor suppressor gene but its precise function is still unknown.

Autocrine/paracrine stimulation Several compounds are able to induce hyperfunction and proliferation of adrenocortical cells. In addition to ACTH, serotonin, vasopressin, and other molecules can stimulate adrenal function in a paracrine way.

Fumarate hydratase Fumarate hydratase (FH) is a mitochondrial enzyme. Rare cases of BMAH were associated with mutations of FH.

Menin Menin is a tumor suppressor protein, known to regulate cell proliferation and differentiation. In MEN-1 mutation carriers, a higher incidence of adrenal nodules or BMAH is reported.

Wnt/β-catenin signaling The Wnt (Wingless-related integration site) signaling pathways are a group of signal transduction pathways made of proteins that pass signals into a cell through cell surface receptors. In the absence of a Wnt signal, β-catenin interacts with a destruction complex composed by adenomatous polyposis coli (APC), AXIN proteins, and glycogen synthase kinase-3 β (GSK3 β), thus facilitating its phosphorylation by casein kinases 1 alpha (CK1α). The destruction of the phosphorylated complex is mediated by the activation of the ubiquitin pathway. BMAH can occur in patients with familial adenomatous polyposis (FAP).

Introduction

Endogenous Cushing syndrome (CS) is a morbid condition secondary to chronic excess production of cortisol which is secondary to diverse tumors with complex molecular mechanisms (Lacroix *et al.*, 2015). The syndrome is divided as either ACTH-dependent or independent; the majority are ACTH-dependent resulting from excess production of ACTH by pituitary corticotropinomas in 70% of cases (Cushing disease) or less frequently from nonpituitary malignant or benign tumors (ectopic ACTH syndrome) (Lacroix *et al.*, 2015). Approximately 15%–20% of cases are independent of ACTH of pituitary origin, and those are mainly secondary to cortisol-secreting unilateral adenomas or carcinomas (Lacroix *et al.*, 2015). CS rarely (<2%) results from primary bilateral nodular hyperplasias, either bilateral macronodular (nodules larger than 1 cm) adrenal hyperplasia (BMAH or PBMAH—which have replaced the previous term ACTH-independent macronodular adrenal hyperplasia (AIMAH)) or micronodular (nodules <1 cm) hyperplasia including primary pigmented nodular adrenal dysplasia (PPNAD) (Stratakis, 2008; Lacroix, 2009; Lacroix *et al.*, 2015). BMAH with mild or modest cortisol secretion (previously referred to as subclinical) is more frequent than those with overt CS, but its precise prevalence has not been determined in population studies (Lacroix, 2009). As 10%–15% of adrenal incidentalomas found in ~4% of adults are bilateral, a high proportion is secondary to BMAH with modest production of cortisol (Fassnacht *et al.*, 2016; Lacroix, 2009). BMAH needs to be distinguished from ACTH-dependent bilateral macronodular

adrenal hyperplasia secondary to long-term adrenal stimulation in patients with Cushing's disease or ectopic ACTH syndrome (Smals *et al.*, 1984; Lacroix *et al.*, 2015). Despite progressively suppressed ACTH levels in circulation, abnormal cortisol secretion in primary BMAH is frequently regulated by G-protein coupled receptors (GPCR) aberrantly expressed in adrenocortical tissues, which increase cyclic AMP (cAMP) levels and protein kinase A (PKA) activity (Lacroix *et al.*, 2010; El Ghorayeb *et al.*, 2015). BMAH's primary molecular mechanisms are still not completely understood and are heterogeneous, but much progress has been accomplished in recent years (De Venanzi *et al.*, 2014; Fragoso *et al.*, 2015; Drougat *et al.*, 2015), and will be reviewed here with its clinical characteristics and therapy.

Epidemiology

BMAH was first described in 1964 (Kirschner *et al.*, 1964) and in 1994, only 24 cases had been published (Lieberman *et al.*, 1994). Since then, a much larger number of cases has been reported and the characteristics of BMAH have been increasingly delineated (Malchoff and Malchoff, 1996; Swain *et al.*, 1998; Hsiao *et al.*, 2009, Lacroix, 2009; Libe *et al.*, 2010; Hofland *et al.*, 2013). BMAH accounts for $<1\%$ of overt CS etiologies (Lacroix *et al.*, 2015). It more often presents as an incidental radiological finding with underlying modest level of dysregulated cortisol secretion (Lacroix, 2009). BMAH with overt CS is usually diagnosed in the fifth or sixth decade of life, but careful history identifies subtle hypercortisolism symptoms on average of 7.8 years evolution (Malchoff and Malchoff, 1996). Its diagnosis occurs at a later age than other forms of primary bilateral adrenal hyperplasias, in particular compared with PPNAD with an average age of 18 years (Stratakis and Kirschner, 1998). Hypercortisolism in the first years of life is rarely due to BMAH, but can be part of McCune–Albright syndrome (MAS), in which somatic *GNAS* (stimulatory G-protein alpha subunit) postzygotic mutation during embryogenesis generate mosaic diverse organ lesions including adrenal macronodules; the nonmutated internodular adrenal cortex becomes atrophic secondary to suppressed ACTH levels (Kirk *et al.*, 1999).

While BMAH was equally distributed between genders in initial reports, recent publications report a higher female incidence in sporadic cases with a F/M ratio of 2–3:1, while there is an equal sex distribution in familial cases (Malchoff and Malchoff, 1996; Swain *et al.*, 1998; Hsiao *et al.*, 2009; Libe *et al.*, 2010; Hofland *et al.*, 2013; Assié *et al.*, 2013; Louiset *et al.*, 2013; Alencar *et al.*, 2014; Elbelt *et al.*, 2015; Bourdeau *et al.*, 2016).

Imaging in BMAH

On an abdominal CT scan, several bilateral adrenal nodules measuring up to 4–5 cm, of soft tissue density, are present and the internodular adrenal tissue can also be enlarged (Doppman *et al.*, 2000; Malayeri *et al.*, 2013). In some cases, the adrenal glands appear diffusely enlarged but lack distinct nodules. On MRI, T1-weighted images are hypointense relative to the liver and isointense relative to muscle. T2-weighted images tend to be hyperintense relative to the liver (Doppman *et al.*, 1991; Rockall *et al.*, 2004). In contrast, the nodules of patients with chronic ACTH stimulation appear isointense relative to the liver on T2-weighted MR images (Doppman *et al.*, 1991; Rockall *et al.*, 2004). Occasionally, there is an asymmetric development of nodules in BMAH, leading to the erroneous diagnosis of unilateral pathology (N'Diaye *et al.*, 1999; Alencar *et al.*, 2014). Iodine 131-6-β-iodomethyl-19-norcholesterol (NP-59) scintigraphy usually shows bilateral uptake (Doppman *et al.*, 2000). One study reported increased fluorodeoxyglucose-positron emission tomography (FDG-PET) signal in BMAH tissues despite the absence of malignancy; the frequency of such increased FDG-signal uptake remains to be confirmed in further studies (Alencar, *et al.*, 2011; Cavalcante, *et al.*, 2016).

Pathology

By definition, BMAH nodules diameter is >1 cm and can reach 5 cm or more (Doppman *et al.*, 1991). Each gland usually contains several nodules and adrenal size may reach 10–12 cm and 200 g in weight (normal adrenal glands are 4–6 g in weight) (Doppman *et al.*, 1991; Cugini *et al.*, 1989; Cheitlin *et al.*, 1988). The combined adrenal weight is usually above 60 g; the mean combined weight in one series was 132 g (Doppman *et al.*, 1991), which is usually larger than found in patients with Cushing's disease, where it was 22.9 g in a series of 30 patients (Smals *et al.*, 1984). On cut sections, the nodules are yellow due to their high lipid content (Aiba *et al.*, 1991). The nodules are composed of two cell types either with clear cytoplasm (lipid-rich) that form cordon nest-like structures, or with compact cytoplasm (lipid-poor) that form nest- or island-like structures (Aiba *et al.*, 1991; Sasano *et al.*, 1994). Two different subtypes are distinguished: BMAH with atrophic internodular cortex (type 1) and hyperplasia of both nodular and internodular tissue (type 2) (Swain *et al.*, 1998). The histology identifies nodules composed of large clear cells forming cordon nest-like structures staining for 3β-HSD, and smaller compact cells forming island-like structures including P-45017α positive cells (Sasano *et al.*, 1994). The sectorial enzymes distribution may contribute to inefficient steroidogenesis with a low rate of cortisol production not proportional to the large gland size. BMAH is a benign process that has not been shown to acquire a malignant potential or to metastasize (Lacroix, 2009).

Laboratory Findings

As the majority of patients with BMAH present with bilateral incidentalomas, the endocrine evaluation should include the recommended incidentaloma testing: 1 mg overnight dexamethasone suppression test, 24-h urinary metanephrine or plasma free metanephrine levels, aldosterone/renin ratio (if the patient has hypertension) (Lacroix, 2009; Fassnacht *et al.*, 2016). In addition, in cases of bilateral incidentalomas, it is recommended to measure early-morning cortisol and ACTH levels (to rule out adrenal insufficiency from bilateral infiltrative/infectious/metastatic diseases), and serum 17-OH-progesterone levels to rule out nonclassic congenital adrenal hyperplasia due to partial 21-hydroxylase deficiency (Lacroix, 2009; Fassnacht *et al.*, 2016).

BMAH most often secretes mainly cortisol, usually in modest amounts; therefore, the integrated urinary free cortisol (UFC) values will only rarely exceed the normal range in patients with overt CS. More frequently, milder inadequate cortisol production revealed by lack of normal suppression after 1 mg overnight dexamethasone suppression test (cortisol above 50 nmol/L (1.8 mcg/dL)) or the loss of diurnal rhythm of cortisol using late night salivary cortisol will be found (Lacroix, 2009). Some cases secrete aldosterone or estrogens concurrently, and rarely isolated androgens' hypersecretion was found (Wada *et al.*, 2002; Goodarzi *et al.*, 2003; Ghayee *et al.*, 2011). Depending on the level of cortisol hypersecretion, plasma ACTH and its stimulation by CRH will become progressively suppressed (Lacroix, 2009; Hsiao *et al.*, 2009; Libe *et al.*, 2010). In BMAH cells, there is decreased expression of ACTH receptor (melanocortin-2, *MC2R*) and of several steroidogenic enzymes compared with normal adrenal cortex (Antonini *et al.*, 2006; Assié *et al.*, 2013). Because of the large cell mass and despite inefficient steroidogenesis, ACTH administration produces a large increase of cortisol in blood and of its precursors such as plasma 17-OH-progesterone (Libe *et al.*, 2010); urinary 17-OH-corticosteroids (U17OHCS) can be proportionally more elevated than UFC (Hsiao *et al.*, 2009). The progression of cortisol secretion to reach overt CS over time seems highly infrequent, and rare published cases progressed during a follow-up period of 7 years (Ohashi *et al.*, 2001).

Genetic Studies

The bilateral nature of adrenal enlargement suggested that BMAH was caused either by a somatic gene mutation occurring during the early phases of embryogenesis or by an inherited germline mutation (Lacroix *et al.*, 2001; Drougat *et al.*, 2015). Heterogeneous genetic etiologies have been identified in BMAH (**Table 1**): in 16 BMAH cases, three patients had a family history of BMAH, and three other patients without family history were found to carry either germline mutations of *MEN1* (multiple endocrine neoplasia 1), *APC* (adenomatous polyposis coli), or somatic *GNAS1* mutation (Hsiao *et al.*, 2009). In one patient with hereditary leiomyomatosis and renal cell cancer (HLRCC), a germline mutation was identified in fumarate hydratase *FH* gene (Matyakhina *et al.*, 2005); 4 bilateral adrenal lesions were found in 255 cases of HLRCC (Shuch *et al.*, 2013). One of the three familial BMAH cases was a carrier of the R867G *PDE11A* (phosphodiesterase isoform 11A) gene polymorphism (Hsiao *et al.*, 2009). Several *PDE11A* missense variants are more frequent in BMAH (28%) than in controls (7.2%), and cells transfected with the variants had baseline and stimulated cAMP levels higher than cells with wild-type isoform of the gene (Vezzosi *et al.*, 2012).

Several familial cases of BMAH were described recently, with an autosomal dominant pattern of transmission (Mazzuco *et al.*, 2012; Drougat *et al.*, 2015; Fragoso *et al.*, 2015). In series of MEN1 patients, up to 21% presented mostly nonfunctional bilateral adrenal lesions, possibly BMAH (Mazzuco *et al.*, 2012). A retrospective analysis of 715 French MEN1 patients found adrenal lesions in 20% of them; bilateral lesions were present in 12.9% of patients with adrenal nodules but it is unknown how many had BMAH by histology. Most unilatral or bilateral tumors were nonfunctional, but primary aldosteronism was more frequent than in a control group of adrenal incidentalomas (Gatta-Cherifi *et al.*, 2012). The association of BMAH with hyperparathyroidism, insulinomas, and/or pituitary tumors without MEN1 mutation was also reported (Yoshida *et al.*, 2011; Lee *et al.*, 2011; Sato *et al.*, 2006). A few cases of bilateral adrenal nodules have been found in patients with familial adenomatous polyposis (FAP) (Hsiao *et al.*, 2009; Mazzuco *et al.*, 2012).

The most frequent genetic finding in BMAH, recently identified using SNP arrays, linkage analysis, and whole genome or exome sequencing, are germline mutations of armadillo repeat containing 5 gene protein (*ARMC5*) in ~25%–50% of patients with

Table 1 Main genes associated with primary bilateral macronodular adrenal hyperplasia

Gene	*Locus*	*Action*	*Type of mutation*
ARMC5	16p11.2	Causes apoptosis and adrenal cell death	Germline and somatic
MEN-1	11q13	Regulation of cell proliferation and differentiation	Germline
APC	5q12–22	Prevention of β-catenin accumulation	Germline
PDE11A	2q31–35	Catalyzes the hydrolysis of cAMP and cGMP	Germline inactivation
GNAS	20q13.1	Stimulates cAMP production	Somatic during embryogenesis
MC2R	18p11.2	Regulates cortisol production and adrenal growth	Somatic
FH	1q42.1	Involved in Krebs cycle (mitochondria) and amino acids metabolism (cytosol)	Germline

Abbreviations: *ARMC5*, armadillo repeat containing 5 gene; *APC*, adenomatous polyposis coli; *FH*, fumarate hydratase; *GNAS*, stimulatory G-protein alpha subunit; *MC2R*, melanocortin 2 receptor; *MEN1*, multiple endocrine neoplasia 1; *PDE11A*, 11A phosphodiesterase isoform.

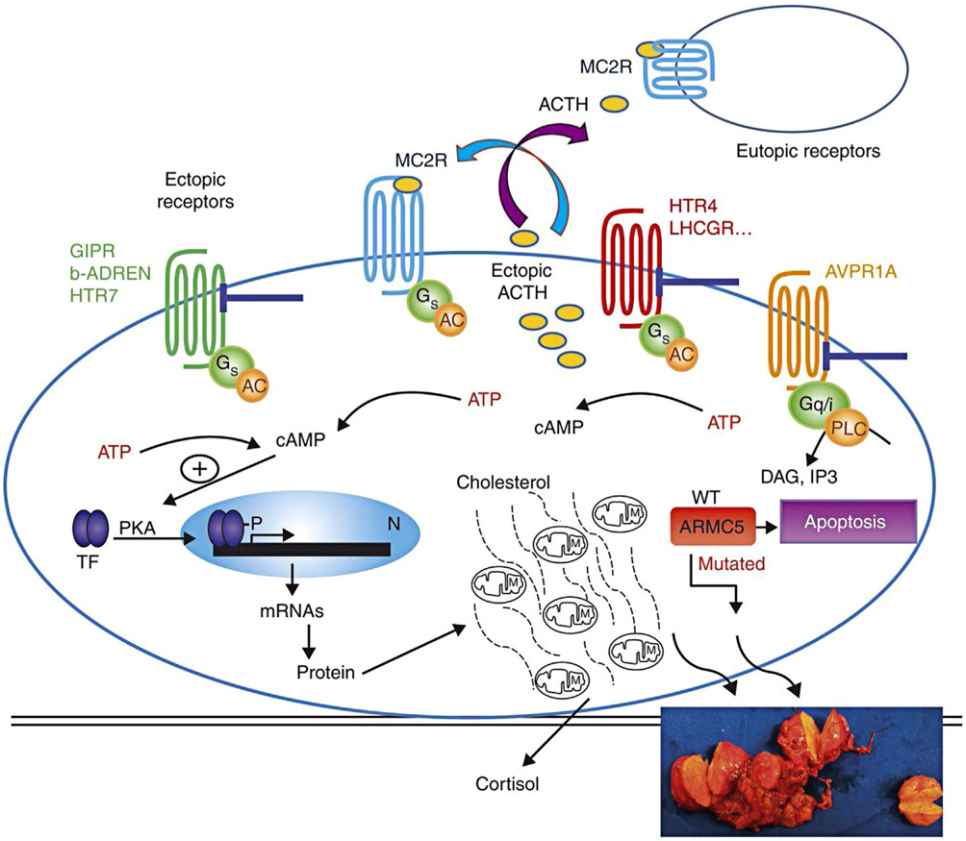

Fig. 1 The main mechanism for BMAH development. The *MC2R* is a G protein-coupled receptor of ACTH, expressed in adrenal zona fasciculata. Abnormal regulation of the adrenal cortex can be mediated by aberrant hormone receptors. Various hormones, including gastric inhibitory peptide (GIP), epinephrine (E), norepinephrine (NE), luteinizing hormone (LH), human chorionic gonadotropin (hCG), serotonin, and vasopressin, can bind to their respective aberrant membrane receptors (ectopic or eutopic) coupled to assorted G proteins (Gs, Gi, and Gq), thereby determining the activation of adenylate cyclase (AC)-mediated signaling pathways by cAMP and protein kinase A (PKA). Ectopic ACTH produced in clusters of BMAH cells acts in autocrine/paracrine regulatory mechanisms on *MC2R* to increase cortisol production after stimulus by the various aberrant G-protein coupled receptors. The activation of this pathway leads to phosphorylation of a number of transcription factors (TFs), culminating in the expression of steroidogenic enzymes during cortisol synthesis in the adrenal glands, as well as hyperplasia. The inactivating mutations of ARMC5 prevent its proapoptotic function probably involved in adrenal hyperplasia; however, this mechanism is unclear. *MC2R*, melanocortin 2 receptor; CYP11A1, cholesterol desmolase; CYP11B1, 11β-hydroxylase; CYP17, 17α-hydroxylase; CYP21A2, 21-hydroxylase; DAG, diacylglycerol; IP3, inositol triphosphate; M, mitochondrion; N, nucleus; PLC, phospholipase C; V1R, V1 vasopressin receptor; 3β-HSD, 3β-hydroxysteroid dehydrogenase; ARMC5, armadillo repeat containing 5 gene protein. Genetics of primary macronodular adrenal hyperplasia. *Journal of Endocrinology* **224**, R31–R43.

apparently sporadic cases and in familial BMAH (Assié *et al.*, 2013; Alencar *et al.*, 2014; Faucz *et al.*, 2014; Gagliardi *et al.*, 2014; Elbelt *et al.*, 2015; De Venanzi *et al.*, 2014; Drougat *et al.*, 2015; Espiard *et al.*, 2015; Fragoso, *et al.*, 2015; Albiger *et al.*, 2017) (**Table 1** and **Fig. 1**). They were mostly frameshift and nonsense mutations leading to *ARMC5*'s loss of function. Interestingly, 6 out of 11 (54%) first degree relatives of 7 probands carried a germline *ARMC5* mutation; 5 of these showed at least one nodule on CT scan, coupled with increased cortisol secretion in 3 cases (Assié *et al.*, 2013). In the first large BMAH family studied, a heterozygous germline variant in the *ARMC5* gene (p.Leu365Pro) was identified in all 16 affected Brazilian family members, as well as other mutations in two of three other families (Alencar *et al.*, 2014). Interestingly, only two mutation carriers had overt CS and the majority had subclinical disease and one carrier had no manifestations despite being 72 years old. In addition, in one-third of the affected individuals, only unilateral adrenal lesion was present as progression of the full-blown disease, requires many years and the occurence of additional somatic mutations to develop several macronodules. This raises the question of the prevalence of the *ARMC5* mutation in apparently unilateral incidentalomas in the general population. In fact, screening of sporadic cases of patients with bilateral incidentalomas revealed a low frequency (1 out of 39 patients) of *ARMC5* mutation (Emms *et al.*, 2016). The index cases operated for CS with *ARMC5* mutations presented more severe CS than cases operated for CS without *ARMC5* mutation; carrier patients had larger adrenals glands on imaging with a higher number of nodules (Faucz *et al.*, 2014; Espiard *et al.*, 2015).

The search for *ARMC5* or eventually other responsible genes should allow familial screening through a simple blood test to select who should undergo further evaluations (Lacroix, 2013; Fragoso *et al.*, 2015; Drougat *et al.*, 2015). Further family studies will be useful to clarify the clinical penetrance of *ARMC5* mutations.

ARMC5 is located at 16p11.2 and its function was unknown. It codes for a 935-amino acids protein and contains an approximate 40-amino acid long tandemly repeated sequence motif; similar repeats are found in the mammalian armadillo homolog β-catenin and the APC tumor suppressor protein (Berthon and Stratakis, 2014). It behaves as a tumor suppressor gene and causes apoptosis when transfected in H295 adrenal carcinoma cell lines (Assié *et al.*, 2013). *ARMC5* inactivation decreased the expression of *MC2R* and steroidogenic enzymes (Assié *et al.*, 2013). As it is a tumor suppression gene, a second hit is needed for disease development: an additional different somatic *ARMC5* mutation, deletion, or loss of heterozygosity was found in each adrenal macronodule examined and appears important in accelerating the proliferation of affected cells (Assié *et al.*, 2013; Alencar *et al.*, 2014). In internodular hyperplasia, only germline mutation was present (Assié *et al.*, 2013). As BMAH patients usually develop several nodules, germline-independent and distinct somatic *ARMC5* mutations were identified in each one of the macronodules; in one extreme example, 1 germline and 15 different somatic mutations were found in a patient with BMAH (Correa *et al.*, 2015). Thus, *ARMC5* mutations may be associated with very high mutability and genetic heterogeneity of the other allele (Correa *et al.*, 2015). Previous studies identified that beyond a common event such as ectopic glucose-dependent insulinotropic peptide (GIP) receptors or germline *ARMC5* mutation in diffuse hyperplasia, several somatic genetic events occurred in the different macronodules (Lampron *et al.*, 2006; Almeida *et al.*, 2011); thus second somatic *ARMC5* or other second hits may contribute to the progression of macronodules. A germline deletion in exon 1–5 of *ARMC5* gene rather than mutation of *ARMC5* was reported in a family presenting with vasopressin responsive SCS and BMAH (Suzuki *et al.*, 2015). In addition, DNA sequencing from the right and left adrenal nodules and peripheral blood of the son revealed the presence of another germline: missense mutation in *ARMC5* exon 3 (p.P347S) (Suzuki *et al.*, 2015).

The *ARMC5* gene is widely expressed in various normal human tissues including the brain and pituitary gland (Berthon *et al.*, 2017a), supporting the theory that mutations may be responsible for additional pathologies beyond BMAH. This was confirmed by the association of meningiomas in patients with BMAH (Lee *et al.*, 2005; Alencar *et al.*, 2014) with distinct somatic *ARMC5* mutation in meningiomas found in a patient with familial BMAH carrying a distinct germline mutation (Elbelt *et al.*, 2015).

Two models of *ARMC5* gene knockout (KO) in mice were published recently (Hu *et al.*, 2017). In the first model, Hu and collaborators showed that *ARMC5* is involved in T-cell immune response through an important role for T-cell proliferation and differentiation demonstrating that *ARMC5*'s function is not limited to the adrenal cortex. KO mice presented normal adrenal gland histology and serum glucocorticoid levels at a young age (less than age 12 months) but older (>15 months) KO mice showed enlarged adrenal glands with adrenal hyperplasia, and their serum glucocorticoid levels were significantly increased compared with wild-type mice (Hu *et al.*, 2017).

A second mouse model of *ARMC5* inactivation was developed bearing *LoxP* sites, to allow tissue-specific inactivation (Berthon *et al.*, 2017b). *ARMC5* KO (KO) mice (*ARMC5* −/−) died during early embryonic development, demonstrating an essential role of *ARMC5* during gastrulation. The heterozygote mouse (*ARMC5* +/−), developed hypocorticosteronism at least in part due to a downregulation of some steroidogenic enzymes (*star*, *cyp11a1*, *cyp21*) at 12 months of age. This was associated with a decrease of PKA catalytic subunit α (Cα) expression both at the RNA and protein levels that were also seen in human patients with BMAH and *ARMC5* defects. However, this was transient, as corticosterone levels normalized later, followed by the development of hypercorticosteronemia in one-third of the mice at 18 months of age, which was associated with increases in PKA and Cα expression. Adrenocortical tissue analysis from *ARMC5* +/− mice at 18 months showed an abnormal activation of the Wnt/β-catenin signaling pathway in a subset of zona fasciculata cells (Berthon *et al.*, 2017a,b).

Pathophysiology

The pathophysiology of BMAH is complex, as the adrenal process of growth and hypersecretion appears to be explained through different mechanisms (**Fig. 1**). A large number of alterations implicate activation of the cAMP pathway, alterations of PKA subunits expression and activity, with frequent participation of aberrant GPCR and, in rare cases, activating mutations of *MC2R* and *GNAS* (De Joussineau *et al.*, 2012; Swords *et al.*, 2004; Fragoso *et al.*, 2003). A growing interest concerns the local production of hormones by the steroidogenic cells of BMAH generating autocrine/paracrine regulation of cortisol production (Lefebvre *et al.*, 2013).

Aberrant GPCR

Systematic studies of patients affected by BMAH with subclinical or overt CS showed that 77%–87% of patients had aberrant cortisol response to at least one stimulation and usually to several (Hsiao *et al.*, 2009; Libe *et al.*, 2010; Hofland *et al.*, 2013; El Ghorayeb *et al.*, 2015). Vasopressin (V1) and serotonin (HT4) agonists were the most frequent causes of aberrant responses, but receptors for vasopressin (V2 or 3), serotonin (HT7), GIP, catecholamines, luteinizing hormone/human chorionic gonadotropin, and angiotensin can also be activated (Hsiao *et al.*, 2009; Libe *et al.*, 2010; Hofland *et al.*, 2013; Lacroix *et al.*, 2010; El Ghorayeb *et al.*, 2015). The overall prevalence and magnitude of aberrant cortisol increase were similar in patients with subclinical and overt CS (El Ghorayeb *et al.*, 2015). When comparing *in vitro* data to *in vivo* testing, some discrepancies are found, suggesting that the criterion of 25%–50% serum cortisol elevation to establish the partial/complete responsiveness should be re-evaluated, at least when V1R and HT4R are tested (Hofland *et al.*, 2013). A transcriptome study discovered further GPCR overexpressed in BMAH

including for motilin (MLNR), g-aminobutyric acid (GABBR1), and α2 adrenergic receptor (ADRA2A) (Assié *et al.*, 2010). Detailed studies to correlate the aberrant GPCR to specific genetic causes have not been conducted yet; however, aberrant response to upright posture and serotonin agonists but none to GIP were found in *ARMC5*-mutated patients (Espiard *et al.*, 2015).

Specific aberrant GPCR including vasopressin, β-adrenergic, and HT4 receptors was found in all members from several families with BMAH, either alone or in combination, while different aberrant receptors were found in some members of one large Brazilian family (Lee *et al.*, 2005; Vezzosi *et al.*, 2007; Alencar *et al.*, 2014).

The question of whether the expression of aberrant GPCR plays an initiating role or is a secondary event following a proliferative imitating event remains controversial. Transient hypercortisolism and adrenal hyperplasia due to aberrant LH/CG receptors during pregnancies with BMAH and overt CS occurring only after sustained increase of LH secretion after menopause is an interesting model to examine this question (Lacroix *et al.*, 1999). Detailed studies were conducted recently in a 22-year-old woman who presented with transient bilateral adrenal hyperplasia and severe CS during two pregnancies: *in vivo* and *in vitro* studies in resected adrenals demonstrated that hCG could stimulate the transformation of progenitor subcapsular adrenal LHCG receptor expressing cells into hyperplastic adrenocortical cells, increasing their steroidogenesis under HCG stimulation (Plöckinger *et al.*, 2017). Thus, in this case, the aberrant expression of LHCGR was an early event which persisted even when transient adrenal hyperplasia regressed between pregnancies.

The molecular mechanisms underlying the aberrant expression of GPCR in adrenocortical tissues are still mostly unknown. In a recent study of adrenal tissues from 14 patients with GIP-dependent adrenal CS and 1 patient with GIP-dependent aldosteronism, *GIPR* expression in all 3 unilateral adenomas and 11 BMAH samples occurred through transcriptional activation of a single allele of the *GIPR* gene (Lecoq *et al.*, 2017). No abnormality was detected in proximal *GIPR* promoter methylation, but somatic duplications in the chromosome region 19q13.32 containing the *GIPR* locus in the adrenocortical lesions was found in resected adrenal from 3 patients. In 2 adenoma samples, the duplicated 19q13.32 region was rearranged with other chromosome regions, whereas a single tissue sample with BMAH had 19q duplication only. Juxtaposition with *cis*-acting regulatory sequences such as glucocorticoid response elements in the newly identified genomic environment was driving abnormal expression of the translocated *GIPR* allele in cells of one adenoma. The specific molecular mechanism responsible for the monoallelic overexpression of *GIPR* in the other cases of GIP-dependent Cushing's BMAH remains to be identified; however, this study indicated for the first time that in some cases, the aberrant GPCR expression can be the direct consequence of a genetic initiating event (Lecoq *et al.*, 2017).

Paracrine Production of ACTH in Bilateral Macronodular Adrenal Hyperplasia

Ectopic ACTH production was previously reported in steroidogenic adrenocortical cells in a few cases of BMAH (Mazzuco *et al.*, 2007; Iwata *et al.*, 2012). In a more extensive study, proopiomelanocortin (POMC) mRNA was detected in 26 BMAH samples analyzed; moderate/intense immunostaining for ACTH were detectable in all but 1 sample, which did not express prohormone convertase 1 (Louiset *et al.*, 2013). No ACTH staining was present in normal cortex or primary cortisol-secreting adenomas (Louiset *et al.*, 2013). ACTH secretion was demonstrated by a gradient of ACTH in adrenal vein samples in 2 BMAH patients (Louiset *et al.*, 2013); ACTH levels remained low in their blood samples and adrenal secretion was estimated to be 50 times less than in normal pituitary gland (Mazzuco *et al.*, 2007). Perfused BMAH cells secreted ACTH in pulses followed by cortisol secretion (Louiset *et al.*, 2013). ACTH secretion was not regulated by CRH, dexamethasone, or the GR antagonist mifepristone. In contrast, tissues expressing aberrant GPCR released ACTH and cortisol during perifusion with GIP, serotonin, or hCG; ACTH receptor antagonists cortistatin and corticotropin 7-38 inhibited cortisol secretion induced by aberrant ligands by 40% in these tissues (Louiset *et al.*, 2013). Thus, cortisol production is controlled both by aberrant GPCR and ACTH produced within the adrenocortical tissue, amplifying the effect of the aberrant receptors ligands (**Fig. 1**). The co-expression in the ACTH-positive cells of insulin-like 3, a Leydig and luteal-cell marker, suggests an abnormal tissue differentiation event occuring during embryogenesis in common gonadal–adrenal progenitor (Louiset *et al.*, 2013). Other studies indicate that BMAH tissues may also produce serotonin, vasopressin, glucagon, and other factors that suggest further paracrine regulatory loops of cortisol secretion and cell proliferation (Lefebvre *et al.*, 2013). The confirmation that paracrine adrenal production of ACTH is central in cortisol regulation of BMAH will necessitate clinical studies to examine whether new drugs which would block the ACTH (*MC2R*) receptor can reverse the cortisol excess of affected patients (Lacroix, 2013).

The ectopic expression of POMC and synthesis of ACTH was recently confirmed in BMAH primary cultures (Cavalcante *et al.*, 2017); the mRNA expression of POMC of prohormone convertase type 1 (PCSK1), of ACTH synthesis, and of aberrant GPCR were maintained in primary cultures of cells with or without *ARMC5* mutations. Interestingly, stimulation of the cells by ACTH increased POMC expression and ACTH secretion and as found in normal pituitary corticotroph cells, transcriptional activity of the POMC promoter is dependent on PKA-mediated regulation of calcium channels (Cavalcante *et al.*, 2017).

Other Molecular Mechanisms

The *MC2R* activation is the first step of cAMP/PKA downstream pathway activation, and every step may be affected (**Fig. 1**) (De Joussineau *et al.*, 2012). Rare cases of mutation resulting in *MC2R* activation have been reported (Swords *et al.*, 2004). The chronic *in vitro* administration of ACTH increases *MC2R* expression in adrenal cells, while acute stimulation causes internalization of the receptor (De Joussineau *et al.*, 2012; Hofland *et al.*, 2012). In recent years, two *MC2R* associated trafficking proteins called MRAP

and MRAP2 were identified. They exert regulatory function on *MC2R*: MRAP positively affects trafficking of *MC2R* to cell surface and its signaling transduction, while MRAP2 has opposite functions; they are in turn regulated by some intracellular signaling, particularly cAMP (Hofland *et al.*, 2012). *MC2R* function would thus be submitted to various signals from the aberrant GPCRs and by the paracrine release of ACTH. The decrease in *MC2R* levels in BMAH is not related to any changes in MRAP or MRAP2, but could be related to *ARMC5* mutation (Assié *et al.*, 2013; Hofland *et al.*, 2012). Recently, in one case of BMAH, a germline copy number gain of a chromosome 19 region which includes the protein kinase A (*PRKACA*) gene was found in a patient with BMAH resulting in increased tissue enzyme activity (Beuschlein *et al.*, 2014). In contrast, in unilateral adrenal adenomas secreting high amounts of cortisol, somatic mutations in the catalytic subunit of PRKACA were found in up to 50% of cases; the mutation inactivates the site where the negative regulatory subunit RIIβ should bind, resulting in increased PKA activity and constitutive cortisol secretion (Beuschlein *et al.*, 2014).

Therapy

Steroidogenesis inhibitors such as ketoconazole or metyrapone can be efficient options in acute situations or before adrenalectomy (Lacroix, 2009; van der Pas *et al.*, 2012).

Specific Medical Therapy

BMAH with aberrant GPCR can benefit from specific medical therapies. Long-term control of CS was achieved with beta-blockers or leuprolide acetate when β-adrenergic or LH/CG receptors were functional (Lacroix *et al.*, 1997, 2010; El Ghorayeb *et al.*, 2015; Mazzuco *et al.*, 2009). In catecholamine-dependent CS and BMAH, beta-adrenergic receptor antagonists can be effective in the long-term control of hypercortisolism (Lacroix *et al.*, 1997; Mazzuco *et al.*, 2009; Bourdeau *et al.*, 2016; Miyamura *et al.*, 2003). Administration of the long-acting gonadotropin-releasing hormone (GnRH) agonist, leuprolide acetate, resulted in suppression of endogenous LH and normalization of cortisol production (Lacroix *et al.*, 1999). In a 59-year-old woman with androgen-secreting BMAH resulting in virilization, aberrant LH/hCG receptors were identified in one resected adrenal gland. Suppression of endogenous LH with leuprolide acetate normalized androgen secretion from the contralateral adrenal, thereby avoiding bilateral adrenalectomy (Goodarzi *et al.*, 2003).

Only short-term control of GIP-dependent BMAH was possible using octreotide or pasireotide, following desensitization of somatostatin receptors in GIP-secreting duodenal cells (Preumont *et al.*, 2011; El Ghorayeb *et al.*, 2015). No clinically effective antagonists for the frequent vasopressin V1 or serotonin HT4 receptors are currently available (El Ghorayeb *et al.*, 2015).

Surgical Therapy

Bilateral laparoscopic adrenalectomy (BA) was initially suggested as the main treatment for BMAH (Lacroix, 2009; Karapanou *et al.*, 2013; Ritzel *et al.*, 2013; Aggarwal *et al.*, 2013; Dalvi *et al.*, 2012). In 45 BA or BMAH, no surgery-related death was noted (Ritzel *et al.*, 2013). Since BA requires lifelong steroid replacement and may induce an adrenal insufficiency crisis, unilateral adrenalectomy (UA) was proposed in selected cases (Lacroix, 2009; Xu *et al.*, 2013; Kobayashi *et al.*, 2012). Remission was achieved by UA in patients with mild CS (Kobayashi *et al.*, 2012). A study reported a 93% success rate from UA with a median follow-up of 69 months; two patients experienced transient symptoms of hypocortisolism (Xu *et al.*, 2013). UFC <2 times the upper limit of normal and marked asymmetry of adrenal enlargement are the best predictors of UA effectiveness (Lacroix, 2009).

In a French study, 15 BMAH patients with moderate CS were treated by UA; resection of the larger gland led to hypercortisolism remission after 3 months in all 15 patients and a low risk of recurrence (2 of 15 [13%]) after 7–9 years of follow-up (Debillon *et al.*, 2015). Six patients had transient hypothalamic–pituitary–adrenal (HPA) insufficiency after UA. Thus, careful postoperative evaluation of the HPA axis should be performed, and glucocorticoids replacement should be provided if needed (Debillon *et al.*, 2015). Glucocorticoids are then tapered as the axis recuperates over the following months.

NP-59 scintigraphy was used rarely to lateralize the source of cortisol, but is no longer available in many countries (Wong *et al.*, 2010). Adrenal venous sampling to select which adrenal gland to remove plays a marginal role and standardization for data interpretation are lacking. In the largest study in 10 patients, an adrenal/peripheral vein ratio ≥ 6.5 was consistent with cortisol hypersecretion and a ratio ≤ 2.0 was in favor of bilateral source of cortisol (Martins *et al.*, 2012).

Conclusion

The molecular and genetic findings identified recently should enable early diagnoses and the identification of new targets to develop personalized pharmaceutical therapy. It is likely that other genes implicated in the development of BMAH will be identified. Genetic screening should allow identification of mutation carriers. Longitudinal follow-up of larger cohorts of patients in an international collaborative effort should define the natural history and indications for intervention therapies in these patients.

Adrenal Incidentalomas☆

Massimo Terzolo, Soraya Puglisi, and Giuseppe Reimondo, University of Turin, Turin, Italy

Glossary

Adrenal incidentaloma Incidentally detected adrenal tumor.

Adrenocortical carcinoma (ACC) Malignant tumor of the adrenal glands.

Chemical shift MRI (CSI) Identifies benign adrenal adenomas with high lipid content by a typical signal intensity loss on chemical shift imaging relative to the liver.

Computerized tomography (CT) Series of detailed pictures of areas inside the body taken from different angles; the pictures are created by a computer linked to an X-ray machine.

Fine needle aspiration cytology (FNA) A method to aspirate tumor cells by a fine needle, which is punctured in the tissue of interest.

Magnetic resonance imaging (MRI) Procedure in which a magnet linked to a computer is used to create detailed pictures of areas (imaging) inside the body.

Definition and Clinical Presentation

Adrenal masses are among the most prevalent human tumors and are frequently detected unexpectedly by an imaging study performed for reasons unrelated to any suspect of adrenal diseases (such as abdominal, or back pain, or kidney stone) (Terzolo *et al.*, 2011; Fassnacht *et al.*, 2016). The widespread use of diagnostic ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) resulted in the frequent discovery of incidental adrenal masses (Chidiac and Aron, 1997). Such masses are commonly defined as "adrenal incidentalomas" and represent a public health challenge because they are increasingly recognized in current medical practice. The term adrenal incidentaloma is an 'umbrella' definition encompassing a spectrum of different pathological entities that share the same path of discovery (National Institutes of Health, 2002; Terzolo *et al.*, 2011; Fassnacht *et al.*, 2016).

Based on autopsy studies the prevalence of adrenal incidentalomas is around 2%, ranging from 1% to 8.7%. Radiological studies report an increasing frequency parallel to advancing age, from around 3% in the age of 50 years up to 10% in the elderly (Fassnacht *et al.*, 2016). Most of these tumors are small adrenal adenomas. The etiology of adrenal incidentalomas includes mostly benign non-secreting tumors, however a number of lesions are malignant or can lead to hormonal diseases (pheochromocytoma, aldosterone producing adenoma, and cortisol producing adenoma). The frequency varies in the context of different studies; however, overestimation of malignant and secreting tumors id likely in surgical series (**Table 1**), (Kloos *et al.*, 1995; Latronico and Chrousos, 1997; Mantero *et al.*, 2000).

Up to 20% of patients bearing an incidental adrenal adenoma present the so-called subclinical Cushing syndrome (Reincke, 2000). It is a highly debated condition as to its diagnostic definition, clinical relevance and management. Ascertainment of subclinical Cushing syndrome should stand on three criteria: first, the adrenal incidentaloma has radiologic characteristics of an adrenal adenoma; second, the patient does not present any specific Cushingoid sign; third, the endocrine work-up shows at least partial autonomous (pituitary ACTH-independent) cortisol secretion (Reincke, 2000; Terzolo *et al.*, 2012). This condition very rarely progresses into a full-blown Cushing syndrome over a prolonged follow-up. However, studies have shown that this low-grade cortisol excess may be associated with various comorbidities (hypertension, type 2 diabetes mellitus, obesity, dyslipidemia, and osteoporosis) (Barzon *et al.*, 1999; Morelli *et al.*, 2014; Reincke, 2000). Therefore, the term subclinical may be equivocal because the condition may well have clinical consequences and for these reasons in the recent European Society of Endocrinology (ESE) guidelines it was decided to avoid the term "subclinical Cushing syndrome" and use instead the term "autonomous cortisol secretion" (Fassnacht *et al.*, 2016).

Clinical Questions

Adrenal incidentalomas raise challenging questions for both physicians and their patients and represent one of the leading reasons for seeking endocrinological consultation. In a patient with an adrenal incidentaloma, the following issues have to be considered:

☆*Change History*: March 2018. Massimo Terzolo, Soraya Puglisi and Giuseppe Reimondo added Abstract and Keywords, updated the text, modified Table 1, deleted Figs. 1 and 2, and added new Fig. 1.

This article is an update of Martin Reincke, Incidentaloma, Adrenal, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004.

Table 1 Epidemiology of different types of adrenal incidentaloma

Type of tumor	*Average (%)*	*Range*
Clinical studies including patients with adrenal mass		
Adenoma	80	33–96
Nonfunctioning	75	71–84
Cortisol secreting	12	1.0–29
Aldosterone secreting	2.5	1.6–3.3
Pheochromocytoma	7.0	1.5–14
Carcinoma	8.0	1.2–11
Metastasis	5.0	0–18
Surgical studies		
Adenoma	55	49–69
Nonfunctioning	69	52–75
Cortisol secreting	10	1.0–15
Aldosterone secreting	6.0	2.0–7.0
Pheochromocytoma	10	11–23
Carcinoma	11	1.2–12
Myelolipoma	8.0	7.0–15
Cyst	5.0	4.0–22
Ganglioneuroma	4.0	0–8.0
Metastasis	7.0	0–21

Table adapted according to Terzolo M., Stigliano A., Chiodini I., *et al.* (2011). AME position statement on adrenal incidentaloma. *European Journal of Endocrinology* 164, 851–870.

- How to assess the risk of malignancy?
- How to assess hormone excess?
- Who should have surgical treatment?
- What is the appropriate follow-up for patients treated conservatively?

Diagnostic Approach

The patient with an adrenal incidentaloma requires a complete history and careful physical examination, which may sometimes detect Cushingoid signs missed at first evaluation, a biochemical workup, and (possibly) additional radiological studies. The diagnostic dilemma is to avoid missing potentially dangerous conditions (i.e., adrenocortical carcinoma, pheochromocytoma) avoiding overdiagnosis and overtreatment.

Assessment of the Risk of Malignancy

The probability of malignancy is influenced by several factors, including young age (portending increased risk of adrenocortical cancer), history of extra-adrenal cancer and constitutional symptoms (low-grade fever, weight loss, malaise). Among patients with a history of cancer, up to 25% of incidentalomas are metastases. In contrast, in non-cancer patients, $>75\%$ of adrenal incidentalomas are benign. ACC is an extremely rare tumor, with an estimated annual incidence of 0.5–2 cases per million population. The prevalence of ACC in incidentaloma patients is related to mass size. In surgical series, ACC accounts for 2% of tumors <4.0 cm, 6% of tumors between 4.1 and 6.0 cm, and 25% of tumors >6.0 cm. Although size is classically viewed as a strong predictor of malignancy, other imaging characteristics should be considered to distinguish between benign and malignant lesions (National Institutes of Health, 2002; Kloos *et al.*, 1995; Terzolo *et al.*, 2011). Although limited data are available and no randomized study comparing imaging tests have been performed, non-contrast CT is the first line imaging investigation. The most consistent support to the diagnosis of a benign adrenal adenoma is the presence of a ≤ 4 cm homogenous mass with smooth borders and lipid-rich, hypodense texture, defined by an attenuation value of <10 Hounsfield units (HU) on a non-contrast CT. This parameter has a high sensitivity ranging from 91% to 100% but low specificity, because 20%–30% of benign adrenal adenomas are lipid poor, thus showing mass density >10 HU. In this case, the mass is considered of indeterminate nature and second-line imaging tests are needed to define the diagnosis. The ESE guidelines suggest three possible alternative tests: (1) CT with delayed contrast media washout with an absolute washout $>60\%$ or a relative washout $>40\%$ that are indicative of a benign lesion; (2) chemical shift MRI with a loss of signal intensity on out-phase imaging that is indicative of a benign lesion; (3) FDG-PET/CT with mass uptake less than liver that is indicative of a benign lesion. The available literature does not allow concluding which test has superior diagnostic performance (Boland *et al.*, 1998; Dinnes *et al.*, 2016).

In patients with adrenal incidentalomas who have no history of extra-adrenal malignancy, fine needle aspiration (FNA) has no proven efficacy. FNA is not free of side effects and may lead to pneumothorax, frank retroperitoneal bleeding, or needle track

metastasis in the case of ACC. In patients with a history of malignancy and with a lesion not conclusively characterized as benign by imaging, FNA is a valuable tool (sensitivity and specificity of approximately 90%) and should be performed to exclude the presence of adrenal metastasis if this information may alter management. Pheochromocytoma should always be ruled out prior to FNA because of the risk of hypertensive crises or even death (Bancos *et al.*, 2016a).

Endocrine Work-Up

In non-surgical series roughly 20% of all incidentalomas are functional. Several studies have shown that the risk of subclinical endocrine activity increases with size. Lesions smaller than 1 cm are generally nonfunctional. However, the prevalence of hormone excess increases to 40% in lesions that are 6 cm or larger (Fassnacht *et al.*, 2016).

All subjects with an incidentally discovered adrenal mass should be screened for both catecholamine overproduction and hypercortisolism, with the exception of patients with adrenal masses whose imaging characteristics are typical for myelolipoma or adrenal cyst. Primary hyperaldosteronism should be considered only in hypertensive and/or hypokalemic patients. Using the strictest inclusion criteria and the purest definition of incidentaloma, which imply the lack of the more specific signs of hypercortisolism, will reduce the proportion of secretory tumors and will virtually eliminate the possibility of overt Cushing syndrome. Moreover, sex hormones and steroid precursors should be determined in patients with clinical or imaging features suggestive of adrenocortical carcinoma (Ross and Aron, 1990; Terzolo *et al.*, 2011; Fassnacht *et al.*, 2016).

A major challenge is that Cushing syndrome includes a spectrum of clinical presentations that is difficult to sort out in different categories. The heterogeneity of the clinical phenotype mainly depends on the variability of cortisol secretion that is distributed continuously from apparently non-functioning adrenal adenomas to overtly cortisol-producing adenomas. Categorization of Cushing syndrome is also influenced by clinical experience, because physicians who have less expertise might overlook (mild) signs of hypercortisolism. For these reasons, demonstration of mild partially autonomous cortisol secretion is extremely difficult in practice.

According to the ESE guidelines, the best mean to uncover autonomous cortisol secretion is the 1 mg overnight dexamethasone suppression test. It is recommended to consider the test results as a continuous rather than categorical variable; thus, cortisol levels <1.8 μg/dL (50 nmol/L) exclude an autonomous cortisol secretion. Cortisol values between 1.8 and 5 μg/dL (51–138 nmol/L) are considered as evidence of "possible autonomous secretion," while cortisol levels ≥ 5 μg/dL (138 nmol/L) are diagnostic of "autonomous cortisol secretion." In these two categories an extended biochemical assessment should be undertaken (i.e., ACTH, 24 h urinary free cortisol, late-night salivary cortisol), in particular in younger patients and in patients presenting potential cortisol-related comorbidities, who may benefit of the surgical treatment. In fact, several studies (although not all) have demonstrated that patients with impaired suppression of cortisol after 1 mg dexamethasone test have a higher risk of type 2 diabetes, hypertension, cardiovascular events and vertebral fractures. Although only few studies are available that include a low number of events, the risk of mortality seems to increase in parallel to increasingly higher cortisol levels after 1 mg dexamethasone (Fassnacht *et al.*, 2016).

In hypertensive patients, serum potassium and a plasma aldosterone/plasma renin ratio should be determined to evaluate primary aldosteronism. A normal potassium concentration does not exclude primary hyperaldosteronism given that the majority of patients are normokaliemic under random conditions. The reader is referred to the Endocrine Society Guidelines on primary aldosteronism for further details on screening and confirmation of diagnosis (Funder *et al.*, 2016).

Pheochromocytoma among adrenal incidentalomas is found in approximately 5% of patients. Most patients do not show the typical clinical symptoms such as tachycardia, sweating, and headache, and up to 40% are completely asymptomatic. In all patients with adrenal incidentalomas, fractionated metanephrines should be measured in urine (sensitivity 97%) or free metanephrines in plasma (sensitivity 99%) (Fassnacht *et al.*, 2016). Normal results rule out pheochromocytoma, while an elevation of more than threefold above the reference interval establishes the diagnosis. False-positive results should be considered in patients with equivocal elevation of plasma, or urinary normetanephrine. In these subjects, measurements should be repeated in the absence of possible interfering conditions (Fassnacht *et al.*, 2016; Lenders *et al.*, 2014).

Therapeutic Considerations

It is overall accepted that adrenal tumors leading to clinically significant hormone excess (primary aldosteronism, pheochromocytoma, overt Cushing syndrome) or radiological suspicion of malignancy should be surgically removed. More difficult is to define which subjects with benign imaging studies and non-functioning adrenal masses may require surgery. The systematic review of several papers reported a very low estimated risk for developing malignancy (0.2%) or overt Cushing syndrome (0.3%). The estimated risk for developing autonomous cortisol secretion without signs of overt Cushing syndrome is up to 11%, but the clinical meaning of this finding is uncertain. Due to increased risk of malignancy in larger masses, it is accepted to consider surgery in patients with adrenal masses larger than 4 cm, although non-functioning and with benign imaging characteristics (Terzolo *et al.*, 2011; Fassnacht *et al.*, 2016).

The introduction of laparoscopic adrenalectomy has significantly reduced surgical-related morbidity (5%–10%) and mortality ($<1\%$). However, widening surgical indications, even with a safe procedure, may lead to increased morbidity. It has to be emphasized that this operation may be performed in specialized centers with experienced laparoscopic surgeons (Fassnacht *et al.*, 2016).

Treatment of Autonomous Cortisol Secretion

It remains doubtful whether all patients with autonomous cortisol secretion may benefit from adrenal surgery. There are some data indicating the improvement of comorbidities potentially related to cortisol excess, such as obesity, hypertension, hyperglycemia, and dyslipidemia with surgery. However, there are no long-term data on mortality and cardiovascular events (Bancos *et al.*, 2016b; Fassnacht *et al.*, 2016). Thus, the ESE guidelines suggest to individualize the therapeutic approach and consider surgery in younger patients, in patients with a higher degree of cortisol excess, or in patients with comorbidities, particularly if there are worsening clinical features because of suboptimal control despite adequate medical therapy. (see **Fig. 1**, near here) (Terzolo *et al.*, 2012; Fassnacht *et al.*, 2016).

Follow-Up in Patients Not Undergoing Adrenal Surgery

How to organize follow-up remains a most controversial issue. The ESE guidelines recommend that homogeneous ≤ 4 cm mass with density ≤ 10 HU on non-contrast CT do not need any further imaging for diagnosis or follow-up. In masses >4 cm, it could be reasonable to repeat CT or MRI 6–12 months after the initial study to exclude significant growth. In patients who experience enlargement of the lesion by $>20\%$, in addition to a 5 mm increase of the maximum diameter, surgical resection should be considered (Fassnacht *et al.*, 2016).

There is also limited utility in repeating endocrine tests and patients with a normal hormonal work-up at the initial evaluation should avoid repeated hormonal assessment unless new clinical signs of endocrine activity appear, or in presence of worsening comorbidities. In patients with non-suppressed cortisol levels after 1 mg dexamethasone test at initial evaluation, an annual assessment for cortisol excess and comorbidities may be considered to detect a worsening course. In some cases, surgical treatment should be reconsidered. There are few data on the optimal duration of follow-up and different studies proposed follow-up periods ranging from 2 to 5 years (Fassnacht *et al.*, 2016).

Adrenocortical Carcinoma: Diagnosis and Therapy

Massimo Terzolo, Soraya Puglisi, and Paola Perotti, University of Turin, Turin, Italy
Mélanie Claps, Elisa Roca, and Alfredo Berruti, University of Brescia, Brescia, Italy

Glossary

Adrenal incidentaloma Incidentally detected adrenal tumor.
Adrenocortical carcinoma (ACC) Malignant tumor of the adrenal glands.
Chemical shift MRI (CSI) Identifies benign adrenal adenomas with high lipid content by a typical signal intensity loss on chemical shift imaging relative to the liver.
Computerized tomography (CT) Series of detailed pictures of areas inside the body taken from different angles; the pictures are created by a computer linked to an X-ray machine.
Fine needle aspiration cytology (FNA) A method to aspirate tumor cells by a fine needle, which is punctured in the tissue of interest.
Magnetic resonance imaging (MRI) Procedure in which a magnet linked to a computer is used to create detailed pictures of areas (imaging) inside the body.

Diagnosis

Hormonal Assessment

Adrenocortical carcinoma (ACC) has the propensity to produce and secrete steroids; thus, in all patients with a (suspected) ACC signs and symptoms of cortisol excess, androgen excess in women, mineralocorticoid excess, and estrogen excess in men should be actively searched for with careful history and physical examination (Allolio and Fassnacht, 2006). About 50%–60% of patients with ACC will show clinical and biochemical evidence of steroid excess, mainly hypercortisolism and/or hyperandrogenism. Concomitant secretion of different steroids is a hallmark of ACC (Fassnacht and Allolio, 2009). Steroid secretion may be clinically silent (i.e., subclinical cortisol excess) and should therefore be excluded even in asymptomatic patients. Since ACC have an inefficient steroid factory due to decreased expression of several steroidogenic enzymes (Fassnacht *et al.*, 2011), excessive amount of adrenal steroid precursors can be detected in urine by gas chromatography/mass spectrometry or LC-MS in tumors classified as nonfunctioning with conventional diagnostic methods. Therefore, the so-called steroidobolomic approach may find evidence of steroid oversecretion in the majority of patients and may represent a powerful technique in the differential diagnosis between benign and malignant adrenal tumors, and in the early detection of ACC recurrence (Arlt *et al.*, 2011).

A detailed endocrine assessment has to be performed preoperatively since it may allow: (i) to establish the adrenocortical origin of a tumor excluding other differential diagnoses (i.e., lymphoma, sarcoma) if steroid secretion is present; (ii) to suspect the malignant potential of an adrenal tumor (i.e., estradiol excess in males, high concentration of androgens or steroid precursors); (iii) to predict the risk of life-threatening postoperative adrenal insufficiency in patients with cortisol secreting tumors; (iv) to make available tumor markers in the postoperative follow-up to assess persistence or recurrence of disease (Fassnacht and Allolio, 2009; Fassnacht *et al.*, 2011).

Cortisol excess should be demonstrated by measurement of 24 h urinary free cortisol (UFC) excretion and eventually by measurement of late-night salivary cortisol and the 1 mg overnight dexamethasone suppression test (1 mg DST), which has the highest sensitivity (95% with a threshold of 1.8 μg/dL) particularly for the detection of milder forms (Nieman *et al.*, 2008; Terzolo *et al.*, 2012). ACTH levels that are undetectable, or at the lower end of the normal range, confirm the condition of excess cortisol secretion. Aldosterone-producing carcinoma is rare and hypokalemia found in ACC patients is usually due to severe cortisol excess. However, screening for hyperaldosteronism is recommended in all hypertensive and/or hypokalemic patients with an adrenal mass, by measuring plasma aldosterone or precursors and plasma renin activity (PRA), or direct renin concentration (PRC) (Terzolo *et al.*, 2011). Hypersecretion of sexual steroids is frequently observed in ACC patients, with increased levels of plasma 17-OH progesterone, androstenedione and DHEAS, leading to increased plasma testosterone in females. Estrogens hypersecretion, though rare, should be ascertained in males (particularly when presenting gynecomastia) and postmenopausal females (Zeiger *et al.*, 2009).

Radiological Assessment

Imaging has a prominent role in diagnosis of ACC, staging of the disease, and monitoring of tumor response to treatment. On cross sectional imaging, morphological features suggesting that an adrenal mass may be an ACC include tumor heterogeneity (due to necrosis or hemorrhage), lobulated shape, irregular margins, calcifications and a large size. None of these features can be considered as a definitive sign of malignancy, with the exception of venous thrombus, infiltration of surrounding structures, or metastatic spread to lymph nodes or distant organs (Fishman *et al.*, 1987; Zhang *et al.*, 2012).

 doi:10.1016/B978-0-12-801238-3.65243-1

The probability that an adrenal mass be an ACC is correlated to its size; however, since ACC is infrequent among adrenal incidentalomas, the posttest probability associated with any tumor size remains low (Terzolo *et al.*, 2012). Recent findings from the SEER database confirmed that an increased tumor size correlates with a higher likelihood of malignancy. The analysis of data on 192 ACCs presenting with localized disease showed that a tumor size of 4 cm had a sensitivity of 96% and specificity of 52% for diagnosing ACC (Kebebew *et al.*, 2006), a figure very close to that observed in the Italian survey on adrenal incidentaloma (Mantero *et al.*, 2000).

Although no randomized study comparing imaging tests has been performed, noncontrast CT is generally considered as the first-line imaging test. The most consistent support to the diagnosis of a benign adrenal adenoma is the presence of a ≤ 4 cm homogenous mass, with smooth borders and lipid-rich, hypodense texture, defined by an attenuation value of <10 Hounsfield units (HU) on a noncontrast CT. This parameter has a high sensitivity ranging from 91% to 100% but low specificity, because 20%–30% of benign adrenal adenomas are lipid poor, thus showing mass density $>$ 10 HU (Vassiliadi and Tsagarakis, 2011). In this case, the mass is considered of indeterminate nature and second-line imaging tests are needed to define the diagnosis. The ESE guidelines on management of adrenal incidentalomas suggest three possible alternative tests: (1) CT with delayed contrast media washout with an absolute washout $>60\%$ or a relative washout $>40\%$ indicative of a benign lesion; (2) chemical shift MRI with a loss of signal intensity on out-phase imaging that is indicative of a benign lesion; (3) FDG PET/CT with mass uptake less than liver indicative of a benign lesion (Fassnacht *et al.*, 2016). The available literature does not allow concluding which test has superior diagnostic performance. Enhanced CT is extremely useful to assess organ invasion and metastatic spread. Metastases from ACC generally involve lungs, liver, regional and para-aortic lymph nodes and bones. Enhanced CT is the technique of choice for ACC staging and assessment of response to treatment, while MRI is generally preferred for assessment of vascular involvement by tumor thrombus (Chiche *et al.*, 2006). Fine needle aspiration (FNA) has no established role in securing the diagnosis, if not in case of unresectable ACC, when it can serve to inform further management (Fassnacht *et al.*, 2016).

FDG PET may be useful in ACC staging; however, practice varies as to its standard use in this setting. In a recent study, FDG PET/CT was complementary to total body CT in detection of metastatic sites of disease (Leboulleux *et al.*, 2006). Research from our group showed the utility of FDG PET/CT as a second-line test in the postoperative surveillance of ACC patients following CT findings of a potential recurrence. The greater specificity of FDG PET/CT was particularly useful in ruling out suspected ACC recurrences found by CT and results of the test had an impact on patient management (Ardito *et al.*, 2015).

Staging classification

Several staging systems have been used in the past, but in the last years most studies in the field have employed the system developed by the European Network for the Study of Adrenal Tumors (ENSAT). The ENSAT staging system represents an improvement over previous classifications because it is based on the analysis of disease-specific survival curves for each stage obtained in larger series (**Table 1**). The ENSAT staging system allows a more precise prognostic differentiation among stages, which in the original study showed a progressively reduced 5-year survival of 81%, 61%, 50%, and 13%, from stage 1 to stage 4, respectively (Fassnacht *et al.*, 2009). In this system, tumor infiltration in surrounding tissues, tumor thrombus in caval or renal vein, and/or positive lymph nodes define stage III, whereas the presence of distant metastasis is the only criteria for stage IV (Fassnacht *et al.*, 2009). Comparative studies confirmed that the ENSAT staging system has better prognostic accuracy for ACC-specific survival than previous classifications (Lughezzani *et al.*, 2010; Berruti et al., 2012a).

Pathological Assessment

The Weiss score is the cornerstone of pathological diagnosis and may have also a prognostic stratification power (**Table 2**). Weiss score includes nine criteria of proliferation, nuclear abnormality and tumor extension (Weiss *et al.*, 1989). A Weiss score of 0–2 defines benign adrenal tumors, while tumors with a Weiss score ≥ 3 are considered malignant. Tumors with a Weiss score of 2 or 3 may eventually display an undetermined behavior. A correct assessment of this morphological score is strictly dependent on individual expertise and an easier standardization is urgently needed. Intraindividual variability in readings of Weiss score has been pointed out, particularly for the parameters of venous invasion and sinusoidal invasion (Tissier *et al.*, 2012).

Table 1 Staging system for ACC proposed by the European Network for the Study of Adrenal Tumors (ENSAT) (Fassnacht *et al.*, 2009)

Stage	
I	T1, N0, M0
II	T2, N0, M0
III	T1–T2, N1, M0; T3–T4, N0–N1, M0
IV	Any T, any N, M1

T1, tumor ≤ 5 cm; T2, tumor >5 cm; T3, tumor infiltration into surrounding tissue; T4, tumor invasion into adjacent organs or venous tumor thrombus in vena cava or renal vein; N0, no positive lymph nodes; N1, positive lymph node(s); M0, no distant metastases; M1, presence of distant metastasis.

Table 2 The Weiss score (Weiss *et al.*, 1989)

Nuclear atypia
Atypical mitoses
Mitotic rate > 5 in 50 HPF
Character of cytoplasma
Architecture of tumor cells
Necrosis
Invasion of venous structure
Invasion of sinusoidal structure
Invasion of the capsule of tumor

It is matter of debate if Weiss score as a whole may predict prognosis (Morimoto *et al.*, 2008; Volante *et al.*, 2009; Papotti *et al.*, 2011). One component of the Weiss score, mitotic activity, has been found to be the most significant determinant of survival. High mitotic activity was found to be a predictor of poor outcome either in localized or metastatic ACC (van Slooten *et al.*, 1985; Tissier *et al.*, 2012). Also the presence of tumor necrosis and atypical mitotic figures have been associated with poor prognosis and advanced disease stage (Stojadinovic *et al.*, 2002; Assié *et al.*, 2007; Volante *et al.*, 2009), although they were less powerful predictors. In patients with stage IV ACC, multivariate analysis identified high mitotic index (>20 per 50 HPF) and the number of organs involved as the major factors influencing prognosis (Assié *et al.*, 2007). A recent pathological study showed that it was possible to stratify prognosis on the basis of stage and mitotic index of the primary tumor. Stage III/IV and mitotic index >9 per 50 HPF qualified the worst prognosis group (Volante *et al.*, 2009). These findings support the concept that a grading system based on mitotic count might help in the prognostic stratification of patients (Giordano, 2011).

Since the Weiss score is difficult to apply, subjective and time consuming, despite several attempts of revision and implementation (Aubert *et al.*, 2002; Stojadinovic *et al.*, 2002), Duregon et al. have introduced a new method, the "reticulin algorithm." This method identifies malignancy through detection of an altered reticulin framework evaluated using a specific staining associated with one out of three parameters among necrosis, high mitotic rate and vascular invasion (Duregon *et al.*, 2013). This method shows a better accuracy and higher reproducibility than the classic Weiss score among different pathologists (Duregon *et al.*, 2013) and may also represent a valid tool for identification of specific ACC variants, such as pediatric, oncocytic, myxoid, and sarcomatoid tumors. Further studies are needed to confirm its value for securing the diagnosis of ACC.

Therapy

Adjuvant Treatment Concepts

The need to consider adjuvant therapy in ACC is derived from the observation that up to 80% of patients show loco-regional recurrence or distant metastases after an apparent complete surgical excision. Despite en bloc, complete resection of tumor in patients without evidence of metastatic disease, the 5-year survival rate is only approximately 50% (Bellantone *et al.*, 1997; Schulick and Brennan, 1999; Wajchenberg *et al.*, 2000; Vaughan, 2004). It is plainly evident that these findings make a strong case in favor of the use of adjuvant therapy in ACC patients; however, this therapeutic option for patients with stage I-III ACC following radical surgery remains debated. Mitotane is the only drug approved by international pharmaceutical agencies for treatment of advanced ACC but its use in adjuvant setting remains matter of heavy debate, and its in this setting is off-label in many countries (Huang and Fojo, 2008; Wängberg *et al.*, 2010).

Mitotane

Although randomized, controlled trials on the use of adjuvant mitotane in ACC patients following radical surgery are still unavailable, a large retrospective case–control study reported that patients treated with adjuvant mitotane had a significantly longer recurrence-free survival (RFS) and overall survival (OS), compared with two independent groups of patients left untreated following surgery (Terzolo *et al.*, 2007). Recently, the same group has updated the follow-up of these cohorts of patients with almost 10 years of additional observation, confirming that adjuvant mitotane treatment is associated with a significant benefit in terms of RFS regardless of the hormone secretory status (Berruti *et al.*, 2017). Advantage on OS is less evident but this may be explained by different treatment of ACC recurrence between groups. Despite its retrospective nature, this study remains the most informative piece of evidence on the topic and represents a reference for decision making in ACC patients. Strengths of the study are the inclusion of contemporary groups of matched patients, who were allocated to treatment or follow-up based on the treatment policy the center. Conversely, in many studies patients with unfavorable characteristics were more likely selected for adjuvant mitotane, thus introducing a bias. An example of this may be found in a recent study reporting a multicenter, retrospective analysis on 207 ACC patients, showing that adjuvant mitotane was associated with decreased RFS and OS. However, 42% of the patients treated with mitotane had stage IV ACC and, indeed, chemotherapy was frequently associated to mitotane therapy (Postlewait *et al.*, 2016). A retrospective study from the University of Michigan confirms the finding that adjuvant mitotane

treatment is associated with a significantly improved RFS although it failed to prolong significantly OS (Else *et al.*, 2014). The lack of effect on OS may be explained with the short follow-up (25.6 months).

Despite controversy on this issue, there is general agreement on the adjuvant use of mitotane following surgical removal of ACC in high-risk patients. The condition of high risk of recurrence has been defined as stage III, or Ki-67 $>$ 10%, or Rx-R1 resection by a panel of international experts (Berruti et al., 2012b). For low-risk patients, who are characterized by stage I or II, R0 resection and Ki-67 $\leq$ 10%, adjuvant mitotane therapy is not mandatory. An international, multicentric, prospective, randomized trial (ADIUVO trial) is currently enrolling low-risk ACC patients, who are randomized to mitotane or observation, in order to definitely establish the effectiveness of adjuvant mitotane in this cohort. A recent retrospective analysis demonstrated that blood mitotane concentrations $\geq$14 mg/L were associated with a prolonged RFS in patients treated with adjuvant mitotane following macroscopically radical surgery (Terzolo *et al.*, 2013). Thus, maintenance of target mitotane concentration may represent a predictor of response to adjuvant treatment. It is common practice in expert centers to monitor regularly blood mitotane concentrations during treatment and to target levels of 14–20 mg/L (Terzolo *et al.*, 2014). There is no consensus on how to start treatment: the ESMO guidelines (Berruti et al., 2012b) recommend that mitotane therapy should be administered following a high-dose regimen with the aim of reaching a daily dose of 6 g/daily rather soon and then adjust the dose according to tolerability and mitotane levels. However, in our personal practice we start treatment at lower doses because they are better tolerated and less patients have to discontinue treatment (Terzolo *et al.*, 2014). Duration of adjuvant mitotane therapy has not been definitively established, but it is reasonable to continue therapy for at least 2 years, because this is the period when most of ACC recurrences are detected. In our practice, we have currently extended treatment till to 3–5 years, if tolerated.

The most common unwanted effects are gastrointestinal manifestations that appear early in the course of treatment, independently on mitotane levels (Faggiano *et al.*, 2006). Diarrhea and nausea are particularly frequent and can be managed with temporary dose reduction and supportive therapy. Elevated γ-glutamyl-transferase levels are also frequently observed but are not actually troublesome unless values are exceedingly elevated. Clinically significant liver toxicity is characterized by a marked increase in transaminases and bilirubin, but is infrequently observed in the absence of predisposing conditions (Terzolo *et al.*, 2014). Central neurologic toxicity (cerebellar symptoms, disturbed cognitive performance) is more closely associated with elevated mitotane concentrations (20 mg/L) but subtler symptoms, such as memory impairment or attention deficit, may be observed in some patients even at lower drug concentrations (Terzolo and Berruti, 2008) In this context, monitoring of circulating mitotane levels may be useful to tailor individually the therapy and limit side effects thus attaining better compliance to treatment. The implementation of blood mitotane monitoring, through a service provided by the company distributing Lysodren® in Europe (Lysosafe, www.lysodren-europe.com), has rendered the use of this drug more feasible because it is possible to some extent to anticipate and prevent toxicity. In our current practice, measurement of circulating mitotane concentration has become mandatory for a proper management of patients with ACC. A general measure to deal with mitotane toxicity is a step down to the previously tolerated dose, or temporary drug withdrawal in the event of severe manifestations. However, well-informed and motivated patients are able to cope with side effects and maintain compliance to treatment. To accomplish this task, it is important to establish a close patient–physician relationship to induce and maintain adherence to treatment. Patients seek advice frequently, also because their local physicians are unfamiliar with mitotane use and its attendant complications, and it is necessary to give a timely counseling to keep patients on treatment.

Because of the adrenolytic effect of mitotane, all patients should receive glucocorticoid replacement to prevent adrenal insufficiency. Steroid doses are typically higher than in Addison's disease, due to an enhanced metabolic clearance rate of glucocorticoids induced by mitotane (Arlt *et al.*, 2011; Fassnacht *et al.*, 2011; Stigliano *et al.*, 2015). An inadequate treatment of adrenal insufficiency increases mitotane-related toxicity, particularly gastrointestinal side effects, and reduces tolerance (Daffara *et al.*, 2008). Mineralocorticoid supplementation is not mandatory in all patients because the zona glomerulosa is partly spared by the toxic effect of mitotane (Daffara *et al.*, 2008). Moreover, mitotane affects thyroid and gonadal function by mechanisms that are still to be completely elucidated. Mitotane administration is associated with low FT4 levels without a compensatory rise in TSH, an effect that becomes apparent early in the course of treatment. This prompts thyroxin replacement, even if the benefit of this measure may be difficult to appreciate (Daffara *et al.*, 2008; Terzolo and Berruti, 2008). In women, gonadal function is usually preserved and most female patients have regular cycles unless PRL levels are significantly increased (Daffara *et al.*, 2008; Terzolo and Berruti, 2008; Fassnacht *et al.*, 2011) due to a weak estrogen-like action of mitotane (Nader *et al.*, 2006). Conversely, in men mitotane treatment causes sexual dysfunction as a late but common unwanted effect, due to inhibition of testosterone secretion. Sex steroid replacement may become necessary to treat hypogonadism in some patients but may worsen gynecomastia (Daffara *et al.*, 2008; Terzolo and Berruti, 2008; Fassnacht *et al.*, 2011). Mitotane use is associated with increasing levels of LDL and HDL cholesterol, and triglycerides (Allolio and Fassnacht, 2006). However, the value of introducing statins remains uncertain although patients may be worried about their lipid levels. The decision to use antilipid drugs, which may further complicate supportive therapy and is not exempt from potential toxicity, should be carefully though at considering patient life expectancy.

Radiotherapy and chemotherapy

In a retrospective analysis from the United States, adjuvant radiotherapy was reported to decrease of 4.7 times the risk of local failure compared with surgery alone (Sabolch *et al.*, 2011). In a retrospective analysis from the German ACC Registry, radiotherapy in an adjuvant setting resulted in a significant better 5-year RFS, but did not affect OS and disease-free survival (Fassnacht *et al.*, 2006). However, no difference between surgery plus radiotherapy and surgery alone was found in another retrospective study done in the United States (Habra *et al.*, 2013). A review of the literature concluded that adjuvant radiotherapy should be considered in

patients with incomplete, or R1 resection, or Rx resection, who are at high risk for local recurrence (Polat *et al.*, 2009). A total dose of >40 Gy with single fractions of 1.8–2 Gy should be administered. However, prospective investigations are required and no definitive conclusions are available at the moment.

As far as chemotherapy is concerned, limited data are available. A recent paper published data on 3982 ACC patients from the National US Cancer Data Base (NCDB), revealing that adjuvant chemotherapy was performed in 10% of cases. By comparing these subjects with those treated with surgery only, OS was not different, while no RFS analysis was reported (Bilimoria *et al.*, 2008). Anecdotal cases reported a more favorable outcome after an adjuvant etoposide—cisplatin based chemotherapy (Keskin *et al.*, 2013). A phase II clinical trial reported that the combination of mitotane plus streptozotocin was effective in an adjuvant setting. However, the study design does not allow discriminating the relative merits of the two drugs (Khan *et al.*, 2000).

Treatment for Advanced Disease

About 50% of newly diagnosed ACC patients present with metastatic or unresectable disease (Berruti et al., 2012b). Moreover, despite initial complete resection of ACC, up to 70%–80% of patients are destined to develop recurrent or metastatic disease (Berruti et al., 2012b; Terzolo *et al.*, 2014). The prognosis of patients with advanced/metastatic ACC is generally poor but it is heterogeneous and long-term survivors have been described (Terzolo *et al.*, 2014; Libé *et al.*, 2015). The management of these patients is mainly centered on systemic therapy including mitotane alone or mitotane in combination with chemotherapy. The standard chemotherapy regimen for advanced ACC is EDP (etoposide, doxorubicin and cisplatin) plus mitotane that was initially tested in two patients (Berruti *et al.*, 1992), its feasibility was further assessed in seven patients (Pia *et al.*, 1995), then the activity was evaluated in a multicenter prospective phase II study conducted in Italy (Berruti et al., 1998, 2005). Finally its efficacy was compared against the combination of streptozotocin and mitotane in a prospective randomized phase III clinical trial conducted worldwide (Fassnacht *et al.*, 2012). Three hundred and four patients were prospectively enrolled in about 6 years. Patients with disease progression to the first-line treatment received the alternate regimen. EDP-M was superior to Sz-M both in terms of disease response rate and progression-free survival (PFS). Analysis of OS also favored patients initially randomized to receive EDP-M but due to the attenuating effect of the cross over to EDP-M of patients randomized to the Sz-M at disease progression, the difference just failed to attain statistical significance. In addition to systemic therapy also local regional therapies, that is, surgery (Bellantone *et al.*, 1997; Deschamps *et al.*, 2014), radiofrequency ablation (RFA) (Wood *et al.*, 2003; Deschamps *et al.*, 2014), and chemoembolization (Wong *et al.*, 2017) can be taken into consideration in a selected patient population. Moreover, in patients, who have contraindications to EDP or poor performance status, either cisplatin or carboplatin administered as single agents could be reasonable options.

In the modern approach to advanced/metastatic patients a careful evaluation of prognostic factors should be performed and the most appropriate treatment strategy should be prescribed accordingly (Baudin, 2015). Finally, the morbidity caused by ACC and the prognosis derives not only from the spread of malignant cells into other organs but also from the consequences of hormone excess. Consequently, the goals of treatment in ACC include both control of tumor growth and mitigation of the effects derived from hormone excess in patients with hormone secreting ACC.

Prognostic factors

In a recent study of the ENSAT network, which analyzed 444 patients with advanced stage III to IV ACC, the stage was redefined by a new modified ENSAT (mENSAT) classification in which the presence of N positive moved from stage III to IV and the number of tumor organs showed a major prognostic role together with four additional parameters (GRAS parameters) (Libé *et al.*, 2015). The GRAS parameters consist in grading (G) assessed by Ki67, which is defined favorable if <20%, primary R0 resection status performed (R favorable), age < 50 years (A favorable) and absence of symptoms at diagnosis (either related to cortisol hypersecretion or tumor mass) (S favorable). GRAS parameters are classified as pejorative in case of: grading as defined by Ki67 > 20% and/or primary R1–2 resection status. By combining mENSAT stage with GRAS parameters, four different prognostic subgroup were defined: group 1) mENSAT stage III and GRAS either favorable or unfavorable: 5 years survival 50%; group 2) mENSAT stage III and GRAS pejorative or stage III-IV A-B (3 or less tumor organs involved) and GRAS favorable: 5 years 25%–50%; group 3) mENSAT stage IV A-B and GRAS unfavorable: 5 years 10%–25%; group 4) mENSAT stage IV C (>3 tumor organs involved) or stage IV A-B and GRAS pejorative: 5 years <10% (Baudin, 2015).

Treatment of patients with limited metastatic spread and more indolent disease

Patients with oligo-metastatic disease with favorable prognostic factor as assessed by GRAS and/or a relatively long disease-free interval from previous surgery (i.e., 12 months or more) represents a minority of advanced/metastatic ACC. These patients have a relative long survival perspective and may not benefit from an aggressive systemic treatment such as the EDP-M regimen. Therefore, single agent mitotane could be a reasonable option. The treatment of these patients also includes loco-regional approaches. Surgery of primary and or metastases can be recommended if a complete resection (R0) is achievable. Surgery of multiple metastases is considered on a case-by-case basis and should be performed mainly in patients with favorable prognostic factors, sustained disease response to systemic therapy, and long-term R0 resection expectations. In patients who are not candidates for surgery, percutaneous image-guided RFA is a locally effective treatment and chemoembolization is another possibility to

treat liver metastases. RFA in combination with surgical resection may allow better disease control in the setting of limited disease (Wood *et al.*, 2003; Deschamps *et al.*, 2014; Wong *et al.*, 2017).

Tumor debulking generally offers little benefit, however surgery of primary disease in newly diagnosed patients with oligometastatic disease and limited extra-adrenal tumor volume can be performed in case of good response to systemic therapy. It should be noted that the efficacy of local regional therapies in the management of such patients has never been assessed in a randomized prospective clinical trial, so we cannot exclude that the long-term benefit obtained in some cases can be ascribed to a patient selection. In the author opinion, the long-term benefit is due at least in part to the efficacy of systemic therapy; therefore, it is recommended that all local regional approaches should be used in combination with systemic therapy, mitotane in particular.

Management of metastatic patients with poor prognostic features

The majority of metastatic ACC patients have poor prognostic features, that is, two or more organ involved and/or unfavorable/pejorative GRAS parameters. For these patients, chemotherapy with EDP-M regimen represents the treatment of choice. In case of painful metastasis, palliative radiotherapy is an option, especially in bone lesions. Due to the latency of mitotane to attain the therapeutic range, the drug administered alone is not indicated in the management of patients with clinical evidence of fast growing tumors.

Metastatic ACC submitted to EDP-M regimen have a survival perspective of 18 months as demonstrated by the results of the FIRM-ACT trial (Fassnacht *et al.*, 2012). However, 15% of patients are alive after 5 years. In terms of progression-free survival, 50% of patients submitted to EDP-M showed disease progression after 5 months, and 25% of patients were free from progression after 12 months, and 15% after 2 years. In addition, few patients were still alive and free from progression after 5 years (Fassnacht *et al.*, 2012). These data show that the efficacy of chemotherapy plus mitotane is overall modest but a small subset of patients are destined to obtain a long-term disease control. The identification of factors that may predict chemotherapy efficacy is very important to select patients destined to benefit from this aggressive strategy and address nonresponding patients to experimental therapies. In a recently published paper, our group has demonstrated that the expression of topoisomerase II was associated with EDP-M efficacy (Roca *et al.*, 2017). These data need confirmation. It should be noted, however, that EDP is usually administered for a maximum of 6–8 cycles while mitotane is usually maintained till progression. It is possible that cytotoxic chemotherapy is useful to attain rapid tumor shrinkage but the long-term efficacy observed in some cases could be attributed to the mitotane maintenance. If this is true, predictive factors of mitotane efficacy are needed. Human cytochrome P450 2B6 (CYP2B6) (D'avolio *et al.*, 2013) and CYP2W1 (Ronchi *et al.*, 2014) that are involved in mitotane metabolism and may activate mitotane in the adrenocortical tissue, respectively, or ribonucleotide reductase large subunit 1 (RRM1) gene expression (Volante *et al.*, 2012) are promising predictive factors of mitotane efficacy.

Management of hormone secreting tumors

Patients with metastatic ACC that exhibits excess steroid secretion should be treated with steroidogenic inhibitors to ameliorate their effects (hypertension, hyperglycemia, hypokalemia, and muscle atrophy). The management of hormone excess in patients with metastatic ACC is often challenging. The presence of Cushing syndrome may consistently increase the toxicity of chemotherapy since it is associated with immune depression that may favor infections particularly in the neutropenia phase. Therefore, a rapid control of hormone hypersecretion is mandatory. Mitotane has both antisecretive and antiproliferative activity; however, the slow onset of mitotane activity is a main limitation for the management of Cushing syndrome (Terzolo *et al.*, 2014). Faster drug in lowering the serum cortisol levels are needed. Ketoconazole is more rapid than mitotane in controlling Cushing syndrome (Kamenický *et al.*, 2011) but it requires several weeks and its clinical employment is hampered by the hepatic toxicity. Metyrapone is an adrenolytic agent targeting the 11-beta-hydroxylase. In a recently published experience by our group, metyrapone was associated upfront to the EDP-M regimen and this combination was very well tolerated and led to a rapid control of Cushing syndrome induced by cortisol secreting ACC (Claps *et al.*, 2017).

Second-line therapies

The results of second-line therapy in patients with disease progression to platinum-containing regimens plus mitotane were as a whole modest. The association of Gemcitabine to metronomic capecitabine showed a limited activity in a prospective multicenter phase II trial conducted in Italy (Sperone *et al.*, 2010). Results have been confirmed a series of patients treated in a real world practice both in Germany and in Italy (Henning *et al.*, 2017). This regimen still remains an option as second-line therapy.

Several small phase II trials have tested the efficacy of molecular agents targeting EGFR, angiogenesis, IGFR, and mTOR pathways. These treatments administered in pretreated patients either alone or in combination with chemotherapy, or with other molecular target agents obtained poor results (Naing *et al.*, 2011; Berruti et al., 2012b; Kroiss *et al.*, 2012). In a multicenter randomized phase III trial involving most referenced centers in Europe and United States, the drug Linsitinib (OSI-906), an orally available IGFR inhibitor failed to demonstrate a superiority over placebo in terms of both progression-free and overall survival in advanced pretreated ACC patients (Fassnacht *et al.*, 2015). Also modern immunotherapy failed to show efficacy in advanced ACC. In a phase 1b cohort (NCT01772004), 50 patients with metastatic ACC and prior platinum-based therapy received avelumab at 10 mg/kg IV Q2W until progression. Only two patients (5%) attained a disease response while PFS was 5.5 and 1.5 months in patients with PDL-1 positive and negative ACC patients, respectively (Le Tourneau *et al.*, 2017).

Concluding Remarks

ACC is generally associated with a grim prognosis; however, there is significant heterogeneity in clinical presentation and biological behavior. Thus, improving our capability of predicting tumor prognosis and its response to drugs will translate in better patient outcome and quality of life.

Despite recent advancements in our understanding of molecular biology of ACC, current treatment protocols are often disappointing. Mitotane remains the cornerstone of treatment and novel data in favor of adjunctive mitotane have been published. The level of evidence remains low in the absence of prospective studies; however, most experts recommend postoperative adjuvant mitotane in patients at high risk of recurrence.

In advanced ACC, the chemotherapy regimen EDP in association with mitotane has been established as the reference treatment after publication of the first controlled study in this rare tumor. Targeted therapies have overall failed to demonstrate sufficient activity although we cannot abandon a vigorous search for most active and less toxic therapies.

Adrenocortical Carcinoma: Genetics and Molecular Markers

Anne Jouinot, Paris Descartes University, Paris, France
Guillaume Assié, Paris Descartes University, Paris, France and Cochin Hospital, Paris, France

Introduction

During the last decade, major breakthrough occurred in the field of ACC, owing to new pan-genomic techniques. A consistent molecular classification of ACC emerged, with strong prognostic impact. The aim is to review this classification, and discuss its clinical impact.

Germline Genetics

Several germline alterations have been reported. The most prominent is TP53—encoding the tumor suppressor p53. Historically, ACC was first reported as part of the Li–Fraumeni syndrome in 1969 (Li and Fraumeni, 1969; Li *et al.*, 1988), and later linked to TP53 mutations in 1990 (Malkin *et al.*, 1990). In terms of prevalence, childhood ACC must be distinguished from adult ACC. Indeed, in children, up to 90% (Wagner *et al.*, 1994; Pinto *et al.*, 2015) of cases are related to TP53 germline mutations. The most spectacular situation is observed in the region of Parana, a South state of Brazil. There, a founder mutation of TP53 (Ribeiro *et al.*, 2001)—R337H—reaches a prevalence as high as 0.3% (Custódio *et al.*, 2013), responsible for an unusually high annual incidence of ACC in this particular region—up to 4 per million children under 15 years (Sandrini *et al.*, 1997). On the opposite germline mutations of TP53 in adults is much lower, reaching less than 5% of patients (Herrmann *et al.*, 2012; Raymond *et al.*, 2013a).

Another constitutive germline alteration is observed in the 11p15 locus. This locus encompasses the IGF2 and CDKN1C genes, submitted to parental imprinting. This locus is altered most often through uniparental disomy, with loss of the maternal allele, responsible for the Beckwith–Wiedemann syndrome (Fraumeni and Miller, 1967; Henry *et al.*, 1989; Wilkin *et al.*, 2000). Childhood ACC is part of this syndrome.

DNA damage repair genes have recently emerged as important germline players in ACC. Mutations in mismatch repair (MMR) genes originally reported in the Lynch syndrome—including MSH2, MLH1, and MSH6 mutations—have been identified in up to 3% of patients (Raymond *et al.*, 2013b). More recently, mutations in MUTYH—encoding a protein responsible for base excision repair—was reported in ACC patients, responsible for a specific molecular phenotype of hypermutation with a specific nucleotide signature (Pilati *et al.*, 2017). Germline mutation in BRCA2—a key player of homologous recombination mediated repair—was also described in ACC (El Ghorayeb *et al.*, 2016).

Anecdotal reports mentioned the occurrence of ACC in patients carrying several other mutations, including genes responsible for endocrine tumors and hyperplasias—including MEN1 (Waldmann *et al.*, 2007), PRKAR1A (Anselmo *et al.*, 2012), CYP21A2 (Hayashi *et al.*, 2013), or SDH genes (Else *et al.*, 2017), or in known tumor suppressor genes—including APC (Gaujoux *et al.*, 2010) or NF1 (Wagner *et al.*, 2005).

Should we today screen for germline predisposition in patients? In children definitely TP53 mutations should be screened systematically (Else and Rodriguez-Galindo, 2016). In adults, some authors propose a systematic screening of germline predisposition in a panel of genes, including TP53 and Lynch syndrome related genes, taking advantage of the new targeted NGS technologies. With such a strategy, up to 10% of adult ACC patients have a germline predisposition (Petr and Else, 2016).

Somatic Genetics

Candidate gene approaches were first used to identify somatic genetic alterations, targeting first the known germline predisposing genes. Thus TP53 was screened, identifying somatic mutations in up to 25% of sporadic ACC (Reincke *et al.*, 1994; Ohgaki *et al.*, 1993).

Somatic alterations of the 11p15 locus have also been identified in sporadic ACC, reaching almost 90% of cases (Gicquel *et al.*, 1994; Gicquel *et al.*, 1997).

Another common gene altered in ACC is CTNNB1, encoding the beta-catenin. Somatic mutations of CTNNB1 are observed in up to 25% of sporadic ACC (Tissier *et al.*, 2005; Gaujoux *et al.*, 2008). These are activating mutations, activating the Wnt/beta-catenin pathway.

More recently new technologies such as exome sequencing and SNP arrays systematically screened for somatic gene alterations (Pinto *et al.*, 2015; Assié *et al.*, 2014a; Zheng *et al.*, 2016; Juhlin *et al.*, 2015). A new prevalent gene came out, ZNRF3, encoding for

E3-ubiquitin Ligase (Assié *et al.*, 2014a; Zheng *et al.*, 2016; Juhlin *et al.*, 2015). This gene is known as a negative regulator of the Wnt/beta-catenin pathway, through regulation of Wnt receptor turnover (Hao *et al.*, 2012). ZNRF3 alterations—mainly homozygous deletions—are observed in up to 20% of ACC. ZNRF3 mutations are mutually exclusive with CTNNB1 mutations (Assié *et al.*, 2014a; Zheng *et al.*, 2016; Juhlin *et al.*, 2015).

These pan-genomic screens provided a list of approximately 20 genes recurrently altered in sporadic ACC, including cell-cycle-related genes (TP53, CDKN2A, RB1, CDK4), Wnt/beta-catenin related genes (CTNNB1, ZNRF3, APC), telomere maintenance related genes (TERT, TERF2, ATRX, DAXX), along with other genes such as MEN1, NF1 or MMR genes. These studies also reported a large list of genes with private somatic mutations, the interpretation of which is challenging.

Somatic Genomics

Beyond genes alterations, the recent advent of genomic technologies—including transcriptome, mirNome, methylome, and genome profiling-opened the way to a comprehensive molecular picture of ACC. Especially two pangenomic characterizations were published, one from ENSAT consortium (Assié *et al.*, 2014a), the other from TCGA (Zheng *et al.*, 2016).

Numerous transcriptome studies compared ACC and adrenocortical adenomas, providing a benign signature enriched in steroidogenic differentiation genes for adenomas, and a proliferation-related signature in cancer (Assié *et al.*, 2014b). IGF2 gene, located in 11p15, appeared as one of the most highly expressed genes in a majority of ACC (Giordano *et al.*, 2003). The most striking transcriptome feature comes from the unsupervised classification of ACC (de Reyniès *et al.*, 2009; Giordano *et al.*, 2009). Indeed two major groups emerged, with striking differences in terms of survival, with one group named C1A with a poor outcome, and the other called C1B with a much better outcome. Though tumor grades and stages are higher in C1A compared to C1B, distributions of these two strong prognostic parameters overlap between the 2 groups, raising the interest of a molecular classification in a prognostic aim. This two-group classification was more recently further granulated into subgroups: C1A was divided into "steroid high—proliferation high", "steroid low—proliferation high", and "steroid high—proliferation low" subgroups, and C1B was affiliated to the "steroid low—proliferation low" subgroup, along with a small subset of "steroid high—proliferation low" subgroup (**Fig. 1**). Steroid-low subgroups are characterized by a high expression of immunity related genes (Zheng *et al.*, 2016).

MiRNome profiling was also performed by several teams in ACC, especially in comparison with adenomas. Variable lists of miRNAs were identified as differential. The most robust one is probably the mir483-5p overexpression in ACC, a miRNA encoded within the IGF2 locus on 11p15 (Soon *et al.*, 2009; Özata *et al.*, 2011; Patterson *et al.*, 2011; Duregon *et al.*, 2014; Chabre *et al.*, 2013; Feinmesser *et al.*, 2015). Within ACC, different subgroups have emerged, more or less consistent between studies, potentially owing to technical variability. Further studies will probably conciliate these apparent discrepancies.

Methylome profiling reported hypomethylation of ACC compared to adenomas, due to global hypomethylation of CpGs in intergenic regions, as observed in a majority of cancers. In contrast, focusing specifically on CpGs in CpG islands—corresponding to genomic regions enriched with at least 50% of CpG, generally observed in the promoter regions of genes—a subset of ACC appeared as globally hypermethylated (Rechache *et al.*, 2012; Fonseca *et al.*, 2012; Barreau *et al.*, 2013). Interestingly hypermethylation in CpG island is strongly associated with a poor survival (Barreau *et al.*, 2013).

Chromosome alteration profiling reported differences between ACC and adenomas, mainly in terms of numbers of alterations. Within ACC, a subset displays loss of heterozygosity (LOH) extended to half or more of the genome, reflecting a loss of one DNA copy for a majority of chromosomes—referred to as hypodiploidy (Assié *et al.*, 2014a; Zheng *et al.*, 2016; Ronchi *et al.*, 2013). These tumors can remain hypodiploid, or replicate the remaining genome either once, twice or more, generating chromosome profiles paradoxically associating LOH and normal or even high DNA copy numbers. These extended LOH profiles have been called "chromosomal" profiles. Another subset of ACC displays numerous anarchic chromosomal losses and gains, and has been referred to as "noisy". A third and more limited subset of ACC has limited chromosomal alterations, and is referred to as "quiet" (**Fig. 2**). These distinct genome profiles are associated with distinct

outcomes. Especially "noisy" ACC are associated with a worse prognosis. In addition ACC with polyploidy seem also more aggressive (Zheng *et al.*, 2016).

Combination of these various genetic and genomic alterations into a single classification generated a global classification of ACC in three groups. A first subgroup associates C1A transcriptome profile, CpG island hypermethylation, a "noisy" genome profile, and an accumulation of mutations in cell-cycle related and Wnt-beta-catenin related genes. In terms of clinical significance, this subgroup is associated with an obviously poor outcome. On the opposite, a subgroup of ACC associate a C1B transcriptome profile, along with no CpG island hypermethylation, and "chromosomal" or "quiet" genome profiles. This subgroup is associated with a much better outcome. Finally an intermediate subgroup of ACC, characterized with a C1A transcriptome along with one or two additional pejorative molecular alterations, shows an intermediate prognostic (**Fig. 3**).

Prognostic Molecular Markers

Historically molecular markers were developed in the 1990s, targeting 17p13 region—locus of TP53- and 11p15 region—locus of IGF2. Loss of heterozygosity (LOH) in these regions were shown to be associated with a shorter disease-free survival (Gicquel *et al.*, 2001), probably reflecting the malignant nature of adrenal tumors harboring these features. Along with 11p15 genome alterations, IGF2 overexpression was also identified as a malignancy feature.

More recent genomic classifications also provide new generations of markers. The general strategy is to try and recapitulate pan-genomic information into targeted molecular measures, for obvious cost and efficiency reasons. A first approach was the design of targeted gene expression signatures in ACC recapitulating the transcriptome prognostic information. Two pairs of gene differential expression have been proposed—BUB1B/PINK1 and DLGAP5/PINK1—combining one gene high and one gene low in C1A compared to C1B (**Fig. 3**). These combinations have shown significant association with disease-free and overall survival, in two independent and distinct cohorts (de Reyniès *et al.*, 2009; Fragoso *et al.*, 2012). Interestingly survival prognosis remained significant after stratification on tumor stage.

More recently targeted measures of DNA methylation in ACC was proposed as a molecular prognostic marker, reflecting methylome classification (**Fig. 3**). Methylation measured in CpG islands of four genes—PICARD, PAX5, PAX6, and GSTP1—were associated with disease-free and overall survival. Prognostic value remained significant in multivariate models including both tumor stage and tumor grade (Jouinot *et al.*, 2017).

Several miRNAs measured in ACC have shown some potential prognostic value (Cherradi, 2015), and validation in independent cohorts is awaited. miRNAs have also opened the perspective of liquid biopsies, with molecular markers measurable in blood. Indeed, circulating miRNAs associated with ACC prognosis have been identified (Chabre *et al.*, 2013; Patel *et al.*, 2013; Szabó *et al.*, 2014; Salvianti *et al.*, 2017). Larger validation cohorts are expected in the coming years, to define the potential value in clinical use.

A last development for liquid biopsy focused on cell-free circulating tumor DNA (ctDNA). Two recent studies demonstrated that ctDNA is detectable in some ACC patients, but not in all (Creemers *et al.*, 2017; Garinet *et al.*, 2017). In addition, ctDNA may reflect tumor burden evolution (Garinet *et al.*, 2017). It is not clear now how sensitive detection is, nor whether ctDNA detection is relevant in terms of prognostic value.

Conclusion and Perspectives

After a couple of decades using candidate genes-based approaches, the recent advent of pan-genomic techniques has boosted molecular characterization of ACC in the recent years. Now is time for post-genomic development of molecular markers suitable for clinical routine. This effort is ongoing, and relies on multicentric networks to reach the critical size for including patients with such a rare disease. At the present time, a strong molecular prognostic signature seems to emerge, with an expected clinical benefit of better determining the risk of recurrence after a complete surgery. How these molecular measures will concretely be performed in clinical setting remains to be determined.

Finally, up to now the impact of these massive molecular information on therapeutic aspects has been quite limited, despite the urgent need for new efficient treatments. A better prognostic stratification of patients may help therapeutic decision, especially for orienting the need for—and potentially the type of—adjuvant therapy after complete surgery. Hopefully in the coming years research will focus more on markers predicting response to treatment, and optimistically will identify efficient therapeutic targets?

Fig. 2 Chromosome alterations profiles determined by SNP array analysis.The upper part of each panel represents the proportion of the two investigated alleles "A" and "B" and determines the genotype (homozygous AA/BB or heterozygous AB) at each locus. Chromosomes are separated with vertical lines and numbered in ascending order. The lower part of each panel represents the copy number (Nbr). Red horizontal lines correspond to normal copy number (diploid). "Quiet" profile (A) is characterized by few number of large alterations. "Chromosomal profile" (B) shows copy-loss loss of heterozygosity (LOH) in several chromosome arms. "Noisy" (C) profile displays numerous chromosome breaks, with many anarchic losses and gains.

Indications for Adrenalectomy

Nonfunctioning Adrenal Mass

Nonfunctioning adrenal masses are usually found incidentally and are rarely found due to locoregional symptoms. Adrenal incidentalomas are defined as lesions >1 cm detected on imaging studies performed for unrelated conditions. The prevalence of adrenal incidentalomas on abdominal imaging increases with age and is 1% or less in patients below 40 years of age versus up to 6% in patients in their seventh decade of life (Abecassis *et al.*, 1985). The main indication for adrenalectomy in patients with nonfunctioning adrenal tumors is the risk of malignancy. A malignant nonfunctioning adrenal mass may be due to adrenocortical carcinoma (ACC) or an adrenal metastasis from another primary.

Primary nonfunctioning adrenocortical carcinoma versus adenoma

The assessment of an adrenal mass to distinguish between a primary ACC versus adenoma is important when considering adrenalectomy for nonfunctioning adrenal masses and when selecting the surgical approach and technique. One of the most predictive factors for malignancy is tumor size. The risk of malignancy increases with tumor size and is 1%–2.9% for tumors <4 cm and 78% for tumors 8 cm and greater (Sturgeon *et al.*, 2006).

Although tumor size on imaging is an important predictive variable for malignancy, other radiologic features on computed tomography (CT) and/or magnetic resonance imaging (MRI) and functional imaging with 18F-FDG positron emission tomography (PET) CT are also helpful for evaluating the risk of malignancy in patients with a nonfunctioning adrenal mass. Also, several benign lesions that do not require adrenalectomy have pathognomonic imaging features that allow for active surveillance in patients with these types of tumors (unless they are symptomatic) (**Table 1** and **Fig. 1**). Features associated with a higher risk of malignancy on anatomic imaging studies include irregular margins, tumor heterogeneity, >10 Hounsfield units (HU), and the presence of necrosis or calcifications (**Fig. 2**) (Zhang *et al.*, 2012; Petersenn *et al.*, 2015). On MRI, malignant lesions are usually isointense compared to the liver on T1 and hyperintense on T2 (**Fig. 3**). ACC have higher ^{18}F-FDG PET/CT SUV as compared to adrenocortical adenomas (ACA). A maximum tumor SUV >4.1 and SUVmax of tumor-to-liver ratio >1.5 has a sensitivity of 86.7% and specificity of 75%, respectively, in differentiating ACA from ACC (**Fig. 4**) (Guerin *et al.*, 2017; Boland *et al.*, 2011).

The decision to perform an adrenalectomy for a nonfunctional adrenal mass is made on a case-by-case basis. When the risk of malignancy is high based on the imaging characteristics described, adrenalectomy is warranted regardless of tumor size or the patient's age. The threshold for adrenalectomy should be low in patients younger than 30 years old with even a small adrenal mass because adrenal incidentalomas are rare in this age group. On the other hand, in an older age group, adrenalectomy is recommended for lesions >6 cm, though some older patients with large adrenal masses and nonworrisome imaging features and comorbidities could have active surveillance (Arnold *et al.*, 2003).

Nonfunctioning adrenal mass suspected to be a metastasis

The most common primary tumor sites that spread to the adrenal gland are lung, melanoma, renal cell carcinoma, and gastrointestinal adenocarcinomas. Less common ones include breast cancer and sarcoma. In cases with indeterminate previous biopsy results or where the primary site is not amenable to biopsy, adrenalectomy may be indicated to establish the diagnosis. When performing adrenalectomy to achieve no evidence of disease, patient selection is important. Patients may benefit from adrenalectomy if the metastasis is isolated to the adrenal gland or in the presence of oligometastatic disease, where curative surgical resection of the primary tumor along with other metastatic sites is performed. The median overall survival after adrenalectomy for adrenal metastasis is 24–46 months with a 5-year survival rate of 22.5%–38% (Marangos *et al.*, 2009; Howell *et al.*, 2013). Factors associated with longer survival time in patients who have adrenal metastasectomy include synchronous metastasis (diagnosed within 6 months of treatment of the primary disease site), R0 resection (negative gross and microscopic margin), and primary tumor site (renal cell carcinoma and colon cancer as compared to melanoma and nonsmall cell lung carcinoma) (Vazquez *et al.*, 2012; Muth *et al.*, 2010). Retrospective studies suggest that laparoscopic (lateral or retroperitoneal approach) adrenalectomy may have similar outcomes to open adrenal metastasectomy in terms of tumor margin status, rate of local recurrence, and rate of port site metastasis/recurrence (Sarela *et al.*, 2003; Heniford *et al.*, 1999).

Table 1 Differential diagnosis of adrenal incidentaloma and imaging characteristics

Differential diagnosis (% of total cases)	*Imaging features (Allen and Francis, 2015)*
Adrenal cortex adenoma	
Nonfunctional (60%–90%)	CT: HU <10;[a]
Functional (2%–20%)	Absolute contrast washout (AW) $\geq 60\%$;
Cushing syndrome	Relative contrast washout (RW) $\geq 40\%$;[b]
Conn syndrome	
Adrenocortical carcinoma	Large
	Heterogeneous
	Irregular margins
	Areas of necrosis and calcifications
	AW $< 60\%$
	RW $< 40\%$
Adrenal medulla	
Pheochromocytoma (1%–10%)	Heterogeneous
	Hypervascular with arterial enhancement
	AW $< 60\%$
	RW $< 40\%$
	Hyperintense on T2-weighted MRI
Metastasis (10%–75%)	Nonspecific
Cyst (4%–22%)	Thin-walled
	Homogeneous
	Fluid attenuations
Hematoma/hemorrhage (0%–5%)	Acute: round high attenuation mass
	Chronic: dense calcifications, pseudocyst with peripheral calcifications
Myelolipoma (5%–15%)	Presence of macroscopic fat
Ganglioneuroma (0%–6%)	CT: HU < 40
	Punctate or discrete calcification
	MR: T2 increase signal intensity
Tumors from adjacent organs ($<1\%$)	

[a]Hounsfield unit.

[b]Absolute contrast washout (AW) = 100 [(ICT–DCT)/(ICT–UCT)]; relative contrast washout (RW) = 100 [(ICT–DCT)/ICT] (I = initial, D = delayed, U = unenhanced).

Functioning Adrenal Masses

Functioning adrenal masses may hypersecrete catecholamine and their metabolites (pheochromocytoma), aldosterone causing primary hyperaldosteronism (PA) (Conn syndrome), cortisol causing overt or subclinical hypercortisolemia (adrenal Cushing syndrome), and less commonly, androgens (virilizing/feminizing tumors) or multiple hormones. Functioning adrenal masses may be malignant in patients with pheochromocytoma, adrenal Cushing syndrome (over 40% of ACCs are functional), and virilizing/feminizing syndromes (Ayala-Ramirez *et al.*, 2013; Luton *et al.*, 1990). Patients with each type of functional adrenal mass require attention to specific perioperative management issues to ensure optimal patient outcome (covered at the end of the article).

Pheochromocytoma/abdominal paragangliomas

Pheochromocytomas and paragangliomas (PC/PGL) are present in 0.2%–0.6% of patients with hypertension and account for 4% of adrenal incidentalomas (Darr *et al.*, 2017). Patients may present with symptoms of headache, anxiety, diaphoresis, and palpitations, or they may be asymptomatic. The diagnosis of PC is established by biochemical testing for plasma-free metanephrines, or urinary fractionated metanephrines, which have a sensitivity of 97%–100% and a specificity of 69%–89% (Lenders *et al.*, 2002). Chromogranin A may also be elevated and is a useful marker in biochemically silent tumors. PGLs are extra-adrenal tumors that may or may not hypersecrete catecholamines and their metabolites. The surgical management of abdominal paragangliomas is included in this article. Once the diagnosis has been established, anatomic and functional imaging are used for localization and to evaluate for multiple tumor sites or metastases.

The only curative treatment for functional PC/PGL is surgical resection and, if it is left untreated, patients have significant morbidity/mortality from catecholamine oversecretion, which includes diabetes and cardiovascular events such as malignant hypertension, stroke, and heart failure (Stolk *et al.*, 2013). The extent of surgical resection and approach is dictated by the risk of malignancy, presence of synchronous disease/multiple primary tumor sites, and risk of developing metachronous primary PC/PGL. Malignant PC/PGL is defined by the presence of gross locoregional invasion or metastatic disease in tissue where chromaffin cells are not present and include lymph nodes, bone, lung, and liver (Fliedner *et al.*, 2010).

Germline and somatic mutations in up to 15 genes have been reported in patients with PC/PGL (Gupta and Pacak, 2017). Germline mutations in susceptibility genes for PC/PGL have been shown to have genotype–phenotype associations, and knowledge of this information is important in the surgical management of patients with PC/PGL. Patients with germline *RET*, *VHL*, or *NF1* mutations are at low risk for having or developing metastatic disease, whereas patients with

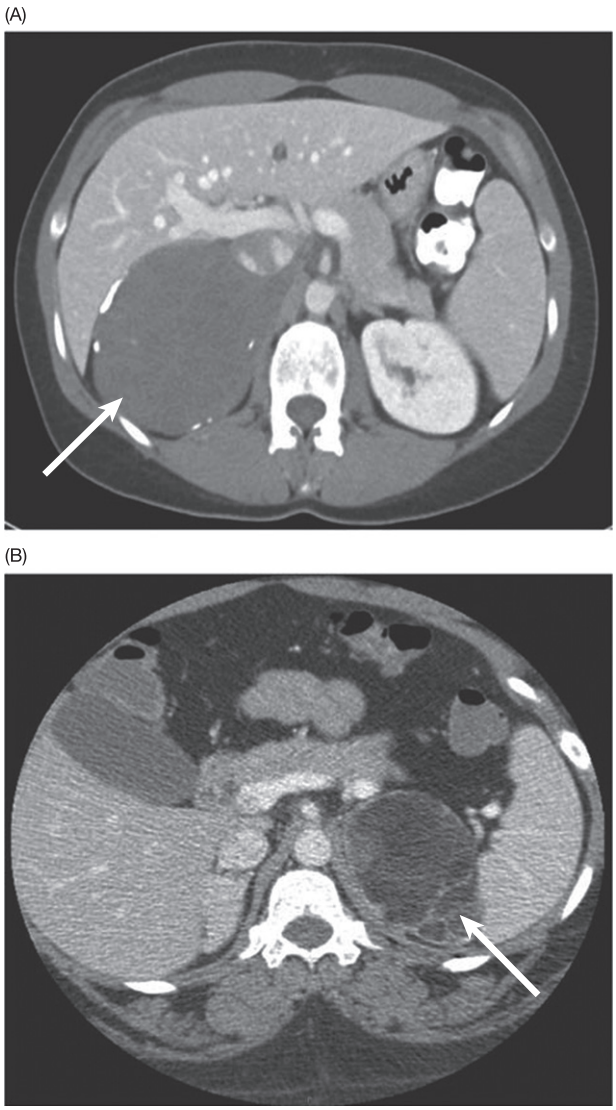

Fig. 1 Computed tomography (CT) of a ganglioneuroma (A) and myelolipoma (B). CT with intravenous contrast of a ganglioneuroma of the right adrenal gland. The tumor has a low Hounsfield unit on contrast and is isointense with the muscle, and it has peripheral fine calcifications. CT with intravenous contrast showing a myelolipoma of the *left* adrenal gland. The mass is hypointense and isointense with the peritoneal fat and has interspersed higher attenuation tissue.

germline mutations in *SDHB*, *FH*, and *MAX* have a higher risk of metastatic disease, which may be up to 90% in patients with the *SDHB* germline mutation (Matro *et al.*, 2013; Castro-Vega *et al.*, 2014). Patients with *RET*, *VHL*, and *NF1* germline mutations have a high risk of having synchronous or metachronous bilateral PC (**Fig. 5**); therefore, given the low risk of malignancy, adrenal-sparing adrenalectomy has been advocated in patients harboring these mutations in order to avoid the need for life-long steroid replacement as well as Addisonian crisis (Castinetti *et al.*, 2014; Aufforth *et al.*, 2015). Germline mutations in susceptibility genes are present in over 40% of patients with PC/PGL, and approximately a quarter of these patients may present with no family history of PC/PGL. Thus, all patients with PC/PGL should have preoperative genetic testing for susceptibility genes and genetic counseling, as this information could optimize surgical management. The development of next-generation sequencing platforms to test for germline mutations in PC/PGL susceptibility genes is becoming widely available and cost-effective; therefore, it should be performed preoperatively in patients with PC/PGL to allow for precision adrenal surgery.

Functional imaging studies including FDOPA PET/CT, F-dopamine, MIBG, and ^{18}F FDG PET/CT have been used in patients with PC/PGL to detect sites of multifocal or metastatic disease, which is present in up to 90% of patients with the germline *SDHB* mutation. ^{18}F FDG PET/CT is currently the recommended functional imaging modality in patients with PC/PGL (Lenders *et al.*, 2014). Although functional imaging is recommended both when malignant disease is suspected and in patients with germline *SDHB* mutation, all patients with PC/PGL may benefit from preoperative imaging with at least one functional imaging study.

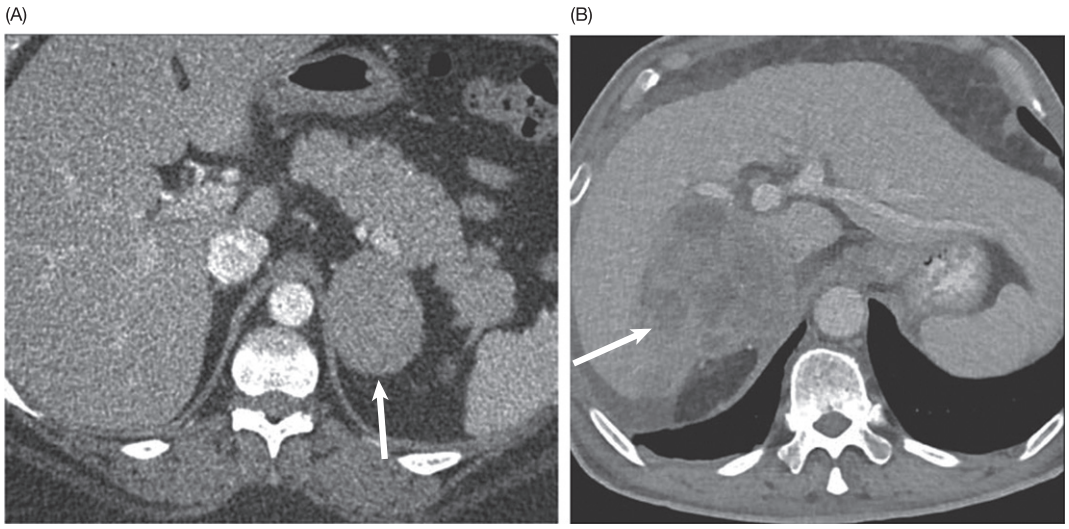

Fig. 2 Computed tomography (CT) of an adrenocortical tumor with typical features for an adenoma (A) and carcinoma (B). CT scan with intravenous contrast of a left adrenocortical adenoma on histology shows a well-circumscribed tumor with a Hounsfield unit of <10 U, no necrosis, and no calcification in (A). CT scan with contrast in (B) shows an adrenocortical carcinoma in the *right* adrenal gland with invasion into the *right* lobe of the liver and abutting the *right* portal vein that is also invading the inferior vena cava. There is necrosis and irregular margins.

Janssen *et al.* compared ^{68}Ga DOTATATE, a newer functional imaging modality, to anatomic and other functional imaging modalities and showed its superior detection rates (Janssen *et al.*, 2016).

Patients with PC/PGL should have alpha blockade therapy with phenoxybenzamine or doxazosin for 7–14 days before their operation. The target blood pressure readings are systolic <140 and diastolic <80 mmHg. If tachycardia develops and the blood pressure is adequately controlled, then beta blocker therapy should be instituted. Alternative agents for better blood pressure control include calcium channel blocker or tyrosine hydroxylase inhibitors (Pacak, 2007; Wachtel *et al.*, 2015). Prolonged exposure to excess catecholamines can cause contraction of the intravascular volume; therefore, hydration should be initiated when the patient starts on alpha blockade therapy as well as intravenously 24 h prior to the operation. Intraoperative manipulation of the tumor should be minimized to avoid intraoperative hemodynamic instability. The anesthesiologist should be prepared to treat hypertensive crisis with phentolamine, sodium nitroprusside, or nicardipine. Continuous blood pressure monitoring with an arterial line is imperative, and a central venous line for fluid and drug administration should be considered in all patients with PC/PGL.

At the time of the operation, once the tumor is removed or when the main adrenal vein is ligated and divided, patients may develop significant hypotension. Thus, close communication with the anesthesiologist is imperative during the operation to allow a coordinated management plan. Patients may require significant fluid resuscitation to maintain their blood pressure, and a central venous line is helpful for accurately determining the patient's fluid status. If the patient has persistent hypotension after adequate fluid resuscitation is established, then norepinephrine or dopamine agonists may be required to maintain a normal blood pressure. Blood glucose should also be measured in the postoperative period until stable glucose levels are observed, as patients may experience hypoglycemia due to the sudden drop in catecholamine levels (Chen *et al.*, 2014).

Primary Hyperaldosteronism

PA is diagnosed in 11% of patients with hypertension (Rossi *et al.*, 2006). PA is associated with cardiovascular morbidity that is worse than essential hypertension, even when having similar blood pressure levels (Milliez *et al.*, 2005). Patients should be screened for PA if they have persistent hypertension ($>150/100$); require more than three antihypertensive medications ($>140/90$); have hypokalemia; or have hypertension with an adrenal mass, sleep apnea, or family history of hypertension or stroke prior to the age of 40. The diagnosis of PA is established by an aldosterone level >15 ng/dL and an aldosterone-to-renin ratio >20 (Young, 2007). Some patients with an aldosterone level of 9–16 may still have PA (Mosso *et al.*, 2003). Confirmatory testing with a saline suppression test, oral sodium loading test, fludrocortisone suppression test, or a captopril challenge test are recommended (Funder *et al.*, 2016).

In 65%–70% of PA cases, PA is due to bilateral adrenal hyperplasia, for which medical management is the treatment of choice. If medical management fails and patients develop severe metabolic complications, bilateral adrenalectomy may be considered—though it is rarely necessary. PA is due to ACA, unilateral hyperplasia with ACA in 30%–35% of patients, and rarely due to isolated unilateral hyperplasia. Typically, patients with unilateral disease are referred for adrenalectomy unless there is a contraindication (Funder *et al.*, 2016). Other rarer causes of PA include ACC, familial hyperaldosteronism (Type I–III), and ectopic aldosterone-producing tumor. Type I familial hyperaldosteronism is due to the *CYP11B1* (11-β-hydroxylase) promoter region, which is fused

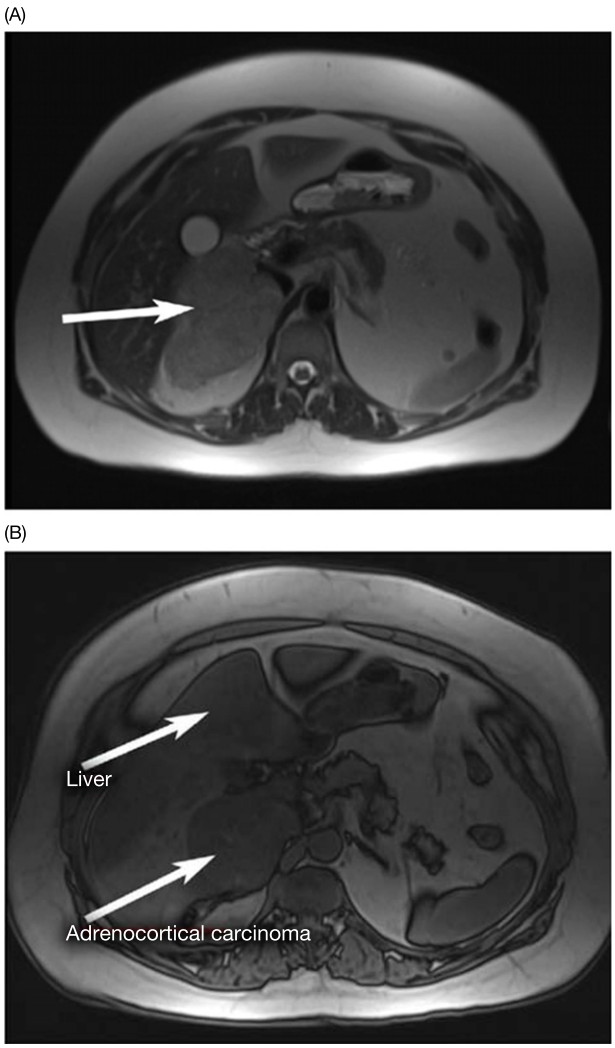

Fig. 3 Magnetic resonance imaging (MRI) features of an adrenocortical carcinoma. (A) Adrenocortical carcinoma enhancing on T2-weighted image shows higher intensity than the liver. (B) T1-weighted imaging of adrenocortical carcinoma showing similar intensity to the liver.

to *CYP11B2* (aldosterone synthase gene), resulting in a CYP11B1/2 chimera that results in ACTH-dependent aldosterone hypersecretion. Thus, glucocorticoid therapy is effective, and patients do not require adrenalectomy. The cause of Type II familial hyperaldosteronism is unknown, but patients may be treated medically or with adrenalectomy. Lastly, type III familial hyperaldosteronism is due to a *KCNJ5* germline mutation, and patients with uncontrolled metabolic complications with medical therapy may rarely require bilateral adrenalectomy (**Fig. 6**).

Once the biochemical diagnosis of PA is made—and if the patient is interested and is a candidate for adrenalectomy—then anatomic imaging with CT or MRI should be performed. It is impossible to differentiate an aldosterone-producing adenoma from a nonfunctioning adenoma based on imaging characteristics, so patients who are either older than 35 years of age, have bilateral adrenal lesions, or have normal bilateral adrenal glands should undergo adrenal vein sampling (AVS) to lateralize the disease and to differentiate unilateral from bilateral disease (Mathur *et al.*, 2010). Many criteria for AVS to distinguish between bilateral and unilateral PA have been used and have shown variable accuracy (Webb *et al.*, 2012). The most accurate criterion is using ACTH stimulation to determine proper catheter positioning: cortisol [adrenal]/cortisol [periphery] >5.0 and to determine lateralization: aldosterone/cortisol [A/C] dominant: A/C nondominant $>4{:}1$. AVS in patients with PA ensures they have unilateral disease and are likely to benefit from an adrenalectomy, and it helps avoid wrong-side surgery in the case where there are bilateral normal or abnormal adrenal glands.

Stringent blood pressure control should be pursued prior to adrenalectomy, and potassium levels should be repleted to normal. The surgeon should personally review the results of AVS as well as imaging studies to make sure the operation is being performed on the correct side.

Postoperative patients should be monitored for mineralocorticoid insufficiency and hyperkalemia, though in most patients it is self-limited. Factors associated with a higher risk of hyperkalemia include older age (>50 years), increased duration of

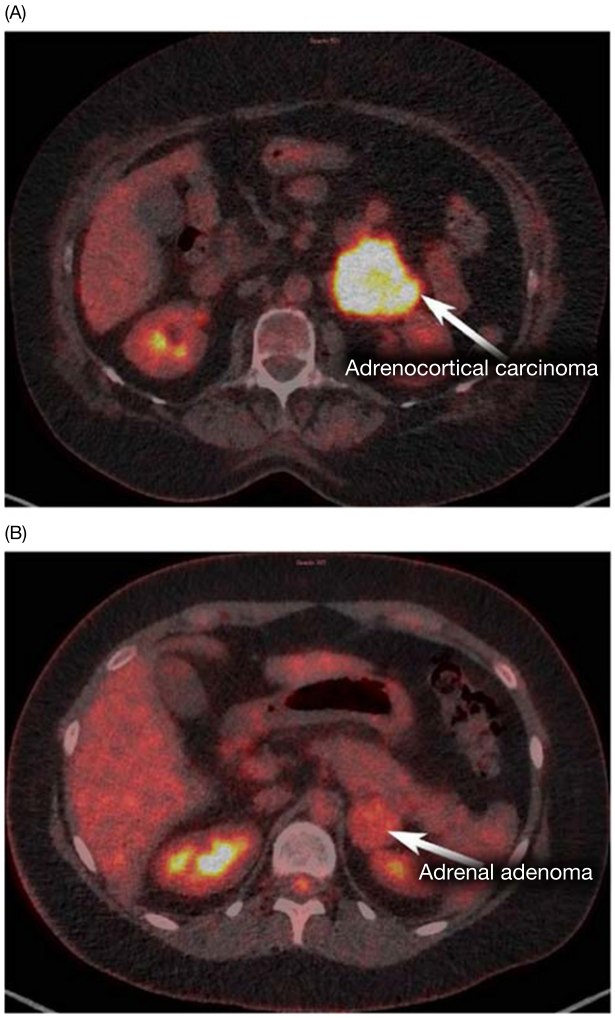

Fig. 4 ^{18}F-FDG PET/CT scan of an adrenocortical carcinoma (A) and adrenocortical adenoma (B). *Arrow* showing tumor with a high SUVmax in the left adrenal gland in (A) consistent with an adrenocortical carcinoma and arrow showing low SUVmax in the *left* adrenal mass in (B) consistent with an adrenocortical adenoma.

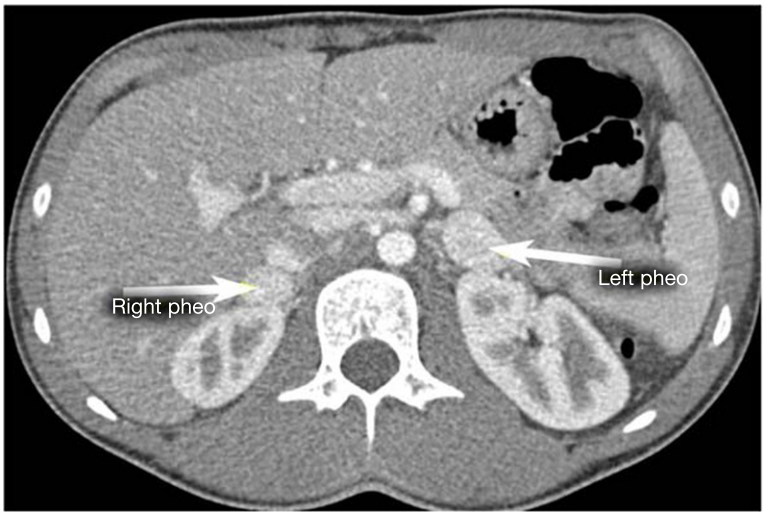

Fig. 5 Computed tomography with intravenous contrast shows enhancing bilateral pheochromocytomas in a patient with MEN2A due to a germline *RET* mutation in codon 634.

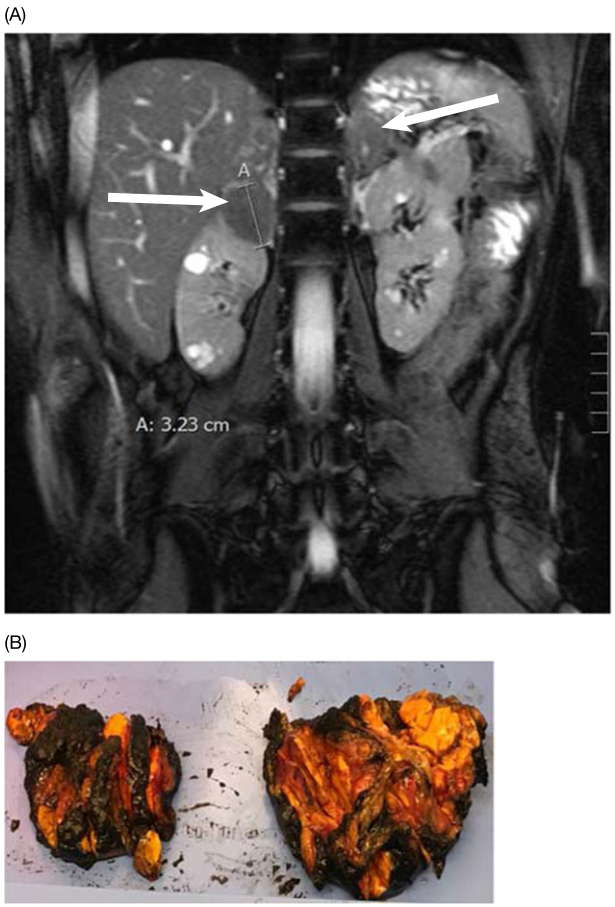

Fig. 6 Bilateral adrenal hyperplasia in a 24-year-old woman with a germline *KCNJ5* mutation who required bilateral laparoscopic adrenalectomy for uncontrolled hypertension and chronic renal failure. hypertension (>10 year), and renal insufficiency (Tahir *et al.*, 2016). Hypertension may improve over a period of up to 1 year, but it does not always resolve. An PA resolution score has been developed to provide a precise outcome measure with respect to several clinical endpoint variables after adrenalectomy for unilateral PA. Patients older than 55 years, males, patients with a body mass index >25, patients requiring three or more antihypertensive medications, and patients with a history of hypertension for more than 6 years are associated with a lower rate of hypertension resolution (<25%) (Aronova *et al.*, 2014). However, improvement in hypertension is achieved in 98% of patients as defined either by better control on antihypertensive medication than before adrenalectomy or by requiring a reduced number of antihypertensive agents. In addition to better blood pressure control, some patients with PA who have adrenalectomy will see cardiac and renal dysfunction reversal, and some report improvements in quality of life 3–6 months after adrenalectomy (Funder *et al.*, 2016).

Cushing Syndrome

Cushing syndrome is due to hypercortisolism presenting with typical physical features such as abdominal striae, facial plethora, proximal myopathy, weight gain, and decrease in growth in pediatric patients, to name a few. Patients may also present with metabolic complications and behavioral abnormalities. Patients with incidentally found adrenal mass, metabolic complications not expected for their age, and pediatric patients with growth stunting and obesity should be tested for hypercortisolism. Cushing's syndrome may be either ACTH-dependent (excess ACTH secreted by a pituitary tumor or ectopic tumor) or ACTH-independent, caused by hypersecretion of cortisol from the adrenal gland. In 80% of the cases, it is the result of an ACA (**Fig. 7**), followed by ACC in 15% of the cases and finally by bilateral micro/macronodular adrenocortical hyperplasia. The initial diagnostic evaluation includes midnight salivary cortisol, a low-dose dexamethasone suppression test, and 24-h urine-free cortisol. Exogenous hypercortisolism should be ruled out, and the tests should be repeated to confirm the diagnosis (Nieman *et al.*, 2008).

Lack of typical physical exam findings such as purple striae, truncal obesity, or cervical fat pat does not exclude a state of hypercortisolism. The condition of excess cortisol without physical characteristics is defined as Subclinical Cushing syndrome (SCS). These patients often have metabolic complications of excess cortisol such as hypertension, obesity, and diabetes mellitus

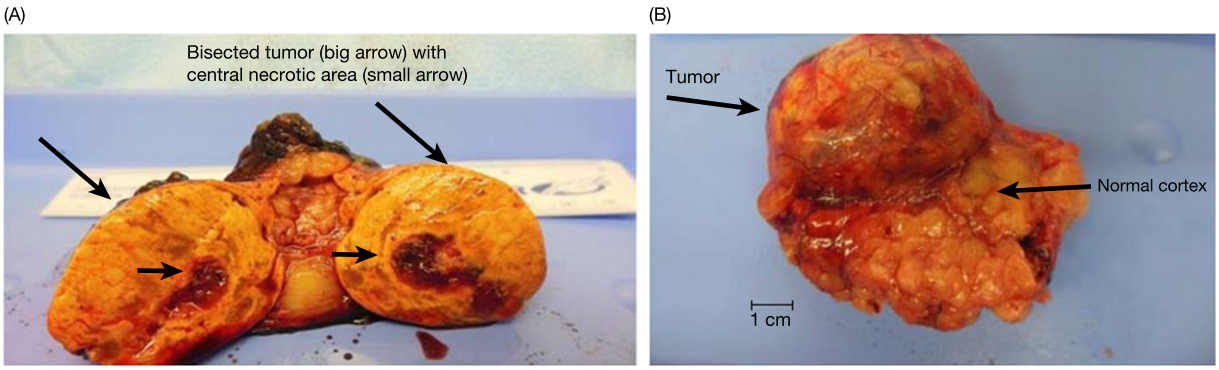

Fig. 7 An adrenocortical cortisol-secreting adenoma in a patient with adrenal Cushing syndrome. (A) Bisected adrenocortical adenoma. (B) Adrenocortical adenoma and adjacent normal cortex.

type 2, but the diagnostic criteria for SCS vary, and there is no "gold standard" diagnostic tool to confirm SCS (Chiodini, 2011). There is no consensus on the optimal management of SCS, but adrenalectomy is beneficial in many patients and is associated with improved blood pressure, reversal of obesity, and better glucose control (Chiodini *et al.*, 2010; Chiodini, 2011; Iacobone *et al.*, 2015).

Patients with Cushing syndrome (ACTH-independent and those who fail primary treatment for ACTH-dependent tumors) benefit from adrenalectomy. The benefits of adrenalectomy in patients with Cushing syndrome include improvements in hypertension, diabetes, and quality of life, as well as improvements in physical characteristics such as weight gain, proximal muscle wasting, skin changes (striae, easy bruising, darkening, thinning), and level of anxiety and depression (Neychev *et al.*, 2015; Brunt *et al.*, 2001; Thompson *et al.*, 2007).

Perioperative preparation in patients with Cushing syndrome includes postoperative administration of stress dose hydrocortisone of 100 mg with a rapid (24 h) taper postoperatively. Surgeons should be aware that prolonged hypercortisolemia makes the tissues friable and prone to injury with minimal manipulation, so they should be handled with extra caution. The risk of venous thromboembolism is also up to tenfold higher, so we continue deep vein thrombosis and pulmonary emboli prophylaxis for a total of 28 days and start prophylaxis the day before the operation (Small *et al.*, 1983; van der Pas *et al.*, 2013; Tirosh *et al.*, 2017). The need for continued steroid replacement until recovery of hypothalamus–pituitary axis (HPA) should be evaluated. Some centers perform an immediate postoperative cosyntropin stimulation test and, if the unstimulated cortisol level is normal and the stimulated cortisol level is ≥ 18 μm/dL, then the patient may be discharged without steroid replacement. Otherwise, it should be rechecked every 3–6 months (Benhammou *et al.*, 2010). Almost all patients experience adrenal insufficiency, and the average recovery time of the HPA axis is 11.2 months (Di Dalmazi *et al.*, 2014).

Surgical Approach

There are multiple surgical approaches and extents of adrenalectomy that can be utilized in patients requiring adrenalectomy, but the optimal procedure should be dictated by the individual patient characteristics, functional status of the tumor, imaging and biochemical features, and the genetic predisposition. Most functional benign tumors can be addressed using a minimally invasive approach, whereas large tumors suspicious for malignancy or tumors that are locally invasive should be resected using an open surgical approach. Both surgical approaches should be considered as a continuum in a patient requiring an adrenalectomy.

Currently, minimally invasive adrenalectomy is regarded as the gold standard surgical approach for the management of benign adrenal disorders, although there are no prospective randomized trials comparing this technique with open adrenalectomy. Minimally invasive adrenalectomy as compared to open adrenalectomy is associated with less blood loss, earlier patient mobility, decreased length of hospital stay, faster return to regular activity, and decreased morbidity, including pulmonary, renal, and cardiac complications (Prinz, 1995; Thompson *et al.*, 1997). Since 2000, robotic technology has been introduced into laparoscopic clinical practice (Gagner *et al.*, 1997; Lombardi *et al.*, 2008; Lezoche *et al.*, 2008; Bonjer *et al.*, 2000). The robotic system has been used for adrenalectomy but does not appear to offer patient or surgeon-specific benefits as compared to laparoscopic adrenalectomy. Below, each surgical approach is discussed with the proper patient population defined for each surgical approach as well as the extent of adrenalectomy.

Open Adrenalectomy

Several open approaches have been used for adrenalectomy using a subcostal, thoracoabdominal, midline, or posterior flank incision (**Fig. 8**). In 1889, Thornton first performed the transperitoneal approach (Thornton, 1890). The flank approach was described by Charles Mayo in 1927 (Mayo, 1927), and in 1936, Young, from Johns Hopkins, reported the first posterior approach

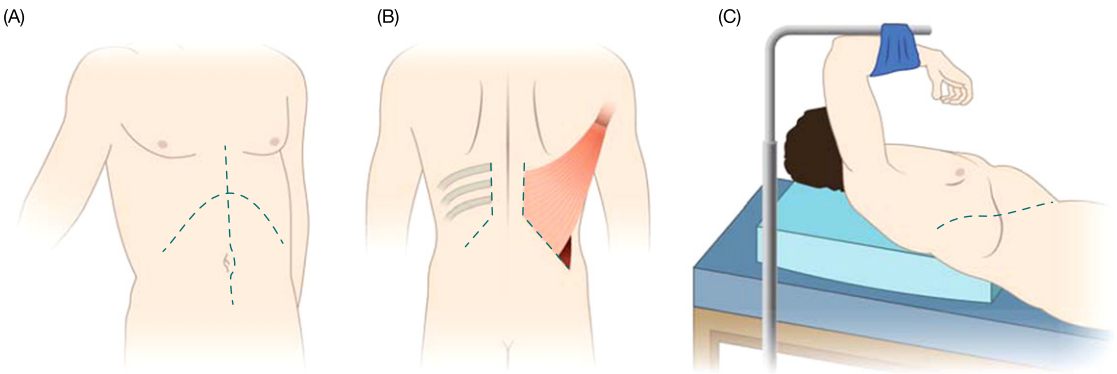

Fig. 8 Open adrenalectomy approaches. (A) Incision for an anterior open approach through either a bilateral subcostal incision or a midline incision. (B) Incision for a posterior approach. (C) Incision for a thoracoabdominal incision with a bump when required.

Table 2 Surgical approach and indications

Open adrenalectomy	*Laparoscopic transperitoneal*	*Retroperitoneal*	*Partial adrenalectomy*
Radiologic/clinical signs of malignancy:[a]	No malignant potential		
– Local invasion – Regional lymphadenopathy			
Large tumor size		History of multiple abdominal surgeries	Genetic predisposition for metachronous or synchronous pheochromocytoma in contralateral gland as in patients with germline *RET*, *VHL*, and *NF1* mutations
Contraindication for laparoscopic surgery	Surgeons' skills level	Surgeons' skills level	Adrenal remnant >30% of normal adrenal gland

[a]Role of laparoscopic adrenalectomy is controversial.

(**Table 2**) (Young, 1936). An open adrenalectomy should be performed for known ACC and metastatic/malignant PC/PGL or when the likelihood of malignancy is high, such as in large tumors (>6 cm) (Zeiger *et al.*, 2009), a tumor with suspicious features for local invasion, or locoregional disease or recurrence.

In the open transperitoneal approach (**Figs. 8** and **9**), a subcostal or midline incision is usually used, and a thoracoabdominal incision is used for a tumor invading the diaphragm or a vena cava tumor thrombus extending into the supra or intrahepatic cava. For a right adrenalectomy, the falciform and triangular ligament of the liver are divided, and the right hepatic lobe is mobilized medially to allow exposure of the inferior vena cava (IVC) and the adrenal gland in the retroperitoneum. If further exposure is necessary, the liver can be completely mobilized by releasing the coronary ligaments. Small veins from the IVC can be ligated and divided to help with mobilization. Vascular control is imperative in cases of large or invasive tumors or when there is invasion of IVC with tumor thrombus. An extended Kocher maneuver is performed to expose the infra hepatic IVC. Once the suprahepatic IVC and the infrahepatic IVC (preferably above the renal veins, if technically feasible) are controlled, dissection of the right border of the IVC is then carried out by incising the peritoneal reflection along the right border of the IVC all the way up to the diaphragm. Care should be taken not to injure the right hepatic vein. When thrombosis into the right atrium is anticipated, adrenalectomy should be performed under veno-venous bypass or cardiopulmonary bypass (**Fig. 10**). If IVC tumor thrombus is suspected, a venotomy is performed with extraction of the tumor thrombus. In rare instances of IVC invasion, resection of the IVC and an interposition graft may be necessary but should be done on veno-venous or cardiopulmonary bypass.

Dissection along the right border of the IVC leads to the identification of the right adrenal vein, which is then ligated and divided. The arterial supply of the right adrenal gland is controlled and divided as it is encountered along this dissection (it usually consists of three main arterial branches, from the right renal artery, the aorta, and the right inferior phrenic artery). Care should be taken not to injure any accessory or superior branches of the right renal artery. The dissection along the right border of the IVC is then carried further posteriorly until reaching the quadratus lumborum muscle and then inferiorly until reaching the right renal hilum. In the case of a locally invasive tumor, it may be necessary to resect a portion of the diaphragm to achieve negative margins, and this can be repaired by simple primary repair or with a Gortex™ patch.

On the left side, the adrenal tumor is exposed by medial rotation of the spleen, pancreas, and left colon. Care should be taken to avoid any injury to the splenic vessels and pancreatic tail during the dissection. If invasion into the renal hilum is anticipated, then the renal vascular pedicle should be controlled before resection. If the diaphragm is resected, either a primary closure or Gore-

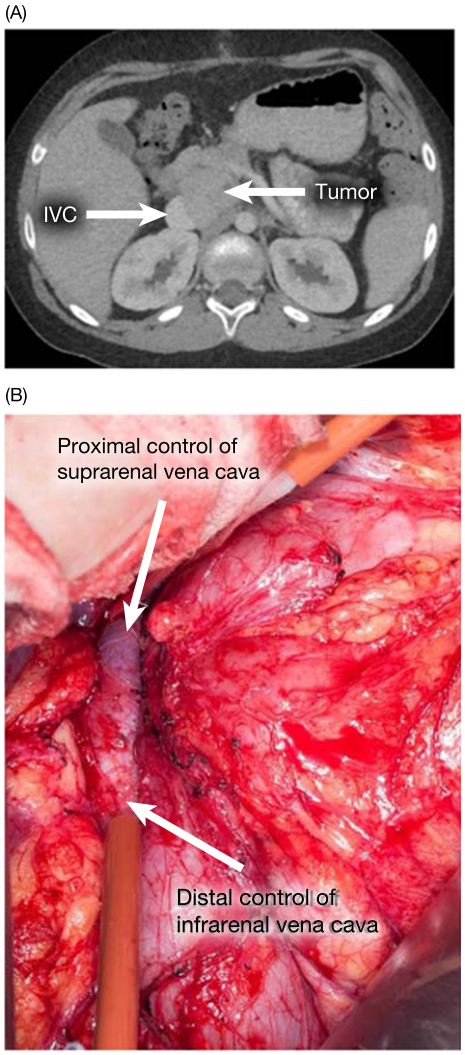

Fig. 9 Open resection of an aortocaval paraganglioma invading the inferior vena cava (IVC). (A) Computed tomography scan of tumor invading IVC. (B) Intraoperative image after extended Kocher maneuver, medial mobilization of right colon with proximal and distal control of the IVC.

Tex patch graft can be used for repair along with an angled chest tube left above the diaphragm. If the tumor is locally invasive or if the goal is to achieve negative margins for malignant tumors, it may be necessary to perform en-bloc resection with distal pancreatectomy, splenectomy, and or partial/complete nephrectomy (**Fig. 11**).

In patients with a lesion highly suspicious for a malignant adrenal neoplasm based on preoperative imaging studies or intraoperative assessment, it is imperative that the surgical resection achieve negative margins (R0 resection), as the completeness of the initial surgery is a major prognostic factor (Schulick and Brennan, 1999; Nilubol *et al.*, 2016). In stage I ACC, a wide margin, including the surrounding retroperitoneal fat and lymphatics, is necessary. In stage II or III, complete removal of the tumor en-bloc with invaded nearby organs is essential (Nilubol *et al.*, 2016). Lymph node involvement is an important prognostic factor, and lymph node metastasis is present in approximately 20% of patients with ACC (Gaujoux and Brennan, 2012). However, the role of prophylactic lymphadenectomy in patients with ACC is unclear. A multicenter, retrospective analysis from Germany showed a significantly lower rate of tumor recurrence and disease-related mortality in patients with ACC who had lymphadenopathy (Reibetanz *et al.*, 2012). However, a study on the surveillance, epidemiology, and end results database showed no survival benefit in 8% of patients with ACC who had lymphadenectomy (Nilubol *et al.*, 2016). Other follow-up studies have found that lymphadenectomy in patients with ACC is associated with better overall survival (Gerry *et al.*, 2016).

Minimally Invasive Adrenalectomy

Numerous studies have shown the safety and feasibility of minimally invasive adrenalectomy, which has become the gold standard operation for functioning and nonfunctioning benign and small-to medium-sized adrenal tumors (Gagner *et al.*, 1997; Kebebew *et al.*, 2001). The most frequently used approach is the lateral transperitoneal laparoscopic adrenalectomy,

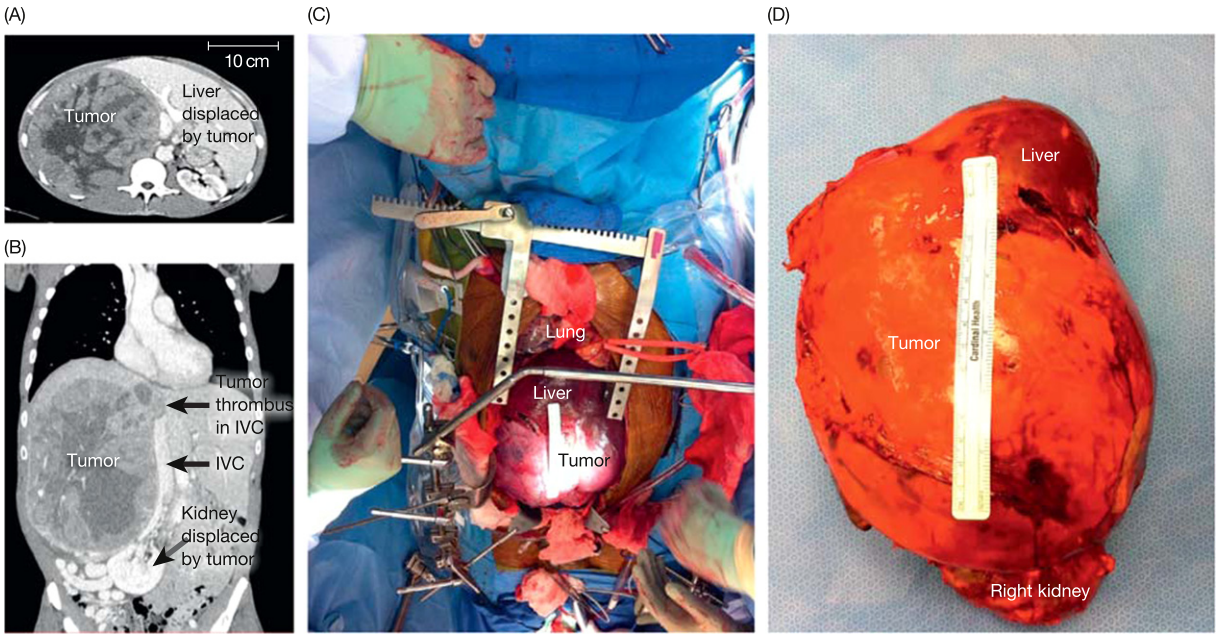

Fig. 10 En-bloc resection of a right adrenocortical carcinoma with tumor thrombus extending into the right atrium on cardiopulmonary bypass. (A and B) Computed tomography of right adrenocortical carcinoma displacing the kidney and invading the IVC with tumor thrombus. (C) Intraoperative image of a combined midline abdominal incision and median sternotomy with tumor in situ. (D) Tumor specimen after resection.

with the patient in the lateral decubitus position (Lombardi *et al.*, 2008). Other techniques include the anterior transperitoneal technique (Lezoche *et al.*, 2008) and retroperitoneal approach, which consists of either a posterolateral or a true posterior approach. Posterior retroperitoneoscopic adrenalectomy (PRA) has gained some popularity in certain regions and was first described by Mercan (Mercan *et al.*, 1995) and popularized by Walz *et al.* (2001). There are some advantages and disadvantages to each minimally invasive adrenalectomy approach. Meta-analyses of retrospective and randomized controlled trials have shown no superiority to either approach (Nigri *et al.*, 2013; Constantinides *et al.*, 2012). Recently, in a randomized controlled trial, PRA was shown to be superior in terms of shorter surgery duration, lower blood loss, lower postoperative pain, faster recovery, improved cost-effectiveness, and lower risk of surgical access site herniation as compared to laparoscopic transperitoneal adrenalectomy (Barczynski *et al.*, 2014). Further studies are needed to objectively evaluate these techniques, excluding selection bias and bias related to differences in surgeons' experiences and clinically meaningful patient-related outcome variables.

In the transperitoneal approach, the patient is placed in a lateral decubitus position with anterior superior iliac spine aligned with the point of flexion on the operating room table, which is flexed (**Fig. 12**). The peritoneal cavity is entered one finger breadth below the costal margin in the midclavicular line. For a right adrenalectomy, four trocars are placed between the *midaxillary* line and midclavicular line approximately two finger breadths apart. The triangular ligament is divided, and the right lobe of the liver is medially mobilized. A snake, fan, or paddle retractor is placed through the medial-most port to create the working space. The peritoneum and Gerota's fascia are opened lateral to the IVC from the top down. Care must be taken to avoid manipulating or grasping the tumor: this is known as the "no touch technique." The right adrenal vein is identified between the IVC and the gland and is clipped and divided (**Fig. 13**). A plane between the gland and the kidney is created, and the posterior attachments of the gland to the quadratus lumborum muscle are divided. The adrenal gland is freed posteriorly all the way up to the diaphragm. The specimen is removed through the lateral port site.

For the left adrenalectomy, three trocars are inserted from the midclavicular line to the midaxillary line, two finger breadths apart (**Fig. 14**). The peritoneum is incised 1 cm lateral to the edge of the spleen. The peritoneum is opened all the way up to the diaphragm until the gastric fundus is visualized (**Fig. 15**). The spleen is retracted medially by gravity, and the dissection is carried down posteriorly over the quadratus Lumborum muscle. The inferior phrenic vein is traced from the diaphragm until it joins the adrenal vein before emptying into the left renal vein. Once the left adrenal vein is identified, it is clipped and divided. The inferior aspect of the gland is retracted anteriorly and superiorly and divided off the posterior muscles (**Fig. 16**). Care must be taken to avoid injury to the left renal vein. Once the gland is completely detached, hemostasis is secured, and then the specimen is removed from the lateral-most port site.

The posterior/retroperitoneal approach (PRA) is most useful in patients who have previously undergone abdominal surgery and in patients who require bilateral adrenalectomy to avoid patient repositioning. The primary contraindication to this approach is a large-sized tumor due to the limited working space available in the retroperitoneum. The PRA may be contraindicated in patients with copious retroperitoneal fat, as it makes identifying the adrenal gland and tumor difficult.

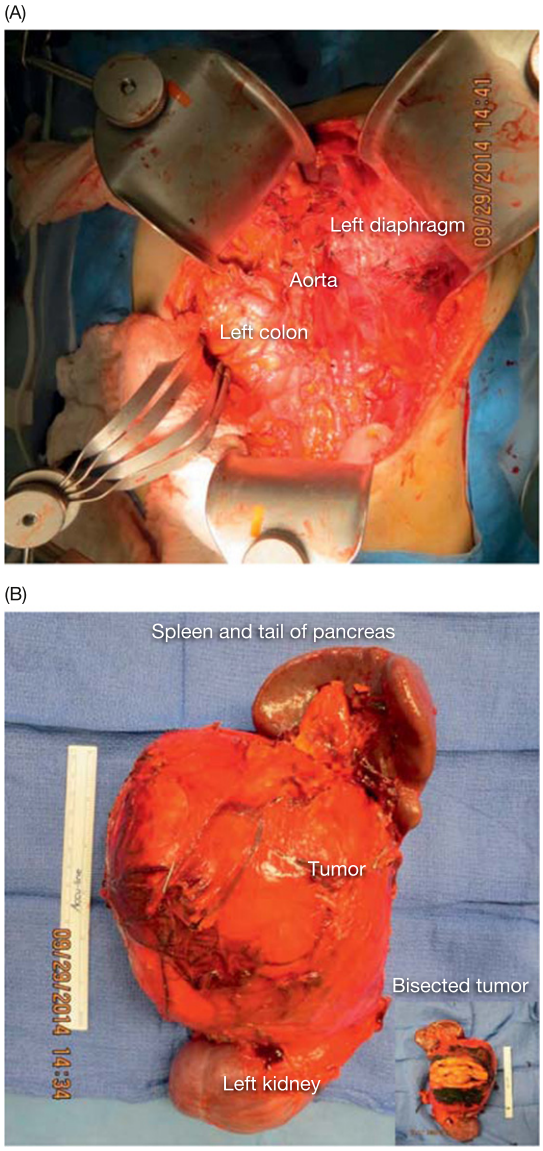

Fig. 11 Open en-bloc resection of a left adrenocortical carcinoma with tail of pancreas, spleen, and left kidney and regional lymphadenectomy through a left subcostal incision. (A) Intraoperative image of resection bed. (B) Resected gross specimen.

For the PRA, the patient is placed in a prone jackknife position (**Fig. 17**). A trocar is placed 1.5 cm below the tip of the 12th rib. The working space is created by blunt digital dissection of the retroperitoneal fat. Then, a 5-mm lateral trocar is inserted 4–5 cm from the initial one, and a 10-mm trocar is inserted medially 2–3 cm at the same level as the first port under finger guidance. A 10-mm balloon blunt trocar is inserted, and insufflation with carbon dioxide of up to 20 mmHg is initiated. The gland is dissected free from the diaphragm and the superior pole of the kidney. Then it is mobilized medially and inferiorly. The adrenal vein is clipped and divided (**Fig. 17**). The remaining attachments are dissected free laterally and superiorly, and the specimen is extracted (**Fig. 17**).

Laparoscopic Adrenal-Sparing Adrenalectomy

In order to avoid lifelong steroid replacement and to minimize the risk of Addisonian crisis, adrenal-sparing adrenalectomy should be considered in patients who have PC and have a low risk of malignancy but have bilateral PC or are at risk of metachronous PC, such as patients with MEN2, VHL, or NF1 (Castinetti *et al.*, 2014). The goal of adrenal-sparing adrenalectomy is to ensure the removal of all PC while leaving an adequate adrenal remnant. Large PC along with the presence of several smaller tumors in the same gland could preclude this approach, as generally at least one-quarter to one-third of a normal gland is needed to maintain adequate adrenocortical function (Brauckhoff *et al.*, 2003). An intraoperative laparoscopic ultrasound is helpful for identifying smaller tumors and for defining the margin of resection. The adrenal gland

parenchyma is transected using electrocautery, Harmonic®, and/or LigaSure® scissors (**Fig. 18**). Preservation of the main adrenal vein is not necessary to have sufficient cortical function but is preferable if technically feasible (Walz *et al.*, 1998). The disadvantage of adrenal-sparing adrenalectomy is the risk of recurrent PC, which has been reported to be 3% at a median follow-up of 6–13 years in patients with MEN2 and 9% at a median follow-up of 17 years in patients with VHL (Castinetti *et al.*, 2014; Aufforth *et al.*, 2015).

Robotic Adrenalectomy

Robotic adrenalectomy has been proven to be feasible and safe. It may offer the surgeon greater dexterity and a more ergonomic procedure than other minimally invasive adrenalectomies; however, to date, no study has shown this approach to be superior. A meta-analysis of 1162 patients including only one randomized controlled trial comparing laparoscopic versus robotic adrenalectomy reported no significant difference for intraoperative complications, postoperative complications, mortality, conversion to

laparotomy or laparoscopy, and blood loss (Economopoulos *et al.*, 2017) Most centers do not use robotic adrenalectomy, given the unclear benefit for patients and the cost of the procedure.

Summary

The evaluation of adrenal lesions, which includes interpreting laboratory work-up and anatomic and functional imaging as well as incorporating genetic information, requires a multidisciplinary approach. New knowledge on the genetics of adrenal neoplasms will likely continue to impact the surgical management of patients with adrenal neoplasms, including the indications for adrenalectomy and the approach and extent of adrenalectomy in patients with adrenal Cushing syndrome, PC/PGL, and PA. The surgeon's experience and technical expertise is important for optimal patient outcome. In patients with functioning adrenal neoplasms, adrenalectomy has a great and often instantaneous impact on the patients' health and well-being, which is gratifying for both patients and providers.

Long-Term Complications of Hypercortisolism

Rosario Pivonello, Davide Iacuaniello, Chiara Simeoli, Maria Cristina De Martino, and Annamaria Colao, University of Naples Federico II, Naples, Italy

Introduction

Chronic endogenous hypercortisolism is responsible for a rare and severe endocrine disease named Cushing syndrome (CS). CS can be classified in ACTH-dependent and ACTH-independent forms. The formers are due to the presence of ACTH-secreting pituitary tumors (70% of cases), named Cushing disease (CD), or ACTH-secreting or CRH-secreting ectopic tumors (10% of cases), named ectopic CS (ECS), whereas the latter are due to the presence of cortisol-secreting adrenal lesions, including adrenal hyperplasia, adenoma or carcinoma (20% of cases), named adrenal CS (ACS) (Lacroix *et al.*, 2015; Pivonello *et al.*, 2017, 2016a, 2015a, 2008). The estimated prevalence of CS is 40 cases per million people and the estimated incidence is 0.7–2.4 cases per million people per year, mainly affecting females aged between 40 and 60 years (Lacroix *et al.*, 2015; Pivonello *et al.*, 2017, 2016a, 2015a, 2008). The clinical picture of CS is variable, resulting from a cohort of different signs, including weight gain, moon face, facial plethora, buffalo hump, supraclavicular and dorsal fat pads, purple striae, easy bruising, skin thinning, proximal myopathy, hirsutism, acne and alopecia, as well as symptoms, mainly including asthenia, fatigue and mood disorders (Lacroix *et al.*, 2015; Pivonello *et al.*, 2017, 2016a, 2015a, 2008). This clinical picture is complicated by several comorbidities including metabolic syndrome, which is characterized by visceral obesity, impairment of glucose metabolism, dyslipidemia and systemic arterial hypertension (SAH) and it is strictly associated with cardiovascular diseases, including vascular atherosclerosis and cardiac damage. These comorbidities, together with thromboembolism, contribute to increase the cardiovascular risk in CS patients. Additional clinical complications include musculoskeletal diseases, such as osteoporosis, skeletal fractures and myopathy; immune disorders characterized by increased susceptibility to infections, and possibly complicated by sepsis; neuropsychiatric diseases, such as impairment of cognitive function, depression, anxiety and bipolar disorders; impairment of gonadal function with consequent infertility or sexual disturbances (Lacroix *et al.*, 2015; Pivonello *et al.*, 2017, 2016a, 2015a, 2008). These clinical complications negatively impact on quality of life (QoL) and increase the mortality, mainly due to cardiovascular events and sepsis. Therefore, a prompt screening, a confirmatory diagnosis and an effective multidisciplinary therapeutic approach are mandatory in the attempt to improve clinical picture, morbidity, QoL and mortality (Lacroix *et al.*, 2015; Pivonello *et al.*, 2017, 2016a, 2015a, 2008). Nowadays, the first line treatment for all CS forms still remains surgery, whereas radiotherapy and medical therapy represent a second choice (Nieman *et al.*, 2015; Pivonello *et al.*, 2015a).

Metabolic Syndrome

Metabolic syndrome (MS) is a chronic and systemic syndrome defined by the presence of abdominal visceral obesity (measured by elevated waist circumference) plus two of the following factors: elevated blood pressure, fasting glucose or triglycerides or reduced HDL cholesterol (Alberti *et al.*, 2006; Ford, 2005). Chronic hypercortisolism induces visceral obesity, hypertension, impairment of glucose metabolism and dyslipidemia causing a specific form of MS in about 50%–63% of patients (Barahona *et al.*, 2009a; Giordano *et al.*, 2014), apparently without significant differences in men and women (Giordano *et al.*, 2014). The mechanisms leading to this metabolic disorder are complex and probably only partially understood, although several direct or indirect effects of glucocorticoids (GCs) on liver, skeletal muscle, adipose tissue, pancreas and the central nervous system have been indicated (Pivonello *et al.*, 2016a). GCs act on the liver stimulating gluconeogenesis, hepatic glucose output, lipoprotein secretion and fatty acid synthesis, inducing hepatic insulin resistance and liver steatosis (Pivonello *et al.*, 2016a; Wang, 2005). These effects contribute to the abnormal glucose and lipid metabolism observed in CS (Pivonello *et al.*, 2016a). The effects of GCs on skeletal muscle include an increased lipid oxidation and a reduced translocation of GLUT4, which contribute to the generation of a peripheral insulin resistance (Pivonello *et al.*, 2016a, 2010). In adipose tissue, the GCs stimulate the lipolysis and the differentiation of preadipocyte to adipocyte, whereas they reduce the amino acids uptake, the GLUT4 translocation and the lipogenesis. These effects contribute to generate peripheral insulin resistance and fat accumulation (Lee *et al.*, 2014; Pivonello *et al.*, 2016a). Additionally there are evidences that GCs also inhibit the insulin secretion from the pancreas and stimulate the appetite, which also contribute to the abnormal glucose and lipid metabolism observed in CS (Pivonello *et al.*, 2016a, 2010; Tataranni *et al.*, 1996) (**Fig. 1**).

After CS remission, the prevalence of MS has been reported to be significantly lower than in patients with active CS (16% vs. 50%) (Giordano *et al.*, 2014); however, the effects of hypercortisolism resolution after surgery or medical treatment on the prevalence of MS, considered as the presence of all the criteria to full-fit this diagnosis, as well as the effect of specific intervention to treat MS or the influence of possible hormonal deficits associated with CS have been scantly investigated. Conversely, more data have been reported on the presence and the outcome of the different disorders that compose the MS. Hypertension is one of the

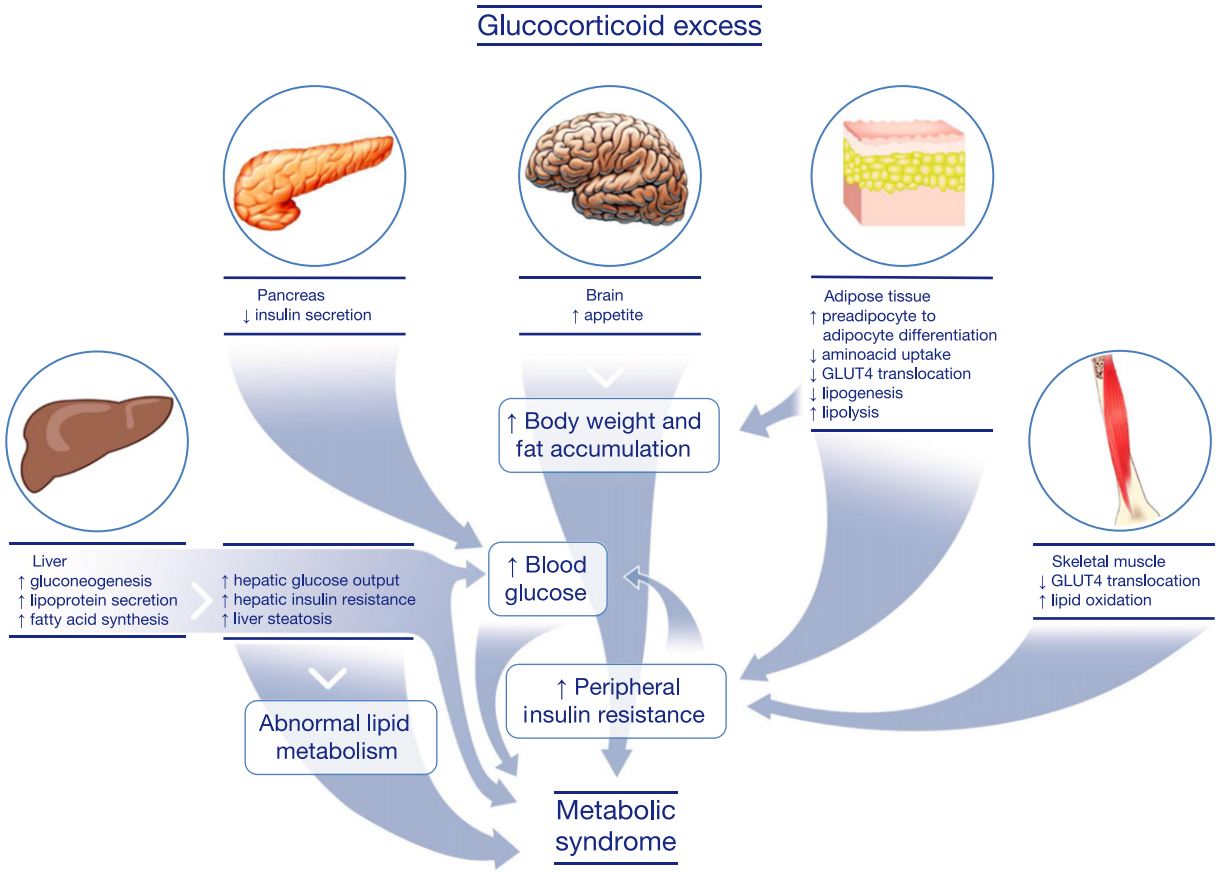

Fig. 1 Metabolic alterations in CS.

components of MS, but because it is largely involved in the pathogenesis of cardiovascular diseases associated with CS, it has been extensively described in the paragraph dedicated to cardiovascular alterations.

Visceral Obesity

Visceral obesity is currently considered a prerequisite in the diagnosis of MS (Alberti *et al.*, 2006; Ford, 2005) and is considered an important risk factor for obesity-related diseases in the general population (Klein *et al.*, 2007). The pathological increase in the body mass index (BMI) is one of the most common feature of CS (57%–100% of patients). Particularly, obesity and overweight have been reported in 25%–100% and 33%–48% respectively of patients with active CS (Colao *et al.*, 2000; Faggiano *et al.*, 2003b; Giordano *et al.*, 2011; Mancini *et al.*, 2004; Pivonello *et al.*, 2016a, 2008, 2005). The above mentioned direct effects of GCs responsible for insulin resistance and MS are also involved in the mechanisms leading to preferential visceral fat accumulation (Bonora, 2006; Chanson and Salenave, 2010; Pivonello *et al.*, 2016a, 2010). A differential expression in visceral versus subcutaneous adipose tissue of 11β-hydroxysteroid dehydrogenase type1 (11β-HSD1), an enzyme converting inactive cortisone to active cortisol, might influence the local availability of cortisol, contributing to the abdominal fat distribution (Lee *et al.*, 2014; Pivonello *et al.*, 2016a). Recently, it has been reported that also a differential expression of different GCs receptor types (type 1 and 2) in visceral versus subcutaneous adipose tissue, might play a role in preferential visceral fat accumulation, determining a differential response to GCs in the two different adipose tissues (Lee *et al.*, 2014; Pivonello *et al.*, 2016a). The visceral adipose tissue in patients with CS has been reported to be structurally and functionally different from normal subjects. Particularly, an increased lipogenesis has been described in patients with Cushing's disease (CD) compared to obese controls (Galton and Wilson, 1972; Pivonello *et al.*, 2016a), whereas enlarged abdominal fat cells, elevated lipoprotein lipase activity and low lipolytic capacity has been described in women with CS compared with normal women (Lee *et al.*, 2014; Pivonello *et al.*, 2016a). Adipose tissue secretes adipokines, proteins with multiple functions, that contribute to cardiovascular disease in patients with MS (Nakamura *et al.*, 2014) and seem to play a role in cardiovascular disease also in CS patients (Valassi *et al.*, 2012; Wagenmakers *et al.*, 2015).

The presence of visceral obesity in patients with active CD and CS have been documented by the presence of increased waist to hip-ratio or waist circumference, markers of visceral obesity (Faggiano *et al.*, 2003b; Giordano *et al.*, 2011; Pivonello *et al.*, 2016a), and confirmed also in studies using whole body magnetic resonance imaging (Geer *et al.*, 2010). The duration of hypercortisolism correlates with the presence of obesity (Mancini *et al.*, 2004). In CD patients waist to hip-ratio correlates with glucose, insulin and

blood pressure levels, suggesting a pivotal role of visceral obesity in determining MS in CS (Faggiano *et al.*, 2003b). The prevalence of obesity seems similar in women and men, but a higher BMI has been reported in female as compared with male CS patients (Giordano *et al.*, 2014; Pecori Giraldi *et al.*, 2003). One or even five years after surgical hypercortisolism resolution, obesity has been reported to be significantly improved, but not normalized (Colao *et al.*, 1999; Faggiano *et al.*, 2003b; Giordano *et al.*, 2011). However, an improvement in waist to hip-ratio or waist circumference has been reported (Faggiano *et al.*, 2003b; Giordano *et al.*, 2011). Hypercortisolism control with medical treatment can also ameliorate obesity in patients with CS (Pivonello *et al.*, 2016a). Among pituitary directed drugs, treatment with cabergoline in CD patients has been associated with an amelioration of waist to hip-ratio already after 3 months of treatment and an improvement also in BMI after 24 months (Pivonello *et al.*, 2009). More recently, treatment with pasireotide has been reported to improve weight, BMI and waist circumference already after 6 months of treatment (Pivonello *et al.*, 2014a). Among other drugs the inhibitors of steroidogenesis ketoconazole and mitotane and the GC receptor antagonist mifepristone have also been reported to ameliorate weight excess in CS patients (Baudry *et al.*, 2012; Katznelson *et al.*, 2014; Moncet *et al.*, 2007). However the long-term effects of surgical or medical hypercortisolism resolution on obesity in CS deserve further investigation. Several hormonal deficits can be potentially associated with CS and they or their suboptimal treatments might play a role in obesity, both during the active and remission phases of disease, but these effects have been scantly investigated (Pivonello *et al.*, 2016a). Patients with CS probably deserve a specific nutritional regimen to improve their metabolic profile, but studies on the effects of diet or other interventions specifically targeting obesity as complication of CS both during the active and remission phases of disease are missing. These interventions, together with a tailored approach to the hormonal deficits, might play an important role in the long-term management and outcome of CS patients.

Impairment of Glucose Metabolism

Impairment of glucose metabolism is also frequent (27%–87%) in patients with CS. Particularly, diabetes has been described in 11%–47%; impaired glucose tolerance in 7%–64% and impaired fasting glucose in 6%–14% of patients (Etxabe and Vazquez, 1994; Faggiano *et al.*, 2003a; Giordano *et al.*, 2014, 2011; Pivonello *et al.*, 2016a). In patients with CS the impairment of glucose metabolism has been ascribed to the increased gluconeogenesis and the presence of insulin resistance associated with the inability of beta-pancreatic cells to adequately compensate the insulin resistance (Pivonello *et al.*, 2016a,b; Giordano *et al.*, 2014). Additionally, hypercortisolism stimulates proteolysis and lipolysis increasing levels of amino acids and fatty acids respectively, which contribute to impair insulin sensitivity (Pivonello *et al.*, 2010). The prevalence of diabetes or impaired glucose tolerance in patients with CS has been reported to be higher than BMI-matched controls (Giordano *et al.*, 2011) and patients with CD have higher glucose and insulin levels after glucose loading than BMI-matched controls (Faggiano *et al.*, 2003b) suggesting that the excess in body weight can contribute to the impairment of glucose metabolism in CS, but it is not the only determinant factor (Pivonello *et al.*, 2016a). The prevalence of glucose abnormalities seems similar in women and men (Pecori Giraldi *et al.*, 2003), whereas a higher prevalence of diabetes has been reported in patients with ectopic CS as compared with other CS etiologies (Valassi *et al.*, 2011). The high frequency of abnormalities in glucose metabolism in CS patients suggests the need of specific investigation in all patients with CS. This evaluation should include the measurement of fasting glucose and glycated hemoglobin in all CS patients, and the oral glucose tolerance test in patients without overt diabetes. These investigations should be repeated during the follow-up of CS patients and they should contribute to drive specific interventions aimed at glycemic control. One or even 5 years after surgical hypercortisolism resolution, glucose abnormalities has been reported to be significantly improved, but not normalized (Colao *et al.*, 1999; Faggiano *et al.*, 2003b; Giordano *et al.*, 2011; Pivonello *et al.*, 2007). One year after surgical hypercortisolism resolution for adrenal CS or CD, a significant reduction in the prevalence of impaired glucose tolerance was observed only in adrenal CS (Giordano *et al.*, 2011), suggesting that in this subgroup of patients abnormal glucose metabolism might recover faster than in others. In most cases, medical treatment is associated with an improvement of glucose metabolism, with the exception of pasireotide. Particularly, cabergoline seems capable to improve insulin sensitivity and the prevalence of glucose abnormalities (Pivonello *et al.*, 2009), whereas pasireotide has been reported to worsen glycemic control in CD patients, particularly in those with preexisting alterations of glucose metabolism (Colao *et al.*, 2012; Pivonello *et al.*, 2014a). This adverse event of pasireotide is likely related to a direct inhibition of pancreatic insulin and gastrointestinal incretin secretion (Henry *et al.*, 2013). Therefore, in patients on pasireotide treatment, glucose metabolism should be monitored and glycemic control should be obtained by the introduction of metformin and staged treatment intensification with a dipeptidyl peptidase-4 inhibitor, or a glucagon-like peptide 1 receptor agonist or the initiation of insulin, as required (Colao *et al.*, 2014). Among other drugs, the inhibitors of steroidogenesis and the GC receptor antagonist mifepristone have been reported to ameliorate glucose metabolism in CS patients (Castinetti *et al.*, 2009, 2014; Fleseriu *et al.*, 2012; Pivonello *et al.*, 2016a; Pivonello *et al.*, 2015a). Several hormonal deficits can be potentially associated with CS and they or their suboptimal treatments might affect glucose metabolism, both during the active and remission phases of disease, but these effects have been scantly investigated (Pivonello *et al.*, 2016a). Therefore, a tailored approach to the treatment of hormonal deficits might play an important role in the long-term management and outcome of CS patients. Taking into account the central role of insulin resistance in the pathogenesis of glucose abnormalities in CS, the use of insulin sensitizers might be useful in patients with this type of complication; however, in patients with a more difficult glycemic control other specific treatments, including the use of insulin, can be required (Pivonello *et al.*, 2016a). These interventions, together with an appropriate nutritional approach and a prolonged follow-up of glucose parameters, both during the active and remission phases of disease, might play an important role in the long-term management and outcome of CS patients.

Dyslipidemia

Dyslipidemia in patients with CS has been poorly investigated and a variable prevalence has been described (12%–72%) (Bolland *et al.*, 2011; Faggiano *et al.*, 2003a; Giordano *et al.*, 2014, 2011; Pivonello *et al.*, 2016a). Several GCs effects involved in the pathogenesis of the MS associated with CS can contribute to determine lipid abnormalities in CS patients, particularly the direct and indirect cortisol actions on lipolysis, free fatty acid and very low density lipoprotein cholesterol (VLDL) production (Arnaldi *et al.*, 2010). Common findings are elevated total and low density lipoprotein cholesterol (LDL) and triglycerides levels and reduced high density lipoprotein cholesterol (HDL) levels (Chanson and Salenave, 2010; Colao *et al.*, 1999; De Leo *et al.*, 2010; Faggiano *et al.*, 2003b; Giordano *et al.*, 2011; Mancini *et al.*, 2004). Similar abnormalities in lipid profile have been described in patients with CD or adrenal CS (Giordano *et al.*, 2011). An abnormal lipid profile could contribute to the increased cardiovascular risk in CS, therefore it is advisable to screen for the presence of these metabolic disorders all patients with CS, by performing a complete lipid profile evaluation. One or even 5 years after surgical hypercortisolism resolution, the lipid profile has been reported to be significantly improved, but not normalized (Colao *et al.*, 1999; Faggiano *et al.*, 2003b; Giordano *et al.*, 2011). Particularly total- and LDL-cholesterol were higher than age- and sex matched controls, but not than BMI-matched controls, suggesting a role of obesity in the persistence of these metabolic abnormalities (Pivonello *et al.*, 2016a). The effect of medical treatment on lipid profile has been scantly investigated. Pasireotide seems to positively affect lipid profile, reducing total- and LDL-cholesterol in treated patients (Pivonello *et al.*, 2014a). By contrast mitotane increases total- and LDL-cholesterol, which generally is associated with a rise of HDL-cholesterol and is managed with the addition of statins not metabolized by CYP3A4 (e.g., pravastatin, rosuvastatin) when LDL/HDL cholesterol consistently increases during the follow-up (Berruti *et al.*, 2012). The presence of hormonal deficits or their suboptimal treatments can potentially affect lipid profile, both during the active and remission phases of disease, but these effects have been scantly investigated (Pivonello *et al.*, 2016a). The role of optimal management with specific intervention to correct lipid profile in CS patients and the consequence on long-term management and outcome of CS patients deserve further investigation.

Cardiovascular Complications

CS is characterized by a wide range of cardiovascular complications, including systemic arterial hypertension (SAH), morphologic and functional heart and vessels alterations as well as thrombotic diathesis, which all compete in increasing the cardiovascular mortality (Pivonello *et al.*, 2016a) (**Fig. 2**).

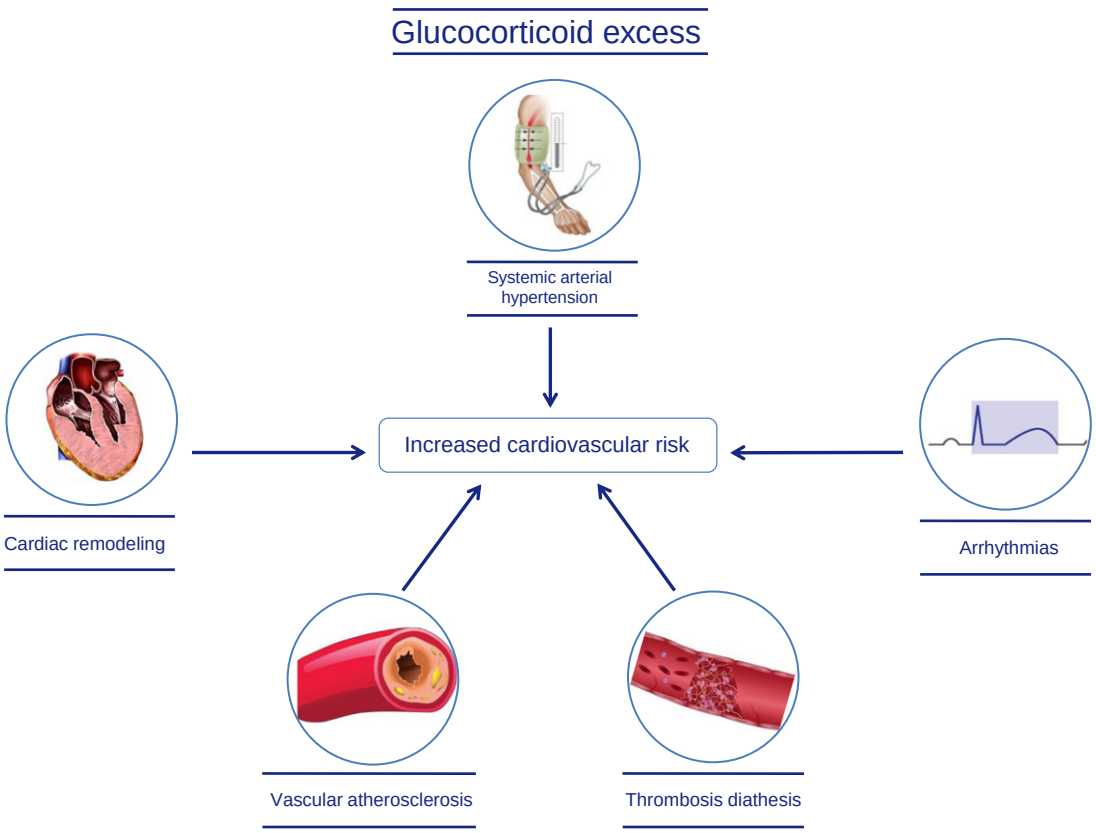

Fig. 2 Cardiovascular alterations in CS.

Systemic Arterial Hypertension (SAH)

SAH, according to the new American Heart Association (AHA) guidelines, is defined as systolic blood pressure levels $\geq$130 mmHg or diastolic blood pressure levels $\geq$80 mmHg (Whelton *et al.*, 2017). However, it is noteworthy that most clinical studies focusing on SAH in CS, published nowadays, defined SAH as systolic blood pressure levels $\geq$140 mmHg or diastolic blood pressure levels $\geq$90 mmHg, according to the previous AHA guidelines (Chobanian *et al.*, 2003). The pathogenesis of SAH in CS is still not completely understood and involves a large number of mechanisms including renin–angiotensin system (RAS), mineralocorticoid (MC) receptors hyperactivation, sympathetic nervous system and vasoregulation dysfunction (Isidori *et al.*, 2015a; Pivonello *et al.*, 2016a). RAS is the most widely studied system; the increased angiotensinogen liver synthesis and the increased angiotensin II receptors (type 1A) expression, induced by chronic hypercortisolism, seem to be the main two factors underlying RAS involvement in SAH development (Isidori *et al.*, 2015a; Pivonello *et al.*, 2016a; Ritchie *et al.*, 1990; Saruta *et al.*, 1986; Shibata *et al.*, 1995; Yasuda *et al.*, 1994). MC receptors hyperactivation is an additional important mechanism involved in the SAH pathogenesis. In physiological conditions, MC receptors, mainly expressed in kidneys and able to bind MC and cortisol with the same affinity, usually maintain their specificity because of the transformation of intracellular active cortisol to inactive cortisone by 11β-hydroxysteroid-dehydrogenase type 2 (11βHSD2) enzyme, expressed in the renal cortex (Fuller and Young, 2005; Isidori *et al.*, 2015a; Quinkler and Stewart, 2003). In case of CS, the protective 11βHSD2 activity is overwhelmed by hypercortisolism, leading to a spill-over effect of cortisol on MC receptors, that along with the proper GC receptors activation, cause the epithelial sodium channel (ENaC) hyperactivation and glomerular hyperfiltration, with a consequent sodium retention and hypervolemia, all contributing to SAH development (Bailey *et al.*, 2009; Heaney *et al.*, 1999; Isidori *et al.*, 2015a). Furthermore, the additional role of sympathetic nervous system in SAH development is still controversial; indeed, a possible, but not confirmed, enhanced vasoconstriction response to the sympathetic mediators is described (Heaney *et al.*, 1999; Isidori *et al.*, 2015a; Ritchie *et al.*, 1990). The last major pathogenetic role in SAH development is played by vasoregulation dysfunction, characterized by increased vasoconstriction tone due to a rise of vasoconstrictor endothelin- 1 (ET-1) circulating level, enhanced response to vasoconstrictor factors because of the downregulation of vascular sodium–calcium exchanger, and reduced synthesis of vasodilators, including nitric oxide, prostaglandins, prostacyclins and kallikrein-kinin system compounds (Axelrod, 1983; Kirilov *et al.*, 2003; Isidori *et al.*, 2015a; Radomski *et al.*, 1990; Shimamoto *et al.*, 1995; Simmons *et al.*, 1996; Smith and Smith, 1994; Wallerath *et al.*, 1999).

SAH in CS, usually characterized by the loss of physiological nocturnal blood pressure decrease (nondipper profile), showed a prevalence of 25%–93% (Pivonello *et al.*, 2016a). Noteworthy, no significant prevalence differences were reported among genders or etiologies, although a positive relation was described between SAH onset and hypercortisolism duration (Isidori *et al.*, 2015a; Mancini *et al.*, 2004; Pivonello *et al.*, 2016a). The long-term hypercortisolism resolution after surgery is usually associated with an improvement of SAH, even if a persistence in 25%–54% of patients was reported (Pivonello *et al.*, 2016a). Beyond surgical approach, medical therapy also demonstrated a proper efficacy on SAH control. Considering the pituitary directed drugs, cabergoline improved the blood pressure levels in 33%–100% of CD responsive patients (Ferriere *et al.*, 2017; Pivonello *et al.*, 2009) whereas daily pasireotide induced a reduction in systolic and diastolic blood pressure of $-$6.1 mmHg and $-$3.7 mmHg, as well as of $-$11.3 mmHg and $-$7.2 mmHg, after 12 and 24 months of treatment, respectively (Colao *et al.*, 2012; Pivonello *et al.*, 2014a; Schopohl *et al.*, 2015). Similarly, monthly pasireotide induced a reduction in systolic and diastolic blood pressure of $-$4.8 mmHg and $-$3.2 mmHg, after 12 months of treatment (Lacroix *et al.*, 2017). Among the adrenal directed drugs, ketoconazole and mitotane, improved the blood pressure levels in 40%–80% (Castinetti *et al.*, 2014; Moncet *et al.*, 2007; Nieman, 2002) and 63% (Donadille *et al.*, 2010; Lee *et al.*, 2014; Pivonello *et al.*, 2016a) of patients, respectively; whereas, metyrapone and newer compound osilodrostat, inducing an increase of aldosterone precursor levels, showed a potential paradoxical hypertensive effect (Bertagna *et al.*, 2014; Fleseriu *et al.*, 2016; Verhelst *et al.*, 1991). The GC receptor antagonist mifepristone improved blood pressure levels in 38%–50% of patients, although a potential hypertensive effect cannot be excluded because of increased cortisol levels due to the drug action, with consequent spill-over effect on MC receptors (Castinetti *et al.*, 2012; Fleseriu *et al.*, 2012). The impact of hormonal deficits potentially associated with CS and they or their suboptimal treatments on SAH requires further investigation, even if it is largely known that a suboptimal replacement therapy can affect the blood pressure levels and contributes to a poor cardiovascular outcome (Pivonello *et al.*, 2016a; Johannsson and Ragnarsson, 2014).

A specific antihypertensive algorithm was elaborated for CS patients, considering the mechanisms involved in SAH pathogenesis. According with this algorithm, the initial treatment should include compounds such as angiotensin I-converting enzyme inhibitor (ACEi) or angiotensin receptor blocker (ARB), which also exert protective effects on heart and kidney. If the treatment goal is not achieved, potassium levels should be accounted; in case of hypokalemia, mineralocorticoid antagonists, such as spironolactone or eplerenone, should be used, considering also the potential positive effect on heart failure; in case of normal potassium levels, calcium antagonists should be preferred, considering also the potential effects in the prevention of stroke and atherosclerosis. Moreover, when treatment goal is not achieved, a third compound should be started, preferring nitric-oxide donors and α-blockers. At last, if the blood pressure levels are not normalized, an additional treatment with β-blockers or diuretics should be considered. These latter compounds are not usually preferred because of demonstrated low efficacy and frequent contraindications occurrence, such as diabetes mellitus and obstructive sleep apnea syndrome (OSAS) for β-blockers, or hypokalemia, hyperuricemia and nephrolitiasis for diuretics (Isidori *et al.*, 2015a).

No recommendations regarding the long-term monitoring of SAHare available, but the assessment of blood pressure levels every 3–6 months and eventually, the execution of a 24 h ambulatory blood pressure measurement (24 h ABPM) in case of uncontrolled SAH, may be a valid clinical suggestion.

Cardiac Damage

Cardiac damage is characterized by left ventricular hypertrophy, concentric remodeling and myocardial fibrosis, in CS. The cardiac damage pathogenesis mainly involves two different mechanisms, both related to hypercortisolism: (1) the enhanced cardiac noradrenaline and angiontensin II response; (2) the MC or GC cardiac receptors hyperactivation. However, the hypercortisolism-induced SAH and MS can also play an important additional role in cardiac damage (Ainscough *et al.*, 2009; Isidori *et al.*, 2015a; Mihailidou *et al.*, 2009; Muiesan *et al.*, 2003; Ritchie *et al.*, 1987; Sudhir *et al.*, 1989; Toja *et al.*, 2012). Cardiac morphologic damage usually turns into functional alterations, indeed, systolic and diastolic dysfunction, including reduced left ventricular systolic performance and change of diastolic filling toward abnormal relaxation pattern, were observed at echocardiography (Muiesan *et al.*, 2003; Toja *et al.*, 2012). Recent cardiac magnetic resonance findings also reported a reduced biventricular systolic performance and a reduced left atrial ejection fraction (Kamenický *et al.*, 2014). All these features contribute to explain the higher risk of heart failure (hazard ratio: 6) and acute myocardial infarction (hazard ratio: 2.1) reported in CS patients when compared to matched controls (Isidori *et al.*, 2015a). Furthermore, ventricular hypertrophy together with hypokalemia may be also responsible for QT interval prolongation in CS patients. QT interval prolongation seems to be more pronounced in males than females, suggesting an additional pathogenetic role played by testosterone deficiency in CS male patients (Pecori Giraldi *et al.*, 2011). Considering the importance of cardiac hypertrophy, occurring in 24%–42% of CS patients (Kamenický *et al.*, 2014), an echocardiography should be performed in all patients at CS diagnosis. The hypercortisolism resolution seems to improve, and sometimes normalize, the cardiac alterations: indeed, a reduction of left ventricular mass index and relative wall thickness, an improvement of left and right ventricular systolic ejection fractions, a normalization of left ventricular diastolic function as well as an improvement of left atrial ejection, were reported in CS patients, mainly after surgery (Kamenický *et al.*, 2014; Pereira *et al.*, 2010a; Toja *et al.*, 2012). The impact of hormonal deficits potentially associated with CS and they or their suboptimal treatments on cardiac damage persistence requires further investigation (Pivonello *et al.*, 2016a).

In patients with active persistent disease, a specific treatment with aldosterone antagonists could be useful to control the cardiac alterations (Mihailidou *et al.*, 2009), as well as an adequate treatment of SAH, especially with ACEi (Isidori *et al.*, 2015a). A yearly echocardiography execution may be a valid clinical suggestion to monitor the cardiac damage progression.

Vessels Damage

Vessels damage, is characterized by atherosclerosis and vascular remodeling hypertrophy, including increased intima-media thickness (IMT), wall thickness, wall fibrosis and media to lumen ratio (Rizzoni *et al.*, 2006). The pathogenesis of atherosclerosis and vascular remodeling involves multiple variables, already described in MS, including SAH, insulin resistance and dyslipidemia, as well as additional factors due to hypercortisolism, such as smooth cells MC receptors hyperactivation, increased levels of vascular endothelial growth factor (VEGF), an important angiogenic factor, and thrombotic diathesis (Albiger *et al.*, 2006; Geer *et al.*, 2010; Molnar *et al.*, 2008; Pivonello *et al.*, 2016a; Zacharieva *et al.*, 2004). In CS patients, the additional presence of endothelial dysfunction was also reported. This functional vascular alteration is characterized by impaired microvascular reactivity, related to SAH, and smooth cell dysfunction, related to hyperinsulinemia and hybrid insulin/IGF-1 receptors formation (Bender *et al.*, 2013; Gatenby and Kearney, 2010; Prázný *et al.*, 2008). The carotid and aortic arteries IMT increase, and the consequent premature atherosclerotic lesion onset, results in arised susceptibility to develop cardiovascular events, particularly stroke and acute myocardial infarction, showing an hazard ratio of 4.5 and 2.1 compared to matched healthy controls, respectively (Albiger *et al.*, 2006; Dekkers *et al.*, 2013; Isidori *et al.*, 2015a); therefore a carotid echo-Doppler should be performed at CS onset. One or even five years after radiotherapic or surgical hypercortisolism resolution, carotid IMT has been reported to be significantly improved, but not normalized because of partial persistence of some risk factors such as SAH or inflammatory state (Colao *et al.*, 1999; Faggiano *et al.*, 2003b). The effects of medical therapies on vessels damage have been scantly investigated. The effect of GCs replacement therapy after hypercortisolism resolution should be further investigated, however, it is noteworthy that in studies comparing hypopituitaric patients with ACTH deficiency in GCs replacement therapy and hypopituitaric patients without replacement therapy because of ACTH sufficiency, the cardiovascular morbidity is similar, resulting in a stroke and coronary heart disease prevalence of 2.1% and 4.3% in both groups, respectively (Filipsson *et al.*, 2006; Pivonello *et al.*, 2016a). No specific treatment recommendation are available to reduce the cardiovascular morbidity in CS, but an adequate control of risk factors including SAH, insulin resistance and secondary diabetes, dyslipidemia and thrombotic diathesis, is strictly suggested. Lastly, considering the persistence of increased risk of cardiovascular events after hypercortisolism resolution, an yearly carotid echo-Doppler execution also after CS remission, may be a valid clinical suggestion.

Thrombotic Diathesis

Thrombotic diathesis, resulting from an imbalance among prothrombotic and fibrinolytic factors, in favor of hypercoagulative state, is typical of CS and competes in determining the increased cardiovascular risk (**Table 1**). The pathogenesis of thrombotic diathesis, due to increased abdominal fat mass, chronic endothelial damage, atherosclerosis and direct effect of hypercortisolism (Mertens and Van Gaal, 2002; Pivonello *et al.*, 2016a; Targher *et al.*, 2010; Van der Pas *et al.*, 2013), involves multiple factors including the hyperactivation of coagulative cascade and the reduced fibrinolytic activity. The hyperactivation of coagulative cascade is due to the increased production and activation of prothrombotic factors, including Factor VIII (Boscaro *et al.*, 2002; Casonato *et al.*, 1999; Kastelan *et al.*, 2009; Ikkala *et al.*, 1985; Patrassi *et al.*, 1992; Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013,

Table 1 Pathological alterations involved in thrombotic diathesis

Thrombotic diathesis
Coagulative cascade hyperactivation
↑Factor VIII
↑von Willebrand Factor antigen
↑von Willebrand Factor:ristocetin cofactor
↑Fibrinogen
Fibrinolytic activity reduction
↑Plasminogen activator inhibitor type I
↑Thrombin-activatable fibrinolysis inhibitor
↑α2 antiplasmin

2012), fibrinogen (Ambrosi *et al.*, 2000; Boscaro *et al.*, 2002; Erem *et al.*, 2009; Manetti *et al.*, 2010; Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2012, 2013), von Willebrand Factor (vWF) antigen (Boscaro *et al.*, 2002; Casonato *et al.*, 1999; Ikkala *et al.*, 1985; Patrassi *et al.*, 1992; Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013), and vWF:ristocetin cofactor (Boscaro *et al.*, 2002; Casonato *et al.*, 1999; Ikkala *et al.*, 1985; Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013), which all compete in determining hypercoagulability, platelet adhesion to subendothelium and platelet aggregation increase, resulting in a shortening of activated partial thromboplastin time (aPTT) (Boscaro *et al.*, 2002; Casonato *et al.*, 1999; Erem *et al.*, 2009; Kastelan *et al.*, 2009; Manetti *et al.*, 2010; Patrassi *et al.*, 1992; Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013, 2012). The reduced fibrinolytic activity is due to the increased levels of plasminogen activator inhibitor type I (PAI-I) (Boscaro *et al.*, 2002; Erem *et al.*, 2009; Kastelan *et al.*, 2009; Manetti *et al.*, 2010; Patrassi *et al.*, 1992; Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013, 2012), thrombin-activatable fibrinolysis inhibitor (TAFI) (Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013, 2012) and α2 antiplasmin (Manetti *et al.*, 2010; Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013, 2012) which all compete in determining inhibition of tissue plasminogen activator (tPA)-induced plasmin formation, reduced tPA and plasminogen binding to fibrin, and plasmin-induced fibrin degradation, resulting in increase of clot lysis time (CLT) (Boscaro *et al.*, 2002; Patrassi *et al.*, 1992; Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013, 2012). Additionally, also inhibitors of fibrin formation, including antithrombin III, protein C and protein S, are often increased, probably due to a compensatory effect (Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013). The thrombotic diathesis is reflected by a >10-fold increased risk of venous thromboembolism (VTE) occurrence, with an incidence of 6%–20% (Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013). After surgical hypercortisolism resolution, a normalization of vWF concentration, Factor VIII and vWF:ristocetin cofactor activity, as well as an increased of aPTT and fibrinolytic activity with reduced levels of PAI-I and α2 antiplasmin were observed, even if hemostasis was not fully normalized 1 year later in CS patients (Casonato *et al.*, 1999; Manetti *et al.*, 2010; Pivonello *et al.*, 2016a; Van der Pas *et al.*, 2013), probably due to the persistence of abdominal fat mass (Van der Pas *et al.*, 2013). Noteworthy, when biochemical remission was obtained with medical therapy using pasireotide, cabergoline and ketoconazole, in mono- or combined therapy, the hemostasis did not normalize 12 weeks later, indeed prothrombotic factors and fibrinolytic inhibitors remained elevated (Van der Pas *et al.*, 2013, 2012); however further studies are needed to clarify the long-term effects of medical therapy. Nowadays, no studies focused on the hemostasis alterations and GCs replacement therapy, are available (Isidori *et al.*, 2015b). Moreover, considering the high risk of VTE in active phase and within 3 months following surgery, because of proinflammatory rebound related to cortisol levels fall, thromboprophylaxis should be considered for all CS patients, at least from diagnosis until to 4 weeks after surgery (Van der Pas *et al.*, 2013; Nieman *et al.*, 2015).

Musculoskeletal Diseases

Musculoskeletal diseases include the damage of skeletal system and skeletal muscle; this damage are responsible not only of the generalized weakness and fatigue, but also for the increased risk of fractures and consequent disability that significantly contribute to the impairment of the quality of life affecting patients with CS.

Skeletal Damage

Skeletal damage has been reported in 64%–100% of patients with CS (skeletal fractures in 11%–76%; osteoporosis in 22%–57%; osteopenia in 40%–78%) (Bolland *et al.*, 2011; Di Somma *et al.*, 2003, 2002; Kawamata *et al.*, 2008; Minetto *et al.*, 2004; Ohmori *et al.*, 2003; Pivonello *et al.*, 2016a; Tauchmanova *et al.*, 2007, 2006; Valassi *et al.*, 2011). GCs affect bone metabolism both directly uncoupling bone turnover, and indirectly altering pituitary hormone secretion, calcium balance and muscle strength (Canalis *et al.*, 2007; Pivonello *et al.*, 2016a; Seibel *et al.*, 2013; Weinstein, 2011). Particularly, GCs induce an imbalance between bone formation and bone reabsorption inhibiting osteoblast cell differentiation (attributed to inactivation of the Wnt/β-catenin signaling pathway, induction of nuclear factors of the CCAAT enhancer binding protein family and peroxisome proliferator-activated receptor gamma type 2) and function (impaired type I collagen synthesis, that reduces the bone matrix available for

mineralization), promoting osteoblast and osteocyte apoptosis (activating caspase 3), prolonging osteoclast life span and promoting osteoclastic activity (modulating receptor activator of nuclear factor kappa-B ligand and osteoprotegerin production in osteoblasts) (Canalis *et al.*, 2007; Pivonello *et al.*, 2016a; Seibel *et al.*, 2013). The decreased number of osteocytes induces bone microarchitectural alterations, reducing bone surface turnover in response to mechanical forces (Canalis *et al.*, 2007; Pivonello *et al.*, 2016a). A role of some polymorphism in GC receptor or higher 11β-HSD1 activity in determining a different predisposition to GCs induced bone damage, has also been suggested (Canalis *et al.*, 2007; Pivonello *et al.*, 2016a; Seibel *et al.*, 2013) (**Fig. 3**). Prompt diagnosis of CS seems to be crucial to reduce skeletal complications, as supported by the evidence that low-energy fractures occurs, particularly within the 2–3 years before disease recognition and treatment of CS (Gatenby and Kearney, 2010; Vestergaard *et al.*, 2002). A potential negative influence of disease severity or adrenal androgen suppression on bone status in CS has been suggested by the evidence that some studies reported an higher prevalence of vertebral fractures in ectopic CS than in CD (Tauchmanova *et al.*, 2006; Valassi *et al.*, 2011) and an higher prevalence of osteoporosis in patients with adrenal CS as compared with those with CD (Minetto *et al.*, 2004; Ohmori *et al.*, 2003), although these data are still controversial (Pivonello *et al.*, 2016a). Testosterone deficiency could have a negative impact on bone status in male CS, as suggested by the reported higher prevalence of osteoporosis and vertebral fractures in male than female patients (Pecori Giraldi *et al.*, 2003; Pivonello *et al.*, 2016a; Valassi *et al.*, 2011). Conversely, the negative effects of GCs on bone seem to overcome the estrogenic bone protection in female CS patients because similar prevalence of fractures were described in amenorrhoeic and eumenorrhoeic women (Pivonello *et al.*, 2016a; Tauchmanova *et al.*, 2007, 2006). The frequent impairment of bone status suggests that in all patients with active CS a careful medical interview for the presence of anamnestic report or symptoms suggestive of traumatic or nontraumatic fractures should be conducted and all patients should be screened and followed for the presence of osteoporosis, osteopenia or fractures thought appropriated methodologies such as dual-energy X-ray absorptiometry and X-ray scan. Bone damage seems to be reversible after surgical hypercortisolism resolution although the time to complete bone recovery can be relatively long and variable (Pivonello *et al.*, 2016a). Several studies report an amelioration of bone mineral density (Bolland *et al.*, 2011; Di Somma *et al.*, 2003; Futo *et al.*, 2008; Kawamata *et al.*, 2008; Kristo *et al.*, 2006), which is generally slower in the femoral neck than the lumbar spine (Futo *et al.*, 2008; Kawamata *et al.*, 2008; Kristo *et al.*, 2006). In some cases of CS, an improvement in bone status has been observed already 3 months after surgery (Kawamata *et al.*, 2008), but generally several months seem necessary to observe the normalization

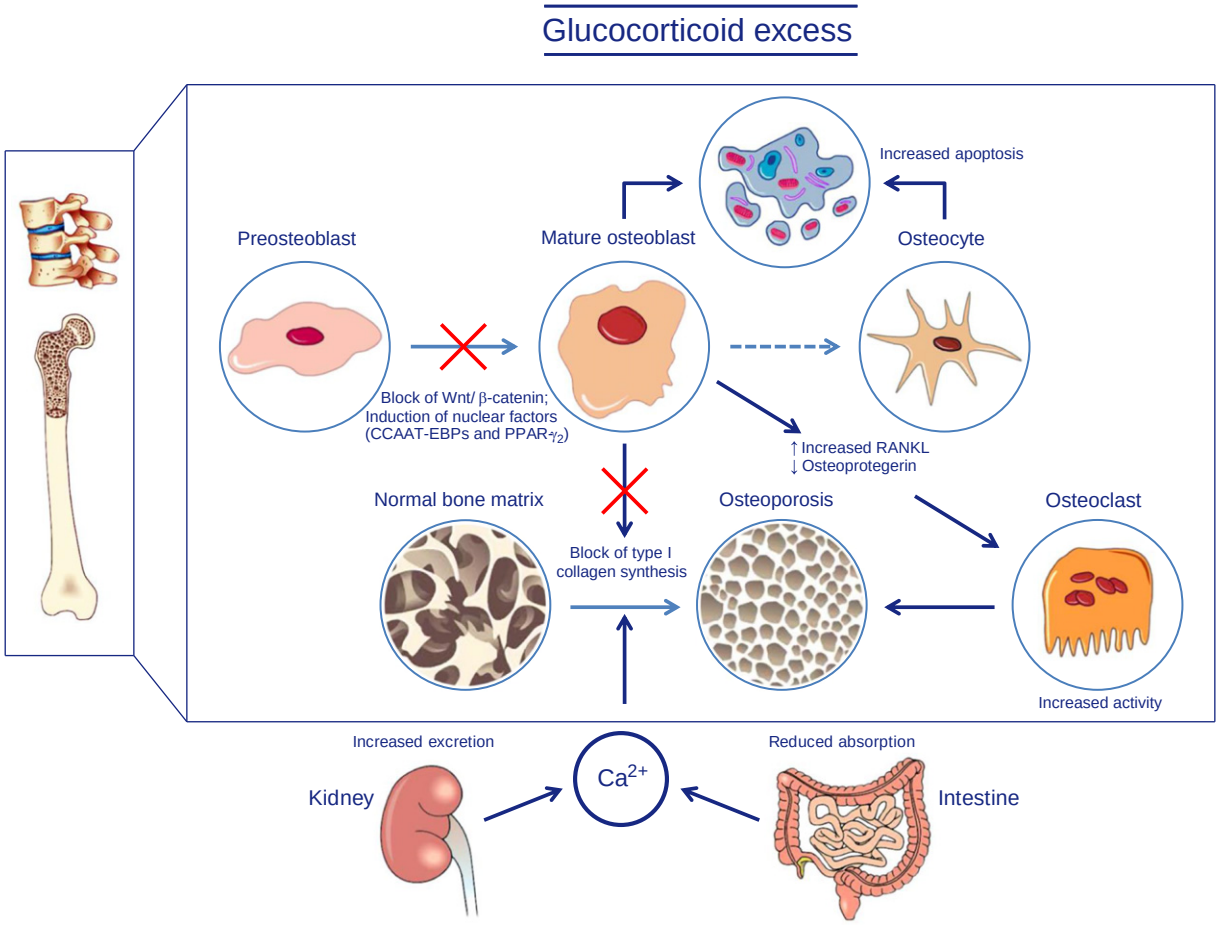

Fig. 3 Bone alterations in CS.

of lumbar spine and femoral neck bone mineral density in CS patients (Kristo *et al.*, 2006). After remission, a greater increase in bone mineral density has been reported in men as compared with women (Futo *et al.*, 2008). The effect of medical treatment on skeletal damage has been scantly investigated. In small cohorts of patients treated with ketoconazole controversial effects on bone status have been reported (Castinetti *et al.*, 2008; Di Somma *et al.*, 1998; Luisetto *et al.*, 2001), whereas the association of ketoconazole with alendronate seems to ameliorate bone status already after 6 months of treatment (Di Somma *et al.*, 1998). The presence of hormonal deficiencies or their suboptimal treatments can potentially affect bone status, during both the active and remission phases of disease. Particularly, sex and GC over-replacement might influence the time to bone recovery as suggested by the evidence that in female patients with CS after surgical remission since long time, the duration of GCs replacement was negatively correlated with lumbar spine bone mineral density (Barahona *et al.*, 2009a,b; Pivonello *et al.*, 2016a). Specific guidelines for the treatment of skeletal damage in patients with CS are still missing, although a stratification of patients in subgroups according with CS etiology, age, gonadal status, presence of fractures and expected time for hypercortisolism resolution, has been recently suggested (Scillitani *et al.*, 2014). According with this stratification, active bone therapy with bisphosphonates, teriparatide, or denosumab should be reserved to patients with an higher risk of skeletal damage (severe hypercortisolism, prevalent hip or vertebral fractures, older than 70 years), whereas in patients with a lower risk (absence of fractures, pre-menopausal women, men younger than 50 years) calcium and vitamin D supplementation should be used (Pivonello *et al.*, 2016a; Scillitani *et al.*, 2014). Considering the high prevalence of skeletal damage in patients with CS and the long time to recover after treatment, a long-term follow-up of bone status should be performed also after disease remission. In all CS patients the requirement of calcium and vitamin D and a careful tailoring of hormonal replacement treatments should be considered.

Muscle Damage

Muscle damage has been reported in 42%–83% of patients with CS (Pecori Giraldi *et al.*, 2003; Pivonello *et al.*, 2016a, 2008). GCs excess induces type 2 muscle fiber atrophy impairing skeletal muscle structure and function. These effects are mediated by both antianabolic and catabolic actions of GCs (Minetto *et al.*, 2011; Schakman *et al.*, 2013) (**Table 2**). Particularly, the antianabolic actions include the inhibition of aminoacid uptake; the repression of the insulin-like growth factor 1 (IGF-1)-activated mechanistic target of rapamycin pathway, and the inhibition of myogenesis by myogenin downregulation, whereas the catabolic actions are mainly represented by the stimulation of proteolysis, particularly through the activation of the ubiquitin–proteosome system (Minetto *et al.*, 2011; Pivonello *et al.*, 2016a; Schakman *et al.*, 2013). Additional mechanisms might include the impairment in mitochondrial function and sarcolemmal excitability and the alteration of local growth factors such as the inhibition of IGF-1 and the stimulation of myostatin (Minetto *et al.*, 2011; Pivonello *et al.*, 2016a; Schakman *et al.*, 2013).

In CS myopathy, the proximal part of the lower limbs is more severely affected (Minetto *et al.*, 2011). In subgroups analysis muscle damage seems to be more frequent in ectopic CS and in male patients (Pecori Giraldi *et al.*, 2003; Valassi *et al.*, 2011). The resolution of myopathy after surgical remission seems to take months. Additionally, musculoskeletal pain and acute bilateral carpal tunnel syndrome can be part of a withdrawal syndrome after surgical remission. However, the effects of surgical or medical hypercortisolism resolution, as well as the effects of hormonal deficiencies and their treatment on muscle damage in CS deserve further investigation (Pivonello *et al.*, 2016a). Further investigation are also required to define how diagnose and follow-up muscle damage in CS patients and to understand if the use of anabolic factors or physical activity programs can be helpful in the management of this complication in CS patients (Minetto *et al.*, 2011).

Immunological Disorders

CS is associated with a wide range of immunological alterations, in both innate and adaptive immune system, resulting in increased risk of infections and sepsis, particularly in disease active phase, and autoimmune disorders, particularly in disease

Table 2 Pathological alterations involved in muscle damage

Muscle damage

Th2 humoral immunity increase

remission phase (**Table 3**). Infections and sepsis represent one of the most important causes of mortality in CS patients (Pivonello *et al.*, 2016a).

Hypercortisolism induces an immunodepression state, altering the cellular response to infections of innate immune system, through the inhibition of antigen presentation by dendritic cells, the reduction of natural killer and neutrophil cells action, the decreased production of eosinophil and monocyte cells, as well as the impaired maturation of macrophage cells (Da Mota *et al.*, 2011; Fareau and Vassilopoulou-Sellin, 2007; Pivonello *et al.*, 2016a). Additionally, hypercortisolism also alters the humoral response to infections of innate immune system, through the reduced expression of inflammatory cytokines, complement factors, as well as the lymphocytes proliferation impairment (Da Mota *et al.*, 2011; Fareau and Vassilopoulou-Sellin, 2007; Pivonello *et al.*, 2016a). At last, hypercortisolism also affects the response to infections of adaptive immune system, through the reduced T- and B-cells maturation and proliferation (Da Mota *et al.*, 2011; Fareau and Vassilopoulou-Sellin, 2007; Pivonello *et al.*, 2016a). Particularly, a decreased ratio of circulating CD4 + /CD8 + was described, as well as an imbalance among the subclass of T-helper (Th) cells, with a decrease in Th1 cellular immunity and an increase in Th2 humoral immunity, in favor of the latter (Da Mota *et al.*, 2011; Fareau and Vassilopoulou-Sellin, 2007; Pivonello *et al.*, 2016a). Th1 cells produce a wide range of cytokines which induce B-cells to release IgG antibodies capable to opsonize virus, bacterium and fungus, favoring their phagocytosis and elimination, whereas Th2 cells produce cytokines which induce B-cells to release IgE antibodies capable to opsonize parasites, but also responsible for the immune response activation in presence of allergens. This phenomenon explains the increased risk of infections in CS patients, particularly the increased risk of opportunistic infections during the active phase of disease, and together with the phenomenon of proinflammatory rebound, it contributes to explain the presence of autoimmune diseases in these patients, particularly during the remission phase of disease (Da Mota *et al.*, 2011; Fareau and Vassilopoulou-Sellin, 2007; Pivonello *et al.*, 2016a). Opportunistic infections are very common in CS, reaching a prevalence of 21%–51% of cases, and positively related to hypercortisolism duration and severity, as well as to ectopic etiology (Broder *et al.*, 2015; Fareau and Vassilopoulou-Sellin, 2007; Pivonello *et al.*, 2016a). Additionally, the infection prevalence further increased 1 year before (hazard ratio 5.7) and 3 months after surgery approaches (hazard ratio 38.2) (Gatenby and Kearney, 2010). The most common forms of pathogens, associated with a severe and prolonged infective disease, are represented by bacteria, including *Staphylococcus* spp., *Streptococcus* spp., *Listeria* spp., *Nocardia* spp., Enterobacter, Legionella; viruses, including herpes simplex, herpes zoster, cytomegalovirus, adenovirus, influenza virus, Epstein-Barr virus; and fungi, including *Candida* spp., *Aspergillus* spp., *Cryptococcus* spp., *Pneumocystis jirovecii* (Fareau and Vassilopoulou-Sellin, 2007; Lionakis and Kontoyiannis, 2003; Pivonello *et al.*, 2016a; Rizwan *et al.*, 2014). Considering that hypercortisolism may induce an asymptomatic course of infective disease, hemocrome should be periodically assessed in all CS patients. The infection treatment should be chosen according to the pathogen, considering that the treatment response is also related to hypercortisolism control. In patients with very severe hypercortisolism, such as plasma cortisol level higher than 2500 nmol/L, a prophylaxis with cotrimoxazole should be considered in order to avoid *Pneumocystis jirovecii* infection (Pivonello *et al.*, 2016a). The impact of GC replacement therapy on infection risk in remission phase has been scantly investigated, although it is widely known that in case of uncontrolled hypocortisolism, infections represent one of the main causes of mortality (Chabre *et al.*, 2017). Autoimmune disorders are also very common in CS, showing a prevalence of 0%–20% in active phase of disease and reaching a prevalence of 60% after hypercortisolism resolution (Pivonello *et al.*, 2016a). The most common autoimmune diseases are represented by thyroiditis and celiac disease (Colao *et al.*, 2000; Da Mota *et al.*, 2011; Pivonello *et al.*, 2016a; Takasu *et al.*, 1993, 1990). For this reason, although autoimmune alterations should be further investigated, a screening for thyroiditis and celiac disease, in all CS patients within 6 months after hypercortisolism resolution might be useful (Pivonello *et al.*, 2016a).

Neuropsychiatric Disorders

Neuropsychiatric disorders are one of the most serious and disabling complications of CS and should be always considered during the current management of CS, both in the active phase of disease and after disease remission (Pereira *et al.*, 2010a,b; Pivonello *et al.*, 2016a, 2015a; Sonino and Fava, 2001). Indeed, chronic brain exposure to hypercortisolism is able to cause deep structural changes in various cerebral areas, mainly in the hippocampus, the amygdala and the prefrontal cortex, namely limbic system, in which GC receptors have a pleiotropic distribution, and are considered to be structural modulators (De Kloet *et al.*, 1998).

Particularly, hippocampus plays a key role in learning, memory, spatial abilities and emotional behaviors, whereas prefrontal cortex is involved in executive functions, memory and emotional responses. Therefore, it is not surprising that hypercortisolism can lead to structural and functional central nervous system changes, mainly consisting in brain atrophy (De Kloet *et al.*, 1998). The mechanisms by which hypercortisolism induces brain atrophy are largely unknown, although four theories have been suggested (Bourdeau *et al.*, 2002; De Kloet *et al.*, 1998; Jacobs *et al.*, 2000; Patil *et al.*, 2007; Pivonello *et al.*, 2015a,b; Simmons *et al.*, 2000). The decrease of glucose uptake: according with this first theory, GCs induce brain damage by reducing brain glucose utilization, as supported by evidence of a generalized reduction in cerebral glucose metabolism in all brain areas of CD patients (Patil *et al.*, 2007). The increase of excitatory aminoacids is responsible of "toxic" effects on nervous cells: GCs increase the release or enhance the effects of excitatory aminoacids, such as glutamate, which cause dendritic cell atrophy, particularly in the hippocampus (Patil *et al.*, 2007). The inhibition of "long-term potentiation," that is believed to be the mechanism behind learning processes and memory formation, is responsible of cognitive deficits: GCs reduce the synthesis of neurotrophic factors, mainly nerve growth factor-b and brain-derived neurotrophic factor, which through a presynaptic mechanism inhibit the long-term potentiation (Patil *et al.*, 2007). Additionally, this neurotrophic factor reduction can be per se responsible of brain atrophy (Patil *et al.*, 2007). Lastly, hypercortisolism may suppress neurogenesis in the dentate gyrus, which determines hippocampus volume loss (Bourdeau *et al.*, 2002; Jacobs *et al.*, 2000; Patil *et al.*, 2007; Simmons *et al.*, 2000). All these mechanisms seem to explain the GC-induced brain and mainly hippocampus damage, responsible for neuropsychiatric disorders. The atrophy of the prefrontal cortex (Patil *et al.*, 2007) and the suppression of neurogenesis in the dentate gyrus (Jacobs *et al.*, 2000) have been specifically identified as crucial pathophysiological events for depression (**Fig. 4**).

Although CS has repeatedly been related to different neuropsychiatric disorders, frequently literature detected only the presence or absence of symptoms rather than providing a complete major diagnosis through structured interviews and not many articles have addressed the specific issue of prevalence of the different neuropsychiatric disorders associated with CS, except for depression. A few studies have reported the presence of anxiety disorders using specific diagnostic criteria.

Major depression, the neuropsychiatric disorder better explored in CS patients, represents the most severe and life-threatening disorder associated with CS with all domains, including mood, affect, vegetative, and cognitive functions, possibly compromised. Its prevalence is reported to be about 50%–86% (Cohen, 1980; Dorn *et al.*, 1997, 1995; Haskett, 1985; Hudson *et al.*, 1987; Jeffcoate *et al.*, 1979; Kelly, 1996; Kelly *et al.*, 1996; Loosen *et al.*, 1992; Pereira *et al.*, 2010b; Pivonello *et al.*, 2015a,b; Sharma *et al.*, 2015; Sonino and Fava, 2001; Sonino *et al.*, 1998, 1993; Starkman, 2013; Starkman *et al.*, 2001, 1986, 1981). Different degrees of severity were observed, ranging from latent to very severe melancholic forms, also associated with suicidal thoughts and attempts (5%–17%) (Cohen, 1980; Haskett, 1985; Jeffcoate *et al.*, 1979). Early manifestations might be represented by irritability, insomnia and decreased libido (Starkman, 2013; Starkman *et al.*, 1981). Episodic exacerbations at irregular intervals without cyclicity, usually 1–2 days a week, rarely more than 3 days is the most common major depression "pattern." In up to 86% of CS patients depression is associated with anxiety disorders, irritability, anger, "over-reactivity and hypersensitivity to stimuli," 74% of CS patients show depressed mood, often characterized by "oversentimentality," increased feeling of crying, short spells of sadness,

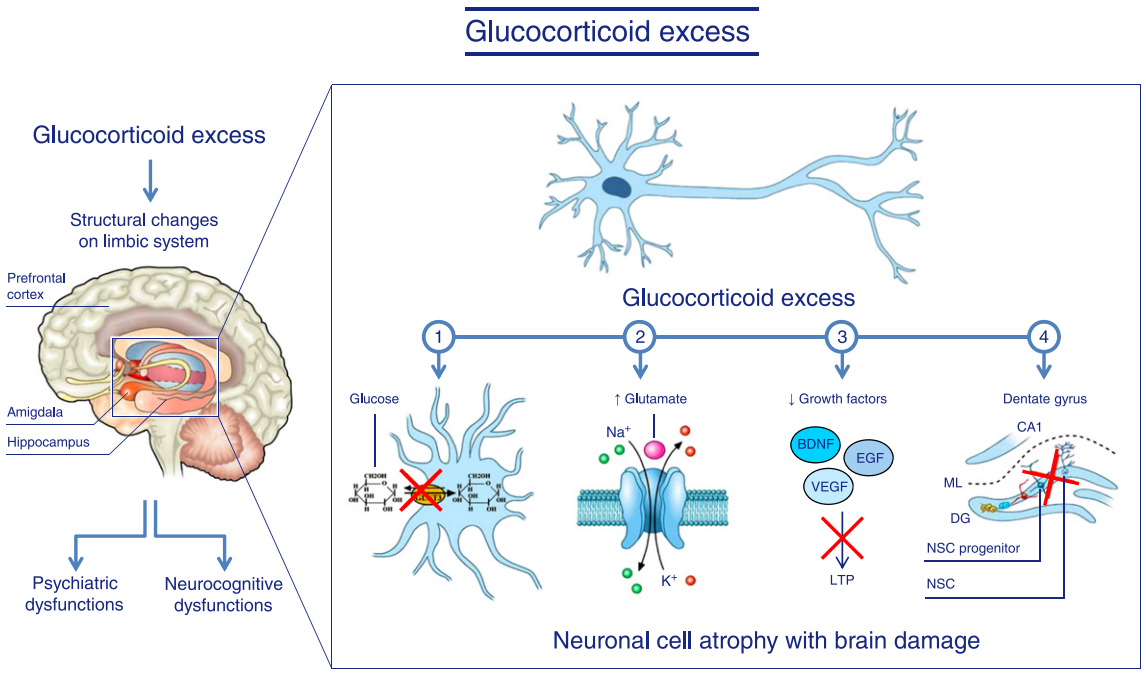

Fig. 4 Neuropsychiatric alterations in CS. *LTP*, long-term potentiation; *BDNF*, brain-derived neurotrophic factor; *VEGF*, vascular endothelial growth factor; *EGF*, Epidermal growth factor; *CA1*, Cornu Ammonis 1; *ML*, molecular layer; *DG*, dentate gyrus; *NSC*, neural stem cells.

constant hopelessness, social withdrawal with discomfort in large groups, intermittent inability to experience pleasure, rarely persistent anhedonia, and less often self-accusatory or irrational guilt (Starkman, 2013; Starkman *et al.*, 1981). Anhedonia with inability to experience pleasure is infrequent (Starkman, 2013; Starkman *et al.*, 1981). Also vegetative functions have been frequently reported impaired: fatigue in almost all patients and a decreased libido in about two-thirds; increased or decreased appetite in about 34% and 20% respectively, and sleep disturbances with insomnia and alterations in the frequency and type of dreams in 29%–69% and about 33%, respectively (Haskett, 1985; Starkman *et al.*, 1981).

Interestingly, focusing on 162 CD patients, major depression was reported significantly associated with female gender, older ages, higher urinary cortisol levels, more severe clinical conditions and undetectable pituitary tumor (Sonino *et al.*, 1998). No differences were reported among CS etiologies: hypercortisolism itself appears to be the cause.

Generalized anxiety and panic disorders have also been reported in a significant percentage of 53%–79% of CS patients, more frequently described in the chronic and advanced stage of active hypercortisolism. Also bipolar disorders, including maniac and hypomanic episodes, have been observed in about 30% of CS patients and may represent also an early manifestation of CS (Cohen, 1980; Haskett, 1985; Hudson *et al.*, 1987; Loosen *et al.*, 1992; Starkman, 2013; Starkman *et al.*, 1981).

Chronic hypercortisolism is also associated with neurocognitive dysfunctions reported in about two-thirds of CS patients, with variable degrees from mild to severe, including impairment of memory in 83% of CS patients, with difficulties in processing new information and forgetfulness of information, impaired concentration in 66% of CS patients, with mind-wandering when reading, watching television and during the course of conversations, inattention, distractibility, difficulties with reasoning ability and comprehension, impairment in verbal learning and language performance, visual and spatial abilities (Haskett, 1985; Starkman, 2013; Starkman *et al.*, 2001, 1981; Whelan *et al.*, 1980).

To date, the issue of whether CS remission may completely resolve neuropsychiatric disorders remains controversial. Several studies demonstrated a significant improvement after hypercortisolism resolution in CS patients treated with surgery, radiotherapy or medical treatment, with a progressive, although slow, improvement in brain atrophy (Dorn *et al.*, 1997; Howland, 2013; Jeffcoate *et al.*, 1979; Sonino *et al.*, 2007, 2006; Starkman *et al.*, 2001, 1986; Whelan *et al.*, 1980; Wolkowitz and Reus, 1999). However, cortisol levels normalization was associated with partial reversal of structural and functional changes observed in several cerebral areas involved during the active phase of hypercortisolism, mainly in limbic system and in frontal and prefrontal cortex, suggesting that neuropsychiatric improvement may be incomplete (Andela *et al.*, 2015; Dorn and Cerrone, 2000; Forget *et al.*, 2002; Howland, 2013; Ragnarsson and Johannsson, 2013; Ragnarsson *et al.*, 2012; Resmini *et al.*, 2012; Sonino *et al.*, 2007, 2006; Sonino and Fava, 2001; Tiemensma *et al.*, 2010a,b; Wolkowitz and Reus, 1999). Even occasionally an increase in the frequency of panic attacks and suicidal ideation was observed, probably due to the relative GC deficiency and unrestrained increase in catecholamines (Dorn *et al.*, 1997). Neurocognitive features slightly and not always significantly improve after remission, remaining impaired compared to controls (Dorn and Cerrone, 2000; Forget *et al.*, 2002). Memory, learning and concentration are reported to be impaired even after 10 years remission (Ragnarsson *et al.*, 2012;Tiemensma *et al.*, 2010b). A proper neuropsychiatric diagnosis, not easy to establish, is essential to choose the most suitable treatment. Firstly, it should be considered that some symptoms might not necessarily imply a clinical diagnosis (Santos *et al.*, 2017). Different instruments can be used for the evaluation of neuropsychiatric symptoms and disorders: clinical interviews and screening tools, mainly self-reported questionnaires, may be used to decide if a more complete neuropsychiatric evaluation is necessary. Major depression, anxiety and panic disorders may be diagnosed according to Diagnostic and Statistical Manual of Mental Disorders (Santos *et al.*, 2017).

The first therapeutic recommendation is a prompt hypercortisolism treatment, according to guidelines, before prescribing psychotropic drugs (Resmini *et al.*, 2012; Santos *et al.*, 2017). Indeed, patients may not respond properly to psychotropic drugs until cortisol normalizes. GC lowering drugs, mainly ketoconazole, metyrapone or aminoglutethimide, can also lead to an improvement in psychiatric symptoms, especially depression, in patients with a more severe CS (Santos *et al.*, 2017). Psychotropic drug treatment is recommended especially for moderate or severe symptoms or in patients with a past history of major depressive disorder prior to CS. In CS patients, selective serotonin reuptake inhibitors (SSRI) are now the most commonly prescribed group of antidepressants; low-dose clonazepam may be used for treating anxiety, whereas clozapine and mifepristone, alone and/or combined with etomidate, risperidone, aripiprazole, olanzapine or quetiapine, can be useful in case of severe psychotic symptoms, acute psychotic crises and psychotic depression (Santos *et al.*, 2017). Because cortisol normalization may take a long time, patient and family information, psychotherapy and psychoeducation are essential (Pivonello *et al.*, 2015b; Santos *et al.*, 2017). Once hypercortisolism normalization is achieved, reassessing neuropsychiatric symptoms is essential for a proper management. Also after CS remission, SSRI are the most commonly prescribed group of antidepressants, whereas short-term benzodiazepine treatment may be considered in patients with moderate to severe anxiety symptoms (Santos *et al.*, 2017). All these evidence highlight the importance of a long-term follow-up and careful periodic investigation of neuropsychiatric symptoms in CS patients, also after hypercortisolism resolution.

Reproductive and Sexual Disorders

Reproductive and sexual disorders are one of the most common complications of CS that should be considered during the disease management, both in females and males (Pivonello *et al.*, 2016a). Hypercortisolism can lead to reproductive dysfunction: GCs inhibit the release of gonadotropin-releasing hormone (GnRH), leading to a decline in circulating luteinizing hormone (LH) levels, resulting in hypogonadotropic hypogonadism (Whirledge and Cidlowski, 2010). Moreover, the localization of GC

receptors in testis and ovary suggests a direct influence of GCs on reproductive function at the gonadal level, through inhibition of steroid hormone production or GC-induced apoptosis (Whirledge and Cidlowski, 2010). Therefore, in CS a decline in estrogens concentration in females and testosterone concentration in males is not surprising and clearly associated with the occurrence of fertility impairment, although fertility impairment may also be a consequence of metabolic CS comorbidities, mainly including visceral obesity, and decrease in libido and sexual activity (24%–90%), which is more prevalent in males than in females (Pivonello *et al.*, 2016a; Valassi *et al.*, 2011; Whirledge and Cidlowski, 2010).

In CS females, menstrual irregularities, including oligomenorrhea, amenorrhea and polymenorrhea, were reported as common findings (43%–80%), more frequently observed in CD than in ACS (Pivonello *et al.*, 2016a; Valassi *et al.*, 2011). Beyond menstrual irregularities, hirsutism, acne, obesity and insulin resistance frequently characterize the CS clinical picture, rendering challenging the differential diagnosis with polycystic ovary syndrome (PCOS), the most common endocrine disorder causing female infertility. Particularly, a high prevalence of CS females, >50%, was reported to be erroneously diagnosed and treated for PCOS (Brzana *et al.*, 2014). Therefore, a differential diagnosis is required, aimed at excluding the possible presence of endogenous hypercortisolism, and at avoiding the serious clinical outcomes associated with a missing CS diagnosis. However, it should be also considered that CS and PCOS may coexist, with few distinctive features: in the ovaries of CS patients, the number of primordial follicles is reduced, fibrosis and a volumetric decrease is observed and the cortical stromal hyperplasia and luteinization is absent (Iannaccone *et al.*, 1959; Kaltsas *et al.*, 2000).

The influence of hypercortisolism on reproductive axis in CS females is also testified by the rarity of pregnancy in patients with active CS. The etiology of CS in females who become pregnant is most frequently adrenal (Caimari *et al.*, 2017). The past obstetrical history of CS females is clearly worse in comparison to the general population, as well as the frequency of spontaneous abortion (34.8%) and fetal loss (10.1%), respectively 2-fold and 10-fold higher than in healthy subjects (Caimari *et al.*, 2017). Females with CS who become pregnant are at higher risk of developing gestational diabetes mellitus (25%), hypertension (68%), preeclampsia (14%), wound infection and risk of death (2%) compared with healthy pregnancies (Pivonello *et al.*, 2016a). Risks also affect the fetus, which is at higher risk of prematurity (43%), intra uterine growth retardation (21%), spontaneous abortion or intrauterine death (5%), and several other more rare complications, including infections, hypoglycemia or respiratory distress (Caimari *et al.*, 2017; Pivonello *et al.*, 2016a). After CS remission, patients normalize both maternal and fetal risks, becoming similar to healthy pregnancies: these evidence highlight that the gonadal status impairment in CS is reversible and that pregnancy should be discouraged in the presence of active hypercortisolism, given the increased incidence of both maternal and fetal complications (Caimari *et al.*, 2017). This latter recommendation is reinforced by the limited number of cases described in literature that precludes any definitive conclusion on the optimal management for CS during pregnancy, which is usually individualized for each patient depending on the cause, the stage of pregnancy and the severity of hypercortisolism (Caimari *et al.*, 2017). Neurosurgery has been recommended as a first choice treatment, since surgical risks are lower than those of wait-and-see management (Pivonello *et al.*, 2014b). It appears safer in the second trimester due to the lower risk of fetal and maternal complications (Caimari *et al.*, 2017; Pivonello *et al.*, 2014b). As alternative treatment, when surgery is contraindicated, or initially after diagnosis for symptomatic control, different drugs have been used in a significant number of pregnant patients, with metyrapone being the most commonly used drug and generally well tolerated (Caimari *et al.*, 2017; Pivonello *et al.*, 2016a,b). Hypogonadism hormone replacement therapy in active CS females is not suggested, due to the high thromboembolic and cardiovascular risk; however, it should be considered after CS remission in case of irreversible gonadal status impairment (Pivonello *et al.*, 2016a).

In CS males, hypogonadism was reported in 50%–75% of cases, mainly consisting in loss of libido, erectile dysfunction and oligospermia (Pivonello *et al.*, 2016a). An historical histological examination of testes in CS patients revealed disorganization of the seminal epithelium, sloughing of immature elements, hypospermatogenesis, seminiferous tubular thickening and fibrosis (Gabrilove *et al.*, 1974). Maturation arrest, advanced tubular atrophy, fibrosis and decreased Leydig cells number were observed only in severe and untreated hypercortisolism cases (Gabrilove *et al.*, 1974). Although hypogonadism reversibility has been frequently reported after CS remission, with a spontaneous normalization of testosterone levels, no data are available on semen quality, rendering uncertain the reversibility of testicular damage. Hypogonadism hormone replacement therapy is suggested in CS males without normal testosterone levels within 3 months after hypercortisolism treatment (Pivonello *et al.*, 2016a).

Mortality

CS is a severe endocrine disease characterized by a large series of systemic, particularly metabolic and cardiovascular comorbidities, which cause an increased mortality ratio in active phase and, probably, also in remission phase of disease, when compared to general population mortality rate (Pivonello *et al.*, 2016a).

The main mortality causes vary according to CS etiology, including cardiovascular diseases, sepsis and suicide in case of CD and benign ACS, neoplastic progression and pulmonary thromboembolism in case of malignant ACS as well as neoplastic progression and sepsis in ECS (Pivonello *et al.*, 2016a).

The reported overall standardized mortality ratio (SMR) is 0.98–9.3 in CD, 1.14–12 in benign ACS, up to 48 in malignant ACS and 13.3–68.5 in ECS (Pivonello *et al.*, 2016a). Discordant data are available about mortality in cured CS patients, indeed, an unchanged (SMR = 0.31–1.8) (Dekkers *et al.*, 2007; Hammer *et al.*, 2004; Lindholm *et al.*, 2001; Yaneva *et al.*, 2013), or increased (SMR = 2.47–8.3) (Bolland *et al.*, 2011; Clayton *et al.*, 2011; Hassan-Smith *et al.*, 2012; Ntali *et al.*, 2013) mortality rate was

observed. However in studies considering only the subgroup of patients with persistent or recurrent disease, the increased mortality rate (SMR = 2.4–16) (Clayton *et al.*, 2011; Dekkers *et al.*, 2007; Hammer *et al.*, 2004; Lindholm *et al.*, 2001; Ntali *et al.*, 2013; Yaneva *et al.*, 2013) was confirmed.

Recently, three important literature metaanalysis, reported an increased mortality ratio in overall CD patients (SMR = 1.84) (Graversen *et al.*, 2012); a similar (SMR = 1.2) (Graversen *et al.*, 2012), or increased (SMR = 1.61–2.5) (Clayton *et al.*, 2016; Van Haalan *et al.*, 2015) mortality rate in cured patients; and an increased mortality rate in uncured patients (SMR = 3.3–4.6) (Graversen *et al.*, 2012; Van Haalan *et al.*, 2015). Lastly, different positive predictive factors were identified, including older age at diagnosis, presence and duration of disease, etiology, comorbidities occurrence (particularly hypertension and diabetes mellitus 2), as well as the number of treatments received and the presence of GCs replacement therapy after the cure (Bolland *et al.*, 2011; Etxabe and Vazquez, 1994; Gabrilove *et al.*, 1974; Pivonello *et al.*, 2016a; Yaneva *et al.*, 2013). A possible predictive role of gender has also been suggested, but further investigation are still required, because discordant and not definitive data are available (Etxabe and Vazquez, 1994; Yaneva *et al.*, 2013). Nowadays, further studies are needed to have definitive data and to eliminate confounding factors as well as the heterogeneity of different studies (Pivonello *et al.*, 2016c).

Conclusions

Chronic endogenous hypercortisolism is responsible for a rare and severe endocrine disease named CS, complicated by several comorbidities, mainly including metabolic syndrome, characterized by visceral obesity, glucose metabolism impairment, dyslipidemia and SAH, strictly associated with cardiovascular diseases, characterized by vascular atherosclerosis and cardiac damage. These comorbidities, together with thromboembolism, contribute to increase cardiovascular risk. Additional clinical complications include musculoskeletal diseases, such as osteoporosis, skeletal fractures and myopathy; immune disorders, characterized by increased susceptibility to infections, sepsis and autoimmune disorders; neuropsychiatric diseases, such as impairment of cognitive function, depression, anxiety and bipolar disorders; impairment of gonadal function, with consequent infertility and sexual disturbances. Disease duration and hypercortisolism severity appear to have a negative impact on comorbidities, with consequent QoL impairment and mortality risk increase. Therefore, a prompt screening, a confirmatory diagnosis and an effective multidisciplinary therapeutic approach are mandatory to improve clinical picture, reducing morbidity and mortality.

Several studies have explored whether comorbidities persist after hypercortisolism resolution, although the persistence of an increased mortality risk remains debated. Metabolic syndrome, cardiovascular alterations, myopathy, immune disorders and neuropsychiatric dysfunctions can persist even after remission, requiring a challenging long-term management. Conversely, skeletal damage, reproductive and sexual disorders seem to be reversible, although the time to complete recovery can be relatively long and variable.

In conclusion, prospective studies, aimed at better clarifying the potential persistence of comorbidities and increased mortality risk after hypercortisolism resolution will be helpful to improve CS management.

Introduction

Physiological Regulation of Glucocorticoid Secretion and Action

Glucocorticoids, cortisol in the human and cortisone in rodents, are synthesized in the adrenal cortex and secreted under the control of the hypothalamus–pituitary–adrenal (HPA) axis. Corticotrophin releasing hormone (CRH), secreted from parvocellular neurons of the paraventricular nucleus (PVN) in the hypothalamus, stimulates the pituitary to release adrenocorticotropin (ACTH) after cleavage from the pro-opiomelanocortin precursor. Subsequently, activation of ACTH receptors in the adrenal cortex leads to the synthesis and secretion of glucocorticoids. The secretion of ACTH and cortisol is characterized by a circadian rhythm with highest secretion in the early morning and a gradual decrease during the day reaching its nadir around midnight (Roelfsema *et al.*, 2016; Young *et al.*, 2004). In addition, ACTH and cortisol secretion is characterized by a pulsatile, ultradian rhythm with the biological purpose. This ultradian rhythmicity seems to be an intrinsic characteristic of the pituitary-adrenocortical feedforward-feedback loop, as can be evoked by constant infusion of CRH in the rat (Walker *et al.*, 2012). It has been argued that such dynamics also allow constant responsiveness of the system. Glucocorticoids act via two nuclear receptor types: the mineralocorticoid (MR) and the glucocorticoid receptor (GR) (de Kloet *et al.*, 2005). Availability to bind to the receptor is regulated via expression of the 11-beta-hydroxydehydrogenases type 1 and 2 (11-beta HSD1 and -2) different tissues (Draper and Stewart, 2005), and via co-activators and repressors (Zalachoras *et al.*, 2016). The regulation of the basal, spontaneous activity of the HPA axis, occurs by so-called negative glucocorticoid feedback at the level of the anterior pituitary and hypothalamus (de Kloet *et al.*, 2005). In addition to the well-known genomic actions of glucocorticoids, recent evidence suggests that also rapid, nongenomic effects of glucocorticoids are mediated via lower affinity MR and GR variants localized in the cell membrane (Jiang *et al.*, 2014; Karst *et al.*, 2005). This, so-called fast negative-feedback control of glucocorticoid action, appears to be mediated by another pleiotropic physiological system: the endocannabinoid system. Endocannabinoids play a pivotal role in the control of glucocorticoid action, via modulation of the excitatory action of glutamate on CRH neurons in the PVN (Evanson *et al.*, 2010). Glutamate activation is a crucial step in the activation of the HPA axis, and the inhibition of glutamate release appears to be specifically mediated by cannabinoids in the hypothalamic PVN.

The Brain as Target of Glucocorticoids: From the Evolutionary Perspective of the Stress Response

The brain is the major target for glucocorticoids orchestrating the stress response. Evolution has provided us with powerful tools to ensure survival, and an adequate response to a stressor in this respect is fundamental. A normal stress response is a prerequisite for a normal behavioral and metabolic adaptation to the stressor. When an individual is exposed to a stressor, the response is characterized by stimulation of the sympathetic nervous system (leading to catecholamine release) and activation of the hypothalamus–pituitary–adrenal (HPA) axis. Cortisol, or corticosterone in the rodent, is the main mediator of the adrenocortical stress response that ultimately serves only one purpose: to induce the required behavioral and metabolic adaptations enabling the individual to adequately cope with the stressor. Thus, activation of the HPA axis, and, consequently, increased cortisol secretion is fundamental for modeling the stress response (de Kloet *et al.*, 2005).

The regulation of stress-induced HPA activation, occurs, like nonstressed/basal HPA axis activity, by negative glucocorticoid feedback at the level of the anterior pituitary and hypothalamus. In clinical endocrinology, this negative feedback action exerted at the pituitary by synthetic glucocorticoids is exploited in the diagnostic workup and subsequent treatment of primary and secondary adrenal insufficiency. However, this clinical model of the HPA axis actually is a truncated model from a biological perspective, because higher centers, including brain stem catecholamines, modulate CRH production by the hypothalamus and limbic brain structures such as the amygdala (McCall *et al.*, 2015). This activation is of paramount importance in the responses to psychological stressors, which trigger emotional arousal and require cognitive operations for coping and storing the experience in the memory for future use. Glucocorticoids exert a strong feedback and feedforward action on these limbic forebrain areas (Laugero *et al.*, 2002). Two nuclear receptor types mediate this action exerted by these steroids: the mineralocorticoid (MR) and the glucocorticoid receptor (GR) (de Kloet *et al.*, 2005). Dysregulation of the activity of the HPA axis occurs when the glucocorticoid response is either inadequate, or too extreme and prolonged. This aberrant glucocorticoid response to stressors can have deleterious consequences for the organism. The inability to effectively terminate the stress response may lead to continued hypersecretion of glucocorticoids, which eventually leads to wear and tear of tissues and organs with an increased risk for metabolic and cardiovascular diseases, compromised immune responses, and psychopathology. Alternatively, an inadequate cortisol response is unable to restrain the initial stress reactions, as is the case for instance in inflammatory disorders and autoimmune diseases.

The Regulation of Emotion and Cognition by the HPA Axis (for Coping and Storing Experience in the Memory for Future Use)

It is well established that the action of cortisol in the central nervous system is mediated by two steroid receptors, the mineralocorticoid (MR) and glucocorticoid receptor (GR). In the principal neurons of the hippocampus both MR and GR are expressed, and mediate opposite effects on neuronal excitability. This has led to the MR—GR hypothesis in which balanced activation is key for optimal control of emotion and cognition that is regulated by the limbic system. However, MR and GR may also cooperate, and there are also GR effects that are not necessarily counterbalanced by MR. A central role of cortisol action in regulating mood and cognition is supported—and was initially indicated—by high MR and GR expression especially in the hippocampus, amygdala, and prefrontal cortex (Datson *et al.*, 2001, de Kloet *et al.*, 2000). Basal levels of cortisol activate MR even before the onset of stressors, given their high affinity. MRs stimulate neuronal excitation and in this way, determine the initial defense against the stressor, a finding that translates to vulnerability and resilience to psychiatric disease (Klok *et al.*, 2011). MRs at the neuronal membrane mediate rapid (within minutes) effects of cortisol through nongenomic but ill-understood mechanisms. These effects require considerable higher cortisol levels, and thus MR acts here as a sensor for stress-induced cortisol. The effects are thought to support the initial response to stress, and sometimes prime later genomic effects (Karst *et al.*, 2005). In contrast, stress-induced activation of GR coordinates the recovery, processing of information, and storage of the experience in the memory through reduction of neuronal excitation.

In a general sense, these effects on excitability affect the overall activity of brain regions and circuits in ways that bias emotional and behavioral responses toward more likely survival in response to immediate threat (e.g., by increasing likelihood of habitual rather than goal-directed responses, Sousa and Almeida, 2012).

These roles of MR and GR in the response to a "model" acute and transient stressor are well understood and make for a satisfactory scenario. Importantly, cortisol levels may also be elevated for much longer periods of time, the face of more chronic stressors (be it disease of psychosocial threats and challenges). Even in the case of stressors that last for a number of hours, GRs role may also change from mainly "containing" the stress response to ongoing support of the response. Transient changes in excitability can be consolidated through changes in synaptic density, dendritic spine turnover, reorganization of dendritic morphology and long-term changes in the activity of (neurotransmitter) signaling activity. In these cases, mildly elevated trough levels may also bias receptor activation toward the MR (Meijer *et al.*, 1997). It is still incompletely understood how different brain regions get functionally reorganized in chronic stress, how MR and GR play a role in this, and what the trade-off is between chronic adaptation (or "allostatic" change) and risk for brain disease.

The effects of cortisol on different brain structures do not only depend on (free) plasma hormone concentrations and intracellular receptor levels. In the brain stem nucleus of the solitary tract, the enzyme 11-beta OH-dehydrogenase (11-HSD) type 2 inactivates cortisol. In these cells aldosterone has exclusive access to the MR, to regulate blood pressure but also affect higher brain areas in relation to for example, salt hunger. In the hippocampus, the 11-HSD type 1 is present, which regenerates cortisol from inactive cortisone, leading to stronger activation of MR and also GR in this area. Inhibition of the type I HSD has been suggested to ameliorate cognitive decline during age-related cumulative overexposure to cortisol (Chapman *et al.*, 2013; Sandeep *et al.*, 2004).

Expression of MR and GR can vary as a consequence of genetic variation (van Leeuwen *et al.*, 2011), epigenetically mediated early life programming effects (Turecki and Meaney, 2016), and regulation during adult life. Because of MRs activation even at basal concentrations of cortisol, regulation of receptor amount is an important level of regulation. However, receptor regulation of expression is also a relevant variable for GR, and long-term changes in receptor expression after early life stress have been suggested to have significant functional consequences (Green *et al.*, 2011). Next to expression levels, the receptors are subject to post-translational modifications, such as specific phosphorylations, that modulate receptor activity of stability.

MR and GR by themselves primarily induce changes in *responsiveness* of neurons and other cells (de Kloet, 2014). Transcriptional changes will only lead to immediate effects in case of regulation of factors that are rate limiting for ongoing processes. For example, corticosterone affects the ongoing turnover of dendritic spines, the microstructures that form the attachment point for synaptic inputs. More obvious examples from the clinic are steroid effects on ongoing processes such as bone turnover and liver metabolic processes. Thus, while a steroid psychosis may occur in rare occasions (Judd *et al.*, 2014), in a typical situation increased activation of MR and GR in absence of stimuli has no obvious immediate effects. However, the response to (threating or rewarding) stimuli will be affected by changes in cortisol exposure.

In case of acute stressors, MR and GR act in conjunction with central stress-responsive transmitters such as noradrenalin, corticotrophin releasing hormone (CRH), and urocortins. For example, noradrenalin and glucocorticoid hormones interact in the amygdala and hippocampus with glutamatergic transmission to facilitation of memory consolidation (Roozendaal and McGaugh, 2011). The increase in GR occupancy that occurs in the hippocampus after 20–30 min after an acute stressor strengthens hippocampal memory consolidation processes, as a logical part of adaptation to a stressor that allows anticipation and optimal coping for reoccurrences of the same stressor. Conversely, activation of brain GRs is detrimental to *retrieval* of stored memories, when the increase in cortisol is out of context and not relevant to the actual memory content. This context-dependence of GR action is likely linked to the negative consequences of chronic exposure to high levels of cortisol, as the actual signaling function of the receptor is lost in such settings (de Kloet *et al.*, 1999).

The context dependence of MR and GR action is also present at the level of the intracellular signaling cross-talk. For example, brain-derived neurotropic factor (BDNF) can increase GR phosphorylation in the hypothalamus, which in turn potentiates GR

effects on gene expression (Lambert *et al.*, 2013). Likewise, a prior history of stressful circumstances led to a dramatic change in the genes that were regulated in the rat hippocampus upon treatment with a single dose of corticosterone (Qin *et al.*, 2004). Thus, present state and individual history jointly determine both the nature and the magnitude of the response to corticosteroids. While in many cases similar outcomes of cortisol exposure occur, the mechanisms of action of MR and GR, and their placement in brain signaling events, explain why the eventual outcome of acute and chronic exposure can be so different between individuals.

Animal Models of HPA Axis Disturbances

As a rule of thumb, the effects of glucocorticoids under acute stress conditions tend to be adaptive, while chronic or excessive exposure is detrimental to brain function. The particular components of time, pattern and level of brain exposure have best studied in laboratory animals, although human stem cell derived neuronal cultures may add substantially to our knowledge in the near future (de Kloet *et al.*, 2009). Classic models of glucocorticoid exposure include treatment via implanted pellets and drinking water. Recent developments include the generation of adrenal Cushing's disease in mice, and it will be interesting to see how the brain changes in these naturalistic disease models (Leccia *et al.*, 2016).

Such studies—in absence of stressors—have revealed many effects of corticosteroids on the "ongoing" processes mentioned in the previous paragraph. These studies have emphasized that chronic hypercortisolemia has substantial effects on the morphology of neurons and size of brain areas, including shrinking of dendrites of the principal cells in the CA3 area, and effects on adult neurogenesis in the dentate gyrus.

Apart from overall cortisol exposure, the pattern of exposure over the day is an important factor. For example, increased levels of cortisol that have been observed during the trough of the circadian rhythm have been associated with major depression. Animal studies have allowed to show relevance of the pattern of corticosterone exposure via treatment with low, constant levels of corticosterone, which leads to suppression of the endogenous secretion at the time of the circadian peak. This regimen ensures flattened diurnal rhythms in absence of overt hypercorticism (Akana *et al.*, 1992; Meijer *et al.*, 1997; Sarabdjitsingh *et al.*, 2010b). Even the *ultradian* rhythm of hourly glucocorticoid secretory bursts seems to be relevant, as its abolishment in rats, led to marked effects on behavioral and endocrine stress responsiveness that correlated with changes in neuronal activation in the amygdala (Sarabdjitsingh *et al.*, 2010a).

Underexposure to corticosteroid (and the option for controlled substitution) can be achieved via adrenalectomy, but this is of course a complex manipulation that also leads to depletion of mineralocorticoids, adrenal androgens, and epinephrine. A more elegant approach creates a state of selective central hypocorticism by treatment with a low dose of dexamethasone (Karssen *et al.*, 2005). Dexamethasone strongly suppresses ACTH secretion at the level of the pituitary, but at low doses do not penetrate into the brain leaving brain GRs and MRs underactivated (de Kloet *et al.*, 1975; Meijer *et al.*, 1998). This is the approach that was used to demonstrate the importance of glucocorticoid rhythmicity for the plasticity of dendritic spines. Circadian glucocorticoid peaks allowed the formation dendritic spines, while troughs were required for stabilizing newly formed spines, which are important for long-term memory retention (Liston *et al.*, 2013).

As mentioned before, many potential effects of corticosteroids will go undetected in animal models that are not appropriately challenged. In this respect, region specific manipulation of has yielded interesting information. Mice that are devoid of GR specifically in dopamine sensitive neurons have a much lower response to cocaine (Ambroggi *et al.*, 2009).

More recently the relationship between glucocorticoids, reward and addiction was emphasized in a study where the GR antagonist mifepristone was efficacious both in a rat model of alcohol abuse and in a group of addicted human subjects (Vendruscolo *et al.*, 2015). Of note, studies using receptor antagonists or cortisol-lowering agents (Sooy *et al.*, 2015) in specific disease models can point to involvement of cortisol in pathogenic processes, even in situations without an obvious or dominant stress-related component.

Human Models for the Effects of Glucocorticoids on Neuropsychological Function and the Central Regulation of Metabolism

Cushing Syndrome

Cushing syndrome is a rare endocrine disorder characterized by long-term exposure to elevated glucocorticoid levels. The most common cause of endogenous Cushing syndrome is an ACTH secreting pituitary adenoma (70% of cases); other causes include ectopic ACTH secretion (mostly bronchial carcinoids), autonomous cortisol hypersecretion secondary to an adrenal adenoma/carcinoma, or adrenal hyperplasia. Cushing syndrome can also be induced by long-term administration of supra-physiological doses of synthetic corticosteroids, as is prescribed in clinical practice for a variety of inflammatory conditions and autoimmune diseases. This is a highly prevalent condition, and is called exogenous Cushing syndrome. Exogenous Cushing syndrome is insufficiently recognized in routine clinical practice, especially in the milder cases.

Regardless the underlying cause, and in accordance with the earlier described biological effects of glucocorticoids, the vast majority of patients with Cushing syndrome have both physical and psychological morbidity (Crespo *et al.*, 2015, van Aken *et al.*, 2005). In a United States population based study, the prevalence of all features of the stress response, like hypertension, increased

insulin resistance and diabetes, major depression, and osteoporosis was much higher in patients with Cushing disease than in controls that had a similar prevalence of overweight and obesity (Feelders *et al.*, 2012). In accordance, a Danish epidemiological study demonstrated a 2–6 increased relative risk for specific cardiovascular morbidity (venous thromboembolism, myocardial infarction, stroke, heart failure) and threefold increased relative risk for fractures in patients with Cushing syndrome (Dekkers *et al.*, 2013).

When neurocognitive function (that includes cognition, mood, and personality), is assessed in patients with Cushing syndrome, virtually all patients are affected during active or uncontrolled disease, and psychopathology is also often observed (Santos *et al.*, 2017). The frequency of psychiatric symptoms in active Cushing syndrome was reported starting in the early 1980s, demonstrating that symptoms like irritability, depressed mood, and anxiety were present in the majority of the patients (Starkman and Schteingart, 1981). In accordance, depression was present in $>50\%$ of patients in a large cohort of patients with Cushing disease reported by Sonino and colleagues, and was significantly associated with older age, female sex, higher pretreatment urinary cortisol levels, a more severe clinical condition, and no pituitary adenoma on pituitary imaging (Sonino and Fava, 2001). Intriguingly, an increased overall psychiatric disability score was associated with increased cortisol secretion. In addition, patients with active Cushing syndrome report cognitive impairments, like memory problems and lack of concentration. Thus, the most common comorbid disorder is major depression, and a severe clinical presentation of Cushing often also includes depression (though to a lesser extent, mania and anxiety disorders have also been reported). These observations are in line with the pivotal evolutionary role ascribed to cortisol in the control of mood and behavior. Because limbic structures like the hippocampus and the prefrontal cortex are rich in glucocorticoid-receptors, these clinical observations suggest that these structures are particularly vulnerable to the cortisol excess as is present in Cushing syndrome.

The limited numbers of patients that have been reported after treatment indicate that a significant improvement occurs within the first year after treatment (Pereira *et al.*, 2010). In addition, reduction of glucocorticoid synthesis or action, either with metyrapone, ketoconazole, or mifepristone, rather than treatment with antidepressant drugs, is generally successful in relieving depressive symptoms, as well as other disabling symptoms (Pereira *et al.*, 2010). Thus, following successful correction of cortisol excess, both physical and psychiatric signs and symptoms improve substantially. In the long-term, however, it now becomes evident from an accumulating number of studies that patients do not completely return to their premorbid level of functioning. These studies demonstrated residual physical and psychopathological morbidity despite long-term biochemical remission (Dorn *et al.*, 1997; Milian *et al.*, 2014; Tiemensma *et al.*, 2010a). In addition, patients with long-term remission of CD reported persistent impairments in cognitive functioning (Resmini *et al.*, 2012; Tiemensma *et al.*, 2010b) and a reduced quality of life (van Aken *et al.*, 2005). To which extent psychopathology still affects general well-being after long-term cure of CS is still, however, not clear.

An emerging topic of interest in this respect is the relation between glucocorticoid excess and changes in brain structure and function, and consequently, its relationship with neuropsychological dysfunction.

The first observations in the human indicating that long-term exposure to elevated glucocorticoids may affect the brain were reported by Lupien *et al.* (1998). In that particular study, exposure to prolonged elevated cortisol levels in aged humans lead to reduced hippocampal volumes as well as memory deficits (when compared to controls with normal cortisol levels). In later studies, however (in healthy young men), a larger hippocampal volume associated with a greater cortisol response both in a social stress test (Trier social stress test) and in the cortisol awakening response, questioning the relevance of the former finding in aged individuals for younger individuals (Pruessner *et al.*, 2007). Many psychiatric diseases, like major depressive and bipolar disorder have been linked to alterations in the HPA axis (Antonijevic, 2006; Belvederi Murri *et al.*, 2016), and GC receptor polymorphisms that alter glucocorticoid sensitivity have been associated with depression (reviewed in reference Spijker and van Rossum, 2009). In addition, other studies in patients with psychiatric diseases indicate that limbic structure volumes, like the hippocampus and the amygdala, are smaller (Harrisberger *et al.*, 2015; Malykhin and Coupland, 2015), though these changes may also be associated with brain aging and interact with the progression of the disorder (Alves *et al.*, 2014).

The effects of Cushing syndrome on the brain, reflecting long-term excessive overexposure to endogenous cortisol, were recently reported in a systematic review (Andela *et al.*, 2013). This review systematically evaluated all studies in patients with active and remitted Cushing disease or syndrome using MRI ($n = 19$). These studies demonstrated that structural abnormalities in the gray matter were present in patients with active disease, that were characterized by smaller hippocampal volumes, enlarged ventricles, and cerebral atrophy (see also reference Burkhardt *et al.*, 2015). In addition, functional changes occurred, characterized by alterations in neurochemical concentrations and functional activity. Intriguingly, the reversibility of structural and neurochemical alterations after correction of cortisol excess was incomplete, even when patients were evaluated after long-term remission. The structural alterations after long-term remission included smaller gray matter volumes of the anterior cingulate cortex, greater gray matter volume of the left posterior lobe of the cerebellum (Andela *et al.*, 2015) (see also **Fig. 1**), and widespread reductions in white matter integrity (Pires *et al.*, 2015; van der Werff *et al.*, 2014). Long-lasting functional alterations included increased resting state functional connectivity between the limbic network and the subgenual subregion of the anterior cingulate cortex (van der Werff *et al.*, 2015), and altered neural processing of emotional faces (Bas-Hoogendam *et al.*, 2015). Some findings as obtained using MRI were related to the severity of the cortisol excess, and others also to neuropsychological functioning (as reflected by mood, cognition, and emotional functioning), and quality of life. This points toward persistent changes in brain function after previous exposure to hypercortisolism. In agreement with these findings, the first prospective study found persistent negative effects after 36 months on attention, executive performance and nonverbal memory in 18 patients treated for Cushing syndrome (Forget *et al.*, 2016).

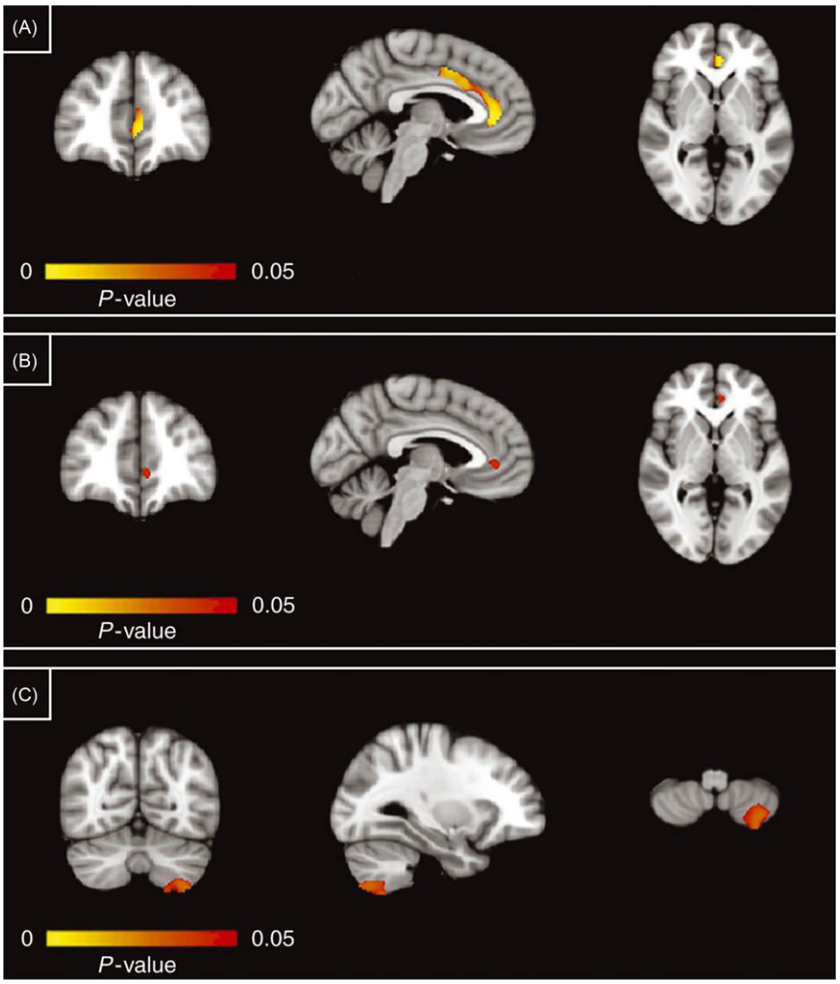

Fig. 1 VBM analysis results. (A) Results of regions of interest analysis, with lesser *gray* matter volumes in patients than that in controls ($P < .05$; 617 voxels, 2 mm isotropic). (B) Results of whole brain analysis with lesser *gray* matter volumes in patients than that in controls ($P < .05$; 37 voxels, 2 mm isotropic). (C) Results of whole brain analysis with lesser *gray* matter volumes in patients than that in controls ($P < .05$; 323 voxels, 2 mm isotropic). Effects are presented on the MNI-152 1 mm standard brain at a threshold of $P < .05$. Coordinates are $x = -4$, $y = 42$, and $z = 0$ for (A and B) and $x = -29$, $y = -66$, and $z = -56$ for (C). The left hemisphere corresponds with the right side of the image.

Adrenal Insufficiency

Not only glucocorticoid excess but also adrenal insufficiency per se, by definition, will result in impaired stress responsiveness. In the human, this is best exemplified by the clinical application of the insulin tolerance test that is considered the golden standard for the diagnosis of adrenal insufficiency. The test is based upon induction of the stress response by insulin-induced hypoglycemia, that from an evolutionary perspective is one of the most potent physiological stressors because severe hypoglycemia is potentially lethal. In accordance, the response to severe hypoglycemia is characterized both by a sympathetic noradrenergic response (tachycardia, agitation, sweating, etc.) and by activation of the HPA axis with resultant stimulation of cortisol secretion. Patients with adrenal insufficiency (regardless the cause) are not able to secrete sufficient cortisol after hypoglycemia (and thus fail this test). The subsequent metabolic and behavioral adaptations orchestrated by cortisol via the mineralo and glucocorticoid receptor, are not, or insufficiently induced. Thus, by definition, these patients exhibit impaired stress responsiveness. Intriguingly, even patients with adrenal insufficiency that were on long-term stable hydrocortisone replacement reported impairments in quality of life (Aulinas and Webb, 2014; Bancos *et al.*, 2015; Tiemensma *et al.*, 2014).

Cognitive function in patients with adrenal insufficiency on hydrocortisone replacement has been reported only in seven studies involving a total of 195 patients (Harbeck *et al.*, 2009; Henry *et al.*, 2014; Klement *et al.*, 2009; Schultebraucks *et al.*, 2016, Tiemensma *et al.*, 2016; Tytherleigh *et al.*, 2004; Werumeus Buning *et al.*, 2015). These studies indicate that mild cognitive deficits may persist, especially in memory and executive functioning tasks. Intriguingly, patients performed better on concentration and attentional tasks when compared with controls (Tiemensma *et al.*, 2016), and cognitive function was neither affected by the dose

used (high vs. low daily dose) (Werumeus Buning *et al.*, 2015), nor by postponement of the first daily dose by a few hours (Tiemensma *et al.*, 2016).

Neurocognitive functioning, besides cognition, also includes mood and personality. Patients with adrenal insufficiency may present solely with psychiatric manifestations (Anglin *et al.*, 2006; Pavlovic and Sivakumar, 2011) and epidemiological studies indicate that patients with adrenal insufficiency may be at increased risk of developing severe affective disorders. When hospitalized patients with Addison's disease were compared to hospitalized patients with osteoarthritis the former had a more than two times greater rate of affective disorders and 1.7 times greater rate of depressive disorders (Thomsen *et al.*, 2006). In the Leiden cohort more psychosocial morbidity (irritability and somatic arousal) were observed in the presence of impairments in quality of life when patients with adrenal insufficiency were compared with controls. Patients and controls did not differ regarding maladaptive personality traits, however, the daily hydrocortisone dose proved to be strongly associated both with the prevalence of maladaptive personality traits and with depression (Tiemensma *et al.*, 2014).

Patients Using Glucocorticoids

Glucocorticoids are frequently prescribed for various conditions like chronic obstructive pulmonary diseases and autoimmune diseases to inhibit the inflammatory response. Soon after their introduction in the 1950s, the first cases were reported on severe neuropsychiatric manifestations after the initiation of glucocorticoid therapy (Manzini, 1958; Piguet, 1958). In agreement with the studies in endogenous CS reported by Sonino and colleagues, more than 50% of patients exposed to glucocorticoids for >3 months developed neuropsychiatric symptoms/manifestations (Fardet *et al.*, 2007). A recent review beautifully summarized the topic of the adverse neuropsychological consequences of glucocorticoid therapy (Judd *et al.*, 2014). The acute and long-term effects on both mood and cognition have been studied in prospective studies, and the severe neuropsychiatric effects in case studies and with the use of epidemiological databases (Fardet *et al.*, 2012). The observed rates and spectrum of manifestations of depression, anxiety disorders, and cognitive dysfunction are similar to those observed in endogenous Cushing syndrome, and exemplifies that glucocorticoids can induce the same neuropsychological phenotype (in predisposed individuals). The most prominent risk factors identified were gender (male patients being more prone to develop mania and delirium, and female patients being more prone for depression), a past history for psychiatric disorders, and the initial daily glucocorticoid dose (in general above 40 mg of prednisone daily equivalent). Finally, withdrawal from long-term glucocorticoid therapy also increases the risk for severe psychiatric manifestations. Again, a past history of psychiatric disease, but also the use of long-acting glucocorticoids (especially dexamethasone) increased the risk for depression and delirium following discontinuation of glucocorticoid therapy (Fardet *et al.*, 2013).

Summary and Conclusions

The evolutionary pivotal role of glucocorticoids is reflected by the widespread expression of both receptors for glucocorticoids in the brain. Glucocorticoids play a key role in the control of neuropsychological functioning, which is exemplified by the evolutionary conserved control of behavior in the "fight or flight response". In accordance, both animal and human models of uncontrolled, (and therefore abnormal) exposure to glucocorticoids show impaired stress responsiveness, alterations in feeding behavior, cognitive dysfunction, and a broad spectrum of neuropsychiatric disorders, ranging from severe depression and anxiety disorders to acute psychosis and delirium. The fact that the same phenotype can be induced by exogenous glucocorticoid administration proves the causal role of glucocorticoids per se on neurocognitive and neuropsychiatric functioning. Finally, it now becomes clear that these effects on the brain may be long-lasting and even may not be completely reversible, because cognitive dysfunction and maladaptive personality traits persist in the presence of altered coping strategies and affected illness perceptions despite long term optimal treatment. This implies that long-term care for both patients with pituitary and adrenal disorders and patients using glucocorticoids should incorporate self-management interventions that help to improve health perception and quality of life.

Hypertension; Overview☆

Morton P Printz and Rebecca L Jaworski, University of California San Diego, San Diego, CA, United States

Glossary

Autonomic nervous system A network of nerves that carry information from the central nervous system (brain and spinal cord) to nearly all internal organ systems; this nerve system can operate with minimal, if any, conscious effort and functions to maintain internal homeostasis.

Cardiac output The volume of blood pumped by the left ventricle of the heart in 1 min; cardiac output is a measure of the pumping action of the heart.

Cardiovascular system The organ system that includes the heart and all of the blood vessels—arteries, veins, and capillaries; it serves to supply all parts of the body with nutrients and to transport waste products for elimination.

Diastolic pressure The minimum arterial blood pressure measured in large arteries during the rest phase (termed diastole) of the heart; this pressure, measured in millimeters of mercury (mmHg), is largely determined by the rate of outflow of blood from the arterial vascular compartment into the capillaries.

Neurotransmitters and neurohormones Chemicals made by and stored in nerve cells that, on release by a process termed exocytosis, carry information from one nerve cell to another or from a nerve cell to a target cell (e.g., smooth muscle cell); neurotransmitters travel very short distances, whereas neurohormones enter the bloodstream and may travel throughout the body.

Systolic pressure The maximum arterial blood pressure (mmHg) measured in large arteries during contraction of the left ventricle and ejection of blood into the arterial compartment; this pressure is determined by the contractile functions of the left ventricle of the heart and the arterioles and compliance of the large arteries.

Total systemic vascular resistance The resistance of the arterial compartment to the flow of blood being pumped by the left ventricle; the resistance comes from the state of contraction of vascular smooth muscle cells located in the terminal arterioles.

Blood Pressure: Definition, Physiological Importance, and Characterization

Definition

Blood pressure is simply the pressure of the liquid within blood vessels. This article focuses on excessive blood pressure within the arterial blood vessel network, or arterial compartment, that is, the network of blood vessels that carry blood away from the left ventricle of the heart toward all tissues except the lungs, which receives blood from the right ventricle. Most measurements yield values that reflect arterial blood pressure (ABP) distributed across this entire arterial compartment and therefore are measures of "systemic" ABP. Likewise, systemic arterial hypertension refers to a chronic excessive elevation of systemic ABP across the entire arterial blood vessel compartment. At a first approximation, systemic ABP levels are determined by several factors: (1) the force of blood being ejected into the arterial compartment by contraction of the left ventricle of the heart; (2) the rate of flow of blood out from the arterial compartment into the capillaries of tissues that is controlled by "resistance elements" in the smallest arteries, termed terminal arterioles; (3) total blood volume; and (4) tension generated by the walls of the largest blood vessels (termed conduit arteries) in resisting the pulse of blood ejected into the arteries by the heart. Therefore, the origins of systemic hypertension may be multifactorial.

Systemic Vascular Compartments

All multicellular organisms, from the most primitive to humans, have one key requirement for survival: a functional circulatory pathway whereby all of the organism's cells may be reached so that nutrients and critical gases (e.g., oxygen) may be distributed and waste products (e.g., carbon dioxide) may be removed. Evolution has matched complex multicellular organisms with comparably complex circulatory systems. In mammals, blood, containing both cells and dissolved materials, circulates continuously through an extensive closed network of tubes (blood vessels). This vascular system actually consists of three separate but connected sections, or compartments: arterial (arteries), capillary, and venous (veins).

The arterial compartment carries blood away from the heart, beginning with the aorta, which branches to the carotid arteries (subserving the head and brain) and to the descending aorta, which extends in an ever-branching manner to all other organ systems and tissues. The arterial system is a high-pressure circuit that allows all organ systems an equitable portion of the arterial

This article is an update of Morton P. Printz and Rebecca L. Jaworski, Hypertension, Overview, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 577-588.

blood. Large arteries leaving the heart (termed conduit arteries) receive the full pressure and flow of the pulse of blood pumped (or ejected) from the left ventricle with each contraction of the heart. Conduit arteries serve as "feeder vessels" to an increasing number of smaller arterial vessels ultimately connecting with the capillary compartment within organ systems. The capillaries are the simplest blood vessels designed to facilitate exchange of nutrients and cellular waste between tissues and blood. Arterial pressure is highest in conduit vessels (aorta and carotid) and declines steadily as the arterial vessels become smaller with the lowest arterial pressure at the junction with the capillary network. Conduit arteries also serve to dampen the large "pressure pulse" generated by contraction of the left ventricle, and function to smooth out the pressure wave that spreads from the heart to the smallest blood vessels. One way this dampening and smoothing is accomplished is through the elasticity of the conduit vessel wall. This elasticity allows "capture" of a portion of the energy of the pulse of blood ejected by the heart into the arterial compartment. As the pressure wave progresses away from the heart, the conduit arterial walls relax and return the energy to the blood, supporting the arterial pressure while the heart is not contracting. This process is like the rebound of a stretched rubber band of a slingshot that exerts a force on the object being propelled (here blood), a process termed the "windkessel effect." The windkessel effect of the conduit arteries is related directly to the elasticity (termed compliance) of the arterial wall. When conduit arteries lose their elasticity, systolic hypertension, a disorder common in the elderly, may result.

Arterial blood vessels are complex consisting of multiple cell types and several discrete layers. In immediate contact with blood is a single cell-thick lining of endothelial cells with underlying associated connective tissue proteins. This layer is termed the "intima" of the vessel. Arterial endothelial cells serve many functions, including local release of chemicals that may relax or contract the vessel wall and regulation of hemostasis and clot formation. The intima is very important with many major functions including the following: (1) reduce viscosity and turbulence of flowing blood; (2) provide a source of chemicals that regulate thrombosis or clot formation; and (3) release chemical mediators that affect the state of contraction or relaxation of underlying smooth muscle cells. The middle layer of the arterial vessel wall is termed the "media" and consists primarily of multiple layers of contractile smooth muscle cells that can directly and indirectly affect local arterial pressure or vessel compliance. The state of contraction (termed "tone") of the smooth muscle cells imparts strength to the wall to resist the ABP within the lumen of the vessel, and determines the resistance to flow of blood through the vessels. At the junction of the smallest arteries (arterioles) with the capillary compartment, the smooth muscle cells provide "resistance elements" that determine the rate of flow of blood out of the arterial compartment into the capillary network. Total systemic arterial resistance (TSVR) is a measure of the average tone (contraction state) of all the resistance elements of the arterial compartment. The outer layer of the artery wall is the "adventitia," consisting of connective tissue cells such as fibroblasts, elastic and connective tissue proteins, nerve endings of the sympathetic branch of the autonomic nervous system (ANS), and other cell types that vary according to the size of the vessel and the organ system. Large conduit arterial blood vessels also contain a microvascular blood network within the adventitia that serves to insure all cells within the adventitia get perfused with oxygenated blood. Chronic hypertension results in cellular and functional changes within all three layers of arterial blood vessels and constitutes part of the hypertension syndrome.

The capillary network constitutes the smallest blood vessels in all three compartments of the vascular system. These vessels consist of only a single-cell layer of endothelial cells with associated connective tissue proteins, and no media or adventitia. This structure permits rapid diffusion of materials, in both directions, between the blood within the vessel and fluids in the adjoining tissue. This vascular compartment is primarily a circuit for material and cellular exchange between the blood and tissues of the organ system. For this reason, it has significant importance in maintaining the amount of fluid outside of the vascular compartments and in tissues. An imbalance in fluid exchange, due to altered control of fluid dynamics between the arterial and venous compartments, contributes to tissue fluid retention in individuals with compromised heart function as well as in uncontrolled hypertension. Although antihypertensive drugs are not designed to work directly on the capillaries, many of these drugs do affect capillary functioning indirectly through improved fluid dynamics and enhanced elimination of retained fluids within tissues.

The third compartment is the network of vessels, termed the venous compartment, which collects the fluid output from the capillary compartment. The venous compartment commences at the outflow from the capillary compartment and extends to the right atrium of the heart. There are two functions of this compartment that directly influence arterial pressure. First, by collecting the blood from the capillary compartment and returning it to the heart (termed "venous return"), this insures that the heart has the available blood both to pump into the arterial circuit and to pump to the lungs for gas exchange. Secondly, the veins serve as a major reservoir of blood for the body. Large veins are termed "capacitance vessels" because they have the capacity to expand and hold large amounts of blood. When needed, contraction of the capacitance vessels (through contraction of venous smooth muscle) allows the recruitment of blood back into the arterial and capillary compartments. This is accomplished by contraction or relaxation of venous smooth muscle in large part through the activity of the sympathetic branch of the ANS. The venous compartment is a mirror image of the arterial compartment with small veins, highly ramified, joining into successively larger vessels. Veins are complex vessels, like arteries, and consist of an endothelial cell lining, medial smooth muscle, nerves, and multiple types of cells; however, the venous system is a low-pressure circuit, so the media and adventitia of the vessel wall are thinner than arteries.

There are other vascular compartments that are unique to the organ system they serve and which will not be discussed in detail in this article. Among such vascular compartments are the pulmonary and cerebral vascular compartments. Blood vessels that connect the heart and lung constitute the pulmonary vascular compartment, whereas arteries from the left ventricle of the heart to all of the organ systems (except the lungs) carry highly oxygenated blood, and veins returning to the right atrium of the heart carry low-oxygenated blood from the tissues, the converse exists in the pulmonary vascular compartment. The pulmonary artery, from the right ventricle of the heart to the lungs, carries venous blood of low oxygen content, whereas the pulmonary vein, from the lungs to the left atrium of the heart, carries highly

oxygenated blood. Pulmonary blood pressure normally is a low-pressure system; however, similar to the arterial pressure compartment, pulmonary hypertension is a condition of excess blood pressure in the pulmonary artery from the heart to the lung. This can affect the right pumping chambers of the heart and fluid exchange in the lungs. Pulmonary hypertension differs in both cause and treatment from systemic arterial hypertension, the subject of this article. For this reason, this article does not deal with this form of hypertension. Likewise the cerebral vascular compartment is also unique. While delivering blood to brain tissue (parenchyma), it also has other important functions. First, it is autoregulatory, that is, cerebral vasculature responds to changes of pressure within the compartment so as to maintain constant blood flow to brain tissues. Secondly, its structure and function are designed to dampen the systolic arterial pressure pulse so the brain parenchyma does not feel the full force of the pulse pressure wave—it has high smooth muscle tone. Headaches can be one symptom of relaxing the inherent tone of cerebral vasculature smooth muscle. Thirdly, much of the cerebral vascular compartment is structurally designed to be selective to the passage into the brain parenchyma of blood-borne biological materials as well as chemicals, proteins, and cells. This physical structure acts like a selective molecular and cellular sieve and is termed the "blood brain barrier." However, there are brain areas which function by monitoring blood-borne materials so are partially selective or without a blood brain barrier.

Many organ systems have unique aspects to their intraorgan vascular system. Very relevant to hypertension is the kidney vascular compartment which allows that organ to control both total body electrolytes (particularly sodium and potassium) and water. Through control of these two aspects of volume homeostasis, systemic blood pressures are also directly controlled. Abnormal functioning of ion and volume homeostasis by the kidney underlies many aspects of systemic hypertension.

ABP Gradient

Blood pressure is highest in the large conduit arteries, which leave the left ventricle of the heart, and decreases steadily through the arterial, capillary, and venous compartments; the largest drop in pressure occurs on the arterial side. Maintenance of this decreasing gradient of pressure is essential to ensure adequate blood delivery to all tissues, to optimize fluid and material exchange in the capillary network, and to deliver the blood back to the right side of the heart. A disease process that interferes with any of these three functions will invariably result in a form of arterial hypertension.

Determinants of Levels of Arterial Pressure

Arterial pressure derives from the pumping action of the left ventricle of the heart; therefore, the level of arterial pressure at any point in the arterial vascular compartment reflects functioning of the left ventricle. During each contraction of the left ventricle (termed systole), the highest systemic pressure generated within the arteries is termed the "systolic pressure." When the left ventricle stops contracting, the heart valve controlling outflow from the left ventricle into the aorta closes and the left ventricle relaxes and refills (between beats). This phase of the heart is termed diastole. During diastole the arterial pressure drops as the arterial blood rapidly flows out of the arterial compartment into the capillaries. The lowest arterial pressure during this rest phase of the left ventricle is termed the "diastolic pressure." The rate of drop of arterial pressure is primarily controlled by the terminal resistance arterioles, located at the junction of artery to the capillaries, which meter the rate of outflow of blood from the arteries. A second factor is the interbeat interval, the time between contractions of the left ventricle, the heart rate (HR). At constant arteriole resistance, increasing HR may increase apparent diastolic pressure since there is less time for blood to leave the arterial compartment. A third factor is the rebound of the conduit arteries, the windkessel energy effect that sustains the arterial pressure during diastole. Diastolic pressure also is indirectly determined by the systolic pressure in that an increase in systolic pressure leads to a higher starting point from which the arterial pressure may descend between contractions. This leads to a higher diastolic pressure starting point. In a normally functioning and contracting heart, the lowest systemic arterial pressure level is reached just prior to the next contraction. Thus, systolic pressure reflects multiple contributions—the action of the heart, resistance to outflow from the arterial compartment, and the windkessel effect.

The pressure difference between systolic and diastolic pressure is termed the "pulse pressure." Pulse pressure, which is sensed by the blood vessel elements, has recently been deemed a potential contributor to the development of both systemic arterial hypertension and arterial wall damage contributory to atherosclerosis.

Arterial pressure is influenced by many factors. These include age, gender, body weight, level of physical conditioning, current physical activity, and behaviors of all kinds, for example, stress, eating, drinking, and exercise. Arterial pressure can also be influenced by many agents, both prescription and over-the-counter drugs, herbal products, caffeine-loaded energy drinks, psychoactive drugs, and drugs of abuse. Further, arterial pressure varies continuously with variations caused by changes in heart beat-to-beat intervals, periods of rest and sleep, as well as levels of psychological stress.

Quantifying Arterial Pressure

Human systemic arterial pressure is typically measured with an occlusive device (cuff) placed on one arm. When arterial pressure is measured in this manner, two values are derived: an upper value and a lower value are quoted, for example, systolic pressure of 120 over diastolic pressure of 80. The units of pressure are traditionally expressed as "millimeters of mercury" (mmHg) based on the traditional use of mercury manometers to measure blood pressures. A more recent unit is "millibars." An average between these two extremes is occasionally used, namely mean arterial pressure (MAP), which is an approximate average pressure over the

period of one systole and the trailing diastole. A discussion of MAP provides insight into what determines arterial pressure. Mathematically, MAP is defined by the following relationship involving cardiac output (CO) of the heart and TSVR of the arterial vascular compartment: MAP = CO × TSVR. TSVR is the sum total resistance to the flow of blood out from the arterial compartment into the capillary network, and reflects the summary of the actions of all the terminal arterioles. CO is the amount of blood (in liters) pumped by the left ventricle of the heart over a full minute. The force of contraction of the left ventricle, the HR, the amount of blood ejected from the left ventricle chamber during each contraction, and the stroke volume (SV) determine this volume of blood. The latter results from venous return and by the resistance encountered when the heart pumps the blood into the arterial circuit. Because capacitance veins influence venous return, changes in both blood volume and the degree of constriction of venous smooth muscle influence the low blood pressure in the veins and the amount of blood returned to the heart. Because CO is defined by volume of blood ejected by the left ventricle with each beat and by HR, arterial pressure is determined by SV, HR, and TSVR.

$$\text{MAP} = \text{CO} \times \text{TSVR} = \text{SV} \times \text{HR} \times \text{TSVR}$$

Therefore, the two single numbers, systolic and diastolic pressures, are influenced and determined by many organ systems and cardiovascular components.

Within all organisms arterial pressure control is the resultant of exchange of information through the actions of both nervous systems and chemical mediators. The major nervous system that regulates and sets arterial pressure is the ANS, which works in an integrated fashion with the central nervous system (CNS), which constitutes the brain and spinal cord. There are two identifiable "branches" of the ANS—termed sympathetic and parasympathetic—that work together to control arterial pressure. In some respects the sympathetic system is viewed as being the "excitatory" branch while the parasympathetic is the "inhibitory" branch. The actions of these two separate nervous networks have been viewed as working in opposition to each other so as to affect cardiovascular functions, including arterial pressure. However, it is more accurate to view the two systems as being highly integrated and working cooperatively in a coordinated fashion to achieve the immediate goal of the organ system, namely, to respond to demands of the organism. What is the ultimate goal? It is to permit the organism to survive by allowing each organ system to meet the immediate and long-term needs of the whole organism. Transient changes in arterial pressure, high and low, occur numerous times per day. Hypertension is a chronic, frequent or continuous high arterial pressure. If systemic arterial pressure is high, the first question that should be asked is why, and potentially what need of the organism might this high blood pressure be satisfying? Of course, the pathophysiological origin of the hypertension might reside in an abnormally functioning ANS control mechanism. Appreciation of this concept is important to understand the importance of blood pressure dynamics and how to treat chronic hypertension.

For example, the sympathetic system is considered the "stress-responsive" branch of the ANS because it alters organ system functions to optimize an organism's response to a stressor, a stress that can arise externally or internally. The parasympathetic system is considered the "vegetative" branch of the ANS, regulating the most primitive and essential biological actions necessary for mere survival of the organism and the species. An organism (human or animal) can live for a long time without the sympathetic system, but not without the parasympathetic system. The sympathetic system (1) can increase HR and force of contraction thereby increasing systolic pressure; (2) can increase tone of the smooth muscle in the terminal arterioles thereby increasing systemic vascular resistance and decreasing the rate of outflow of blood from the arterial compartment between heart beats—raising both systolic and diastolic pressures; (3) stimulate release of chemicals from the kidney and adrenal glands that are important for control of blood volume, blood electrolytes, and contraction or relaxation of smooth muscle in the arteries and arterioles, affecting both pressures; and (4) control a myriad of additional functions from metabolism, to functioning of eyes, to sexual functions. However, one of the most important functions of the sympathetic system is facilitation of the dynamic shifting of blood flow among organ systems in order to meet the needs of the tissues, and ultimately the organism as a whole. Each organ system gets a fraction of total CO; however, during some functions (e.g., "flight-or-fight" responses) one organ system might need more for survival of the organism. The CNS through a selective increase in sympathetic nerve activity to particular organ systems accomplishes this "shunting" of blood to organ systems that need more blood.

In contrast, the parasympathetic system controls many organ systems so as to maintain normal homeostasis in the absence of stress. For example, the parasympathetic system slows HR and decreases cardiac function leading to a decrease in CO, increases gastrointestinal activity and secretion to aid digestion, facilitates elimination of waste products from the body, protects the lungs from inhaling toxic chemicals and substances, protects the retina from excessive light, and facilitates vision at short distances. Both the sympathetic and parasympathetic branches of the ANS project from the CNS to the heart; however, only the sympathetic system sends nerve projections to blood vessels. To summarize, in blood vessels the sympathetic system increases smooth muscle tone, increasing TSVR and decreasing rate of outflow of blood from the arterial compartment, and on the venous side contributes to increasing venous return. The ANS originates in the CNS and links brain areas important in coordinating cardiovascular and respiratory functions (brainstem) with areas that are important for both primitive and complex behaviors, even cognition. Under normal nonstressful situations each organism behavior or action of an individual requires an appropriate and selective ANS response; otherwise, the organism could not perform the desired action. For example, "fear" generally increases sympathetic activity and diminishes parasympathetic activity. Yet, although both fear from an external threat and fear derived from an internally perceived cognitive threat may result in activation of a sympathetic response (e.g., increased HR), the totalities of specific changes in autonomic functioning are not the same. Thus, one cannot generalize and say that all fear responses will have the same effect on the cardiovascular system; some may be

more demanding or even more detrimental than others. The relationships between behavior and normal or abnormal cardiovascular functioning are being elucidated with new molecular and cellular technologies allowing studies to define coordination of behaviors with observed cardiovascular responses. Such studies comprise an area of psychophysiological investigation termed "behavior–autonomic coupling" (Printz *et al.*, 2003). That such coupling is dictated by genes, and thus becomes controlled partly by inheritance, has been established through studies both within our laboratory and by other investigators. One basic question is whether an individual may inherit genes that lead to aberrant behavior–autonomic coupling and thereby be more susceptible to developing hypertension, or other cardiovascular or organ system disorders, as a consequence of behavioral or cognitive stress (Alemayehu *et al.*, 2002). A second fundamental question is whether and how abnormal cardiovascular responses might feed back into determining an individual's behavior.

Systemic arterial pressure varies over 24 h in a diurnal rhythm that is generally higher during the awake/day period and lower during the rest/sleep period. Generally an individual's arterial pressure decreases from a high, during the awake or active period, to a low during the sleep or rest period. Such an individual is classified as a "dipper." Some individuals, including some human hypertensive subjects, exhibit a failure to "dip" and are termed "nondippers." The implications of nondipping to chronic hypertension remain an area of investigation. Sleep periods and resting states are also important to normal arterial pressure as well as to behavioral states. This may be another example of the importance of behavior–autonomic coupling.

The endocrine system also has direct and indirect effects in determining the levels of systemic arterial pressure (Buijs *et al.*, 2003). Steroids, both of gonadal and adrenal cortex origins, exert direct influences on cellular components of the arterial compartment, including smooth muscle and endothelial cells, on kidney functions that relates to retention of sodium and water and on actions of the heart. Endocrine systems are also linked with control of diurnal rhythms and will directly influence the CNS including cognitive areas. Given that every behavior must have an appropriate and coordinated autonomic and cardiovascular response, it is clear that subtle endocrine-mediated changes in behavior, when exerted over an extended period, may have profound effects on the level of systemic arterial pressure.

Hypertension as a Disorder in Humans

As discussed above, arterial pressure while easy to measure in humans is a very complex trait influenced directly and indirectly by many factors among which are functioning of the heart, resistance to the outflow of blood from the arterial compartment, state of constriction of veins, total volume of the system, behavior–autonomic coupling, and endocrine state. For this reason, the pathophysiology leading to human hypertension could involve many different factors or causes. This complexity underlies the concept that most forms of chronic arterial hypertension reflect a "syndrome" rather than a single complex disorder. It is believed that nearly 80% of human hypertension, termed essential hypertension (EHT), is of unknown etiology but with a strong genetic component. EHT is considered to be the consequence of multifactorial and multigene contributions likely exacerbated and enhanced by gene–environment interactions. However, what further denotes this disorder as a syndrome is that evidence from genetic animal studies argues that the major contributory factor or factors that sustain the hypertension vary with progression of the hypertension over time. Early stages of EHT reflect excessively heightened sympathetic nervous system activity, the origins of which remain controversial. Since EHT has major genetic origins, it may originate from "susceptibility genes" that predispose the individual to an elevated arterial pressure. Over time, early primary symptoms (see below) lead to loss of homeostatic control mechanisms, in part arising from remodeling of organ systems in response to the high pressure along with direct organ system damage. These secondary factors begin to add their contributions to the causation or sustainment of the elevated arterial pressure. It is established that chronic hypertension is a risk factor for other cardiovascular disorders, which also have strong genetic determinants, such as diabetes, kidney failure, blood vessel disorders including atherosclerosis, and heart function abnormalities. These secondary disorders may then further complicate and potentially change the etiology of the hypertension. Thus, the "cause" of the EHT inherently varies with progression and duration of the hypertension syndrome. This is one reason why treatment must be designed to stem progression of the hypertension and to return arterial pressure to "normative" levels based on age, gender, and physical condition (Printz *et al.*, 2003).

Failure and Resetting of Homeostatic Mechanisms

Chronic systemic hypertension is a disorder of regulation of arterial pressure. Numerous integrated control mechanisms function to keep arterial pressure constant (Ciriello and de Olivera, 2002). For example, if TSVR increases and leads to increased arterial pressure, CO is reflexively decreased through homeostatic mechanisms that increase parasympathetic activity to slow HR and reduce contractility. This reflex is known as the high-pressure baroreceptor reflex. Likewise, if CO drops (e.g., due to a sudden loss of blood), there is a homeostatic increase in sympathetic activity to blood vessels, resulting in strong constriction of the smooth muscle in resistance arterioles and thereby a concomitant increase in TSVR so as to maintain diastolic pressure. This response is critical because aberrant low diastolic pressure threatens venous return and the ability of the left ventricle of the heart to supply blood into the arterial vascular compartment. These homeostatic regulatory systems operate continuously and dynamically on a beat-by-beat basis. Chronic arterial hypertension results in a loss of homeostasis through a physiological process of "resetting," the consequence of which is that the higher level of arterial pressure is maintained and becomes the "new set point."

One organ system important to determining arterial pressure and a component of this resetting process is the kidney that functions to maintain systemic (total body) sodium and volume homeostasis. There are forms of hypertension that arise from abnormal kidney function. Elimination of sodium and water requires appropriate arterial perfusion pressure to the kidneys, as well as properly functioning intrakidney filtration and reabsorption mechanisms. With chronic and long-standing elevated arterial pressure the kidney structurally remodels which contributes to the loss in homeostasis. The consequence is the retention of sodium (salt) and correspondingly, water, which elevates volume and further raises arterial pressure. Elevating systemic arterial pressure may initially correct this failure to excrete salt and water; however, this also may result in further loss of kidney function. Thus, the resetting process becomes part of the hypertension syndrome! This becomes a challenge as well in lowering arterial pressure in hypertensive subjects by drugs. As pressure is lowered, kidney perfusion pressure may be inadequate and the net effect is retention of sodium and water. This requires treatment with another class of drugs known as diuretics which function by enhancing sodium and water elimination by the kidney.

Chronic hypertension also leads to a compensatory thickening of the media smooth muscle layer of arteries to resist the increased pressure within the vessel. However, this thickening of the media also causes the lumen of the vessel to become smaller in diameter which raises resistance to blood flow (TSVR), which by the above equation directly affects blood pressure. If it is not reversed in time, this thickened lumen leads to a resetting of the basal state of resistance to flow. Thus, structural remodeling of the blood vessel becomes a determinant of the level of systemic arterial pressure. High arterial pressure over years also can result in a decrease of conduit vessel compliance and a failure to dampen out pulse pressure. Structural changes also take place in the heart, termed left ventricular hypertrophy, to increase pumping strength against the high conduit arterial pressure, which can progress to heart failure if the hypertension is not treated.

Arterial Pressure: A Quantitative Trait

Systemic arterial pressure is termed a "quantitative trait" because it is a measurable trait and because it shows continuous variation; there is not a single value for normal arterial pressure. In addition to reflecting age, gender, body mass, and potentially ethnic (genetic) origins of the individual, it is also a trait that changes continuously depending on an individual's behavior. Therefore, a value for normal systemic arterial pressure must be defined from studies of large populations of individuals with multiple measurements taken of each individual in the population, and under stringently controlled conditions. Further, the population individuals must be "equivalent"; for example one cannot combine children and adults in a population study to arrive at normal values since a child's blood pressures are generally lower than adults, and normal arterial pressure increases systematically with age of the individual, even after adulthood. Generally, the rate of increase of arterial pressures with age is steeper for those with hypertension than for those with normotension. Several studies have presented evidence that hypertension may exist even in young children, and how to define and treat such subjects remains a controversial issue. Quantitative traits, such as arterial pressure, are determined largely by the genes of the individual. This means that arterial pressures, and causes of hypertension, likely vary among diverse ethnic populations. With genetic mapping, investigators are beginning to dissect the role of genes in determining "normalcy."

Population studies provide a distribution of values of arterial pressures, even for subjects considered as having normal arterial pressure, with some individuals on the extreme low end and others on the extreme high end. An important and controversial discussion is whether the extremes in a normal population should be considered abnormal or normal. Are there definable "absolute" low and high values of arterial pressure that warrant clinical intervention and treatment (This issue is discussed further below in the section on JNC7 and JNC8). Rat and mouse studies also describe a range of arterial pressure values even among individuals identical in their genetic makeup. From many years population studies of young to middle-aged healthy adults, a set of values for "normal average" have become accepted starting points, namely 120 mmHg systolic and 80 mmHg diastolic. These values are, at best, approximations for the population of adults as a whole. To derive a position on what is normal and abnormal pressure and to get a consensus on how and when to treat individuals, several national commissions have evaluated population and clinical studies of clinicians and researchers. However, controversies remain following these commission recommendations.

It must be appreciated that an individual's pressure may be higher or lower than the normative average due to environmental factors. This is especially the case in the early stages of hypertension when other elements of the hypertension syndrome are not yet evident. Many factors must be considered in deciding "normalcy." Gender: arterial pressures of normally cycling females are generally lower than those of age-matched males or postmenopausal females. Body weight: blood pressure is influenced by body mass (increased body mass generally leads to increased pressures) and by physical conditioning. Behaviors: nonpharmacological treatments such as weight loss of 5%–10% or behavioral modification have had dramatic effects in lowering apparent hypertension to the normal values even in subjects who have been under drug treatment for years. Further, anxiety can have a profound effect in raising arterial pressure, especially systolic. For example, a well-described phenomenon termed "white coat hypertension" is an elevated arterial pressure whenever pressure is measured in a physician's office or clinical setting. This form of apparent hypertension likely reflects an over-reactive cardiovascular response to the stress or anxiety associated with the environment. White coat hypertension often disappears when the pressure is taken in a less forbidding environment, such as the residence of the individual. The use of 24 h ambulatory monitoring of arterial pressure can be used to exclude white coat hypertension and to identify extremes of arterial pressure over a typical 24 h activity day. All these, and other influences, including genetics and epigenetics, lead to "biological variability." For this reason, a thorough patient history and physical examination with appropriate and repeated blood pressure testing are essential in defining the disorder of systemic arterial hypertension.

What Defines Systemic Arterial Hypertension

When does an individual become classified as having hypertension? Based on years of studies and measurements of young, healthy adults, a generally accepted position is that systolic pressures should not exceed 140 mmHg and diastolic pressures should not exceed 90 mmHg. Critical to this definition is that arterial pressures be measured several times, over weeks, in both the physician's office and if possible a less anxious environment, and all potentially extenuating circumstances or influences be defined and excluded, to the extent possible. For many years a high diastolic pressure was a cause of major concern by the physician since it likely reflected structural remodeling of the blood vessel wall and resistance arterioles. Thus, the structural remodeling would reflect chronic or frequent episodic elevations of arterial pressure over the 24 h period. On the other hand, high systolic pressure in the office could reflect "stress" or anxiety elevation and was deemed of lesser diagnostic significance. However, more recently concerns about systolic pressure have taken the forefront, especially when diastolic pressures are "normal." The challenge is to understand the origins of the values since high systolic pressure could be compensation to high diastolic pressure, and not the primary origin of the hypertension. One may visualize this concept as systolic pressure "riding on the back" of diastolic pressure. Recall that systolic pressure is determined largely by the action of the heart and vessel compliance. In contrast, diastolic pressure is determined largely by systemic vascular resistance that controls the rate of flow of the blood out of the arterial compartment between left ventricular contractions.

Joint National Committee Reports

In 2003 the National Heart Lung and Blood Institute issued the Seventh Report of the Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, titled the JNC7 Report. The JNC7 Report argued that healthy adults should have target average (awake) systolic/diastolic pressures not exceeding 140/90 mmHg, whereas that of individuals with diabetes or chronic kidney disease should not exceed 130/80 mmHg. The JNC7 Report concluded that for individuals over 50 years of age, a systolic pressure over 140 mmHg is a more important cardiovascular risk factor than diastolic pressure. Certainly, loss of conduit artery compliance raises systolic pressure and this is much more common in an aging population. However, could lowering systolic pressure in some elderly individuals below 140 mmHg raise the potential of cerebrovascular or behavioral consequences due to underperfusion of the brain, and is there a gender component to this risk? Additionally, the JNC7 Report recommended that individuals with systolic pressures of 120–139 mmHg or diastolic pressures of 80–89 mmHg be considered as being "prehypertensive" and therefore strong candidates for lifestyle-promoting activities to prevent future cardiovascular risks. This replaced the prior concept of borderline hypertension that had, for years, extended the decision point for treatment to 90–94 mmHg. These recommendations were based on population studies showing increased risk of developing hypertension for systolic/diastolic pressures over 115/75 mmHg. The JNC7 Report also recommended treatment goals and regimens for subjects with uncomplicated hypertension (i.e., without diabetes or chronic kidney disorders).

In 2014 the Eighth JNC Report was issued which did not change or redefine the definition of hypertension or prehypertension, but did recommend new thresholds for when pharmacological therapies should be added onto lifestyle modifications. There is little disagreement that a sustained diastolic pressure exceeding 90 mmHg or a repeatable systolic pressure over 140 mmHg warrants appropriate therapeutic intervention—both pharmacological and nonpharmacological. The question of intervention becomes a physician's decision based on the individual's clinical and behavior/body mass historical parameters history, and should in this genetic era factor in gender, ethnicity, familial history of hypertension or cardiovascular disorders, diet, and environment. The rapid and facile movement of individuals from one part of the world to another clearly shows that nation's environment (and diet) change risk factors and hypertension susceptibility. Within a decade it is likely that both genetic maps and biomarkers will begin to redefine hypertension and the hypertension syndrome. Ultimately, it is likely that personalized treatments of EHT and other forms of arterial hypertension will become available based on genetics and biological markers of syndrome progression.

In 2017, in place of another Joint National Committee set of guidelines on clinical practice for hypertension and associated cardiovascular disorders, writing and evaluative committees of the American College of Cardiology (ACC) and the American Heart Association (AHA) combined with committees from other stakeholder groups to draft an extensive set of clinical practice recommendations and guidelines for cardiovascular disorders primarily for adults with definable hypertension (Whelton *et al.*, 2017). The overall intent was that it be applicable to patients with risk factors that associate with hypertension and/or complications of hypertension. One objective of this new coordinated effort was to publish updates of the guidelines on a 6-year cycle. A second objective was to try and address issues that have been somewhat controversial such as recommendations on salt intake, blood pressure levels that define hypertension, when to institute pharmacotherapy versus behavioral modification to lower systemic arterial pressure, the effect of body weight and obesity on arterial pressure, etc. The effort involved numerous ACC/AHA committees evaluating published clinical studies and basic science reports related to hypertension. The effort sought to address questions that had remained controversial after JNC7 and JNC8, and to integrate into clinical practice guidelines new findings that might advance the clinical approach to the treatment of patients with complex cardiovascular disorders. In effect this effort relates directly to the objective of advancing personalized medicine as well as the advances being made in the genetics of hypertension and other cardiovascular disorders.

The ACC/AHA Guidelines also modified the categorization of hypertension based on age and levels of systolic and/or diastolic arterial pressures *provided* arterial pressure is measured in the correct manner, as recommended. Specifically, the Guidelines

recommend that blood pressure in patients be measured on two separate occasions, using the appropriate instrumentation, such as cuff size, and under conditions that mitigate environmental or behavioral influences on the nervous system control of arterial pressure. In adults, the ACC/AHA Guidelines define "normal" adult systolic blood pressure as being less than 120 mmHg *AND* diastolic as being less than 80 mmHg. The Guidelines further define an "elevated" systolic arterial pressure as being 120–129 mmHg *AND* diastolic being less than 80 mmHg. Further, "Hypertension" is subdefined within two stages: stage 1 hypertension as systolic being 130–139 mmHg *OR* diastolic being 80–89 mmHg, while stage 2 hypertension as having a systolic pressure as *EQUAL TO OR* greater than 140 mmHg *OR* diastolic being *EQUAL TO OR* greater than 90 mmHg.

How Is Hypertension Diagnosed

Hypertension has been termed the "silent killer" because it often does not present with obvious symptoms. Although some believe that headaches and rapid heartbeat are indicators of hypertension, these symptoms are not most commonly associated with the disorder. However, frequent headaches should be discussed with your physician as it might relate to circulatory anomalies. Annual physical examinations, which include repeat blood pressure measurements, are most important to identify chronically elevated blood pressure; however, home or drug store testing can also permit a subject to track their blood pressures and HR—provided the instrumentation is reliable. This is especially important to subjects with overt anxieties who might present with white-coat hypertension. If individuals use store instruments, they should check their pressures at different sites to exclude instrument problems. Ophthalmologists and opticians may discover hypertensive individuals while examining the retina (the back inner surface of the eye). The retina is highly vascularized, and chronic untreated hypertension damages the retinal vascular bed (a damage that can be observed on examination). However, atherosclerosis and diabetes may cause similar changes in the retina, and such conditions must be excluded.

Identification of hypertension during routine physical examination should be rigorous and replicated. A single finding of elevated diastolic or systolic pressure does not constitute sufficient proof to initiate therapy, whereas dismissal of borderline readings of heightened arterial pressure without follow-up also places the patient at risk for future disease. Accurate measurement of arterial pressure is not trivial. Nearly all methods of measurement employ a form of the sphygmomanometer technique, an indirect method using the cuff occlusion. This involves measurement of the external pressure required to occlude, totally or in part, blood flow in a readily accessible artery such as the brachial artery of the upper arm. The procedure involves wrapping a "correctly sized" pressure cuff around the upper arm and inflating it to transiently stop the flow of blood through the major artery. The resumption of blood flow as the pressure is lowered is tracked. In the traditional method using a stethoscope, two characteristic sounds (termed Korotkoff sounds) are monitored. The first is the start of flow into the vessel as the cuff pressure is lowered and defines systolic (maximal) pressure while the second is when no flow sounds are present and indicates no restriction on flow, defining the diastolic (minimal) pressure. It is critical that the cuff fits the individual; too small a cuff may give an anomalously high value, whereas too large a cuff may give a falsely low value. Arterial pressure is measured with the subject sitting and, most importantly, with the cuff and occluded hand/arm being at the level of the heart. Pressures may also be taken with the subject standing (termed upright) or when the individual is in a lying-down (termed supine) position. Measurements should be taken in a calming environment to minimize stress and anxiety effects. Although automated cuff arterial pressure measuring devices found in pharmacies and food stores may be quite reliable, they cannot be used to exclude or diagnose hypertension. Repeated measurements are necessary to confirm suspected hypertension and some physicians utilize 24 h ambulatory monitoring especially if they suspect highly variable pressures over the 24 h period.

Forms of Arterial Hypertension

The most common form of human hypertension, EHT, is believed to have a strong genetic component and its origins are complex, multigenic, that is, arising from different genes in different individuals, and multifactorial. Some investigators believe that EHT reflects a variety of forms of hypertension, each due to a different abnormality of arterial pressure and/or volume regulation. EHT, being a disorder of genetic origins, explains why there is a strong sensitivity to environmental factors including salt-dependent or obesity-dependent forms of hypertension. Genetic hypertension in humans (and rodents) is believed to be the consequence of the inheritance of multiple genes that predisposes the individual (or organism) to develop the disorder, usually after puberty. EHT is age-dependent in symptom expression; however, studies indicate that elevated arterial pressures may be observed even at very early ages, leading to increased efforts to evaluate arterial pressure in children (Anyaegbu and Dharmidharka, 2014).

A smaller percentage of individuals (estimated at 10%–25%) have a form of hypertension that is attributable to a known or identifiable cause, most often of endocrine-related origins. This form of hypertension is termed "secondary hypertension." Secondary hypertension may also have a significant genetic component to disorder expression. Such genes may be directly involved (causative genes) or secondarily involved (susceptibility genes). Renovascular hypertension, believed to be responsible for 5%–10% of all human hypertension, is caused by a pathophysiological process that affects kidney blood flow and function and that results in activation of a peptide hormonal system, the renin–angiotensin system. Renovascular hypertension may be caused by a tumor or growth that impedes and restricts blood flow to the kidney. Removal of the tumor may reverse the hypertension provided that the elevated arterial pressure was not of sufficient duration to lead to irreversible changes in the kidney blood vessels structure. Chronic secondary hypertension will also trigger the hypertension syndrome, the consequence of which is that correcting the initiating causes does not reverse the hypertension and pharmacological or nonpharmacological treatments need to be

implemented. Another potential cause of secondary hypertension is a rare tumor of the adrenal medulla, a pheochromocytoma, which episodically releases into the blood stream large quantities of the neurohormones epinephrine and norepinephrine, along with other adrenal medullary mediators. Such patients exhibit episodes of very high arterial pressure. Again, removal of the tumor before it metastasizes may reverse the hypertension if irreversible changes in the arteries or kidney have not occurred.

Hypertension may also result from taking drugs that exert their direct actions on the kidney, arterial or venous smooth muscle, or endocrine systems. For example, oral contraceptive-induced hypertension became widespread shortly after the birth control pill was released for general use. Changing the composition of the pill greatly reduced the incidence of this drug-induced hypertension. This form of secondary hypertension has been attributed to sex steroid induction of the synthesis by the liver of angiotensinogen, the protein precursor of the angiotensin peptide. Angiotensin functions to promote salt and water conservation and retention, as well as increased contraction of arterial smooth muscle. Excessive formation of angiotensin may result in many actions, including increased synthesis and release of the steroid aldosterone from the adrenal cortex that directly drives salt and water retention, heightened TSVR, and blunting of the high-pressure baroreceptor reflex. Another form of secondary hypertension strikes some women during the second and third trimesters of pregnancy and poses significant risks for both the fetus and the mother. Although the causes of pregnancy-induced hypertension remain controversial, this too is a secondary form of hypertension because it generally reverses following delivery. There is evidence that these latter forms of secondary hypertension may also be under some gene influences. Lastly, there is an extreme form of hypertension termed malignant hypertension. This is a term used for patients who show extremely high and frequently irreversible hypertension. This term does not imply a cancerous origin to the disorder; rather, patients with malignant hypertension are those who have had long-standing, untreated hypertension or who fail to respond to drug therapy and combinations of antihypertensive drugs. Malignant hypertension is often associated with severe kidney failure and constitutes a medical emergency necessitating bold drug treatment to lower the blood pressure and prevent further organ damage and heart failure.

Genetic Predisposition to Hypertension

As discussed above, human EHT has a genetic origin; that is, the potential for developing hypertension may be passed from one generation to another within a family. This means that there are hypertensive-prone individuals. However, because there is also a strong influence of environment on many genes that might increase susceptibility to hypertension, it is not clear whether all hypertensive-prone individuals will eventually become hypertensive. In fact, there is evidence from animal and human studies that hypertension may be significantly delayed in onset or even prevented by appropriate control of the environment, diet, lifestyle, and exercise/activity. Remember that hypertension develops with age, so changes in lifestyle that delay the development of elevated arterial pressure will likely prevent its occurrence. Is it possible that earlier generations were hypertensive prone but that their lifestyle prevented the disorder from appearing until they were quite elderly? An interesting study conducted nearly 20 years ago with a strain of rat that spontaneously develops hypertension at 6–12 weeks of age (due to inheritance of hypertension genes) showed that if the animals were raised from birth in a stress-free environment under controlled dietary conditions, the rate of development of hypertension was greatly delayed and nearly prevented. Environmental effects also influence the state of the endocrine system, and altered hormonal secretions may be coupled to the rate of onset and progression of arterial hypertension.

Potential Causes of EHT

EHT is a multigene disorder with strong contributions from environmental factors on disease development. Discovering the cause is complicated by the many factors that determine the level of arterial pressure. A complete discussion of these factors is beyond the scope of this article; however, a brief introduction is warranted because therapy is directed at one or more of these possible causative mechanisms.

There is ample evidence from both animal and human studies that an elevation of activity of the sympathetic branch of the ANS is observed in all forms of hypertension. This system is critical to arterial pressure regulation and nearly all the effective antihypertensive drugs in use today interfere, directly or indirectly, with sympathetic activity or its physiological effects. Physiologically, if the sympathetic branch of the ANS is blocked with drugs, individuals show a loss of arterial pressure control in going from a supine position to an upright one (termed postural hypotension). In addition to effects on the heart and blood vessels, the sympathetic system is important in autonomic regulation of glucose and fat metabolism, coupling hypertension with diabetes, atherosclerosis, and obesity. Perhaps most important, the sympathetic branch is a major mechanism for stimulating secretion of the proteolytic enzyme renin into the blood by the kidney. Renin enzymatically releases an inactive angiotensin peptide from a precursor protein, angiotensinogen, which undergoes enzymatic conversion by an enzyme known as ACE, to a family of biologically active peptides of which angiotensin II is the major active peptide hormone. Angiotensin II promotes salt and water retention, will directly increase TSVR and arterial pressure, and is also a potent inhibitor of the high-pressure baroreceptor reflex, which would normally reduce sympathetic activity if arterial pressure became too high. Blockade of the receptor for angiotensin II or its enzymatic formation constitutes a class of drugs very important to the therapy of almost all forms of arterial hypertension.

In addition to autonomic control, regulation of systemic arterial pressure is achieved through electrolyte (e.g., sodium, potassium, chloride) and water homeostasis. Endocrine mechanisms are central to volume control mechanisms and operate both

within the CNS and in peripheral organ systems. A very common finding with established EHT and many forms of secondary hypertension are abnormalities in kidney function that lead to abnormal retention of sodium and, with it, water. Adrenal cortex steroid hormones, such as aldosterone, and vasopressin secreted by the pituitary, are also involved in salt and water homeostasis. Restriction of sodium (or salt) intake can lower arterial pressure in most hypertensive patients, yet severe restriction may be counterproductive because too little sodium intake actually activates the renin and angiotensin systems.

There is strong epidemiological evidence that excessive dietary salt intake elevates population averages of arterial pressure, and many studies have demonstrated a positive relationship between the amount of salt consumed in the diet and the incidence of hypertension. Yet we now know from human and rodent genetic studies that salt intake and the effect of salt on arterial pressure are also genetically controlled. We have found in rodent genetic studies that genes that control salt sensitivity of arterial pressure are inherited independently of genes for hypertension, at least in this rodent genetic hypertension model. Therefore, salt sensitivity of arterial pressure is an inherited trait; however, coinheritance of genes for salt sensitivity with one or more genes predisposing to hypertension may exacerbate the disorder and likely leads to onset of hypertension at an earlier age.

As discussed above, kidney function is central to sodium-volume homeostasis and through this mechanism has a very important role in normal homeostasis of systemic arterial pressure. However, there is also crosstalk between the kidneys and the CNS in this process, through nervous system pathways. The kidney communicates information on its functioning to the CNS (via the spinal cord to the brainstem) through sensory nerves, termed kidney afferents, and receives action signals via motor nerves, termed efferent, as well as from CNS-controlled hormonal (chemical) mediators. The role of the kidney afferents in normal and aberrant arterial pressure control has received much study over the past three to four decades. Recent clinical trials are investigating the effect of interrupting kidney–CNS communications as a mechanism of controlling hypertension, especially in subjects with a form of salt-sensitive hypertension resistant to pharmacological control. This kidney–brain communication should be appreciated as another mechanism for homeostatic control of volume and arterial pressure.

An attractive theory is that repeated exposure to stress in everyday life activities may result in abnormal cardiovascular responses in genetically predisposed, hypertensive-prone individuals. This would constitute a gene—environment interaction as a potential cause or contributor to EHT. It is possible that repeated stress leads to irreversible changes in arterial blood vessels and endocrine mechanisms resulting in a sustained elevation of TSVR and ultimately to hypertension. Behavioral stressors have been shown to result in adjustments in CO, and repeated changes in blood pressure due to stress may cause a resetting of the baroreceptor reflex associated with hypertension. There is genetic evidence that supports the effects of stress on increases in blood pressure. Individuals with family histories of hypertension exhibit heightened cardiovascular responses to both physiological and psychological stressors compared with those with no family histories of hypertension. Although it may be intuitive to expect that repeated exposure to stressful situations would have some adverse cardiovascular effects, there is no evidence supporting a "hypertensive personality."

The potentially deleterious effects of mental stress on the cardiovascular system may reflect an impaired "coping" mechanism. A failure to habituate to, or cope with, stress appears to pose an inherent risk factor in the development of hypertension; however, it remains uncertain whether it merely exacerbates the hypertension, increases its rate of development, or increases the risk of hypertension-induced organ system damage. Finally, the majority of research suggests that stress-induced increases in arterial pressure and changes in CO that lead to the development of hypertension, over time, are the result of increased activity of the sympathetic nervous system. One reason why it is difficult to resolve the role of stress in the development of hypertension is the complex interplay of multiple endocrine mechanisms that regulate arterial pressure and blood volume. There is also a complex genetic component in both physiological and psychological coping or adjustment to stress that has not been resolved.

Not only arterial pressure and HR but also metabolic factors (Cao, 2014), such as blood glucose, insulin, other neurohormones, and endocrine secretions, exhibit inherent diurnal rhythms. Some hypertensive individuals (and genetic hypertensive rats) exhibit abnormal diurnal arterial pressure and HR rhythms (nondippers). This abnormal rhythm has been associated with evidence of cardiovascular damage. However, unpublished animal genetic studies suggest that dipping or nondipping is an "independent factor" from susceptibility to exhibit hypertension. In other words, separate genetic influences determine both traits —diurnal variations and genetic hypertension; independent inheritance leads to subjects showing both traits. The indirect effect of abnormal diurnal endocrine and metabolic mechanisms could also tie with and have a direct role in the complex hypertension syndrome in some subjects.

Therapy of Hypertension

When to initiate therapy for suspected arterial hypertension and which type of therapy to implement first have been quite controversial. Therapy takes the form of either antihypertensive drugs (i.e., pharmacological therapy) or nonpharmacological approaches such as behavior and lifestyle modification. For secondary forms of hypertension drug therapy, along with surgery as needed, may be the treatment choice. However, with EHT whether to treat or not depends on the classification of severity and the presence or absence of other risk factors (e.g., diabetes, atherosclerosis, obesity, heart condition). Borderline or prehypertension should always be addressed first by behavior and lifestyle modification before pharmacotherapy. Mild to moderate hypertension warrants both nondrug and drug therapy. The primary goal of all therapeutic approaches must be to lower the excessive arterial pressures into the normal range for the individual's population norm, or achieve a pressure as low as possible consistent with patient acceptability and compliance. All therapeutic approaches must be individualized to the patient.

Among nonpharmacological approaches are weight reduction, restriction of salt intake, stress reduction including meditation, lifestyle changes, exercise, potentially acupuncture, discontinuance of alcohol intake, and cessation of smoking. For some individuals, these nonpharmacological therapeutic approaches may be all that is needed. For example, three decades ago it was shown that a relatively small reduction in body weight (less than 10%) markedly lowered arterial pressure in EHT subjects allowing a reduction or even total discontinuance of antihypertensive drugs in some patients. Weight reduction achieves two immediate goals: reduction of the workload placed on the heart and reduction in total blood volume. Stress reduction lowers sympathetic drive, thereby lowering activation of neurohormones and decreasing heart stimulation. Nondrug therapies such as stress reduction may take several months before evidence of their effectiveness is clear. For this reason, patients are usually placed on limited antihypertensive drug therapy to assist in lowering the blood pressure more quickly. Whether or not this is necessary depends on the individual patient.

The JNC7 and JNC8 Reports differ somewhat in their recommendations for treatment approaches. While both have similar treatment goals (targets for optimum arterial pressure control), they differ somewhat in treatment approaches when the disorder is confounded by other factors such as diabetes, kidney disease, and heart problems. Pharmacotherapy of hypertension has always employed what is termed a "stepped care approach." Specifically, this approach starts with trying a single drug to control the hypertension and adding or substituting additional drugs to get to the target goal of arterial pressure. The JNC7 recommended starting with a diuretic while JNC8 provides several potential starting first-line agents: diuretics; calcium channel blockers; angiotensin converting enzyme inhibitors (ACEI); or angiotensin receptor blockers (ARB). Due to the baroreflex resetting phenomenon (discussed above), almost every first line antihypertensive drug necessitates co-addition of a diuretic. Again, this is because the increased arterial pressure was necessary to adequately blood-perfuse the kidneys and allow for optimum sodium and water excretion. When increasing the dumping of sodium and water, the function of a diuretic, there may be excessive potassium wasting as well. This can lead to adverse cardiovascular effects and some physicians prefer to use a diuretic that is "potassium sparing," that is, does not lose blood potassium ion along with the sodium ion and water. Popular first-line drugs today are beta-adrenergic blockers (which block cardiac stimulation or decrease sympathetic nervous system activity) and angiotensin system blockers (ACEI or ARB). For both classes of antihypertensive agents a diuretic must be added for long-standing hypertension so as to control against sodium/water retention. To get further insight into pharmacological agents useful to treat arterial hypertension, access the JNC7 and JNC8 Reports that are available via the Internet.

It is generally considered that, with time (years), patients will progress to either combinations of drugs or the stronger third-line agents. However, many investigators believe that there has been inadequate attention to combining nondrug methods with pharmacotherapy. Reliance on pharmacotherapy without strong efforts to promote concurrent nondrug therapies has demonstrated that progression is inevitable.

Conclusion

Hypertension is a disorder of regulation of systemic arterial pressure and constitutes a complex syndrome, not a single-entity disorder. EHT and many forms of secondary hypertension have major genetic elements that dictate predisposition to the disorder. Early recognition of abnormal regulation of arterial pressure is essential if progress to additional cardiovascular damage is to be arrested. All therapeutic approaches must focus on slowing progression of the disorder and returning, if possible, the arterial pressure to population-defined normative limits. However, what is normal arterial pressure for one individual may be abnormal for another, or conversely, what is abnormal for one individual may be normal for another. Arterial pressure permits organisms to function and survive. It must be understood that hypertension may be the result of efforts by the body to satisfy the cardiovascular and autonomic requirements of the individual. Reversing hypertension without addressing the origins of the elevated arterial pressure may be therapeutically inadequate and potentially detrimental. Until more is known about the genes that regulate cardiovascular and autonomic coupling, the approach to the treatment of hypertension must be to slow progression of the disorder. Thus, treatment of hypertension involves an ongoing series of decisions and evaluations by the physician based on the individual patient. Continued interaction and communication among patient, physician, and health professional are essential to the prevention of the damaging effects of hypertension. In the case of hypertension, as with many diseases or disorders, prevention remains the preferred first step in treatment.

Autonomic Cardiovascular Control

Several are the hypothesis for the autonomic dysfunction occurring in the hypertensive state. The first is related to the impairment of the baroreflex, that is, of a major restraining mechanism of parasympathetic tone. The impaired parasympathetic modulation of the heart by the arterial baroreceptors is documented by the less responses to the vasoactive drug technique or by the spontaneous baroreflex sequence technique. This impairment does not involve the sympathetic component of the baroreflex function (Grassi, 2010). However this do not mean that reflex cardiovascular regulation may not be involved in the adrenergic overdrive. Several data have observed that a resetting of baroreflex toward elevated blood pressure levels is present in hypertension thus indicating a preservation of its influence rather than a suppression of the increased sympathetic activity (Grassi *et al.*, 1998). Second is the observation that the sympathoinhibitoy influences of cardiopulmonary receptors, which control circulating blood volume and release of vasoactive substances such as atrial natriuretic peptides, vasopressin and renin, is reduced in the hypertensive state (Grassi, 2010). The third hypothesis claims that the sympathetic activation and the parasympathetic inhibition seen in hypertension depend on the hyperinsulinemia and the related insulin resistance which are frequently ($>40\%$) present in the hypertensive state (Scherrer and Sartori, 1997). It is also evident the opposite, that is sympathetic activation may cause insulin resistance. This is supported by the evidence of a greater sympathetic activation when conditions characterized by insulin resistance, such as obesity and complicated obesity, are associated with hypertension (Seravalle and Grassi, 2017).

Adrenergic Tone and Target Organ Damage

Different techniques to investigate the adrenergic tone have clearly shown an increased norepinephrine spillover in the kidney and in the heart in young borderline hypertensives. This condition and the pre-hypertensive state are also characterized by an increased sympathetic nerve traffic directly recorded to the skeletal muscle (Seravalle *et al.*, 2015). This hyperadrenergic activation undergoes a progressive and further potentiation with the increase in blood pressure values and with the increase in age.

Metabolic alterations associated with an increase in insulin resistance (Seravalle and Grassi, 2016), alterations in dipping profile, presence of white coat and masked hypertension, are all characterized by a sympathetic overdrive.

The hypertension-related increase in adrenergic outflow appears to be peculiar to the hypertensive state of essential nature. This is documented by the evidence that the secondary forms of high blood pressure elevation caused by primary hyperaldosteronism, renal arterial stenosis or by adrenal pheochromocytoma appear not to be characterized by an elevated sympathetic outflow (Grassi *et al.*, 1998) (**Fig. 1**).

Several evidences have clearly shown that the sympathetic activation is able to promote cardiac and vascular alterations and to impair renal function. The increase in left ventricular hypertrophy (Grassi *et al.*, 2009) and the development and progression of arterial wall hypertrophy and remodeling (Heagerty, 1997) not only are able to maintain the blood pressure elevation but also contribute to the increase in morbidity and mortality rate described in untreated hypertension.

☆*Change History*: December 2017. G. Seravalle, G. Grassi and G. Mancia included two new paragraphs on "autonomic cardiovascular control" after "cardiac and neural mechanisms" and "adrenergic tone and target organ damage" at the end of the chapter. The last new paragraph included also a new Figure.

GWAS	Genome-wide association studies
RAS	Renin–angiotensin system
THP	Uromodulin or Tamm–Horsfall glycoprotein
UMOD	Uromodulin gene

Introduction

Arterial hypertension and cardiovascular disease have been identified both as a cause and as a consequence of chronic kidney disease (CKD) (Anon, 1996; Mailloux and Levey, 1998; Walker, 1993). Even today hypertension is the major single more important risk factor for CKD (defined as glomerular filtration—GFR—rate less than 60 mL/min) (U.S. Renal Data System, USRDS, 2017).

Epidemiology

The specific aspect of epidemiology of CKD in relation to hypertension. At least 30% of adult individuals can be diagnosed as hypertensive (Kearney `*et al.*, 2005), also if classification criteria vary somehow according to differences in guidelines (Mancia *et al.*, 2013; Whelton *et al.*, 2017). Whatever the case, the prevalence of hypertension is higher among patients with CKD. This is of particular clinical relevance since CKD must be considered as part of the rising worldwide burden of noncommunicable disease as hypertension, diabetes mellitus (DM), and obesity. Moreover hypertension, DM, and obesity are strong risk factors for CKD itself. While the rate of hypertension control is discouraging, since less that 50% of hypertensives have controlled blood pressure (BP) with treatment (Pereira *et al.*, 2009; Crim *et al.*, 2012), the rate of hypertension increases with the severity of renal insufficiency (Coresh *et al.*, 2001). As GFR decreases, the prevalence of hypertension rises significantly (**Table 1**).

To conclude, CKD prevalence is relevant to hypertension because hypertension is extremely common in CKD patients. As GFR decreases the prevalence of hypertension rises significantly.

Hypertensive Nephrosclerosis

Also if the precise cause of hypertension is not clear for the majority of affected individuals, the idea that the kidney plays a role in hypertension dates back almost 200 years. Among the first who shed some light on the relationship between kidney and hypertension, in the 19th century, Richard Bright (Jay, 2000) found an association between abnormalities of urine composition (albuminuria), of urine production (dropsy) or kidney macroscopic appearance (contracted kidneys) with hard pulse and

Table 1 CKD stage definitions and prevalence of hypertension

	CKD stage[a]		*% HBP*
eGFR (mL/min/1.73 m^2)	≥90 normal and high	G0	23.3%
	≥90 normal and high + *markers*	G1	35.8%
	89–60 mild reduction	G2	48.1%
	60–30 moderate–severe reduction	G3	59.9%
	30–15 <15 severe reduction—kidney failure	G4–G5	84.1%

[a]CKD stage: A patient is said to have chronic kidney disease (CKD) if abnormalities of kidney function or structure are present for more than 3 months. The definition of CKD includes all individuals with markers of kidney damage or those with an eGFR of less than 60 mL/min/1.73 m^2 on at least two occasions 90 days apart (with or without markers of kidney damage).

According to one recent NHANES survey. Prevalence of hypertension also varies with the cause of CKD. Strong association with hypertension in presence of renal artery stenosis (93%), diabetic nephropathy (87%), and polycystic kidney disease (74%) (Crim *et al.*, 2012).

Markers of kidney disease may include albuminuria (ACR >3 mg/mmol), hematuria (or presumed or confirmed renal origin), electrolyte abnormalities due to tubular disorders, renal histological abnormalities, structural abnormalities detected by imaging (e.g., polycystic kidneys, reflux nephropathy) or a history of kidney transplantation.

CKD classification. CKD is classified based on the GFR and the level of proteinuria.

hypertrophied hearth as in the case of long lasting hypertension (Bright, 1836). Shortly after, besides confirming the association of increased arterial pulse tension, hypertrophy of the left ventricle with contracted, sclerotic kidneys, Toynbee and Johnson reported also that there was hypertrophy of the arterial walls and obstruction of systemic capillaries in the microdissections of the diseased kidneys (Toinbee, 1843; Johnson, 1868). In 1856, Ludwig Traube argued that cardiac hypertrophy in Bright's disease was due to increased pressure within the arterial system, renal disease being always the prime mover (Traube, 1856).

Only a century later the importance of the kidney in the pathogenesis of hypertension was unquestionably acknowledged, though leaving unresolved the question whether hypertension is cause or consequence of kidney disease. Indeed, the kidney is unique among the target organs of hypertension as it both suffers damage and contributes to its pathophysiology through several different pathways. The observation was synthetized in a seminal clinical paper by Chasis and Baldwin who pointed clearly in the sixties to the frequent association of hypertension and intrinsic renal diseases as well as to the relationship between hypertension and the occurrence of major renal artery disease and/or specific renal functional abnormalities as adrenal hyperplasia or chronic glomerulonephritis (Chasis and Baldwin, 1966).

Today hypertensive nephrosclerosis or glomerulosclerosis is considered a major cause of CKD or of end-stage renal disease (ESRD). Though more frequent in individuals of African origin, they are present in all ethnicities. While the terms themselves remain an easy escape that indicates our limited ability to classify the kind of renal insufficiency (potentially also an underlying neglected chronic glomerulonephritis complicated by hypertension), metabolic derangements, as obesity, oxidative stress, dyslipidemia, and atherosclerosis are often confounding factors as well as precipitating cofactors. Some sort of accelerated aging of the renal microvascular bed and glomerular sclerosis are a fairly common morphologic finding, with arteriolar intimal thickening (in more severe cases arteriosclerosis or hyalinosis), explaining the association hypertension (Glassock and Rule, 2016). Together with the vascular and glomerular, an at least equally severe tubulointerstitial damage occurs, with tubular atrophy and interstitial fibrosis due to loss of peritubular capillaries (Nangaku, 2006).

Pathophysiologic Considerations

A century after Bright's observation, Harry Goldblatt demonstrated that he could induce severe hypertension in dogs by obstructing one of the renal arteries (Goldblatt *et al.*, 1934), while the conclusive achievement was provided by Arthur C Guyton, demonstrating that the kidney affects BP regulating extracellular fluid volume, argued that chronic hypertension could not occur in the absence of impairment of renal handling of sodium. Guyton showed that any acute rise in BP resulted in brisk increase in renal sodium excretion and normalization of BP unless sodium excretion was hampered by renal ablation (e.g., as in the Goldblatt model), or by angiotensin or aldosterone infusion (Guyton *et al.*, 1980; Hall, 2003). Conversely when sodium excretion was hampered, BP increase was first mediated by extracellular fluid (ECF) volume expansion, slight reduction of total peripheral resistance, and reflex increase of cardiac output. Later ECF volume and cardiac output tended to normalize and high BP resulted from high peripheral resistance, substantially indistinguishable from high BP observed in essential hypertension (Guyton, 1990).

Though the exact nature of renal defect or defects responsible for inappropriate sodium excretion, or of factors that mediate the subsequent rise in peripheral resistance, remain unclear in essential hypertension, Guyton introduced the concept of pressure–natriuresis, meaning that when BP increases from any cause, renal perfusion pressure increases as well, with a resulting increase of sodium and water excretion. Based on the substantial capacity for a normal kidney to excrete sodium, this BP-tempering mechanism has sufficient gain to limit intravascular volume and thereby to lower BP. Guyton demonstrated that the system works in response to several tested experimental hypotheses as increased heart rate and peripheral resistance (Guyton, 1991). Guyton's model *imposes* that some change of the pressure–natriuresis response must happen to perpetuate a chronic elevation in intraarterial pressure in such a way that the equilibrium point for salt and water excretion is shifted to a higher level of arterial BP (Guyton, 1990). A rightward shift and less steep slope of the pressure–natriuresis function could account for the primary mechanism leading to Na/volume retention (**Fig. 1**).

While Guyton did most of his experimental observations on computer simulations and on nonhuman mammals, some indirect evidences on the primacy of the kidney in the pathogenesis of hypertension are available also for humans. At least two family history studies tell us that kidney transplant recipients of a kidney from a normotensive family need less antihypertensive treatment and have lower BP than the recipients of a kidney from a hypertensive family (Guidi *et al.*, 1996) or see their BP treated after transplantation (Curtis *et al.*, 1983) while one pathology study on victims of car accidents that were otherwise healthy besides their BP demonstrated that those with high BP had fewer nephrons at autopsy than those with normal BP (Keller *et al.*, 2003).

Severity of Renal Damage and Salt Sensitivity

While it is relatively easy to assign to the kidney a causal role in hypertension when gross morphological damage is evident, it is less intuitive to accept it when such damage is minimal or even absent. Experiments performed inducing hypertension with the "two-kidney, one-clip maneuver," where only one kidney is clipped and the other is left in site, untouched provide the best example for it. BP is mildly increased and often returns to normal with time. Hypertension is initiated by the activation of the renin–angiotensin system from the clipped, ischemic kidney and removal of the clip may rapidly normalize BP. However, if the clip is kept in place for enough time, some damage may have occurred in the unclipped kidney, as it has been perfused at high BP.

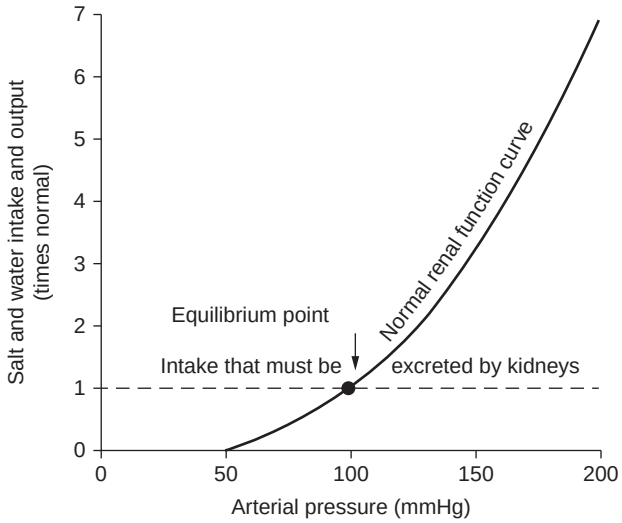

Fig. 1 Equilibration of the normal renal function curve with the salt and water intake. Point labeled "equilibrium point," where the curve crosses the line, gives pressure level at which kidney-fluid mechanism will control arterial pressure. From Guyton, A. C. (1990). The surprising kidney-fluid mechanism for pressure control—Its infinite gain! *Hypertension* **16**, 725–730.

On histological examination the lesions are very mild indeed, but are enough to cause a form of salt sensitive hypertension and similar to those obtained experimentally after angiotensin infusion (Johnson *et al.*, 2002).

Salt Intake, Kidney and Blood Pressure

This ability of the kidney to tolerate a sodium load declines with age, so that even small increases in salt intake may lead to a rise in BP at later ages.

Though short-term effects of change of salt intake on BP are evident in hypertensive and prehypertensive subjects, some still debate the long-term effects on stable BP and on cardiovascular prevention debated (Cappuccio, 2016; Graudal, 2016). However, not only general opinion but also current WHO recommendations propose a strong action for reducing salt intake to about half actual value (Beaglehole *et al.*, 2011), in order to reduce BP and cardiovascular and renal risk. The reason for the persistence of the debate against generalized measures of salt reductions can be found in the large interindividual differences in the response to salt restriction, as in **Fig. 2**. The figure reports an old, but crucial experiment that showed how large can be the heterogeneity of the response to such maneuver in individuals. In order to maintain optimal environmental homogeneity, healthy, normotensive free-living volunteers participated. The study investigated the effect on BP of the reduction of salt intake for 3 months from an average intake of sodium of 150 mmol/day (which is standard for a western diet) to less than 75, which approximates the level now proposed by WHO. Results indicated significant decrease in both systolic and diastolic BP, however with such a large inter-individual variability that at least 10% of the participants experienced BP increase and another 25% did not see substantial BP change (Miller *et al.*, 1987). The experiment tells us not only that BP can be reduced lowering salt intake also in normotensives, but that the response to reduced salt intake is largely heterogeneous. Indeed, lowering sodium intake has larger pressor effect on individuals of African ancestry, middle and older-aged subjects (Luft *et al.*, 1983) and those with already high BP values, with DM or with CKD. Notably, categories that share blunted RAS (He *et al.*, 2001).

The heterogeneity in BP response to change in salt intake is defined salt-sensitivity, classifying those that respond with BP change to change in salt intake or to Na load or depletion as salt-sensitive and those that do not despond as salt-resistant. The detection of salt-sensitivity has substantial clinical relevance, not only because salt-sensitivity is an important risk factor for cardiovascular and renal disease (Weinberger *et al.*, 2001), but also for the simple, intuitive factor that salt-sensitive hypertensives can reduce substantially their BP reducing salt intake.

Renal Sodium Handling Along the Nephron and Blood Pressure Regulation

Sodium homeostasis depends on the intrinsic capacity of the kidney to produce glomerular ultrafiltrate and on its ability to reabsorb salt at different levels along the nephron. Due to their complex regulation, the renal epithelial sodium channels (ENaC) are a major player of sodium balance. Located in the cortical collecting duct, they are under renin–angiotensin–aldosterone system control. The complex interplay of the system depends from the fact that Angiotensin II is produced as a response to decreased renal oxygen tension or decreased perfusion pressure. Angiotensin II production aims to bring back BP to its normal value, causing vasoconstriction, increasing sympathetic nerve activity and myocardial contractility. Angiotensin II also directly stimulates

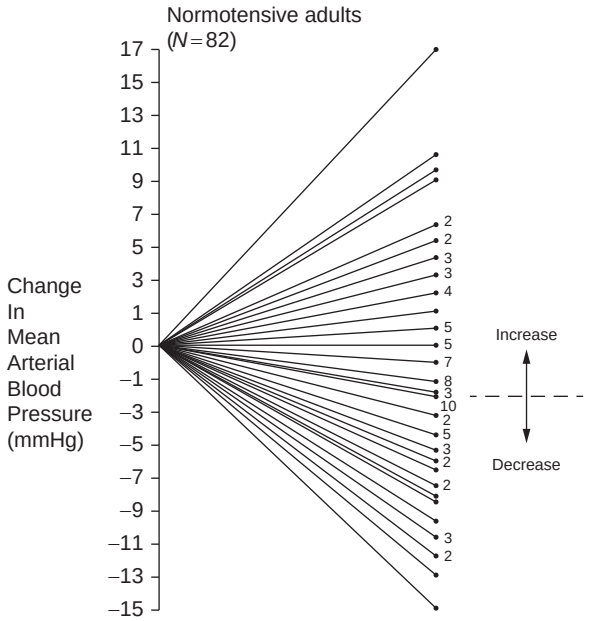

Fig. 2 Change in blood pressure with sodium restriction for 3 months from the average Caucasian diet of 150 mmoles Na day to 75 mmoles Na day in 82 adults. Displayed are the differences between the mean BP before staring diet and after and diet intervention for each individual. Overall BP decreased slightly but significant ($P < .01$) with sodium restriction. Older individuals were more likely to respond to sodium restriction. It is evident that the individual BP responses were heterogeneous, with increases in pressure observed in some subjects. Notably, sodium restriction in all normotensive adults *may not* be innocuous. From Miller, J. Z., Weinberger, M. H., Daugherty, S. A., Fineberg, N. S., Christian, J. C., Grim and C. E. (1987). Heterogeneity of blood pressure response to dietary sodium restriction in normotensive adults. *Journal of Chronic Disease* **40**, 245–250.

aldosterone production that induces the synthesis of ENaC subunits that assemble in channels in the plasma membrane or by increasing the probability that the channels are open permitting the passage (reabsorption) of sodium (Fuller and Young, 2005).

As renal sodium handling plays a crucial role in BP regulation, the systems involved in sodium handling and the underlying genetic mechanisms have been object of research for many years for understanding their roles in sodium homeostasis and salt sensitivity.

While there is no doubt that a positive salt balance plays a fundamental role in renal hypertension, other factors as the activation of the renin–angiotensin system (RAS) (Rassler, 2010), increased production of endothelin (Elijovich and Laffer, 2002), and endogenous digitalis-like substance (Blaustein *et al.*, 2009); reduced generation of vasodilators such as nitric oxide (Raij, 1999) and kinins (Mamenko *et al.*, 2014).

Family studies estimated heritability of salt-sensitive phenotype from moderate to high (Gu *et al.*, 2007; Svetkey *et al.*, 1996), with large difference between different studies, probably due at least in part to differences in ethnicities. Whatever the case, elucidation of the genetic contribution to BP salt sensitivity provides important information on how polymorphism in the genes controlling sodium reabsorption interact with sodium intake influencing individual BP value. Dissecting Mendelian forms of BP variation where mutations in single genes impart large effects on BP helped to identify fundamental pathways which could affect BP in humans (**Fig. 3**; Lifton *et al.*, 2001). While the figure summarizes only the diseases of Na reabsorption inherited in Mendelian forms (hypertensive disorders in *red* and hypotensive disorders in *blue*), a large number of proteins performing or controlling renal Na transport or other proteins controlling hormone synthesis or release affecting sodium transport became candidates for genomic research since they took part to the same physiological pathway. The list of candidate genes associate to hypertension is very long but provided however inconsistent results (Basson *et al.*, 2012; Singh *et al.*, 2016) except for the face that the vast majority of the positive findings was pointing to renal mechanisms.

The picture does not seem having been improved by genome-wide association studies (GWAS) (Padmanabhan *et al.*, 2017). In spite of a tremendous effort spent by large consortia involving tents of groups worldwide and typing thousands of individuals along the genome, also in this case, despite the increasing pace of discovery of variants associated with BP, CKD, and HTN, the utility of the discoveries seems limited, with the sole exception of the UMOD gene.

Uromodulin Rediscovery

Uromodulin or Tamm–Horsfall glycoprotein (THP) (Tamm and Horsfall, 1952) is a glycoprotein well known to nephrologists. It can be found in abundance in the urines of all mammals and is part of the matrix of renal stones. What seems important is that it is the most abundant protein excreted in urine, low urinary levels of uromodulin suggest predisposition to renal stone formation,

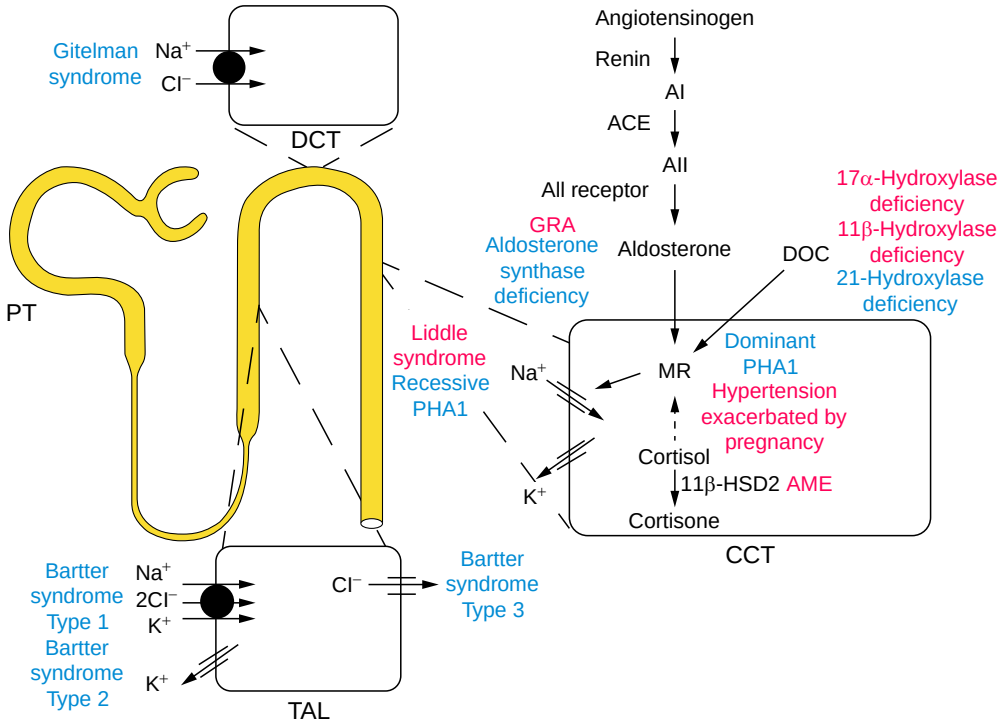

Fig. 3 Schematic representation of a nephron. The molecular pathways mediating NaCl reabsorption in individual renal cells in the thick ascending limb of the loop of Henle (TAL), distal convoluted tubule (DCT), and the cortical collecting tubule (CCT) are indicated, along with the pathway of the renin–angiotensin system, the major regulator of renal salt reabsorption. Inherited diseases affecting these pathways are indicated, with hypertensive disorders in *red* and hypotensive disorders in *blue*. *AI*, angiotensin I; *ACE*, angiotensin converting enzyme; *AII*, angiotensin II; *MR*, mineralocorticoid receptor; *GRA*, glucocorticoid-remediable aldosteronism; *PHA1*, pseudohypoaldosteronism, type-1; *AME*, apparent mineralocorticoid excess; *11 HSD2*, 11-hydroxysteroid dehydrogenase-2; *DOC*, deoxy-corticosterone; and *PT*, proximal tubule. From Lifton, R. P., Gharavi, A. G. and Geller, D. S. (2001). Molecular mechanisms of human hypertension. *Cell* **104**, 545–556.

uromodulin binds to *Escherichia coli* and seems to mitigate renal bacterial infections. It is encoded in humans by the UMOD gene. More importantly uromodulin regulates the activity of the sodium–potassium–chloride transporter (Mutig *et al.*, 2011) and of the renal outer medullary potassium channel (ROMK) (Renigunta *et al.*, 2011), the two main ion transporters involved in NaCl reabsorption by the thick ascending limb of Henle's loop, crucial for sodium reabsorption. In 2009 UMOD locus was associated to CKD (Köttgen *et al.*, 2009) and in 2010 to HTN (Padmanabhan *et al.*, 2010). Susceptibility variants detected in the UMOD gene are located in the promoter of the gene, have a high frequency in the general population and confer increased risk for CKD and for hypertension (between 15% and 20%). Transgenic mice overexpressing UMOD increase THP renal excretion, have BP higher and more sensitive to furosemide than controls (Trudu *et al.*, 2013), while UMOD knockout mice have low BP and are salt-resistant (Graham *et al.*, 2014). Interestingly, also humans carrying the risk allele in homozygous form were, like transgenic rodents more sensitive to furosemide (had prompt natriuretic response and reduced their BP more than the rest of the sample) (Trudu *et al.*, 2013).

Endocrine Hypertension☆

Inga Harbuz-Miller, Ryan Woodman, and Guido Lastra, University of Missouri, Columbia, MO, United States

Glossary

Atherosclerosis A disease of the intima of the arterial wall characterized by smooth muscle migration and proliferation with extracellular lipid deposition.

Atrial natriuretic peptide A polypeptide synthesized, stored, and released by atrial myocytes in response to expended extracellular volume.

Leptin A hormone that helps regulate the energy balance, mainly secreted by adipocytes.

Microalbuminuria The ratio of albumin to creatinine of more than 30 μg/mg but less than 300 μg/mg that is detected by sensitive radioimmune assay but not by conventional urine dipstick.

Natriuresis The process of excreting sodium in the urine.

Plasminogen (tissue) activator A thrombolytic factor that activates plasminogen to plasmin.

Plasminogen activator inhibitor-1 A substance produced by visceral and omental fat cells that inhibits tissue plasminogen activator; elevated in persons with diabetes and cardiometabolic syndrome.

Von Hippel–Lindau disease Hemangiomas of the retina, cerebellum, brainstem, and spinal cord as well as pancreatic cysts, adenomas, and carcinomas; autosomal dominant inheritance, with 20% developing pheochromocytomas.

Introduction

Hypertension represents one the single most important preventable contributing factor to morbidity and mortality worldwide (James *et al.*, 2014). Multiple endocrine disorders present with HTN as the initial clinical sign and early recognition can lead to successful medical or surgical treatments that in some cases are curative (Young *et al.*, 2017). This article explores the most frequent endocrine causes of HTN. Understanding the relationships between different hormonal axis and their impact on regulation of blood pressure is important to the diagnosis and management of HTN.

Obesity-Induced Hypertension

Obesity is a major public health burden in the United States and more than 300,000 deaths each year are attributable to obesity or overweight (Flegal *et al.*, 2010). The relationship between obesity and HTN was first shown in the Framingham Heart Study where the prevalence of HTN with obesity accounted for over 60% of incident HTN (Kannel *et al.*, 1967). Furthermore, it has been demonstrated that the prevalence of HTN increases in relation to body mass index (BMI) (Brown *et al.*, 2000; Shihab *et al.*, 2012).

Potential mechanisms contributing to HTN in patients with obesity include inappropriate activation of the renin–angiotensin–aldosterone system (RAAS), increased sympathetic nervous system (SNS) activity, insulin resistance, impaired pressure natriuresis, structural changes in the kidneys that will eventually lead to chronic kidney disease (CKD) and further potentiate HTN (**Table 1**) (Demarco *et al.*, 2014; Hall *et al.*, 2015).

Obese individuals have been shown to have mild-to-moderate increase in circulating renin levels, angiotensinogen, angiotensin-converting enzyme (ACE), angiotensin II (Ang II), and aldosterone (Engeli and Sharma, 2001). The effects of obesity-induced RAAS activation was further demonstrated in obese individuals who lost 5% of their body weight, which resulted in decreased angiotensinogen, renin, ACE activity, and aldosterone levels (Engeli *et al.*, 2005). Despite sodium retention, volume expansion and HTN, the RAAS remains active in obesity-induced HTN.

Obesity is associated with activation of the SNS and with baroreflex dysfunction. SNS activity is increased in the setting of excess body weight, with obese individuals noted to have increased renal SNS activity compared to nonobese counterparts, as well as increased cardiac SNS activity in obese individuals with HTN compared to normotensive obese people (Rumantir *et al.*, 1999). Several factors have been suggested to promote obesity-associated HTN by activating the SNS, including hyperinsulinemia, hyperleptinemia, RAAS activation (via Ang II), baroreflex dysfunction, and obstructive sleep apnea (OSA) (Hall *et al.*, 2010; Lohmeier and Iliescu, 2013). Of note, OSA activates the SNS independently of obesity-related mechanisms (Narkiewicz *et al.*, 1998; Goodfriend and Calhoun, 2004). A study of both lean and obese hypertensives has demonstrated that increased SNS activity

This article is an update of Angelo M. Capricchione, Nathaniel Winer and James R. Sowers, Hypertension, Endocrine, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 592-602.

 doi:10.1016/B978-0-12-801238-3.95896-3

Table 1 Metabolic and cardiovascular risk factors associated with insulin resistance and/or visceral obesity

- Increased systolic and diastolic blood pressure
- Hyperinsulinemia/insulin resistance
- Endothelial dysfunction
- Low high-density lipoprotein cholesterol levels
- High triglyceride levels
- Increased apolipoprotein B levels
- Small, dense low-density lipoprotein levels
- Increased fibrinogen levels
- Increased plasminogen activator inhibitor-1 levels
- Hypercoagulability (increased PAI-1/plasminogen activator ratio)
- Increased blood viscosity
- Increased C-reactive protein and other inflammatory markers
- Microalbuminuria
- Absent nocturnal dipping of blood pressure and heart rate
- Increased uric acid levels
- Increased left ventricular hypertrophy
- Premature atherosclerosis (coronary artery disease and stroke)

may be an important factor in the development and maintenance of HTN in obesity, by showing that blood pressure is more sensitive to alpha- and beta-adrenergic blockade in obese than in lean hypertensive patients (Wofford *et al.*, 2001).

Insulin resistance and compensatory hyperinsulinemia are present in the majority of hypertensive individuals, and constitutes a common pathophysiologic feature linking obesity, glucose intolerance, and HTN (Modan *et al.*, 1985). Additionally, when hypertensive patients, whether obese or of normal body weight, are compared with age- and weight-matched normotensive control subjects, a heightened plasma insulin response to a glucose challenge is consistently found (DeFronzo and Ferrannini, 1991). Hyperinsulinemia may not be a major cause of obesity-induced HTN; however, insulin resistance contributes to HTN by other mechanisms including inflammation, oxidative stress resulting from abnormal glucose and lipid metabolism, activation of the SNS, renal sodium retention, altered membrane cation transport, vascular smooth muscle growth, remodeling, and vasoconstriction (McFarlane *et al.*, 2001; Demarco *et al.*, 2014).

The role of visceral adiposity and ectopic accumulation of fat in the kidney in obesity has been discussed previously. This is associated with increases in intrarenal pressure, impaired pressure natriuresis, in addition to renal sodium retention and volume expansion (Hall *et al.*, 2014). Increased tubular sodium reabsorption is closely linked to activation of the SNS and RAAS, and possible changes in intrarenal physical forces due to medullary compression by excess visceral adiposity. Obesity causes renal injury and functional nephron loss, contributing to elevated blood, further renal injury and therefore initiating a vicious cycle of further pressure increase and renal tissue damage (Aneja *et al.*, 2004).

Of interest is the progression to a chronic hypertensive state in obese individuals that appears to be preceded by a loss of nocturnal blood pressure dipping in the absence of elevated daytime blood pressure (Lurbe *et al.*, 2008; Demarco *et al.*, 2013). Although, the exact mechanisms for this nondipping pattern of blood pressure remain to be fully clarified, it has been proposed that insulin resistance, autonomic nervous system dysfunction, increased SNS activity, and increased inflammation may be contributing factors (Demarco *et al.*, 2013; Dangardt *et al.*, 2011).

The pathophysiology of obesity-related HTN remains complex, with continuous accumulation of hormonal, environmental, and genetic factors that contribute to its pathogenesis. As the prevalence of obesity continues to increase, the effect of obesity on HTN and related cardiovascular, renal, and metabolic disorders is becoming ever more important.

Diabetes Mellitus

HTN is present in more than half the patients diagnosed with diabetes mellitus (DM), regardless of type, and contributes significantly to both microvascular and macrovascular disease (Sowers *et al.*, 2001, 2011; Sowers, 2013; Stamler *et al.*, 1993). The risk for cardiovascular disease (CVD) is fourfold higher in patients with both DM and HTN compared with the normotensive nondiabetic controls (Stamler *et al.*, 1993; Hu *et al.*, 2007). Recent studies conducted in the Framingham population cohort with DM (Kivimäki *et al.*, 2010) indicate that the presence of HTN in these participants was a resulting risk factor for CVD (Chen *et al.*, 2011).

Features of HTN in diabetic patients include increased sensitivity to salt and volume expansion; accelerated atherosclerosis, which lead to premature increased stiffness of larger arteries and results in isolated systolic HTN at a relatively younger age; and loss of nocturnal dips in blood pressure and heart rate (Sowers, 2013; Kario, 2007). All of these characteristics are associated with

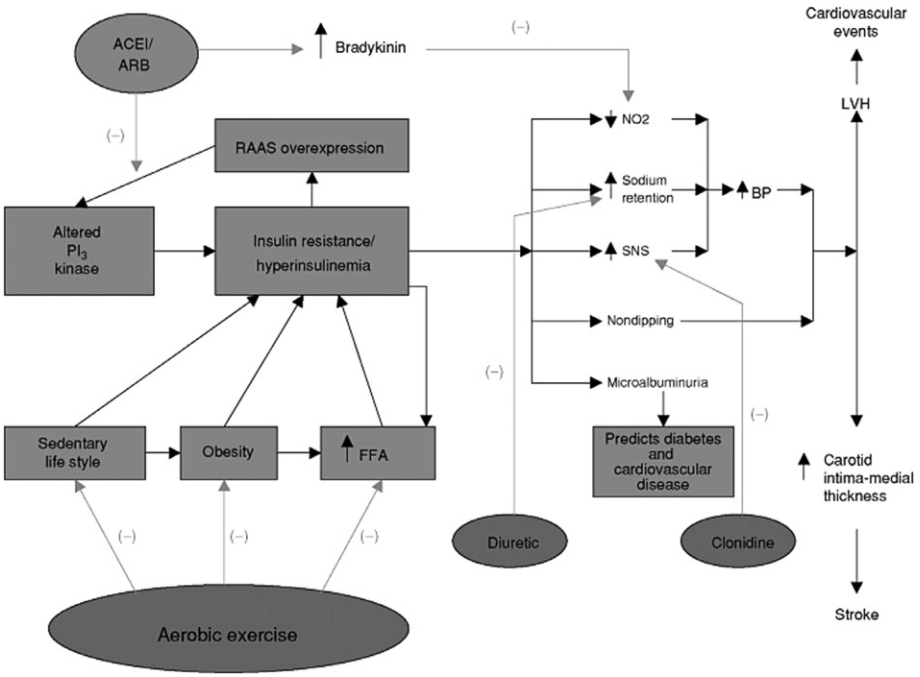

Fig. 1 Insulin resistance and cardiovascular disease. RAS, renin–angiotensin–aldosterone system; FFA, free fatty acids; BP, blood pressure; SNS, sympathetic nervous system; LVH, left ventricular hypertrophy; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; NO2, nitric oxide. Minus sign (–) indicates inhibition of pathological process.

microalbuminuria in type 2 diabetics (**Fig. 1**). Furthermore, DM and HTN share several pathophysiologic mechanisms, including inappropriate RAAs activation, excessive production of reactive oxygen species (ROS), inflammation, impaired insulin-mediated vasodilatation, increased sympathetic nervous system (SNS) activation, dysfunctional innate and adaptive immune responses, and abnormal renal processing of sodium (Sowers *et al.*, 2011; Sowers, 2013; Lastra *et al.*, 2014).

Appropriate control of blood pressure in patients with DM is important for preventing and delaying both microvascular and macrovascular complications (UK Prospective Diabetes Study Group, 1998; Hansson *et al.*, 1998). Data from landmark trials such as the United Kingdom Prospective Diabetes Study (UKPDS), Hypertension Optimal Treatment (HOT), Systolic Hypertension in the Elderly (SHEP), Systolic Hypertension in Europe (Syst-Eur), and The Appropriate Blood Pressure Control in Diabetes (ABCD) demonstrated that strict blood pressure control is beneficial in hypertensive patients with DM (Hansson *et al.*, 1998; Tuomilehto *et al.*, 1999; Curb *et al.*, 1996; Schrier *et al.*, 1996; Cushman *et al.*, 2010). Overall, these studies showed significant benefits of blood pressure management, including reductions in macrovascular diseases, including MI, sudden death, stroke, and peripheral vascular disease. Although specific targets for blood pressure are still controversial, control of HTN in the setting of DM is strongly supported by current evidence showing the critical impact that blood pressure has on CVD in diabetic individuals.

Primary Hyperaldosteronism

The incidence of primary hyperaldosteronism (PA) in individuals with HTN is 5%–10% (Mulatero *et al.*, 2004; Rossi *et al.*, 2006) and it reaches up to 20% in resistant HTN (Calhoun *et al.*, 2002; Eide *et al.*, 2004). Early diagnosis results in reduced cardiovascular morbidity and mortality. Aldosterone causes cardiac and vascular fibrosis in animals, an action prevented by mineralocorticoid receptor (MR) blockade (Lastra *et al.*, 2008; Stas *et al.*, 2007). Aldosterone antagonists improve endothelial dysfunction and decrease hospitalization, symptoms, and mortality from progressive CHF and other heart-related deaths. Eplerenone, a selective MR blocker, displays similar results and has fewer incidence of side effects, in particular related to antiandrogenic actions.

The mechanism of HTN can be attributed to excessive mineralocorticoid action, which leads to an increase in the number of epithelial sodium channels (ENaC) that reabsorb sodium in the collecting duct of the kidney. HTN is caused by sodium and water retention by the kidney, which leads to expansion of the extracellular fluid compartment. Direct effects of aldosterone on the central nervous system may contribute to HTN as well (Leenen *et al.*, 2010).

Screening for PA should be considered in all patients with refractory or severe HTN, with spontaneous hypokalemia or diuretic provoked low serum potassium levels requiring excessive potassium supplements. Importantly, approximately 61%–70% of all PA cases have normal potassium. Therefore, utilizing the association of severe HTN and hypokalemia as an indication to work up patients for PA is a poor screening method.

The ratio of aldosterone to plasma–renin activity (A/R) is a good screening test (Funder *et al.*, 2016), but may be limited due to confounding factors including: posture, dietary sodium intake, plasma potassium level, and medication. False-positive results with A/R ratio may occur in cases of renal impairment due to suppression by sodium retention, and aldosterone may be increased by the associated hyperkalemia (McKenna *et al.*, 1991). Beta-blockers, methyldopa, and clonidine may suppress renin and give false-positive results. Drugs that stimulate renin, such as diuretics, ACEIs, and dihydropyridine calcium channel blockers, falsely lower the A/R. False-negative results may occur with severe sodium restriction, pregnancy, and malignant HTN due to excessive renin, and may also occur in patients with hypokalemia, which should always be corrected prior to biochemical testing for PA (Stowasser *et al.*, 2010). Verapamil and hydralazine have little effect, whereas prazosin has no effect on A/R. Although there are no golden standard test recommended, the diagnosis should be confirmed by a high 24-h urinary aldosterone on a high'sodium diet, acute saline loading, captopril challenge, or fludrocortisone suppression (Funder *et al.*, 2008).

Once the diagnosis is established, it is necessary to distinguish between a unilateral and bilateral adenoma. Computed topography (CT) of the adrenals is the initial imaging modality and, if surgical intervention is desired, it should be followed by adrenal venous sampling for localization (Funder *et al.*, 2016). A solitary tumor greater than 1 cm in a young patient is consistent with unilateral aldosterone producing adenoma and usually constitutes an indication for surgery. A nondiagnostic CT or an adrenal mass less than 1 cm requires bilateral adrenal vein sampling to demonstrate and lateralize an adenoma, especially because CT scans miss 50% of adenomas and can incorrectly lateralize the mass. Lateralization based on an elevated aldosterone/cortisol ratio associated with contralateral suppression is more sensitive and specific than imaging and is an indication for unilateral adrenalectomy. For nonlateralization, or if sampling is not available, spironolactone is the treatment of choice.

Of the enzyme abnormalities that cause congenital adrenal hyperplasia (CAH), the two that are more frequently associated to HTN are the deficiencies of 11β-hydroxylase (CYP11B1) and 17α-hydroxylase (CYP17A1).

11β-Hydroxylase Deficiency(S)

Approximately 5%–8% of CAH cases are due to CYP11B1 deficiency (Merke and Bornstein, 2005). In cases of CYP11B1 deficiency, production of both cortisol and corticosterone is inhibited, and enhanced adrenocorticotropic hormone (ACTH) secretion further increases the production of cortisol precursors, in particular deoxycorticosterone (DOC) and 11-deoxycortisol (S), as well as androgens. Plasma renin activity (PRA) and aldosterone are both suppressed. Hypokalemia leading to muscle weakness and cramping is seen in a minority of patients. The severe homozygous classic form is common in Jewish populations (mostly Sephardic) from Morocco (White *et al.*, 1991), and at least 40 mutations have been identified with varying degrees of severity (New *et al.*, 2005). Signs of androgen excess are demonstrated in both sexes, and female infants are typically masculinized. Accelerated skeletal growth and short stature with acne and premature adrenarche are usually clinically manifest. Most patients have mild-to-moderate HTN. Diagnosis is established by demonstrating an increase in basal and/or ACTH-stimulated serum DOC, S, and adrenal androgens or elevated levels of urinary metabolites, tetrahydro-DOC and tetrahydro-S, and 17-ketosteroids in a 24-h urine collection. Steroid replacement suppresses ACTH levels, subsequently lowering both mineralocorticoid and adrenal androgen production. Potassium-sparing diuretics, such as spironolactone and amiloride, may be needed to control persistent HTN.

17α-Hydroxylase Deficiency

Delayed puberty or lack of development of secondary sexual characteristics or primary amenorrhea differentiates CYP17A1 deficiency from CYP11B1 deficiency, which might not be apparent until the expected onset of puberty. Prepubertal females appear to be normal but may later fail to develop expected normal sexual characteristics. Genetic males are phenotypically female, with a blind-ending vagina, inguinal testes, or undescended testes, or they may present with genital ambiguity. Although cortisol is not produced, adrenal insufficiency does not develop because corticosterone, which has glucocorticoid activity, is still produced in sufficient amounts. DOC is produced in excess, resulting in low-renin HTN and hypokalemia. Goals of treatment are to minimize mineralocorticoid excess, and can be achieved with the use of glucocorticoids to suppress ACTH stimulation, or spironolactone (Peter *et al.*, 1993; Mantero *et al.*, 1995).

Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism (GRA), also called dexamethasone-suppressible hyperaldosteronism or familial hyperaldosteronism type 1, was first described by Sutherland and colleagues in 1966 (Halperin and Dluhy, 2011). Inherited in an autosomal dominant fashion, GRA results from a chimeric gene fusion, where the 5′-promotor region of the 11b-hydroxylase gene (regulated by ACTH) fuses with the coding sequences of the aldosterone synthase gene. Consequently, the aldosterone production is abnormally under the control of ACTH (Lifton *et al.*, 1992a,b). This results in aldosteronism with diurnal elevations of aldosterone and responds to lowering ACTH with glucocorticoids (Vaidya and Dluhy, 2000). GRA is a mineralocorticoid excess condition, characterized by low PRA with an A/R ratio greater than 30, HTN, and spontaneous hypokalemia. Since blood pressure elevation ranges from moderate to severe and patients have normal plasma potassium levels, GRA can be mistaken as essential

HTN. However, although seldom seen GRA can be associated with an increased prevalence of early, and often fatal, cerebrovascular hemorrhage.

The diagnosis is supported by improved blood pressure following a dexamethasone suppression testing (DST), which also shows a decrease in aldosterone to nearly undetectable levels, thus demonstrating the dependency of this condition on production of ACTH. A plasma aldosterone of less than 4 ng/dL post-DST is considered sensitive and specific for diagnosis. Although suppression can also occur with aldosterone-producing adenomas (APAs) and bilateral adrenal hyperplasia (BAH), aldosterone usually falls to a lesser degree in these conditions. Furthermore, elevated 18-hydroxy and 18-oxy cortisol in the urine of patients with GRA will help to distinguish it from APA and BAH. However, sometimes these urinary metabolites are also elevated with APA. Sustained ACTH stimulation may cause an initial rise in aldosterone followed by a decline in normal persons and patients with APA and BAH, whereas in GRA the rise in aldosterone is sustained, similar to that seen with CAH. However, in contrast to CAH, patients with GRA show a normal cortisol and 17-hydroxy urinary corticosteroid response to ACTH. Since the biochemical tests used for diagnosis are subject to numerous pitfalls, genetic testing is essential for confirmation of GRA.

Although glucocorticoid suppression is the treatment of choice, normalization of blood pressure might not always occur. Linear growth should be monitored in children, and manifestations of Cushing syndrome should be avoided. Furthermore, hypoaldosteronism may occur with hypotension. Spironolactone is also effective as monotherapy; amiloride and triamterene may be used as alternatives.

Liddle Syndrome

In 1963, G.W. Liddle described a syndrome of HTN, increased potassium excretion, metabolic alkalosis, decreased sodium excretion, and suppressed plasma aldosterone concentrations (Botero-Velez *et al.*, 1994). The mechanism is related to an abnormal increase in the function of the sodium channel located in the collecting tubule, also known as the epithelial sodium channel (ENaC) or the amiloride-sensitive sodium channel. The disorder is inherited in an autosomal dominant pattern and it is the result of a gain of function mutation on chromosome 16p12 that encode the beta and gamma subunits of the ENaC, also called SCNN1B and SCNN1G (Devonald and Karet, 2004; Hansson *et al.*, 1995; Snyder *et al.*, 1995). The defective ENaC cannot bind an intracellular ubiquitin protein ligase (Nedd4) that normally removes them from the cell surface (Goulet *et al.*, 1998; Abriel *et al.*, 1999), which explains why patients do not respond to aldosterone antagonists.

HTN with hypokalemia and lack of response to spironolactone is usually a giveaway for the diagnosis. Triamterene, amiloride along with salt restriction can correct hypokalemia and HTN (Young *et al.*, 2017). Renin is suppressed by a volume-expanded state with atrophy of the juxtaglomerular apparatus. It has been observed that HTN, hypokalemia, and metabolic alkalosis can be ameliorated by renal transplantation. The absence of edema may be attributed to aldosterone escape due to suppressed sodium reabsorption in other parts of the nephron and to enhanced release of atrial natriuretic peptide (ANP) in response to volume expansion. Thus, this is a salt-retaining, volume-expanded, genetic form of HTN (Botero-Velez *et al.*, 1994).

Pseudohypoaldosteronism Type 2 (Gordon Syndrome)

In 1970, R.D. Gordon described a congenital renal tubule defect that includes HTN and severe hyperkalemia, in association with suppressed renin and aldosterone, which was completely reversed with dietary sodium restriction (Gordon *et al.*, 1970). This syndrome is characterized by hyperkalemia despite normal renal glomerular filtration and HTN with variable findings of hyperchloremia, metabolic acidosis, and suppressed plasma renin (Mansfield *et al.*, 1997). The underlying genetic abnormalities of Type 2 pseudohypoaldosteronism are due to gain-of-function mutation in the serine-threonine kinases WNK1 and WNK4, which localize to the distal nephron enhancing sodium chloride reabsorption (Wilson *et al.*, 2001; Choate *et al.*, 2003; Kahle *et al.*, 2003). Additionally, recently identified mutations in Type 2 pseudohypoaldosteronism patients include Kelch-like 3 (KLHL3) and Cullin 3 (CUL3) genes, which are components of Cullin/RING E3 ligase complexes (CRLs) that ubiquitinate substrates bound to Kelch propeller domains, that localize in the distal convoluted tubule of the nephron, suggesting a mechanistic link between *KLHL3*/*CUL3* mutations, increased Na–Cl reabsorption, and HTN (Boyden *et al.*, 2012). Thiazide diuretics correct the physiologic abnormalities associated with Type 2 pseudo hyperaldosteronism, suggesting that increased Na–Cl cotransporter activity is likely to be the common pathogenic mechanism (Boyden *et al.*, 2012).

Syndrome of Apparent Mineralocorticoid Excess

The syndrome of apparent mineralocorticoid excess (AME), is an autosomal recessive form of low-renin HTN that classically presents in infancy and childhood with hypernatremia, hypokalemia, metabolic alkalosis, and low-aldosterone. In some cases, patients also present with diabetes insipidus, hypercalciuria, nephrocalcinosis, and chronic kidney disease (Morineau *et al.*, 2006; Bockenhauer and Bichet, 2013). The first patient was identified in the early 1970s, and by the late 1970s a handful of patients with similar features of AME were identified and their clinical presentation was termed "apparent mineralocorticoid excess" (Werder *et al.*, 1974; New *et al.*, 1977; Ulick *et al.*, 1979). Cortisol is converted to its metabolite, cortisone, which has no mineralocorticoid

activity, by a reversible kidney enzyme, type 2 11β-hydroxycorticosteroid dehydrogenase (11βHSD2). Once 11βHSD2 was identified, investigators found mutations in the encoding gene, HSD11b2, and these were identified in patients with AME (Mune *et al.*, 1995; Wilson *et al.*, 1995; Dave-Sharma *et al.*, 1998; Morineau *et al.*, 2006; Alzahrani *et al.*, 2014). 11βHSD2 is a gate-keeping enzyme that protects the mineralocorticoid receptor (MR) from activation by glucocorticoids. A decreased activity of 11βHSD2 caused by genetic mutations or inhibition, by agents such as glycyrrhizic acid from licorice root and its semisynthetic analogue carbenoxolone, can induce HTN mediated by the excess activation of the MR by cortisol, which results in sodium and fluid retention (via over-activation of epithelial sodium channel in the distal nephron), hypokalemia, metabolic alkalosis, low renin, and low aldosterone. The diagnosis of AME is based on measuring the ratio of urinary free cortisol to cortisone and their respective metabolites tetrahydrocortisol, allotetrahydrocortisol, and tetrahydrocortisone (Morineau *et al.*, 2006; Antonelli *et al.*, 2014). Treatment of AME is directed toward reducing endogenous cortisol production with dexamethasone or blockade of mineralocorticoid effects by inhibiting the MR via spironolactone or eplerenone or inhibition of ENaC with amiloride (Morineau *et al.*, 2006; Alzahrani *et al.*, 2014). There are reports that kidney transplantation may be curative (Palermo *et al.*, 1998; Khattab *et al.*, 2014).

Cushing Syndrome and Hypertension

In Cushing syndrome 75%–80% of patients present with HTN (Sacerdote *et al.*, 2005; Baid and Nieman, 2004). The pathogenesis of glucocorticoid induced HTN is complex and involves multiple mechanisms including intrinsic mineralocorticoid activity, activation of the RAAS, enhancement of cardiovascular inotropic and pressor activity of vasoactive substances (e.g., catecholamines and or/vasopressin and angiotensin II) and suppression of the vasodilatory systems (NO synthase, prostacyclin, and kinine/kallikrein systems). These phenomena ultimately result in upregulating cardiac output, peripheral vascular resistance, and plasma volume (Magiakou *et al.*, 2006). Although cortisol and aldosterone have equal binding affinity to the MR, 11β-HSD, by locally transforming cortisol to cortisone, prevents it from binding to the mineralocorticoid receptor in the nephron-collecting tubule. Excess cortisol may overwhelm this enzyme and bind to MR (Ulick *et al.*, 1992; Walker *et al.*, 1991). Indeed, aldosterone and renin levels are low in Cushing's HTN, suggesting an apparent mineralocorticoid overactivity that causes sodium and volume retention. Despite this, hypokalemia, metabolic alkalosis, and edema are more often associated with ectopic secretion of ACTH, due to its very high levels. Elevated levels of corticosterone and deoxycorticosterone associated with ectopic ACTH production may also contribute. Since ANP and decreased sodium reabsorption occur with volume expansion, thereby causing aldosterone (in this case mineralocorticoid) escape, the amount of sodium being exchanged is increased. This may explain the presence of normal potassium levels and the lack of edema seen with Cushing syndrome. Nonetheless, plasma volume is expanded with salt intake, although not to the point of causing edema.

Screening for Cushing's starts with a careful history taking and appropriate physical exam in the search for evidence of clinical features. A biochemical profile should be established by initial screening with at least two positive tests, such as measurement of 24-h urinary free cortisol, overnight low dose (1 mg) dexamethasone suppression test or measuring late night salivary cortisol (Nieman *et al.*, 2008). After identifying clinical and biochemical evidence of Cushing syndrome, it is imperative to determine its dependence on ACTH before further investigations with imaging for localization. ACTH-dependent Cushing syndrome represents about 80% and consists of Cushing disease (CD)—the most common—a pituitary corticotroph secreting adenoma, and extrapituitary or ectopic tumors secreting ACTH comprised of occult or neuroendocrine tumors (Newell-Price *et al.*, 2006; Biller *et al.*, 2008). ACTH-independent—about 20% of cases of Cushing's, include primary unilateral adrenal adenomas or carcinomas that suppresses ACTH and rarely primary bilateral macronodular adrenal hyperplasia or primary pigmented nodular adrenocortical disease (Lacroix, 2009).

Pituitary MRI and confirmation with inferior petrosal sinus sampling (IPSS) is indicated in CD. Adrenal tumors producing cortisol could be evaluated with adrenal imaging and confirmed with adrenal vein sampling.

Treatment of the HTN should be directed at the primary source of excess cortisol: ectopic/pituitary ACTH, adrenal, or exogenous. Calcium channel blockers or drugs that improve endothelial NO production, such as ACEIs and ARBs, may be used until a final diagnosis is reached.

Secondary Hyperaldosteronism and Renovascular Hypertension

Secondary hyperaldosteronism may be an appropriate physiological response to hypovolemia, renal ischemia, or low perfusion state in context of liver or heart failure the latter not being associated with HTN. However, renovascular HTN (RVH) in context of renal artery stenosis represent a noncompensatory and detrimental pathophysiological process where systemic blood pressure raises in response to renal hypoperfusion. A vast majority is attributed to atherosclerosis which increases with age but a small percentage is related to fibromuscular dysplasia, particularly young or middle-aged women. Although 14%–33% of patients subjected to angiograms have renal artery stenosis, only a 1%–5% of patients with HTN have RVH.

Clinical features of RVH due to occlusive pathology varies from malignant HTN to flash pulmonary edema to acute reversible or permanent kidney injury. Particularly important for clinicians is HTN before age 30, malignant HTN, increase creatinine more

than 30% after treatment with ACEI or ARB, unexplained pulmonary edema or asymmetric kidney on imaging with sudden loss of function.

Once suspected, duplex ultrasound is an inexpensive noninvasive diagnostic tool. Other diagnostic modalities include magnetic resonance imaging (MRI), magnetic resonance angiography (MRA), computed tomography (CT), computed tomography–angiography, scintigraphy, and captopril-enhanced renography or scintigraphy. Selective use of renal MRA can avoid invasive, potentially nephrotoxic conventional angiography in high-risk patients. Biochemical evidence of secondary aldosterone excess including plasma aldosterone and plasma renin activity lack specificity, however, renal vein renin sampling which allows localization of the culprit has been helpful in predicting effectiveness of revascularization or nephrectomy (Goupil *et al.*, 2015). Randomized controlled trials show limited benefits in revascularization for atherosclerotic renal artery stenosis (Herrmann *et al.*, 2015), but each case should be evaluated and treated in a personalized fashion depending on the clinical scenario. Gill and colleagues reported improved blood pressure in a majority of resistant cases with recovery of renal function post stenting (Gill and Fowler, 2003). Ischemic nephropathy is best treated before the onset of renal failure. Revascularization with surgery or stenting should be considered with creatinine less than 2 mg/dL, bilateral renal artery stenosis, absence of proteinuria, and/or evidence of end-organ injury.

Severe HTN with secondary hyperaldosteronism can occur in patients with systemic sclerosis due to renal artery vasospasm and subsequent hyperreninemia. Nifedipine has led to normalization of BP, renin, and aldosterone. Secondary hyperaldosteronism and HTN from renin-secreting juxtaglomerular cell tumors can present in young adults. Surgical treatment results in prompt normalization of BP, and a calcium channel blockade may control blood pressure until surgery. Renal cell carcinoma rarely causes hyperreninemia or secondary hyperaldosteronism.

Pheochromocytoma

Pheochromocytoma and paraganglioma (PPGL) are tumors derived from chromaffin cell of the adrenal medulla or paravertebral ganglia of the sympathetic chain. Paroxysmal HTN is the most common sign, present in 95% of cases due to excess catecholamines and is the result of increased peripheral resistance (Calhoun *et al.*, 2008). Norepinephrine activates α_1 receptors found on peripheral smooth muscle arteries and veins, producing vasoconstriction with an increase in systemic pressure, and has a positive inotropic effect. Norepinephrine acts as a negative feedback via α_2 receptors which are located on the presynaptic terminal of postganglionic sympathetic neurons by inhibiting further release of norepinephrine. β_1 receptor is stimulated by both epinephrine and norepinephrine with positive inotropic and chronotropic effect on cardiomyocytes and heart pacemaker respectively; it also stimulates renin production and increases blood pressure via RAAS. Epinephrine acts on β_2 receptor inducing vasodilatation of muscular arteries and incites the release of norepinephrine from the sympathetic ganglia (Manger and Gifford, 1996). High levels of dopamine can activate α and β_1 receptors.

PPGL can be life threatening and thus early recognition is critical. HTN can present with paroxysmal episodes or sustained, the prevalence of PPGL in patients with sustained HTN is 20–60 per 10,000 persons (Manger, 2006; Mansmann *et al.*, 2004). A crisis can be associated with signs and symptoms of myocardial infarction, supraventricular tachycardia, or CHF. Sudden elevations in arterial pressure do not correlate with the levels of plasma catecholamines. Even in patients with persistent elevations of BP, symptoms may be paroxysmal; the classic symptoms include headache, diaphoresis, and palpitations that can last from minutes to an hour. Other symptoms may include pallor, nausea, tremor, anxiety, abdominal pain, chest pain, dyspnea, and (rarely) flushing. Frequently, an orthostatic drop in blood pressure is observed because of relative intravascular volume depletion. A patient may be normotensive between episodes. Sometimes, paroxysms may be absent, mimicking essential HTN. Approximately 10% are bilateral, extra-adrenal (paragangliomas), familial, multiple (other than bilateral), or malignant.

Diagnosing PPGL requires a high clinical index of suspicion, biochemical profile is necessary to confirm the diagnosis: adrenal pheochromocytomas primarily make epinephrine or a combination of norepinephrine and epinephrine, whereas extra-adrenal PPGL produce norepinephrine predominantly and small amounts of dopamine due to lack of the enzyme phenylethanolamine-*N*-methyl transferase (PNMT) required in norepinephrine metabolism. Of critical importance is the technique for blood sample collection when measuring plasma free metanephrines. To avoid false positive results, the patient should rest in supine position for at least 30 min after the insertion of the indwelling cannula. If not feasible, a 24-h urine collection for fractioned metanephrines can be used.

The urine fractionated metanephrines quantified by mass spectrometry yields a 97% sensitivity and a 91% specificity (Perry *et al.*, 2007). Free plasma metanephrines alone have a specificity of 96% and a sensitivity of 97% for the familial form of PPGL. Although the sensitivity remains high for the sporadic form, the specificity drops to 82%. Combining plasma metanephrines with urinary metanephrines increases the specificity to 89%. Intermediate values require further testing. A clonidine suppression test can be used to distinguish true-positive from false-positive borderline patients when measuring normetanephrine with a low false-negative rate (Eisenhofer *et al.*, 2003).

Once biochemical diagnosis is established, next step is imaging and localization. According to 2014 Endocrine Society guidelines, CT is the first-choice imaging modality with an 88%–100% sensitivity (Lenders *et al.*, 2014). Important features include large size (>3 cm), more than 10 Hounsfield Units, $<50\%$ washout at 10-min, heterogeneous appearance with areas of necrosis with some calcifications, solid, or cystic regions. A T2-weighted image of a PCC has a characteristically hyperintense image in comparison with that of the liver. MRI is preferred for skull base and neck PPLG with sensitivity between 90% and 95% (Gimenez-

Roqueplo *et al.*, 2013). Scintigraphy with ^{123}I-metaiodobenzylguanidine (MIBG) is used in metastatic disease as a functional imaging prior to radiotherapy treatment with ^{131}I-MIBG. 18F-FDG PET/CT scanning is recommended in patients with metastatic PPGLs and is preferred over ^{123}I-MIBG scintigraphy (Lenders *et al.*, 2014).

Treatment involves avoidance of hypertensive episodes during surgery and postsurgery. The nonselective alpha blocker phenoxybenzamine and a high sodium di*et al*lows for volume repletion, but is associated with significant reflex tachycardia and orthostasis and may prolong postsurgical hypotension. After volume repletion, selective alpha$_1$ blockers such as prazosin have a shorter duration of action and do not cause reflex tachycardia. Alpha$_1$ blockers can still be associated with postoperative hypotension as well as mask the hypotension associated with the removal of the tumor. The latter is used by surgeons as an indication of complete tumor removal. Boutros and colleagues suggest use of alpha blockers and CCBs, as CCBs seldom cause orthostasis or hypotension and are safe to use in normotensive patients. They also prevent catecholamine-induced spasm of the coronary arteries (Boutros *et al.*, 1990). By decreasing the norepinephrine-induced increases of calcium entry into the VSMCs, CCBs can prevent the hypertensive response in PPGL. Beta-blockers should be used only after alpha blockade. An acute hypertensive crisis can be treated by sodium nitroprusside and a beta$_1$-selective blocker can control supraventricular or reflex tachycardia. Esmolol is preferred for its rapid onset and short duration. Definitive treatment is surgical and laparoscopic approach is preferred (Pacak, 2007).

Primary Hyperparathyroidism

Primary hyperparathyroidism is the most common cause of hypercalcemia and has been associated with an increase frequency of HTN (Richards *et al.*, 1988). However, the exact etiology of how hyperparathyroidism-induced HTN remains unclear as there is no direct correlation with elevated parathyroid hormone or calcium levels. Furthermore, this is compounded by inconsistencies in studies where patients with primary hyperparathyroidism and HTN who underwent parathyroidectomy showed decreased, increased, or no change in blood pressure (Heyliger *et al.*, 2009; Rydberg *et al.*, 2010; Richards *et al.*, 1988). Although the relationship between hyperparathyroidism and HTN remain unclear, recent studies have shown that mild hyperparathyroidism may cause endothelial dysfunction, increased vascular stiffness, and increased carotid intimal thickening (Walker and Silverberg, 2008; Rubin *et al.*, 2005; Smith *et al.*, 2000; Walker *et al.*, 2009). Additionally, observational studies have suggested a relationship between parathyroid hormone and the RAAS, with more recent studies showing that PTH enhances secretion of renin and aldosterone (Brown *et al.*, 2014; Vaidya *et al.*, 2015). Further work remains to elucidate the etiology by which parathyroid hormone may induce clinically relevant changes in blood pressure.

Acromegaly

Cardiovascular disease is the primary cause of mortality in acromegalic patients, which is characterized by HTN, left ventricular hypertrophy, and cardiomyopathy. The cardiomyopathy of acromegaly has been contributed to both HTN and acromegaly itself (López-Velasco *et al.*, 1997). HTN is reported to occur in up to 40% of patients with acromegaly and is associated with sodium retention and extracellular volume expansion (Berg *et al.*, 2010; Terzolo *et al.*, 1999). Although the exact etiology of HTN in acromegalic patients remains unclear, more recent studies have shown that growth hormone and insulin-like growth factor 1 (IGF-1) act on the kidney to increase sodium and fluid retention, without major contributions of the RAAS or antinatriuretic peptides. Growth hormone and IGF-1 most likely act together to stimulate ENaC-dependent transepithelial sodium transport in the distal nephron, independent of aldosterone, as demonstrated in an acromegalic model of rats (which have increased ENaC activity and normal-to-low aldosterone levels) and in a small cohort of acromegalic patients who had an increased natriuretic response to amiloride but a reduced response to furosemide (Kamenicky *et al.*, 2008; Kamenický *et al.*, 2014). HTN in acromegaly is most effectively treated by removing the etiology of excess growth hormone. However, in cases where surgical cure is not possible, hypertensive patients with acromegaly respond well to diuretic therapy.

Hypothyroidism

Hypothyroid patients have predilection for HTN threefold compared to general population, and 1% of patients with diastolic HTN have hypothyroidism (Streeten *et al.*, 1988). Treatment with thyroxine contributes to reductions in blood pressure. Hypothyroidism is also associated with an increase in cholesterol, triglycerides, homocysteine, and total cholesterol/HDL ratio as well as with accelerated atherosclerosis and coronary artery disease (Nyirenda *et al.*, 2005). Subclinical hypothyroidism is also associated with HTN and lipid disorders. In one study, treatment of hypothyroidism improved coronary insufficiency, with relapse on therapeutic withdrawal. The increase in blood pressure may be due, in part, to increased vascular resistance and aortic stiffness. A correlation of blood pressure reduction with an associated decrease in aortic stiffness occurred with thyroxine treatment in hypothyroid patients (Kalra *et al.*, 2016). Stimulation of adrenal function by augmenting PRA, with an increase in aldosterone and cortisol, occurs in hypothyroidism. This also is reduced with thyroxine treatment (Barreto-Chaves *et al.*, 2010; Marcisz *et al.*, 2011).

Hyperthyroidism

A decreased total peripheral resistance occurs in hyperthyroidism. HTN associated with an overactive thyroid is mainly systolic and is due to increased cardiac output. This may be the result of an increased number of beta adrenergic receptors in the heart making it more sensitive to catecholamines (Nyirenda *et al.*, 2005). Treatment with beta adrenergic receptor blockers can control many of the symptoms of hyperthyroidism, including elevated blood pressure. Furthermore, treatment of the hyperthyroid state leads to a decrease in or complete control of blood pressure in those who are younger and without essential HTN (Danzi and Klein, 2003). Another cardiovascular effect of thyrotoxicosis, is the development of LVH, which was prevented by valsartan, suggesting that the RAAS plays a role (Tamer *et al.*, 2005).

Resistant Hypertension

Robert M Carey, University of Virginia Health System, Charlottesville, VA, United States

Introduction

Resistant hypertension (RH) is defined as the blood pressure (BP) of a hypertensive patient that is elevated above target level in spite of the use of three antihypertensive drugs of different classes, one of which must be a diuretic (Calhoun *et al.*, 2008). All antihypertensive agents must be administered at optimal doses and with the correct dosing frequency. The term RH also applies to patients with BP controlled below the target level when the patient is taking four or more antihypertensive agents. The importance of RH is that patients with this disorder have increased risk for target organ damage, morbidity and mortality in spite of ongoing antihypertensive drug therapy (Calhoun *et al.*, 2008). Patients with RH also have increased prevalence of secondary forms of hypertension, most of which are endocrine disorders, compared to hypertensive patients without drug resistance.

Recommendations for new BP targets have been published in the 2017 American College of Cardiology/American Heart Association Clinical Practice Guideline for the Prevention, Detection, Evaluation and Management of High Blood Pressure in Adults (Whelton *et al.*, 2017). In this guideline, the BP goal of treatment is reduced from its previous level of $<140/90$ to $<130/80$ mmHg. Thus, RH is now defined as BP $\geq$ 130/80 mmHg in the presence of three or more antihypertensive agents (Whelton *et al.*, 2017). The prevalence of RH (using the 140/90 mmHg cut point) has been estimated at approximately 13% of the hypertensive population (Persell, 2011). Because the new hypertension guideline reduces the threshold for initiating antihypertensive agents from $\geq 140/90$ to $\geq 130/80$ mmHg in patients with cardiovascular disease (CVD) and in those with increased CVD risk [10-year atherosclerotic CVD (ASCVD) risk $\geq 10\%$ according to the American Heart Association Pooled Cohort Equations (2)] as well as reduces the goal of therapy, the 2017 guideline recommendations (Whelton *et al.*, 2017) are expected to increase the prevalence of RH. In this article, I will outline the sequential steps necessary to diagnose, evaluate and manage RH.

Excluding Pseudoresistance

Before diagnosing RH, several important factors must be taken into account. These include inaccurate BP measurement, medication nonadherence and the "white coat" effect, each of which interfere with the diagnosis of true RH. The term "pseudoresistance" refers to patients with apparent treatment RH but presence of one or more of these interfering factors.

Errors of office BP measurement can account for the misdiagnosis of RH. The 2017 ACC/AHA guideline (Whelton *et al.*, 2017) emphasizes the proper methods to insure accurate BP measurement, including the preparation of the patient, environmental conditions, cuff size and technique of BP measurement (Whelton *et al.*, 2017). Because of BP variability, it is critical to obtain an average of at least two BP readings on two separate occasions before making a diagnosis of treatment resistance. Thus, inaccurate BP measurement must be excluded before making the diagnosis of RH.

Nonadherence in taking prescribed antihypertensive medications also must be excluded before diagnosing RH. Indeed, nonadherence is highly prevalent in patients with RH (Hameed *et al.*, 2016). The prevalence of nonadherence is underscored by observations that one-quarter of patients newly initiated on antihypertensive therapy fail to fill their initial prescriptions; that during the first year of treatment the average patient has possession of antihypertensive medication only half of the time; and that only 20% of patients have sufficient adherence to achieve the benefits observed in clinical trials (Gwadry-Sridhar *et al.*, 2013). Identification of medication nonadherence has proven difficult in clinical practice. Indirect methods such as pill counts, self-report and prescription refill data are simple, inexpensive and widely employed but can be manipulated to overestimate adherence. Direct methods such as observed drug ingestion and urine or blood measurement of drug or metabolite levels are more accurate, but are relatively expensive and do not perfectly estimate the level of adherence. Since all methods have limitations, the best assessment of adherence should likely involve a combination of approaches (Berra *et al.*, 2016).

The "white coat" effect also must be excluded before diagnosing true RH. The white coat effect is defined as office BP above goal but out-of-office BP levels, measured preferably by ambulatory BP monitoring (ABPM) or, if ABPM is unavailable, by home BP monitoring (HBPM), at or below target in a patient taking ≥ 3 antihypertensive drugs. The risk of CVD complications in patients with the white coat effect similar to that in patients with controlled hypertension (Mancia *et al.*, 2013; Franklin *et al.*, 2016). Because intensifying antihypertensive therapy in this setting would not be warranted, out-of-office BP monitoring should be performed on every patient with apparent RH to exclude the white coat effect.

Identifying and Reversing Contributing Lifestyle Factors

Lifestyle factors contribute greatly to treatment resistance. These include obesity, physical inactivity, high sodium intake and excessive alcohol consumption. In several large cohort studies, body mass index ≥ 30 kg/m^2 has been associated with a high prevalence of RH (approximately twofold above patients with BMI below this level) (Egan *et al.*, 2011; de la Sierra *et al.*, 2012; Sim

 doi:10.1016/B978-0-12-801238-3.65192-9

et al., 2013). Although it is clear that weight loss can reduce BP in hypertension, the impact of weight loss on BP in RH has not specifically been studied. However, it is generally recommended that, while the best goal is ideal body weight, weight loss should be directed towards at least a 1-kg reduction in body weight for most adults who are overweight, with the expectation of about 1 mmHg BP reduction for every 1-kg reduction in body weight (Whelton *et al.*, 2017). Dietary sodium excess has been strongly implicated in the pathophysiology of RH, as marked reduction of BP has been observed in patients with RH in response to low sodium diet (Pimenta *et al.*, 2009). The optimal goal is <1500 mg sodium/day, but a practical approach consists of at least a 1000-mg/day reduction in most adults (Whelton *et al.*, 2017). While evidence is still lacking on the role of physical inactivity in RH, there is no question about its importance to lower BP in hypertension. Current recommendations are for 150 minutes of structured exercise per week (Whelton *et al.*, 2017). Excessive alcohol intake is also associated with hypertension, and the recommendations are limitation to one standard drink for women and two or less for men (Whelton *et al.*, 2017). Importantly, the BP reduction expected from each of these individual lifestyle changes is additive.

Discontinuing or Minimizing Interfering Substances

Several classes of pharmacologic agents can increase BP and contribute to the development of treatment resistance. These include non-steroidal anti-inflammatory agents (NSAIDs), oral contraceptives and hormone replacement therapy, sympathomimetic amines, glucocorticoids and mineralocorticoids, immunosuppressive agents, recombinant erythropoietin, tyrosine kinase inhibitors, cocaine, amphetamines and antidepressants. Among these agents, perhaps the most important in terms of frequency of use in medical practice are NSAIDs. NSAIDs may interfere with the BP lowering effect of diuretics, angiotensin converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and beta-blockers (White, 2007). However, they do not usually interfere with the antihypertensive effect of calcium channel blockers (CCBs) (White, 2007). BP effects from NSAIDs are due to cyclooxygenase (COX) inhibition, but selective COX-2 inhibitors have less BP raising effects than general COX inhibitors (Ruschitzka *et al.*, 2017). With each class of potentially interfering agent, it is important to discontinue or at least minimize the dose of these drugs in a trial-and-see approach to determine their effect on BP.

Screening for Secondary Causes of Hypertension

Patients with RH should be screened for secondary causes of hypertension, almost all of which are endocrine in nature. The frequency if secondary hypertension is markedly increased in drug resistant patients compared with those with controlled hypertension.

Primary aldosteronism is the most common form of secondary hypertension with a prevalence of about 20% in RH (Calhoun, 2013). The disorder includes hypertension due to volume expansion and sympathetic nervous system activation, hypokalemia, metabolic alkalosis, and advanced cardiovascular and renal disease. Due to the toxic effects of aldosterone on the heart and blood vessels, primary aldosteronism is associated with a major increase in CVD and CVD events compared to that observed with primary hypertension, including stroke, myocardial infarction and atrial fibrillation (Milliez *et al.*, 2005). Screening for primary aldosteronism should be conducted using the plasma aldosterone concentration (PAC) to plasma renin activity (PRA) ratio (ARR) from a blood sample obtained in the morning with the patient seated for at least 30 minutes prior to sampling (Funder *et al.*, 2016). A positive screening test entails ARR ≥ 30, or ≥ 20 if PAC is ≥ 16 ng/dL (Funder *et al.*, 2016). Prior to the test, hypokalemia which decreases aldosterone secretion, should be corrected and agents that markedly affect the renin-angiotensin-aldosterone system, especially spironolactone and eplerenone, should be withdrawn for at least 5 weeks (Funder *et al.*, 2016). Beta-blockers, central α_2 receptor agonists and renin inhibitors suppress PRA and ACEIs, ARBs and non'potassium sparing diuretics increase PRA, thus potentially affecting ARR. If the initial test results suggest that any of these medications may be interfering, they can be selectively withdrawn 1 or 2 weeks prior to testing. During withdrawal, BP may be controlled by agents that do not influence the renin-angiotensin-aldosterone system, such as the α_2 receptor antagonists (preferably doxazosin), hydralazine and/or slow-release verapamil. If the screening test is positive, the patient is usually referred to an endocrinologist or hypertension specialist for further workup and treatment.

Renal parenchymal disease is both a cause and complication of poorly controlled hypertension. Screening is by serum creatinine and estimated glomerular filtration rate (eGFR). Treatment resistance is in large part related to sodium and fluid retention and intravascular volume expansion. Thus, special attention should be focused on dietary sodium restriction in combination with diuretic therapy that evolves from thiazide-like agents to loop diuretics as renal function declines.

Renal artery stenosis is one of the most common causes of drug treatment resistance. Most cases are due to ASCVD, but renal artery stenosis can also occur due to fibromuscular dysplasia, renal dissection or infarction, Takayasu's arteritis, radiation fibrosis or aortic endovascular stent graphs. Screening is with renal Duplex Doppler ultrasound or magnetic resonance or computerized tomographic arteriography. Moderate degrees of renal vascular hypertension can be managed with medical therapy, especially with agents that block the renin–angiotensin system such as ACEIs or ARBs (Raman *et al.*, 2016).

Pheochromocytoma/paraganglioma is a chromaffin cell tumor that induces hypertension by secretion of catecholamines. The disorder is suggested by a variety of symptoms including paroxysmal hypertension associated with headache, palpitations, pallor and piloerection. Because of the high morbidity and mortality of these tumors, the usual 3-year delay in diagnosis and that at least

1/3 are inherited, it is essential to consider the diagnosis in any patient with RH. The screening test of choice is measurement of either circulating free metanephrines or fractionated urinary metanephrines (Eisenhofer *et al.*, 2003). Only after biochemical evidence of pheochromocytoma has been obtained, imaging should be pursued with either abdominal CT or MRI scanning. Patients who screen positively for pheochromocytoma/paraganglioma should be referred to an endocrinologist for further workup and preparation for surgery (Lenders *et al.*, 2014).

Cushing syndrome, caused by increased glucocorticoid exposure from exogenous or endogenous sources, is a relatively uncommon cause of hypertension. The syndrome is characterized by a constellation of classic symptoms (e.g., mood disorders, menstrual irregularity and muscular weakness) and signs (e.g., central weight gain, abdominal striae, hirsutism, dorsal and supraclavicular fat, and cutaneous fragility) that suggest the diagnosis. Screening for Cushing syndrome includes multiple 24-hour urine cortisol measurements and the overnight dexamethasone suppression test (Nieman *et al.*, 2008).

Other uncommon or rare causes of secondary hypertension include coarctation of the aorta, hypo- and hyperthyroidism, primary hyperparathyroidism, congenital adrenal hyperplasia, other mineralocorticoid excess syndromes and acromegaly.

Managing Resistant Hypertension

Management of RH first entails introducing or modifying lifestyle interventions, including weight loss, dietary sodium restriction, dietary potassium supplementation, heart-healthy diet such as the Dietary Approaches to Stop Hypertension (DASH) diet, exercise and alcohol restriction (Whelton *et al.*, 2017).

If the patient is adherent to three antihypertensive agents of different classes at maximum or maximally tolerated doses and BP is uncontrolled, diuretic therapy should be maximized. This includes substitution of a thiazide-like diuretic (i.e., chlorthalidone or indapamide) for a thiazide diuretic (e.g., hydrochlorothiazide). Recent studies have demonstrated a 7–8 mmHg BP reduction with thiazide-like diuretics over thiazide diuretics (Roush & Sica, 2016). If the BP remains out of control, a mineralocorticoid receptor antagonist (MRA) (i.e., spironolactone or eplerenone) should be added. Recent randomized trials have demonstrated the superiority of spironolactone over other antihypertensive agents as add-on drugs in RH (Williams *et al.*, 2015). With the substitution of a thiazide-like diuretic and addition of a MRA, the vast majority of patients with RH will have their BP controlled.

Beyond this management step, there is very little or no randomized clinical trial evidence for the efficacy of specific drug additions. Among other possibilities, addition of a beta-blocker or alpha-beta blocker would be reasonable given that sympathetic nervous system activity may be increased by the hypertensive process itself or by the other pharmacologic agents administered. Further considerations include addition of a vasodilator such as hydralazine, which must be taken a minimum of three times daily accompanied by a beta-blocker to block vasodilator-induced reflex tachycardia. Ultimately, if BP is still not able to be controlled, referral to a hypertension specialist is recommended.

Hypertension and Target Organ Damage

Maria Lorenza Muiesan, Anna Paini, Claudia Agabiti Rosei, Fabio Bertacchini, Carlo Aggiusti, Carolina De Ciuceis Damiano Rizzoni, and Massimo Salvetti, Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Italian Society of Arterial Hypertension, Brescia, Italy

Introduction

Hypertension-induced mortality and morbidity is produced through the impact of elevated blood pressure on the heart, the brain, the small and large arterial vessels and the kidney. Evaluation of early target organ damage (TOD) in these organs is an important step in a risk stratification strategy to reduce cardiovascular and renal damage. The European Society of Hypertension/European Society of Cardiology (ESH/ESC) Guidelines 2013 (Mancia *et al.*, 2013) underscored the convenience of assessing target organ damage for global risk stratification and of repeating TOD assessment during the follow-up.

A panel of TOD was included in the ESH-ESC guidelines in 2013. Some TOD, such as the ankle/brachial index or the presence of estimated glomerular filtration rate (eGFR) <60 mL/min/1.73 m^2, indicates advanced organ damage, while others are not yet routinely available. Based on availability, cost and clinical significance, the evaluation of left ventricular hypertrophy (LVH) by electrocardiography and possibly by echocardiography, the measurement of urinary albumin excretion and glomerular filtration rate are the minimal recommended among all TOD.

Several studies have shown that the regression of asymptomatic TOD induced by antihypertensive treatment reflects the treatment-induced reduction of morbid and fatal cardiovascular (CV) events. Therefore, the evaluation of TOD during treatment may offer valuable information on whether patients are more or less effectively protected by the treatment strategies adopted.

The effect of aldosterone on the development and regression of target organ damage has been studied in patients with adrenal gland disease, in particular with primary aldosteronism, and the results are reported and discussed.

Heart

Electrocardiographic LVH is a powerful marker of CV morbidity/mortality in the general population as well as in different clinical settings (Agabiti-Rosei *et al.*, 2006). In hypertensive patients LVH may predict the occurrence of CV events, including myocardial infarction, stroke sudden death and heart failure (Angeli *et al.*, 2015; Vakili *et al.*, 2001). The incidence of atrial fibrillation and of renal events, such as creatinine doubling, eGFR <30 mL/min/1.73 m^2 or the need for end-stage renal disease replacement, are also higher in the presence of LVH (Tsioufis *et al.*, 2010).

BP values, mainly measured during 24 h monitoring, and body mass index (BMI) are strictly associated to LVH development (Peer *et al.*, 2013). In addition metabolic syndrome, diabetes mellitus (Wijkman *et al.*, 2012), hyperuricemia and chronic neurohormonal activation may further influence LVH development; the risk of incident LVH is particular relevant among women (**Fig. 1**).

Available data suggest that in patients with secondary hypertension due to hyperaldosteronism LV mass (LVM) is higher; conflicting results have been published on changes of geometric adaptation of the left ventricle, showing an increase in relative wall thickness in some patients, while in other groups of primary aldosteronism (PA) patients an increase in LV diameter was observed. Denolle *et al.* (1993) found that LVM index in increased to a greater extent in patients with primary aldosteronism and adrenal adenoma, as compared to patients with pheochromocitoma or renovascular hypertension.

Muiesan *et al.* (2008) have hypothesized that in primary aldosteronism the increase in LVM may be the consequence of excess aldosterone, leading to an increase in LVM inappropriate for demographic characteristics and hemodynamic load; in fact patients with primary aldosteronism, even in the absence of LVH, had a greater prevalence of inappropriate LVM.

Marker of OD	*Prognostic value*	*Change detection sensitivity*	*Time for evaluating changes*
LVH (electrocardiogram)	++++	+	>6 months
LVH (echocardiography)	++++	++	>6 months
Albuminuria	++	+++	Weeks–months
Estimated glomerular filtration rate (eGFR)	(+)	++	Years
Pulse wave velocity (PWV)	(+)	+++	Weeks–months
Ankle brachial index (ABI)	−	+	−
Carotid wall thickness	−	−/+	>1 year

Fig. 1 Prognostic value of changes during treatment of markers of asymptomatic organ damage. *LVH*, left ventricular hypertrophy. Modified from Mancia, G. (2013).  doi:10.1016/B978-0-12-801238-3.64326-X

In PA (Rossi *et al.*, 2002) and more recently in pheochromocytoma patients (Ferreira *et al.*, 2016), a diffuse cardiac fibrosis has been documented, leading to both systolic and diastolic functions impairment.

Treatment with antihypertensive drugs is associated with a significant reduction in ECG LVH and in echocardiographic LVM. The magnitude of the decrease is related to the baseline LVM and to changes in clinic BP; the correlation between changes of LVM and changes in BP is more significant when average 24 h BP is considered (Mancia *et al.*, 1997).

Among all classes of antihypertensive drugs, ACE-inhibitors, angiotensin receptor blockers and calcium antagonists seem to be more effective as compared with beta-blockers (Fagard *et al.*, 2009). In most studies, however, patients were not receiving monotherapy but a combination of drugs (usually with a diuretic). The choice of a specific class of antihypertensive drugs seems to be less relevant then the adequate and long-term BP control.

A normalization of LVM is not always possible and seems to be more difficult to obtain in women (Devereux *et al.*, 2004), obese or diabetic patients (De Simone *et al.*, 2013), elderly subjects with isolated systolic hypertension (Mancusi *et al.*, 2014) or patients with coronary artery disease, despite effective BP reduction. A normalization of LV geometry is possible during antihypertensive treatment and may have relevant prognostic significance (Muiesan *et al.*, 2004).

Regression of ECG-graphic LVH assessed by voltage and strain criteria may be induced by treatment (Levy *et al.*, 1994; Mathew *et al.*, 2001; Okin, 2003; Wachtell *et al.*, 2007; Okin, 2009; Prineas, 2001), and large changes in ECG voltage and strain results in improved prognosis (Bang *et al.*, 2014; Okin *et al.*, 2004). Changes in echocardiographically LVH induced by treatment reflect the effects on cardiovascular events; however a residual risk may be observed in patients with LVH regression, in whom LVM remains higher, although in the normal range, than in patients with persistently normal LVM (Angeli *et al.*, 2015). Changes in echocardiographic LVM and in renal function may independently predict the occurrence of cardiovascular events (Salvetti *et al.*, 2012).

During antihypertensive treatment the modifications of LV geometry, of left atrial size, of midwall fractional shortening and of diastolic dysfunction parameters have been also shown to be associated with the incidence of cardiovascular events, independently of LVM change (Kurt *et al.*, 2009; Muiesan *et al.*, 2004; Wachtell *et al.*, 2010).

In patients with PA surgical or medical treatment are both effective in reducing LV mass (Catena *et al.*, 2012).

Vascular Damage

Carotid arteries

The thickness of intima-media complex in the carotid arterial wall may be measured noninvasively by high resolution ultrasound, according to a validated method. Carotid intima-media thickness (C-IMT) is the most widely accepted non-invasive marker of subclinical atherosclerosis (Bots *et al.*, 2003; Lorenz *et al.*, 2007; Touboul *et al.*, 2004), and the threshold of >0.9 mm is considered a risk of future myocardial infarction and/or cerebrovascular disease (Bots *et al.*, 1997; Salonen and Salonen, 1991; Chambless *et al.*, 1997; Hodis, 1998; Lorenz *et al.*, 2007; Den Ruijter *et al.*, 2012). The use of Radiofrequency C-IMT measurements has been recently shown to have an additional stratification power for coronary artery disease, in addition to the Framingham risk score (O'Leary *et al.*, 1999).

The presence of plaques and plaque morphology may be assessed by ultrasound. More recently plaque volume assessment by three-dimensional reconstruction of ultrasound or nuclear magnetic resonance images has been proposed to better evaluate atherosclerotic lesions changes, and to stratify patients' risk (Moreo *et al.*, 2015; Wannarong *et al.*, 2013). Traditional risk factors, including aging, male sex, being overweight or obese, elevated blood pressure, diabetes, smoking, are all positively associated with an increase in carotid IMT in observational and epidemiological studies. Hypertension, and particularly high systolic BP values, seems to have the greatest effect on IMT (Van Engelen *et al.*, 2014); patients with metabolic syndrome have higher IMT than patients with individual metabolic risk factors.

Carotid IMT has also been found to be associated with preclinical cardiovascular alterations, in the heart, in the brain, in the kidney, and in the lower limb arteries.

Double blind randomized trials have shown that different classes of antihypertensive drugs may have a more or less marked effect on carotid IMT and plaque progression. Compared with no-treatment, diuretics/+ beta-blockers or ACE inhibitors, CCBs attenuate the rate of progression of carotid intima-media thickening (Zanchetti *et al.*, 2002). Few studies have shown a lower thickness of intima-media during treatment with angiotensin II antagonists in respect with patients treated with betablockers (Wang *et al.*, 2006).

The odds ratio for all fatal and nonfatal cardiovascular events in trials comparing active treatment with placebo reached statistical significance ($P = 0.007$).

Comparative studies assessing the effect of statins on IMT progression have demonstrated a beneficial effect on common carotid mean IMT; the effect was greater in the setting of secondary prevention versus primary prevention, in younger patients versus older patients and in studies with a greater proportion of male patients (Kang *et al.*, 2004; Agabiti-Rosei, 2006). Plaque volume was reduced to a greater extent with the long term treatment with angiotensin II blocker in respect to the betablocker was demonstrated by noninvasive 3D plaque measurement (Stumpe *et al.*, 2007). A significant change in 3D plaque volume was also observed during short term treatment with a high dose of statin in a small group of 20 patients (Huang *et al.*, 2013), while no significant changes in plaque composition were observed after 4 years of treatment with either lacidipine or atenolol (Paliotti *et al.*, 2005).

It has not been demonstrated whether a decrease of IMT progression may be associated with a reduction of cardiovascular events and an improvement in prognosis (Zanchetti *et al.*, 2009; Costanzo *et al.*, 2010).

Changes in plaque volume and composition characteristics seem to have additional prognostic significance (Van Engelen *et al.*, 2014).

Aortic stiffness

In more recent years it has become possible to evaluate the vascular aging process by the measurement of arterial stiffness with non-invasive technique (Nilsson *et al.*, 2013). Regional and local arterial stiffness can be measured noninvasively, at various sites along the arterial tree, based on direct measurements of parameters strongly linked to wall stiffness. By arterial tonometry carotidofemoral (aortic) pulse wave velocity (PWV) may be measured and the threshold of 10 m/s indicates the presence of increased large artery stiffening (Mancia *et al.*, 2013). Nuclear magnetic resonance may be the most appropriate method for the evaluation of less superficial vessels (Laurent *et al.*, 2006; Mancia *et al.*, 2013; Van Bortel *et al.*, 2012).

The importance of carotidofemoral (aortic) PWV as a sub-clinical organ damage for a more accurate and precise CV risk stratification has been underscored by the 2013 ESH/ESC guidelines. Several studies have documented a correlation between arterial stiffness measures (in particular aortic PWV) and aging, arterial hypertension, diabetes mellitus, metabolic syndrome, hypercholesterolemia and even markers of chronic inflammation processes (Laurent *et al.*, 2006).

A large number of publications and several reviews have reported the various pathophysiological conditions associated with increased arterial stiffness and wave reflections, including arterial hypertension and in particular isolated systolic hypertension (Asmar, 2015; Mitchell *et al.*, 2003). Arterial stiffness is associated with target organ damage including LVH (Asmar, 1995), micro-albuminuria, carotid intima-media thickening, endothelial dysfunction and microvascular alterations (Muiesan *et al.*, 2013)).

Aging and BP are the main determinants of vascular stiffness, inducing a reduced synthesis and an increased degradation of elastin, in association with an increased synthesis and reduced degradation of type 1 and type 3 collagen (Cliff, 1970); calcification of the vessel wall may also occur, as frequently observed in elderly subjects and in hypertensive patients.

In recent years numerous studies have reported an association between alterations of arterial stiffness or of pulsatile hemodynamic parameters and the occurrence of CV events (Vlachopoulos *et al.*, 2010). The increase in cfPWV has been shown to predict all-cause mortality, CV mortality, fatal and non-fatal coronary artery events, fatal stroke in the general population (Mattace-Raso *et al.*, 2006; Shokawa *et al.*, 2005; Willum-Hansen *et al.*, 2006) and in different groups of patients, with arterial hypertension (Laurent *et al.*, 2001; Laurent *et al.*, 2003), diabetes mellitus (Cruickshank *et al.*, 2002), end stage renal disease (Blacher *et al.*, 1999; Shoji *et al.*, 2001), elderly patients (Meaume *et al.*, 2001; Sutton-Tyrrell *et al.*, 2005). Most importantly the prognostic significance of PWV is independent of brachial BP values, of major CV risk factors, and of the Framingham risk score (Boutouyrie *et al.*, 2002), indicating that aortic stiffness has a better predictive value than each of the classical risk factors (Ben-Shlomo *et al.*, 2014).

Data about prognostic significance of arterial stiffness measured at other arterial sites are less consistent. Carotid stiffness was predictive of CV events in a small number of patients with ESRD (Pannier *et al.*, 2005) or following renal transplantation (Barenbrock *et al.*, 2002) and in a large prospective cohort with a high prevalence of insulin resistance (Van Sloten *et al.*, 2014), while no predictive value was demonstrated in a larger number of patients with manifest arterial disease (Dijk *et al.*, 2005).

Data on changes in PWV and occurrence of CV events are still limited. Guerin *et al.* (2001) have demonstrated that in end stage renal disease patients the persistence of elevated cfPWV was associated with a worse survival as compared to patients with a decrease of cfPWV, independently of brachial BP changes. It remains to be demonstrated in hypertensive patients at lower CV risk that a reduction or anormalization of arterial stiffness is effective in reducing CV events beyond brachial BP reduction.

It remains to be demonstrated in hypertensive patients at lower CV risk that a reduction or a normalization of arterial stiffness is effective in reducing CV events beyond brachial BP reduction.

The reduction of BP per se may induce a decrease of cfPWV (Ong *et al.*, 2011). Several non-pharmacological measures, such as exercise training, weight loss, low to moderate sodium diet, moderate alcohol consumption, and dietary supplements may have a beneficial effect on changes in arterial stiffness.

Among antihypertensive classes of drugs, diuretics, beta blockers, ACE inhibitors, angiotensin II type 1 receptor blocker (AT1 blockers), and calcium channel antagonists are able to reduce arterial stiffness (Ghiadoni *et al.*, 2009; Laurent *et al.*, 2006).

Some studies have also shown that a non-dihydropiridinic calcium-antagonist (acute administration) or an ACE-inhibitor (Asmar *et al.*, 2001; Tropeano *et al.*, 2006) or an angiotensin II receptor blocker (Laurent and Boutouyrie, 2014) are able to reduce arterial stiffness and/or wave reflections independently of the reduction in brachial BP.

A decrease in arterial stiffness has been induced in congestive heart failure patients by ACE inhibitors, nitrates, and aldosterone antagonists, statins, and antidiabetic drugs. The additional BP independent effect of different pharmacological interventions remains to be further evaluated.

Microvascular structure

Essential hypertension is associated with the presence of structural alterations in the microcirculation (Mulvany and Aalkjaer, 1990; Schiffrin, 2004b), that may be also the result of adaptive mechanisms to the increased blood pressure load. Since structural alterations might have hemodynamic consequences, their evaluation represent an important target, also in terms of cardiovascular risk stratification (Izzard *et al.*, 2005; Aalkjaer *et al.*, 1989).

The mechanisms underlying the development of microvascular structural alterations are only partially elucidated. The extent of structural alterations in subcutaneous small resistance arteries is particularly pronounced in hypertensive patients with type 2 diabetes mellitus (Endemann *et al.*, 2004; Rizzoni *et al.*, 2001) or obesity (Grassi *et al.*, 2010; De Ciuceis *et al.*, 2011), suggesting that the association of several cardiovascular risk factors may have a synergistic, deleterious effect on the microcirculation.

The increase of media to lumen ratio of small resistance arteries, taken from a mesenteric or gluteal region subcutaneous tissue biopsy, was related to the incidence of cardiovascular events in 3 different studies (Rizzoni *et al.*, 2003; De Ciuceis *et al.*, 2007; Mathiassen *et al.*, 2007) including patients at high or moderate global CV risk. The media to lumen ratio was significantly associated to the occurrence of cardiovascular events, independently of other CV risk factors, strongly indicating a relevant prognostic significance of small resistance artery structural alterations in a high risk population. In addition Buus *et al.* (2013) have demonstrated that changes of small resistance arteries structure during antihypertensive treatment may have a prognostic role. Antihypertensive treatment may induce the reversal of increased media to lumen ratio and inhibitors of the RAS (including ACE-inhibitors, angiotensin II receptor antagonists, aliskiren) and calcium antagonist are more effective in this regard (Agabiti-Rosei *et al.*, 2009).

Other new techniques for evaluation of microvascular morphology in the retinal vasculature are presently used or under clinical investigation, representing a promising and interesting future perspective (Ritt *et al.*, 2008; Koch *et al.*, 2014).

Endothelial dysfunction, oxidative stress, chronic inflammation and fibrosis may be responsible for vascular damage in patients with secondary hypertension, in particular when the renin angiotensin aldosterone system is activated (Rizzoni *et al.*, 1998). Aldosterone may induce vascular smooth muscle cells hypertrophy and hyperplasia (Schiffrin, 2004c) leading to an increase in the media to lumen ratio of small resistance arteries (Rizzoni *et al.*, 1996) and may alter extracellular matrix composition, stimulating collagen deposition and fibroblasts proliferation (Schiffrin, 2004a).

Vascular changes and aldosterone

Rizzoni *et al.* have demonstrated that in patients with renovascular hypertension and in those with PA, the media to lumen ratio of small resistance arteries was increased, according to hypertrophic or eutrophic remodeling, with a narrower diameter and an increased stiffness of media layer, due to excessive collagen III content (Rizzoni *et al.*, 1998; Rizzoni *et al.*, 2006). The effect of aldosterone could be mediated, at least in part, by endotelin-1, as suggested by Schiffrin *et al.* (1997).

Several studies have evaluated large arteries changes in patients with primary aldosteronism, in order to assess the effect of aldosterone beyond blood pressure induced damage. Changes in aortic stiffness, carotid intima-media thickness or carotid plaque have been measured, with conflicting results.

Rossi *et al.* have observed that carotid IMT and the number of plaques are greater in patients with renovascular hypertension, but not in those with primary aldosteronism, as compared with essential hypertensive patients (Rossi *et al.*, 1993). Similar results were obtained by Rizzoni *et al.* (1998) and more recently confirmed by Muiesan (2015). Turchi *et al.* have observed in patients with PA a higher CV risk, due to a greater prevalence of hyperglycemia, metabolic syndrome and LVH, but similar IMT and arterial peripheral disease before and after medical or surgical treatment (Turchi *et al.*, 2014). On the opposite an increase in IMT was reported by some authors (Holaj *et al.*, 2007; Bernini *et al.*, 2008), when comparing patients with PA and essential hypertensives and/or normotensive subjects.

In some other studies, conducted in a small number of patients an unfavorable effect of aldosterone on large arteries structure and function was observed. Štrauch *et al.* (2006) and Bernini *et al.* (2008) have observed an increase in cfPWV and of augmentation index (AI) in patients with PA as compared with normotensives and essential hypertensives. Mark *et al.* (2014) report similar findings, obtained with nuclear magnetic resonance measurements of aortic distensibility. Park *et al.* observed a significant correlation between heart-femoral PWV and plasma aldosterone levels, and a significant increase in heart-femoral PWV but not of peripheal PWV (brachial-ankle PWV) in PA as compared to essential hypertensives (Park *et al.*, 2007). More recently Rosa *et al.* (2012) reported a significantly higher cfPWV and femoro-tibial PWV in PA patients as compared to essential hypertensives.

Chang *et al.* (2014) suggested that levels of serum potassium may exert a role on aortic stiffness, based on a correlation observed between serum potassium concentration and augmentation index.

On the opposite no significant differences cf. PWV were observed by Tsioufis *et al.* (2008) between essential hypertension and PA patients.

More recently Fujii *et al.* have not found significant differences between patients with adrenal bilateral hyperplasia and essential hypertensive patients as related to endothelial function (evaluated by flow mediated vasodilation), cardio-ankle vascular index (CAVI), IMT and coronary artery calcium score (Fujii, 2016).

Only one study has investigated the role of endothelial progenitor cells (EPC) in PA patients, showing a reduced number of circulating EPC with a significant increase 6 months after adrenalectomy or medical treatment with spironolactone (Wu *et al.*, 2011).

The effect of surgical adrenalectomy on cardiovascular alterations has been analyzed in different studies, suggesting a favorable effect of adrenalectomy on blood pressure control, possibly restoring normal vascular structure. In one study (Strauch *et al.*, 2008) a significant decrease in aortic stiffness was observed after adrenalectomy, but not during medical treatment with spironolactone. Other studies (**Table 1**) have addressed this point, with conflicting results.

Table 1 Main studies evaluating vascular target organ damage in primary aldosteronism patients

Authors study	*Publication year*	*PA patients (N)*	*IMT*	*Plaque prevalence*	*Cf PWV*	*Peripheral PWV*	*AI*	*FMD*

IMT, carotid intima-media thickness; *PWV*, pulse wave velocity; *AI*, augmentation index; *FMD*, flow mediated vasodilatation.

Renal TOD

According to the 2013 ESH/ESC Guidelines the assessment of serum creatinine and the calculation of estimated glomerular filtration rate (eGFR) is recommended to assess renal excretory function (Mancia *et al.*, 2013; Sternlicht and Bakris, 2017), and urinary albumin excretion is considered a biomarker of early renal damage. Both measurements are low-cost and easy to perform. Urinary albumin excretion and eGFR should be measured both in hypertensive patients, in order to better stratify cardiovascular risk (Mancia *et al.*, 2013; Viazzi *et al.*, 2016).

Albuminuria

The increase in blood pressure values, but also other risk factors, such as insulin resistance, salt sensitivity, central obesity, smoke, atherogenic lipid profile, have been found to be associated to microalbuminuria. In addition the presence of albuminuria is usually related to other signs of extra-renal organ damage such as left ventricular hypertrophy, carotid atherosclerosis and biomarkers of vascular endothelium damage (Sternlicht and Bakris, 2017). Moreover a relationship between even modest increase in albuminuria and cardiovascular morbidity and mortality (Currie and Delles, 2013) has been observed, leading to the estimation of microalbuminuria as an integrated marker of cardiovascular risk.

As shown by Redon *et al.* albuminuria reaches normal values in about 50% of patients, during antihypertensive treatment, while in about 10% of them a progression towards more severe proteinuria occurs (Redon and Martinez, 2012; Pascual *et al.* 2005). Poor blood pressure control and a progressive increase in glucose plasma levels are the main determinants of a new development of microalbuminuria during treatment. However, since a reliable change in albuminuria requires a regression or an increase of more than 50% of the initial value, some caution should be taken when evaluating albuminuria changes during treatment. The variability in microalbuminuria changes evaluation may be reduced by the calculation of the average value of two different measurements performed in different days.

A recent meta-analysis of trials evaluating blood pressure targets with respect to proteinuria progression has shown that a more aggressive target (<130 mmHg vs. <140 mmHg) is associated with a lower prevalence of albuminuria (Lv *et al.*, 2013; Viazzi *et al.*, 2016).

Some randomized clinical trials have suggested that drugs acting on the renin–angiotensin–aldosterone system (RAAS) are more effective in reducing albuminuria in respect to placebo in individuals with diabetic or nondiabetic nephropathy and with cardiovascular disease 104 (Pascual *et al.*, 2005). The association of two RAAS blockers is not recommended, when a combination treatment is needed.

In patients with resistant hypertension, treated with ACE inhibitor or ARB monotherapy, the addition of a mineral corticoid receptor antagonist was associated with a further reduction of albuminuria, possibly because of the greater efficacy in home BP reduction.

The reduction of albuminuria during treatment may favorably affect cardiovascular and renal prognosis (Redon and Martinez, 2012).

Glomerular filtration rate

Glomerular filtration declines with increasing age, and high blood pressure values, diabetes, and dyslipidemia represent the main factors accelerating the decrease glomerular filtration rate over time (Sternlicht and Bakris, 2017), when all diseases producing a direct renal damage are excluded.

The diagnosis of chronic kidney disease (CKD) corresponds to the presence of eGFR values below 60 mL/min/1.73 m^2. CKD is observed in a significant proportion of hypertensive patients, mainly in older individuals, in women and in diabetics. A lower eGFR is associated with a higher risk for CV events (Sternlicht and Bakris, 2017) but few data have demonstrated that changes in eGFR may influence cardiovascular prognosis in hypertensive patients.

The adequate and long term control of BP values during antihypertensive treatment favors the preservation of renal function and delays progression to end-stage renal disease in hypertensive patients with or without chronic nephropathy, although a slight increase in serum creatinine, due the transient renal hypoperfusion, may occur immediately after starting antihypertensive treatment. Blood pressure targets with respect to CKD progression have shown that a more aggressive target (<130 mmHg vs. <140 mmHg) is not associated with a reduction in eGFR (Viazzi *et al.*, 2016; Lv *et al.*, 2013). Recent data from the SPRINT study (Systolic Blood Pressure Intervention Trial) have shown that in hypertensive non diabetic patients with CKD who achieved during treatment a value of unattended blood pressure lower than 120 mmHg the risk of cardiovascular events was lower (SPRINT Research Group *et al.*, 2015).

In patients with even mild degree of CKD a combination treatment of a RAAS blocker with other classes of antihypertensive drugs is usually needed to reach adequate BP control. In the ACCOMPLISH study the association of an ACE-inhibitor and a calcium antagonist was more effective in preventing the progression to creatinine doubling and/or to the development of end stage renal disease, as compared with the combination of an ACE-inhibitor and a diuretic (Jamerson *et al.*, 2008).

An excessive amount of aldosterone may induce an increase in glomerular filtration rate and an increase in renal perfusion and albuminuria independently of BP values.

In patients with PA the presence of renal disease has been investigated with conflicting results. A modest level of renal parenchymal damage has been observed at renal biopsies by Danforth *et al.* (1977). According to Catena *et al.* (2007) CKD (i.e. eGFR <60 mL/min/1.73 m^2) was found in 7% of a relatively large number of PA patients ($n = 56$). In the multicenter PAPY study the prevalence of microalbuminuria was twice greater in PA patients (around 30%) as compared to essential hypertensives (around 15%) (Rossi *et al.*, 2006); in patients with adrenal adenoma the amount of albuminuria is even higher.

In patients with PA higher values of both eGFR and albuminuria have been observed, suggesting a condition of glomerular hyperfiltration, caused by sodium retention and volume expansion induced by aldosterone excess (Sechi *et al.*, 2009). Albuminuria and eGFR were significantly increased in PA patients as compared to essential hypertensive patients and normotensive subjects (Catena *et al.*, 2007) and after adrenalectomy, but not during medical treatment, these changes were significantly reduced (Ribstein *et al.*, 2005). On the opposite medical treatment was as effective as adrenalectomy in another group of PA patients (Sechi *et al.*, 2006).

In the German registry of PA patients, Reincke *et al.* have observed an increased prevalence of patients with serum creatinine values >1.25 mg/dL in PA (29%) as compared to essential hypertensives (10%). In addition after adrenalectomy, but also after medical treatment with spironolactone, eGFR was reduced and serum creatinine values were increased (Reincke *et al.*, 2009).

In conclusion it seems that surgical or medical treatment may reduce renal hyperfiltration induced by the aldosterone excess, revealing the presence of renal dysfunction (Ribstein *et al.*, 2005; Sechi *et al.*, 2006; Reincke *et al.*, 2009).

Moreover a higher prevalence of renal cysts was reported in PA patients (44%) as compared to essential hypertensives (25%) by Torres *et al.* (1990). During a long period of follow-up after adrenalectomy or medical treatment no changes in the number and dimensions of renal cysts was found, suggesting that both therapeutic solutions may be effective in halting the development and or progression of renal cysts (Novello *et al.*, 2007).

Conclusions

ESH/ESC guidelines 2013 recommend the measurement of serum creatinine, urine albumin excretion and electrocardiographic LVH in all patients with hypertension both at baseline and during treatment. In addition echocardiographic left ventricular mass, ultrasonic carotid wall thickness, aortic PWV and ankle-brachial index measurements should be considered to better stratify the cardiovascular risk.

In the future, more effort should be made to identify which combination of markers to measure, at what time points, in which patients, and with which consequence for a better clinical use of TOD during antihypertensive treatment.

Glossary

Lacunar syndrome Set of signs and symptoms indicating a stroke that is related to disease of a single small perforating artery.

Pituitary apoplexy Term for an ischemic or hemorrhagic stroke of the pituitary gland.

Introduction

According to the World Health Organization (WHO), a stroke constitutes the sudden occurrence of signs and symptoms of a focal disorder in the brain (paresis, sensory loss, ataxia, or disturbance of higher cortical functions) for which there is no other cause than a vascular one. The WHO requires the signs and symptoms to be present for at least 24 h. If signs and symptoms clear completely within 24 h, the term "TIA" (transient ischemic attack) is used.

In practice, the World Health Organization's (WHO) definitions of stroke and TIA (transient ischemic attack) would not allow the diagnosis of stroke during the first 24 h. It should be noted that in the vast majority of TIAs (where signs and symptoms clear completely within 24 h), the signs and symptoms clear within 30–60 min. Any syndrome lasting longer than 60 min is much more likely to become a stroke than a TIA. Strokes are ischemic in approximately 80% of patients and are hemorrhagic in 20%.

Diabetes Mellitus and Other Disorders of Glucose Metabolism

The one endocrinological disorder that stands out because of its intricate associations with stroke is diabetes mellitus. All types of associations with stroke occur in the case of diabetes mellitus.

First, diabetes mellitus is an important risk factor for stroke, independent of other risk factors such as hypertension and age. The risk of ischemic stroke is increased two- to fourfold in patients with diabetes mellitus. Approximately 15% of patients with diabetes mellitus will eventually have a fatal stroke. Conversely, approximately 20% of patients with stroke have diabetes mellitus. Diabetes mellitus is more strongly related to stroke in the presence of hypertension and hypercholesterolemia. In patients with such risk factors, small vessel disease is especially likely. Such small vessel disease accounts for approximately 20% of strokes. Strokes due to small vessel disease are typified by lacunar syndromes (which lack cortical symptomatology and manifest as pure motor, pure sensory, sensorimotor, ataxic hemiparesis or dysarthria clumsy hand syndromes). Imaging shows lacunar strokes that have a subcortical distribution and are smaller than 1 cm in diameter. The pathological finding in small vessel disease is lipo-hyalinosis of small penetrating arteries. Retinopathy and autonomic neuropathy are other markers of an increased risk of stroke in diabetic patients. The pathogenesis of stroke in patients with diabetes mellitus involves increased fibrinogen, factor V and VII levels, increased hematocrit, platelet aggregation and adhesion, decreased red blood cell deformability, decreased fibrinolytic activity, and increased release of B thromboglobulin. Unfortunately, tight glycemic control in diabetic patients has not been shown to reduce the risk of stroke (as either a primary or a secondary preventive measure), although it does reduce the risk of many other mostly microvascular complications. However, the intensive concurrent treatment of various risk factors for cardiovascular disease, including diabetes in a study by Gaede and colleagues was shown to decrease the risk of stroke. In patients with myocardial infarction, treatment of hyperglycemia (blood sugar levels >11 mmol L^{-1}) was shown to decrease mortality. Although nonfatal stroke was not the primary end point, and intensive treatment was simultaneously targeted at a number of risk factors such as diabetes, there were only 3 nonfatal strokes in the intensive treatment group and 11 in the control group. However, the specific contribution of glycemic control to this overall risk reduction is not clear.

Second, diabetes mellitus and acute hyperglycemia are related to the outcome in a complex way. Hyperglycemia at the onset of stroke is associated with a poorer outcome of the presenting stroke if it is cortical yet a better outcome when the stroke is subcortical. These observations have been made in animal and clinical data. The detrimental effects of hyperglycemia on cortical strokes have been hypothesized to be due to the larger penumbral areas in cortical compared to subcortical strokes. The mechanisms leading to the increased vulnerability of these penumbral zones (=hypoperfused but viable border zones surrounding brain infarction) are not clearly understood, but include increasing tissue acidosis secondary to anaerobic glycolysis, increased blood–brain barrier permeability, and vascular changes. Animal studies have shown convincingly that hyperglycemia, as

☆*Change History:* December 2015. PCAJ Vroomen and GA Donnan updated the text and further readings to this entire article.

This article is an update of Patrick C.A.J. Vroomen, Geoffrey Donnan, Stroke, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 333-338.

compared with euglycemia, increases the extent of ischemic damage in rats and monkeys. However, in focal ischemia models, this effect was shown only for reperfused brain tissue, albeit less consistently. The negative effects of hyperglycemia on outcome of brain ischemia are probably mediated through increased lactic acidosis and increased release of excitatory amino acids (glutamate in particular) that may contribute to neuronal cell death (excitotoxicity), exaggeration of edema formation, blood–brain barrier disruption, and hemorrhagic transformations. In humans, the data underlining a causal relation between hyperglycemia and stroke are still only circumstantial. This is explained partly by the intricate relations between the pathogenesis of hyperglycemia and the evolution and type of the stroke.

Reperfused brain tissue may be especially vulnerable to hyperglycemia, whereas anoxic tissue may even benefit from hyperglycemia. It has been shown that the ischemic penumbra in stroke patients, represented as a mismatch between perfusion and diffusion on magnetic resonance imaging (MRI) (**Fig. 1**), is more likely to progress to infarction when the patient had hyperglycemia at presentation. Also, hyperglycemia levels were related to lactate levels, which in turn were independently related to salvage of mismatch tissue. In a previous study, a poorer outcome of strokes had been reported when hyperglycemia occurred in nonlacunar strokes that may show reperfusion but not in lacunar strokes with little or no reperfusion. A special vulnerability of reperfused brain tissue to hyperglycemia is also suggested by the experiences with thrombolysis in stroke patients. In the first trial showing the benefit of thrombolysis in acute stroke patients, the negative effects of hyperglycemia on outcome of thrombolysis were also reported. Further studies have shown that it was specifically in patients with reperfusion after tissue plasminogen activator (tPA) that hyperglycemia was associated with poor outcome. In these patients, there is a relation with hemorrhagic transformation of the infarct. Interestingly, diabetes mellitus has actually been reported to carry a decreased risk of primary intracerebral haemorrhage, so it seems less likely that diabetic vasculopathy explains the increased incidence of hemorrhagic transformation in thrombolyzed strokes. The fact that stroke type determines the association between hyperglycemia and stroke outcome is also underlined by the fact that, in hemorrhagic strokes, hyperglycemia is not related to a poorer outcome in both nondiabetic and diabetic patients.

It seems that acute hyperglycemia may be more strongly related to poor outcome than is hyperglycemia due to diabetes mellitus. In a large meta-analysis, hyperglycemia was found to have a relative risk of mortality after ischemic stroke of 3.1 in nondiabetic patients and only 1.3 in diabetic patients. In conclusion, the literature suggests a causal relation between hyperglycemia and stroke outcome rather than hyperglycemia as a paraphenomenon of strokes with more severe outcome. It seems sensible to withhold intravenous fluids containing glucose during the acute phase of a cortical stroke, and hyperglycemia should be controlled with the usual measures, especially when blood sugar levels higher than 16 mmol L^{-1} are measured. However,

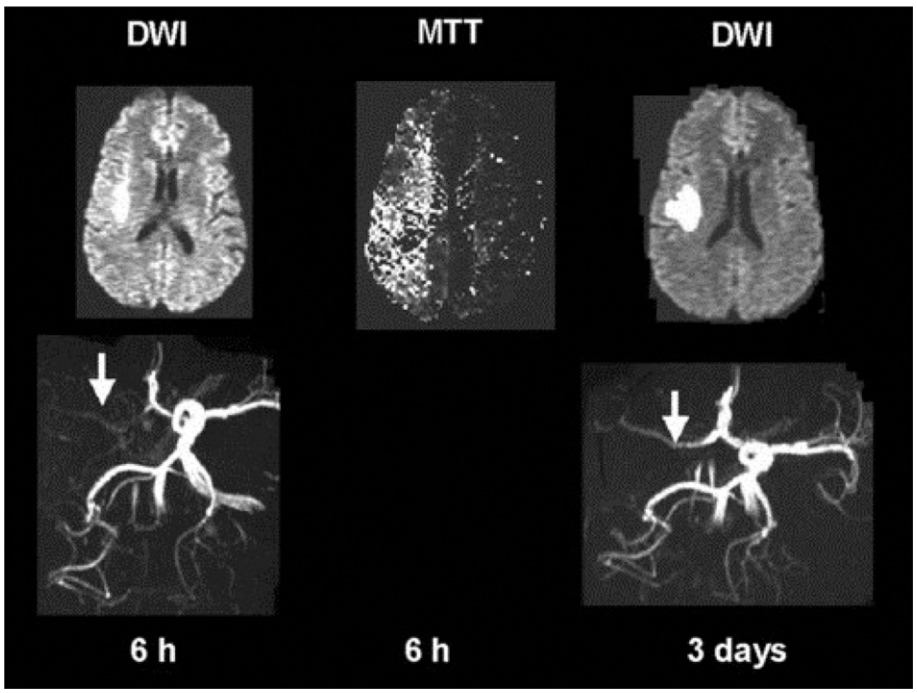

Fig. 1 Diffusion weighted imaging (DWI) sequence 6 h after the onset of a stroke showing a circumscribed area of high signal indicating disturbed diffusion. This represents infarction of the brain. The magnetic resonance (MR) angiography after 6 h shows absent flow in the right middle cerebral and carotid artery. The mean transit time (MTT) MR shows hypoperfusion of the total right middle cerebral artery territory. The area of hypoperfusion on the MMT MR minus the area of disturbed diffusion on the DWI MR is generally considered to be the penumbra. The DWI MR after 3 days shows that the hypoperfused area has not progressed to infarction. The MR angiography shows reperfusion of the right middle cerebral artery through the circle of Willis. Courtesy of Geoffrey Donnan, National Stroke Research Institute.

whether tight control of hyperglycemia should be the goal in patients with stroke cannot be determined with certainty. A British trial was stopped due to slow recruitment but failed to show any significant effect of acute treatment of hyperglycemia on the outcome of stroke. In a recent meta-analysis, intensive glucose lowering had no effect on outcome/mortality of stroke.

Hyperglycemia occurs in 20–50% of stroke patients. One-third of these hyperglycemic patients were known to have diabetes mellitus. In another third, the hyperglycemia is the initial presentation of *de novo* diabetes, demonstrated by an elevation of glycosylated hemoglobin (HbA1c) levels. In the remainder (with a normal HbA1c at the time of hyperglycemia), the hyperglycemia is considered to be a result of the stroke, but the mechanism for this is unclear. Although a general stress response may lead to hyperglycemia, this is probably not the predominant cause in patients with a stroke. Other parameters of the stress response, such as levels of catecholamines, have been shown not to be related to blood sugar levels after stroke. Because the effects of focal ischemic events on neurotransmitter release at a distance from the focal ischemia can operate in the entire ipsilateral hemisphere of the stroke, the neuroendocrine axis may well be influenced by these alterations in neuronal excitation. Alternatively, the focal ischemic brain may mediate hyperglycemia directly through as yet unclarified mechanisms. If this were to occur preferentially in inadequately reperfused brain, the association of hyperglycemia and poor outcome of stroke would represent a paraphenomenon and not a causal relationship.

Although hyperglycemia will rarely be confused with stroke, the differential diagnosis between stroke and hypoglycemia can be problematic. The blood sugar level in the patient presenting with coma or focal neurological deficit is obviously of crucial importance. If it is normal, hypoglycemia is unlikely. However, in the case of focal neurological deficit, the hypoglycemia may have been corrected by the patient's oral glucose intake before the neurological signs and symptoms resolve. When the patient is comatose, established hypoglycemia will be the likely cause. More difficulties arise when the patient presents with hypoglycemia and focal neurological deficits. Hypoglycemia can occasionally present with focal neurological deficit without any accompanying symptoms of hypoglycemia. Correction of blood glucose levels will generally lead to a rapid recovery of the deficit, but excluding a transient ischemic event might be impossible in these cases. In patients with previous strokes, hypoglycemia reproduces or worsens the previous deficit. When there are accompanying signs and symptoms of hypoglycemia, the balance will definitely shift toward hypoglycemia as a cause of the neurological deficit.

Thyroid Disease

Both hyperthyroidism and hypothyroidism can contribute to a cardioembolic source for stroke. The most frequent event is hyperthyroidism leading to atrial fibrillation, a factor that generally leads to a fivefold increase in risk of subsequent stroke and also a factor that, if it cannot be cured, leads to anticoagulation. Hypothyroidism can affect cardiac function and, thereby, the risk of intracardiac thrombus formation. Graves–Basedow disease is rarely associated with cerebral vasculitis, an entity also referred to as Hashimoto's encephalopathy. In a large cohort study of 47,573 subjects subclinical hypothyroidism was related to an increased risk of stroke only in subjects younger than 65 years.

Thyroid disease has not been firmly established as affecting the outcome of strokes. However, in general, a range of systemic diseases affect the outcome of stroke, and it seems appropriate to diagnose and treat thyroid disease promptly in patients in these circumstances.

Strokes have not been shown to lead to thyroid disease.

Thyrotoxicosis may feature in the differential diagnosis of stroke. Delirium and coma may be a feature of both, but the fever, tachycardia, hypotension, vomiting, and diarrhea should point toward thyrotoxicosis. Hyperthyroidism has been reported to lead to isolated corticospinal tract dysfunction, the mechanism of which is not known. Hypothyroidism may present with limb and gait ataxia as signs of cerebellar dysfunction. The onset is often more gradual than in strokes.

Parathyroid Disease

Hyperparathyroidism has been shown to contribute significantly albeit weakly to overall cardiovascular risk. Hyperparathyroidism contributes to hypertension. Patients with osteoporosis and compensatory hyperparathyroidism may have an increased risk of stroke due to this contribution. Hypoparathyroidism has not been identified as a risk factor for stroke, but it is related to MELAS syndrome. MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, stroke) is a mitochondrial disorder related to a point mutation in the transfer RNALeu(UUR) gene. It is typified by mitochondrial (ragged red fiber) myopathy, epilepsy, lactate acidosis, and stroke-like episodes. Frequently, this syndrome is associated with hypothalamo–pituitary axis dysfunction, diabetes mellitus, and/or hyperthyroidism.

Parathyroid dysfunction has not been shown to affect the outcome of stroke or to be the result of stroke.

Hypercalcemia, whether as a result of hyperparathyroidism or secondary to malignancy, may be confused with a stroke when a patient presents with confusion, nausea, and vomiting. In hypercalcemia, there is fatigue, anorexia, constipation, increased urination, a short QT interval, and generally a serum calcium level higher than 2.9 mmol L^{-1} (11.5 mg dL^{-1}).

Hypothalamo–Pituitary Axis Disease

Hypopituitarism is associated with an increased risk of stroke, reflected in an excess mortality rate for cerebrovascular disease of 2.4. Because of the complexity of hormonal and metabolic disturbances in hypopituitarism, the causes of this excess mortality are

poorly defined. A prothrombotic tendency due to growth hormone deficiency (which tends to persist even when hormones are adequately substituted), Cushing syndrome, and secondary hyperthyroidism are among the factors that may be implied in the pathogenesis of strokes. In a population of pituitary adenomas this excess risk of stroke was also shown. It was shown not to be related to radiation therapy of the pituitary region.

Pituitary disease has not been shown to affect the outcome of stroke, although it may affect the chances of recurrence of stroke.

Pituitary apoplexy is the term that refers to a stroke in the pituitary gland. Such strokes can be either ischemic or hemorrhagic and are often complications of pituitary adenomas or the surgery or radiotherapy thereof. The condition is probably underdiagnosed given that the pathological correlate of apoplexy has a prevalence of 1–3% in autopsy studies. The clinical presentation is highly variable but should be suspected in any patient with severe headache, visual field defects, ophthalmoplegia, and/or altered mental status. In some cases, there is only headache at first. This headache is accompanied by nausea, vomiting, nuchal rigidity, fever, stupor, and coma (when blood and necrotic tissue leak and cause the features of subarachnoid hemorrhage or aseptic meningitis). In tumorous apoplexy, the destruction of the pituitary in most cases leads to hypopituitarism because most underlying adenomas are endocrinologically silent. In cases of endocrinologically active adenomas, there can be spontaneous resolution of preexisting endocrinopathy after apoplexy. The slowly evolving expansion of adenomas rarely leads to cranial nerve deficit because the nerves slowly lengthen in response to this expansion. In apoplexy (**Fig. 2**), there is sudden compression of cranial nerves due to hemorrhage or infarction and swelling. Compression of the optic nerve leads to visual field defects and decreased visual acuity, whereas compression of nerves III, IV, and VI leads to oculomotor disturbances. Compression of the trigeminal nerve may result in facial paresthesias and absent corneal reflex. Compression of the cavernous sinus may result in proptosis and eyelid edema. Finally, there can be Horner syndrome due to compression of the sympathetic chain and hyperpyrexia, and there can be diabetes insipidus or SIADH (syndrome of inappropriate antidiuretic hormone) when the hypothalamus is compressed.

The radiological diagnosis can be made on computed tomography (CT) if the stroke is hemorrhagic or if the adenoma is sufficiently large. The investigation of choice is MRI, which shows hemorrhage and underlying adenomas in great detail (**Fig. 3**). Infarction can be difficult to diagnose on routine magnetic resonance sequences. Diffusion-weighted images greatly increase the accuracy of the diagnosis of pituitary infarction. Peripheral enhancement of intrasellar masses can be another less specific sign. The hypothalamic–pituitary unit can be tested as outlined elsewhere. Pregnant women have a special predisposition to apoplexy due to the prothrombotic state related to pregnancy (and the resulting 12-fold increase in risk of stroke) and the dramatic enlargement of the pituitary gland due to the proliferation of prolactin-secreting cells. The classical features of postpartum pituitary apoplexy are absence of lactation, persistent amenorrhea, and lethargy. Other predisposing factors to pituitary apoplexy include bleeding disorders, anticoagulation, upper respiratory tract infections, trauma, carotid angiography, Cushing's disease, diabetes mellitus,

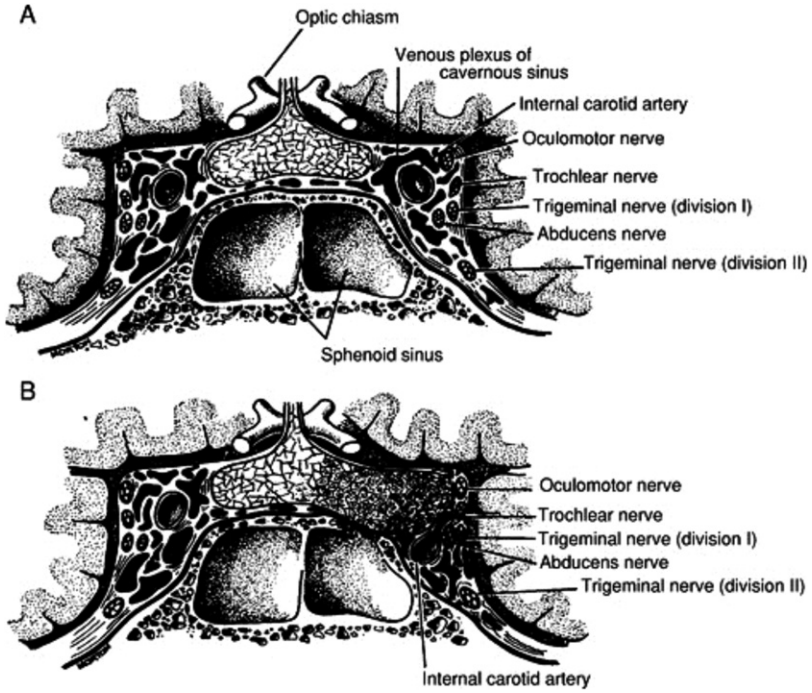

Fig. 2 (A) Posterior coronal view showing anatomical relationship of pituitary gland to optic chiasm superiorly, sphenoid sinus inferiorly, and cavernous sinus laterally. (B) Mechanism of acute compression of structures within cavernous sinus from sudden expansion of pituitary adenoma due to hemorrhage or infarction and edema. Note that the further the tumor has eroded the floor of sella turcica prior to apoplectic episode, the more likely it is that multiple structures within the cavernous sinus will be involved. Reproduced from Reid, R., Quigley, M., and Yen, S. (1985). Pituitary apoplexy. *Archives of Neurology* 42, 712–719.

adrenalectomy, atherosclerosis, sickle cell trait, and acromegaly. Surgical intervention is advocated in the majority of patients, with radiotherapy a less likely option.

Less catastrophic is the effect of nonpituitary stroke on the hypothalamic–pituitary–adrenal (HPA) axis. Stroke is associated with increased activity of the HPA, manifested particularly by hypercortisolism. The normal regulation of cortisol secretion by adrenocorticotropic hormone (ACTH) is disturbed after stroke, a process in which cytokines seem to be implicated. Such a pathological HPA axis may exhibit an overriding function on established risk factors for cardiovascular disease, diabetes mellitus, and stroke such as abdominal obesity, hypertension, cholesterol, and triglycerides. Whether there is a causal relation between stroke and increased HPA axis activity needs to be further elucidated given that depression, anxiety, alcohol consumption, and smoking all have been shown to have similar effects. Also, changes in growth hormone, prolactin, and thyrotropin response to thyrotropin-releasing hormone have been reported, and some of these changes may be a consequence of the hypersensitive HPA axis. They may explain some of the insulin resistance after stroke. It has been postulated that stroke in the caudate nucleus interrupts neurotransmitter pathways involved in the control of secretion of gonadotropins. Although hypercortisolism and some of the other disturbances have been related to disorientation and levels of motor impairment, the clinical relevance of many of the changes remains uncertain. In general, stroke leads to an increase in antidiuretic hormone (ADH) levels. However, this usually does not lead to hyponatremia. Patients with subarachnoid hemorrhage are especially likely to develop a syndrome of inappropriate ADH secretion (SIADH). However, it is important to distinguish SIADH from cerebral salt wasting, which is the more likely explanation for hyponatremia in patients with subarachnoid hemorrhage.

Adrenal Gland Disease

The intermittent hypertension in pheochromocytoma increases the risk of stroke. In some cases, the pheochromocytoma is actually not identified until the patients present with a stroke. Also, Cushing's disease has been postulated to have an increased risk of stroke due to hypercortisolism or to the effects of treatment of Cushing's disease such as external pituitary irradiation and post-treatment hypopituitarism. There are indications that stroke leads to mild relative adrenal insufficiency.

Normetanephrine and Metanephrine☆

Jacques WM Lenders, Radboud University Medical Center, Nijmegen, The Netherlands and Technical University Dresden, Dresden, Germany
Graeme Eisenhofer, Technical University Dresden, Dresden, Germany

Glossary

Catecholamines Include norepinephrine, epinephrine and dopamine and exert their biological activity on adrenergic receptors.
Metanephrines *O*-methylated metabolites of norepinephrine and epinephrine and have no biological activity.
Catechol-*O*-methyl transferase (COMT) Is the enzyme responsible for the conversion of catecholamines into metanephrines. Metanephrines are sensitive biomarkers for the presence of chromaffin cell tumors such as pheochromocytoma and paraganglioma.
Pheochromocytoma and paraganglioma Tumors originating in the adrenal medulla and in the sympathetic ganglia respectively. They produce an excess of catecholamines and metanephrines

Introduction

The metanephrines normetanephrine (NMN) and metanephrine (MN) are *O*-methylated metabolites of the catecholamines norepinephrine (NE) and epinephrine (E). The common basic structure of both molecules is the methylated catechol ring (3-methoxy 4-hydroxy phenyl) in conjunction with an ethylamine group (Fig. 1).

In humans, the physiological enantiomers are L-NMN and L-MN. Metanephrine has a higher molecular weight (197) because, in contrast to NMN (183), it contains a methylated amino group. Metanephrines are not biologically active. The metanephrines provide markers of the extraneuronal metabolism of the parent catecholamines. In clinical medicine, they also provide useful diagnostic tools for patients suspected of having a tumor of chromaffin cells such as pheochromocytoma and paraganglioma. Both metabolites can be measured in plasma and urine. Measurement of conjugated metanephrines in urine is a long-standing and well-established technique. The emergence of a reliable test for plasma-free metanephrines and urinary free metanephrines has fostered a more extensive assessment of the metabolism of catecholamines.

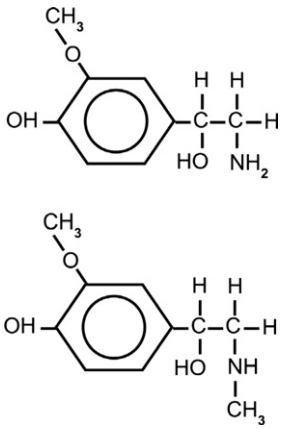

Fig. 1 The chemical structure of normetanephrine (*upper panel*) and metanephrine (*lower panel*).

☆*Change History:* October 2017. JWM Lenders and G Eisenhofer replaced Figs. 1 and 2 by more updated ones and an extra figure on the structure of metanephrines has been added. In the paragraph on Kinetics and metabolism, a short section has been added on the upper reference limits of plasma free metanephrines as related to age. At the end of the paragraph on Kinetics and metabolism, a short section has been added on the seasonal variations in plasma free metanephrines. In the paragraph on Measurement of metanephrines, three short sections have been added on the use of measurements of plasma and urinary metanephrines by the LC-MS/MS assay and made a few textual changes and one reference was added.

 doi:10.1016/B978-0-12-801238-3.03975-1

Source of Metanephrines

The exclusive source of metanephrines is the parent catecholamines NE and E. Catecholamines are biological active amines that play a pivotal role in the regulation of neuroendocrine and cardiovascular function (Lenders and Eisenhofer, 2014). NE functions as a neurotransmitter in the sympathetic nervous system, whereas E is a hormone released from the adrenal medulla. Sympathetic nerves release NE by exocytosis from neuronal vesicular stores into the synaptic cleft. NE leaking from the intraneuronal vesicular stores is converted to 3,4-dihydroxyphenylglycol (DHPG) by the mitochondrial-bound enzyme monoamine oxidase (MAO) (Eisenhofer *et al.*, 2004). Approximately 90% of the NE released into sympathetic neuroeffector junctions is recaptured by neuronal NE transporters (uptake-1) (Eisenhofer, 2001). Some of this is also deaminated by MAO to DHPG, but most is sequestered into storage vesicles for re-release. Of the approximately 10% of neuronally released NE that escapes reuptake, approximately half is removed by extraneuronal uptake (uptake-2), leaving the other half to reach the systemic circulation. After extraneuronal uptake, the NE is metabolized by catechol-*O*-methyltransferase (COMT) to NMN and then by MAO to 3-methoxy-4-hydroxyphenylglycol (MHPG) (Eisenhofer *et al.*, 2004). A small amount of NMN is not metabolized by MAO and enters the bloodstream. Smaller amounts of NMN are formed from extraneuronal metabolism of NE that escapes into the blood stream. Extraneuronal uptake and metabolism accounts for approximately 20% of the total turnover of NE, but only a small proportion of this is represented by circulating and urinary levels of NMN (Eisenhofer *et al.*, 1995b).

COMT is not located in neurons but is found in nonneuronal tissues, such as liver, muscles, and kidneys. An additional important location of COMT is the adrenal medulla, in which the enzyme is responsible for the conversion of E to MN and that of NE to NMN. Circulating E is also subject to uptake-2, but $<10\%$ of MN is derived from this source. $>90\%$ of circulating MN and 23%–40% of circulating NMN are derived from *O*-methylation of E and NE within adrenal medullary chromaffin cells (Eisenhofer *et al.*, 1995a; Eisenhofer *et al.*, 1995b). The importance of the adrenal medulla for production of MN and NMN reflects the fact that COMT is predominantly present in this tissue as the membrane-bound enzyme, an isoform of COMT with particularly high affinity for catecholamines. Therefore, plasma metanephrines are specific markers for extraneuronal and intra-adrenal metabolism of catecholamines, whereas plasma DHPG is a specific marker for neuronal metabolism of catecholamines. From a quantitative standpoint, the neuronal pathway of metabolism greatly predominates over extraneuronal and intra-adrenal pathways for metabolism of NE, whereas the extraneuronal and intra-adrenal pathways are more important for metabolism of E.

Kinetics and Metabolism of Metanephrines

Metanephrines are present in plasma and urine in the free and conjugated form. In plasma, the levels of free plus conjugated metanephrines are approximately 20-fold higher than the levels of the free (unconjugated) metanephrines (Lenders *et al.*, 1995; Pamporaki *et al.*, 2013). In human urine, most metanephrines ($>80\%$) are in the conjugated form. Conjugation of metanephrines by the specific sulfotransferase isoenzyme, SULT1A3, represents an important route of NMN and MN metabolism (Eisenhofer *et al.*, 2001). This enzyme is located mainly in extraneuronal tissue of the mesenteric organs, particularly the wall of the gut. These conjugates are excreted by the kidneys. Other routes of metabolism of free metanephrines involve their conversion by MAO to MHPG. MHPG is further oxidized in the liver by alcohol dehydrogenase to the final end product of catecholamine metabolism, vanillylmandelic acid (**Fig. 2**) (Goldstein *et al.*, 2003).

Plasma levels of free metanephrines in healthy subjects under resting baseline conditions average approximately 0.60 nmol L^{-1} for NMN and 0.30 nmol L^{-1} for MN (Lenders *et al.*, 2002). In contrast to plasma levels of MN, those of NMN increase with age

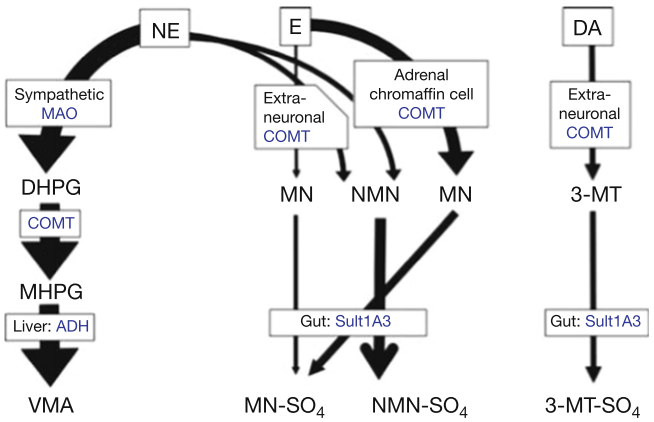

Fig. 2 Diagram showing the major metabolic pathways of norepinephrine (NE), epinephrine (E) and dopamine (DA). The main metabolic pathway for NE is deamination by monoamine oxidase (MAO) within sympathetic nerves to dihydroxyphenylglycol (DHPG) which is the basis for the final metabolite vanillylmandelic acid (VMA). A small part of NE is converted by catechol-*O*-methyltransferase (COMT) extraneuronally and intra-adrenally into normetanephrine (NMN). Epinephrine is mainly converted in the adrenal medulla to metanephrine (MN). Extraneuronal conversion of E contributes to a minor degree to MN formation. Dopamine is *O*-methylated by COMT to 3-methoxytyramine (3-MT). Both metanephrines and 3-MT are conjugated by gut sulphotransferase type 1A3 (Sult1A3) to sulphates ($-SO_4$).

while plasma metanephrine is 30% higher in female than in male subjects. The upper reference limit of plasma MN is 0.45 nmol L^{-1} while that of NMN increases from 0.47 below the age of 18 years to 1.05 nmol L^{-1} over the age of 60 years (Eisenhofer *et al.*, 2013). The plasma half-lives of free (unconjugated) metanephrines are similar to those of catecholamines (approximate 3 or 4 min) (Eisenhofer and Lenders, 2012; Eisenhofer *et al.*, 1995b). The plasma clearances of free NMN and MN are approximately 1.5 L min^{-1}, slightly lower than that of catecholamines (2 L min^{-1}). In contrast, the plasma half-lives of conjugated NMN and MN are much longer (>60 min) and their circulatory clearances are much lower (0.1 L min^{-1}). Since the circulatory clearance of conjugated metanephrines is determined almost exclusively by their extraction by the kidneys, plasma levels of conjugated metanephrines do not always reflect production of free metanephrines. For example, plasma levels of conjugated metanephrines are substantially increased in patients with renal failure, whereas those of free metanephrines are only mildly affected (Eisenhofer *et al.*, 2005).

Plasma levels of metanephrines increase during activation of the sympathetic nervous and/or adrenomedullary hormonal systems. However, increases in plasma levels of NMN and MN above baseline levels are relatively less than those of their parent catecholamines (Eisenhofer *et al.*, 1995a). Even during intense adrenomedullary stimulation induced by hypoglycemia, plasma MN levels increase only 3-fold, in contrast to a 25-fold increase in plasma E levels (Eisenhofer *et al.*, 1998). During less intense stressful conditions, such as mental stress, the responses of catecholamines are proportionally much greater than those of metanephrines. Consequently, metanephrines are inferior to catecholamines for gauging stress responses. Recently it was shown that there is a seasonal variation in plasma NMN levels with higher levels in colder than warmer seasons. This reflects partly an increased sympathetic activity associated with a lower ambient temperature (Pamporaki *et al.*, 2014).

Measurement of Metanephrines

Measurements of metanephrines in urine have been available for clinical purposes since the early 1960s (Manu and Runge, 1984). Historically, the term total metanephrines was coined to indicate the combined measurement of both NMN and MN by early spectrophotometric assays that did not allow separate measurement of NMN and MN. The development of high pressure liquid chromatography (HPLC) techniques has allowed separate measurement of both amines, hence the term fractionated metanephrines. However, urinary measurements of NMN and MN are usually carried out after subjecting samples to acid hydrolysis or enzymatic deconjugation with sulfatase, which liberates the free from conjugated metanephrines. These measurements therefore reflect levels of both the free and conjugated forms of NMN and MN. Specific measurements of urinary free metanephrines has become feasible with the advent of liquid chromatography with mass spectrometric detection (LC-MS/MS) (Boyle *et al.*, 2007).

In plasma, metanephrines can be measured as free metanephrines or as free plus conjugated metanephrines by HPLC with electrochemical detection (ED) (**Fig. 3**) or by LC-MS/MS (Lagerstedt *et al.*, 2004; Lenders *et al.*, 1993; Peitzsch *et al.*, 2015). LC-MS/

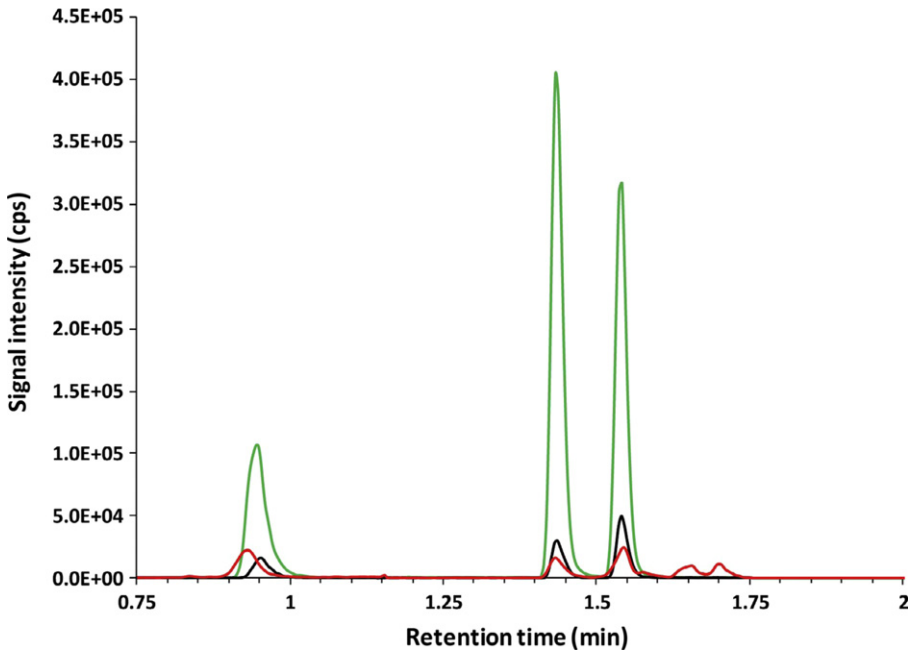

Fig. 3 Peaks of normetanephrine (NMN) at a retention time of 0.9 min and of metanephrine (MN) at a retention time of 1.4 min. The green curve represents the internal standard (500 pg mL^{-1} each), the black line represents the calibrator (50 pg mL^{-1} each) and the red line represents a sample of healthy subject (NMN: 99 pg mL^{-1} and MN 24 pg mL^{-1}). The third peak at the retention time 1.53 min is methoxytyramine, the *O*-methylated metabolite of dopamine.

MS is nowadays the preferred assay method since it provides a higher specificity and suffers from less analytical interference of drugs than HPLC-ED. In addition, it is more cost-effective. In view of the much lower plasma concentrations of free metanephrines as compared to the conjugated metanephrines, the required analytical sensitivity is much higher for free metanephrines. Many factors should be considered as potential sources of falsely high or falsely low test results. Despite the fact that plasma metanephrines are less sensitive than plasma catecholamines to sympathoadrenal excitation, sympathoadrenal excitation must still be considered a potential cause of falsely high test results (Lenders *et al.*, 2002). Analytical interference from drugs depends on the type of assay and is usually more frequent for HPLC-ED than LC-MS/MS assays. Pharmacokinetic interference, resulting in falsely-positive results of plasma or urinary metanephrines can be caused by several drugs such as tricyclic antidepressants and sympathomimetics (Lenders *et al.*, 2014). Conversely, COMT inhibitors and central sympatholytic drugs may lower NMN and MN levels. Despite the availability of high specific assays, caution for drug interference remains warranted in the interpretation of test results.

Application of Measurement of Metanephrines

The development of plasma metanephrines has enabled investigators to obtain more detailed and comprehensive insights into the metabolism of catecholamines. This has led to several promising applications. First, measurement of plasma free metanephrines provides a test for the diagnosis of pheochromocytoma with the highest sensitivity (Lenders *et al.*, 2002). The abundant presence of COMT in pheochromocytoma tumor tissue is responsible for a continuous intratumoral conversion of catecholamines to metanephrines (Eisenhofer *et al.*, 2004). These metanephrines diffuse to the circulation, independently of the release of catecholamines by the tumor. >94% of the increased circulating levels of NMN and MN in patients with pheochromocytoma is derived from catecholamine metabolism within tumor cells (Crout and Sjoerdsma, 1964; Eisenhofer *et al.*, 1998). Thus, only small increases in NMN and MN levels indicate metabolism of catecholamines after their secretion by the tumor into the circulation. This largely explains why plasma free metanephrines have an approximately 100% sensitivity. Elevations of plasma metanephrines in patients with pheochromocytoma show larger relative increases above normal levels compared to the parent catecholamines. This also contributes to the higher diagnostic sensitivity of measurements of free metanephrines over catecholamines (Lenders *et al.*, 2002). The continuous production of metanephrines within the tumor tissue also explains why levels of plasma metanephrines are less apt to increase compared to plasma catecholamines during paroxysmal catecholamine release from a pheochromocytoma or during surgical manipulation of the tumor.

Other applications of plasma free metanephrines include a role in the assessment of COMT activity. In conjunction with measurements of plasma DHPG levels, measurements of free NMN can also be used to assess the activity of MAO: An increased NMN/DHPG ratio indicates inhibition of MAO and can also be used to establish MAO-deficiency states (Lenders *et al.*, 1996). Finally, since plasma free MN is almost completely derived from intramedullary conversion from adrenomedullary E, plasma MN levels can serve as a marker of the adrenomedullary E stores (Merke *et al.*, 2000).

Adrenergic Mechanisms☆

Peter W de Leeuw and Abraham A Kroon, Maastricht University Medical Center, Maastricht, The Netherlands

Glossary

Glucosensitive, thermosensitive, and barosensitive fibers These words refer to sympathetic nerve fibers that respond to alterations in blood glucose, temperature and blood pressure respectively.

Introduction

The autonomic nervous system regulates many bodily functions. It is a classical control system with an input function, provided by afferents from various parts of the body, a central processor and output responses mediated by parasympathetic and sympathetic fibers as well as the adrenal medulla. Parasympathetic fibers can be afferent and efferent; sympathetic fibers are always efferent. The sympathetic system, in conjunction with its central nuclei and the adrenal medulla, is also known as the adrenergic system (AS). The AS comprises all neurons which use norepinephrine or epinephrine as transmitter substance.

The central part of the AS consists of nuclei located, amongst others, in the cerebral cortex, the hypothalamus, the periaqueductal gray of the midbrain, the ventrolateral pons with the area postrema at the floor of the fourth ventricle, the nucleus tractus solitarii (NTS), the caudal ventrolateral medulla (CVLM), the rostral ventrolateral medulla (RVLM) and the intermediolateral (IML) region of the T1–T5 spinal cord. The hypothalamus and the NTS are the main sites where autonomic functions such as the regulation of metabolism, body temperature and blood pressure are integrated.

The efferent AS consists of preganglionic neurons originating in the thoracolumbar area of the spinal cord and their postganglionic connections. Functionally, these neurons show some differentiation in the sense that when the sympathetic system is activated, this does not always produce the same effector response but one which is required to restore the primary functional disturbance.

Acetylcholine and the catecholamines norepinephrine (NE) and epinephrine (EPI) serve as the main neurotransmitters within the AS. Acetylcholine is the neurotransmitter at preganglionic sites in both sympathetic and efferent parasympathetic fibers. It is also the neurotransmitter in postganglionic parasympathetic neurons and at the interface between sympathetic fibers and the adrenal medulla. NE acts as transmitter in postganglionic sympathetic fibers, which are also known as adrenergic neurons. EPI is synthesized only in adrenal medullary cells.

At the level of the target organs the neurotransmitters react with specific receptors which can be classified as alpha-1, alpha-2, beta-1, beta-2 and beta-3 adrenoceptors.

Central Adrenergic Pathways

Adrenergic influences on neuroendocrine/autonomic function originate in NE-synthesizing cell groups referred to as A1, A2, and A5, located in the CVLM, the NTS, and the ventrolateral pons, respectively on the one hand and in EPI-synthesizing neurons that are found in the C1, C2, and C3 groups, located in the RVLM, the NTS, and the rostral dorsomedial medulla on the other (Jänig, 2008). The A2/C2 neurons are innervated by primary visceroceptive afferents carried by the vagal and the glossopharyngeal nerves that convey information from mechano- and chemoreceptors related to cardiovascular, pulmonary, and gastrointestinal systems. Neurons in the NTS that receive visceral afferents in turn project to A1 and C1 neurons. Descending projections from C1 cells to the spinal cord innervate sympathetic preganglionic neurons and so can directly activate catecholamine-mediated responses to visceral changes. Ascending projections from A1/C1 and A2/C2 cells travel through the ventral adrenergic bundle and terminate in several limbic nuclei and hypothalamic areas. AS terminals are found in the ventromedial, arcuate, dorsomedial, and lateral hypothalamic nuclei, and a particularly dense innervation reaches the paraventricular hypothalamus (PVH). Neurons in these nuclei (particularly in the paraventricular and lateral hypothalamic area) are in turn connected to (1) the pituitary (e.g., driving pituitary–adrenal and pituitary–thyroid activities), (2) mesencephalic and prosencephalic limbic nuclei (thereby influencing the expression of behavioral, learning/memory, and emotional responses), (3) premotor and preganglionic autonomic neurons (thereby controlling autonomic function), and (4) A1/C1/A2/C2 neurons (where they can modulate visceral reflexes mediated by these cells). Other hypothalamic, hypophysiotropic (e.g. somatostatin, luteinizing hormone-releasing hormone) and

☆*Change History*: December 2017. Peter W de Leeuw and Abraham A Kroon have completely rewritten the text.

This chapter is an update of José Marino-Neto, Marcelo Sabi and Marta Aparecida Paschoalini, Adrenergic Mechanisms, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 106–111.

neurosecretory (arginine vasopressin and oxytocin) neurons are also innervated by NE/EPI terminals. It is also important to point out that although terminals from A6 (the locus ceruleus) NE-synthesizing neurons are ubiquitous in the central nervous system, these neurons have limited direct input to the hypothalamic circuitry. The locus ceruleus receives a major, essentially inhibitory innervation from EPI- and NE-producing medullary neurons, through which the latter gain access to a "brain-wide web" of NE-mediated modulation of cognitive and arousal functions as well as to indirect influences on neuroendocrine mechanisms through prosencephalic limbic nuclei.

Abundant evidence from experimental studies has shown that several adrenergic cell types are sensitive to local changes in glucose levels with a fall in glucose provoking eating and a rise in glucose. These neurons, therefore, are in a perfect position to mediate metabolic and behavioral responses to central (or systemic) changes in glucose levels and/or energy status.

A1/C1 and A2/C2 cells are also activated by other stressful situations such as hemorrhage, immune challenge, noise and restraint. In each case, activation of medullary adrenergic systems occurs either directly through visceral afferents or after processing of the stressful stimulus at a higher level. Thus, these circuits may be of importance under different conditions of stress and energy demand.

The PVH is by far the most sensitive area with respect to feeding-related AS activity. Feeding responses are mediated by central alpha-2 adrenoceptors, whereas activation of central alpha-1 adrenoceptors suppresses food intake. As far as adrenergic systems are concerned, the lateral hypothalamic nuclei mainly have a hypophagic effect, mediated by central beta-2 adrenoceptors.

Another AS circuitry that is of importance is the one which is related to control of the cardiovascular system. Again, available information rests primarily on observations in animals. Cardiovascular effector responses use either fast transmitters (such as glutamate) or slow transmitters (such as NE). Ascending noradrenergic neurons (classified as A1–A7) are found mainly in the locus ceruleus; most descending fibers stem from A5 and A6 + A7 neurons. EPI-using neurons of the C1 type are most prevalent in the RVLM while C2 neurons are located close to the NTS (Korner, 2007). Numerous experiments have been performed to pinpoint which structures in the brain are responsible for which cardiovascular responses. By and large, the RVLM as well as hypothalamic nuclei and several other centers which synapse in RVLM neurons determine resting sympathetic tone.

Although it is virtually impossible to study central adrenergic systems in man, an interesting observation comes from Australian investigators who sampled blood simultaneously from both jugular veins in patients with essential hypertension. Using a sophisticated technique, they were able to measure NE spillover from nerve endings into the blood. As only one of the two jugular veins drains blood from the hindbrain and hypothalamus, the NE spillover which the investigators measured in this vessel, is thought to reflect the activity of central adrenergic neurons in these areas. The data show that there is a close relationship between central noradrenergic neuron activity and peripheral sympathetic activity (Ferrier *et al.*, 1993).

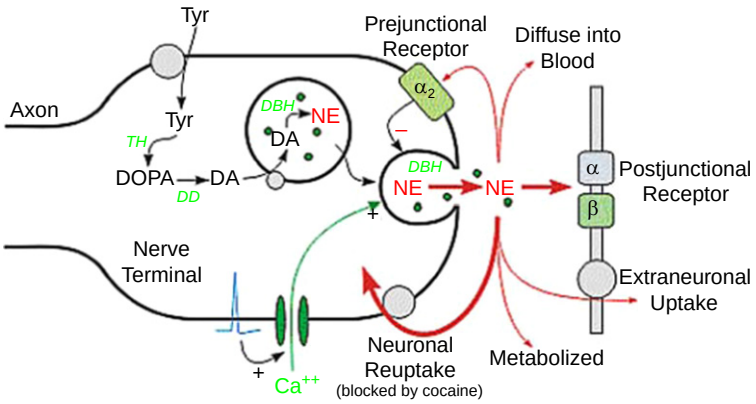
Peripheral Adrenergic Neurotransmission

The information carried forward through preganglionic parasympathetic and sympathetic fibers is first relayed to postganglionic fibers and then via a neuroeffector junction to specific target organs. The adrenal medulla is directly innervated by fibers from the IML nucleus of the thoracolumbar segments of the spinal cord.

The neurotransmitter NE is synthesized in the axoplasm from tyrosine which is actively transported into the nerve. The enzyme tyrosine hydroxylase which converts tyrosine into DOPA is the rate-limiting step in the biosynthesis of NE and EPI. Cytoplasmic enzymes convert DOPA to dopamine and this, in turn, is converted to NE by dopamine beta-hydroxylase (DBH). In adrenal medullary cells NE is further converted to EPI by the enzyme phenylethanolamine-*N*-methyltransferase (PNMT). In the nerve terminals NE is kept in storage vesicles which fuse with the plasma membrane and liberate their NE by exocytosis as soon as an action potential has caused an influx of calcium into the cell.

When NE is released from the nerve terminals, its fate and effect are determined by a complex array of mechanisms. First, only a part of the neurotransmitter activates the adrenoceptors in the membrane of the postsynaptic cell as synaptically released NE is subject to active re-uptake into the nerve terminal (uptake 1) by the norepinephrine transporter (NET), a process which can be blocked by cocaine and a variety of antidepressant drugs. Second, the NE that penetrates the target cell (uptake 2) is rapidly inactivated by monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT). A third mechanism that is important is the potential of NE to stimulate presynaptic alpha-2 receptors which inhibit further exocytotic release of the neurotransmitter and beta-adrenoceptors (presumably of the beta-2 subtype) which enhance its release. Finally, recent research has shown that several different mediators are co-transmitted at the same time (Macarthur *et al.*, 2011). Indeed, neuropeptide Y (NPY) and adenosine triphosphate (ATP) are co-localized with NE in the storage vesicles and are released at the same time as the "classical" neurotransmitter NE. Both substances activate postsynaptic receptors which lead to amplification of the effects of NE. In addition, they may inhibit their own release as well as that of NE through activation of presynaptic receptors on the nerve terminal (**Fig. 1**).

The most powerful mechanism of the body to regulate the effects of adrenergic stimulation, is by re-uptake 1. This is exemplified by the fact that inhibitors of this process can markedly potentiate the adrenergic symptoms while inhibitors of the uptake-2 mechanism have little effect. Moreover, there is evidence to suggest that prejunctional modulation of NE is more dependent upon the endogenously released NE than on its co-transmitters (Macarthur *et al.*, 2011). Apart from these sympathetic mediators, several other substances such as angiotensin II, nitric oxide, endothelin and prostaglandins may



Tyr = tyrosine; TH = tyrosine hydroxylase; DD = DOPA decarboxylase;
DA = dopamine; DBH = dopamine β-hydroxylase; NE = norepinephrine

Fig. 1 Schematic representation of adrenergic neurotransmission at effector sites. Reproduced with permission from: http://cvpharmacology.com.

modulate the degree of neurotransmission. All these modulating factors make that the final response to an adrenergic stimulus is difficult to predict.

Sympathetic Efferents

The sympathetic nervous system can be viewed upon as a highly organized and differentiated system which transmits the final "order" that comes from the central nuclei, after they have integrated all afferent information, to the relevant effector organs. Neurophysiological studies in various species, including man, indicate that sympathetic neurons exhibit substantial differentiation with respect to their target cells and thus, their function (Janig and Habler, 2003). In other words: when a certain physiological function gets disturbed, the autonomic response, mediated through the sympathetic fibers, will be specifically directed towards the variable that needs to be regulated and will, in general, not affect other systems. Based on the final physiological responses, the system functionally consists of three main types of fibers: those that are involved in metabolic regulation (glucosensitive efferents), in the regulation of body temperature (thermosensitive efferents) and in the regulation of the cardiovascular system (barosensitive efferents).

Glucosensitive Efferent Adrenergic Mechanisms

Glucosensitive efferents are involved in the autonomic response to hypoglycemia and physical exercise or a state of negative energy balance. Data obtained in experimental animals suggest that NPY-containing neurons in the hypothalamus, particularly in the arcuate and paraventricular nuclei, can sense changes in the concentrations of blood glucose and insulin. In addition, glucosensing elements have been identified in the area postrema and the NTS. When a fall in blood glucose is perceived, downstream integrative networks and motor neurons activate the adrenergic system and stimulate the adrenal medulla to release EPI. Through sympathetic nerve fibers, the central neurons also stimulate the release of growth hormone and corticotrophin-releasing hormone which, in turn, causes the anterior pituitary to secrete more ACTH. Finally, the autonomic system stimulates the liver to enhance gluconeogenesis and pancreatic cells to increase glucagon and reduce insulin output (Thorp and Schlaich, 2015; Watts and Donovan, 2010).

Insulin can bind to specific insulin receptors on central NPY-neurons and in doing so, may exert an inhibitory effect on appetite and energy expenditure. Conversely, a lack of insulin signaling in these NPY-neurons leads to increased energy stores and an obese phenotype (Loh *et al.*, 2017). Although very little is known about these mechanisms in man, a post-mortem study showed that in patients with type II diabetes NPY immunoreactivity is increased in the arcuate nucleus of the hypothalamus (Saderi *et al.*, 2012). This seems to suggest that in type II diabetes, the NPY neurons act as if glucose levels are lower than normal. It could explain also why diabetic patients have an ongoing increased sympathetic tone with all its metabolic and vascular consequences (Thorp and Schlaich, 2015).

Whereas central NPY neurons also play a role in appetite and eating behavior, it is largely unknown how and to what extent adrenergic mechanisms are involved in humans.

When hypoglycemia occurs (e.g. after too much insulin has been administered), it is primarily the adrenal medulla that is activated (by the glucosensitive system) with a relatively mild response of the other components of the adrenergic system. Accordingly, plasma levels of EPI rise far more than those of NE.

Thermosensitive Efferent Adrenergic Mechanisms

The maintenance of body temperature during thermal challenges is of paramount importance for survival. Within the brain, the hypothalamic preoptic area (POA) serves as the main site of thermoregulation. Thermal threats to the body include changes in both ambient temperature and in internal temperature due to e.g. exercise or illness. Again, most of our understanding of thermoregulation is based on experiments in animals but there are good reasons to believe that the situation is not much different in humans.

Exposure of the body to cold activates two basic mechanisms, both of which are mediated by the sympathetic system: cutaneous vasoconstriction to prevent heat loss and thermogenesis (production of heat) by brown adipose tissue (Morrison, 2016). Constriction of skin vessels by adrenergic fibers is accompanied by visceral arterial and venous dilation to increase core blood flow. Stimulation of brown adipose tissue leads to an increase in energy expenditure due to enhanced oxidation of fatty acids and glucose. Thermogenesis, therefore, is determined largely by the degree of adrenergic outflow to brown adipose tissue and the degree of NE binding to beta-3 adrenoceptors on the cell membrane of brown adipocytes. Although the brown fat was initially seen as a thermoregulatory organ in rodents and small mammals only, it is now known that this thermoregulatory effector system is also important in humans (van Marken Lichtenbelt *et al.*, 2009). Except by cold, thermosensitive efferents are also activated by, for instance, emotional stimuli and hyperventilation.

Basically, opposite reactions occur during heat stress, although the mechanism of cutaneous vasodilation is less well understood (Smith and Johnson, 2016). At first sight, one would think that the sweating response to heat is also adrenergic in nature. While this response certainly involves sympathetic fibers, these are cholinergic rather than adrenergic.

Barosensitive Efferent Adrenergic Mechanisms

By far the largest part of the sympathetic system is concerned with the control of the cardiovascular system. Although an adequate tissue perfusion is the most important aim of circulatory regulation, it is the mean arterial pressure (MAP) that mainly determines this tissue perfusion. From that perspective, it is not too surprising that systemic blood pressure is the primary regulated variable. Cardiac output (CO) and total peripheral vascular resistance (TPVR) together determine MAP according to the formula: $MAP = CO \times TPVR$. Besides these purely hemodynamic factors, the filling of the arterial system is also of importance (Guyton, 1980). Sympathetic fibers run to blood vessels and the heart to cause vasoconstriction and an increase in cardiac performance respectively. In addition, they innervate the kidney at several levels to promote, for instance, renin release and tubular reabsorption of sodium and water.

The afferent information that these peripheral adrenergic fibers respond to mainly comes from baroreceptors which, in fact, are more like mechanoreceptors because they do not measure the pressure but rather arterial distension. Arterial (high-pressure) baroreceptors are located in the carotid sinus area and in the aortic arch. Low-pressure baroreceptors can be found in large systemic veins and at several places in the cardiopulmonary circulation, including the right atrium and ventricle of the heart. Via the glossopharyngeal and vagal nerves, the information from the baroreceptors reaches the central nuclei which integrate the information from the various parts of the body. These nuclei are located in the NTS, the CVLM and the RVLM.

As a short-term feedback loop, the baroreceptor reflex is the primary homeostatic system to compensate for sudden changes in systemic blood pressure. Its most important task is to prevent a fall in blood pressure which may occur, for instance, during standing or because of blood loss or forced vasodilation. Under normal conditions, the arterial baroreceptors exert a tonic inhibitory influence on sympathetic outflow via central alpha-2 adrenoceptors. In fact, the NTS stimulates the CVLM and this nucleus, in turn, inhibits sympathetic outflow from the RVLM (**Fig. 2**). However, when blood pressure at the level of the carotid baroreceptors falls (either because systemic pressure is too low or because of a sudden reduction in blood flow through the carotid artery), the stretch on the baroreceptors diminishes. Their firing rate decreases (so-called unloading of the receptors) and the inhibitory effect on sympathetic tone wanes off. The ensuing increase in adrenergic tone leads to arteriolar and venular vasoconstriction, increased cardiac contractility and tachycardia. The venular constriction will increase venous return (preload) to the heart, while arteriolar vasoconstriction will raise resistance and hence blood pressure. As pointed out by Guyton, the gain of the baroreceptor reflex is less than zero, meaning that this reflex does not fully restore the change in pressure (Guyton, 1980). This makes sense because then adrenergic stimulation will continue until the challenging threat is over. Otherwise, blood pressure would fall again as soon as it would have reached its original value. The opposite chain of events occurs in case the pressure rises, e.g. when an endogenous signal such as stimulation of the renin–angiotensin system increases vascular resistance.

Stimulation or inhibition of the adrenergic system is paralleled by inhibition or stimulation respectively of the cholinergic system. Thus, there always exists a delicate balance between the activities of the sympathetic and parasympathetic system.

It should be stressed that barosensitive efferent activity is not solely dependent upon the input from the arterial baroreceptors in the carotid as similar influences come from baroreceptors in the aortic arch. Moreover, barosensitive efferent output is also modified by the activity of the low-pressure receptors. The role of the latter is primarily to maintain volume control.

Finally, chemoreceptors, located also in the carotid body and the aortic arch, may influence cardiovascular adrenergic activity. For instance, when partial oxygen pressure in arterial blood falls, the firing rate of chemoreceptors will be augmented and this, in turn, will raise adrenergic activity to the cardiovascular system. Although the afferents also project onto the NTS, signals are relayed from the NTS directly into the RVLM, thus bypassing the inhibitory influence of the CVLM.

Clinical Significance of Adrenergic Mechanisms

It will come as no surprise that the adrenergic system with its vast array of functions plays a significant role in various disease processes. First, the adrenergic system is needed to maintain homeostasis during periods of stress to the body. When an individual is confronted with a serious drop in pressure or even circulatory shock due to, for instance, hypovolemia (massive blood loss), reduced cardiac output (myocardial infarction) or redistribution of blood volume (sepsis), activation of the barosensitive adrenergic efferents is necessary to restore blood pressure and peripheral perfusion. Usually, the sympathetic activation will also cause tachycardia, increased transpiration and a number of other symptoms such as pupillary dilation and agitation. In the case of hypovolemia or myocardial infarction, cutaneous vasoconstriction and increased sweating are usually apparent and the patient feels cold. However, septic shock is often associated with cutaneous vasodilation and less perspiration and the patient feels warm. This points towards some degree of selective activation of the three efferent adrenergic pathways. Also, during severe surgical stress there may be a slight increase in blood glucose which is probably mediated, at least in part, by glucosensitive efferents.

While in many instances adrenergic compensation works well to help the individual survive, a problem may arise when the insult is so strong that adrenergic activation (causing vasoconstriction) comes into conflict with the process of autoregulation which strives to vasodilation when perfusion pressure falls (Guyton, 1980). It will depend upon the severity of disease how tissue perfusion will then be affected. Also, In the case of heart failure, the adrenergic overdrive may be so overwhelming that the heart will no longer be able to cope with the high afterload (due to the massive vasoconstrictor response). Subsequently, a vicious cycle starts in which the heart increasingly fails with an ultimately fatal outcome.

Whereas the adrenergic system is meant to serve a protective role in disease states, there are situations where the system itself is part of a disease process. Logically, there are two ways the adrenergic system can be involved in pathological processes. Either its activity is too low or too high. In both cases the disturbance may be due to a primary defect in the sympathetic fibers or to an otherwise adequate response to a pathological afferent signal. In the following, a few examples will be presented to illustrate these possibilities. In nearly all cases an abnormal blood pressure is the presenting symptom.

Insufficient Adrenergic Activity

The "simplest" form of adrenergic dysfunction is due to neurodegenerative disease in which various parts of the autonomic system may be affected separately or collectively. This condition is called pure autonomic failure (PAF) and it is caused by abnormal accumulation of the protein alpha-synuclein in nerve cells. When the central nervous system is involved as well, patients may have Parkinson's disease, multiple system atrophy or Lewy body dementia. Some of the other causes of adrenergic dysfunction may be diabetic neuropathy, auto-immune disease, amyloidosis and intoxications.

The most conspicuous symptom of adrenergic failure is orthostatic hypotension, i.e. an excessive fall in blood pressure upon standing. In true PAF, the orthostatic fall in pressure does occur without any increase in heart rate, reflecting the defective innervation of the heart. There is, however, another syndrome which is characterized by only a tendency to orthostatic hypotension but with an excessive heart rate. This syndrome is called postural orthostatic tachycardia syndrome (POTS). Probably, the

accelerated heart rate response is compensatory so that blood pressure falls less or not at all during standing. Whether POTS is a precursor or a less severe variant of PAF, is currently unknown.

Other features of PAF are anhidrosis (impaired sweating) with resultant heat intolerance, urine retention, constipation, incontinence and impotence. All these symptoms can be easily explained on the basis of (reduced) sympathetic activity. For reasons that are not completely understood, patients with PAF often have supine hypertension.

Because EPI is a main effector hormone in glucose homeostasis, one would also expect some degree of hypoglycemia to occur when the adrenergic system fails. However, while blood sugar levels may indeed be slightly lower in patients with autonomic failure, the other important hormones (insulin and glucagon) are able to keep glucose levels within acceptable limits.

In patients with diabetes mellitus, in particularly those who are being treated with insulin, the problem of hypoglycemia unawareness (HU) may develop. This means that the patient does not feel the symptoms of hypoglycemia because the sympathoadrenal response is attenuated or absent. This does not necessarily mean that the adrenergic system itself is at fault but it is a condition in which the central monitoring of glucose and several other putative mechanisms play a role. However, the exact nature of the abnormality remains enigmatic. Because (HU) usually develops only after the patient has gone through various episodes of hypoglycemia, one hypothesis states that the autonomic system gets exhausted when it has been activated so often after periods of hypoglycemia.

In some cases, adrenergic failure is due to an impaired or even absent ability to synthesize NE. This is the case in the rare syndrome of DBH-deficiency in which dopamine cannot be metabolized to NE. Patients with this disorder have all the signs of adrenergic failure but their sweating response is normal because the sympathetic cholinergic fibers can still work properly.

Finally, patients with adrenocortical insufficiency from whatever cause tend to have lower EPI levels than controls indicating that the adrenal part of the adrenergic system is less active. In these patients, functions which are dependent on adrenergic nerve fibers remain intact though.

Excessive Adrenergic Activity

The role of sympathetic overdrive in disease states is far less clear than deficient adrenergic activity. Of course, signs and symptoms of increased adrenergic activity are most noticeable during periods of physical or mental stress but that could be considered an adequate reaction. There exists an erratic syndrome, called "paroxysmal sympathetic hyperactivity," the etiology of which is unknown but which seems to preferentially affect people who sustained traumatic brain injury (Perkes *et al.*, 2010). So far, there is still no consensus about the significance of this syndrome that bears resemblance to, for instance, malignant hypothermia or neuroleptic malignant syndrome.

A particular situation where excessive adrenergic activity is apparent, is that of baroreceptor failure (Robertson *et al.*, 1993). This afflicts mostly patients who had extensive neck surgery and radiation treatment for cancers of the neck and in whom afferent nerve fibers from the carotid body have been damaged. In addition, paragangliomas, trauma to the neck and carotid calcifications in the carotid body area have been implicated as potential causes. Due to the loss of afferent signals, the brain no longer exerts its tonic inhibitory influence on sympathetic outflow which then increases considerably. This produces a volatile type of hypertension that may be paroxysmal and be accompanied by tachycardia. The disorder may be difficult to differentiate from pheochromocytoma, a tumor of the adrenal medulla, that causes similar symptoms.

Baroreceptor failure usually is nonselective, meaning that efferent parasympathetic activity is impaired as well. Occasionally, however, the efferent parasympathetic fibers are spared (selective baroreceptor failure). When the latter is the case, hypotension and bradycardia are more common symptoms.

Essential hypertension is yet another condition in which excess sympathetic activity is thought to have pathogenetic significance. Indeed, many studies support the concept that a dysbalance between parasympathetic activity (supposedly reduced) and sympathetic activity (supposedly increased) underlies the development of essential hypertension but the exact nature of this dysbalance is still not well understood. Studies using the technique of measuring NE spillover have shown that the increase in sympathetic outflow is not uniform but preferentially affects the heart and the kidneys and is associated with higher renin levels, particularly in younger patients (Esler *et al.*, 1989). It is unclear whether the defect is primary or not, whether it originates in the central nuclei of the brain or not and to what extent the baroreceptor system is involved.

Other conditions in which adrenergic activity has been found to be increased include type II diabetes, even in the very early stages of this disease, obesity and the metabolic syndrome, chronic kidney disease, ischemic heart disease, obstructive sleep apnea and preeclampsia.

Although it is beyond the scope of this article to discuss all therapeutic potentials, basically there are two ways to reduce excessive sympathetic activity: with ant-adrenergic drugs or with devices which electrically or mechanically stimulate the baroreceptor area. As far as drugs is concerned, one has the possibility to stimulate central alpha-2 adrenoceptors with, for instance, clonidine or methyldopa. This stimulation leads to a reduction in sympathetic outflow. Another possibility is ganglionic blockade but this is not selective for sympathetic fibers. Finally, one can block the peripheral alpha- and beta-adrenoceptors on the target organs. Due to unacceptable side-effects, centrally acting drugs and ganglion blockers are hardly used anymore these days.

Another method to reduce sympathetic outflow is to electrically stimulate the baroreceptors and, by doing so, to elicit an enhanced firing response through afferent fibers which, in turn, will shift the balance between sympathetic and parasympathetic activity towards the latter. As shown in **Fig. 3**, continued stimulation over a period of several years leads to a sustained fall in blood pressure without any signs of "exhaustion" (de Leeuw *et al.*, 2017). Recently, a variant form of "barostimulation" was successfully implemented, namely the insertion of an intra-carotid stent which alters the geometry of the vessel (Spiering *et al.*, 2017).

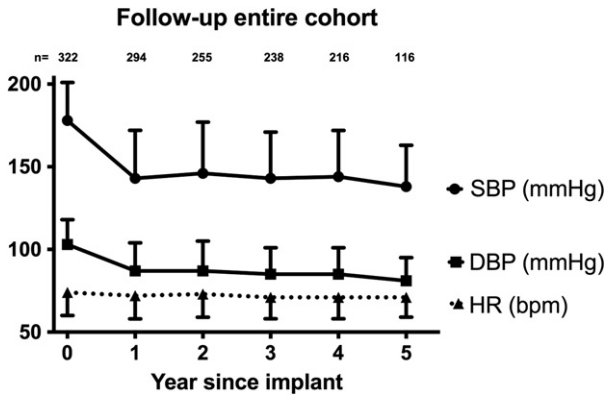

Fig. 3 Sustained reduction in blood pressure over a 5-year period in hypertensive patients who have been treated with electrical stimulation of the baroreceptor area. Reproduced from de Leeuw, P. W., et al. (2017). Sustained reduction of blood pressure with baroreceptor activation therapy: Results of the 6-year open follow-up. *Hypertension* **69**(5), 836–843.

Conclusions

Adrenergic mechanisms are important for a variety of physiological functions. Although the main targets of the sympathetic system are the heart and the vasculature, the system is also crucially involved in metabolic activities and thermocontrol. Both a reduced and an increased activity of the sympathetic efferents may lead to disease states. Recent developments have made it possible to modulate sympathetic activity by means of device-based stimulation of the baroreceptor area.

Novel Insights in β-Adrenergic Receptor Signaling☆

Guido Iaccarino, University of Salerno, Baronissi, Italy
Daniela Sorriento, University Naples, Naples, Italy

Introduction

The adrenergic receptors (ARs) are part of a large family of G-protein-coupled receptors (GPCR) which trigger the intracellular signaling in response to several stimuli, including light, odorants, neurotransmitters, lipids, and various peptides and proteins (Marinissen and Gutkind, 2001). GPCR activation promotes interaction with heterotrimeric guanosine triphosphate-binding proteins (G-proteins), resulting in guanosine diphosphate/guanosine triphosphate exchange and subsequent dissociation of the α and $\beta\gamma$ subunits. These subunits regulate the activity of multiple effector proteins, including adenylyl cyclases, phospholipases, phosphodiesterases, ion channels, and phosphatidylinositol 3-kinase. Thus, GPCRs regulate several key biologic functions including cellular proliferation, cell differentiation, survival, sensory perception, neurotransmission, chemotaxis, development (Sorriento *et al.*, 2011).

The ARs family includes α and β receptors which mediate physiological responses to catecholamines. βARs are vasodilators which are divided into three subtypes: β_1AR is found at its highest levels in the heart, β_2AR is distributed extensively throughout the body and β_3AR is mainly expressed in the white and brown adipose tissue (Liggett, 2002; Weitl and Seifert, 2008; **Table 1**). αARs mainly induce vasoconstriction and include three α_1 receptor subtypes ($\alpha_{1\alpha}$ AR, $\alpha_{1\beta}$ AR, α_{1D} AR) and three α_2 receptor subtypes ($\alpha_{2\alpha}$ AR, $\alpha_{2\beta}$ AR, α_{2C} AR) which differ in their localization and responsiveness to drugs (Molinoff, 1984; **Table 1**).

Adrenergic Receptors From the Discovery to the 2012 Nobel Prize

For several decades, it was a mystery how cells could sense and interact with their environments. Given the notion that hormones, like adrenalin, had several effects on humans (an increase of blood pressure and heart beats), it started to take hold the idea that cell surfaces could contain something that interacted with hormones. In 1948 the American pharmacologist Raymond Ahlquist was the first to identify two types of receptors for adrenaline, that he called α and β receptors based on the different abilities of ligands to stimulate several physiological processes (Ahlquist, 1948). This was the proof that cellular receptors existed on plasma membrane even if their structure and function remained obscured for decades. Then, the development of new techniques allowed the study of ARs structure and actions. Robert Lefkowitz was the first to develop the radioligand binding method to study the β-adrenergic receptor (Mukherjee *et al.*, 1975) and the α-adrenergic receptor (Williams and Lefkowitz, 1976). He used the radioactivity of ^{125}I to trace cellular receptors by attaching the radioactive iodine isotope to various hormones. This technique allowed to study the regulation of the receptors in response to several factors (Stiles *et al.*, 1984), to discover unknown receptor subtypes (Lorenz *et al.*, 1990) and to better understand the mechanisms of actions of such receptors. By this technique, Lefkowitz team identified a new membrane component which was part of the agonist/receptor complex, the guanine nucleotide regulatory protein (G protein) (Kent *et al.*, 1980). Then, Lefkowitz team extracted the receptor from its hiding place in the cell wall to study how it works (Cerione *et al.*, 1984). The next big step in the knowledge of adrenergic receptors was the isolation of the gene coding for the β-adrenergic receptor from gigantic human genome which was performed in the lab of Prof. Kobilka (Kobilka *et al.*, 1987). This led to the notion that the receptor was similar to one in the eye that captures light. Thus, it started to realize that a complete family of receptors should exist that have a similar structure and act in the same manner. From these great discoveries, the puzzle has been assembled piece-by-piece till obtaining a detailed knowledge about GPCRs functions and regulation. In 2011 Kobilka and his team captured an image of the β-adrenergic receptor at the exact moment that it is activated by ligand binding and sends a signal into the cell (Rasmussen *et al.*, 2011a,b). For their contribution to the study of GPCRs, in 2012 Lefkowitz and Kobilka were awarded the Nobel Prize in Chemistry.

New Findings in Canonic ARs Signaling

The canonic pathway of activation of adrenergic receptors is based on structural changes promoted by agonist binding, which allow their coupling to heterotrimeric G proteins. Subsequent activation and dissociation of G proteins lead to the generation of second messengers and cellular responses (Whalen *et al.*, 2011; Lefkowitz and Shenoy, 2005; Shukla *et al.*, 2014a). It has been demonstrated that the binding of agonists to adrenergic receptors promotes a desensitization process via phosphorylation by the G

☆*Change History*: December 2017. Daniela Sorriento and Guido Iaccarino completely updated the text, summarizing the information of the previous version of the article in Table 1 and added two tables and three figures.

Table 1 The main characteristics of adrenergic receptors subtypes

Type of receptor	*Localization*	*Signaling*	*Physiological responses*
β1 AR	Cardiac and adipose tissue, cerebral cortex, caudate, and cerebellum	• Elevation of intracellular cyclic AMP • Calcium reuptake into the sarcoplasmic reticulum	• Positive inotropic effect • Lusitropic effect
β2 AR	Smooth muscle, liver, human white cells, cardiac tissue cerebral cortex, caudate, and cerebellum	• Elevation of intracellular cyclic AMP • Calcium reuptake into the sarcoplasmic reticulum • Phosphatidylinositol 3′ kinase pathway	• Positive inotropic effect • Lusitropic effect • Anti-apoptotic mechanisms
β3 AR	White and brown adipose cells as well as in skeletal muscle	• Coupling to both stimulatory and inhibitory G proteins and activation of nitric oxide synthase • Activates a mitochondrial uncoupling protein • Reduction of leptin expression	• Left ventricular dysfunction • Thermogenesis • Antiobesity and antidiabetic properties
α1 AR	Vasculature, heart, lung, kidney, liver, and brain	• Coupling to Gq/11 and Activation of phospholipase C	• Control of vascular tone
α2 AR	Presynaptically and postsynaptically	• Inhibition of Ca^{2+} channels, activation of K^{+} channels, activation of phospholipase C, increased Ca^{2+} release from intracellular sources, and stimulation of mitogen-activated protein kinase	• Neurotransmitter release, control of vascular tone, regulation of renin release, inhibition of insulin secretion, inhibition of lipolysis, and platelet aggregation • Vasoconstriction peripherally and hypotension centrally

Receptors are classified based on their localization, signaling and physiological effects.

protein-coupled receptor kinases (GRKs) with the involvement of β-arrestins (Kohout and Lefkowitz, 2003). GRK-phosphorylated receptors recruit β-arrestins, which compete with G protein coupling and desensitize the G protein signaling response (Shenoy and Lefkowitz, 2003a). Moreover, β-arrestins also promotes receptors clathrin-dependent endocytosis (Goodman *et al.*, 1996).

The αARs are GPCRs that couple to $G_{\alpha q}$ protein that is a primary activator of phospholipase C (PLC). This latter, in turn, promotes the cleavage of the inositol substrate phosphatidyl-inositol 4,5 bisphosphate (PIP2) to yield diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP3). Then, DAG and IP3 promote the activation of protein kinase C (PKC). The α_1AR subtype can also activate specific adenylate cyclases (AC) leading to an increase in cAMP levels. DAG and cAMP are second messengers that affect several cell signaling pathways and responses.

Agonist-activated βARs couple to the stimulatory G protein, G_s, leading to the activation of adenylyl cyclase and the accumulation of cAMP (Dixon *et al.*, 1986; Emorine *et al.*, 1989). The increase of cAMP induces the activation of protein kinase A (PKA) which in turn phosphorylates several substrates to activate specific intracellular signaling. Among these latters, it has been shown that the activation of the axis β_2AR/PKA regulates the synthesis of catecholamines in the endothelium (Sorriento *et al.*, 2012). It is a new interesting finding in the field of βARs-dependent regulation of vascular function even if the pathophysiological role of endothelial catecholamines is still unknown. Recent studies indicate that under certain conditions βAR, and particularly β_2AR, can also couple to G_i (Asano *et al.*, 1984; Buxton *et al.*, 1987; Chaudhry *et al.*, 1994; Gauthier *et al.*, 1996; Xiao *et al.*, 1995). Indeed, the β_2AR itself become a PKA substrate. The PKA-dependent phosphorylation of the third intracellular loop of the β_2AR increases the affinity of the receptor for G_i protein (Okamoto *et al.*, 1991; Zamah *et al.*, 2002). G_i activation inhibits adenylyl cyclase activity, leading to the reduction of cAMP levels and to the increase of "non-cAMP dependent signaling," such as the activation of the extracellular signal-regulated kinases ERK1/2 and PI_3K (Baillie *et al.*, 2003; Jalali *et al.*, 1998; Luttrell and Lefkowitz, 2002; Nagao *et al.*, 1999; Xiao, 2001). Several factors have been identified which are able to regulate membrane protein structure and activity. Among them, lipids seem to have a key role in the regulation of adrenergic receptor activation since they act as direct allosteric modulators of receptor activity (Dawaliby *et al.*, 2016). Specifically, phosphatidylglycerol markedly favored agonist binding and facilitated receptor activation, whereas phosphatidylethanolamine favored antagonist binding and stabilized the inactive state of the receptor (Dawaliby *et al.*, 2016). Protein post-translational modifications also affect ARs activation and signaling. In this context, it has been recently shown that N-glycosylation of β_2AR regulates receptor function by affecting its dimerization (Li *et al.*, 2017). Furthermore, new phosphorylation sites on β_1AR have been identified in mouse heart which affect receptor function (Hayashi *et al.*, 2017). In particular, the phosphorylation at Ser274, Ser280, and Ser462 have been found to be enhanced in response to stimulation with agonists (Hayashi *et al.*, 2017).

The "Biased Signaling"

Classically, adrenergic receptors activate G protein-dependent signaling pathways in response to ligands stimuli. For many decades, these receptors were thought to possess just a simple "on/off" status which was dependent on the type of ligand (the agonist

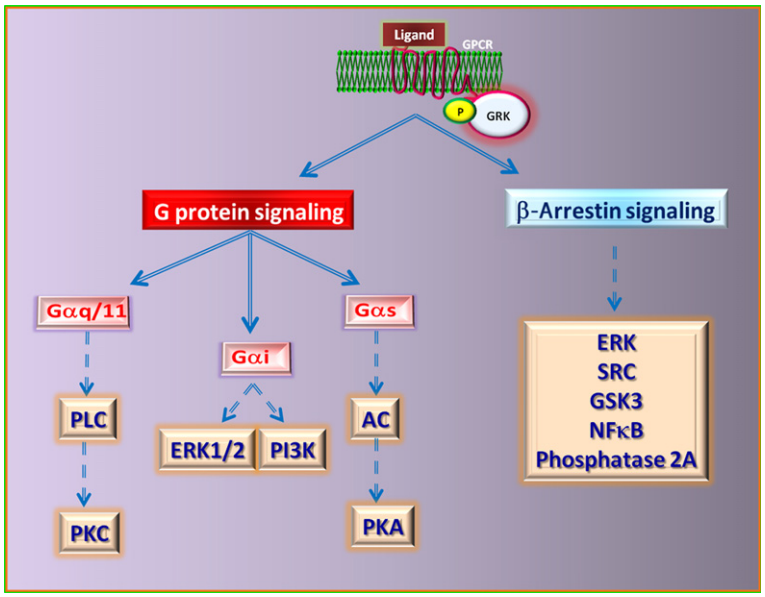

Fig. 1 GPCR signaling. In response to ligands, GPCR can signal through G protein or β-arrestin. Traditionally, adrenergic receptors ligands signal through both mechanisms. However, there are specific ligands, known as "biased agonists," which are able to induce the conformational state of the receptor that selectively activates one of the two signaling pathways. Reproduced from Bologna, Z., Teoh, J. P., Bayoumi, A. S., Tang, Y., Kim, I. (2017). Biased G protein-coupled receptor signaling: New player in modulating physiology and pathology. *Biomolecules & Therapeutics* **25** (1), 12–25.

turns on and the antagonist turns off the signal). In the last decade, however, it has been shown that several GPCR, including β_2AR, can signal independently from G protein activation, through the GRK/β-arrestin pathway (**Fig. 1**).

Traditionally, adrenergic receptors agonists and antagonists signal through both mechanisms. However, some ligands are able to favor one mechanism over the other and are known as "biased agonists." These ligands can induce the conformational state of the receptor that selectively activates one of the two signaling pathways (Liu *et al.*, 2012).

β_2AR ligands, such as the β-blocker carvedilol (Shenoy and Lefkowitz, 2011) and the agonist isoetharine (Drake *et al.*, 2008), have been shown to promote differing degrees of signaling in G-protein and arrestin pathways (Urban *et al.*, 2007). Indeed, carvedilol, a β_1/β2-AR–blocker used for the treatment of pathological cardiac diseases (including high blood pressure), is now recognized as a "biased agonist" that is able to stabilize a β-AR conformation promoting the uncoupling to G_s and to induce the β-arrestin-mediated signaling (Wisler *et al.*, 2007). In the same manner, the β_1-AR-blocker nebivolol is also considered a β-arrestin biased agonist (Erickson *et al.*, 2013).

The study of the complexes of the β_2-adrenergic receptor with various ligands suggests that the cytoplasmic ends of helices VI and VII adopt two major conformational states. Different ligands affect the conformational equilibrium involving helices VI and VII (Liu *et al.*, 2012). In particular, ligands that induce G protein signaling active state of helix VI whereas β-arrestin-biased ligands predominantly promote the conformational states of helix VII (Liu *et al.*, 2012).

βAR-Dependent β-Arrestin Signaling

β-arrestins are ubiquitously expressed proteins that were first described for their role in desensitizing G protein-coupled receptors (GPCRs). Indeed, β-arrestins are recruited to receptors in response to agonist-induced phosphorylation by GRKs (Krasel *et al.*, 2005). Besides their ability to disrupt receptor/G-protein signaling, these proteins are now recognized as multifunctional adapter proteins that regulate several cellular functions. In fact, arrestins confer novel GPCR-signaling capacity by recruiting protein kinase, phosphatase, phosphodiesterase, and ubiquitin ligase activity into the receptor complexes with proteins (Shukla *et al.*, 2014a).

The β_2AR-β-arrestin 1 complex has been studied in detail by means of electron microscopy, hydrogen-deuterium exchange mass spectrometry and chemical cross-linking (Shukla *et al.*, 2014b). β-arrestin seems to trigger a biphasic mechanism to engage the receptor, involving two different interactions, in the carboxy-terminus of the receptor and in the seven-transmembrane core (**Fig. 2**; Shukla *et al.*, 2014b). These interactions should preclude receptor engagement of G-protein heterotrimers, thereby blocking classical GPCR signaling.

β-arrestins recruited to agonist-activated and phosphorylated receptors can promote several G protein-independent signaling pathways, such as ERK, c-Src, GSK3, protein phosphatase 2A, and NFκB signaling (Luttrell and Miller, 2013). Actually, β-arrestins exert a triple function on GPCR which includes the regulation of receptors desensitization, endocytosis, and signaling (Shenoy and Lefkowitz, 2011).

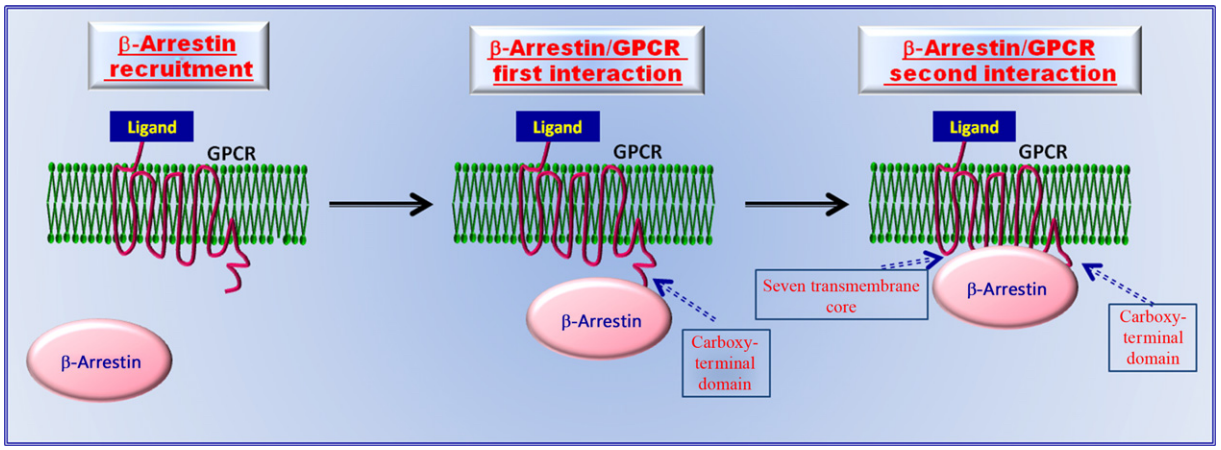

Fig. 2 β-arrestin/GPCR interaction. The interaction of β-arrestin with GPCR involves two separate sets of interactions, the first in the carboxy-terminus of the receptor and the second in the seven-transmembrane core (see *white arrows*). These interactions should preclude receptor engagement of G-protein heterotrimers, thereby blocking classical GPCR signaling. Adapted from Shukla, A. K., Westfield, G. H., Xiao, K., Reis, R. I., Huang, L. Y., Tripathi-Shukla, P., Qian, J., Li, S., Blanc, A., Oleskie, A. N., Dosey, A. M., Su, M., Liang, C. R., Gu, L. L., Shan, J. M., Chen, X., Hanna, R., Choi, M., Yao, X. J., Klink, B. U., Kahsai, A. W., Sidhu, S. S., Koide, S., Penczek, P. A., Kossiakoff, A. A., Woods, V. L. Jr., Kobilka, B. K., Skiniotis, G. and Lefkowitz, R. J. (2014). Visualization of arrestin recruitment by a G-protein-coupled receptor. *Nature* **512**, 218–222.

β-arrestins is able to promote ERK1/2 activation by inducing Raf-1/MEK1 pathway and sequestering ERK in the cytosol (Luttrell *et al.*, 2001). This precludes ERK-mediated transcription and prolongs ERK signaling. Similarly, arrestin 3 can scaffold JNK1/2 favoring their phosphorylation by the kinases MKK4 and MKK7 (Kook *et al.*, 2013).

β- arrestins can directly bind to Src family kinases and recruit them to an agonist-occupied receptor. The stimulation of β2 adrenergic receptors triggers the assembly of a protein complex containing activated Src, β-arrestin and the receptor (Luttrell and Lefkowitz, 2002). Such complex affects several GPCR-dependent mechanisms, such as dynamin phosphorylation (Miller *et al.*, 2000), ERK activation (Defea *et al.*, 2000), neutrophil degranulation (Barlic *et al.*, 2000). Moreover, it has been shown that both β-arrestin 1 and 2 are able to interact with IκBα, the inhibitor of the transcription factor NFκB, and inhibit NFκB signaling (Witherow *et al.*, 2004).

The Role of Calcium in β-Adrenergic Receptors Signaling

It is known that adrenergic receptors are able to regulate intracellular calcium flux. Indeed, in some cell types, β2AR activation has been linked to the mobilization of Ca^{2+} from intracellular stores through the actions of cAMP on PKA (Betzenhauser *et al.*, 2009; **Fig. 3**). In animal models of heart failure, the stoichiometry and function of the RyR2 macromolecular complex are altered due to hyperphosphorylation by PKA, promoting Ca^{2+} influx (Reiken *et al.*, 2001). The treatment with β blockers reverses PKA hyperphosphorylation of RyR2, restores the stoichiometry of the RyR2 macromolecular complex, and normalizes the single-channel function (Reiken *et al.*, 2001). Recently, it has been shown in vitro that β2AR regulates Ca^{2+} mobilization from intracellular stores also through the exchange protein activated by cAMP (EPAC) (Pereira *et al.*, 2012). This latter leads to the activation of phospholipase C and the opening of inositol trisphosphate (InsP3) receptors (**Fig. 3**; Galaz-Montoya *et al.*, 2017), without involving members of the canonical β2AR signaling cascade (Galaz-Montoya *et al.*, 2017).

Targeting β-Adrenergic Receptors

To date, GPCRs, including adrenergic receptors, represent one of the largest therapeutic targets in clinical medicine from cancer to cardiovascular diseases (Lappano and Maggiolini, 2011; Pacher *et al.*, 2006). In fact, adrenergic receptors ligands account for almost 40% of approved drugs, such as α- and β-blockers and β-agonist (Chalmers and Behan, 2002).

Commercial Drugs

Among available therapeutic ligand of ARs, beta-blockers are categorized as "selective" or "non-selective" based upon whether they block only beta-1 receptors, that are predominantly present in cardiac muscle, or also beta-2 receptors, mainly found in bronchial and smooth muscles (**Table 2**).

β-blockers, such as metoprolol, bisoprolol, and carvedilol, antagonize the effects of catecholamines on beta-adrenergic receptors leading to a reduction in the contractile force and the rate of contraction, to the inhibition of renin release from the

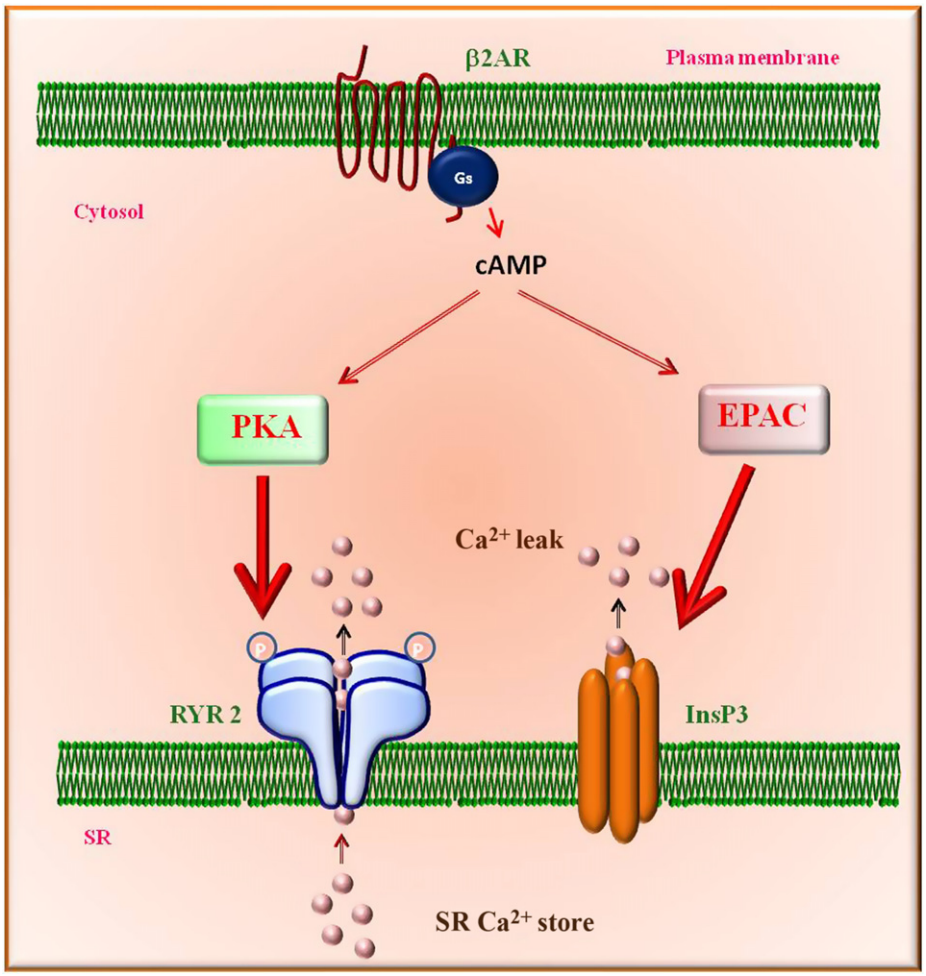

Fig. 3 βAR and calcium flux. Adrenergic receptors activates PKA which in turn phosphorylates RyR2 promoting sarcoplamic reticulum (SR) Ca^{2+} leak. This leads to a depletion of SR Ca^{2+} stores and a reduction of EC coupling. Reproduced from Reiken, S., Gaburjakova, M., Gaburjakova, J., He Kl, K. L., Prieto, A., Becker, E., Yi Gh, G. H., Wang, J., Burkhoff, D. and Marks, A. R. (2001). Beta-adrenergic receptor blockers restore cardiac calcium release channel (ryanodine receptor) structure and function in heart failure. *Circulation* **104**, 2843–2848; Galaz-Montoya, M., Wright, S. J., Rodriguez, G. J., Lichtarge, O., and Wensel, T. G. (2017). Beta-2 adrenergic receptor activation mobilizes intracellular calcium via a non-canonical cAMP-independent signaling pathway. *Journal of Biological Chemistry* **292** (24), 9967–9974; Pereira, L., Ruiz-Hurtado, G., Morel, E., Laurent, A. Epac enhances excitation-transcription coupling in cardiac myocytes. *Journal of Molecular and Cellular Cardiology* **52**, 283–291.

kidney and to a decrease in blood pressure. These drugs are actually used for the treatment of hypertension, ischemic heart disease, myocardial infarction, arrhythmias, congestive heart failure.

Nebivolol has the highest β_1-receptor affinity among β-blockers. It has been demonstrated that this drug also has antioxidant properties and regulate endothelial functions by promoting the activity of the endothelial nitric oxide synthase (Mason *et al.*, 2005).

Some drugs, such as carvedilol, are able to block both $\alpha 1$ and β_1/β_2 receptors. Thus, carvedilol is mainly used for the treatment of hypertension but it is also effective in congestive heart failure. Indeed, besides the inhibition of adrenergic receptors signaling, this drug is able to reduce the production of reactive oxygen species (Cardinale *et al.*, 2015; Spallarossa *et al.*, 2004).

$\alpha 1$-receptor blockers, such as prazosin, are commonly used for the treatment of hypertension since they reduce blood pressure and also have diuretic effects.

Clonidine, methyldopa, guanabenz, and guanfacine are $alpha_2$ receptors agonists which decrease sympathetic outflow to the heart and blood vessels. Among them, clonidine is the most widely used drug in this class.

Besides the commercially available drugs, the new findings on the ability of adrenergic receptors to signal via both G protein and non-G protein effectors has prompted the search for new ligands that can "bias" downstream signaling in favor of one selective signaling. Thus, the increase of knowledge on ARs biased signaling will be helpful for designing drugs with higher specificity and effectiveness than the commercially available ones.

Table 2 List of beta blockers that are commonly used in clinic

Drug name	*Generation*	*Selectivity on βAR*	*Selectivity on αAR*	*Other properties*	*Biased agonist*
Propanolol	First	Non-selective	–	–	–
Esmolol	Second	Selective	–	–	–
Atenolol	Second	Selective	–	–	–
Metoprolol	Second	Selective	–	–	–
Nebivolol	Third	Selective	–	NO-vasodilation and Antioxidant properties	Yes (Mason et al., 2005)
Labetalol	Third	Non-selective	a1AR	–	–
Carvedilol	Third	Non-selective	a1AR	Antioxidant properties	Yes (Cardinale et al., 2015; Spallarossa et al., 2004)

Several selective and non-selective βAR drugs are commonly used for the treatment of hypertension and cardiovascular diseases. Among them, carvedilol and nebiovilol are considered biased agonists giving their ability to activate G protein independent signaling.

Potential Molecular Targets

Beyond the above described available class of drugs which are able to target ARs and block adrenergic signaling, several peptides have been identified that affects ARs activation and could become useful target for drugs. Among them, GRK2 and β-arrestins are the most suitable since they act upstream of ARs signaling. Different strategies have been put in place to inhibit GRK2 in cardiovascular diseases both in vivo (Raake *et al.*, 2013; Casey *et al.*, 2010; Schumacher *et al.*, 2015) and in vitro (Lorenz *et al.*, 2003; Mayer *et al.*, 2008; Sorriento *et al.*, 2015) which are based on different molecular mechanisms from the inhibition of the kinase catalytic activity to the regulation of its shuttling within the cell (Sorriento *et al.*, 2016). GRK2 inhibition is commonly achieved through the viral mediated expression of βARKct, which resembles the carboxy-terminal domain of GRK2 that is responsible for its translocation to the plasma membrane and its binding to Gβγ. It has been shown that the long-term expression of βARKct induced a significant amelioration cardiacfunction in animal models of heart failure and myocardial infarction (Raake *et al.*, 2013). Recently, an alternative approach has been suggested based on the synthesis of small molecules which selectively inhibit GRK2 activity. Small molecules has the advantage to autonomously cross the plasma membrane, thus avoiding the immune response and cytotoxicity often associated with viral use. Several promising compounds that bind to the Gβγ binding site of GRK2 have been identified (Anis *et al.*, 2004; Gomez-Monterrey *et al.*, 2014) which effectively restores cardiac function in animal models of pathology (Sorriento *et al.*, 2015). Similarly, β-arrestins appears to be promising targets for therapeutics, given their multiple functions within GPCR activation and signaling. It has been shown that their effects are regulated by several protein post-translational modifications. Indeed, β-arrestins dephosphorylation (Lin *et al.*, 2002), ubiquitination (Shenoy and Lefkowitz, 2003b) and nitrosylation (Ozawa *et al.*, 2008) affect receptors internalization and trafficking. Thus, targeting these modifications could be an useful strategy to regulate AR signaling.

Baroreceptor Responses

AF Sved and EM Stricker, University of Pittsburgh, Pittsburgh, PA, USA
SD Stocker, Penn State University College of Medicine, Hershey, PA, USA

Glossary

Bradycardia Decreased heart rate.
Catecholamines A distinctive chemical structure common to epinephrine and norepinephrine.
Hypotension Reduced arterial blood pressure.
Hypovolemia Reduced blood volume.
Tachycardia Increased heart rate.

Introduction

Given the importance of the cardiovascular system in maintaining adequate perfusion of tissues, it is not surprising that elaborate mechanisms have evolved to promote the stability of arterial blood pressure and blood volume, which are essential for maintaining tissue perfusion. These mechanisms include well-known physiological responses that restore blood pressure and volume after blood loss with or without accompanying decreases in arterial blood pressure, including autonomic reflexes, endocrine secretions, and ingestive behaviors motivated by thirst and salt appetite.

Animals must be able to detect changes in blood pressure and volume for any of these compensatory responses to occur. Insight into the location of the receptors, and their properties, comes from a consideration of how changes in blood volume and pressure affect the cardiovascular system. After a moderate hemorrhage, for example, the blood loss is not distributed uniformly throughout the cardiovascular system but instead is borne almost entirely on the venous side of the circulation. The veins, which are very distensible, collapse around the remaining blood and thereby help to reduce the impact of the blood loss on venous blood pressure. Together with an appropriate increase in heart rate, arterial blood volume and pressure undergo little change. Thus, it makes sense that receptors are situated to monitor blood volume on the venous side of the circulation. In contrast, after severe hemorrhage the effects of blood loss may extend to the arterial side of the circulation and reduce arterial blood volume and pressure. Thus, it also makes sense that additional receptors are situated to monitor blood pressure on the arterial side of the circulation. Indeed, as arterial blood pressure is a key determinant of tissue perfusion, this parameter is sensitively monitored and tightly regulated. The receptors that monitor the stretch of venous and arterial blood vessels are known to be located at key sites in the cardiovascular system. On the venous side, the most important site is at the junction of the inferior vena cava and the right atrium. On the arterial side there are two key sites, the aortic arch through which arterial blood leaving the heart is carried and the carotid arteries through which blood flows to the brain.

The receptors in question are cells called 'baroreceptors', which literally means that they are responsive to changes in pressure. The sensory endings of these cells are mechanoreceptors, located on the outside walls of the blood vessels and cardiac atria, which respond to changes in the conformation of the vessel wall, much like other stretch receptors on the outside walls of the stomach and bladder detect the fullness of those organs. Thus, following a moderate hemorrhage, the loss in blood volume from the venous side decreases venous pressure and stretch of the right atrium and vena cava thereby decreasing the firing rate of these sensory nerves. Following a more severe hemorrhage, blood pressure in the proximal aorta and carotid sinus decrease, leading to decreased distention of these blood vessels and thus decreased activity of the aortic and carotid sinus baroreceptors. Three additional points regarding baroreceptors should be noted. First, although this chapter is written from the perspective of decreases in blood volume, any changes in stretch, increased or decreased, whatever the cause, will be detected. Second, baroreceptors, like other stretch receptors, adapt to chronic stretch, and so baroreceptor activity does not simply reflect the pressure but it also is affected by the rate of change in pressure. Third, other circulating substances (e.g., hormones) or locally released signaling molecules acting on baroreceptors can influence their activity as well.

Responses

Neural afferents from these low- and high-pressure baroreceptors project as part of the ninth and tenth cranial nerves to the nucleus of the solitary tract (NST) in the caudal brain stem. From there, complex neural circuitry enables the variety of responses that occur in response to decreases in blood volume or arterial blood pressure (see **Fig. 1**). Among the most prominent responses are the following.

Cardiac Reflexes

Changes in heart rate and cardiac contractility (and therefore cardiac output) help to compensate for changes in blood volume and pressure. Thus, for example, an increase in heart rate and cardiac contractility occurs during hypovolemia or hypotension, which is

 doi:10.1016/B978-0-12-801238-3.03960-X

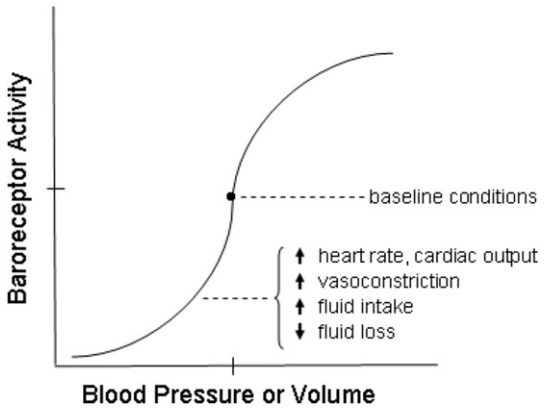

Fig. 1 Baroreceptor-evoked responses to hypovolemia and hypotension. The activity of veno-atrial baroreceptors and arterial baroreceptors are related to changes in blood volume and blood pressure, respectively. Neural and endocrine baroreceptor reflex responses to decreases in blood volume or blood pressure produce increases in heart rate and cardiac output, increases in vasoconstriction, and decreases in fluid excretion by the kidneys. Additionally, baroreceptor input to the brain elicits ingestive behaviors to increase fluid body fluid volume. In general, increases in blood volume and blood pressure elicit baroreceptor-evoked responses that are the converse of those seen with decreases in these parameters.

one of the well known 'baroreceptor reflexes'. This response appears to reflect the three autonomic effects that result from baroreceptor input to the NST. The first involves the control of cardiac sympathetic neural activity, which accelerates heart rate and increases cardiac contractility when stimulated during volume contraction or decreases in arterial pressure. The second is the converse inhibitory effect on parasympathetic neural activity, which also causes tachycardia. The third involves stimulation of the adrenal medulla and the release into the systemic circulation of epinephrine, which has a prominent effect on beta-adrenergic receptors on the heart and thereby further stimulates heart rate and cardiac contractility. The multiple controls of heart rate ensure that these responses are rapid and precise.

Vasoconstriction

Blood vessels are also responsive to sympathetic neural input. During hemorrhage, norepinephrine is released from sympathetic nerve fibers and binds to alpha-adrenergic receptors located on vascular smooth muscle to cause vasoconstriction. The constriction of blood vessels raises peripheral resistance and blood pressure. At the same time, constriction of some arterioles versus others permits the cardiovascular system to maintain blood flow to critical organs. Activation of sympathetic neural input to veins causes venoconstriction, thereby increasing venous return of blood to the heart and cardiac output.

Renin-Angiotensin System

Increased sympathoadrenal activity, brought about by decreased arterial blood pressure and or blood volume, stimulates renin secretion from the kidneys, which begins a cascade of biochemical events that result in the generation of the peptide hormone angiotensin II, the most potent pressor agent available to the animal in response to blood loss. Briefly, renin is a proteolytic enzyme that is synthesized in renal juxtaglomerular cells and released in response to increased activation of beta-adrenergic receptors on these cells, either by sympathetic nerves or by circulating epinephrine, by decreased renal sodium concentration, or by a direct action of large decreases of renal arterial perfusion pressure. Renin acts by cleaving angiotensinogen, a large protein synthesized in the liver and always present in the circulation, to produce a 10-amino acid protein (angiotensin I) that then quickly loses two more amino acids through the action of an enzyme that converts angiotensin I to angiotensin II. This enzyme, angiotensin converting enzyme or ACE, is heavily concentrated in the lung capillaries, an arrangement that allows the hormone to be delivered into the arterial blood that leaves the heart. Circulating angiotensin II acts directly on angiotensin II receptors in vascular smooth muscle to support blood pressure. In addition, it acts in the adrenal cortex to stimulate secretion of the mineralocorticoid aldosterone, which promotes urinary Na^+ retention (and, secondarily, fluid retention) as well as urinary K^+ excretion (which is especially useful when blood loss is associated with tissue damage). Angiotensin II also acts on angiotensin receptors in the brain, in particular in the subfornical organ (SFO). The SFO, which is situated dorsal to the third cerebral ventricle, lacks a blood–brain barrier and therefore can detect variations in blood levels of the hormone. Neural circuits from the SFO then appear to stimulate central systems that increase sympathoadrenal activity. They also stimulate secretion of vasopressin, another hormone with pressor properties, from the posterior lobe of the pituitary gland.

Vasopressin

The release of pituitary vasopressin (also called antidiuretic hormone) is stimulated by neural pathways connecting the NST to the supraoptic and paraventricular nuclei of the hypothalamus, in response to decreased baroreceptor input during hemorrhage. Whereas low physiological blood levels of vasopressin (1–10 picomolar) have prominent effects on water retention by the kidneys, vasopressin release stimulated by decreased blood volume or arterial blood pressure results in much higher levels of vasopressin (>25 picomolar) and at these high levels vasopressin causes constriction of arteriolar smooth muscle. Thus, in response to hemorrhage, vasopressin causes vasoconstriction, thereby helping to maintain arterial blood pressure. Pituitary secretion of the other neurohypophyseal hormone, oxytocin, parallels the secretion of vasopressin in response to these stimuli. The contribution of oxytocin to the regulation of blood volume and arterial blood pressure is presently unclear, though studies in rats revealed that it constituted yet another significant stimulus of renin secretion.

Pituitary-Adrenal Axis

Neural projections from the NST to the paraventricular nuclei of the hypothalamus also stimulate release of corticotrophic releasing factor (CRF), which elicits secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. ACTH, in turn, stimulates the adrenal cortex to increase its synthesis and release of two steroid hormones, aldosterone (mentioned above) and the glucocorticoid cortisol. Cortisol improves vascular reactivity to the catecholamines and other general responses to stress.

Ingestive Behavior

In addition to these physiological responses, hypovolemia is known to stimulate thirst and, in rats and some other species (but not in human subjects), salt appetite. Remarkably, the resultant ingestion of water and NaCl solution occurs in amounts equivalent to a fluid mixture that is isotonic to plasma. Baroreceptor input to the brain stem is presumed to provide the main signal of thirst under hypovolemic conditions, although angiotensin II is a known dipsogen and presumably contributes stimulation as well. The signal of salt appetite is less clear and presently is controversial, although an important role of angiotensin II seems apparent. Thirst (but not salt appetite) also is stimulated by arterial hypotension in rats, but the induced water intake is mediated exclusively by angiotensin II, and baroreceptors do not appear to provide a direct neural signal.

Summary

Many adaptive responses occur during hypovolemia and arterial hypotension that appear to involve signals that originate in the activity of cardiovascular baroreceptors. These responses include several chemical agents that independently provide vasoconstriction and support of arterial blood pressure, hormone secretions that promote urinary conservation of water and Na^+, and the sensations of thirst and salt appetite that lead to water and NaCl consumption, respectively. The precise stimulus of each response is not always certain, but it may involve neural signals, blood-borne signals, or both. This redundancy of stimuli is a common feature of homeostatic regulatory systems, which is adaptive because it allows compensation for damage- or disease-induced impairments of individual components of the system. On the other hand, this redundancy makes it very difficult for investigators to identify all the contributing signals and effector systems that participate in homeostasis, and their importance relative to one another.

Although this description has focused on the baroreceptor responses seen after reductions in blood volume and pressure, it is important to recognize that many, but not all, of these same variables are influenced by increases in blood volume and pressure. For example, hypervolemia or high blood pressure causes a reflexive bradycardia through low and high-pressure receptors, respectively. Other baroreceptor responses to hypervolemia and hypertension are generally analogous although some inconsistencies are evident. Thus, vasopressin secretion is decreased when blood volume is expanded though not when blood pressure is elevated. Conversely, thirst is decreased when arterial blood pressure is elevated acutely though not when blood volume is expanded. In short, baroreceptors mediate a variety of adaptive autonomic, endocrine, and behavioral responses both to decreases and increases in blood volume and pressure.

Antiadrenergic Agents☆

Enrico Agabiti-Rosei, University of Brescia, Brescia, Italy

Glossary

Adrenergic nervous system The sympathetic part of the autonomous nervous system, where the neurotransmitters (norepinephrine and epinephrine) are adrenergic.

Cholinergic nervous system The parasympathetic part of the autonomic nervous system, where the neurotransmitter (acetylcholine) is cholinergic.

Pre/postganglionic Anatomical position of the sympathetic neuron with respect to the ganglion.

Pre/postsynaptic Anatomical position of receptors with respect to the synapse/nerve ending.

Synapse Anatomic/functional structure allowing the transition of nerve activity from the nerve ending (postganglionic) through the synaptic cleft and toward the target organ (blood vessel, heart, etc.).

Antiadrenergic agents are drugs that suppress the activity of the sympathetic (adrenergic) nervous system, targeting the cardiovascular system and other organs.

Introduction

The autonomic nervous system is responsible for the homeostasis/regulation of several internal organs, tissues, and metabolic systems. Well-known examples of such targets of the autonomic nerves are the cardiovascular system (heart and blood vessels), the gastrointestinal system (stomach, intestine, biliary duct, etc.), the respiratory tract (lungs and airways), and glucose/lipid metabolism. The autonomic nervous system is subdivided into the sympathetic and parasympathetic systems. The sympathetic or adrenergic system is activated with the purpose of adapting the individual organism for "flight, fright, or fight"—that is, the short-term availability and release of energy and alertness. In contrast, the parasympathetic nervous system facilitates the storage of energy and metabolic components to allow the release of energy in a situation of flight, fright, or fight. As such, the sympathetic and parasympathetic systems counteract each other's activities in a sort of "yin-yang" balance. Activation of the sympathetic nervous system implies the stimulation of the cardiovascular system, thus increasing heart rate, cardiac output, cardiac contractility, and blood pressure. During sympathetic stimulation, the activity of the gastrointestinal system is attenuated. Stimulation of the parasympathetic system implies the activation of the digestive system, particularly the gastrointestinal tract, with the aim of facilitating the storage of energy. During parasympathetic activation, the cardiovascular system's activity is reduced. Both the sympathetic and parasympathetic systems are subject to modulation by the central nervous system, particularly the brainstem. However, higher (cortical) brain centers can also modulate both subgroups of the peripheral autonomic nervous system. Several diseases are associated with dysregulation of either subgroup of the autonomic nervous system. Relevant examples of this pathophysiological involvement particularly concern the sympathetic nervous system, which is known to be overactive in important cardiovascular derangements or diseases, such as hypertension, congestive heart failure, or cardiac tachyarrhythmia. For this reason, a vast body of research has accumulated with the aim of finding drugs that can attenuate the hyperactivity of the sympathetic nervous system. Drugs with such activity are called antiadrenergic agents.

Sympathetic (Adrenergic) Nervous System and Its Receptors

The brainstem, consisting predominantly of the pons/medullary region, controls the peripheral sympathetic nervous system (Fig. 1). The peripheral sympathetic nervous system contains a kind of relay station called the sympathetic ganglion. Transmission in the ganglion is performed by the neurotransmitter acetylcholine (ACh), which targets the nicotine-like AChN receptors. Peripheral sympathetic neurons are subdivided into pre- and postganglionic types according to their anatomical position with respect to the ganglion. The sympathetic activity is transferred from the postganglionic neuron to the target organ (e.g., the heart or a blood vessel). The anatomical Transition structure required for this process is called the synapse (Fig. 2). The process of humoral neurotransmission within the synapse occurs as follows: The neurotransmitter norepinephrine (NE; also called noradrenaline) is

☆*Change History*: February 2018: Enrico Agabiti-Rosei updated the text and references to the entire article.

This article is an update of P.A. van Zwieten, Antiadrenergic Agents, In *Encyclopedia of Endocrine Diseases*, edited by Luciano Martini, Elsevier, New York, 2004, pp. 249–254.

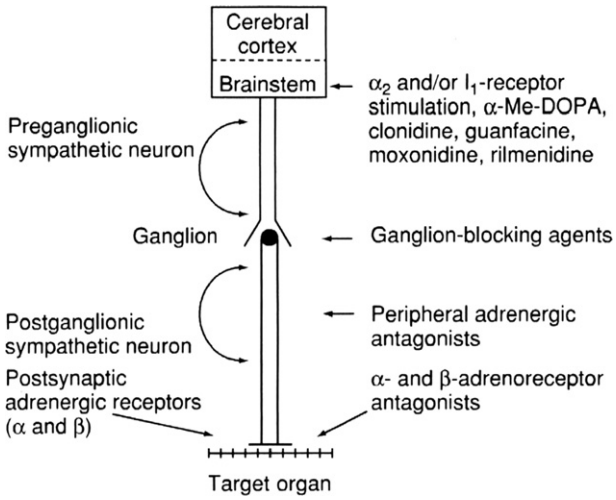

Fig. 1 Schematic representation of the sympathetic (adrenergic) nervous system. Adrenergic structures and receptors in the brainstem modulate the activity of die peripheral sympathetic nervous system. The targets of all relevant antiadrenergic drugs are shown. Virtually every structure/receptor of the system can be manipulated selectively by drugs.

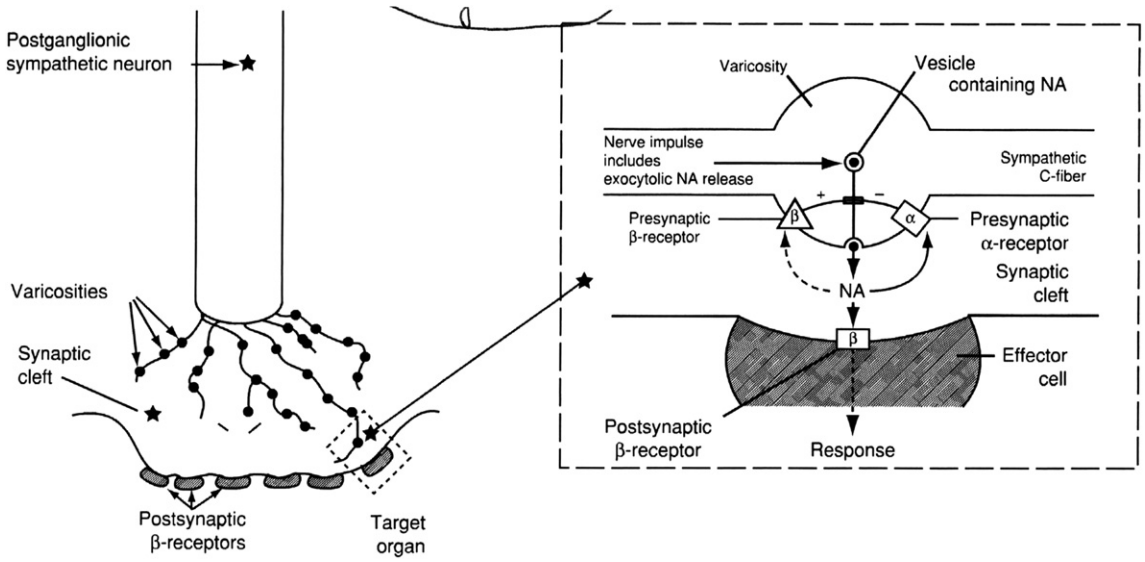

Fig. 2 Schematic representation of a sympathetic (adrenergic) synapse. Nerve activity releases the endogenous neurotransmitter from the varicosities at the nerve endings. Stimulation of postsynaptic α-adrenoceptors causes a physiological/pharmacological effect (e.g., vasoconstriction). Blockade of the α-adrenoceptor (postsynaptic) counteracts the effect of norepinephrine. Stimulation of presynaptic α-adrenoceptors inhibits the release of the neurotransmitter. Conversely, presynaptic α-receptor blockade stimulates the release of the neurotransmitter.

released from the postsynaptic nerve ending, diffuses through the synaptic cleft, and then binds to the receptors in the target organ. The receptor thus activated mediates a physiological/functional process (e.g., constriction of a blood vessel) or an increase in cardiac frequency or contractility. The receptor in the target organ is activated by the endogenous neurotransmitter NE but also by synthetic drugs, such as methoxamine, phenylephrine, and isoprenaline, that imitate the effects of NE. These activator drugs are called sympathomimetic agents. They are agonists with respect to the receptor. Antagonists are chemical compounds that block the stimulating effect of NE (the neurotransmitter) and that of sympathomimetic agents. The antagonist or blocker binds to the receptor, thus preventing the stimulating effect of the endogenous neurotransmitter NE. In the sympathetic nervous system, the receptor antagonists are also called antiadrenergic agents. The sympathetic or adrenergic receptors are subdivided into a variety of subtypes. α-Adrenoceptors are predominantly located in blood vessels but also in the brainstem. 3-Adrenoceptors are mainly present in various structures of the heart but also in the bronchi. In a later stage, there is a further subdivision into α_1/α_2 and $\beta_1/\beta_2/\beta_3$. The functional roles of the most important α- and β-adrenoceptors are summarized in **Tables 1** and **2**. The tables also note the effects of stimulation by an agonist and the effects of blockade by an antagonist.

Table 1 Functional effects of the stimulation/blockade of α-adrenoceptors by an agonist and an antagonist

Receptor	*Stimulation by an agonist causes*	*Blockade by an antagonist (blocker) causes*
α_{1A}	Vasoconstriction	Vasodilation
α_{1A} (prostate)	Contraction	Smooth muscle relaxation
α_2 (postsynaptic) vascular	Vasoconstriction	Vasodilatation
α_2 (presynaptic)	NE release↓	NE release↑
α_2 (brainstem)	Sympathoinhibition Blood pressure↓	

Table 2 Functional effects of the stimulation/blockade of β-adrenoceptors by an agonist and an antagonist

Receptor	*Stimulation by an agonist causes*	*Blockade by an antagonist causes*
β_1 (cardiac)	Heart rate↑ Contractility↑ A–V conduction↑	Heart rate↓ Contractility↓ A-V conduction↓
β_2 (vascular)	Vasodilatation	Vasoconstriction
β_2 (bronchi)	Bronchodilatation	Bronchoconstriction
β_2 (metabolic)	Blood glucose↑	Blood glucose↓
β_3 (metabolic)	Lipolysis—thermogenesis in brown fat	Antilipolysis—less thermogenesis
β_3 (cardiovascular)	Less oxidative stress—vasodilatation	Oxidative stress—vasoconstriction

The α- and β-adrenoceptors in the brainstem deserve special attention. These receptors in the pons/medulla region are involved in the central nervous regulation of the cardiovascular system, particularly that of blood pressure. The receptors belong to the α_2 subpopulation. Their stimulation by an agonist causes sympathoinhibition in the periphery, resulting in a reduced release of NE from the nerve endings and a decrease in blood pressure. These central α_2-adrenoceptors are also the target of centrally acting antihypertensives, such as clonidine and α–methyl-DOPA (through its active metabolite α-methylnorepinephrine).

Antiadrenergic Agents

As illustrated in Fig. 1, virtually any structure or receptor of the sympathetic nervous system can be modulated more or less selectively by antiadrenergic drugs. Several of these drugs play a role (or have played a role) as therapeutic agents in the treatment of cardiovascular or respiratory diseases.

α-Adrenoceptor Antagonists (α-Blockers)

Competitive inhibition of α-adrenoceptors by appropriate antagonists predominantly causes vasodilatation and a reduction of blood pressure, particularly in hypertensive patients. Doxazosin and prazosin are the prototypes of α_1-blockers. They are selective for the postsynaptic α_1-adrenoceptor subtype: This means that presynaptic α_2-adrenoceptors are not blocked, thus preventing the enhanced release of NE from the sympathetic nerve endings (Fig. 2). Nonselective, older α_1-blockers, such as phentolamine or phenoxybenzamine, are no longer used because they are poorly tolerated.

Doxazosin and prazosin are moderately effective antihypertensive drugs. Orthostatic hypotension, and sometimes headache, and reflex tachycardia are well-known adverse reactions, which are caused by vasodilation (also in the venous blood vessels). A few newer α-adrenoceptor antagonists display a certain degree of selectivity for the α_{1A}-receptor in the smooth muscle of the prostate. These agents cause relaxation of this smooth muscle tissue and hence facilitate urinary flow in patients with benign prostate hyperplasia (BPH). Alfuzosin, terazosin, and tamsulosin are examples of such agents. Silodosin is an α-blocker more uroselective and therefore may induce less postural hypotension, but ejaculation disfunction may be even more frequent.

β-Adrenoceptor Antagonists (β-Blockers)

β-Adrenoceptor antagonists are competitive inhibitors of the effects of endogenous catecholamines (norepinephrine and epinephrine) at the level of β-adrenoceptors in various tissues. In clinical medicine, they are widely used in the treatment of

hypertension, angina pectoris, supraventricular tachyarrhythmias, congestive heart failure, and as secondary prevention following myocardial infarction. Their main therapeutic activity is to counteract the detrimental effects of catecholamines released by the hyperactive sympathetic nervous system. Well-known adverse reactions are bronchoconstriction, cold hands and feet (caused by peripheral vasoconstriction), and sleep disturbances. Patients with COPD may receive β-blocker treatment, but careful titration and the use of β_1-selective blockers is advised. The therapeutic actions are all mediated by the blockade of β_1-adrenoceptors, whereas blockade of β_2-adrenoceptors is the cause of most of the side effects. For this reason, β_1-selective blockers are preferable. Atenolol, bisoprolol, and metoprolol are examples of β_1-selective blockers. Newer β-blockers, such as carvedilol and nebivolol, contain an additional vasodilator component that may offer a hemodynamic and metabolic (i.e., less or no interference with insulin sensitivity and lipid metabolism) advantage. Among vasodilating β-blockers, the mechanism of action for arteriolar dilatation is different. Carvedilol acts through blockade of the α_1-receptors while Nebivolol increases availability of endothelial-derived NO through stimulation of nitric oxide synthase (eNOS) and possibly is also β_3-adrenoceptor agonist.

Postganglionic Neuron Blockers

The electrical membrane activity in postganglionic neurons can be blocked (via the inhibitory influx of Na + ions) by drugs such as guanethidine, cyclazenine, and bretylium. Although they are effective blood pressure-lowering drugs, these agents have been abandoned because of their poor tolerability.

Ganglion Blocking Drugs (Ganglioplegic Agents)

These agents are competitive blockers of the AChN receptors in the sympathetic and also the parasympathetic ganglia. Ganglionic blockade in the sympathetic ganglia accounts for their effective lowering of blood pressure, particularly in hypertensive patients. Pentamethonium, hexamethonium, and trimethaphan are examples of ganglioplegic agents. These agents have been abandoned as therapeutics because of their low tolerability, which is partly due to the blockade of the parasympathetic ganglia.

Rauwolfia Alkaloids

These older drugs have lost their importance as therapeutics because of their poor tolerability. Reserpine and related alkaloids (from Rauwolfia serpentina) destroy the storage sites (granules) of norepinephrine in the sympathetic nerve endings and hence impair the function of the sympathetic system. Although reasonably effective blood pressure lowering agents, their adverse reactions preclude their use in the treatment of hypertension.

Centrally Acting Antihypertensives

α-Adrenoceptors present in the pontomedullary region of the brainstem (e.g., the nucleus tractus solitarii and the vasomotor center) will cause peripheral sympathoinhibition when stimulated with endogenous norepinephrine and also centrally acting antihypertensives. Clonidine, guanfacine, and α-methyl-DOPA (through its active metabolite α-methylnoradrenaline) are α_2-adrenoceptor agonists and, accordingly, cause peripheral sympathoinhibition and the reduction of elevated blood pressure in hypertensive patients. The centrally acting drugs are effective antihypertensives, and their mode of action appears to be attractive on hemodynamic grounds. Their adverse reactions are unpleasant (sedation, dry mouth, and male sexual impotence). These side effects are also mediated by α_2-adrenoceptors (although not located in the brainstem) and thus it is virtually impossible to develop drugs with the same mode of action as clonidine, etc., but with a better profile of adverse reactions. Imidazoline (I1) receptors in the brain (in the ventrolateral medulla) have been identified as targets for centrally acting drugs. Stimulation of central I1 receptors also causes peripheral sympathoinhibition and lowering of blood pressure. Newer drugs causing this effect are moxonidine and rilmenidine, which display lower affinity for α_2-adrenoceptors than clonidine or α-methyl-DOPA. It is hoped that these newer agents display a better tolerability.

Therapeutic Use of Antiadrenergic Drugs

Essential Hypertension

A subtle association between essential hypertension and hyperactivity of the sympathetic nervous system has been repeatedly demonstrated. On the other hand, the treatment of hypertension was initially based on the use of various antiadrenergic drugs, which seems a rational approach. Other types of drugs have been introduced, such as diuretics, calcium antagonists, and suppressants of the renin–angiotensin system (ACE inhibitors and AT 1 blockers). β-Blockers continue to be widely used in antihypertensive treatment, and this approach is supported by numerous clinical trials and several meta-analyses. α-Blockers, particularly doxazosin, have obtained a moderate position in antihypertensive treatment, which is not clearly supported by evidence on an epidemiological scale. Centrally acting agents such as clonidine and α-methyl-DOPA have been largely abandoned

because of their poor tolerability. This approach may be somewhat improved by the introduction of the imidazoline agonists (moxonidine and rilmenidine), but the clinical follow-up for the use of these agents is insufficient. α-Methyl-DOPA is still one of the drugs that still may be used for the treatment of hypertension in pregnancy. Rauwolfia alkaloids, postganglionic neuron blockers, and ganglioplegic agents have been abandoned because of their poor tolerability.

Angina Pectoris

Stable angina pectoris is routinely treated with a variety of anti-ischemic drugs in addition to invasive interventions for revascularization, such as balloon dilatation of a stenosis, or cardiac surgery. Nitroglycerin and other nitrates are used for the treatment of acute symptoms. β-Blockers are first choice for long-term treatment, unless contraindications preclude the use of these drugs. The reduction in heart rate is the major basis of the anti-ischemic action of β-blockers, thus reducing myocardial oxygen consumption. Calcium antagonists, long-acting nitrates, low-dose aspirin, and a statin are usually included in the treatment schedule.

Secondary Prevention After Myocardial Infarction

Recurrent infarction and/or sudden death after myocardial infarction (MI) are major risks in post-MI patients. β-Blockers have been demonstrated to be significantly protective against these risks, probably as a result of their antiarrhythmic activity, which protects against the toxic effects of endogenous catecholamines released by the sympathetic system.

Supraventricular Tachyarrhythmia

The antisympathetic effects of β-blockers explain their antiarrhythmic potency in the treatment of supraventricular tachyarrhythmia. Sotalol, frequently used as an antiarrhythmic agent, is a β-blocker with additional antiarrhythmic potency because of its class III (Vaughan-Williams' classification) activity. β-blockers are indicated in order to reduce an high ventricular rate in patients with atrial fibrillation. They may also prevent new onset or recurrent atrial fibrillation in patients with heart failure, after myocardial infarction and following cardiac surgery.

Congestive Heart Failure

β-Blockers are recognized as beneficial therapeutics in the management of congestive heart failure (CHF). CHF is usually accompanied by sympathetic overactivity, which is detrimental for the decompensated heart. β-Blockers counteract this process. Inotropic activity of the β-blockers that is too negative can be avoided if these agents are initiated in clinically stable patients at a low dose and gradually uptitrated to the maximum tolerated dose. Beneficial activity in CHF has been demonstrated for carvedilol, bisoprolol, metoprolol and nebivolol. β-blockers have been shown to be able of reducing mortality and hospitalization for heart failure in symptomatic patients with reduced ejection fraction, despite treatment with an ACEI and a diuretic in most cases. There is no evidence so far that they may improve prognosis in patients with heart failure and ejection fraction above 50% or/and atrial fibrillation.

Glaucoma Simplex

In patients with glaucoma simplex (open-angle glaucoma), intraocular pressure can be lowered by the topical application of β-blockers such as timolol. The therapeutic activity is based on reduction of the production of aqueous humor.

Benign Prostate Hyperplasia

The moderately beneficial effect of α_{1A}-blockers in the symptomatic treatment of BPH was mentioned previously. Drugs used for this purpose are alfuzosin, terazosin, tamsulosin and silodosin. Hypotension is a side effect of these agents, probably less with silodosin.

Pheochromocytoma and Paraganglioma Syndromes☆

Vitaly Kantorovich and Karel Pacak, University of Connecticut Health Center, Farmington, CT, United States and National Institutes of Health, Bethesda, MD, United States

Introduction

Catecholamine-producing tumors arise from adrenal medulla (pheochromocytoma (PHEO) or adrenal paraganglioma) or paraganglia (paraganglioma (PGL) or extra-adrenal pheochromocytoma). The last associates with either sympathetic or parasympathetic paraganglia – each having unique anatomic (location) and functional (secretory) characteristics. Sympathetic PGL (sPGL) are secretory and follow sympathetic ganglia, widely distributed from skull base down along paravertebral sympathetic chain, while parasympathetic PGL are mostly nonsecretory and usually found in the head and neck area along the branches of glossopharyngeal and vagus nerves (head and neck PGL – HNPGL). PHEO/PGL is a rare disease – its prevalence is low (0.1–0.6%) in patients with hypertension. On the other hand, because of the high prevalence of hypertension, as well as lack of specific symptoms and signs and, as in case of HNPGL, lack of any functional sign other than local effect of the tumor, disease has to be suspected and worked up in a very large number of patients. To further complicate this situation, PHEO/PGL presents with mainly nonspecific and at times surprisingly vague symptoms and signs, so unless thought about, it could be easily missed and progress to potentially preventable but rather devastating complications.

Conceptual Shift

Recent decades propelled our knowledge in PHEO/PGL field to a qualitatively different level. These developments significantly changed both diagnostic and management strategies, but rather than displace, integrated them into main conceptual approach to PHEO/PGL as part of neuroendocrine neoplasia. These also deepened our understanding of pathophysiology of PHEO/PGL and overall tumorigenesis. We will discuss below these conceptual shifts based on recent discoveries and the current stand of the PHEO/PGL field.

Definition – "Who Is Who"

Definition of adrenal tumors as pheochromocytomas and their paragangial counterparts as paragangliomas is rather a historical nod of respect to initial chromium salt staining of pheochromocytomas that generated the original name of the tumor. It was logical to divide them into adrenal and extra-adrenal pheochromocytomas, combining the idea that historical positive staining of the tumorous tissue correlates closely with its secretory activity. Definition of the disease at this point was one of catecholamine-producing tumors arising from chromaffin (chromium salt affine) cells. What is known now as HNPGLs were called glomus tumors and thought to be unrelated to PHEO, treated by surgeons mostly for local effects and seldom seen by endocrinologists. It is not surprising that our current definition of this group of tumors differs dramatically from both initial "catecholamine-producing neoplasms" and more updated – "tumors bearing catecholamine-metabolizing cells" – based on phenomenon of intracellular methylation of catecholamine compounds, currently used for biochemical diagnosis of the disease (see below). Based on identical histology, it is more universal and relies on the fact that PHEO/PGL are tumors arising from single embryonic origin (neural crest), whenever it is intra- (medulla) or extra-adrenal (paraganglia), sympathetic or parasympathetic, secretory or nonseretory, benign or malignant.

Etiology – "The Not so Much Rule of 10 Anymore"

PHEO/PGL was usually seen as mostly sporadic disease with only rare – around 10% – hereditary causes and this area is probably the most significant of recent changes in our understanding of the disease. We know now that 30–40% of PHEO/PGL are associated with inherited mutations and additional 14% of sporadic tumors are found to have somatic mutations. As the number of additional hereditary forms of PHEO/PGL continues to grow, we know now of at least 13 susceptibility genes, associated with PHEO/PGL and the whole spectrum of hereditary can be divided into two large clusters: pseudoxypoxia and kinase signaling pathways (**Tables 1** and **2**). While the last pathway is relatively common in current oncology, the pseudohypoxia-driven tumorigenesis is unique and empowers us to deeper understand events and processes that lead to tumor formation – important for both diagnosis and treatment not only of these particular tumors, but very possibly many others. Syndromatic classification of genetically determined tumors had dynamic history and, in addition division by signaling pathways could also be classified historically as follows:

Table 1 PHEO/PGL with hypoxic transcriptional signature

Gene	*Age*	*Tumor*	*Biochemistry*	*Malignancy*	*Additional features*
VHL	30s	PHEO	NE or NE/DA	Low	CCRC, retinal hemangiomas, CNS hemangioblastomas
SDHA	27–77	HNPGL, sPGL, PHEO	Not clear	Not clear	CCRC, GIST, pituitary adenoma
SDHB	30s	sPGL	NE or DA	High	CCRC, GIST, pituitary adenoma, neuroblastoma, pulmonary chondroma
SDHC	40s	HNPGL	NE or NS	Low	CCRC
SDHD	30s	HNPGL or sPGL	DA or NS	Low	CCRC, GIST, pituitary adenoma, pulmonary chondroma
SDHAF2	30s	HNPGL	Not clear	Low	
HIF2α	17–35	HNPGL	NE	Low	Polycythemia, somatostatinoma

Table 2 PHEO/PGL with kinase receptor transcriptional signature

Gene	*Age*	*TumorBiochemistry*	*Malignancy*	*Additional features*
RET	30s	PHEO E or E/NE	Low	MTC, HPT, marphanoid habitus, mucosal ganglioneuromas
NF1	40s	PHEO E or E/NE	Low	Café-au-lait spots, neurofibromas, MTC, carcinoid, neural sheath tumors
TMEM127	40s	PHEO E	Low	
MAX	30s	PHEO E/NE	Moderate	
HRAS	31–76	PHEO E or NE	Low	

Abbreviations: CCRC, Clear cell renal carcinoma; E, epinephrine; NE, norepinephrine; DA, Dopamine; GIST, Gastrointestinal stromal tumor; NS, nonsecretory; MTC, medullary thyroid cancer; HPT, hyperparathyroidism.

"The good old trio"

von Hippel–Lindau syndrome

Described over 100 years ago, the type 2 of this syndrome associates with predisposition to several tumors, apart from pheochromocytomas: hemangioblastomas, retinal angiomas, clear cell renal carcinomas, renal and pancreatic cysts, pancreatic tumors and epididymal cystadenomas. The mechanism of tumorigenesis is probably one of the best understood in current oncology and is carried through interaction of the von Hippel-Lindau (VHL) protein and hypoxia-inducible factor (HIF). In normoxic conditions, HIF is hydroxylated, which opens a binding site for VHL protein. The last possesses an E3 ubiquitin ligase activity, thus "marking" HIF for ubiquitination/degradation. In physiologic/pathologic hypoxia, HIF1α overexpression induces angiogenesis to promoted increased glucose supply. With mutated and nonfunctional VHL protein, the overexpression of HIF1α is accompanied by significant shift towards expression of HIF2α, which adds anti-apoptotic effect and increased cellular proliferation through upregulated cyclin D1, which results in tumorigenesis. Undegraded HIF1α forms heterodimer with HIF1β, becoming a transcription factor able of direct activation of VEGF and erythropoietin production and interaction with mTOR. Pheochromocytoma in VHL is usually adrenal, frequently bilateral and mostly benign. Because of low expression of phenylethanolamine N-methyltransferase (PMNT) in VHL pheochromocytomas, secretory profile consists almost exclusively of norepinephrine.

Multiple endocrine neoplasia type 2

Multiple Endocrine Neoplasia type 2 (MEN2) is an autosomal dominant syndrome related to the mutation in *RET* proto-oncogene. The last encodes for tyrosine kinase receptor that regulates cell proliferation and apoptosis. MEN2 is characterized by combination of medullary thyroid cancer in most of the patients, risk of pheochromocytoma later in the course of the disease in about half of the patients and either hyperparathyroidism (MEN2A) or mucosal ganglioneuromas and marphanoid habitus (MEN2B). Pheochromocytomas in this syndrome are also adrenal, often bilateral, rarely malignant (unless developed in childhood) and display epinephric secretory profile.

von Recklinghausen's disease (Neurofibromatosis type 1)

von Recklinghausen's disease represents an autosomal dominant disorder related to mutation in the neurofibromatosis type 1 tumor suppressor gene, which controls cellular growth and differentiation through inhibition of RAS signaling cascade and mTOR kinase pathway. Pheochromocytomas are rare in these patients, who usually display following findings: café-au-lait spots, cutaneous or plexiform neurofibromas, iris hamartomas, optic nerve gliomas, and extensive freckling. When found, pheochromocytomas are of epinephric secretory profile, adrenal and mostly benign.

The paraganglioma syndromes

The history of paraganglioma syndromes shows that even in very recent history new clinical syndromes are described and uncover very exciting pathological processes. It was in early 1970's when first association between high altitude and carotid body tumors was described. Later four distinct clinical PHEO/PGL syndromes strongly believed to be hereditary were described and awaited their genetic conformation. In meantime, pathophysiologic background of these conditions started to emerge, based on the decreased activity of the succinate dehydrogenase (SDH) in some of these tumors. Finally, genetic cause of these syndromes was discovered, starting with the D subunit of the complex (SDHD), further through all subunits. Although uncovering actual complex mutations remains to be extraordinary achievement in the history of hereditary PHEO/PGL, it is the physiologic phenomenon that makes this discovery many times more exciting. SDH is an enzyme complex, located on the inner mitochondrial membrane. This complex plays dual role – as complex II of the mitochondrial electron transport chain and as an enzyme that oxidases succinate to fumarate within citric acid cycle. The complex is assembled from 4 independent units – SDHA, SDHB, SDHC and SDHD – each encoded by respective gene. Mutation of either, as well as associated SDHAF2 – accessory protein that flavinates SDHA and thus maintains its proper functional activity, results accumulation of succinate and reactive oxygen free radicals, which stabilize HIFα (see above).

Type 1 (SDHD)

Tumors with SDHD mutations associate with HNPGL, often multifocal, bilateral and recurrent. On the other hand, the rate of malignancy is low. While most of tumors are nonsecretory, these that do secrete show dopaminergic and norepinephric secretory prolife.

Type 2 (SDHAF2)

Patients with SDHAF2 mutation-associated disease usually develop benign multiple nonsecretory HNPGL.

Type 3 (SDHC)

These mutations predispose to formation of HNPGL, usually nonsecretory and, while nonmalignant, can often be multifocal.

Type 4 (SDHB)

Best studied, this mutation associates with mostly sPGL, although PHEO and HNPGL also occur. Secretory profile represents dopamine and norepinephrine, while nonsecreting tumors also occur. This condition occurs in younger patients and has significantly increased rate of malignancy.

SDHA

The last of the SDH complex mutations causing PHEO/PGL to be discovered, this association is very rare – only half dozen patients have been described till now, show variable penetrance, appears as both PHEO and PGL, showing mostly norepinephric or nonsecretory profile.

The newbies

Several additional gene mutations-associated PHEO/PGL have been recently discovered, thus further expanding out understanding of the tumor formation processes.

Transmembrane protein (TMEM) 127

Patient with TMEM127 mutation-related disease develop adrenal epinephrine secreting PHEO, although several cases of extra-adrenal tumors were also described. The disease is frequently bilateral and benign. TMEM127 protein was suggested to play role in intracellular protein trafficking, as well as associates with components of mTOR signaling cascade.

Myc-associated factor X (MAX)

Pheochromocytomas in patients with MAX gene mutation are often bilateral, at times metastatic and show both epinephric and norepinephric secretory profile. Several sPGL were also described. The protein is involved in the regulation of cellular proliferation, differentiation and apoptosis.

PHD2

There is a very rare association between mutation in the PHD2 gene and PHEO/PGL. The prolyl-hydroxylases domain (PHD) proteins hydroxylate propyl residues at the oxygen dependent degradation domain of HIFα, thus allowing binding of the VHL protein and further degradation of HIFα. Mutation of PHD2 associates with overproduction of erythropoietin that leads to Chuvash polycythemia. It was also described in one patient with polycythemia and recurrent PGL.

H-RAS

There were only few patients described with H-RAS mutation-related PHEO/PHL – secretory profile is epinephric. The protein represents part of the same signaling pathway, affected in patients with MEN2 and NF1 mutations.

HIF2α

Gain-of-function mutations of HIF2α were recently described to associate with PHEO/PGL with or without polycythemia and somatostatinomas, showing norepinephric secretory profile. In context of this mutation, the Pacak-Zhuang syndrome includes multiple PHEO/PGL and duodenal somatostatinomas associated with polycythemia in females only.

Carney triad and diad (Carney–Stratakis syndrome)

Patients are found to have PHEO/PGL with (triad) or without (diad) pulmonary chondromas, and while in triad no single gene was found to be responsible for the disease, in the diad majority shows mutations in one of the SDHx genes, suggesting complex genetic cause of these clinical syndromes.

Others

Mutations of isocitrate dehydrogenase (ID) and fumarate hydratase (FH), which like SDH complex, are part of the citric acid cycle were found to associate with rear cases of PHEO/PGL, in addition to glioblastoma multiforme (ID) and renal cell cancer (FH). Mutation of KIF1Bβ was found in rare cases of PGEO and neuroblastomas, possibly through its' function of apoptosis regulation.

Genetic testing

Genetic testing for familial PHEO/PGL is indicated in all cases of disease that presents in young patients, patients with family history suggestive of PHEO/PGL or components of combined syndromes, patients with multiple or metastatic disease. Currently, mutations in *SDHx* (subunits A, B, C, D), *SDHAF2*, *MAX*, *RET*, *TMEM127* and *VHL* are available as a combined panel, providing with high 98.7% sensitivity for detecting mutations associated with PHEO/PGL.

Clinical Presentation

Clinical presentation of PHEO/PGL relates to several different processes – acute/paroxysmal hypercatecholaminemia, chronic hypercatecholaminemia with end organ effects, existence of co-secretory substances, existence of other syndromic features and local effects. There is significant genotype-biochemical phenotype correlation in cases of mutation-related disease (discussed above). There are also significant differences in clinical presentations related to the unique secretory profile of the tumor. Episodic secretion of catecholamines, especially with predominance of norepinephrine, will associate with the "classic PHEO attack" – paleness, tachycardia, paroxysmal hypertension, anxiety, palpitations and post-attack dermal hyperemia, diaphoresis and severe fatigue. About a third of cases present with persistent hypertension and mask well under the rest of the idiopathic hypertension patients' pool. Patients with epinephric and dopamine-secreting profiles, on the other hand, present with hypotension and orthostatic complains, resulted from peripheral vasodilatatory effect of these compounds. Long standing hypertension will afterall result in loss of vascular elasticity and cardiac hypertrophy. Of particular importance are rare cases of PHEO crises, resulting in severe malignant hypertension, strokes, acute heart attacks, arrhythmias and multiorgan failure. Some of these happen acutely during significant stress events, like unrelated surgeries in relatively healthy individuals. PHEO/PGL earned its famous nickname of the "Great Masquerader" also for range of nonspecific symptoms like leukocytosis, hypercalcemia, hyperglycemia, constipation, megacolon, hematuria, nausea and vomiting etc. Additional signs and symptoms could also relate to the co-secretory substances like ACTH, PTHrP, vasopressin, calcitonin etc.

Diagnostic Approach

The mainstay of the diagnostic approach changed significantly in means, but remains same in concept: a]. as a rare disease, PHEO/PGL has to be suspected – based on symptoms or signs, family history or clinical findings, b]. clinical suspicion has to be proven biochemically, supporting the existence of PHEO/PGL, c]. tumor/tumors are to be localized. The sequence of events has significantly changed over recent decades – it became "the rule out" rather than "rule in" diagnoses, because of majority workups carried for imaging or surgical incidentalomas, suggestive of disease because of location or histologic findings.

Biochemistry

Demonstration of biochemical hypercatecholaminemia represents biochemical proof of existing PHEO/PGL. Although still correct, this statement had been significantly modified over recent decades. Catecholamines – epinephrine, norepinephrine and dopamine are secreted episodically and show relatively short half-life. Majority of norepinephrine is synthesized in sympathetic neurons and in case of significant stress acute systemic spill-over can reach significant values. Adrenal medulla, on the other hand, possesses significantly higher amount of phenylethanolamine-N-methyltransferase (**Fig. 1**), which converts norepinephrine to epinephrine. One of recent changes in concept relies on the fact that less differentiated and more malignant tumors also express less "advanced" catecholamine-producing enzymatic machinery and drop synthesis at earlier stages, ending up secreting precursors, including dopamine, rather than more advanced end products – nor- and epinephrine. This finding can be used not only as diagnostic but also as prognostic sign. Another important concept is acceptance of the fact that HNPGL are

norepinephrine analogue has high affinity to the norepinephrine transporter, which allows intracellular transfer and accumulation of ^{123}I- or ^{131}I- tracer within catecholamine-producing tumor. Positron emission tomography (PET) technology uses both standard glucose-based tracer, as well as PHEO/PGL-specific catecholamine-based tracers (DOPA and dopamine). The fact that some PHEO/PGL express somatostatin receptors is used in somatostatin receptor imaging – octreoscan.

Fig. 1 Catecholamine synthesis, metabolism and secretion in different PHEO/PGL syndromes. Short arrows define active secretion or spill-over of catecholamines and their metabolites from chromaffin cell of PHEO/PGL into systemic circulation. Abbreviations: DOPA, dihydroxyphenylalanine; DA, dopamine; NE, norepinephrine; E, epinephrine; MTY, methoxythyramine; NMN, normetanephrine; MN, metanephrine; TH, tyrosine hydroxylase; LAAD, aromatic *L*-amino acid decarboxylase; DBH, dopamine β-hydroxylase; PMNT, phenylethanolamine *N*-methyltransferase; COMT, catechol-*O*-methyltransferase. For abbreviations of clinical syndromes please see text.

Management

Definitive therapy of PHEO/PGL remains to be surgical resection. Medical therapy plays crucial role is stabilization of acutely decompensated or significantly symptomatic patient in the initial phase of management, preoperative preparation of the patient to assure uneventful surgery, symptomatic treatment of recurrent or inoperable disease. The mainstay consists of initial α-adrenergic blockade with additional β-blockade as needed. Phenoxybenzamine – is an irreversible long acting oral α-adrenergic antagonist and is still widely used because of efficacy and extended safety profile. It does cause longer postoperative hypotension, when compared with shorter acting selective α_1-adrenergic antagonist like doxazosin, prazosin and terazosin. β-blockade is initiated after achieving full α-adrenergic blockade and is used to prevent excessive tachycardia. Combined α- and β-adrenergic blockers – labetalol and carvedilol could have unfavorable ration between α- and β- blocking components and should be used with caution or after completed α-adrenergic blockade. Methyrosine "pre-occupies" tyrosine hydroxylase with production of inactive L-catecholamines and is used as additional therapy in cases of severe hypercatecholaminemia. Different groups have successfully used calcium channel blockers, especially nicardipine. In cases of hypertensive crises or during surgery, IV therapy is carried out with either sodium nitroprusside or phentolamine. After surgery, patients are followed up for disease recurrence, especially in cases of familial syndromes prone to recurrent or malignant disease (SDHB).

Summary

Our knowledge and understanding of PHEO/PGL had significantly changed in recent decades. While the disease is famously called "The Great Masquerader" for its' varying and at times diagnostically challenging clinical appearances, recent changes in our understanding of pathophysiology and genetics could suggest at least some modification in the nickname, maybe between "The Metamorphic Masquerader" or just "The Shapeshifter".

Introduction

The terms pheochromocytoma (PHEO) and paraganglioma (PGL) refer to a broad spectrum of clinical conditions that have as their common denominator the origin from a pathological (neoplastic) proliferation of neural crest cells.

Clinical presentation and evolution of the disease is extremely variable in relation to several factors, such as the secretive functional characteristics of the cells involved, the primitive site of neoplastic proliferation and the tendency to form remote metastases, the presence of a genetic predisposition that may affect the expression of particular phenotypes.

PHEO/PGL is sometimes a complex diagnostic and therapeutic challenge, but the main difficulty is probably the fact that it is a rare condition that is met on very few occasions by most physicians and therefore may remain unrecognized. A diagnostic algorithm is outlined iGn **Fig. 1**.

A good knowledge of the polymorphic expressions of this disease should result in clinical suspicion, which can be confirmed or excluded reliably in most cases. Similarly, the therapeutic management of PHEO/PGL is well established in the overwhelming majority of cases, provided it is entrusted to experienced medical staff.

Clinical Presentation

The presence of a PHEO/PGL can be suspected in different clinical settings.

Signs and Symptoms Related to Catecholamine Excess

The clinical picture of PHEO/PGL is particularly variable and mainly reflects the effects of excessive adrenaline and noradrenaline production (see Manger, 2006). The amount and mode of release of these hormones by the tumor is therefore of paramount importance. In some circumstances a PHEO/PGL is asymptomatic, that is, its manifestations are modest and scarcely perceived by the patient; in fact, not a few PHEO/PGLs are detected incidentally or at the autopsy table. In other cases, presentation may be dramatic, with major complications such as acute myocardial infarction, stroke, fatal arrhythmias or acute aortic dissection.

More than half of patients with PHEO/PGL experience paroxysmal crises. Their frequency varies from occasional to multiple times and generally increases with tumor progression. Sometimes there are identifiable trigger factors, which may include (i) the Valsalva maneuver or any movement that exerts mechanical compression on the tumor mass; (ii) the ingestion of foods containing tyramine (brown cheese, some red wines) or synephrine (orange juice); (iii) the intake of certain drugs (opiates, tricyclic antidepressants, ACTH or steroids, …).

The duration of the crisis varies from a few minutes to several hours and can increase over time. Paroxysmal symptoms are variable, but the clinical picture is fairly constant in the same patient.

In most cases the crisis is reported by tachycardia, followed by headache, sweating, anxiety, tremors, nausea, vomiting, abdominal or thoracic pain, paresthesia, asthenia, dyspnea, in various association. The intensity of the symptoms may increase with the progression of the disease.

Hypertension can manifest itself with a real crisis (~25%) or as a crisis overlapping with a stable hypertension (~25%). Body temperature may slightly increase during the crisis and the patient may experience arrhythmias and/or electrocardiographic alterations.

In patients who do not experience a crisis, or in intercritical phases, patients may chronically manifest the same type of symptoms. Stable hypertension is present in more than half of the patients, often accompanied by significant pressure variability and orthostatic hypotension. Symptoms and signs related to increased metabolic activity (heat intolerance, weight loss, hyperglycemia) are sometimes present. The production of different peptides may be responsible for atypical clinical manifestations (hypercalcemia, Cushing syndrome, …).

Local Effect of Tumor Mass

Occasionally PHEO/PGL may present a palpable abdominal mass, whose compression can trigger a crisis. On the other hand, the presence of a painless mass in the upper part of the neck, below the angle of the jaw, is the typical presentation of carotid body PGLs, whereas pulsatile tinnitus and conductive hearing loss are features of jugulo-tympanic PGLs. In addition, head and neck

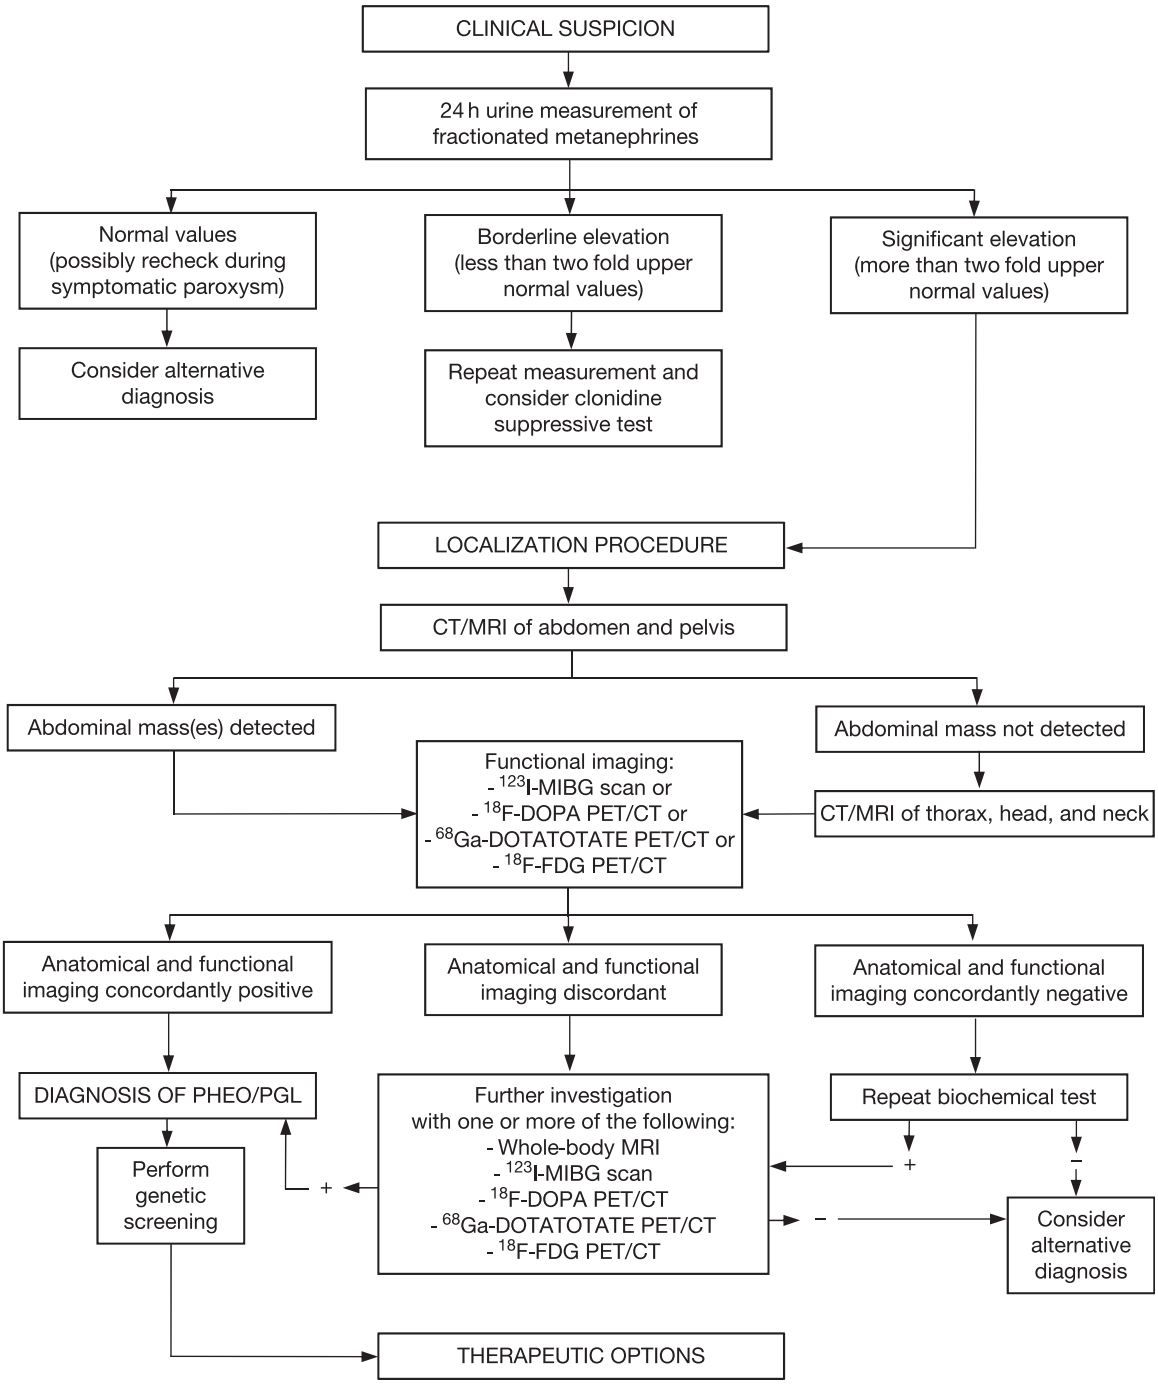

Fig. 1 Diagnostic algorithm of PHEO/PGL.

PGLs may cause several signs and symptoms related to the compression of lower cranial nerves VII, IX, X, XI, and XII (facial nerve paralysis, dizziness, hoarseness, Horner syndrome, dysphagia).

Incidentaloma

An adrenal mass can be incidentally detected when performing imaging techniques [ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography with 18F-2-deoxy-D-glucose (FDG-PET)] not specifically addressed to detect adrenal disease. The prevalence of adrenal incidentalomas varies among studies, ranging from less than 1% up to 4% of abdominal CT scans, and in 1.5%–14% of the cases these masses proved to be PHEOs. More rarely, PGL can be diagnosed as incidentally detected extraadrenal mass.

Associated Syndromic Conditions

A few genetically determined syndromes (including multiple endocrine neoplasia type 2, neurofibromatosis type 1, von Hippel-Lindau, Carney Stratakis dyad) may include PHEO/PGLs, and the presence of clinical features suggestive of these syndromes (Table 1) must prompt the search for the presence of such tumors.

Asymptomatic Carriers of Genetic Predisposition to PHEO/PGL

Many genes have been associated to the pathogenesis of PHEO/PGL (see "Genetic predisposition") and the prevalence of pathogenetic germline mutations among PHEO/PGL patients exceeds 30%. Such a prevalence justifies a systematic genetic screening of *all* patients (irrespective of any evidence of positive family history and/or syndromic presentation), which in turn leads to the detection of a number of relatives carrying the same mutation identified in the proband. Although the penetrance of genetic susceptibility may be rather low, these subjects must undergo clinical evaluation for early detection of PHEO/PGL and possibly associated syndromic lesions.

Biochemical Screening

After the clinical suspicion was formed, diagnosis of PHEO/PGL relies on measurement of urinary and plasma fractionated metanephrines (*o*-methylated metabolites of catecholamines) and catecholamines. The optimal use of these biochemical tests is still matter of debate; however, measurement of urinary fractionated metanephrines in a 24-h urine collection seems to be a

Table 1 Clinical conditions possibly associated to syndromic PHEO/PGLs

Endolymphatic sac tumors of the middle ear	von Hippel–Lindau syndrome (VHL)

reasonable compromise between sensitivity and specificity, is less technical demanding and more widely available than corresponding plasma assay. Plasma fractionated metanephrines are reported to achieve the highest sensitivity, at the expense of slightly reduced specificity; this test is probably appropriate when ruling out PHEO/PGL is the main goal (i.e., subjects with familial predisposition), but its systematic adoption may cause unnecessary recourse to imaging techniques due to false positive findings. To improve specificity, it is necessary to withdraw any pharmacological treatment potentially interfering with biochemical assay (see Lenders *et al.*, 2014 for details).

In case of metanephrines level only slightly elevated, the assay can be repeated after administration of a central inhibitor of sympathetic output, such as clonidine (at our Institution we repeat a 24 h urine collection 48–72 h after the application of a 5 mg clonidine transdermal patch) before proceeding with subsequent diagnostic steps. In case of intermittent symptoms (and catecholamine secretion) urine sampling during or immediately after a crisis may be of some help.

Other tests, such as plasma and urinary fractionated catecholamines, urinary vanillylmandelic acid, plasma chromogranin A, or neuropeptide Y, have less diagnostic accuracy than plasma or urinary fractionated metanephrines.

Imaging Techniques

Imaging techniques for locating the tumor are primarily CT or MRI of the abdomen and pelvis. Overall, they have similar sensitivity in identifying adrenal PHEO; CT has superior spatial resolution but MRI could better identify true pheochromocytomas (hyperintensity on T2 weighted image) and is probably superior in the localization of head and neck PGL. The specificity of the two techniques is similar, but not very high (50%–70%) for the large number of non-catecholaminogenic incidentalomas.

Functional imaging techniques have greatly improved the diagnostic accuracy of PHEO/PGL (see Crona *et al.*, 2017; Lenders *et al.*, 2014). Beside the time-honored scintigraphy with ^{131}I- or ^{123}I-metaiodobenzylguanidine (MIBG), newer PET/CT techniques have shown excellent results in the localization of these tumors. Among them, 18F-dihydroxyphenylalanine (^{18}F-DOPA) positron emission tomography/computed tomography (PET/CT) and ^{68}Ga-DOTATATE/DOTATOC/DOTANOC PET/CT. Current evidence suggests that ^{68}Ga-DOTATATE PET/CT provides excellent and precise diagnostic localization of PGLs but may be inferior to ^{18}F-FDOPA PET/CT in the detection PHEOs. ^{18}F-FDG PET/CT should be used for assessment of metastatic PGLs.

Therapeutic Approach

Once diagnosed with pheochromocytoma, there is an indication of its surgical removal, except for special circumstances that make it necessary to postpone, or contraindicate, the intervention (recent acute coronary syndrome, third trimester pregnancy, concomitant morbid conditions, non-resectable neoplasms, and/or metastatic).

In any case, medical treatment should be initiated immediately to counteract the deleterious effects of excessive circulating catecholamines, including the restoration of adequate volumes (reduced by chronic vasoconstriction) (see Lenders *et al.*, 2014).

The alpha-blocker phenoxybenzamine is still considered a drug of choice by many experts but not available in some countries. However, alpha1-selective blockers (prazosin, doxazosin, and the like) are likely to be equally effective.

Beta-blockers, preferably beta1-selective, may be associated for tachycardia or arrhythmia control, but only with the presence of an appropriate alpha-block (to prevent possible hypertensive crisis of vasodilating effect mediated by beta2-adrenergic).

If necessary, other drugs (e.g., calcium antagonists) may be added to control the pressure values. Medical treatment should be continued for at least 2 weeks in order to minimize the risk associated with anesthesia and surgery but can be maintained indefinitely according to clinical indications.

The laparoscopic technique, associated with lesser perioperative pain, reduced hospitalization, and minor complications, is considered surgical treatment of choice, except in the case of multiple, large, or malignant pheochromocytomas.

Intraoperative treatment of hypertensive crisis, arrhythmias or post-tumor removal hypotension requires an experienced anesthesiologist team. Symptoms disappear after tumor removal; in particular, blood pressure normalize in most patients and the persistence of hypertension could be interpreted as expression of associated primary hypertension or, alternatively, as incomplete removal of tumor mass or the presence of other unrecognized localizations.

Postoperative metanephrines control should be performed a few weeks after intervention; in addition, considering the relatively high percentage of recurrences even after a few years (about 15%), an indefinite follow-up must be initiated, which involves annual urinary or plasma metanephrines measurement. There is no general consensus on indications and timing of imaging surveillance (see Crona *et al.*, 2017; Lenders *et al.*, 2014): in most patients it is not needed unless urinary or plasma metanephrines become elevated. Imaging or other targeted follow-up investigations may be indicated in the case of PGL patients who never presented catecholamine/metanephrine elevation prior to surgical intervention and of potentially syndromic patients.

Malignant PHEO

The percentage of malignant pheochromocytomas, characterized by the presence of local invasion of the tissues surrounding the lesion or the presence of metastases (mainly bones, liver, lymph nodes, and lungs) ranges between 5% and 10% and in these cases

the survival at 5 years falls from 95% to less than 50%. The use of debulking surgery in order to improve survival and/or reduce symptoms is recommended by many experts but with little supportive evidence.

Medical treatment of malignant PHEO/PGLs includes adrenergic receptors blockade, the administration of chemotherapeutic agents (a scheme comprising cyclophosphamide, vincristine, and dacarbazine has shown only partial responses, at best) and the use of ^{131}I-MIBG therapeutic doses (up to 800 mCi and beyond) in the case that the tumor maintains the absorption capacity of such radioligand. According to some preliminary data, in malignant PHEO/PGLs that (hyper)express somatostatin receptors, the administration of somatostatin analogs or a radiotherapeutic approach based on peptide receptor radionuclide therapy (PRRT) with 177Lu-DOTATATE may result in improved survival.

Tyrosine kinase inhibitors (sunitinib, sorafenib, imatinib), VEGF (thalidomide) or mTOR (everolimus) inhibitors are under active study in controlled trials. It should be considered that improving knowledge of tumor driving germline or somatic mutations in PHEO/PGL (see below) might boost targeted therapeutic approach.

In any case, the clinician should be aware that all these treatments are at best palliative and their use should be considered with due attention to patient's quality of life.

Genetic Predisposition

Mutations in more than 25 genes have been associated to the pathogenesis of PHEO/PGL and at least 15 of them have been found as germline mutations underlying familial and/or inheritable conditions (see Crona *et al.*, 2017; NGS in PPGL (NGSnPPGL) Study Group *et al.*, 2017 for details). Many recent studies have shown a total prevalence of pathogenetic germline mutations in PHEO/PGL patients above 30%.

Accordingly, many experts suggest that a systematic screening of genetic predisposition due to germline mutations is indicated for several reasons in all PHEO/PGL patients, independent of positive familial or syndromic features. Beside of the very high prevalence (probably the highest found in any type of human tumor), the identification (or exclusion) of mutations of genes responsible for syndrome forms can lead to the diagnosis of concomitant morbid conditions otherwise unplanned (i.e., avoid unnecessary monitoring of the time of the same). It should also be considered that some genetically determined forms of pheochromocytoma, and in particular those associated with mutations in the SDHB gene, present a high risk of recurrence and/or malignancy, which should be carefully considered at the time of diagnosis or during the subsequent follow-up. Last but not least, the identification of a genetic predisposition in the patient should be followed by a thorough and extensive search of the same mutation in first degree relatives, equally exposed to the risk of developing the disease.

The genetic heterogeneity of the disease makes impractical the adoption of traditional technologies in the search of pathogenetic mutations; accordingly, the implementation of targeted next generation sequencing technology has become the standard for genetic screening of PHEO/PGL (see NGS in PPGL (NGSnPPGL) Study Group *et al.*, 2017).

Glossary

Antiangiogenic therapy Drugs that stop tumors developing their own blood vassels.
Catecholamines Hormones produced by the chromaffin cells of the sympathetic nervous system.
Computerized tomography X-ray instrumental diagnostic procedure in which a three-dimensional image of body structures is constructed by computer from a series of plane-sectional images made along an axis.
Debulking surgery Surgery reduction of as much of the tumor's volume as possible.
Laparoscopic surgery Surgical technique that provides the assistance of a video camera and several thin instruments placed in the abdominal cavity through small incisions in the abdominal wall.
Laparotomic surgery Surgical procedure involving a large incision through the abdominal wall to gain access into the abdominal cavity.
Magnetic resonance imaging Instrumental diagnostic procedure which employs radio-frequency waves and intense magnetic fields to excite atoms in the body under evaluation.
Malignant Presence of metastases (cromaffin cells in tissues where are usually absent).
Metanephrines Metabolites of cathecholamines created by action of catechol-*O*-methyl transferase.
Next generation sequencing (NGS) Platforms performing sequencing of millions of small fragments of DNA in parallel.
Oncoproteins Proteins encoded by oncogenes which if mutated, play a role in the tumors development.
Pheochromocytoma Sympathetic tumor arising from the adrenal medulla.
Paraganglioma Parasympatetic or sympathetic tumors localized out side the adrenal medulla.
PASS score Pheochromocytoma of the Adrenal Gland Scaled Score. Score used to identify tumors with high (>6) or low (<4) risk of aggressive behavior. Not yet used in the clinical practice.
Radiometabolic therapy Administration of a radionuclide whose radiation will destroy cells that have selectively accumulated the labeled substance.
Radiotherapy External treatment of neoplastic disease by using X-rays or gamma-rays to impair the proliferation of malignant cells by decreasing the rate of mitosis or impairing DNA synthesis.
Scintigraphy Nuclear medicine diagnostic procedure consisting of the administration of a radionuclide with affinity for tissue of interest, followed by recording the distribution of the radioactivity with a stationary or scanning external scintillation camera.
Vanylmandelic acid End-stage metabolite of catecholamines created by action of catechol-*O*-methyl transferase and monoamine oxidase.

 doi:10.1016/B978-0-12-801238-3.65796-3

Introduction

Pheochromocytomas (PCCs) and paragangliomas (PGLs) are rare tumors of neuroendocrine origin, deriving from neural crest cells. They are located in sympathetic and parasympathetic paraganglia. Mostly of these tumors (about 80%–85%) arise in the adrenal medulla and are named pheochromocytomas (PCCs), whereas 15%–20% are located in extra-adrenal chromaffin tissue in the abdomen and the thorax and are referred to as secreting paragangliomas (sPGLs). PCCs and sPGLs are catecholamine-producing tumors. At variance with these latter, PGLs in the head and neck region, are parasympathetic in origin, do not usually release catecholamines and are named Head and Neck PGLs (HNPGLs) (Lenders *et al.*, 2005).

PCCs and PGLs are mostly sporadic, but recent data have demonstrated a high prevalence of hereditary forms (approximately 35%) (Pacak *et al.*, 2007). Hereditary forms are more frequent in young patients whereas sporadic forms are usually diagnosed in patients older than 40–50 years.

Malignant PCCs/PGLs are extremely rare. Their prevalence, as estimated in USA in 2002, is 93 cases per 400 million persons (Welander *et al.*, 2011). At present, no reliable marker of malignancy has been found. Malignancy is diagnosed by the presence of metastases, tumor spread in tissues where chromaffin cells are normally absent such as lymph nodes, liver, lungs, and bones.

The percentage of malignancy varies among the different tumors: it is $<5\%$ in HNPGLs, about 10% in PCCs and 30% or more in sPGLs, depending also on the genetic background (see below) (Brown *et al.*, 1999; Chrisoulidou *et al.*, 2007; Lee *et al.*, 2002).

Genetic Aspects

Until 2000, only 10% of PGLs were considered familial. They were part of syndromic diseases such as the von Hippel–Lindau disease (VHL), due to germ line mutations in tumor-suppressor gene *VHL* (Latif *et al.*, 1993; Walther *et al.*, 1999), multiple endocrine neoplasia type 2 (MEN2) caused by mutations of the proto-oncogene *RET* (Eng *et al.*, 1994a,b, 1996; Neumann *et al.* 1993, 1994) and neurofibromatosis type 1 (NF1), due to mutations in the tumor-suppressor gene *NF1* (White *et al.*, 1991).

More recently, the discovery of new susceptibility genes has increased the frequency of the familial forms to about 35% (Neumann *et al.*, 2002). These genes include those encoding the four subunits (A, B, C, D) of the succinate dehydrogenase (SDH) (Astuti *et al.*, 2001; Baysal *et al.*, 2000; Burnichon *et al.*, 2010; Niemann and Muller, 2000), the *SDHAF2* gene, which is responsible for the flavination of the SDHA subunit (Hao *et al.*, 2009), the *TMEM127* (Qin *et al.*, 2010) and *MAX* (Comino-Méndez *et al.*, 2011) genes, both mainly related to bilateral PCCs and the more recently discovered genes such as the one encoding fumarate hydratase (FH), the gene encoding the Beta form of the Kinesin Family Member1B (KIF1Bβ), that encoding the prolyl hydroxylase domain 2 (PHD2) and that encoding the malate dehydrogenase 2 (MDH2). Germ line mutations in *SDHA*, *SDHB*, *SDHC*, *SDHD*, and *SDHAF2* genes are responsible for the occurrence of syndromes named PGL5, PGL4, PGL3, PGL1, and PGL2, respectively; these syndromes are characterized by the occurrence of both sympathetic (PCC/sPGL) and parasympathetic (HNPGL) tumors (Mannelli *et al.*, 2009) but also, although much more rarely, by other solid neoplasms as gastrointestinal stromal tumors (GIST), renal cell carcinomas and pituitary adenomas (Mannelli *et al.*, 2018). Notably, *SDHB* mutations are generally associated with higher morbidity and mortality than mutations in the other SDHx genes (Gimenez-Roqueplo *et al.*, 2003). A recent meta-analysis of some studies involving *SDHB* mutated patients has highlighted that 31% of their tumors were malignant (Welander *et al.*, 2011).

Finally, an additional 15% of paragangliomas have been demonstrated to harbor somatic mutations in some of the above mentioned susceptibility genes and in other genes like those encoding the isocitrate dehydrogenase 1 (IDH1), the hypoxia inducible factor 2 alpha (HIF2α), the H-RAS proto-oncogene (HRAS) (Dahia, 2017).

Extensive genetic screening has divided sporadic as well as hereditary PGLs in two main clusters associated to different signaling pathways (Dahia *et al.*, 2005): cluster 1 contains *VHL*-, *SDHx*-, and FH-mutated tumors and is associated with angiogenesis, hypoxia, reduced oxidative response (Favier *et al.*, 2009) and aberrant VEGF signaling, leading to abnormal hypoxia inducible factor (HIF) activation and overexpression of angiogenic factors. Cluster 1 tumors also express a hypermethylated profile, while cluster 2 contains all *RET*- and *NF1*-mutated tumors and is associated with abnormal activation of kinase signaling pathways, such as RAS/RAF/MAPK and PI3K/AKT/mTOR (Califano *et al.*, 2000; Johannessen *et al.*, 2005, 2008; Martin *et al.*, 1990) leading to abnormal cell growth and reduced apoptosis; also *TMEM127* (Qin *et al.*, 2010) and *MAX* (Comino-Méndez *et al.*, 2011) mutated tumors have been associated to activation of mTOR signaling pathway. These data have highlighted the molecular defects in PGLs and might be of help in the development of new effective molecular-targeted therapies.

The genotype/phenotype correlation has been suggested in the recent past to facilitating a genetic testing algorithm based on clinical features as a guide for a more quick and cost-effective genetic screening (Mannelli *et al.*, 2009). More recently, the introduction of the next generation sequencing (NGS) which permits the simultaneous screening of all the susceptibility genes, has made the use of the algorithm obsolete. Nevertheless, the genotype/phenotype correlation is still important as one of the tools permitting the interpretation of the pathogenic significance of the many variants revealed by the NGS (Toledo *et al.*, 2017).

Clinical Aspects

PGLs are often referred to as the great mimics because of their extremely variable clinical picture. Such variability is strongly related to the biology of these tumors which can express different catecholamine biosynthetic enzymes and may release other different

vasoactive substances, such as atrial natriuretic peptide, neuropeptide Y, adrenomedullin, or ACTH (Bravo, 1994). Moreover, some clinical manifestations may be related to mass effect or to the involvement of other organs in the syndromic forms.

Generally, malignant PGLs have a clinical presentation similar to benign tumors. Hypertension is the most common feature: it often has a paroxysmal nature but it may also be continuous or intermittent. Hypertensive crises present with headache, palpitations, and diaphoresis, but other signs or symptoms such as dyspnea, nausea, weakness, arrhythmias or mood disturbances are reported. Moreover metabolic effects such as glucose intolerance or diabetes may be present (Lenders *et al.*, 2005). Sometimes malignant PGLs may have a subclinical picture: in fact, due to their less-differentiated nature, they generally secrete noradrenaline and/or dopamine determining milder cardiovascular manifestations (Mannelli *et al.*, 2012). However, at variance with the benign forms, malignant PGLs may cause "systemic" symptoms such as anorexia, fatigue and weight loss or manifestation related to metastatic spread of the disease (i.e., pain in bone metastasis). The most commons metastatic sites for malignant PGLs are local lymph node, bones, liver, and lung.

The most frequent causes of morbidity and mortality in patients with PGLs, are represented by cardiovascular complications such as sudden death, myocardial infarction, heart failure, and stroke. Patients affected by malignant PGLs with an indolent course and progressive increase of circulating noradrenaline suffer from severe constipation which sometimes turns to be lethal (Thosani *et al.*, 2015).

HNPGLs are usually clinically silent. Only when they reach a large volume they can determine symptoms related to mass effect and compression of the adjacent structures. Large HNPGL appear as a palpable neck mass and may cause, dysphagia, tinnitus, or cranial nerve palsies. (Erickson *et al.*, 2001).

Biochemical Diagnosis

The biochemical diagnosis of PGL is based on laboratory assays demonstrating an increase of catecholamines or their metabolites in plasma or urine. The recommended screening test is the measurement of plasma free-metanephrines or urine-deconjugated differential metanephrines (Lenders *et al.*, 2002). In fact, several studies have evidenced the higher sensitivity of metanephrines (ranging around 98%–99%) in comparison with other analytes such as plasma/urine catecholamines or vanilmandelic acid (Davidson, 2002; Grossman *et al.*, 2006). The higher sensitivity of metanephrines is mainly due to their longer half-life and to their non-episodic production by the tumor where catecholamines are continuously converted to metanephrines by the high methyltransferase activity which characterizes the chromaffin tissue (Eisenhofer *et al.*, 1998). The release of catecholamines is influenced by tumor location. In fact, adrenaline is produced only by PCCs, while sPGL do not. Generally the biochemical phenotype is not useful in differentiating malignant from benign PGLs. However malignant PCCs produce mainly noradrenaline (Rao *et al.*, 2000) and in some circumstances they predominantly or exclusively produce dopamine as a consequence of a less-differentiated catecholamine biosynthetic pathway (Brouwers *et al.*, 2006). Therefore in case of large noradrenaline releasing PGLs and/or in the presence of high plasma levels of dopamine or its metabolite methoxytyramine, the risk of malignant tumors should be considered (Grossman *et al.*, 2006; van der Harst *et al.*, 2002).

Neuroendocrine markers such as plasma chromogranin A (CgA) or neuron-specific enolase does not show high sensitivity in biochemical diagnosis of PGLs, and especially CgA often rise false positive results due to concomitant disease (i.e., liver or kidney failure) or therapy with drugs increasing gastrin plasma levels (i.e., proton pump inhibitors) (Algeciras-Schimnich *et al.*, 2008). However, malignant PGLs are generally associated to high plasma levels of these markers (Grossman *et al.*, 2006) and therefore their evaluation may be useful as a surrogate marker to confirm the diagnosis as well as to monitor the response to treatment in the follow up and/or to evidence the recurrence of the disease.

Anatomical and Functional Imaging

Among anatomical imaging tools, computed tomography (CT) or magnetic resonance imaging (MRI) are very useful in the localization of PGLs. CT shows a sensitivity of 77%–98% and a specificity of 29%–92% in detecting adrenal or extra-adrenal tumors. Diagnostic accuracy is slightly better (sensitivity 90%–100% and specificity 50%–100%) for MRI, especially for the localization of extra-adrenal disease (Ilias and Pacak, 2004). Furthermore MRI with diffusion-weighted imaging may also be used to detect especially lymph node and liver metastases (Takano *et al.*, 2008). On the contrary, ultrasound imaging has a limited diagnostic value, but it may have a relevant role in the detection of HNPGLs (Blake *et al.*, 2004; Ilias and Pacak, 2004).

On MRI PGLs usually show high signal on T2-weighted imaging and strong enhancement after contrast-agent administration because are highly vascularized tumors with a high intracellular water content and frequent intratumoral cystic lesions. However large tumors as well as malignant lesion often contain hemorrhagic and/or necrotic areas, which may reduce the signal intensity on T2-weighted images (Mannelli *et al.*, 2010).

In malignant PGLs, nuclear medicine procedures, named "functional imaging," are generally recommended after anatomical detection. These techniques use specific tracers which may be concentrated by chromaffin tissue. Functional imaging permit to perform a whole-body study, providing a better evaluation of extra-adrenal PGLs as well as of multiple tumors and or metastatic localizations (Shulkin *et al.*, 2006). ^{131}I or ^{123}I-metaiodobenzylguanidine (MIBG) scintigraphy represents the first-line functional imaging in the evaluation of patients with PGLs. MIBG has a chemical structure similar to norepinephrine and is concentrated in

chromaffin tissue, via a transporter normally expressed in most of chromaffin cells, responsible for catecholamine uptake (Shulkin *et al.*, 2006). ^{123}I-MIBG has better physical properties than ^{131}I-MIBG and it's superior in terms of quality of images and diagnostic accuracy (sensitivity of 83%–100% vs. 77%–90%) (Ilias and Pacak, 2004). However the sensitivity of ^{123}I-MIBG-scintigraphy may be lower in malignant PGLs, especially in patients with dopamine-secreting tumors which usually do not uptake MIBG, or in SDHB mutation carriers, characterized by a high risk of malignancy (Dubois and Gray, 2005).

In patients with a strong suspect of PGL and negative MIBG scintigraphy, other nuclear medicine techniques may be considered. As MIBG, radiolabeled dopamine (DA) or dihydroxyphenylalanine (DOPA) are transported into chromaffin cells, providing the possibility to use them as tracers in positron emission tomography (PET) imaging. PET with 6-[^{18}F]-fluoro-DA shows a better sensitivity than ^{131}I-MIBG in detecting metastatic PCCs (Ilias *et al.*, 2003), whereas PET with 6-[^{18}F]-fluoroDOPA is superior in imaging sPGLs and HNPGLs (Hoegerle *et al.*, 2002). However, as for MIBG, the sensitivity of these tracers is low in PGLs associated with *SDHB* mutations. The preferred functional imaging modality for staging *SDHB*-related metastatic PGLs is PET with ^{18}F-labeled fluoro-deoxy-glucose (^{18}F-FDG). This technique permits to identify glucose-avid metastatic sites, also the MIBG-negative ones (Mamede *et al.*, 2006), showing a sensitivity close to 100% (Timmers *et al.*, 2007).

Chromaffin cells may express somatostatin receptor type 2, 3, and 5. Therefore radiolabeled somatostatin analogues may be used in order to localized these tumors. Indium-11-DTPA-octreotide (^{111}In-penteotride) is the tracer most commonly used; it may be especially useful in localizing extra-adrenal disease, MIBG-negative metastatic as well as malignant PCCs sites with a sensitivity near to 90% (Ilias and Pacak, 2004; Telischi *et al.*, 2000). On the contrary its sensitivity in benign PCCs is limited. Somatostatin analogues labeled with gallium-68 [^{68}Ga-DOTATOC (DOTA^0-D-Phe^1-Tyr^3-octreotide)] can be used in PET imaging. This functional imaging has shown a better sensitivity than ^{18}F-labeled fluoro-deoxy-glucose (^{18}F-FDG) in detecting malignant PCCs and sPGLs (Buchmann *et al.*, 2007; Hofmann *et al.*, 2001; Kowalski *et al.*, 2003). Finally PET imaging with ^{11}C-hydroxyephedrine has provided high diagnostic accuracy (sensitivity 92% and specificity 100%) in the detection of PGLs, but an higher number of patients have to be studied in order to draw conclusions on its usefulness (Trampal *et al.*, 2004).

Pathology

Unfortunately, at present, no reliable markers of malignancy are available. Malignancy is diagnosed by the presence of metastases. Generally extra-adrenal PGLs, larger than 5 cm, with necrotic areas and high cellularity have a superior risk to be malignant, but still now on the basis of histopathological findings, it remains difficult to predict whether an apparently benign PGL will develop in a malignant tumor.

On the basis of some histological features (i.e., invasion, growth patterns, cytologic appearance as well as mitotic activity), several scoring systems have been proposed to establish the risk of malignancy (Kimura *et al.*, 2005; Linnoila *et al.*, 1990; Thompson, 2002). Among them, the most utilized is "Pheochromocytoma of the Adrenal gland Scales Score (PASS)," proposed by Thompson on 2002. **Table 1** reports items and values used to calculate the score. A score <4 or >6 suggests benign or malignant lesions respectively, whereas a value between 4 and 6 is associated to an intermediate risk.

Some molecular markers can offer additional information (Chrisoulidou *et al.*, 2007). For example inhibin/activin β-subunit is expressed in the normal medulla as well as in benign PGLs, while is almost absent in malignant tumors; neuropeptide Y mRNA is expressed in all benign PGLs and to a lesser extent in the malignant counterpart; on the contrary cyclooxygenase-2, N-cadherin, as well as gene encoding vascular endothelial growth factor (VEGF), endothelin receptor type A (ETA) and type B (ETB), are overexpressed in malignant PGLs. Telomerase seem to be closely related to malignancy: the human telomerase reverse transcriptase (hTERT) promoter has been associated with a number of malignant tumors including PCCs and PGLs (Dwight *et al.*, 2017).

Also the Ki-67 nuclear antigen proliferative index may be useful in predicting malignancy because a value higher than 3%–6% is most commonly found in malignant tumors (Brown *et al.*, 1999; Liu *et al.*, 2004).

Table 1 Pheochromocytoma of the adrenal gland scoring scale (PASS) (Hao *et al.*, 2009)

Items	*Value*
Nuclear hyperchromasia	1
Profound nuclear pleomorphism	1
Capsular invasion	1
Vascular invasion	1
Extension into adipose tissue	2
Atypical mitotic figures	2
>3 of 10 mitotic figures high-power field	2
Tumor cell spindling	2
Cellular monotony	2
High cellularity	2
Central or confluent tumor necrosis	2
Large nests or diffuse growth ($>10\%$ of tumor volume)	2
Total	20

Novel biomarkers are more recently being identified by micro-RNA expression profiling studies. Micro-RNA are small single-strand (~22 bp), non-protein coding RNA fragments, which are able to negatively regulate protein expression by either cleavage or translational repression of mRNA (Engels and Hutvagner, 2006). MicroRNA expression is tissue specific, and it has been demonstrated to be altered in several other human tumors. It has been demonstrated that, in PCCs and PGLs, a reduced expression of specific mRNAs, which are involved in proliferation and apoptosis, such as miR-51a and miR-16 and an increased expression of miR-483-5p are predictive of malignancy (Meyer-Rochow *et al.*, 2010).

However as none of the available molecular markers, as well as histological findings predict malignant development unequivocally, after the removal of PCC/PGL, a follow up of the patient is recommended in order to reveal early disease recurrence.

Therapy

To date, no effective therapy is available to cure malignant PCC/PGL. All the available therapeutic options are aimed at improve patient's survival, slowing the progression of the disease, or at limiting the effects of the catecholamines released by the tumor, improving the patient's quality of life.

Often, patients affected by a malignant PCC/PGL show an indolent course of the disease and maintain a good quality of life. In these cases a prudent "wait and see" behavior should be adopted, reserving more aggressive therapeutic options in case of disease progression.

Medical Therapy

Medical therapy is directed to reduce the negative effects caused by the excess of catecholamines released by the tumor, especially on the cardiovascular system and on the gut. Cardiovascular complications include myocardial ischemia or insufficiency, stroke, sudden death. Alpha blockers as phenoxybenzamine or doxazosin are the drugs of choice. Beta blockers may be added to protect the myocardium but only after alpha blocking therapy has been started. Alpha-methyl-paratyrosine is an other medical option: it blocks the catecholamine synthesis acting both on the tumor tissue and on the sympathetic system thus causing side effects like postural hypotension. At the gut level, catecholamine excess causes a constipation that sometimes is a so severe to be lethal. Constipation should be recognized and promptly treated using laxatives, either stimulant or osmotic, stool softeners, lubricants (Thosani *et al.*, 2015).

Surgery

Surgery, which is the treatment of choice for benign PCC/PGL, may have a role also in the treatment of malignant PCC/PGL. The main purpose of surgical treatment is represented by the removal of the primary tumor and, if possible, the resection of local recurrences and, more rarely, distant metastases. The overall 5-year survival rate of patients with malignant PGLs varies between 34% and 60% and may depend on the sites of the metastatic lesions. In fact, a worse prognosis has been evidenced in patients with liver or lung metastases (<5 years) compared with that of patients with only bone lesions (Pacak *et al.*, 2007).

Generally, the recommended surgical approach to benign adrenal or extra-adrenal tumor is "laparoscopic," but in case of large PCC/PGLs as well as in the presence of high risk of malignancy a laparotomic approach should be considered (Brauckhoff *et al.*, 2004).

Usually surgery alone is rarely curative in the presence of malignant PGLs, but also in case of extensive disease surgical debulking is indicated. In fact, it may permit to reduce clinical manifestations related to catecholamine secretion and it may improve the response to other therapeutic approaches, such radiometabolic therapy. In patients with multiple liver metastases not susceptible to surgical resection, arterial embolization or chemoembolization as well as radiofrequency ablation should be considered (Maithel and Fong, 2009).

It should be remembered that each patient affected by a chromaffin tumor, either benign or malignant, must be preoperatively treated with alpha blockers and fluid administration in order to avoid surgical (i.e., hypertensive crisis, arrhythmias) and/or postsurgical complications (i.e., hypotension) (Lenders *et al.*, 2005).

Radiometabolic Treatment and External Radiotherapy

In patients with metastatic disease and unresectable lesions, radionuclide treatment with beta-emitting isotopes coupled with MIBG or somatostatin analogues should be considered. The evidence of significant radioisotope uptake on diagnostic scintigraphy with ^{123}I-MIBG or ^{131}I-MIBG (>1% uptake of the injected dose) is important in order to select patients who can benefit from this treatment. The treatment may be administered by single or fractionated doses with a cumulative dosage varying between 200 and 1400 (Kaltsas *et al.*, 2003, 2005). A better response is achieved in patients with limited metastatic burden and in those with soft-tissue metastases compared to patients with bone metastases. The therapy with ^{131}I-MIBG is generally well tolerated, especially at low doses. The main side effects include nausea, moderate bone marrow suppression (transient leucopenia and

thrombocytopenia) and moderate hepatic and renal toxicity. Severe bone marrow toxicity (associated with high-dose regimen) is rarely seen. In some cases (10%) also symptoms related to catecholamine release from the irradiated tissue (headache, palpitations, sweating) may appear.

Unfortunately, treatment with ^{131}I-MIBG is rarely curative and other forms of therapy need to be considered.

In patients with metastatic, MIBG-negative PGLs or in those who do not respond to treatment with ^{131}I-MIBG, therapy with radiolabelled somatostatin analogues may be considered. As for ^{131}I-MIBG, the evidence of significant radioisotope uptake on diagnostic scintigraphy with ^{111}In-pentetreotide or especially on PET using ^{68}Ga-DOTA-TOC provides high accuracy in selecting patients (Mamede *et al.*, 2006). Radiolabelled somatostatin analogues are generally used in patients with gastroenteropancreatic neuroendocrine tumors and even if their efficacy is lower in patients with malignant PGLs, they may represent an alternative option for the treatment of surgically incurable PGLs (Forrer *et al.*, 2008). They may determine tumor shrinkage thus reducing catecholamine release. The most commonly used compounds are Yttrium-90-DOTATOC (^{90}Y-DOTA-TOC) and Lutetium-177-DOTA^{0}-Tyr^{3}-octreotate (^{177}Lu-DOTA-TATE) (Kaltsas *et al.*, 2005; Kwekkeboom *et al.*, 2005, 2008). The main side effects associated to these compounds are represented by leucopenia and thrombocytopenia.

In some cases a combined treatment with radiolabelled MIBG and radiolabelled somatostatin analogues may be considered. These two treatments may have a synergistic effect, permitting the use of lower doses of both radionuclides, limiting side effects, particularly bone marrow toxicity.

Although malignant PGLs are relatively radio-resistant, external radiotherapy may be considered especially in patients with bone metastases in order to reduce chronic pain or symptoms related to local compression. During external radiotherapy the patients have to be monitored because the radio-induced damage of the lesion can induce massive catecholamine secretion, thus inducing hypertensive crises (Teno *et al.*, 1996).

Targeted Therapy

The limited effect elicited by chemo- and radionuclide therapy in improving survival highlights the need for novel targeted therapies. The identification of the main PCC/PGL susceptibility genes as well as the understanding of the specific molecular pathways activated by their mutations and responsible for malignancy, provide the bases for the development of multiple molecular-targeted therapy. Genetic profiling has grouped, both benign and malignant PGLs, into two distinct clusters (1 and 2) characterized by different molecular pathways leading to oncogenesis. Moreover, malignant PCCs seem to overexpress HSP90, a molecular chaperone that plays an important role in molecular stability, maintaining the folding and conformation of multiple oncoproteins that play a role in malignant phenotype (Banerji, 2009; Powers and Workman, 2006).

Antiangiogenetic drugs seem to be more appropriate for patients affected by cluster 1 PCCs. Accordingly, sunitinib, a receptor tyrosine kinase inhibitor acting on several targets (VEGF, PDGF, and c-KIT), with strong antiangiogenic and antitumor activity, has been used in the treatment of malignant PCCs, with good results (Canu *et al.*, 2017; Hahn *et al.*, 2009; Jimenez *et al.*, 2009; Joshua *et al.*, 2009; Park *et al.*, 2009). Imatinib, another tyrosine kinase inhibitor already used for hematologic and GIST, has not been found effective in the treatment of malignant PCCs (Gross *et al.*, 2006). Nevertheless, these observations need to be confirmed in larger cohorts of patients and drug effectiveness need to be tested against placebo treatment. Several clinical trials are currently ongoing and will hopefully enable such validations. These trials include the FIRSTMAPPP study, a randomized double-blind phase II international multicenter study that is evaluating the efficacy of sunitinib versus placebo in patients with progressive malignant PGLs [http://clinicaltrials.gov/ct2/show/NCT01371201], and two nonrandomized phase II studies that are evaluating the response to sunitinib [https://clinicaltrials.gov/ct2/show/NCT00843037] and axitinib [https://clinicaltrials.gov/ct2/show/NCT01967576].

Thalidomide, by targeting VEGF and basic fibroblast growth factor, is another antiangiogenic agent. It has been used in combination with temozolamide in patients with metastatic carcinoid, PCC or pancreatic neuroendocrine tumors. These latter seem to be more responsive to this treatment but a positive response was also found in one of the three treated patients with malignant PCC (Kulke *et al.*, 2006).

The HIF1a inhibitors are molecular targeted drugs interfering with HIF hypoxia-driven transcription pathway thus decreasing HIF activity directly. These molecules have shown marked antineoplastic activity in human tumor xenografts in mice and seem to be promising also for malignant PGLs, although conclusive data are missing (Semenza, 2007; Welsh *et al.*, 2003, 2004).

Activators of prolyl hydroxylase (PHD) (such as ERBB2 inhibitors) are on evaluation as promising antitumoral agents. These molecules, by activating the PHD, increase HIF hydroxylation, and promote its degradation, thus reducing the expression of some angiogenic factors (Choi *et al.*, 2008; Temes *et al.*, 2005).

A dysfunction in PI3/Akt/mTOR pathway increases cell proliferation, angiogenesis and decreased apoptosis, thus potentiating malignant transformation (Druce *et al.*, 2009); in vitro studies have involved this pathway in the pathogenesis of malignant neuroendocrine tumors, including PCCs. mTOR inhibitor everolimus (RAD001) has been evaluated in malignant PGLs, but all patients experienced disease progression (Chrisoulidou *et al.*, 2007; Druce *et al.*, 2009). Maybe the low efficacy is due to a compensatory activation of PI3K/AKT and ERK in response to mTOR inhibition, so a specific novel dual PI3k/mTOR inhibitor (NVP-BEZ235) might offer a novel therapeutic approach (Nölting and Grossman, 2012). However the therapeutic response to mTOR inhibitors in patients with malignant PGLs remains to be tested in a clinical trial.

Due to overexpression of HSP90 in malignant PCCs (Boltze *et al.*, 2003a,b), inhibition of its pathway could represent a future therapeutic challenge for the treatment of malignant PCCs. Specific HSP90 inhibitors have been developed and seem promising in

other malignancies (i.e., breast cancer) (Modi *et al*., 2007, 2011); however, at present, no specific trials are currently carried out in patients with malignant PGLs.

Conclusions

Malignant PCC/PGL are very rare and so far incurable tumors. Their clinical course is variable, ranging from aggressive to indolent. There are many risk factors suggesting a potential malignancy but, in the absence of a reliable biological marker, malignancy is proved only by the presence of metastases. Metastatic spread is often found years after the removal of a supposedly benign tumor and therefore studies comparing benign and malignant PCC/PGL are difficult and deserve a long clinical follow up of patients.

Genetic studies of the last 15 years have highlighted the pathways responsible for PCC/PGL development and suggested new targeted therapeutic approaches whose effectiveness has still to be confirmed by large collaborative international studies.

As a whole, at present, malignant PCC/PGL has to be considered an orphan disease.

Pheochromocytoma/Paraganglioma: Management, Genetics, and Follow-up

Anne-Paule Gimenez-Roqueplo and Laurence Amar, Hôpital Européen Georges Pompidou, Paris, France; INSERM, Paris, France; and Paris Descartes University, Paris, France

Introduction

Paraganglioma and pheochromocytoma (PPGL) are neuroendocrine tumors arising from extra-adrenal paraganglia (head and neck paragangliomas and thoracic-abdominal or pelvic sympathetic paragangliomas) and the adrenal medulla, respectively (Lloyd *et al.*, 2017). PPGL is a rare disease (low prevalence, estimated, from autopsy series, at 5–10 per 1000 inhabitants and at 0.2%–0.6% in hypertension patients). The first case of pheochromocytoma to be described was published in 1884 and concerned an 18-year-old woman who died from malignant hypertension. Bilateral adrenal tumors and thyroid gland enlargement, corresponding to bilateral pheochromocytoma and medullary thyroid carcinoma, were detected on autopsy. More than a century later, a diagnosis of multiple endocrine neoplasia type 2 was finally made for this patient, with the identification of a germline mutation of the *RET* gene in her descendants. The princeps case of pheochromocytoma was, thus, genetically determined (Neumann *et al.*, 2007). The management of patients with paraganglioma or pheochromocytoma has greatly benefited from advances in biology and imaging technologies, and from new genetic insight. A dozen new PPGL susceptibility genes have been discovered since the start of the 21st century. A germline mutation in a known susceptibility gene is found in about 40% of cases. The management and follow-up of mutation-carriers depends on the susceptibility gene mutated (Lenders *et al.*, 2014; Favier *et al.*, 2014).

Classical Management of PPGL

Clinical Presentation

PPGL usually has a nonspecific clinical presentation. The time from the onset of the first symptoms to PPGL diagnosis has been estimated at about 3 years, on average (Amar *et al.*, 2005b). The circumstances in which PPGL diagnosis should be considered are listed in **Table 1**. Symptoms may reflect catecholamine production (paroxysmal or permanent hypertension, sweating, tachycardia, headaches, etc.) for pheochromocytoma or catecholamine-producing paraganglioma, or may be caused by the tumor burden (tumoral mass, tinnitus, hearing loss or deafness, etc.) for head and neck paraganglioma. At least 10% of PPGL are diagnosed incidentally or after severe complications, such as adrenergic cardiomyopathy.

Biochemical Testing

The process for PPGL diagnosis is outlined in **Fig. 1**. Briefly, biochemical testing is the first step in PPGL diagnosis. It should include measurements of plasma free metanephrine concentration, with the patient remaining in a supine position for at least 30 min before blood sampling, or urinary fractionated metanephrine determinations on a 24-h urine sample, with the completeness of urinary collection checked by the determination of urinary creatinine concentration. Metanephrines are the methylated metabolites of catecholamines. Both these tests have a sensitivity and specificity for PPGL diagnosis of more than 95% (Lenders *et al.*, 2014). The European Society of Endocrinology clinical practice guidelines recommend assays of 3-methoxytyramine and chromogranin A for the detection of dopamine-producing or nonfunctional PPGL (Plouin *et al.*, 2016).

Table 1 Clinical circumstances of pheochromocytoma and/or paraganglioma diagnosis

Resistant hypertension (SBP $\geq$140 mmHg or DBP $\geq$90 mmHg in a patient treated with at least a diuretic and two other different types of antihypertensive drug) or orthostatic hypotension
Catecholamine crisis presenting as Takotsubo cardiomyopathy, stroke, heart attack, multiple-organ failure or malignant hypertension
Headaches and/or tachycardia and/or sweating
Blood pressure lability recorded on 24-h ambulatory blood pressure monitoring or during surgery
Diabetes + hypertension in a patient under 50 years of age with a body mass index $<$25
Pulsatile tumor mass
Hypoacousia, deafness, tinnitus, dysphagia, cranial nerve paralysis
Incidentaloma
Behavioral disorders and/or schooling difficulties in children, polyuria and polydipsia, unexplained weight loss, gastrointestinal disorders
Clinical screening in a patient with a germline mutation of a pheochromocytoma/paraganglioma (PPGL) susceptibility gene
Clinical screening of at-risk relatives for mutations of PPGL susceptibility genes

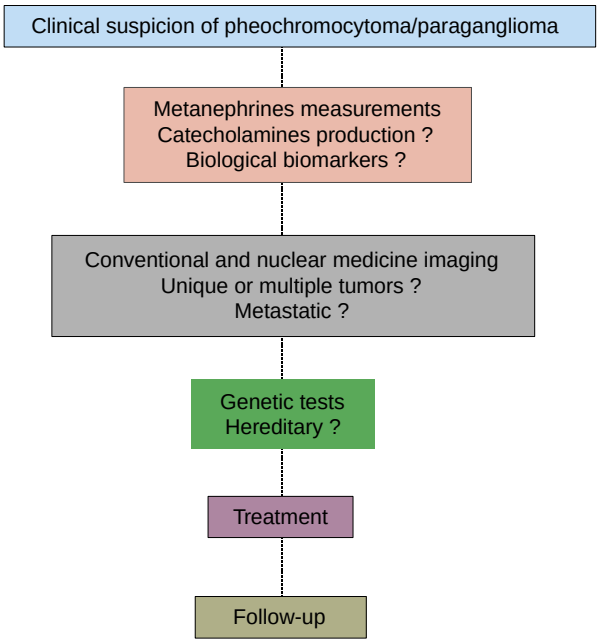

Fig. 1 The different steps in the diagnosis and management of pheochromocytoma and paraganglioma.

Imaging

All patients with positive results for a biochemical test should undergo imaging, to screen for and locate PPGL, and to detect multiple PPGL and/or metastases, if present. The principal conventional imaging method recommended for this purpose is CT-scan with contrast staining, due to its high sensitivity for PPGL diagnosis, which has been estimated at 90%–100%. MRI is indicated in children, pregnant women, patients with allergy to CT contrast agents and patients known to have a germline mutation (Lenders *et al.*, 2014). However, for head and neck PGL, the imaging method of choice is contrast-enhanced angio-MRI (Gimenez-Roqueplo *et al.*, 2013; Gravel *et al.*, 2016). Additional functional imaging examinations can be performed for patients with PGL or suspected metastatic disease. Positron emission tomography (PET) combined with computed tomography (CT) scanning has supplanted ^{123}I-metaiodobenzylguanidine (mIBG) and ^{111}In-pentetreotide (octreoscan) scintigraphy. ^{18}Fluoro-2-deoxy-D-glucose (^{18}F-FDG) PET/CT is the leading nuclear medicine examination for these patients, due to its high sensitivity for the diagnosis of both pheochromocytoma and paraganglioma, and its ability to detect metastases (Timmers *et al.*, 2012). New tracers, such as ^{18}fluorodihydroxyphenylalanine (^{18}F-DOPA) and ^{68}gallium-DOTA (0)-Tyr(3)-octreotate (^{68}Ga-DOTATATE), seem to provide added value, particularly for the assessment of genetically determined forms (see below) (Castinetti *et al.*, 2015).

Genetic Testing

The third main element in the PPGL diagnosis pathway is genetic testing, because the identification of a germline mutation modifies patient management and follow-up (as described below). About 40% of patients with PPGL carry a germline mutation in a known PPGL susceptibility gene. International and European guidelines therefore recommend genetic testing for all affected patients. Genetic counseling should be available to patients before and after testing. The international next-generation sequencing (NGS) in PPGL Study Group, which comprised of experts in PPGLs from 10 separate institutions representing 8 countries, has stated that molecular genetic testing should be performed by specialized and accredited laboratories using NGS technology, which is highly suitable for the screening of all PPGL susceptibility genes identified to date (NGS in PPGL (NGSnPPGL) Study Group *et al.*, 2017).

Treatment

Single apparently benign tumors

The treatment of choice is surgery. However, medical preparation is indicated before surgery, to prevent perioperative cardiovascular complications due to the unpredictable release of catecholamines during resection of the tumor mass. Treatment with alpha-adrenergic blockers should be initiated 7–15 days before surgery. The coadministration of beta-blockers is also indicated, to control heart rate and blood pressure. Moreover, a high-sodium diet and high levels of fluid intake can reduce the risk of severe hypotension after tumor removal. Laparoscopic resection is usually performed for pheochromocytomas of less than 6 cm in diameter. Open resection is restricted to the largest tumors and cases of head and neck paraganglioma (Lenders *et al.*, 2014).

Metastatic PPGL

The presence of metastases, defined as the presence of chromaffin tissue in a nonchromaffin organ (mostly the lymph nodes, bones, liver, and lungs), remains the only definitive criterion for malignant PPGL according to the most recent World Health Organization (WHO) classification of endocrine tumors (Lloyd *et al.*, 2017). At least 10% of PPGL are malignant (Amar *et al.*, 2016). The prognosis is unfavorable, with a median 5-year survival of less than 50% in published studies. Metastases may be diagnosed at presentation or during follow-up and, as mentioned above, ^{18}F-FDG-PET/CT is superior to ^{123}I-mIBG scintigraphy for the detection of metastases. Nevertheless, ^{123}I-mIBG scintigraphy is still used to determine whether targeted radiotherapy with ^{131}I-mIBG is possible, and magnetic resonance imaging of the liver and bones is indicated for the staging and follow-up of metastases. Therapeutic options should be discussed with multidisciplinary teams at expert centers. The therapeutic arsenal for metastatic PPGL includes surgery, interventional radiology, external or targeted radiotherapy, chemotherapy, and targeted molecular therapies (Baudin *et al.*, 2014).

Follow-Up

The risk of new events after complete PPGL resection was recently estimated at about 10%, on average, over the first 5 years of follow-up, in the PPGL cohort (701 patients) of the European Network for the Study of Adrenal Tumors (ENS@T). It has, therefore, been suggested that patients should be followed for at least 10 years. Patients at high risk, such as those young at diagnosis, those with genetic and/or a syndromic disease, a large tumor and/or a paraganglioma, would benefit from life-long annual follow-up, because the risk of recurrence exceeds 20% in such patients. The recommended monitoring methods are blood pressure determination, annual biochemical tests, and thoraco-abdomino-pelvic MRI every 1–2 years (Plouin *et al.*, 2016).

Genetics of PPGL

The "10%" Rule

Before 2000, it was widely thought that about 10% of PPGL were malignant, 10% could be diagnosed during infancy, 10% were multiple, and 10% would appear in patients with a familial history of PPGL. Three genes, *NF1*, *VHL*, and *RET*, had been identified by classical genetic linkage studies (**Fig. 2**). These three genes cause three syndromic diseases (neurofibromatosis type 1, von Hippel-Lindau disease, and multiple endocrine neoplasia type 2). The diagnosis of these diseases in the context of a first PPGL should lead to screening for other syndromic lesions and strict follow-up of all organs at risk.

Neurofibromatosis type 1

Germline mutations of the *NF1* tumor suppressor gene cause neurofibromatosis type 1 (NF1) or von Recklinghausen disease, an almost fully penetrant autosomal dominant syndromic disease. NF1 is generally easy to diagnose in adults, on the basis of the presence of at least two of the seven clinical diagnosis criteria defined by the National Institutes of Health consensus development conference statement of July 1987 (**Table 2**) (Anon, 1988). The risk of PPGL is less than 5%, but the penetrance of the disease is about 1/3000 (Friedman, 1999). In NF1, PPGL usually takes the form of an epinephrine-producing pheochromocytoma diagnosed in patients in their thirties (Bausch *et al.*, 2006).

Von Hippel-Lindau disease

Germline mutations of the *VHL* tumor suppressor gene cause von Hippel-Lindau disease, an autosomal dominant syndromic disease with an incidence of about 1/36,000. Two types have been defined: type 1 (without PPGL) and type 2 (with PPGL)

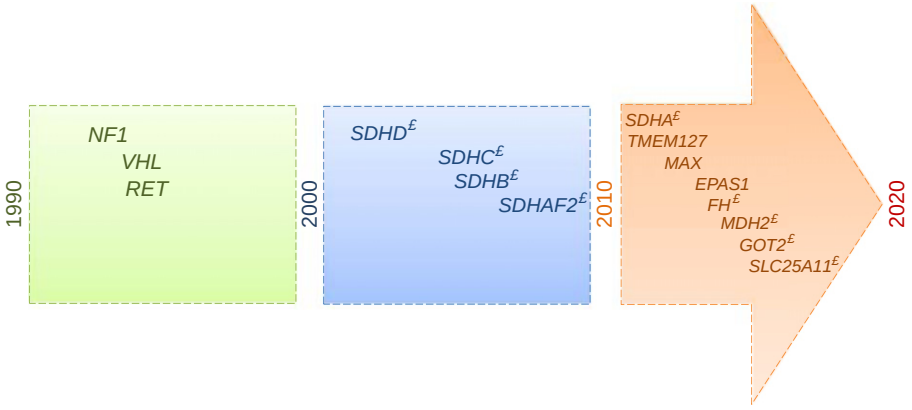

Fig. 2 Timeline of the identification of the main PPGL susceptibility genes (£ indicates TCA cycle genes encoding enzymes or transporters).

Table 2 Diagnostic criteria for neurofibromatosis type 1

Six or more "café-au-lait" spots with a largest diameter exceeding 5 mm in prepubertal individuals or with a largest diameter exceeding 15 mm in postpubertal individuals
Two or more neurofibromas of any type or one plexiform neurofibroma
Freckling in the axillary or inguinal region
Optic glioma
Two or more Lisch nodules (iris hamartomas)
A distinctive osseous lesion, such as sphenoid dysplasia, or thinning of a long bone cortex with or without pseudoarthrosis
A first-degree relative (parent, sibling or offspring) with neurofibromatosis

Table 3 Main syndromic features associated with PPGL in von Hippel-Lindau disease

Retinal hemangioblastoma
Central nervous system hemangioblastoma
Clear-cell renal-cell carcinomas and/or kidney cysts
Pancreatic neuroendocrine tumors or cysts
Endolymphatic sac tumors
Epididymal cystadenoma in men or cystadenoma of the broad ligament in women

Table 4 Main syndromic features associated with pheochromocytoma in multiple endocrine neoplasia type 2

Main syndromic features associated with pheochromocytoma in multiple endocrine neoplasia type 2A
Medullary thyroid carcinoma
Primary hyperparathyroidism
Main syndromic features associated with pheochromocytoma in multiple endocrine neoplasia type 2B
Medullary thyroid carcinoma
Marfanoid appearance
Mucosal neuromas of the tongue, lip, palate
Intestinal ganglioneuromatosis

(Gossage *et al.*, 2015). The various other disorders that can occur in patients with this syndrome are summarized in **Table 3**. In von Hippel-Lindau disease, PPGL is usually diagnosed early, during infancy/adolescence, or in young adults. Tumors may be multiple or bilateral and most produce norepinephrine (Amar *et al.*, 2005a).

Multiple endocrine neoplasia type 2

Gain-of-function germline mutations of the *RET* proto-oncogene cause multiple endocrine neoplasia type 2 (MEN2), an autosomal dominant syndromic disease that affects 1/30,000 individuals. The disease is caused by hot-spot mutations specifically located in several codons of exons 8, 10, 11, 13, 14, 15, and 16. Two clinical types (type 2A and 2B) have been defined and the phenotypic characteristics of these two clinical types are reported in **Table 4**. The American Thyroid Association (ATA) revised its guidelines in 2015 and defined three ATA risk categories for medullary thyroid carcinoma (MTC) caused by *RET* mutations: "highest risk," (HST) "high risk," (H) and "moderate risk" (MOD). The ATA-HST category includes patients with MEN2B and the *RET* codon M918T mutation (in such cases, prophylactic thyroidectomy is recommended before the age of 1 year, to prevent the risk of metastatic MTC). The ATA-H category includes patients with *RET* codon C634 mutations or *RET* codon A883F mutation (in such cases, prophylactic thyroidectomy is recommended before the age of 5 years). The ATA-MOD category includes patients with *RET* codon mutations other than M918T, C634, and A883F. In MEN2, PPGL are diagnosed in 50% of affected patients as single or bilateral pheochromocytomas producing epinephrine, of early onset (before the age of 30 years) (Wells *et al.*, 2015).

SDHx Genes

Our understanding of the genetics of PPGL has progressed considerably since the turn of the century (see **Fig. 2**), with the demonstration that germline mutations of *SDHD*, SDHC, *SDHB*, and then *SDHAF2* and *SDHA* are responsible for hereditary PPGL (Favier *et al.*, 2014). All the *SDHx* genes are tumor suppressor genes encoding the succinate dehydrogenase enzyme. They follow an autosomal dominant mode of inheritance, associated with maternal genomic imprinting for carriers of *SDHD* and *SDHAF2* mutations. As a result, only patients with mutations of the paternal allele of these genes are likely to develop PPGL. Large

phenotype–genotype studies have shown that multiple head and neck PGL is suggestive of *SDHD* mutation, whereas thoracic-abdominal or pelvic PPGL producing dopamine or norepinephrine indicate *SDHB* mutation (Burnichon *et al.*, 2009; Lenders *et al.*, 2014). Nevertheless, multiple PPGL can emerge at sites distant from the initial PPGL in *SDHx* mutation carriers. Thus, thoracic-abdominal or pelvic PGL can be diagnosed in carriers of *SDHD* mutations and head and neck PGL can be detected in carriers of *SDHB* mutations (Gimenez-Roqueplo *et al.*, 2013). Penetrance is incomplete, but higher in individuals carrying *SDHD* mutations than in those carrying *SDHB* mutations. Germline mutations of *SDHC*, *SDHA*, and *SDHAF2* are rarer, but can be identified in patients with PPGL at various sites. It has been shown that mutations of the *SDHB* gene are associated with a high risk of malignancy (Gimenez-Roqueplo *et al.*, 2003) and a poor prognosis in patients with metastatic PPGL (Amar *et al.*, 2007). Finally, rare gastrointestinal stromal tumors (GIST) and kidney cancers caused by *SDHx* mutations have also been reported.

New PPGL Susceptibility Genes Revealed by Massively Parallel Sequencing Technology

Sanger sequencing, based on chain termination techniques performed on capillary sequencing machines, has recently been replaced by next-generation sequencing (NGS) methods, which facilitate massively parallel sequencing at low cost (Toledo and Dahia, 2015). Since 2010, new PPGL susceptibility genes have frequently been identified by the whole-exome sequencing of constitutional and tumoral DNA from one or a few affected patients (see **Fig. 2**). Each of these new PPGL genes accounts for less than 3% of all inherited forms of PPGL. *TMEM127* and *MAX* germline mutations were the first to be identified in patients with a familial presentation (Qin *et al.*, 2010; Comino-Méndez *et al.*, 2011). Nevertheless, *TMEM127* mutations can be found in patients with apparently sporadic epinephrine- and norepinephrine-producing PPGL, whereas *MAX* mutations are usually diagnosed in younger patients (about 30 years old) with norepinephrine-producing PPGL (Abermil *et al.*, 2012; Burnichon *et al.*, 2012).

Germline mutations of *FH* (Letouzé *et al.*, 2013), *MDH2* (Cascón *et al.*, 2015), *GOT2* (Remacha *et al.*, 2017), and *SLC25A11* (Buffet *et al.*, 2018) have been found in patients with norepinephrine-producing PPGL, which was malignant in some cases. *FH* is the only one of these genes for which mutations are known to cause a syndromic disease characterized by the association of cutaneous and uterine leiomyomas and, in 15% of cases, aggressive renal cell carcinoma (papillary type 2).

Two genes have been found to display somatic mutations and a low level of constitutional mosaicism in patients. The first, *EPAS1*, has been found mutated in patients with PPGL, polycythemia and/or somatostatinoma, and in patients with apparently sporadic PPGL (Zhuang *et al.*, 2012; Buffet *et al.*, 2014). The second, *H3F3A*, has been found mutated in a very small number of patients with PPGL and giant-cell tumors of the bone (Toledo *et al.*, 2016). These mutations, identified in DNA extracted from tumoral tissue, can arise at a postzygotic stage and deep sequencing should be performed to check for their presence in the germline, to determine the risk of the disease occurring in the patient's descendants.

Finally, germline mutations of *PHD2* (or *EGLN1*), *KIF1Bβ*, and *MERTK* have been identified in a very small number of patients with a predisposition to pheochromocytoma and polycythemia (Ladroue *et al.*, 2008), neuroblastoma and ganglioneuroma (Schlisio *et al.*, 2008), or medullary thyroid carcinoma (Toledo *et al.*, 2016), respectively, and a germline mutation of the *IDH3B* gene was recently reported in a single patient with head and neck PPGL (Remacha *et al.*, 2017). However, the contributions of all these genes, including *H3F3A*, to the genetics of PPGL, should be confirmed in additional studies.

The large number of PPGL susceptibility genes reported to date justifies the recommendation of NGS for genetic testing for PPGL. The PPGL gene panels targeted by NGS should include at least the *FH*, *MAX*, *NF1*, *RET*, *SDHA*, *SDHB*, *SDHC*, *SDHD*, *TMEM127*, and *VHL* genes (NGS in PPGL (NGSnPPGL) Study Group *et al.*, 2017).

Particularities of the Diagnosis and Follow-Up of Inherited PPGL

Personalized Management

Hereditary PPGL is a very rare disease that is likely to recur or to develop into other lesions or metastases. For the best possible outcome, a personalized approach is currently recommended, developed for individual patients by a multidisciplinary team from a specialist center with appropriate expertise (Lenders *et al.*, 2014).

Molecular Classification of PPGL

The comprehensive multiomics profiling studies on large PPGL collections carried out by the COMETE and ENSAT networks in Europe, and by The Cancer Genome Atlas (TCGA) in the United States identified well-defined PPGL subtypes based on mutational status and strongly associated with specific tumorigenic pathways. Unsupervised hierarchical clustering separates PPGL into two main clusters: a "pseudohypoxic" (cluster 1) and a "MAP kinase signaling" cluster (cluster 2). Cluster 1 comprises two different subtypes: cluster 1A and 1B. Cluster 1A contains all tumors due to mutations of genes (*SDHx*, *FH*, *MDH2*, *SLC25A11*, *GOT2*) encoding proteins of the tricarboxylic acid (TCA) or Krebs cycle. Briefly, the inactivation of these enzymes or transporters unbalances the succinate/oxoglutarate ratio in the cell, leading to the inhibition of prolyl hydroxylases, and DNA and histone demethylases. Both these phenomena lead to inappropriate angiogenesis in presence of a normal oxygen concentration in the cell, and the occurrence of an epithelial–mesenchymal transition favoring oncogenesis. Cluster 1B consists principally of PPGL caused by germline or tumoral *VHL* mutations. Like mutations of TCA cycle enzyme genes, *VHL* mutations impair the normal degradation

of the VHL protein by prolyl hydroxylases, leading to HIF protein stabilization and constitutive activation of the hypoxic-angiogenic pathway. All other PPGL of genetic origin belong to cluster 2, and are due to mutations of genes involved in MAP kinase and/or mTOR/AKT signaling (Dahia, 2014). Somatic mutations of *NF1*, *RET*, *MET*, and *H-RAS* have been found in sporadic PPGL classified into cluster 2 (Burnichon *et al.*, 2016). Physicians need to be aware of the biological differences between the two categories of PPGL, and should take these differences into account to ensure the correct management of their patients.

Biochemical Testing

The first step in the processing of catecholamines is the conversion of tyrosine into dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase. DOPA decarboxylase then converts DOPA into dopamine, dopamine beta-hydroxylase converts dopamine into norepinephrine and, finally, phenylethanolamine *N*-methyltransferase (PNMT) catalyzes the production of epinephrine from norepinephrine (**Fig. 3**). Studies of the transcriptome and methylome have shown that the expression of *PNMT* is downregulated in cluster 1-related PPGL, due to the hypermethylation of its promoter (Letouzé *et al.*, 2013). Consequently, PPGL due to mutations of TCA cycle or *VHL* genes cannot produce epinephrine. Thus, in cases of PPGL producing norepinephrine or dopamine, mutations of one of the TCA cycle genes or of *VHL*, should be suspected. By contrast, tumors with mutations of *NF1*, *RET*, or *TMEM127* can process catecholamines to their end product, epinephrine, and may be revealed by a severe catecholamine crisis.

Imaging

The European Association of Nuclear Medicine, the Society of Nuclear Medicine, the Endocrine Society and the European Society of Endocrinology have proposed guidelines and clinical algorithms for the imaging of PPGL according to genetic status (Taïeb *et al.*, 2012). It has been clearly demonstrated that (^{18}F-FDG) PET/CT is the best first-line imaging technique for patients with *SDHB* mutations, because *SDHB*-related primary PPGL and metastases are characterized by a high glucose uptake (Timmers *et al.*, 2007). For somatostatin receptor imaging, the prospective multicenter PGL.EVA study established in 2013 that a combination of ^{111}In-pentreotide scintigraphy with thoraco-abdomino-pelvic computed tomography and head and neck magnetic angiography had a sensitivity of 91.7% with local assessment, or of 98.6% with expert centralized image assessment, for the diagnosis of *SDHx*-related PPGL (Gimenez-Roqueplo *et al.*, 2013). The clinical approval and availability of new tracers differ between countries, but recent studies have suggested that ^{18}F-DOPA and ^{68}Ga-DOTATATE PET/CT are more sensitive than conventional imaging methods and should be used, in particular, for complete tumor staging before therapy (surgery or radiotherapy) in patients with an SDHx-related PPGL (Marzola *et al.*, 2014; Jha *et al.*, 2017).

Treatment

The main features of genetically determined forms are the risk of recurrence or of a new PPGL at the same site or in a different area, the risk of malignancy, particularly in patients with mutations of genes encoding TCA cycle proteins and the risk of other syndromic lesions. For all these reasons a multidisciplinary team should tailor the treatment to the patient.

Single PPGL

Surgery, performed by a specialist anesthetic and surgical team, is usually indicated in patients with a genetically determined PPGL present as a first, single, catecholamine-producing tumor.

Decisions about surgery for head and neck PGL depend mostly on tumor location, tumor burden, and the risk of neurological deficits after surgery. Radiotherapy (external, proton beam therapy or gamma knife radiosurgery) is an alternative approach.

Metastatic PPGL

Most PPGL are caused by a germline or somatic mutation in a single PPGL susceptibility gene. Thus, PPGL patients with hereditary metastatic disease should benefit from precision medicine based on the molecular genomic profiles of their tumors. For example, a large proportion of metastatic PPGL belong to the "pseudohypoxic" cluster 1, and randomized trials are currently underway to

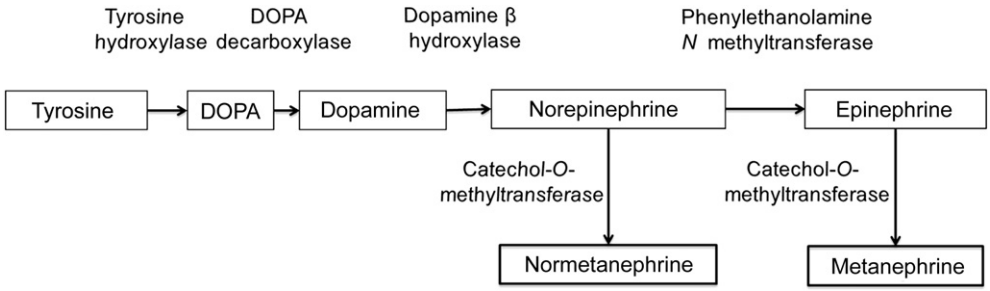

Fig. 3 Synthesis and metabolism of catecholamines.

assess antiangiogenic therapies for progressive malignant PPGL. A retrospective study recently reported that temozolamide was effective against SDHB-related metastatic PPGL, due to silencing of the *O*-6-methylguanine-DNA methyltransferase (MGMT), which normally repairs the DNA damage induced by alkylating chemotherapy, by hypermethylation of the promoter of *MGMT* gene (Hadoux *et al.*, 2014). PPGL genetic testing and molecular profiling would be expected to favor the development of personalized medicine for PPGL in routine practice, potentially improving the prognosis of genetically determined metastatic PPGL (Favier *et al.*, 2014).

Follow-Up

Life-long annual follow-up

Patients with a genetic form of PPGL have a 17% risk of a new event. Life-long annual follow-up is recommended and should include at least blood pressure determination and biochemical testing (Plouin *et al.*, 2016). Cervical and thoraco-abdomino-pelvic MRI should be performed regularly for the detection of nonsecreting PPGL. Imaging methods involving the use of ionizing radiation should be limited during follow-up and restricted to screening for new tumors suspected or detected on the basis of biochemical analysis and/or magnetic resonance imaging (Lenders *et al.*, 2014; Plouin *et al.*, 2016). A disease-specific surveillance program should also be carried out.

Screening and follow-up of relatives

Evidence for a genetically determined PPGL in an index case should lead to all first relatives at risk (taking into account the specific model of inheritance and age at diagnosis) being offered presymptomatic genetic testing, with specific screening for the familial mutation in DNA extracted from leukocytes. Genetic counseling should be offered to all subjects at risk, both before and after testing. Positive genetic tests should lead to the organization of screening to detect small tumors and/or other syndromic lesions and the implementation of specific follow-up (**Table 5**).

Table 5 First screening and life-long follow-up of mutation carriers

Genes	*First screening and life-long follow-up of mutation carriers*
NF1	– Physical examination with blood pressure monitoring every year – Annual metanephrines (plasma free or fractionated urinary) determination – Annual ophthalmologic examination – If patient has hypertension or abnormal metanephrines levels: abdominal MRI (or CT scan)
RET	– Physical examination with blood pressure monitoring every year – Annual metanephrines (plasma free or fractionated urinary) determination – Annual plasma calcitonin determination – Abdominal MRI (or CT scan) at first screening and then, only if hypertension or abnormal metanephrines levels occur during follow-up
VHL	– Annual physical examination with blood pressure monitoring – Annual metanephrines (plasma free or fractionated urinary) determination – Annual ophthalmologic examination – Abdominal-pelvic MRI every 2 years and renal ultrasound every other year – MRI scan of head + spine every 2 years
TCA cycle	– Annual physical examination (+ gynecological and dermatological examination, for *FH* mutation carriers only) with blood pressure monitoring – Annual metanephrines (plasma free or fractionated urinary) determination – At first screening: head and neck plus thoracic-abdominal-pelvic contrast MRI or CT – At first screening: ^{18}F-FDG PET/CT, especially for patients at risk of malignancy, such as *SDHB* or *FH* mutation carriers, or ^{18}F-F DOPA PET/CT – Whole-body MRI every year or 2 years during follow-up
TMEM127 *MAX*	– Annual physical examination with blood pressure monitoring – Annual metanephrines (plasma free or fractionated urinary) determination – At first screening: head and neck plus thoracic-abdominal-pelvic contrast MRI or CT – Whole-body MRI every year or 2 years during follow-up
HIF2A	– Annual physical examination with blood pressure monitoring – Annual hemoglobin determination – Annual metanephrines (plasma free or fractionated urinary) determination – At first screening: head and neck plus thoracic-abdominal-pelvic contrast MRI or CT – Whole-body MRI every year or 2 years during follow-up

Conclusion

Our understanding of PPGL and the management of this disease have been radically modified by new insight into the genetics of PPGL obtained over the last 20 years. PPGL is now considered to be the neuroendocrine tumor most strongly affected by genetics. PPGL management is going to shift from classical approaches to personalized medicine tailored to the patient and driven by the genetic status and molecular profile of the tumor. Patients with PPGL should be managed by specialized multidisciplinary expert centers endowed with the different skills required to deal with the rarity and complexity of the different subtypes of this disease.

Renin and Prorenin

Alberto Morganti, Centro Fisiologia Clinica e Ipertensione, Policlinico Hospital, Milan, Italy and University of Milan, Milan, Italy

Abbreviations

11 β-HSD2 11 β-hydroxysteroid dehydrogenase
ACE Angiotensin converting enzyme
AI Angiotensin I
AII Angiotensin II
Ang 1–7 Angiotensin 1–7
AT 1-AT2 Angiotensin II receptors
HRP Handle regional peptide
JGA Juxtaglomerular apparatus
JGC Juxtaglomerular cells
PRA Plasma renin activity
PRC Plasma renin concentration
PRR (Pro)renin receptors
RAS Renin–angiotensin–system
RVH Renovascular hypertension
SNS Sympathetic nervous system

History

In 1898 the Finnish physiologist Robert Tigerstedt and his Swedish assistant Gustav Bergman observed that the injection of rabbit kidney extracts in the jugular vein of rabbits induced marked elevation in blood pressure. They attributed this pressor effect to a renal substance that for brevity they decided to name "renin." However in the following years several investigators failed to reproduce their findings that thereafter were neglected to the point that in Tigerstedt's obituary the discovery of renin was not even mentioned among his scientific achievements. However some 30 years later Volhard and Hessel reported their experiments in which normal dogs injected with blood from ischemic kidney developed hypertension. In 1927 John Loesch was the first to propose the mechanisms whereby renal ischemia may raise blood pressure. In the early 1930s, Harry Goldblatt developed if famous canine model of hypertension by means of renal ischemia, a prototype of human renovascular hypertension, fueling the interest toward the kidney as a source of pressor agents. In the following two decades all the components of the renin–angiotensin–system (RAS) were purified and sequenced setting the stage for the opening of one the most exciting and rewarding area of basic and clinical research in medical history.

Components and Functions of the RAS

Renin, an aspartyl protease, is the first rate limiting step of the RAS in that it catalyzes the conversion of angiotensinogen, the renin substrate produced and secreted by the liver, to a decapeptide called angiotensin I (AI). AI has no biological action by itself but is the substrate of another endothelial cell-associated peptidase, ubiquitous in the body but primarily localized in pulmonary vasculature, called angiotensin converting enzyme (ACE). ACE cleaving the terminal dipeptide of AI generates angiotensin II (AII) the octapeptide final effector of the system (Sparks *et al.*, 2014) (**Fig. 1**). An isoform of angiotensin converting enzyme called ACE2 catalyzes the conversion of AI to the eptapeptide angiotensin 1–7 (ANG1–7). Angiotensin II actions are exerted through the binding to a family of surface trans-membrane receptors widely distributed in the body, the best known for their effects being the type 1 and type 2 angiotensin II receptors (AT 1 and AT2) whereas ANG1–7 binds to surface MAS receptors. Activation of AT1 results in contraction of vascular smooth muscle cells with increase in peripheral vascular resistance and elevation in blood pressure. These effects are partially counterbalanced by AT2 and ANG1–7 mediated vasodilation. In addition to the regulation of vascular tone AII stimulates sodium reabsorption directly in the distal convoluted tubules of the nephron and, indirectly, augmenting the production from the adrenal cortex of aldosterone, the most potent mineralocorticoid hormone that regulates the sodium–potassium exchange in the collecting tubules. Also, AII enhances the activity of peripheral sympathetic nervous system (SNS) and, interacting with vasopressin, regulates thirst perception in the central nervous system. Because of all these interconnected actions the RAS is indisputably considered a major player in the regulation of blood pressure, sodium balance and body fluid homeostasis.

The scientific and clinical interest for RAS increased exponentially in the last decades because of the overwhelming amount of pathophysiological studies supporting the notion that an excessive activation of RAS via proinflammatory and prothrombotic actions has a mechanistic role in causing cardiovascular and renal damages beyond and above those induced by blood pressure elevation. This knowledge was further reinforced by the results of many randomized controlled studies proving the beneficial effects of RAS blockade on morbidity and mortality in highly prevalent and ominous pathological conditions such as primary and secondary hypertension, diabetes, coronary artery disease, heart failure and chronic kidney disease.

Site of Prorenin–Renin Production and Processing

The kidney is the only source of circulating renin since after bilateral nephrectomy renin is undetectable in blood whereas prorenin, the renin precursor, is also produced by numerous organs including the adrenal gland, testis, placenta and eye. In the kidney renin is synthetized by the juxtaglomerular cell (JGC), specialized epithelioid cells located along the length of the afferent arterioles just at the entrance of the glomerulus. JGC are part of the juxtaglomerular apparatus (JGA) in close contact with the macula densa cells of the ascending limb of the upper nephron that also have the capacity of producing renin (**Fig. 2**). In human JGC the primary transcript of the renin gene located in chromosome 1 is preprorenin that is converted to prorenin in the endoplasmic reticulum. Following glycosylation in the Golgi apparatus prorenin is either secreted by a constitutive pathway or is proteolytically converted to active renin. Active renin is stored in cytoplasmic vesicles ready to be released in response to regulatory stimuli. Cyclic AMP and calcium are the key factors in the intracellular regulation of renin exocytosis with counterbalancing effects in that cyclic AMP stimulates renin release whereas calcium, at variance with other secretory cells, inhibits it. The explanation recently proposed to explain this "calcium paradox" is that in JGC calcium accelerates cyclic AMP degradation via the activation of a calcium calmodulin dependent phosphodiesterase 1C (Ortiz-Capisano *et al.*, 2009).

Regulation of Renin Secretion

Renin secretion and synthesis are dissociated in time in that the secretion in response to an acute stimulus occurs in minutes whereas the increase in synthesis requires hours to take place. However these different time-course of response are unlikely to become a problem because the intracellular stores of renin are large enough to cope even with intense and prolonged stimuli. Also, under conditions of intense homeostatic stress such as profound dehydration, sodium depletion, blood loss, low pressure or prolonged pharmacological blockade of the RAS, the JGC increase in number (hyperplasia) to provide enough renin to reestablish blood pressure and volume. Whenever the disequilibrium persists other cells of JGA, like the vascular pericytes and mesangial cells, are recruited to synthetize renin reassuming the phenotype of fetal life (Gomez and Sequeira-Lopez, 2016).

Renin secretion is under the control of a number of factors (Kurtz, 2011). A fast rise in systemic blood pressure inhibits renin secretion via the direct effect of increased perfusion pressure on preglomerular vessels while circulating renin increases within minutes after a sharp fall in pressure. Augmented intake of dietary sodium chloride with attendant increase in urinary sodium excretion suppresses renin secretion from the macula densa cells that, vice versa, are stimulated by sodium depletion. Any increase in circulating catecholamines, either released from nerve endings or from adrenal medulla cause an increase in renin secretion through the activation of beta 1 adreno-receptors. In man even mild sympathetic stimulation such as that occurring in response to assumption of upright posture doubles plasma renin within 15 min (Morganti *et al.*, 1979). Sympathetic discharge of renal nerves also affects JGC cells number that is halved by renal denervation. Renin secretion is in itself controlled by a short-loop negative feed-back mechanism exerted by AII through the AT1 located in the JGC. Finally renin production is controlled by numerous humoral factors of endothelial (nitric oxide, prostaglandins) and cardiac (natriuretic peptides) origin.

(Pro)Renin Receptors

Plasma concentration of prorenin is on average 10-fold higher than that of active renin and in some body fluids such as the amniotic fluid or the vitreous fluid of patients with diabetic retinopathy even 100-fold higher (Campbell, 2008). However prorenin is enzymatically inactive because a 43 amino acid N-terminal peptide (prosegment) obliterates the pocket where angiotensinogen is cleaved to generate AI. Inside the JGC prorenin is proteolytically converted to active renin but there is no evidence of such conversion in plasma or extrarenal tissues. Thus it was unclear how prorenin could contribute to AII production. However 15 years ago the seminal paper by Nguyen *et al.* (2002) demonstrated the existence of specific (pro)renin receptors (PRR) expressed in the kidney, heart, brain, liver, coronary vessels, and placenta. Moreover these authors reported that upon binding to PRR prorenin undergoes a conformational change that spatially removing the prosegment exposes the catalytic pocket of renin making possible the local formation of AII. In addition they showed that the (pro)renin binding to PRR activates the intracellular signaling pathways in a parallel but distinct way from that of circulating AII. These findings triggered a decade of intense research aimed at clarifying whether and how PRR have a pathophysiological meaning. To this aim a peptide antagonist of the "handle" region of the prosegment (HRP) was developed to assess the effects of preventing the binding of prorenin and renin to PRR. Overall studies with HRP in diabetic and hypertensive animal models yielded conflicting results but it became clear that the micromolar concentration of HRP used in these investigations were well above those reached by (pro)renin at tissue level even in extreme pathological conditions. In last years the research on this topic turned to examine the possible actions of PRR not related to those of RAS. Preliminary results suggest that PRR may participate in embryonic development interacting with the β catenin signaling pathway, in the intracellular acid–base regulation via the action on the V-ATPase system and in the lipoprotein and energy metabolism. The forefront advances in PRR were recently reviewed (Sun *et al.*, 2017).

Growth Defects Associated With Genetic Manipulations of RAS

A large body of evidence from animal studies suggests that RAS is important also for the development during fetal life. Indeed genetic manipulations of RAS lead to severe growth defects in several organs and particularly in the kidney. In mice deletion of the renin gene causes dilation of the renal pelvis, interstitial fibrosis and arteriolar hypertrophy. Similar renal phenotypes were described in mice deficient of angiotensinogen, ACE and angiotensin receptors. These animals also have hypotension and, if males, reduced fertility. Mice lacking ACE2 display reduced cardiac contractility that makes them prone to heart failure while mice lacking the adrenal aldosterone receptors become hyponatremic and hypotensive. In general all these animals survive shortly after birth. In line with these observations it has been repeatedly reported that sheep treated with RAS blockers have a significantly higher rate of abortion than controls sheep. Accordingly guidelines recommend not to treat pregnant women with RAS antagonists, particularly in the early stages of gestation (Mancia *et al.*, 2013).

Also the genetic alterations of PRR are associated with severe malformations or dysfunctions. PRR deletion in mice causes heart failure and loss of lysosomes in smooth muscle cells. In addition PRR knockout is associated with reduction of lipoprotein receptor protein and impaired adipogenesis. Studies in man are limited. However hyperexpression of PRR was found in kidney biopsy samples from patients with chronic kidney disease and in the adipose tissue of insulin resistant obese women.

How to Measure Renin and Prorenin

For more than half a century renin was measured as plasma renin activity (PRA) as a substitute of AII because the very low blood concentration of this short peptide (in the order of few picograms/mL) made its quantification with radioimmunoassay (RIA) quite difficult. PRA instead exploits the capacity of renin to generate, during an incubation step carried out at 37°C and pH 5.7 –6.0, sufficient amounts of AI to be quantified with RIA. Moreover increasing the duration of the incubation step from the conventional 3 h up to 18 h makes the PRA assay suitable to determine the renin levels also when its circulating concentrations are extremely low (Sealey *et al.*, 2005). The basic assumption for using PRA as an index of RAS activity "in vivo" is that angiotensinogen concentration is not altered to the point of changing the kinetics of the renin–renin substrate reaction. This may occur in patients with advanced liver insufficiency, a disease in which the production of angiotensinogen is reduced and in pregnancy where angiotensinogen is markedly augmented. Except in these conditions and provided subjects are not on treatment with drugs interfering with RAS (see below), PRA values are quite strictly correlated with those of AII. Values of PRA, being an enzymatic assay, are expressed in ng AI mL^{-1} h^{-1}.

However PRA is a complex method with several drawbacks, the most relevant being the poor reproducibility among laboratories. The availability of monoclonal antibodies raised against specific epitopes of the renin molecules has made possible the direct quantification of plasma renin as mass concentration (PRC) with immunometric or immunochemiluminescent methods (Perschel *et al.*, 2004). In brief plasma samples are incubated with a capture antibody against both prorenin and renin and with a second antibody specific for active renin conjugated with a radioactive or acridinium tracer. After separation of the" sandwich" immunocomplexes with streptavidin magnetic beads followed by washing of the unbound tracer the radioactive counts or the light signal generated by the addition of a trigger solution are directly proportional to the concentration of renin. Values of PRC are usually expressed in mU mL^{-1} or pg mL^{-1}. These new assays are calibrated against the International Standard Reference Preparation of Renin and their reproducibility among laboratories is greater than that of PRA. (Morganti *et al.*, 1995). In normal conditions PRA and PRC are well correlated except in the very low range. Both PRA and PRC assay can be used to measure prorenin. Prorenin values are calculated subtracting those obtained after the exposure of plasma to the procedures of prorenin activation (irreversible proteolysis with trypsin or reversible unfolding of prosegment with acid or prolonged cold exposure) to those measured before these procedures.

When to Measure Renin

Evaluation of plasma renin is advisable whenever patients have clinical signs suggestive of secondary forms of hypertension (young age, abdominal vascular bruits, low serum potassium, worsening of renal function particularly if during treatment with RAS antagonists, advanced atherosclerosis, kidney asymmetry). In patients with renovascular hypertension (RVH) due to a fibromuscular dysplasia or to an atherosclerotic stenosis of the renal arteries (RAS), usually greater than 80% of vessel diameter, JGC are stimulated to increase renin secretion by the reduction in renal blood flow. In RVH the vascular and cardiac damages caused by the increments in plasma renin and plasma aldosterone contribute to aggravate those due to high blood pressure. However high renin values are not exclusive of RVH. Indeed hyperreninemia is found also in patients with malignant hypertension and in about 20% of those with benign essential hypertension. A high renin profile in relation to 24 h sodium excretion is also found in patients with JGC tumor. At variance with RVH in these rare cases also prorenin is very high as well as in other forms of renal or extrarenal cancers. In JGC tumor the imaging of renal arteries excludes the presence of RAS while the measurement of PRA or PRC in blood collected from the renal veins confirms the lateralization of renin secretion from the suspected side. A similar pattern of renin secretion can be seen in patients with renal infarction where the ischemic process mimics the effects of a tight RAS. High renin levels can also be found in patients with catecholamine secreting tumors (pheochromocytoma and paragangliomas) and in immunological diseases associated with renal vasculitis.

On the other side of the spectrum renin secretion is suppressed and not responsive to physical or pharmacological stimuli in patients with primary aldosteronism. In these cases JGC are silenced by the expansion of body fluids caused by the excess of aldosterone production that can be due either to adrenal hyperplasia or to an adenoma. Recent guidelines recommend the evaluation of aldosterone to renin ratio (ARR) as firs step for the diagnosis of primary aldosteronism (Funder *et al.*, 2016). Suppressed renin and high aldosterone are also observed in the less frequent cases of familial ACTH dependent aldosteronism. A clinical condition that mimics primary aldosteronism but is characterized by very low levels of renin and aldosterone is the apparent mineralocorticoid excess (AME) syndrome. This syndrome is due to mutations in the gene that encodes for 11 β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), the enzyme that metabolizes cortisol to inactive cortisone thus preventing cortisol binding to mineralocorticoid receptors (MR). Because of this mutation inactive forms of 11β-HSD2 are produced allowing the binding of cortisol to MR that, in turn, results in increase sodium and water reabsorption in the kidney, volume expansion, hypertension and suppression of renin and aldosterone secretion. AME syndrome is usually diagnosed in early childhood being associated with low birth weight and growth retardation. In adults the alterations in renin and aldosterone profiles seen in AME syndrome are reproduced by prolonged ingestion of licorice because the glycyrrhizinic acid contained in licorice is a potent inhibitor of 11-β-HSD2. Liddle syndrome is also associated with hypertension and renin and aldosterone suppression, in this case due to mutation of a subunit of the epithelial sodium channel of distal renal tubules, resulting in increased sodium reabsorption

and potassium loss. Spirolactone has little effect in patients with Liddle syndrome whereas they respond well to amiloride or triamterene.

How Drugs Interfere With RAS

The majority of drugs commonly used for treatment of cardiovascular and renal diseases profoundly interfere with renin secretion and their effects often take several weeks to wear off. Thus when assessing RAS activity ideally all medications should be discontinued at least for a fortnight. RAS antagonists blocking AII formation (renin and ACE inhibitors) or its action at receptor level (ARBs) increase renin secretion interrupting the negative short-loop feed-back exerted by AII on JGC. It is important to recall that during treatment with ACEs or ARBs PRA and PRC increase in parallel whereas diverge during treatment with renin inhibitors because PRA measuring the enzymatic activity of renin is reduced by these drugs whereas PRC measuring the concentration of renin molecules is increased. These changes in opposite directions of PRA and PRC are useful to assess whether the blockade of AII production is actually achieved. It is also worth mentioning that during treatment with any of the RAS antagonists plasma aldosterone should decrease as a consequence of the abolished AII stimulation. However, quite unexpectedly, it was found over and over that during treatment with all RAS antagonists, even when combined and irrespective of the doses, in about 50% of patients PAC levels return toward the baseline values and, occasionally, even above those (Bomback and Klemmer, 2007). This phenomenon often referred to as "aldosterone escape" or "aldosterone breakthrough" has clinical relevance in that it may explain why in some patients RAS antagonists are less efficacious than expected.

Loop and distal tubule diuretics as well as aldosterone receptor antagonists stimulate renin secretion through the increased sodium load to the macula densa cells while direct vasodilators like hydralazine stimulate JGC to increase renin release via the fall in systemic and preglomerular blood pressure and the attendant reflex increase in SNS. Among the vasodilators the calcium channel blockers and the alpha adrenergic receptors blockers are the only compounds with little, if any, effect on renin secretion and for this reason are preferentially used in patients who cannot discontinue treatment when undergoing plasma renin measurement.

Blockers of the $\beta 1$ adrenergic receptors (BB) as well as central sympatholytic agents like clonidine markedly suppress renin secretion abolishing the nerve mediated component of its release. The degree of the suppressive effect of BB depends on the partial agonistic action of each compound. It is important to recall that discontinuation of BB is particularly important when assessing the aldosterone to renin ratio (ARR) because these drugs suppress renin to a greater extent than aldosterone causing falsely high ARR values and potentially misleading diagnosis of primary aldosteronism.

Angiotensinogen and Angiotensins

Massimo Volpe and Speranza Rubattu, Sapienza University, Rome, Italy and IRCCS Neuromed, Pozzilli, Italy

Abbreviations

AGT	Angiotensinogen
ACE	Angiotensin converting enzyme
Ang I	Angiotensin I
Ang II	Angiotensin II
ASO	Antisense oligonucleotides
AT1R, AT2R	Angiotensin II type 1 and type 2 receptors, respectively
DPP III	Dipeptidyl peptidase III
MAPK	Mitogen-activated protein kinase
MLDAD	Mononuclear leukocyte-derived aspartate decarboxylase
MrgD	Mas-related G-protein–coupled receptor, member D
NF-κB	Nuclear factor kappa-light-chain-enhancer of activated B cells
RAS	Renin–angiotensin system
SHP-1	Src homology (SH) 2 domain-containing tyrosine phosphatase-1
SNP	Single nucleotide polymorphism

Glossary

Case-control association studies A population-based genetic approach able to compare the allele/genotype distribution of a certain DNA variant in cases versus controls. The prevalence of a variant nucleotide within the DNA sequence in diseased individuals compared to unaffected subjects can help to establish the role of a certain gene into the pathogenesis of a selected disease.

Chromosome 1q32.1 It indicates that the renin gene maps on chromosome 1, on the long (q) arm of the chromosome in a region designated q32.1.

Chromosome 1q42.2 It indicates that the AGT gene maps on chromosome 1, on the long (q) arm of the chromosome in a region designated q42.2.

***Cis*-acting DNA regulatory elements (CRE)** Are regions of noncoding DNA which regulate the transcription of nearby genes. CREs are found in the vicinity of the genes that they regulate. CREs typically regulate gene transcription by functioning as binding sites for transcription factors.

Genetic polymorphisms The term refers to a variation of the standard DNA sequence of a gene, that is, a single base substitution. The gene sequence variation can be used, as a gene marker, for population-based genetic investigations.

hypoAGT mouse model A mouse model carrying a whole body reduction of AGT obtained by placing 3 LoxP sites encompassing exon 2 of the mouse AGT gene and a neo cassette in intron 2.

In vitro site-mutagenesis study By using this method, a mutation can be created at any specific site in a gene whose wild-type sequence is already known. As a result, the effects of specific amino acid changes in a protein can be learned, relative to the protein from the wild-type gene. The resulting structural changes may then be linked to observed changes in function, stability, and/or activity of the protein.

Mice with human AGT and renin transgenes A genetically modified mouse model overexpressing both human AGT and renin genes.

Renovascular hypertension A secondary form of hypertension explained by an atherosclerotic plaque causing a stenosis of the main renal artery or of one of its branches. The resulting renal ischemia activates the RAS with consequent excess of renin, Ang II, and aldosterone production.

Whole-body AGT-deficient mice A genetically modified mouse model carrying a whole body AGT gene deletion (AGT knock-out).

Renin–Angiotensin System Components

The renin–angiotensin system (RAS) represents an important endocrine system in view of its multiple regulatory properties on sodium and water homeostasis as well as on the functions of heart and blood vessels (Ferrario, 1990). Besides its hormonal actions, the RAS has also paracrine and intracrine functions within tissues in multiple organs. Renin, the rate limiting enzyme of the cascade, is a highly specific endopeptidase that generates angiotensin I (Ang I) from the cleavage of angiotensinogen (AGT). Ang I, in turn, is the substrate for angiotensin converting enzyme (ACE) (a kininase II enzyme) to generate angiotensin II (Ang II) (Ferrario, 1990). The renin gene is localized on the human chromosome 1q32.1. It encodes a 406 amino acids long peptide, called prorenin. A 43 amino acids long prosegment covers the cleavage site of the molecule making prorenin inactive. Prorenin becomes activated when the prosegment is cleaved by proteases such as trypsin, kallikrein, cathepsin B, D, and G (irreversible activation) (Sealey and Rubattu, 1989; Pitarresi *et al.*, 1992). On the other hand, both low temperature and low pH lead to a reversible activation of prorenin (Pitarresi *et al.*, 1992). Most importantly, the discovery of the renin receptor led to the observation that prorenin becomes reversibly activated by the binding to the receptor (Jan Danser *et al.*, 2007). Renin is highly expressed in the juxtaglomerular apparatus of the kidneys, where it is stimulated by the β-adrenergic system, by reduced sodium delivery to the

macula densa and by increased cAMP levels (Persson, 2003). Higher blood pressure levels, high sodium concentrations, as well as elevated levels of Ang II and of calcium concentration inhibit the renin release. Apart from the kidney, the renin gene is expressed in the heart, brain, adrenal glands, and the reproductive organs where it exerts local regulatory functions (Persson, 2003). The renin released from the kidneys circulates in the body.

The classical view of the RAS includes prorenin/renin/AGT/Ang I/ACE/Ang II/AT1R-AT2R, with AT2R playing opposing effects to those exerted by AT1R. In fact, AT2R activation leads to vasorelaxation, as opposed to AT1R-induced vasoconstriction (Ferrario, 1990). Importantly, a cross-talk between the two Ang II receptors has been documented (Gigante *et al.*, 1997; De Paolis *et al.*, 1999).

Our knowledge on the RAS has been progressively increased over the years with the discovery of important additional components, such as AGT and derived angiotensins, with additional novel functions in selected tissues.

Angiotensinogen

The binding of renin to the renin receptor increases the catalytic activity of renin on AGT. The latter is the only substrate of renin and is mostly synthetized, in a constitutive manner, from the liver (Lynch and Peach, 1991; Nakagawa *et al.*, 2007; Campbell and Habener, 1986). Renin is a negative regulator, whereas Ang II is a positive regulator of liver AGT synthesis. Multiple putative *cis*-acting DNA regulatory elements, including glucocorticoids, estrogens, and acute phase responsive elements, are located within a region of 1 kb that is immediate upstream of the human AGT gene (Fukamizu *et al.*, 1990; Tewksbury *et al.*, 1978). As a consequence, dexamethasone and estrogens are positive regulators of AGT synthesis in the liver. In fact, plasma AGT concentrations increase during glucocorticoid administration, during pregnancy, and upon synthetic estrogen administration with oral contraceptives (Deschepper, 1994). Although structurally resembling a serin protease inhibitor (SERPIN), AGT is a noninhibitory SERPIN. The gene is located on human chromosome 1q42.2 and includes five exons and four introns (Isa *et al.*, 1990; Gaillard *et al.*, 1989). Human AGT has 485 amino acids, including a 33 amino acids long signal peptide. The 10 N-terminal amino acids are cleaved by renin to provide Ang I, which is the source for an array of active angiotensin peptides (see section later). Although the sequence of AGT protein is highly variable among species, the sequence of the 10-N-terminal amino acids corresponding to Ang I is relatively conserved (Streatfeild-James *et al.*, 1998). Human AGT protein contains four putative sites for N-linked glycosylation (Asn-X-Ser/Thr): Asn14, Asn137, Asn271, and Asn295. In vitro site-mutagenesis studies demonstrated that all four sites can be glycosylated, with preference at Asn14 and Asn271. Asn14 is close to the renin cleavage site (Leu10–Val11), and its glycosylation has been demonstrated to lower the affinity of AGT for renin (Gimenez-Roqueplo *et al.*, 1998). Interestingly, an intermolecular disulfide bond at positions 18 and 138 of human AGT (Cys18–Cys137 in the mice protein) is very much conserved across species and is predicted to expose the N-terminus of AGT by a redox-dependent mechanism (Zhou *et al.*, 2010). Renin cleavage efficacy can also be facilitated by interactions with domains beyond the N-terminal amino acids of AGT. In addition, the cleavage of AGT by renin is highly species specific.

The removal of Ang I from AGT leaves a protein termed des(AngI)AGT which exerts direct biological effects on renal function, blood–brain barrier, angiogenesis, adipose expansion, and liver steatosis (Lu *et al.*, 2016a; Wu *et al.*, 2011).

Genetic manipulations helped to clarify the roles of AGT. Whole-body AGT-deficient mice show low neonatal survival rate, impaired growth and renal development, and low blood pressure levels. Interestingly, mice with human AGT and renin transgenes also have less body weight gain compared with their wild-type controls, although these mice have increased AGT and renin expression, resulting in increased Ang II production. Therefore, the lean phenotype of these two mouse models cannot be explained by changes of Ang II production (Massiera *et al.*, 2001).

Interestingly, a whole-body reduction of AGT (hypoAGT mouse model) did not compromise neonatal survival rate, general growth, and kidney development. Unexpectedly, these mice have diminished body weight gain and liver steatosis when they are fed a diet that has a fat content (42% kcal from saturated fat) similar to the average dietary composition of Western nations (Lu *et al.*, 2016b).

The effects of AGT inhibition have been also explored using antisense oligonucleotides (ASO). ASO against AGT reduces intact AGT and des(AngI)AGT leading to reductions of total AGT (Wu *et al.*, 2011). Inhibition of AGT not only reduces blood pressure levels and atherosclerosis but also diminishes body weight gain. In agreement with AGT inhibition, renin inhibition reduces blood pressure and atherosclerosis; however, it has no effect on diet-induced obesity. These findings support the concept that AGT has both Ang II-dependent and -independent functions. The latter are yet to be understood.

Mouse studies have demonstrated that hepatocyte-derived AGT is a major functional component, with all studies reporting pronounced decrease in blood pressure in the model of hepatocyte-specific AGT depletion (Wu *et al.*, 2011). Moreover, mice with hepatocyte-specific, but not kidney-specific, depletion of AGT have diminished AGT accumulation in kidney proximal convoluted tubules (Wu *et al.*, 2011). These findings provide direct evidence that hepatocytes are the primary source for AGT production and functions in vivo.

Adipocytes can also synthetize AGT (Jones *et al.*, 1997). To determine the role of adipocyte-derived AGT, adipocyte-specific deletion of AGT was produced in mice with an initial evidence of reduction in plasma concentrations by 24%–28%, accompanied by reductions of blood pressure in the absence of effects on body weight, fat mass, adipocyte size, or glucose homeostasis (Jones *et al.*, 1997). Since no consistent findings were obtained in other studies, it is concluded that the adipocyte-derived AGT has modest or no discernable effects on obesity and blood pressure in mice.

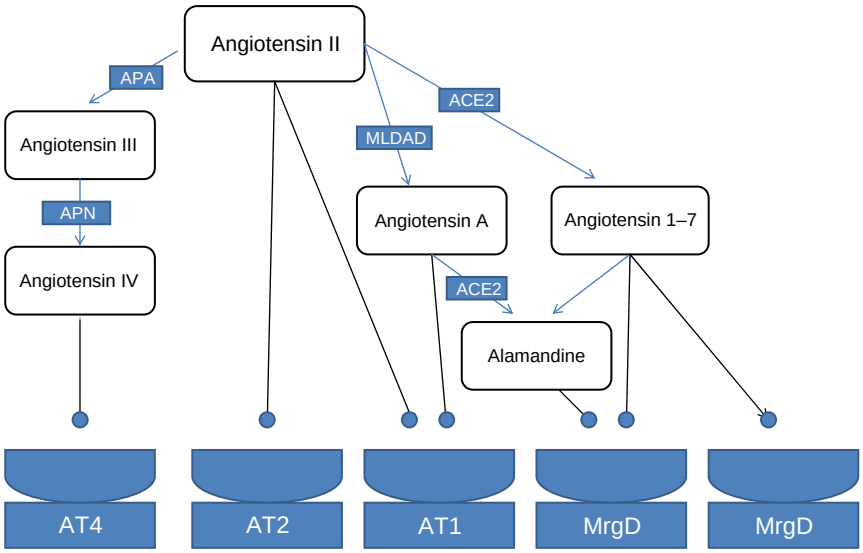

Fig. 1 Schematic representation of Ang II processing. Ang III is produced by aminopeptidase A (APA), and subsequently Ang IV is produced by aminopeptidase N (APN); Ang (1–7) is released by ACE2. Both Ang (1–7) and angiotensin A are precursor peptides of alamandine. The main receptors mediating the effects of the known angiotensins are represented.

Interestingly, the AGT gene has been explored in humans in relation with hypertension, obesity, and atherosclerosis through the investigation of genetic polymorphisms (single nucleotide polymorphisms, SNPs) in case-control association studies. In fact, genetic association studies have shown a significant association of M235T gene variant (that is related with plasma AGT concentrations (Corvol *et al.*, 1997)) with obesity in female hypertensive patients of different populations, although this variant failed to display any correlation in males (Procopciuc *et al.*, 2010; Cooper *et al.*, 1997). Controversial findings were also reported with regard to plasma AGT levels and obesity (Wu *et al.*, 2011). These inconsistent results support the experimental evidence that adipose-derived AGT is not a major contributor to AGT-mediated body weight changes. Two missense mutations, T174M and M235T, and multiple single-nucleotide polymorphisms, including A(-6)G and A(-20)C in the promoter region of the AGT gene, have been investigated in hypertension. However, inconsistent findings were obtained for all mentioned SNPs in association with hypertension (Jeunemaitre *et al.*, 1992; Larson *et al.*, 2000; Province *et al.*, 2000). The AGT gene has also been investigated in patients with atherosclerotic diseases. While a few studies failed to define an association of M235T with atherosclerosis, most studies demonstrated that this polymorphism was associated with atherosclerosis in different populations (Sethi *et al.*, 2003; Katsuya *et al.*, 1995). In addition to M235T, few studies have also reported that T174M, another polymorphism in exon 2 of the AGT gene, is related with risk factors or prevalence of coronary artery disease (Gardemann *et al.*, 1999). In conclusion, the causal relationship, if true, between SNPs in AGT gene and hypertension, atherosclerosis, or obesity remains to be established and the underlying mechanisms have still to be explained. Several confounding and limiting factors including small sample size, population heterogeneity, environmental and culture/ethic differences, multiple disease states, and complex interactions within the gene or with many other genes may complicate the interpretation of these AGT polymorphism studies.

Angiotensins

The cleavage of AGT by renin produces the decapeptide Ang I which is then cleaved by ACE1 to form the octapeptide Ang II, the most potent vasopressor of the RAS (Ferrario, 1990). This peptide, in turn, can be cleaved by both ACE2 to form angiotensin-(1–7) [Ang (1–7)] and by aminopeptidase A to form Ang III (angiotensin 2–8) (Ferrario *et al.*, 2010). The latter can be further processed by aminopeptidase N to obtain the exapeptide Ang IV (angiotensin 3–8) (Ahmad and Ward, 1990). ACE2 has approximately 400-fold less affinity to Ang I than to Ang II. Therefore, Ang II is the major substrate for Ang-(1–7) synthesis (Ferrario, 1990; Donoghue *et al.*, 2000; Tipnis *et al.*, 2000; Vickers *et al.*, 2002). ACE2 can also form Ang-(1–7) less efficiently through hydrolysis of Ang I to Ang-(1–9) with subsequent Ang-(1–7) formation (Vickers *et al.*, 2002; **Fig. 1**).

As a result, we now recognize the existence of four functional angiotensins: Ang II, Ang III, Ang IV, Ang-(1–7) (see **Table 1** and **Fig. 1**). Among them, Ang II, as part of the classic AGT/renin/ACE/Ang II/AT1R, is critical to maintain physiological cardiovascular, blood pressure, and renal homeostasis by the RAS. In fact, a balance between production and degradation of Ang II is of fundamental relevance to avoid cardiovascular, hypertensive, and kidney diseases. Moreover, a potential role of renin as a biomarker in cardiovascular diseases has been proposed (Volpe *et al.*, 2012).

Functions of the four angiotensins are mediated by four distinct receptors: AT1, AT2, AT4/RAP, Mas1.

Both Ang II and Ang III can bind and act through AT1 and AT2 receptors (AT1R, AT2R). However, Ang III has a preferential binding to AT2 receptor, although with a lower affinity than Ang II (Yatabe *et al.*, 2011; Kemp *et al.*, 2012). Interestingly, an AT3 receptor was reportedly cloned but it remains to be recognized (Unger *et al.*, 1996).

Table 1 Sequence of all known angiotensins

Angiotensin I	DRVYIHPFHL
Angiotensin II	DRVYIHPF
Angiotensin III	RVYIHPF
Angiotensin IV	VYIHPF
Ang-(1–7)	DRVYIHP
Alamandine	ARVYIHP
Angiotensin A	ARVYIHPF
Angioprotectin	PQVYIHPF

On the other hand, Ang IV acts on AT4/RAP (Chai *et al.*, 2004). The Mas1 is the receptor of Ang-(1–7) (Santos *et al.*, 2003). All receptors, but Mas1, are G-protein coupled receptors with seven transmembrane domains (Bader *et al.*, 2014). The AT4/RAP receptor is a transmembrane enzyme insulin-regulated membrane aminopeptidase (Chai *et al.*, 2004).

The AT1R signals through the calcium/inositol triphosphate pathway (Li *et al.*, 2006). The AT2R signals through the mitogen-activated protein kinase 1 (MAPK-1), the SHP-1, and protein phosphatase 2A that modulate the cyclic guanosine monophosphate/nitric oxide pathway (Kemp *et al.*, 2014; Carey, 2017). The AT4/RAP signals through an increase of intracellular Ca^{2+} concentration, the modulation of MAPKs, the activation of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), and production of cGMP (Albiston *et al.*, 2001). The signaling pathway of Mas1 is not yet fully understood.

The AT1R mediates vasoconstriction, thirst, release of vasopressin and of aldosterone, renal sodium reabsorption (with consequent increase of blood pressure levels), hypertrophy, proliferation and fibrosis, inflammation, angiogenesis, vascular aging, and atherosclerosis (Ferrario, 1990; Li *et al.*, 2006; Volpe *et al.*, 1995).

The AT2R mediates vasodilation, antiproliferative, antihypertrophic, antifibrotic, and antithrombotic effects (Carey, 2017; Albiston *et al.*, 2001; Matavelli and Siragy, 2015), and therefore plays opposing effects to AT1R. AT2R is mostly embryonic, with a decrease of its expression in adults where it is confined to certain organs such as the kidneys (Matavelli and Siragy, 2015). The binding of Ang III with AT2R leads to a rise of blood pressure, aldosterone release in adrenal cortex, renal and mesenteric vasoconstrictor effects that are less potent than those obtained with Ang II (Chai *et al.*, 2004). Of note, a series of studies support the hypothesis that Ang III is the predominant ligand for proximal tubule AT2 receptors and it induces natriuresis (Yang *et al.*, 2015). Interestingly, the Ang III/AT2R-dependent natriuresis may play a role in the presence of AT1R blockade (Simões e Silva *et al.*, 2013).

The Ang IV/AT4/RAP axis mediates NF-κB activation, interleukin 6 induction, and tumor necrosis factor α induction. In the brain, Ang IV has been shown to markedly enhance learning and memory in normal rodents and reverse memory deficits observed in animal models of amnesia (Chai *et al.*, 2004). In the kidney, Ang IV has been demonstrated to mediate a number of effects including increasing renal cortical blood flow and decreasing Na^+ transport in isolated renal proximal tubules (Chai *et al.*, 2004).

Finally, Mas1 receptor mediates vasodilation, endothelial function, antihypertrophic, antifibrotic, and antithrombotic properties of Ang-(1–7) (Simões e Silva *et al.*, 2013). The great functional relevance of Ang-(1–7) through the Mas receptor has been understood both in physiology and pathology. In fact, following its discovery, it is now proposed that, in addition to the ACE/Ang II/AT1 receptor branch, the RAS possesses a counter-regulatory axis composed by ACE2, Ang-(1–7) and the Mas receptor (Simões e Silva *et al.*, 2013). Whereas Ang II induces vasoconstriction, cardiac hypertrophy, renal vasoconstriction, aldosterone biosynthesis and release, anti-natriuresis, activation of the sympathetic nerve activity the ACE2/Ang-(1–7)/Mas exerts opposing effects and it antagonizes the deleterious effects of Ang II (Zhuo *et al.*, 2013). Thus, the net biological functions of the RAS may result from the balance between the arm of ACE/Ang II/AT1R and that of ACE2/Ang-(1–7)/Mas.

Activation of the ACE2/Ang-(1–7)/Mas axis decreases inflammation and fibrogenesis in diverse models of human diseases, and it exerts a protective role in experimental models of renal diseases (Zhuo *et al.*, 2013). The renoprotective effects of Ang-(1–7) seem to involve the vasodilation of afferent arterioles, an increase of renal blood flow, the modulation of oxidative stress, the production of nitric oxide and prostaglandins, the leukocyte influx and activation, and fibrosis in renal tissues (Pinheiro *et al.*, 2009; Li *et al.*, 2009). The few data provided by human studies also indicate a beneficial role for the activation of this alternative RAS axis in patients with renal diseases (Zhuo *et al.*, 2013). Finally, the beneficial effects of both ACEi and ARBs in renal diseases might involve, at least in part, the elevation of plasma Ang-(1–7) levels. AVE 0991 is a nonpeptide Ang-(1–7) agonist and it stimulates the Mas receptor to counteract the pathophysiological effects of AT1R activation (Santos and Ferreira, 2006; Rodrigues-Machado *et al.*, 2013). Moreover, A779 is a nonpeptide agonist and it inhibits the signaling of Mas producing unfavorable effects (Savergnini *et al.*, 2010).

Dipeptidyl peptidase III (DPP) III is a zinc-dependent aminopeptidase and acts to preferentially cleave two amino acids (dipeptide residues) from the N-terminus of few oligopeptides including Ang II and its metabolites Ang III and Ang IV (Pang *et al.*, 2016). Degradation of the vasopressor peptide Ang II by DPP III leads to the same cardiovascular, blood pressure, and renal protective effects induced by ACE inhibitors and AT1R blockers.

More recently, novel angiotensin-related peptides were discovered.

Alamandine is a heptapeptide derived from the catalytic hydrolysis of the octapeptide Ala1-Ang II (Ang A) by human ACE2 and structurally similar to Ang-(1–7), except that aspartic acid in position 1 of Ang-(1–7) is substituted with alanine in position 1 of alamandine (Lautner *et al.*, 2013). Alamandine can be generated from Ang-(1–7) in the rat heart and it circulates in human blood with increased levels in nephropathic patients (Lautner *et al.*, 2013).

Unlike Ang (1–7), which binds and activates the Mas receptor, alamandine binds and activates the MrgD receptor (Tetzner *et al.*, 2016). It exerts vasodepressor and antifibrotic effects in rats, although more studies are needed to assess its true role in physiology and pathology within the cardiovascular system.

A novel endogenous Ang II-like octapeptide, angioprotectin, was recently discovered. Compared with the sequence of Ang II, angioprotectin substitutes Asp1 and Arg2 in Ang II with Pro1-Glu2 raising the possibility that angioprotectin may be derived from Ang II (Jankowski *et al.*, 2011). Angioprotectin may represent an additional agonist for the Mas receptor. However, very few studies measured its levels in rodent and human plasma and tissues. Moreover, the molecular, biochemical and physiological, or pathological roles and therapeutic implications of angioprotectin remain to be further investigated.

Of note, kallikrein can cleave AGT within the heart to produce a dodecapeptide (Ang 1–12). Thereafter, chymase either produced in cardiac myocytes or released by mast cells during ischemia reperfusion/injury (I/R) or increased oxidative stress generates Ang II intracellularly from Ang-(1-12) (Ahmad *et al.*, 2011, 2013).

Assessment of RAS Activity in Physiology and Pathology

The changes of the RAS activity in the body still represent a valid diagnostic tool in human pathologies, with particular regard to the secondary forms of hypertension related to excess renin production (renovascular hypertension). The measurement of plasma renin activity (PRA) determines the amount of Ang I generated from AGT per unit time during incubation at 37°C of plasma samples in vitro (PRA is expressed as ng Ang I/mL/h). In contrast, the plasma renin concentration is the result of an immunoradiometric assay and it does not relate to the activity of renin. Plasma levels of aldosterone, the hormone stimulated by Ang II from the adrenal glands, can be measured by an Elisa kit and they can integrate information obtained with the PRA values.

Antisera raised against *N*-acetylated angiotensin (Ang) II and *N*-acetylated Ang III analogues were used to develop radioimmunoassays (Lawrence *et al.*, 1990). However, they do not offer a practical procedure for clinical purposes in order to measure plasma angiotensins in human samples.

Ang-(1–7) can be measured in plasma and urine samples collected in healthy subjects and in patients with hypertension (Simões e Silva *et al.*, 2013). Levels of Ang-(1–7) are modulated by changes in blood pressure, extracellular volume, sodium intake, and renal function. Low levels of Ang-(1–7) are associated with hypertension and cardiac hypertrophy (Simões e Silva *et al.*, 2013).

Therapeutic Implications of Angiotensins

Blockade of Ang II. This is a well-established and largely used therapeutic approach that has been introduced several years ago in clinical practice. The blockade of Ang II can be achieved by both the ACE inhibition and the AT1R antagonism with specific molecules (sartan). Their use in treating several cardiovascular diseases, with particular regard to hypertension, ischemic heart disease, heart failure, has significantly reduced major adverse cardiovascular events and mortality (Mentz *et al.*, 2013).

Stimulation of AT2R. Firstly, it has been shown that AT2R contributes to the vascular effects of the AT1R antagonists (Gigante *et al.*, 1998; Cosentino *et al.*, 2005). Due to the known beneficial effects of AT2R, through the stimulation of selected angiotensins, this approach promises to be helpful for treating human cardiovascular diseases (Volpe *et al.*, 2003). Two AT2R agonists are available. CGP42112A, a peptide agonist, induces renal natriuretic responses via AT2R-mediated NO/cGMP signaling, lowers blood pressure in SHR, and inhibits VEGF-induced migration in human endothelial cells (Kumagai *et al.*, 1993). A nonpeptide AT2R agonist, compound 21, has been developed to treat pulmonary fibrosis, hypertension, renal failure, and acute ischemic stroke (Unger and Dahlöf, 2010). The available evidence suggests that this nonpeptide AT2R agonist is not an optimal antihypertensive agent but, through its antifibrotic and antiinflammatory actions, may help to prevent and treat hypertensive-related TOD (Steckelings and Unger, 2012).

Ang-(1–7) as a therapeutic agent. Due to its favorable effects, it is expected that this peptide could help in antagonizing the harmful effects of Ang II. In this regard, a mimetic of Ang-(1–7), the nonpeptide compound AVE0991, appears to behave as a Mas agonist. In vitro studies revealed that it was able to induce NO release from endothelial cells (Santos and Ferreira, 2006). In vivo, AVE0991 exerted protection from postischemic heart failure in rats, prevented diabetes-induced cardiovascular dysfunction, inhibited atherogenesis in ApoE-knockout mice, and attenuated cardiac hypertrophy (Rodrigues-Machado *et al.*, 2013). However, this compound has never been tested in humans.

Kininases

Randal A Skidgel, Ervin G Erdös, and Peter A Deddish, University of Illinois College of Medicine, Chicago, IL, United States

This chapter is reproduced from Randal A. Skidgel, Ervin G. Erdös, Peter A. Deddish, Kininases, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 146–153.

Glossary

Autocrine A hormone that affects the action of the cell that produced it.

Paracrine A hormone that affects the function of a cell that is near but different from the one that produced it.

Kininases are enzymes that cleave peptide bonds in the kinins, bradykinin (BK) and kallidin (Lys-BK). Kininases can be classified according to their structure or, more importantly, according to their function. Thus, the first distinction should be whether the enzyme cleaves a kinin *in vivo* or whether its activity has been characterized only *in vitro*. This has not been uniformly established for all enzymes. Since Lys-BK has nine peptide bonds and BK has eight peptide bonds, many enzymes ranging from serine proteases to metallopeptidases can hydrolyze one or more of the bonds.

Introduction

The term "kininases" is a catch-all term. By 1970, a list of reports on kininases in extracts, tissues, and cells had spread over three pages in the Handbook of Experimental Pharmacology.

BK and Lys-BK are products of the hydrolysis of plasma kininogen by kallikreins as a result of a cascading process. This involves the initial activation of plasma prokallikrein, which releases BK from kininogen, or of tissue prokallikrein, which in turn usually releases Lys-BK. Kinins are agonists of the so-called BK B_2 receptor. This is a seven-transmembrane, G protein-coupled receptor activated by kinins, provided that they have the intact Phe^8-Arg^9 C-terminus. The group of enzymes that inactivates kinins by cleaving the Phe^8-Arg^9 bond, and thereby releasing a single arginine, is collectively called kininase I. However, the discovery of a second kinin receptor showed that this issue is much more complex. This second receptor, B_1, reacts with kinins lacking the C-terminal Arg (des-Arg derivatives). Consequently, kininase I-type enzymes inactivate kinins only as ligands of the B_2 receptor, whereupon they become active agonists of the B_1 receptor.

In contrast to the widely distributed and constitutively expressed B_2 receptor, B_1 is usually induced only under noxious or inflammatory conditions by endotoxins, cytokines, and other agents. B_1 is also a seventransmembrane domain G protein-linked receptor but shares only 36% homology with the B_2 receptor.

Enzymes belonging to a second group of kininases are called collectively kininase II. These enzymes act as peptidyl dipeptidases because, instead of releasing a single amino acid from a kinin, they release the Cterminal dipeptide (Phe-Arg) and thereby completely inactivate it. Angiotensin (Ang) I-converting enzyme (ACE) and neprilysin (NEP, neutral endopeptidase 24.11) are important members of this group.

Kininase I (Carboxypeptidase N)

Historically, carboxypeptidase N (CPN) was the first kininase characterized. Shortly after the synthesis of BK, an enzyme that released the C-terminal Arg was found in human plasma. CPN activity was studied in the plasma of several hundred patients; it was elevated in pregnancy but was below normal in patients with cirrhosis of the liver. CPN is synthesized and released from the liver into the circulation, where it is sustained at a relatively high level (10^7 M). This constitutive activity is probably more important for hydrolyzing substrates other than kinins, such as anaphylatoxins.

The circulating enzyme is a complex protein consisting of two heterodimers of high- and low-molecularweight subunits (83 and 50 kDa, respectively), held together by noncovalent forces to form a tetramer. The high-molecular-weight regulatory subunit is heavily glycosylated (36%), whereas the low-molecular-weight subunit contains the active center with a $Zn^{2þ}$-binding site. The regulatory high-molecularweight subunit can be an allosteric modifier of the active center of the low-molecular-weight subunit. It keeps the 50 kDa subunit in the circulation and protects this sensitive protein against inactivation at 37°C.

CPN is also an anaphylatoxin inactivator because it cleaves the C-terminal Arg of C3a, C4a, and C5a, but their rates of hydrolysis differ. The Gly-Arg bond of C5a is cleaved approximately 10 times slower than the Ala-Arg terminus of C3a.

 doi:10.1016/B978-0-12-812199-3.00795-7

Human CPN is considered to be life-sustaining, since no individuals whose blood completely lacks this enzyme are known. For example, inhibition of CPN activity in guinea pigs resulted in sudden death after complement activation when the generated anaphylatoxins were not inactivated.

In humans, low enzymatic activity may be important in the protamine-reversal syndrome. Protamine, when given to neutralize the effects of heparin after extracorporeal circulation, can trigger a catastrophic reaction: pulmonary vasoconstriction, bronchoconstriction, and systemic hypotension. Protamine is a potent inhibitor of this carboxypeptidase (CP) and can also stimulate the generation of kinins and anaphylatoxins; consequently, the inhibition of anaphylatoxin or kinin inactivation may contribute to the protamine reversal syndrome.

Plasma CPN activity may be an aid in the diagnosis of myocardial infarction where the blood level of creatine kinase (CK) released from heart muscle is measured. CPN cleaves the C-terminal lysine residue from either the M or B subunit of CK to yield des-Lys MM or MB isoforms when separated electrophoretically. A variation in blood carboxypeptidase N activity may affect this CK isoform ratio.

Although CPN cleaves the C-terminal Arg of kinins (see Fig. 1), it preferentially hydrolyzes C-terminal Lys, an important function in the regulation of plasminogenactivation. CPNcanreduceplasminogen binding to cells because C-terminal lysine residues on cell surface proteins are plasminogen "receptors". As bound plasminogen is more efficiently activated, CPN effectively lowers plasminogen binding to cells and thereby influences plasminogen activation.

No individuals have been reported to completely lack CPN but a 65-year-old patient and his sister had only 20% of normal activity. He suffered from weekly occurrence of angioedema. Other members of the family had angioedema, urticaria, hay fever, and asthma, but only slightly depressed CPN levels. An analysis of the 50 kDa subunit genomic DNA from the 65-year-old patient revealed a frameshift mutation in exon 1 that was not present in any of 128 normal controls.

Carboxypeptidase U

Carboxypeptidase U (CPU; thrombin activatable fibrinolysis inhibitor, TAFI; plasma CPB; CPR; EC 3.4.17.20) is another B-type CP synthesized in the liver and secreted into the blood. In contrast to CPN, it is normally in plasma as an inactive proenzyme of 60 kDa bound to plasminogen. CPU is proteolytically activated during coagulation to the active 35 kDa form by the thrombin–thrombomodulin complex, but it is unstable and rapidly inactivated at 37°C or by further proteolytic cleavage. The primary role of CPU is to down-regulate plasminogen binding and activation by cleaving C-terminal Lys residues from cell surface proteins and in fibrin clots.

Regarding the potential function of CPU as a kininase, one of the first groups to identify the enzyme utilized bradykinin as a substrate and studies of the purified enzyme confirmed these findings. However, the reported K_m of bradykinin is extraordinarily high (10 mM), even though it was lower than that of all other substrates (K_m ¼63–290 mM). This brings into question the physiological relevance of CPU as a kininase, although serum degrades bradykinin fivefold faster than can be accounted for only by CPN. Because CPU is normally a proenzyme and is unstable after activation, CPU may be a significant kininase only in certain circumstances, such as shortly after initiation of the coagulation cascade.

Carboxypeptidase M

Early studies indicated that tissues and urine contained CPN-like activity, but it was assumed that the 50 kDa active subunit would enter organs and attach to plasma membranes or be excreted. When the active CP that cleaved basic C-terminal amino acids was

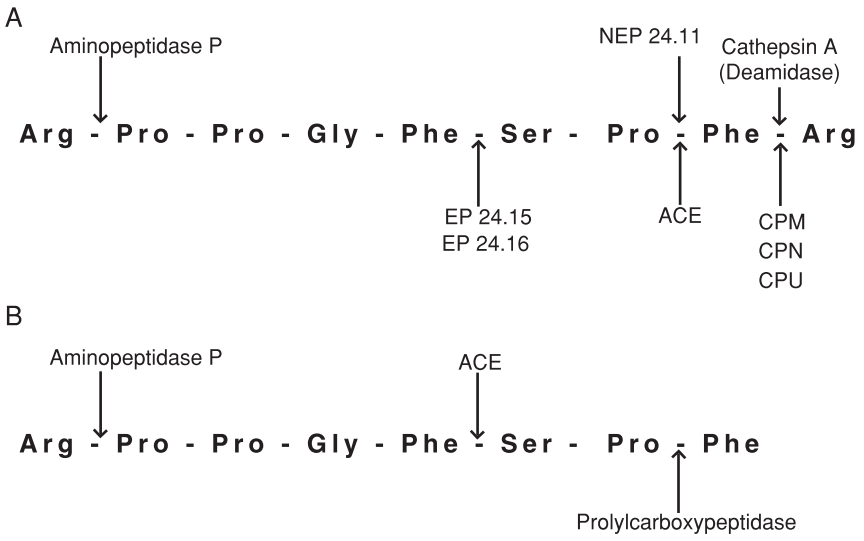

Fig. 1 Bonds hydrolyzed in bradykinin (A) and des-Arg^9-bradykinin (B) by peptidases.

purified from human urine and from placental membrane fractions, it became clear that this was not the case. Purification, cloning, and engineering of recombinant enzyme revealed that this enzyme had a different specificity and structure than those of CPN. Owing to its membrane attachment, it was called carboxypeptidase M (CPM).

CPM is a glycoprotein (23% carbohydrate by weight) with a molecular weight of 62 kDa anchored to the plasma membrane via a glycosylphosphatidylinositol tail. CPM is present in many tissues including kidney, lung, placenta, brain, intestine, peripheral nerves, and blood vessels and in cultured cells such as endothelial cells, fibroblasts, and Madin-Darby canine kidney cells. It is a differentiation-dependent cell surface antigen on white blood cells. The enzyme can be released from the membrane and soluble CPM is found in various body fluids including amniotic fluid, seminal plasma, and urine.

CPM has a pH optimum in the neutral range (6.5–7.5) ideally suited to cleaving peptides at the cell surface. There are no known endogenous inhibitors of the enzyme; thus, it is considered to be constitutively active on the cell surface. Tested with a variety of synthetic and endogenous peptides, CPM cleaved C-terminal arginine in preference over lysine, but the penultimate amino acid residue can also dramatically affect the rate of hydrolysis. The naturally occurring peptide substrates of CPM include bradykinin, $Arg^6$and Lys^6-enkephalins, dynorphin A_{1-13}, and epidermal growth factor (EGF). Of the substrates tested, bradykinin has the lowest K_m (16 mM) and the second highest specificity constant (k_{cat}/K_m).

As a widely distributed ectoenzyme, CPM can participate in a variety of processes, such as control of peptide hormone activity at the cell surface and degradation of extracellular proteins and peptides. It may also carry out the second step in prohormone processing, (i.e., removal of C-terminal Arg or Lys residues from peptides released from prohormones by convertases), if and when incompletely processed peptides are released from secretory granules. Because many peptides work in an autocrine or a paracrine fashion, the location of CPM on the plasma membrane near peptide receptors makes it well suited to control their activities locally.

Within the kinin system, CPM can either inactivate or alter the specificity of kinin peptides by cleaving the C-terminal Arg^9 as mentioned above for CPN. Because CPM is localized on the cell surface, close to the B1 and B2 receptors, it is well suited to this important role. Indeed, it has been shown that CPM-like activity on the surface of human lung microvascular endothelial cells was up-regulated approximately twofold by treatment with interleukin-1β and interferon-γ; these conditions increased B_1 receptor responses approximately fourfold. When BK stimulated these cells, the resulting nitric oxide release was prolonged and enhanced because CPM converted the peptide to des-Arg^9-BK to activate the B_1 receptor. These effects were then blocked by a CP inhibitor or by a B_1 receptor antagonist.

CPM efficiently removes the C-terminal Arg from EGF and may also cleave other growth factors that contain a C-terminal Arg or Lys [e.g., other EGF-like peptides, nerve growth factor (NGF), amphiregulin, hepatocyte growth factor, erythropoietin, macrophage-stimulating protein]. Although the role of the C-terminal basic residue of these factors has not been investigated in detail for most of them, a C-terminal Arg residue is required for association of EGF and NGF with their respective binding proteins.

The role of the up- or down-regulation of CPM in the differentiation of monocytes to macrophages and of B_1 lymphocytes is unknown, but a subject to be investigated further. The released free Arg, as a substrate for the inducible nitric oxide synthase, may provide more nitric oxide in inflammation, possibly just as the related enzyme carboxypeptidase D does in a mouse macrophage cell line.

In the lung, the presence of CPM on type I cells, which constitute 93% of the total alveolar surface, indicates that it may have protective functions here. This enzyme is also readily mobilized from the cell surface. The pulmonary synthesis or release of CPM may be up-regulated in disease states as the enzyme levels in bronchoalveolar lavage fluids were elevated almost fivefold in patients with pneumocystic or bacterial pneumonia or lung cancer.

The functions of CPM in other locations have not been explored. For example, in the placenta it may protect the fetus from maternally derived peptides. CPM in central nervous system (CNS) myelin and in Schwann cells in peripheral nerves may participate in the growth or maintenance of neurons.

Kininase II

Kininase II (ACE)-type activity, the enzymatic release of Phe^8-Arg^9 from BK, was detected first with a *Clostridium histolyticum* preparation and then by an enzyme separated from a membrane-enriched fraction (microsomal) of homogenized kidney and also from human plasma. Originally, ACE was discovered by Skeggs and colleagues in the 1950s in horse plasma. It converted the inactive Ang I decapeptide released by renin – called at that time hypertensin or angiotonin – to the active vasoconstrictor octapeptide Ang II.

After the discovery of kininase II in 1965–1967, it was reported in 1970–1971 that the same enzyme cleaves both BK and Ang I by releasing Phe-Arg from BK and His-Leu from Ang I; thus, it is a peptidyl dipeptide hydrolase called peptidyl dipeptidase I. The conclusion that the two activities were due to the same protein was not readily accepted because different amounts of Cl ions are needed to cleave Ang I or BK. The lack of chloride inhibited Ang I conversion by 93%, but the hydrolysis of BK was reduced by only approximately 50%. The discovery of two independent active site domains of ACE led to the finding that some substrates and inhibitors react preferentially with just one of the two active sites, with different Cl requirements.

The K_m of BK is much lower than that of Ang I (0.1–1 μM versus 10–50 μM), which, taken with the turnover number (k_{cat}), indicates a higher specificity constant with BK than with Ang I for human ACE; generally, ACE (kininase II) is considered to be the most important human kininase.

In addition to Ang I and BK, ACE cleaves a variety of bioactive peptides *in vitro*. Thus, beyond hydrolyzing C-terminal dipeptides, it released *in vitro* Cterminal tripeptides, e.g., from des-Arg^9-BK, protected C-terminal tripeptides [e.g., from substance P, luteinizing hormone-releasing hormone (LHRH)], protected C-terminal dipeptide (e.g., substance P), and even protected

N-terminal tripeptide (e.g., of LHRH). Compared to other ACE substrates, it is likely that the Arg^6-Phe^7 of Met^5-enkephalin-Arg^6-Phe^7 is split off with the highest turnover number by the N-domain active center of ACE. The N-domain of ACE hydrolyzes *in vivo* the tetrapeptide Ac-Ser-Asp-Lys-Pro, which is involved in the control of hematopoietic stem cell proliferation by preventing their recruitment into S phase.

After molecular cloning of the somatic form of ACE, two homologous domains were identified, the N- and C-domains; this was taken as an indication for the duplication of an ancestral gene. The germinal, testicular form has only one domain. The highest (89%) sequence similarity of the two domains of human ACE occurs around the active sites. The catalytic sites contain the canonical zinc-binding motif HEXXH. There is a high level of sequence similarity, 80%–90%, in both the nucleotide and amino acid sequences, between the somatic mammalian ACE cDNA sequences cloned from different species.

ACE is an ectoenzyme anchored to the plasma membrane by a C-terminal transmembrane domain; most of it is exposed at the extracellular surface of the cell. There are two ACE isoforms; the somatic form of approximately 150–180 kDa is in endothelial, epithelial, and neuronal cells and the smaller isoform (90–110 kDa) is present in germinal cells. Germinal ACE contains 732 amino acids, compared to 1306 in somatic ACE, and corresponds to the C-domain of somatic ACE with a single active site. Germinal ACE has the same hydrophobic transmembrane peptide and cytosolic domains as somatic ACE. The inactivation of the ACE gene in the homozygous male mouse leads to reduced fertility attributed to inactivation of the germinal form of ACE. Somatic ACE is highly expressed, for example, in the plasma membrane of vascular endothelial cells in the lung oriented to metabolize circulating substrates. ACE concentration is probably even higher on the microvilli of the brush borders of absorptive epithelia of the small intestine, placenta, and kidney proximal tubules. T lymphocytes and fibroblasts also contain ACE. In brain, ACE is highly expressed in the choroid plexus, which may be the source of ACE in cerebrospinal fluid, and in ependyma, subfornical organ, basal ganglia (caudate putamen and globus pallidus), substantia nigra, and pituitary. Neuronal ACE and the endothelial and epithelial forms of the enzyme have the same specificities and are not distinct isoenzymes.

Soluble ACE is found in many biological fluids such as serum, seminal, amniotic, and cerebrospinal fluids, released from cell membranes by a class of enzymes called secretases.
